Better information on the behaviour of sulphur in slags is supplied by microscopic examinations on air-cooled blastfurnace slags (84). Aggregates of CaS-droplets, partly occuring oriented are found in more vitreous parties on the ladle walls. Frequently twisted wormlike inclusions are embedded mainly in the rim zones, rich in akermanite, of melilites. These intergrowths of akermanite and sulphides must be interpreted as being myrmekitic segregations. Furthermore, sulphide segregations occurred in wedges, especially between merwinite crystal aggregates, hence rich in basic oxide. Here one sees isolated myrmekitic eutectic textures of oldhamite and potassium iron sulphide, deep-brown skeleton crystals, accumulations of sodium iron manganese sulphide and amorphous masses of sodium polysulphides. A number of the textures visible under the microscope indicate that in the course of the first cooling stage, molten sulphide is separated from the molten silicate. If further studies on thin sections substantiate these findings of the existence of a sulphide melt—the replacement of O^{2-} ions by S^{2-} ions in silicates has not been proved as yet—this would mean that, at very high temperatures, structural components of the molten sulphide are distributed in the molten slag, between the silicate structure components. They have a liquidifying effect, since, according to R. E. Boni and G. Derge (57) sulphides lower the interfacial tensions of base oxide-alumina-silica melts. Sulphides lower the surface tensions of alumina-silicate melts containing MgO more than those of melts containing CaO and BaO. This might explain the influence of MgO on viscosity, as described above.

For the vitreous slag this behaviour of the sulphides

in slag melts means: The faster quenching is effected or the more the sulphide melt remains distributed between the cluster like structure components of the liquid slag frozen in, the higher the reacting surface during hydration.

This view at the same time offers an explanation of the finding that vitreous slags having C/S-ratios of 1.1—1.2 and higher MgO content show a more favourable hydraulic behaviour than those having a higher degree of basicity, and confirms the author's opinion that a decline in the degree of basicity may be compensated to a certain extent by higher granulation temperatures (85).

The occurrence and the distribution of the sulphides—especially of the CaS—therefore must be considered as a hydraulicity factor. This view was last taken by I. I. Kholin and S. M. Royak (5).

The Chemical Composition

The chemical composition of the molten slags is responsible for the liquidus temperature, the degree of liquidity above this temperature and, thus, also for the selection of the granulation conditions.

However, as figures on these different physical characteristics are rarely available the values of chemical analysis, for the time being, mostly represent those magnitudes that are taken account of for the appraisal of the hydraulicity of vitreous slag. From the period under review, there also exist studies on the influence of the chemical composition of granulated slags on the properties of slag cements. The view generally held that high CaO contents and at the same time higher alumina contents under otherwise equal conditions constitute the most important active chemical components has been established as a confirmation of the findings obtained in the previous decades by (4) and (5) at the 4th International Symposium on the Chemistry of Cement, Washington 1960. This view is also held in special publications (6) (7) and (8).

In recent years several scientists (37) (38) (86) (87) (88) (89) (90) (91) (92) (93) (94) (95) and (96) reported on the influence of the chemical composition and of various chemical components, respectively. Special attention was devoted to MgO with a view to the strength of cement (37) (86) (87) (88) and to the soundness (38) (89) (90).

Its effect on hydraulicity is rated differently. So D. Heyl (37) when increasing at the same time the MgO content from 8 to 12% and the C/S-ratio from 1.2 to 1.3, did not find any clearly recognizable improvements in quality. A. Oelschläger (86) found improvements in strength by increasing the MgO content (up to 10%), when the degree of basicity remained constant. When the MgO content increased, while the degree of basicity dropped, there resulted a decrease in strength which partly was very high. For C/S 0.88, mixes with 9% MgO in the granulated slag showed poor hydraulic properties only. Thus, according to this author, the MgO content affects the strength less than does the C/S-ratio. J. Janowski (87) considers slags as rich as possible in MgO, but with Al_2O_3 contents not exceeding 11%, better suited than slags rich in lime. According to A. Schillak (88), MgO as a constituent of the vitreous phase is harmless up to contents of 7%, but at the same time the slag should contain more than 12% Al_2O_3. To increase the initial strength of cements made from granulated slags with higher MgO-content Schwiete (89) recommends an increase of the Al_2O_3/SiO_2-ratio.

An adverse influence of higher MgO contents on the soundness has not been found as yet. N. Stutterheim (38) studied the properties of slag cements which contained granulated slag with 13 to 20% MgO. All cements show good technical properties, the expansion in the autoclave was extremely low. J. G. D. Steyn and M. D. Watson (90) find, by microscopy, in the slags with 5 to 22% MgO, a maximum of 2.3% by volume of periclase crystals, but of very small dimensions. With these samples, too, the expansion in the autoclave remained within the limits established by cement standards. E. Mariani and G. Schippa (91) find that higher MgO contents in granulated slags are harmless, since only with contents exceeding 20 to 25% there is a precipitation of periclase.

According to J. Janowski (87), a high content of lime is desirable with a view to hydraulicity. Tests on subsequent enrichment in lime of slags were carried out by A. Achillak (88) and the "Iron and steel Orsk-Chalilovo" (92). At Ors-Chalilovo, enrichment of the slag (C/S = 1.12) in lime was carried out up to a degree of basicity of 2.0. The product obtained proved valuable for cement manufacture. According to A. Schillak (88), very high CaO contents decrease the share of the metastable vitreous phase, which remains a prerequisite for hydraulic setting.

M. Venuat (93), in studying test cements (85% slag—15% clinker) of granulated slags with CaO/SiO_2-ratios of 1.01—1.21 finds an increase in strength with increasing basicity.

The favourable effect of higher Al_2O_3 contents was found by A. Schillak (88), J. Janowski (87), H. Sopora (94), M. Venuat (93) as well as H. E. Schwiete and F. C. Dölbor (59). They confirm the view held hitherto that with equal basicity an increase in Al_2O_3 content considerably increases strength. An increase

to 11% Al_2O_3 may with a low CaO/SiO_2-ratio compensate for the loss of strength to be expected by a decrease of basicity.

According to H. Sopora (95), a higher FeO content indicates trouble in the blastfurnace run and, thus, corresponding quality declines of the slags. A quality decrease is also brought about by a higher MnO share, since then there is more formation of manganese sulphide, which, however, has an adverse effect on the quality of the slag and may possibly make slags unusable for cement manufacture. S. Solacolu and P. Balta (96) study the influence of manganese and of sulphur on the hydraulicity of slags of the system $CaO—MgO—Al_2O_3—SiO_2$. They find—depending on the position of the slag in the four-component-system, varying effects of Mn and S on hydraulicity. An adverse effect occurs especially when at the same time Mn and S exist in higher quantities and when MnS is formed. An adverse influence of MnO, especially with slags of low basicity and low Al_2O_3 content is also assumed by I. I. Kholin and S. M. Royak (5).

Factories producing slag cements are highly interested in being supplied with slags of uniform quality. In connection with this, the research institute at Rheinhausen has for years checked the compositions of the slags of two blastfurnaces producing different pig irons. An impression of the uniformity of the slag produced will be given by Table 4.

Criteria for Evaluation of Hydraulicity Properties

The continuosly growing importance of granulated blastfurnace slags as raw materials for cement has kept alive the interest of cement chemistry in methods permitting rapid appraisal of their hydraulic properties. The relevant methods indicated in the past have since 1960 been applied, checked and critically reviewed with respect to the value of their results (95), (65), (97), (98), (68), (59) and (99).

F. Keil (6) and R. W. Nurse (7) have again discussed all testing methods that provide a) various chemical indices, b) physico-chemical and c) physical reference values.

Also all these indices and reference values have, either on account of the method used or due to the properties of the material, only a limited or doubtful value, they are nevertheless characterized as valuable means of a rapid and rough appraisal. The reason for this lies in the fact that, in deriving them, one has considered the slag melts as homogeneous liquids. According to F. Schröder (65) no account has been taken of the fact that by chemical analysis all interstructural components are destroyed, that exact data on the various factors influencing the energetic condition of the vitreous slag are not supplied, and that, furthermore, the physical parameters proper, such as content of glass, refractive index or specific gravity, always represent statistic averages only.

The uncertainty of chemical indices and of the criteria derived from them will be seen in Table 5 (100). It contains, of technical cement slags, the chemical analysis, the CaO/SiO_2 ratios, the "F-values" in part a), and in part b) the compressive strength values of test cements made from these slags. According to the added criterion of the "F-values", the slag samples No. 12 and No. 37 having F-values > 1.9 (2.02 and 1.91 resp.), as slags of very satisfactory hydraulic properties, should have considerably higher compressive-strength values after 28 days, if the information supplied by the F-value is related to the whole strength evolution.

For appraising the adverse effect of FeO and MnO on the strength evolution separately, H. Sopora (95) has proposed to square the MnO content and to extend the formula as follows:

Table 4. *Uniformity of the chemical slag composition*

$$F = \frac{CaO + 0.5MgO + Al_2O_3}{SiO_2 + FeO + (MnO)^2}$$

H. E. Schwiete and F. C. Dölbor (59) indicate for the appraisal of granulated hematite slags, on the basis of their chemical composition, a more comprehensive degree of basicity:

$$Bg_{Schwiete\text{-}Dölbor} = \frac{\%CaO + (\%Al_2O_3 - 10)}{SiO_2 + 10Al_2O_3}$$

(Bg = basicity degree).

From theoretical considerations of the glass structure, based on the network theory of W. H. Zachariasen (6), and with due regard to the Al/Si-ratio in potash feldspar, up to 10% Al_2O_3 are supposed to be built as networkformers into the SiO_4^{4+} tetrahedron structure and the surplus, in the case of higher Al_2O_3 contents, is supposed to be present in the form of network modifiers.

This assumption is in contradiction to statements by R. Kondo (101) and to those by H. Schenck and T. E. Gammal (21), according to which, on the basis of physico-chemical studies of the reaction equilibria of molten slag/iron bath, the alumina in slags is active as an acid constituent up to a ratio of $CaO/SiO_2 = 1.3$.

Using the above formula, the authors obtained, by calculation, a higher rate of exactitude (86%) for the relationship between chemical composition and compressive strength than by the formula

$$Bg = \frac{CaO + (x - 10)Al_2O_3 + CaS + Na_2O + K_2O}{SiO_2 + 10Al_2O_3 + MgO + MnO}$$

Recently H. E. Schwiete (89) has held the view that the rate of exactitude of $Bg_{Schwiete\text{-}Dölbor}$ can be increased, if the shares of chemical components occurring in combined form in the crystalline inclusions of the vitreous slag is taken account of, as follows, in the formula:

$$Bg_{Schwiete\text{-}Rivas} = \frac{(\%CaO - C') + (\%Al_2O_3 - A' - 10\%) + (\%MgO - M')}{(\%SiO_2 - S') + 10\%Al_2O_3}$$

In this basicity degree, C', A', M' and S' represent the percentage of CaO, Al_2O_3, MgO and SiO_2 combined in the slag minerals. The inclusion of MgO in the sum of the basic oxydes (network modifier) means a revision of the older view that Mg^{2+} with fourfold coordination operates as a networkformer.

In recent years, for the appraisal of the hydraulic hardening capacity, also index n = refraction of light of vitreous slag (102) and devitrifying heat, determined by DTA and DTK testing methods (98), (45), (97), (68) and (103) as well as glass content determinations have been used. While W. Schrämli (97) rejects the information supplied by the DTA curves, J. E. Krüger (98), in consideration of studies by J. E. Krüger, K. H. L. Sehlke and J. H. P. van Aardt (45) on the devitrification phenomena in South-African vitreous slags, and (103) hold the view that the devitrifying heat values found by means of DTA can be used for appraisal. They think the DTA curves applicable also for determining the content of granulated slag in slag cements.

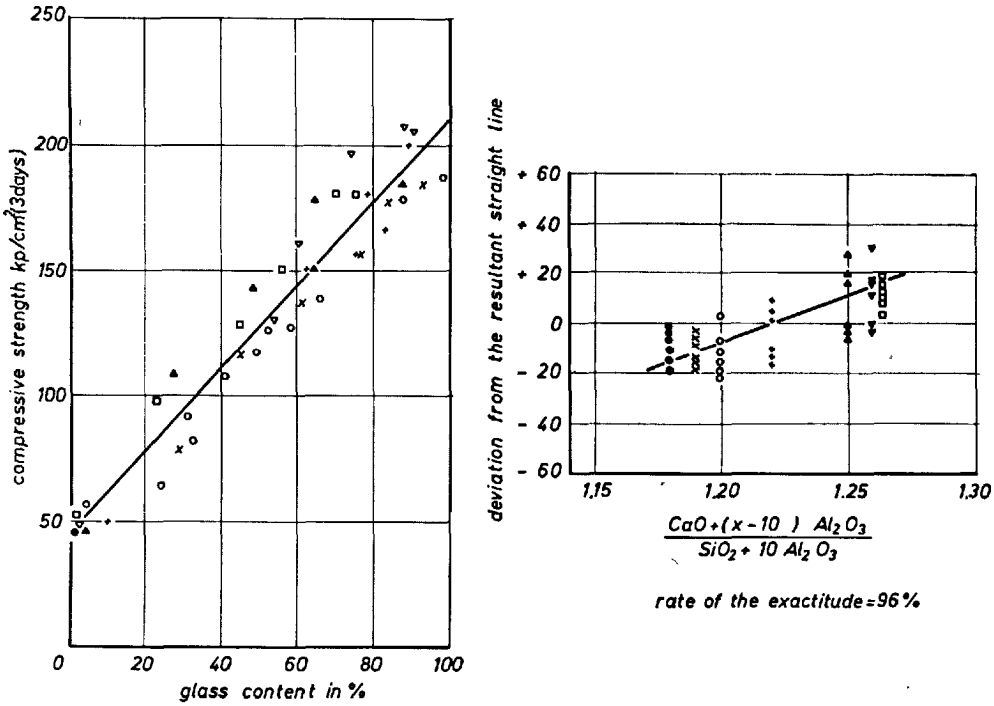

Fig. 6. *Glass content and compressive strength according to H. E. Schwiete & F. C. Dölbor.*

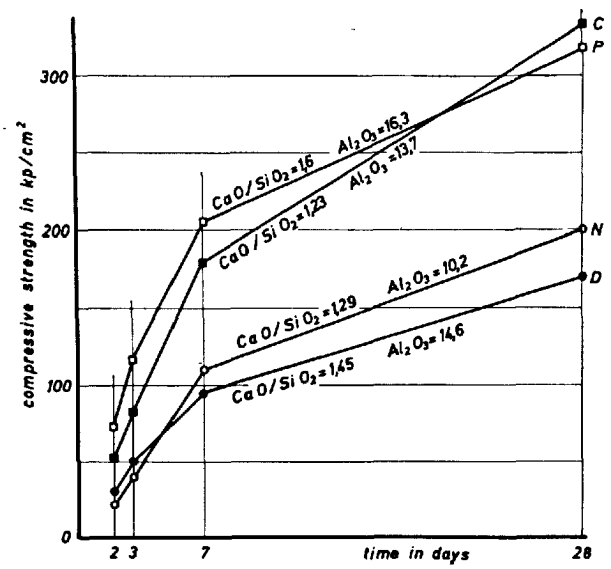
The glass contents, as determined by microscopy, in hematite slags quenched in different ways have been related by H. E. Schwiete and F. C. Dölbor (59) to the strength values of the respective test cements. In comparing content of glass and compressive strength (Fig. 6) they have obtained a rate of exactitude of 96% for the straight line of optimum (as contrasted with 82—86% in the comparison strength—degree of basicity, see above), deviations from the straight line of optimum being related to variations of the degree of basicity.

The evaluation method proposed by F. Schröder (65) and based on the varying fluorescence of vitreous slag is being successfully used at the Research Institute for Blastfurnace Slags, Rheinhausen, as well as at some German blastfurnace cement factories.

At the 4th International Symposium on the Chemistry of Cement W. Kramer (4) reported on the first studies by F. Schröder on the fluorescence and the fluorescence test for the appraisal of vitreous slags. He, furthermore, mentioned the authors view that the index = % red fluorescing glass particles × CaO/SiO_2 ratio may be a reliable one for the comparison of slag hydraulicity for slags of variant origin. Fig. 7 gives an example of such an application.

To the question then raised by J. H. Welch (104) whether such a comparison was justified the following



granulated slag No.	% fluorescing material			
	violet	bright blue bluish white	pink	brown
C	4	2	94	—
P	4	20	69	7
N	15	31	54	—
D	8	5	41	46

Fig. 7. *Compressive strength of four granulated foundry pig iron slags with different fluorescence.*

answer may be given:

The fluorescence of basic vitreous slag is a specific property of its vitreous structure. The percentage of red fluorescent vitreous particles gives the quantity of the hydraulically active vitreous slag with statistically homogeneous distribution of the controlling structural constituents. The CaO/SiO_2 ratio is a value that points to the ratio O/Si in the slag. C/S is a measure of the disproportioning of an originally three-dimensional SiO_4 tetrahedron network into smaller complexes with $(Si_3O_7)^{6-}$ anions and single SiO_4^{4-} tetrahedrons.

The nearly linear dependence of the 28-day-compressive strength values obtained of test cements made from 15 slags of different origins (with equal composition of slag, clinker and anhydrite and of equal grinding fineness) on the above index was good confirmation (65).

A comparison between the compressive-strength values of test cements and the fluorescence radiations —divided into color groups—of the slags used confirms, according to (59), the quality of this rapid test (see Fig. 8). The different chemical composition of two slag samples and their variant picked up pink, salmon, blue and violet fluorescing fractions are demonstrated in Fig. 10.

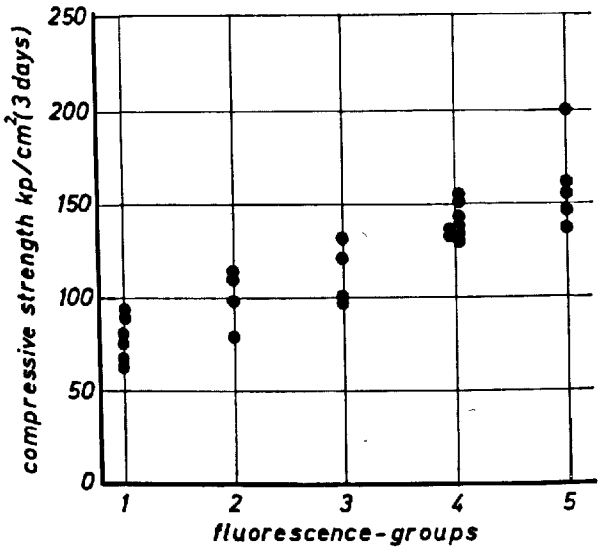
Determinations of the Fluorescence of Granulated Slags (by K. Grade)

Co-worker of the author, has for some time made attempts with a view to quantity determination of the fluorescence colors by measuring their spectral degree of remission. For this purpose the sample crushed to sizes of 0.040 to 0.60 mm is filled into the quartz-glass bulb of spectrophotometer PMQ II with ZFM fluorescence end (Messrs. Zeiss, Heidenheim). The sample is then exposed to ultra-violet radiation (wave length approx. 365 microns) at an angle of 45° and excited to fluorescence. The emitted radiation is resolved into its spectrum, and its intensity is measured at intervals of 10 microns each throughout the spectrum. As a reference value for the respective wave length the degree of remission of MgO exposed to standard light A (white) is used.

From the curves determined by the test data the standard color values X, Y and Z as well as the standard light components x, y and z (107) are calculated by the coordinates method (105) (106). By means of these values the position of the color in the standard color chart and in the identical CIE color chart can be determined and clearly identified.

Fig. 9 shows the positions of the red fluorescence colors radiated by vitreous slag of different origins. The figure shows the variations of the red fluorescence colors pink—red—salmon—red brown in the CIE color chart, the red-brown color being caused by the influence of FeO, MnO and S^{2-}. The range of the granulated slags which were used in the course of 1966 for cement production at a certain factory has been made conspicuous in the diagram by hatching. The portion set out indicates that there was only slight variation in the quality of these granulated slags.

For the visual color impression, an increasing X-value, in the represented portion of the CIE color chart, means an increase in the content of red, whereas, with equal X-values, increasing Y-values means a decrease in color saturation. In the diagram, the light intensity value Y, which, with granulated slags of satistactory hydraulicity, exceeds 35 and may rise to 200, could not yet be plotted. Of the tested slags, the compressive strength values of equal test cements are available. They were related to the results of fluore-



30 slags divided in fluorescence groups	compressive strength in kp/cm² after 3 days
1. violet, blue, single grains brown	67-67-76-80-90-95
2. violet, less reddish brown	78-97-110-112
3. red and reddish brown	98-98-120-130
4. salmon, single grains reddish brown	132-132-133-133-136-136-138-140-150-153
5. salmon, pink	136-145-155-160-200

Fig. 8. *Compressive strength due to fluorescence of the granul. slags. According to H. E. Schwiete & F. C. Dölbor (59)*

scence color measuring. On the basis of the comparison of the two properties, the point cloud in the diagram (Fig. 9) could be divided into areas of high, intermediate and low hydraulicity.

Further attempts will be made to detect the relations between the results demonstrated in Fig. 9, the chemical composition and the compressive strength values.

To be on the safe side, a number of other researchers used, for appraisal of the hydraulic setting capacity of technical and synthetical slags, the time-consuming technological methods of testing the mechanical strength values partly in compliance with the existing standard specifications, partly by leaning on the proposals made by F. Keil and G. Haegermann (108) s.p. (97)–(101), and partly on other technological strength-testing methods (86), (109), (110) and (111).

According to W. Wittekindt (109), the hydraulicity of granulated slags with binding agents (85% slag, 15% lime hydrate, fineness 3,500 cm^2/g Blaine) is to be determined rapidly through the strength of samples heat-treated at 60°C according to the German standard specification for lime, DIN 1060.

Another rapid-testing method, according to A. I. Stepanowa and S. M. Smechowa (110), consists in the four-hour steam curing of standard mortar samples and in the strength test after a cooling time of one hour. Test cements having a specific fineness of 3,000 cm^2/g (Blaine) are supposed to show the 7-day-compressive-strength values, and test cements of 5,000 cm^2/g, the 28-days-compressive-strength figures.

A French rapid-testing method using the compressive-strength test of standard prisms is described by M. Venuat and P. Papadakis (111). The excitation of the latent hydraulicity is caused by NaOH, which is added as mixing liquid (200 gr NaOH granular, dissolved in 1 litre of H_2O). The relationship of solution/cement amounts to 0.5. Testing is performed

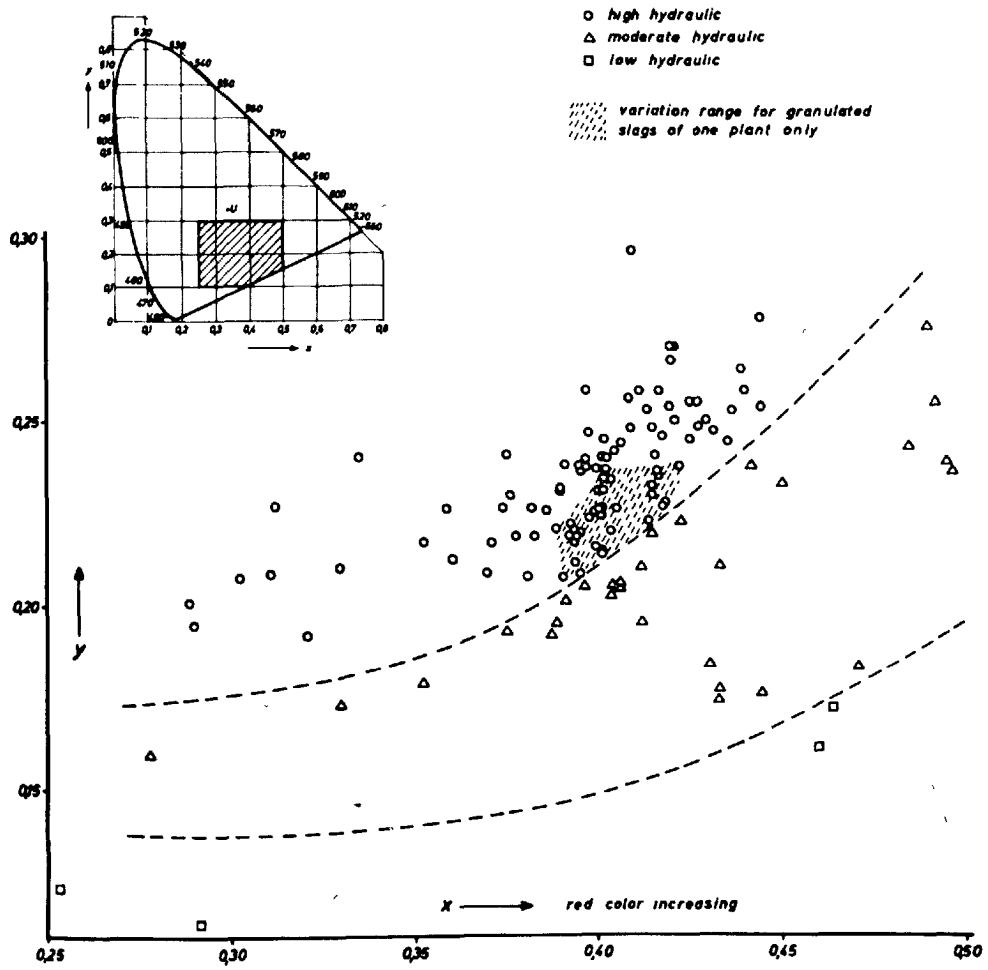


Fig. 9. *Flourescence colors of granulated slags in the CIE standard colorimetric system. (Part of the whole CIE system above on the left.)*

6 hours after forming, and after 24 hours. Vitreous slag of satisfactory hydraulicity must reach values of > 80 kg/cm², and > 125 kg/cm², respectively.

Hydration

Modern methods of research over the last 10 to 15 years have greatly expanded our knowledge of the hydration of hydraulically active, vitreous blastfurnace slag. Yet even today certain points are open to discussion.

The latest work done at the Research Institute for Blastfurnace Slags leads us to assume as a certainty that the calcium silicate hydrates—CSH phases—are the components of the hydration product which govern its strength properties. In considering the other hydrates and the hydration processes, we must distinguish between the hydration which mainly runs off in $CaSO_4$—saturated solution (supersulfated cements) and that which runs off wholly in $Ca(OH)_2$-saturated or almost saturated solution (portland blastfurnace slag cements).

Even without activation by sulfates or $Ca(OH)_2$, blastfurnace slags yield hydration products, in aqueous solutions, according to H. E. Schwiete, U. Ludwig, K. E. Würth and G. Grieshammer (112), but reaction is very weak.

As for sulfate activation of slags, by anhydrite in supersulfated cements, we can assume as certain today that only ettringite and CSH phases will form, (113), (7), (114), and (115) while the pH value of the solution will remain below 12 (7).

During the hardening of supersulfated cements, the ettringite content hardly rises further as from the third to the seventh day, while during the same period compressive strength still increases substantially. So we must assume, contrary to earlier beliefs, that the ettringite makes but a very small contribution to strength properties (114), (116). Moreover, the $CaSO_4$ component added in maximum quantities of 15

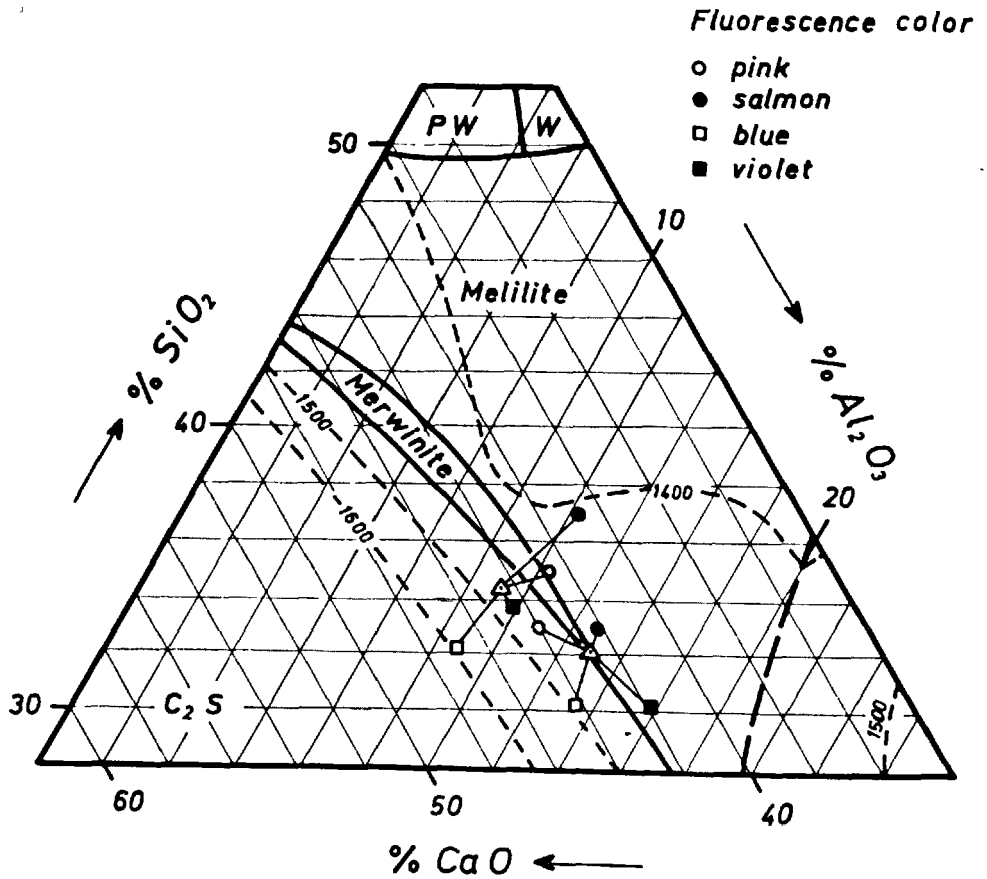

Fig. 10. *Chemical compositions of two granulated slags and their variant fluorescent fractions in the quaternary system CaO-MgO-SiO_2-Al_2O_3 (Plane for 10% MgO)*

percent to the cement can only bind part of the Al_2O_3 in the form of ettringite (116), (117). Consequently, over 90 percent of a slag must react in a different way. According to J. D'Ans and H. Eick (113) the surplus Al_2O_3 separates out as $Al(OH)_3$.

While opinions on the hydration of supersulfated slag cements are fairly unanimous, reports on hydration and hydration products by alkaline activation of slags at pH values above 12 differ in their conclusions. Most of the differences can be attributed to variations in experimental conditions. R. W. Nurse and H. F. W. Taylor (7), as well as R. Sersale and G. Orsini (118) found in hydrated pure cement pastes from blastfurnace slag cements tobermorite phases, ettringite, hexagonal calcium-aluminate-hydrates with and without sulfate, and partly also calcium-hydroxide. F. W. Locher (119) however, in extensive hydration tests with synthetic and technical vitreous slags, partly very rich in Al_2O_3, found detectable quantities of

Gehlenite hydrate C_2ASH_8 and
Hydrogarnet $C_3A(S, H_2)_3$.

F. W. Locher prove larger quantities of these two hydrates in slags with very high Al_2O_3 contents (over 20 percent) or those activated with $Ca(OH)_2$ only (but without sulfate), or those which were not hydrated in paste form but in saturated calcium-hydroxide solutions.

Pursuing the question to what degree these results may be applied to the hydration of cements, rich in granulated slag, in mortars and concretes, H. G. Smolczyk (114) evaluated some 3,000 X-ray diagrams of numerous mortars, made with extremely different slag cements having hydration periods ranging from 1 day to 4 years. The observed hydration products are listed in Table 6.

Table 6. *Hydration products of cements containing high proportions of blastfurnace slag*

Distinctly proved main phases:	
$C_3(A, F)\cdot 3(CaSO_4, Ca(OH)_2)\cdot aq$	AFt-phases

Calciumsilikatehydrates	CSH-phases
Calciumhydroxide	
Very rare or undistinctly observed phases:	
C_2ASH_8	Gehlenite hydrate
$C_3(A, F)\cdot 3(S, H_2)$	Hydrogarnet
C_2AH_8	Dicalcium aluminate hydrate

Clearly, in full agreement with the authors mentioned above, we have here the four main phases of high lime content which also occur in the hydration of portland cements. The complicated composition of the calcium-aluminate-hydrates may be summed up for simplicity's sake in the phases:

AFt for (Aluminate-Ferrite-tri-sulfate, hydroxide, etc.)

and

AFm for (Aluminate-Ferrite-mono-sulfate, hydroxide, chloride, carbonate, etc.)

It was also observed that the sulfate in supersulfated cements was present in the AFt phase only, while in blastfurnace slag cements in some cases the AFt phase reacted with other aluminates forming sulfate-containing AFm phases. H. E. Schwiete, U. Ludwig and P. Jäger (120) noted the same.

In partial agreement with the results of F. W. Locher, formation of C_2ASH_8 after 28 days of water curing was definitely shown in a case of a blastfurnace slag cement extremely rich in Al_2O_3. Within one year this C_2ASH_8 had turned into hydrogarnet.

A semi-quantitative evaluation of the results led to the safe conclusion that in the hydration of slag cements only the four main phases of high lime content are of any importance. W. Richartz (121) arrives at the same conclusion based on further examinations, partly by electron microscopy.

These experimental results lead to two difficulties in the stoichiometric calculation of hydration processes in blastfurnace slag cements.

a) The lime contents of all hydrates are always greater than those of the slags;
b) The slag is always richer in alumina than is the average of all observed hydration products.

The explanation for a) may be found in the fact that the $Ca(OH)_2$ freed by clinker hydration is partly consumed by slag hydration.

This lime binding effect of the slag has meanwhile been proved by many authors (116), (118), (122), (123), (124), (7) and (125). Fig. 11 shows the results obtained by E. W. Nurse and H. G. Midgley.

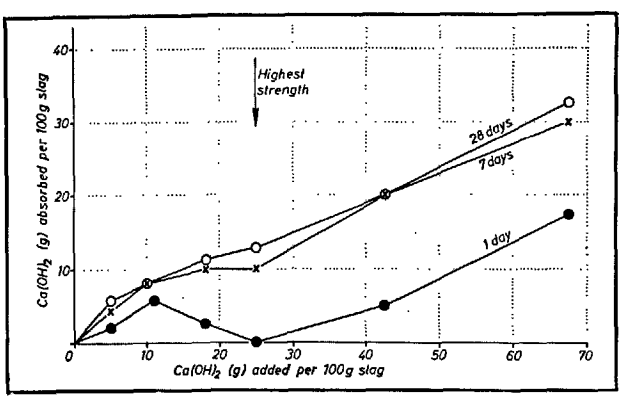

Fig. 11. *Relation between lime added and lime absorbed in slag pastes. Nurse and Midgley*
Water: binder ratio 0.3
Slag analysis: 39.7% CaO; 34.5% SiO_2
15.9% Al_2O_3; 3.9% MgO

Saturation of $Ca(OH)_2$ and NaOH in the paste of cements with high slag content (over 70% ground slag) is partly lowered in the hydration process, (126), but the pH value remains above 12, so that high calcareous calcium silicate hydrates are formed. In supersulfated cements, $Ca(OH)_2$ does not appear as solid component, the pH value remains below 12, so that less calcareous calcium silicates result.

Explanation of point b) is much more difficult. The presence of free aluminium hydroxide is possible only in hardened cement paste having no free $Ca(OH)_2$ as solid component, such as supersulfated cements (113), (7) and (114). In the high alkaline paste of portland blastfurnace slag cements, on the other hand, the entire Al_2O_3 content must be bound in some form in the hydration products. On the basis of quite different experiments carried out by G. L. Kalousek (127), H. G. Smolczyk (114) believes that these "missing alumina" have been incorporated into the calcium silicate hydrate phase.

This assumption has recently received strong support from a paper by L. E. Copeland, E. Bodor, T. N. Chang and C. H. Weise (128). They showed that tobermorite phases can bind subsidiary components, such as Fe^{+++}, Al^{+++} and SO_4^{--}, firmly into the intermediate layers of their crystal lattice. This theory is also apt to explain differences between the quantitative X-ray determination of calcium-aluminate-sulfate hydrates and the SO_4^{--} contents of paste.

Further H. E. Schwiete, U. Ludwig, K. E. Würth and G. Grieshammer (112) reported on MgO-containing tobermorite like phases which have been observed in hydrated slags rich in MgO.

On behalf of a definite solution of the problem of all the hydration products of blastfurnace slag cements the calcium silicate hydrate phases will have to be object to very accurate and thorough investigations.

Blastfurnace Slag Cements

(by F. Schröder and R. Vinkeloe)

Definition and Composition

Today, there exist standard specifications for blastfurnace slag cements in more than 15 countries. These comprise cements to which

Portland cement clinker
Calcium sulphate plus portland cement clinker
Hydrated lime

is added for activation of the latent hydraulic hardenability of granulated blastfurnace slag, and which, furthermore, conform to the minimum strength requirements of the national standards.

Slag cements consisting of granulated slag and 15 to 20% hydrated lime are today manufactured in very few countries only and in very small quantities (example: Ciment de laitier au Portland, in France). Since a number of years in some countries "ternary"-cements composed of slag, pozzolan and portland cement cliker are manufactured (6). Seen from the point of view of strength-properties, these cements do exceed the minimum strength requirements, but are not yet always included in the standards, as for instance in Germany.

Looking at the stipulations on the composition of slag and activator given in the national standards it can be noted that today blastfurnace slag cements are regarded as those consisting of

slag and portland cement clinker,
slag and calcium sulphate + up to 5% portland cement clinker.

Since the standards also specify the mixing ratio of slag and portland cement clinker, the result is, particularly in countries having slag cement industries for more than 30 years, a multitude of types of slag cements with their pertaining definitions. A summary is given by F. Keil (6). It would be very welcome if for the purpose of adjusting the requirements as to the composition on the sector of cement standards, in order to facilitate comparisons and to establish a better basis for the understanding between cement chemists, and in the development and preparation of new or in the modification of existing standard specifications, the recommendations made by International Standards Organisation (ISO) were followed.

The ISO-recommendations for the composition of the present slag cements stipulate the following (7):

Types Proportion of slag in % of the sum slag + portl. cement clinker	Standard Specification
< 35*	Portland blastfurnace cement Ciment de fer Eisenportlandzement
35—80*	Blastfurnace slag cement Ciment de haut fourneau Hochofenzement
possible subdivision:	
35—60*	Blastfurnace slag cement 35–60
60—80*	Blastfurnace slag cement 60–80
> 85	Ciment de laitier au clinker

* According to national standards the limits may vary at ±5%.

Composition of supersulphated cement "Sulfathüttenzement": Supersulphated cement is made from blastfurnace slag, calciumsulphate and a small portion of lime, portland cement clinker or portland cement. The SO_3-contents must be > 5%.

The specific properties mainly attributed to cements with a high slag contents, as for instance the very small heat development and the high resistance against chemical aggressive natural water, sea water, industrial and other waste water, have very much added to the development of this type of cement (129), (123), (130) and have secured them a rather remarkable share in production. About 10 years ago, Japan also started with the production and application of this cement type (131), (132).

Supersulphated cement has a particular place in the range of cements with high slag contents. With a very high initial strength and a very low heat of hydration at the same time, it stands out against others because of its special capability of resisting against sulphate-bearing waters and soils, and also to sea water (133), (134), (135), (136) and (137). However, at low temperatures it does not harden as quick as other cements. Heat treatment is not suitable for this cement type (134), and it does not keep as good as the other types (134), (138) and (139).

Determination of Composition

The determination of the content of slag in blastfurnace slag cements is required for certain aspects, as for instance for the control of production, for the control of the standard requirements, and for the control of long-term supplies for mass-concrete-structures or hydraulic engineering. Applicable test methods base on the physical, the mineralogical and the chemical differences of clinker and granulated slag. A summary and review is made in a report by K. Grade (140).

When the basic components clinker and granulated slag are available, as for instance in the cement plants, then the chemical analysis of clinker, granulated slag and cement, and the following comparison of the concentration of usefull chemical components, as for instance CaO, MnO according to the formula % slag is $\frac{c-k}{s-k}$ times 100, is suitable. In the formula, c is the weight-% of the chemical component in cement, s weight-% in the slag, and k the weight-% in the clinker.

A rapid method advisable for cement laboratories is described by E. Vogel (141). The cement is dissolved with NH_4Cl solution and the ammonia which develops, is titrimetrically determined. The determination of the existing contents of slag is effected by means of calibration curves, which will be drawn with defined mixtures of the slag and clinker used. A determination of the contents of slag by means of the DTA and/or thermogravimetry is, besides others, suggested by J. E. Krüger (98), O. P. Mtschedlow-Petrossian, N. A. Lewtschuk and I. S. Strelkova (103) and by N. S. Zargorodnij, O. P. Mchedlov-Petrosyan, I. M. Sidocenko and I. S. Strelkova (99). In these methods, in which for purposes of comparison the slag and the clinker must be separated, the surface of the exothermic peaks caused by the devitrifying of the slag at a temperature of 860°C, and the increase in weight caused by oxidation of the sulphides, are used for determination. For such cases where clinker and slag are not available separately for comparison, different methods of determination were suggested.

J. Brocard (142) and M. Duriez and M. Cl. Houlnik (143) made use of the differences in the specific weight existing between clinker and granulated slag for a quantity separation of the cement into clinker and granulated slag by heavy liquids.

Combined microscopic and chemical tests on concentrates of varying density are recommended by F. Keil and F. Gille (144) whereas R. E. Cromarty (145) tests fractions of varying magnetic susceptibility. Both use sulphide sulfur as a chemical element for comparison.

Manganese is recommended by P. Catharin (146)

and K. Bleher (147) to serve as reference value, whereby the procedure adopted by P. Catharin meets that of F. Keil and F. Gille, whereas K. Bleher compares the MnO contents of different grain fractions and those of cement.

Detailed studies made by the working group "Mikroskopie" in the "Verein Deutscher Zementwerke" (VDZ) in the years 1966/67 intended for the revision of the cement standard DIN 1164 led to a method of analysis (148) in which the grain particles 30—40 μ are sieved out from the cement and the contents of granulated slag is determined microscopically with reflected light after the clinker grains have been polish-ground and etched.

By analysing chemically CaO and MnO it is tested, whether the grain fraction and the cement are of the same composition, and possible whether the microscopically defined contents of granulated slag is to be corrected.

Strength Properties

Influence of the Testing Method

Strength as a symbol of the quality of the cements to a great extent depends on the specifications prevailing for testing. For this reason it is only possible here to make relative comparisons or to say as far as numerical values are given, these cannot easily be transferred to other cases. An example of the influence of the testing method on the strength is tried in the following.

In 1942 the present form of the standard specification, the DIN 1164, was issued by decree in Germany. In the years before, the compressive strength of the cements was determined from 7 cm test cubes consisting of earth moist mortar, whereas after 1942 testing was carried out on cubes consisting of plastic mortars. R. Grün and K. Obenauer (149) taking 330 different portland cements and 294 blastfurnace slag cements found out which factors must be applied in order to be able to transfer the strength values so far obtained from 7 cm cubes to those of plastic mortar in conformity with DIN 1164. From mean values derived from these tests the following conversion factors resulted:

Cement type	Testing age	Conversion factor
Portland cement	3 days	0.500
	7 days	0.620
	28 days	0.792
Blastfurnace slag cement	3 days	0.376
	7 days	0.466
	28 days	0.622

As can easily be seen from these factors, the plastic mortars had a considerably less compressive strength than the conventional type earth moist mortars. Furthermore, it became obvious that the drop of strength caused by the testing method is not the same for all types of cements. Actually, the blastfurnace cements suffered most, particularly at their early stage of hardening.

At present a new issue of stadard specifications for cement as recommended by RILEM-CEMBUREAU is available for introduction, where as regards the test regulations mainly the composition of mortar and the compaction of the test cubes is changed. This change in the specifications also leads to varied strength results, whereby, however, everybody involved is of the opinion that this testing method allows the best comparison of cement types.

The granulometric composition of the test sand of the ruling German standard specification, the DIN 1164, is not very favourable. So, especially in the case of coarsely ground cements the water/cement-ratio is, for a part, very different from that specified at 0.60. The consequence of this is, that mainly the more coarsely ground portland cements attain higher strength which can no longer be called typical. The effective water/cement ratio in individual cases was determined at 0.52, thus, it was considerably under the theoretical value of 0.60 and also led to substantial increases in strength. Extensive tests have prove that this disadvantage does not longer apply to the new test method of RILEM-CEMBUREAU; here only slight differences in the effective water/cement-ratio and the theoretical value of 0.50 have been observed. From this it can be understood that the increases in strength, which the cement shows because of this new test method, cannot be the same for all cements. A comprehensive summary of the standard specifications on the testing of cement at present available in 35 countries has been published by A. Meyer (150). As it is likely that these are discussed elsewhere, the present indication should be sufficient.

Influence of the Granulated Blast Furnace Slag

The strength properties of the blastfurnace slag cements show certain particularities against portland cements. The German "Eisenportland" cements, which are cements with a relatively small contents of slag, hardly differ from the portland cements with regard to strength. As is explained in the paragraph on the heat of hydration, a small addition of blastfurnace slag will definitely increase the initial strengths. Cements having a high contents of slag, however, show a difference against portland cements with regard to

the increase in strength depending on the age at the time of testing. The evolution of strength here is no longer determined by the properties of the clinker, but by the properties of the slag. Cements which have a high slag contents are such cements which contain much silica; when the final strength is very high and hardening after 28 days is constant and lasting then the initial hardening is smaller (151). Some very good example for this are the tests made with the 20 years old concrete of the navigation lock in Wilhelmshaven/ Germany. A concrete with blastfurnace slag cement with high slag contents, which at the time of pouring

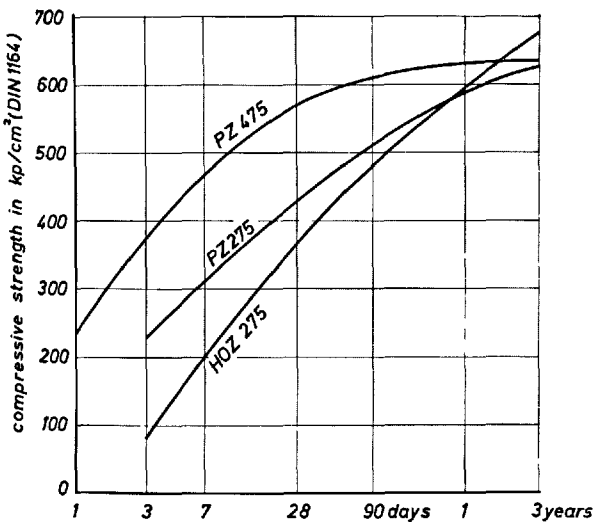

Fig. 12. *Evolution of compressive strength of commercial cements in West Germany acc. E. Spohn 1961 (153)*

is to come up to the specifications of class B 160, i.e. a compressive strength of 160 kg/cm² after 28 days, showed after 20 years a compressive strength of 700 kg/cm² and more. Even presuming that at that time the compressive strength of the concrete could have been 300 kg/cm², it still proves the considerable after-hardening of these type of cements (152).

As comparison with portland cements H. Spohn (153) gives the development of strength for blastfurnace slag cements of class Z 275 as shown in Fig. 12. His statement firstly confines to cements from certain plants. The absolute value of the strengths indicated, therefore, cannot be applied to other cements. The curves, however, show the typical tendency of the increase in strength in case of blastfurnace slag cements with a higher contents of slag, that is to say in such cements for which the development of strength is mainly determined by the behaviour of the slag. Where the initial strengths are low, the final strengths are high (153), (154) and (155).

Fig. 13 illustrates the development of strengths typical for blastfurnace slag cements with three different types of slags. It shows the influence of the type of slag and at the same time the fineness of grinding of the cement made therefrom. Practically both influences cannot be separated, and therefore they shall be explained together as follows.

Influence of Fineness

As for all cements, an increase in the fineness of grinding also in blastfurnace slag cements results in an in-

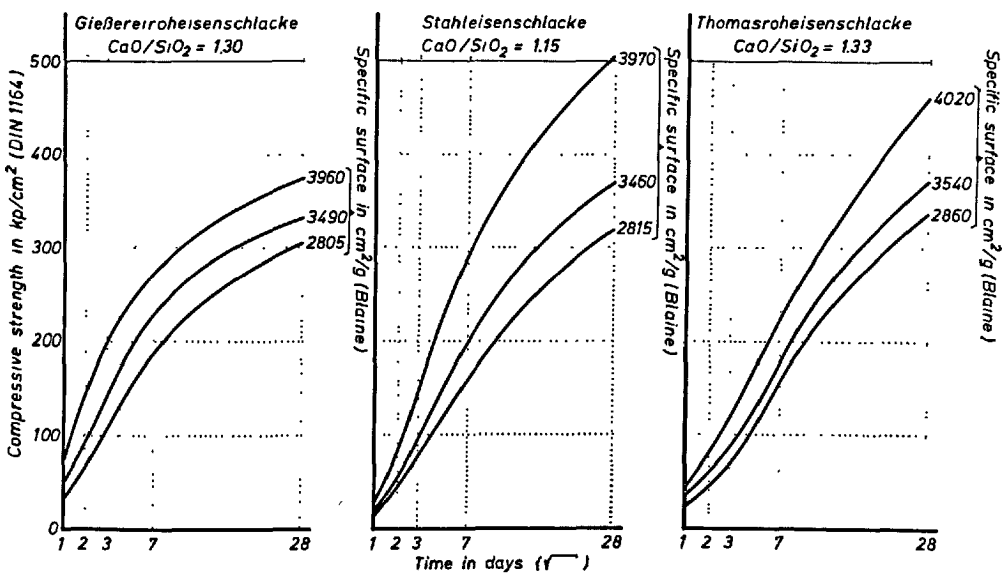

Fig. 13. *Influence of different slags and different fineness on compressive strength vs. time of blastfurnace slag cements (slag 75%)*

crease of strength. The increase of strength is substantially determined by the type of slag involved as may be seen from Fig. 13. The data given in this figure derive from very extensive studies and tests carried out by the Research Institute for Blastfurnace Slag, Rheinhausen, during the past five years; they may be called as typical, they reveral the specific behaviours of the individual slags. For the cements shown in the left part of the illustration a hot foundry pig iron slag with a CaO/SiO_2-ratio of 1.30, and a moderately hot, but relatively acid stahleisen-slag with CaO/SiO_2-ratio 1.15, and for the cements at the right side of the figure a cold Thomas pig iron slag with a favourable CaO/SiO_2-ratio of 1.33 were ground. From Fig. 13 it can be seen, that the cement consisting of foundry pig iron slag increases in strength, such as

after	1 day	from	25 to	60 kg/cm²	} = > 100%
"	2 days	"	50 "	150 "	
"	3 "	"	90 "	190 "	
"	7 "	"	165 "	270 "	= 60%
"	28 "	"	305 "	370 "	= 20%

are obtained by increasing the fineness from about 2,800 to 4,000 cm²/g (Blaine).

In case of a very acid stahleisen-slag the same increase in the fineness only after three days causes an increase in strength from 65 to 125 kg/cm²—so about 100%—but only after 28 days an increase from 320 to 500 kg/cm², which is about 56%. The increased fineness in this case of slag has quite a different effect on the development of strength than the foundry slag. When the increase of initial strengths after one and two days is less, the final strength is raised to a much greater degree. The reason for this is not the chemical composition (here C/S 1.15), but the physical condition. To this point also the results obtained from cements made of cold basic slag. Despite of the better C/S-ratio (1.33) the increase in the fineness as illustrated at the right side of the Fig. 13 has an effect on the blastfurnace slags from cold basic pig iron slag, but a smaller increase in the strength must be expected at all days of testing. These results also show that it is possible, provided the slags are properly cut, to influence the hardening curves of the blastfurnace cements with high slag contents. Furthermore, it can be expected from these test results that primarily the good dispersion of the slag component, namely a very high fineness, is of importance for the development of strength.

This is mainly demonstrated in the following results, which have been chosen from the test results obtained by the Research Institute to serve as examples. Clinker and slag were ground separately to different specific surfaces, and homogeneously mixed to blastfurnace

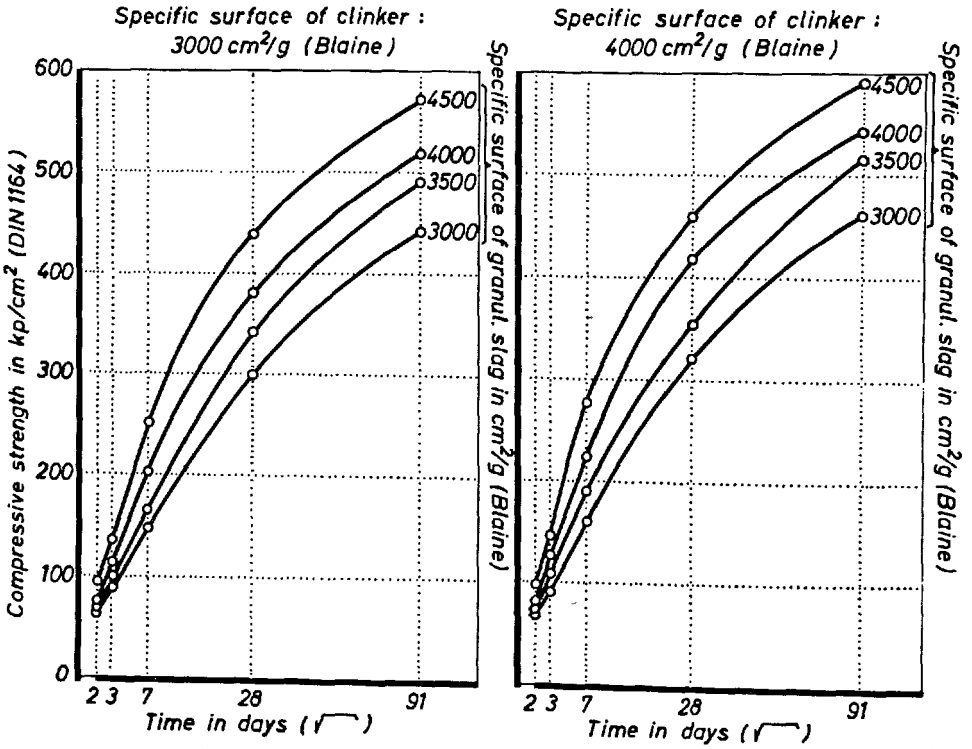

Fig. 14. *Test slag-cements; compressive strength vs. time as a function of fineness (slag 75%)*

slag cement with slag content of as much as 75%. The values of strength as shown in Fig. 14 indicate that the fineness of clinker has attained only little influence on the development of strength, whereas the higher fineness of the slag has led to an increase in strength, as applies to the result shown in Fig. 13.

Further investigations in the Research Institute have shown, moreover, that due to the properties of clinker of standard composition, the development of strength of blastfurnace slag cement with high slag content is influenced only to a minor degree, Tables 7 and 8. However, the test series for the development of strength of blastfurnace slag cements with high slag contents quite early show the influence of the quality of granulated slag. The evolution of strength of the cements made of well granulated slags (No. 1–3 and 5–9) stand out distinctly against those of badly granulated slags (No.11, 10, 4). In the well granulated slags slight differences in the CaO/SiO_2-ratio have a minor effect only on the strength at a later age of the cement. However, they become noticable at the early stage of strengths, just like the tapping temperatures to be derived from the individual types of slag. These results correspond very well to those obtained by H. E. Schwiete and F. C. Dölbor (59).

Influence of the Portland Cement Clinker

Some authors consider also the influence which the composition of the clinker has on the properties of strength of the blastfurnace slag cements. Whereas the average composition of clinker in the Tables 7 and 8 show slighter influences of these components on the strength of blastfurnace slag cements, it must be taken from other analysis that clinker with higher C_3S contents are more advantageous. So according to H. Sopora (94) slightly basic slags attain the best strength with clinkers having a high lime contents. Granulated slags which he examined are relatively slow in reaction and have F-values below 1.5.

V. F. Krylov, V. L. Pankratov and V. M. Kolosovskaja (44) with acid slags (SiO_2 34–37%, CaO 29–38%, Al_2O_3 9–23%, MgO 5–18%) obtain good properties of strength with a clinker having very high C_3S- and C_3A-contents.

K. Goto, M. Hanada and H. Miyairi (156) found out that the early strength is so much the more, the higher the C_3S contents of the clinker used. Simultaneously, the share in strength of the granulated slag increases with the use of clinker with high C_3S-contents.

Against this, the influence of C_3A is smaller, a higher C_3A-contents merely causes negative effects in respect to the rate of the hydration heat.

Influence of Calcium-Sulphates

The effect of the various calcium-sulphate-modifications on the strength and setting of blastfurnace cements is being dealt with by a number of cement chemists in the period under review, H. E. Schwiete and F. C. Dölbor (59), M. Hanada and H. Miyairi (157) R. Nagano and S. Yamawaki (158) and H. Sopora (94).

In general it was found that the use of anhydrite, artificial as well as natural, has the best effect on the early and on the final strengths. H. E. Schwiete and F. C. Dölbor (59) in the range of 0.5 to 4% SO_3, found an increase of the compressive strength in the order semi-hydrate—dihydrate—artificial anhydrite—natural anhydrite—where the compressive strength curves of the test cements (30% clinker) with semihydrate and dihydrate for all ages showed definite maxima with low SO_3-contents (0.5—1%) whereas artificial anhydrite contents constantly improve the early strengths at 3 and 7 days. As concerns the strengths at later ages the compressive strength curves for artificial anhydrite show maxima at about 3—3.5% SO_3, and those for natural anhydrite at about 1% SO_3. Tests carried out with mixing of dihydrate and anhydrite showed that in the range of 0.5 to 4% SO_3, with varying sulphate additions, a mix containing 25% dihydrate and 75% anhydrite provides the most uniform development of compressive strength. Also with regard to the setting, a modification of the calcium sulphate is of importance. Semihydrate according to R. Nagano and S. Yamawaki (158) and also H. E. Schwiete and F. C. Dölbor (59) is not suitable, since it is likely to cause false set. The slightest change in the setting occurs (59) with mixing of 55% dihydrate and 45% anhydrite.

It can be taken from the studies that blastfurnace slag cements do very well agree to contents of 4% SO_3, except in the form of semihydrate.

Separate Grinding

For cements which are made of components having a varying grindability and a varying hydraulic behaviour, the grinding procedure may play an important role for attaining maximum hydraulic properties. The effect of the grinding on the strength-properties of the product to be ground has, therefore, been investigated by several authors in the period under review.

So F. W. Locher, J. Wuhrer and K. Schweden (159) have tested the influence of the fineness and W. Kayser (160) that of particle size distribution on the strength-properties of cement. Both authors found that for blastfurnace slag cements with slag contents

of 50 and 60% the early strength is mainly determined by the fineness of the clinker, and the later process of hardening by the fineness of the granulated slag. In the case of cements with high slag contents, the fineness of the slag and its hydraulic properties are of decisive importance. W. Kayser (160), furthermore, found that the strength-properties of blastfurnace slag cements with a tight grain distribution of the same specific surface exceed that of blastfurnace slag cements with wide-spread grain distribution. Both authors consider a separate grinding to be the most advantageous method.

J. Birthelmer (161) shares this opinion, he found that separately ground cements attain the same strength as those which are ground together with greater specific surfaces.

Separate grinding is also advised by N. Stutterheim (38) for cements made of South African slags with high magnesia contents; these show a much greater resistance to grinding than clinker. Separately ground cements with 50% granulated slag with high magnesia contents provided the same strength-properties as portland cements and were resistant to autoclave test.

H. E. Schwiete and F. C. Dölbor (59) support a separate grinding in such cases where the granulated slag in the cement has higher contents than the clinker, and where it is more difficult to grind than the clinker. They ascertained that with clinker a grinding of 3,500 cm^2/g is of minor, but with granulated slag is of major importance. Regarding to the fineness H. Sopora (94), in the case of combined grinding, finds the strongest dependency of the strength on the fineness in the range 2,500 to 3,200 cm^2/g.

F. Guye (162) recommends a higher fineness for Southafrican cements consisting of clinker with a high MgO-contents (16–25%) and for granulated slag containing much magnesia (up to 22% MgO) for improvement of volume stability of such cements.

Special Properties of Blastfurnace Slag Cements

Elastic Properties

It is known that particularly blastfurnace slag cements with high slag contents show a very high bending strength (123). Cement or concrete test prisms are generally much less resistant against bending- or flexural stresses than against compressive stresses. In blastfurnace slag cements, however, the slag component has a positive influence on the bending strength. With an increase in the content of slag the bending strength grows likewise. Thus, the relation of bending- to compressive strength of the blastfurnace slag cements with less clinker contents explains the good elastic properties of the concretes made from this type of cement (163).

M. J. Challier (164) has made up a brittleness factor K for this;

$$K = \frac{E}{\sqrt{W}}$$

E = dynamic modulus of elasticity
W = compressive strength of the concrete.

The modulus of elasticity (E-module) is a measure for the resistance against deformation which a specimen produces when being subjected to loading.

A high value for E means a small deformation, a low value, however, means a big deformation with equal loading. When the factor K is high, fracture occurs with relatively less deformation. This, however, meets the definition of the brittleness. In other words, the smaller the K-factor, the more elastic is the test specimen. M. J. Challier (164) sets up the following standard of values referring to the test after 28 days:

K = 23,000—26,000 for concretes of medium quality
K = 20,000—23,000 " " " good quality
K = < 20,000 " " " best quality.

The Research Institute for Blastfurnace Slag, Rheinhausen, for instance, has determined values for the K-factor, which are even below 18,000, by taking gravel concretes with blastfurnace slag cements with minor clinker contents and medium cement content between 250 and 300 kg/m^3 mixed concrete after 28 days.

A further reference to the favourable elastic properties of blastfurnace slag cements is made by S. Härig (165) in which especially the values of E-module are set against the bending strength.

Besides other properties such as the high resistance against chemical attack and the low heat development, the elastic properties of the blastfurnace slag cement concrete are of importance for marine- and mass-concrete constructions (166), (167) and (168).

Heat of Hydration

The heat of hydration of slag cements is as specific as the strength evolution. For portland blastfurnace cement (< 35 slag) they do not differ essentially from that of pure portland cements. The hardening of the

blastfurnace cements (> 60 slag) is characterized by more colloidal reaction runs (10). Therefore it seems that/the heat development of these slag cements in the first two to three days is essentially more definite with the portland clinker component and that furhter heat evolution is due to the proportion of granulated slag.

R. Dietrich (155) found that, independently of the slag content, all cements, on full hydration, i.e. after a long time, develop approximately the same amount of heat. Cements, however, differ very much in the process of heat development as referred to the time factor (169), (170), (171), (172), (173), (174), (175) and (176).

H. Lehmann and W. Roesky (170) pointed out that with slag cements the heat of hydration developed per kg/cm² is less than with cements without additional slag, i.e. that for achieving equal strength values on cements with high (> 60%) slag additions less heat is developed. Interesting in connection with this conclusion is the information by H. Lafuma (177) that the maximum increase in temperature in 4 × 4 × 16 cm prisms of pure cement and mortar (1/3 ISO) was measured as follows:

Cements	High alumina	Portland	Ciment de laitier au clinker slag content > 80%
Pure cement paste	14.8°C	5.4°C	0.50°C
Mortar 1/3 ISO	5.6°C	1.65°C	0.13°C

The very low heat of hydration is a specific property of blastfurnace slag cements (with slag > 60%). An example of the decrease in heat development of cements with increasing addition of granulated slag is given by R. Alegre (175) (Table 9). However, a function apparently so linear as shown in this table, does not always exist.

Table 9. *Influence of slag content on heat of hydration publ. by R. Alégre (175)*

Slag content (%)	0	30	50	70	85
Age	Heat of hydration (cal/g)				
12 hours	27	16	11.5	8	6
1 day	62	40	30	23	18
2 days	75	54	43	36	27
3 days	79	60	48	40.5	30
4 days	82	64	52	43	32.5
5 days	85	68	55.5	45.5	34
6 days	87	71	59	47.5	35.5
7 days	90	—	62	49	36.5

Specific surface 3000-3100 cm²/g

H. E. Schwiete and K. H. Karsch (174) and U. Ludwig and K. Rakel (173) have established that the heat of hydration increases with the w/c-value. Referred to the clinker portion in cements containing much slag, the w/c-value is always higher than that of the test mixture. The clinker component, therefore, in combination with a slower reactable slag, reaches faster high hydration degrees (123) and, therefore, positively influences the heat evolution during the first hardening stages.

On account of these facts, the heat of hydration of some cement with a small slag share, e.g. that of an "Eisenportlandzement", can be higher in the early stages of hardening than that of a portland cement containing 100% of the same clinker. A considerable decrease in the hydration heat released during the first days can be observed only on cements containing more than 70% slag.

The low heat of hydration is a great advantage of these particular cements (Table 10), which, on account of their high resistance to aggressive media, is well-suited for all tasks of hydraulic engineering in cases of mostly very large cross sections of solid structures.

As opposed to slim reinforced-concrete structures in building construction, where the heat developed is dissipated sufficiently fast, the high increase in temperature in solid concrete structures of large cross section may be responsible for the formation of fissures. On this problem, test results of our Research Laboratory (178), (168) as well as of other authors (179) (171), (180) and (181) are available. These permit a very good evaluation of the temperature increases to be expected in structure, when the heat of hydration of the cement used is known.

The heat of hydration of cement can be measured adiabatically or by means of a heat-flow calorimeter (182) (in simplified form, vacuum flask method) or from the difference in heat of dissolution. The last mentioned, indirect method is very unsatisfactory for both slag-containing and puzzolanic cements (7), (183), (172), (175) and (182). Most of these cements contain slowly soluble constituents that may render the determination of the heat of dissolution very difficult and inaccurate. Likewise the determination

Table 10. *Heats of hydration of portland and portland blastfurnace cements publ. by R. W. Nurse (7)*

Cement	Heat evolved (cal/g)		
	1 day	2 days	3 days
Ordinary portland	23—42	42—65	47—75
Rapid-hardening portland	35—71	45—89	51—94
Portland blastfurnace	18—28	30—50	33—67

of the loss on ignition cannot be effected directly. F. Gille (183) proposes a determination of the loss on ignition through the CaO content. This method is adopted by the German standardization proposal (184).

Since the heat of hydration is obtained from the difference in heat of dissolution, inaccuracies in the determination of the heat of dissolution may considerably influence the final result.

In solution calorimetry, cement is hydrated under isothermal curing conditions. These results, therefore, are mainly of scientific interest, because they permit drawing conclusions with regard to exact, but also varying curing conditions.

In the U.S.A. and in Italy also conduction calorimetry is used for measuring heat of hydration. In the Research Institute for Blastfurnace slags, Rheinhausen, a process based on heat flow has been used in the last few years. By this method the heat of hydration can be determined directly under isothermal curing conditions. The advantage of this process is that by insoluble residues or loss on ignition no difficulties in measuring occur. This test may be carried out also with mortar and with different w/c-values. The heat evolution is obtained in the form of a curve. The process can be used properly up to a curing time of 28 days.

The heat of hydration, just like the curing of cement, is a function of temperature.

For practical structural engineering purposes, thus, the adiabatic (155) and (185) method gain special importance. Partly, however, also the vacuum flask method, simpler to employ, give useful results for practical purposes (172), (179) and (182), for which either the increase in temperature of a mortar or pure-cement sample is tested, or the heat dissipated through the walls of accurately gauged vacuum flasks is measured, and the heat of hydration determined from it.

The vacuum flask method is generally employed in France (177). Its advantages and drawbacks are described by R. Alegre (175). Also the results obtained are not quite precise, they, nevertheless, constitute a valuable help for the constructional engineer.

Fig. 15 graphically shows the results of the various measuring methods obtained on altogether 325 cement samples in the Research Institute. The influence of temperature on the heat evolution of hydration can be seen from the positions of the scatter bands for the various test methods after 1 to 7 days. The relationships shown in the diagram are in accordance with the data given by R. Alegre (175).

It can be seen that the heat of hydration, as measured by the isothermal method, after 28 days, corresponds approximately to that measured adiabatically after 7 days; the values measured by the isothermal method after 7 days correspond to the adiabatic values after 2 to 3 days (155), (185), (172) and (175). The vacuum flask methods partly give lower results than the adiabatic methods and at the same time show a greater scattering.

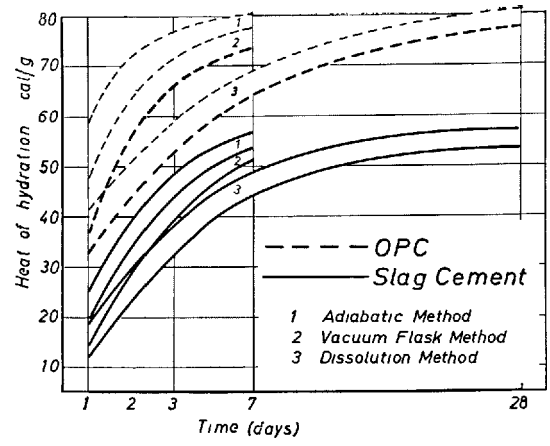

Fig. 15. *Heat of hydration determined by different methods dispersion ronge of values obtained from 325 cement samples*

Influence of Curing Temperature

The reaction speed of blastfurnace slag cement is as much dependent on the curing temperature as is portland cement. At low temperatures the cements—"Eisenportlandzement" and blastfurnace slag cements with < 50 weight-% slag act similar to portland cement. The reaction of cement with high slag contents, however, is partly a little more delayed at temperatures of $+5$°C or below (170).

With temperatures exceeding 20°C, especially in case of heat treatment or steam curing, blastfurnace slag cements generally show very favourable strength results (186), (187) (188), (44), (189) and (190). Firstly, the increase in strength, which can be attained by heat treatment, rises with growing slag contents, and simultaneously the after-hardening is maintained better when the contents of slag is increased. The final strength of blastfurnace slag cements will be lowered only little or not at all with an initial heat treatment.

Behaviour in Aggressive Solutions (by F. Schröder and H. G. Smolczyk)

General Survey

There is ample literature on the behaviour of slag cements in aggressive solutions—especially in sul-

phate solutions and in sea water—as well as on the testing methods. As this group of subjects is assigned to another principal paper (III—2), this paper is to give only a general survey and to deal only with some very recent results.

A great number of laboratory tests—mostly with mortars—have been carried out. This paper, however, refers mainly to all long-time studies that were made, and comments on their results, the reasons for which are the following:

Short-term tests, mortar tests and rapid tests are highly dependent on specific test conditions and especially on the treatment of the samples, mostly very small ones, prior to the chemical attack. Large-size concrete samples are generally more indifferent to such variations.

Moreover, in some cases unsuitable mixtures of clinker and very slightly hydraulic slag were made for such tests and called "blastfurnace slag cement". If, in such tests, the indication of the strength characteristics is missing, i.e. if the mixtures are not qualified as cement, their results are of very little value with respect to the comparison of cement types. The same applies by analogy to all the other cements having several components. P. Pirotte (191) has put emphasis on these facts.

A very critical appraisal must be made of the results of comparisons between fast-setting and slow-setting cements, which after 1 to 3 months may very well have the same strength. For rapid tests, however, they are subjected to chemical reaction mostly at a very early stage, at which the slow-setting cement still has a much lower strength than the fast-setting cement. The behaviour of the sample—e.g. concerning strength —after long-time chemical reaction is frequently, however, not related to the strength which this sample had at the beginning of its immersion, but to the mostly very high strength which another sample, immersed in plain water all the time, has acquired in the meantime. In our opinion, it is misleading to speak in such cases of "loss of strength" or of "increase in strength". In these cases one should at least use the terms "*relative* loss" or "*relative* increase". Many cases can be established in which samples consisting of slow-setting cement, in spite of a *relative loss in strength*, showed a greater *increase in strength*, during the chemical reaction, than the sample of fast-setting cement.

These facts explain why a few papers on laboratory tests also report poorer resistance of slag cements against chemical attack, as compared to portland cement (192), (193), (194) and (195) or an equal behaviour (196) and (197).

The vast majority of all laboratory tests, on the contrary, have shown a higher stability—especially of blastfurface slag cements and supersulphated cements, rich in granulated slag—in sulphate solutions (7), (116), (198), (199), (200), (201), (202), (203), (189), (204), (135), (205), (206) and (207), in chloride solutions (198), (207), (208) and (209), and in acid waters and against leaching (7), (198), (200), (189), (210), and (211) as well as in sea-water solutions (200), (189), (212) and (213).

Likewise during all the long-time studies, known to us, of concrete in sulphate solutions and in sea-water the slag cements have shown a more favourable behaviour than standard portland cements, and the blastfurnace slag cement rich in granulated slag (189), (212), (214), (215/16), (217), (218), (219) and (220) have proved without any exception a better durability.

Results of Long-Time Studies Including Slag Cements

F. Campus (215) reports on immersion of mortars, concretes and reinforced concretes, consisting of altogether 10 cements, in $MgSO_4$ solution (4870 mg SO_3/litre) and in the tidal zone of the North Sea near Ostend up to a period of 30 years. During these studies, the 4 tested slag cements have shown a very good behaviour in either solution—especially in the form of concrete cubes having a mixture ratio of 1: 5.4 and a w/c-factor of 0.45. Concretes consisting of some other cements—especially high calcareous types—had after 20 years in the $MgSO_4$ solution deteriorated to such an extent already that a compressive-strength comparison with the concretes immersed in water was no longer possible. Likewise in sea water the edges and corners of samples with nonresistant cements were very strongly deteriorated.

Experiments carried out by the "Deutscher Ausschuß für Stahlbeton" with the storage of concrete cubes with 13 cements in the tidal zone of the North Sea near Wilhelmshaven for up to 25 years led to virtually the same results. However, these tests will have to be investigated in detail once again, for although experimental conditions and results are accurately known, some confusing facts have lately come to light.

The evaluations so far made by A. Eckhardt and W. Kronsbein (221) after a period of 19 years, and by A. Hummel and K. Wesche (214) after 25 years, had established that durability increased in the following order:

1st Portland cement
2nd "Erzzement"
3rd "Eisenportlandzement"

4th Blastfurnace slag cement
5th High-alumina cement.

Binders with trass additives were comparable with the first three cements and in no case attained the stability of blastfurnace slag cements.

Based on the subsequent determination of the cement content and the pore volume of the paste for test specimen which had not yet been wholly destroyed by sea water after 25 years, K. Wesche (222) tabulated a new sequence. This attributed identical behaviour to portland cement, "Eisenportland" cement and blastfurnace slag cement, while only slag cements with trass additives and high-alumina cements are said to attain a higher durability.

In an attempt to investigate the reasons for these markedly contradictory views, Tables 11 a, b and c list all measured values so far published which may help to elucidate the matter (214), (221) and (222). Three series of concrete cubes, each with 13 binders, were made in the mixing ratios 1:3 (Table 11a), 1:4 (Table 11b) and 1:5 (Table 11c). All cements were mixed with plain freshwater, (methods a) a few extra ones with sea water (method b). The table lists the compressive strengths of the concrete cubes after 28 days and after 2 and 19 years immersion in sea water. Already after 19 years, 25 concretes of cements without or with little slag were no longer in any condition to be tested. Consequently, after 25 years, cubes of 9 cm were cut out of all specimens which had not yet been wholly destroyed. On these the compressive strength of the still undamaged concrete was measured. After 19 years, the loss in weight was determined for three cubes, each, after 25 years the loss of volume for one cube, each of the concrete still intact.

From this summary of the published measurements, we can easily draw the following conclusions:

All concretes with high-alumina cement proved stable, though some loss of strength was noted on some of the cubes mixed with sea water.

On all concretes with the three blastfurnace slag cements (approx. 50%, 60% and 70% slag), even with the lean mixing of only 260 kg/m³, very high strengths were measured after 19 years. After 25 years, they still remained durable as witnessed by the low loss of substance.

The "Erzzement" and the two "Eisenportland" cements (approx. 25% and 35% slag) attained a durability comparable to blastfurnace slag cements only at a cement content around 300 kg/m³. For the three normal portland cements, a content of 350 kg/m³ was clearly required to obtain the same level.

Fig. 16 shows the average behaviour of these 5

(According to test results of A. Hummel and K. Wesche)

cement groups.

Portland cements and "Eisenportland" cements with trass substitute gave poorer results in rich mixing and somewhat better ones in lean mixing than the same cements without trass additive.

The excellent properties of blastfurnace slag cements were in all cases impaired by trass substitution.

A further longtime study extending over 27 years was carried out in Norway near Trondheim (220). Here, reinforced concrete piles from 9 different cements—among them a blastfurnace slag cement with over 60% slag content and a "Eisenportland" cement with less than 30%—were exposed upright in the tidal zone. For the main test, cement content was 313 kg/m³ and the w/c-factor approx. 0.6.

The concrete with blastfurnace slag cement (w/c 0.64) and with portland cement with 3% C_3A (w/c 0.56) showed high stability, while those with portland cement with 11% C_3A (w/c 0.61) were destroyed. The "Eisenportland" cement behaved better than this portland cement, but not as well as another with 6% C_3A, which attained the durability of the lean mixing with blastfurnace slag cement only when the cement content was raised from 313 to 417 kg/m³ (w/c 0.47).

In this long-time study, the specimens were attacked by a combination of sea water, frost and steel corrosion, and the assessment also takes the degree of steel corrosion into account.

In another longtime study carried out in England over 23 years, reinforced concrete piles were exposed in the tidal zone of the Thames estuary near Sheerness and half-immersed in three-fold sea water concentration near Watford. F. M. Lea and C. M. Watkins (212) reported on these experiments. Eleven cements—among them one blastfurnace slag cement—were tested in mixture of 1:2.6; 1:5 and 1:9. Here the order of increase in resistance to chemical attack was again:

1st Portland cement
2nd Trass cement and blastfurnace slag cement
3rd High alumina cement

The same order applies to the resistance against corrosion of the reinforcement. A comparable degree of corrosion protection was achieved for the following mixing and concrete covers of the steel.

Blastfurnace slag	mix.	1:2.6	and	2.5	cm cover
cement:	"	1:5	"	5	" "
Portland cement:	"	1:2.6	"	5	" "

Excellent behaviour of blastfurnace slag cement was also noted on concrete blocks weighing about 10 tons which had been immersed as bulwarks in the North Sea tidal zone on the island of Heligoland (208) and (217). Today after over 50 years their surfaces are rough, corners and edges are lightly rounded, whereas similar blocks of other cements show deep fissures and soft spots and have sustained severe partial damage.

Resistance of Slag Cements against Sulfate Action

Satisfactory behaviour in sea water has often been attributed to the well-known resistance of blastfurnace slag and supersulphated cements to sulfate solutions. But this cannot be the only reason. For "Eisenportland" cements with slag contents up to 30% already show an increase in their resistance to sea water, while resistance against pure sulfate solutions (for instance Na_2SO_4) only rises at slag contents above 50%, as has been shown in an extensive study by F. W. Locher (205).

Using the method developed by Koch and Steinegger (195), F. W. Locher investigated the sulfate resistance of slag cements consisting of portland cement clinker with 0.8% and 11% C_3A and granulated slag with 11 and 17.7% Al_2O_3. He found that for slag contents above 60% sulfate resistance improved in all cases compared with slag-free cements. Where slag

content was below 60%, a difference between the two slags was noted. While the low-alumina slag at contents above 20% brought about an increase in sulfate resistance in every case, the high-alumina slag at first had a negative influence. Sulfate-resistant cements were only obtained when slag contents were raised to over 60%. Fig. 17 shows six diagrams taken from this study which, in our opinion, adequately define the sulfate resistance of blastfurnace slag cements, a question which has sufficiently been discussed for decades.

Other Aggressive Media

Less attention has so far been paid to behaviour in the presence of chloride solution. Unlike the sulfates these have no effect in low concentrations but in concentrated solutions they can cause deterioration or complete destruction of concretes with high-calcareous cements (198), (207), (208), (209) and (223). H. G. Smolczyk (209) was able to show that saturated NaCl solution does not impair the development of compressive strength in blastfurnace slag cements containing over 70% slag, in contrast to portland cements with and without C_3A. In solutions of 3 mol/l $MgCl_2$ or 3 mol/$CaCl_2$ concretes of the latter cements were even destroyed within weeks, while those from blastfurnace slag cements with a slag content above 70% remained resistant. Even in the $MgCl_2$ solution, increases about 70 percent in compressive strength were measured after 2 years.

Clearly, these findings indicate that blastfurnace slag cements are not specially sensitive to the Mg^{++}

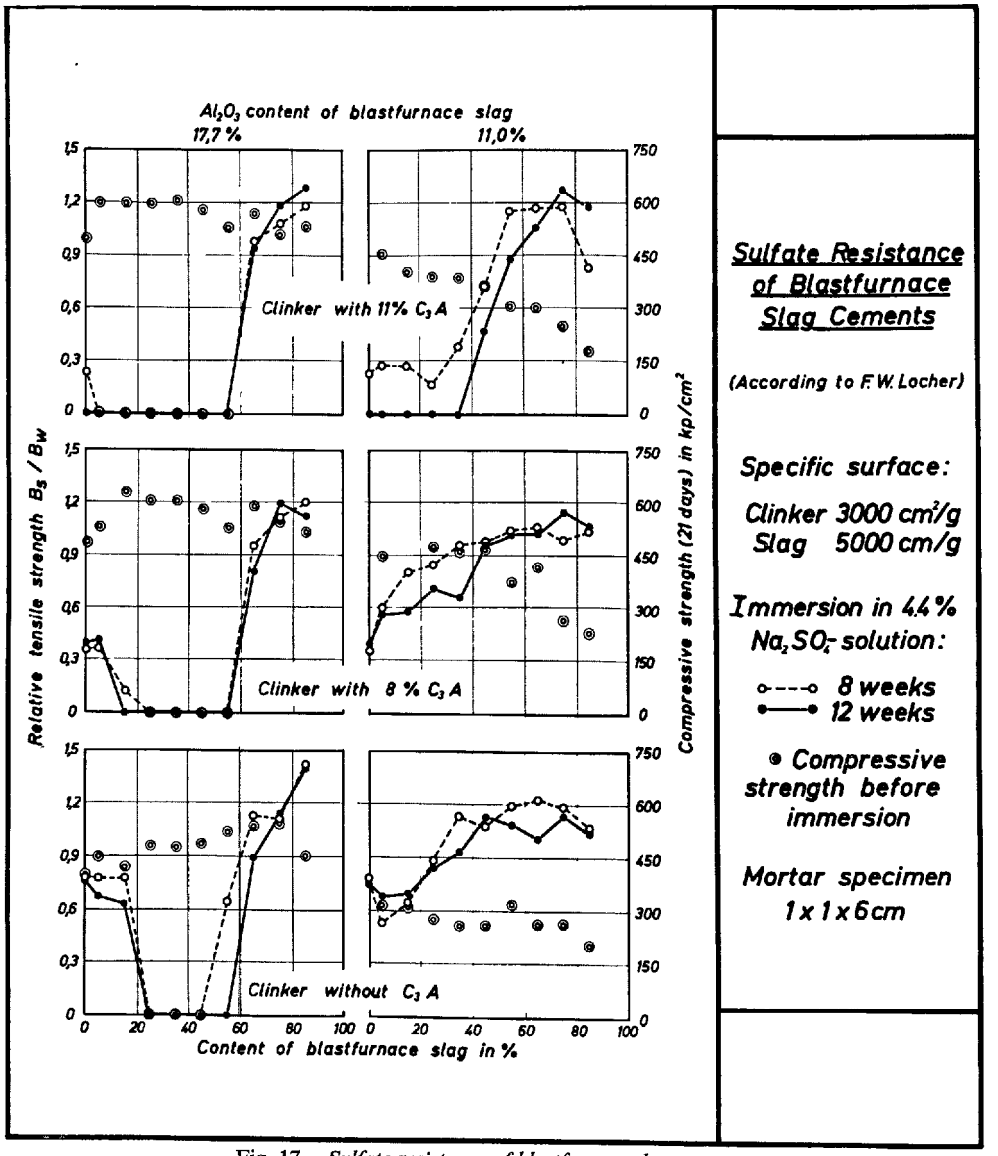

Fig. 17. *Sulfate resistance of blastfurnace slag cements*

ion. Long-time tests in $MgSO_4$ solutions by F. Campus (215/16) produced the same result. Apparently, the term "basic change" coined by E. Burke (224) has only a limited application to slag cements.

Bearing in mind that sea water has a high chloride content and that in tidal zone we must allow for marked increases in concentration within the concrete or on its surface (217) and (11), (see p. 539–553,) we may assume here a direct connection between the resistance of blastfurance slag cement to sea water and chloride solutions. We may also expect blastfurnace slag cements to resist the chemical attack of defrosting salts. Clearly, there is a wide field here for further investigations.

All concretes being strongly alkaline, their resistance to acid waters is comparatively low. Neutral water with very low salt content can also leach out porous concretes in the course of time. In this case, concrete density is a far more important factor than the selection of any given cement type (211). But, here, too it is reported that blastfurnace slag cements have shown rather a better performance than cements of higher lime content without slag (11) (see p. 539–553), (225) and (10) (see p. 710 (Vol. II) and p. 636 (Vol. III)).

Some Reasons for the Resistance of Slag Cements

There must be some fundamental reasons for the good resistance of cements with higher slag content against various solutions aggressive to concrete. A number of authors attribute it to the low CaO content. But this alone cannot explain pronounced differences in behaviour. We can be reasonably certain today that the greater durability of slag cements to given chemical reactions, such as acid waters, sea water or strong chloride solutions, is not merely due to the CaO in the cement, but is largely attributable to the lower content of free $Ca(OH)_2$ in the paste (7), (116), (123) and (225). Blastfurnace slag cements in contrast to supersulphated cements still contain free $Ca(OH)_2$ and have pH values above 12 (7), (126) and (226), but direct chemical attack causes this $Ca(OH)_2$ to be quickly converted, so that the leaching out or diffusion of the $Ca(OH)_2$ bound in the hydrates then proceeds very slowly. Moreover, this reaction leaves behind low-calcareous hydrate gels of lesser permeability which soon arrest many types of chemical attack (227).

These considerations also explain the apparent contradiction that we find the cements with greatest sulfate resistance just among the blastfurnace slag types with the highest Al_2O_3 content. The richer the slag in Al_2O_3, the lower the amount of clinker needed in the cement without any impairment of strength (123). In these cements with high contents of granulated slag, however, little additional ettringite can form under the influence of sulfate, as the ratio of diffusion-inhibiting hydrate gels to free $Ca(OH)_2$ is much greater than in other cements (116) and (228).

In the case of sulfate attack, two further factors must be considered. In the hardened paste of blastfurnace slag cements only a small part of the Al_2O_3 is available for additional ettringite formation, since the larger share has already been bound into the calcium-aluminate-sulfate hydrate phases or can evidently be very firmly bonded into the calcium-silicate hydrate phases (115), (114), (127) and (128). In addition, H. G. Smolczyk (116) established by microscopic examination that the ettringite crystals formed in the paste of cements with high slag contents are so tiny (about 5 micron) that they are not likable to set up any friction.

Effect of Mineral Oils

While the action of mineral oilds on concrete is certainly not in the nature of a chemical reaction, it should be briefly mentioned to complete the picture. Here, we have a very recent comparative experiment by W. Steinbach (229) available. Cement mortars from a portland cement with 12% C_3A and a blastfurnace slag cement with 70% slag were stored for one year in heavy oil, diesel oil and gasoline. The mortar prisms (w/c 0.5 and w/c 0.8), were cured in water for

Table 12. *Compressive strength of cement-mortars after 1 year of immersion in mineral oils. (According to results of W. Steinbach)*

Immersion in	w/c	Portland cement		Blastfurnace slag cement	
		kg/cm²	%	kg/cm²	%
Immediately before immersion	0.5	627	100	531	100
	0.8	330	100	234	100
Heavy oil	0.5	596	95	557	105
	0.8	289	88	219	94
Disel oil	0.5	621	99	600	113
	0.8	305	92	238	102
Petrol	0.5	556	89	619	117
	0.8	285	86	312	133
Air (20°C, 65% r.h.)	0.5	649	104	584	110
	0.8	377	114	271	116
Water (20°C)	0.5	671	107	721	136
	0.8	357	108	352	150

7 days, then in the open air for 21 days and them immersed in the 3 oils with control specimens further exposed to open air and a 5th series cured in water.

Compressive strengths immediately before curing and after one year are compiled in Table 12. It will be seen that while the blastfurnace slag cement registered the highest strength increase in water curing, a higher growth rate was also measured for all other storage methods—including open air curing—than for the portland cement.

In summing up it can be stated that slag cements—and in particular the types with high contents of blastfurnace slag and the supersulphated cements—provide a relatively high resistance against various media which would either attack or weaken concrete of different composition. Admittedly, care must be taken to given them the sufficient wet after-treatment required for all hydraulic binding agents, as laid down in the concrete specifications of practically all countries.

Carbonation and Protection against Steel Corrosion
(by F. Schröder and H.G. Smolczyk)

Carbonation

The carbonation of concrete and possible differences between slag cements and portland cements have been investigated particularly in Germany over the last eight years with often contradictory results.

The research was sparked off by earlier carbonation tests carried out in Japan. Here, K. Kishitani and K. Hamada (230) found that the depth of carbonation rises without limit with the square root of time and that carbonation rate is lowest for pure portland cement. T. Soda and K. Yamazaki (231) noted after five to ten years storage an arrest of carbonation up to altogether 20 years and found no difference in the carbonation depth of blastfurnace slag cements and portland cements. According to K. Kosaka (232) the differences were small. The results of measurements by T. Mori, K. Shirayama and A. Yoda (233) do not show consistently better performance by portland cements.

This work was followed up in Germany during the years 1962 to 1964 by various authors who investigated old and very old concrete structures. Individual results and their interpretations varied to some extent, but on an average no significant differences between slag cements and portland cements were noted (234).

Carbonation tests with mortars and laboratory concrete batches did, however, show very marked differences in both results and their interpretations (235), (236) and (237).

According to A. Meyer, H. J. Wierig and J. Husmann (236), the conditions of storage have a considerable bearing on carbonation, but carbonation speed obeys in all cases the law:

$$\text{Carbonation depth} = \text{const.} \sqrt{\text{time}}$$

In addition, slag cements are said in principle to carbonate faster than portland cements.

F. Schröder, H.G. Smolczyk, K. Grade, R. Vinkeloe and R. Roth (237) by contrast found that this approximate carbonation law was obeyed only under dry storage conditions (20 centigrade and 65% relative humidity) and even then by all the cements not in the same way. Carbonation functions differ in different cement types, particularly at the start of the process. Thus, blastfurnace slag cements with high slag contents tend to carbonate quicker at the start, but are then caught up by portland cements of the same compressive strength. It appears that concrete quality and its after-treatment before carbonation have a far greater influence. In addition, determination of CO_2, X-ray and microscopic investigations of carbonated concrete brought experimental proof that the free $Ca(OH)_2$ content of the paste has virtually no effect on carbonation rate, since all other hydration products of cement are alkaline and carbonate too (238) and (239). Calcite, Vaterite and partly also Aragonite appear as carbonation products (240), (241), (242) and (243).

Why results and interpretations are partly so much at variance may probably be explained by the following reflections as well as recent measurements:

a) So far we have too few long-time carbonation studies with concrete available, so that we too often extrapolate the results of few years on to much longer time spans. All we know about carbonation functions so far can only be regarded as rough approximations and so quite inadequate for extrapolated conclusions and the exact definition of different behaviour.

b) The experimental conditions of many tests are not strictly comparable. Since concrete quality, e.g. its density, is a decisive factor, it must be kept uniform if we want to measure the influence of chemical cement composition. We can roughly approximate this requirement if we compare test specimen of equal compressive strength. In short, we must use cements of comparable compressive strength and store the test specimen in water for a sufficiently long time.

Frequently, however, slag cements with more than 70% slag and portland cements "Z 375" are compared in the form of 4 × 4 × 16 cm mortar prisms, which

are already exposed to ambient atmosphere carbonic acid after 3 to 7 days. Small mortar shapes dry out very fast, so that the start of open-air storage must be directly taken as the reference strength, i.e. not that strength ratio of roughly 1: 1.3 between blastfurnace slag cement "Z 275" and portland cement "Z 375", which correspond to cement quality after 20 days water storage. As blastfurnace slag cement "Z 275" has a different compressive strength increase rate than a portland cement "Z 375", we must, in fact, take a ratio of approximately 1: 1.9 for 7 days pre-storage, and at 3 days only about 1: 2.2. And the square root of these ratios roughly correspond to the carbonation speed ratios, measured and compared in these reports. However, these measurements do not compare types of cement, but merely compressive strengths of test specimen.

Numerous measurements we have carried out ourselves have shown that carbonation depth on mortars and concretes of portland cements, "Eisenportland"-cements and blastfurnace slag cements, stored under identical conditions, after a few years becomes closely proportional to the factor $1/F_0$, where F_0 is the compressive strength of the test specimen at the start of carbonation and includes the influences of the water/cement ratio, the type of cement, its quality class and the after-treatment of the specimen. Any dependence of carbonation on the chemical composition of the cement has so far been noted only for high alumina and supersulphated cements. These carbonate at a markedly faster rate than their factor $1/F_0$ indicates.

These results also provide an answer to the chemically well founded theoretical reflections of H. Steinour (244). But though he points out the reserves of alkalinity of the cement paste, in addition to the free $Ca(OH)_2$, he assigns no significant importance to the degree of this overall alkalinity.

This assumption probably applies only to such cements which do not form any free $Ca(OH)_2$ and so also develop hydrates which are leaner in lime content. Carbonation speed of all other concretes, on the other hand, seems to be governed to all practical purposes exclusively by their physical properties which may be roughly summed up in their compressive strength. Probably, carbonation in concretes containing $Ca(OH)_2$ is not governed by the high speed of chemical reaction but by the slower rate of drying out.

These findings agree with the results of H. E. Schwiete and U. Ludwig (245) who recognised the open porosity of the concrete as a decisive factor and developed suitable testing methods.

Future carbonation tests should, therefore, include the measurement of pore distribution and development of compressive strength in the test specimen. Above all, in order to obtain a basis for valid assessments, we must know the strength of each specimen *immediately before* it starts to dry out and carbonate.

These initial strengths are also required in order to measure the changes in strength as carbonation proceeds. Here again, opinions differ. A. Meyer, H. J. Wierig and J. Husmann (236) state that compressive strength of portland cements rises considerably as a result of carbonation, while that of blastfurnace slag cements containing less than 50% slag remains unchanged. But in their experiments they enforced carbonation by storing tiny cylinders (1 cm) in 10% CO_2 and then compared these minute bodies with others which were stored over 56 days in water. This comparison is inadmissible, because of the marked final hardening of slag cements in water storage, so that it does not tell us the real changes in strength by carbonation. Therefore, it is not surprising that a different experiment, carried out in the same laboratory, produced entirely different results (229). Here, the $4 \times 4 \times 16$ cm test specimen of a blastfurnace slag cement with 70% slag increased in strength to 110% and 116% after only one year's storage in the ambient air (see Table 12).

According to W. Manns and O. Schatz (246) carbonation will only increase the strength of slag cements if they contain more than 40% clinker. In this test, the specimens were first dried at 40 centigrade and then carbonated in 9% CO_2.

These test conditions again do not correspond to practical reality. Extensive tests at the Research Institute for Blastfurnace Slag and two other laboratories of the slag cement industry have yielded results completely different from the ones mentioned above. They are shown in Table 13. Here, lean mortars of 10 cements were stored in water for 28 days and then carbonated completely by 50 weeks open-air storage (20°C, 65% r. h.) or 6 months in 3% CO_2 (20°C, 65% r. h.).

Except for the sulphate slag cement, considerable increases in compressive strength were measured on all samples. The increase in strength, when the samples are exposed to air, range between 50 and 120%, and when they are exposed to CO_2, between 100 and 200%. With blastfurnace slag cements containing more than 50% of slag, the average values were somewhat lower than those of the other cement types, and the portland cement types with $< 3\%$ C_3A showed the greatest increase in strength. Only the supersulphated slag cement lost half of its strength, when exposed either to air or to CO_2.

Table 13. *Compressive strength of cement mortars after total carbonation in air or CO_2*
Mortar bars 4 × 4 × 16 cm, w/c 0.76

SHZ*	85	427	232	194	50	190	45

* SHZ = Supersulfated cement

These tests were carried out with standard cement types bought from commercial sources, and moreover several laboratories obtained the same results. It will be necessary to discuss the reason why some of the results obtained by other authors are different.

Protection of Reinforcement against Corrosion

Many authors see a direct relationship between carbonation of concrete and protection of reinforcing steel against corrosion, and it is certainly true that the safest protection of the steel against corrosion is afforded by the alkaline-reacting concrete. For this, however, the concrete must be compact and resistant to substances that generally attack the concrete itself.

Therefore, it is probably safer to say that a non-compact or unstable type of concrete gives less protection against steel corrosion and also carbonates more rapidly, when exposed to air (237). It is difficult to check by experiment whether steels, if sufficiently covered with carbonated, but compact concrete, may corrode to such an extent that damage occurs, for carbonation of compact concrete takes very long.

This question also could not be clarified definitely during the colloquium of the RILEM Technical Committee on "Corrosion of Reinforcement of Concrete" at Wexham Springs in September 1965. Considerations on this specific subject will be found in the two "General Reports" by P. Halstead (247) and C. A. Lobry de Bruyn (Chairman of the colloquium) (248).

The testing of very old structures has shown that in non-compact concrete types or insufficient concrete covering, damage due to corrosion has often occured, whereas on steels, in compact concrete types which had carbonated very slowly, only traces of rust have been found, even if the concrete contained chloride (249). In this connection, some authors report a lesser rust prevention by slag cement types (234) and (236), other did not find that there was any difference compared to portland cement types (234), (237) and (250).

On the influence of chloride additives and on the behaviour of steam-treated concrete types, extensive concrete tests have been carried out in Belgium, about which R. Dutron and A. Mommens (251) have reported in detail. During these tests great differences with varying test conditions were established, but no systematic differences between slag cement and portland cement.

In old structures near the sea, and in reinforced concrete immersed for decades in sea water in England, Belgium, Italy, France and Norway, the protection of the reinforcing steel against corrosion was clearly better with blastfurnace slag cements than with ordinary portland cements (212), (215/16), (218), (219) and (220).

Discussion on Slag Cement Types in Prestressed Concrete

More recently apprehensions repeatedly have been expressed in Germany that the sulfide in slag cement, harmless for normal reinforcing steel, may, with certain prestressing steels subject to high stresses, lead to cathodic hydrogen embrittlement and to stress corrosion fracture.

These discussions have been brought about by a number of cases of corrosion damage on prestressed prefabricated concrete consisting of sulfide-containing high alumina cement (252).

However, F. K. Naumann and A. Bäumel (253), who had already described this type of stress corrosion, have clearly pointed out in their publication that hydrogen embrittlement cannot occur within alkaline concretes and that, even in high alumina cements, previous conversion and decrease in volume of the hydration products are a prerequisite for it. According to H. G. Smolczyk (243) this decrease in volume alone is not sufficient to explain the fundamentally different and very disadvantageous behaviour of converted concrete consisting of high alumina cement. He rather points to the decisive role of the water of crystallization in the stoichiometric computation of the conversion in % by volume:

$$3CAH_{10} \longrightarrow C_3AH_6 + 2AH_3 + 18H$$

100% by volume ~48% by volume ~55% by volume

This means that after the conversion about half of the previously solid hydrate exists as free water, which may evaporate and leave pores. The same results were

obtained also by H. E. Schwiete, U. Ludwig and P. Müller (254). This conversion is well known (11) (see p. 437-444,) (255) and can be very well established by X-ray analysis, as is shown in Fig. 18 (243).

Since blastfurnace slag cements form the same hydration products as portland cements (7), (114) and (118), such conversions are not possible, and a comparison with high alumina cement is fundamentally wrong (243). Furthermore we do not know of any case of stress corrosion faillure in concrete consisting of slag cement.

Corrosion tests by B. Ost and G. E. Monfore (256) with prestressing steels in mortars of 3 types of portland cement and 5 types of slag cement (slag up to 77%, sulfide up to 0.8%) with and without chloride additive have not shown any difference between portland cement and slag cement.

Two extensive long-time tests with prestressed concrete piles were started at 6 different places by "Arbeitsgemeinschaft Hochofenschlackenforschung" in 1963, and by "Deutscher Ausschuß für Stahlbeton" in 1964. Moreover a prestressed-concrete testing program (257) with samples half-immersed in sea water has been carried out in France since 1961. It may be expected that in 5 to 10 years significant results from these 3 long-time studies will be available.

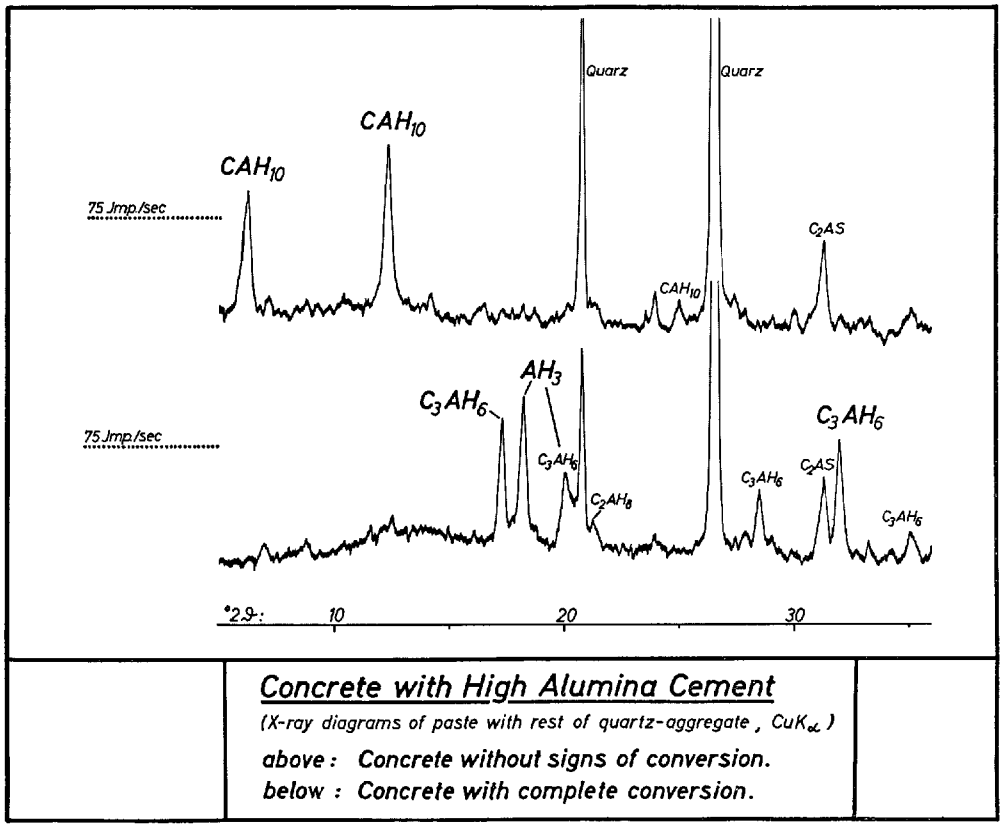

Fig. 18. *Concrete with high alumina cement*

Technical Application of Blastfurnace Slag Cements

Blastfurnace slag cements are used in all branches of concrete and reinforced concrete construction, in civil engineering and building construction, in hydraulic engineering, bridge construction and in the concrete block industry.

There are practically no restrictions on their use in reinforced and prestressed concrete constructional work (189). Only in West Germany high slag cements containing more than 50% by weight are—for the time being—excluded from use in prestressed concrete with direct bonding—i.e. without enveloping tubes. A table showing preferred applications of various cements has been prepared in France (111).

Due to their specific properties, slag cements, mainly those high in slag content are particularly suitable for steam-curing. Steam-cured concretes made from slag

cement are often superior to those without such treatment, but at least equivalent.

A special field of application is moreover the range of concrete for building structures for which cements with a low heat of hydration and/or high resistance to chemical attacks are demanded. Numerous structures in many countries witness the good use of the specific characteristics of slag cements. The following examples are representative for many others:

Bridges: partly prestressed concrete: over the "Oosterschelde"/Netherlands (258), to the Isle Oleron/France (259), along the highway "Autostrada del sole"/Italy (260) and e.g. the motorcar-roads and highways at Düsseldorf/Germany (261);

Marine structures: harbour-locks "Baudoin" Anvers/Belgium (189), "Haringsvliet"/Netherlands (262), "Wilhelmshaven"/Germany (152), and the dams and tides-power station at the Rance/France (263);

Hydraulic engineering structures: Pumping power-station Vianden/Luxembourg (267), Metro-tunnel Rotterdam (268) and airport Shiphol (269), (270) and (271), the canal-locks at the "Mosel"-navigation-way (264), (265) and (266), Montblanc-tunnel/France/Italy (274), barrage "Roselend"/France (272) and (273) and the atom- and nuclear research-center Jülich/Germany (277).

Written Discussion

Alfredo Negro

In this principal paper Mr. Schröder makes evident the various possibilities of ionic structure of the silicates in the vitreous slags, which can be identified by the structure itself after devitrification.

A prominent place is given to the silicates of the melilite group, having the general formula $A_2^{2+}\ B^{2+}\ X^{4-}\ O_7^{2-}$ which are considered as solid solutions in the crystalline state; as is known, usually the two main minerals of this solutions are gehlenite $Ca_2\ Al(AlSi)O_7$, and akermanite $Ca_2\ Mg\ Si_2\ O_7$; having a tetragonal lattice which encloses the ions Ca^{2+} with coordination eight, at the centre or irregular polyhedrons, which are made up of oxygen atoms.

In relation to the experimental results of Goldsmith (1), Nurse (2) and other researchers and to the relative interpretation of Christie (3), we carried out some research with X-ray (4) on the introduction of NaF into gehlenite lattice, in order to break the bonds

Ca–O, putting Na^+ in place of Ca^{2+}, and retaining the electroneutrality by the monovalent unity F^-.

These are the results of our works. It has been found that, when a low quantity of NaF is put into gehlenite, a slight deformation of lattice with increase of the unit cell occurs; when a 3.75 NaF percentage is over, a superstructure is originated; a slight lattice contraction, instead, is found when the NaF approaches to five per cent. Decomposition of the gehlenite is obtained using greater additions.

In successive work (5), in order to examine the possibility of the substitution of F^- with OH^-, the above modified gehlenites were hydrated with a lime-saturated solution: we have found that the 3.75 NaF gelenite, although crystalline, presented the typical interferences of the hydrates C_2ASH_8, the stratal hexagonal compound.

The only reported case of hydration of the crystalline gehlenite is that of Carlson, who operated in steam and obtained the cubic compound C_2ASH.

Another set of researches have been carried out on vitreous melilites at different temperatures and pressures, in order to obtain different hydration compounds and to characterize them using X-ray, I.R., and differential-thermal analyses.

The main results are the following: at 50°C (6), glasses in gehlenite-akermanite system present a decrease of reactivity with increasing the akermanite content; when this content is higher than 25%, no reaction occurs. The principal hydration product is C_2ASH_8 and, increasing the akermanite content, only the a_0 parameter in hexagonal lattice decreases from 9.96 Å to 9.93 Å.

Together with the above specified compound, the C_3AH_6 is present which is transformed with time into the successive terms of the hydrogarnets series.

Successive experiments (7, 8) of autoclave hydration on glasses at a higher content of akermanite (from 75% to 100%) have been carried out; the following results have been obtained: at pressure between five and twentyfive atmospheres in almost all the specimens with above specified composition, has been found αC_2SH with small quantities of compounds of tobermorite group, and in some cases with plazolite and xonotlite; anyway, no magnesium hydroxide was found; the interpretation of these results are in according to the specialized literature, that the magnesium takes the place of calcium in the hydrated silicates; in addition a tobermorite 11 Å has been seen, where aluminium partly substitutes the silicon; similar results, starting with other materials are obtained by Kalousek and Diamond (9).

Oral Discussion

Niko Stutterheim

In his paper, Dr. Schröder quotes Guye as recommending a higher fineness for South African cements consisting of clinker with high MgO contents (16-25%) and for granulated slags containing up to 22% MgO for improvement of volume stability. These high MgO clinkers were purely experimental. No portland cements of abnormally high MgO contents (above 5%) are made in South Africa.

On the other hand, slags with MgO of up to 22% are used extensively for slag cements: although such slags are finely ground, this is not done to improve volume stability—they are stable; soundness of such high magnesia slags was the theme of my paper to the 1960 Washington Symposium."

Oral Discussion

Jean Forest

It is desirable first of all to review the interpretation of published data, extracted from a work concerning particular cements bonded with orthophosphoric acid (1), concerning industrial and synthetic blast furnace slags.

The D.T.A. and S.T.A. of these slags which give identical starting temperatures θ°C of devitrification, and knowledge of analytical results from C. Malquori, R. Pinault (2) and Poliet et Chausson, made possible the use of the statistical method.

Applied to 34 slags without Ba and with little alkali content, it reveals a significant correlation between θ°C and $\frac{Ca^{2+} + Mg^{2+}}{Al^{3+}}$ with $r = 0.62$, for a probability threshold of 0.01 read on student's table.

The linear regression can be written:

$$\theta°C = 715.5 + 10.96 \frac{Ca^{2+} + Mg^{2+}}{Al^{3+}} \text{ (Fig. 1).}$$

Justification of this deduction can be found in the work of G. W. Morey (3) who studied the crystallization of a glass 1.11 N-0.95 C-6S in which Al_2O_3 is substituted for CaO.

The effect (Fig. 2) is marked by an increase of devitrification temperature which diminishes nevertheless when the composition permits the appearance of a new mineral.

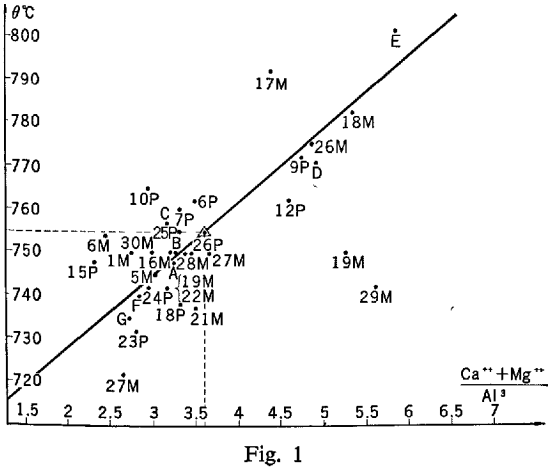

Fig. 1

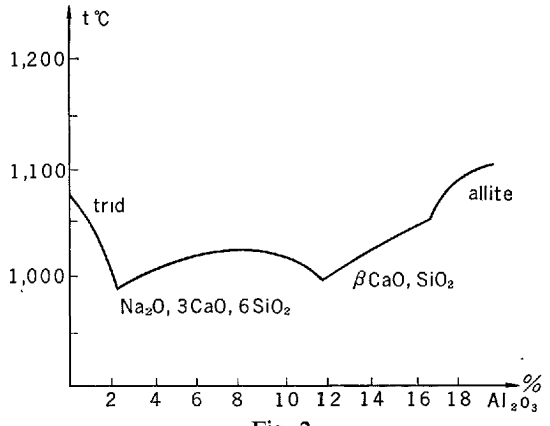

Fig. 2

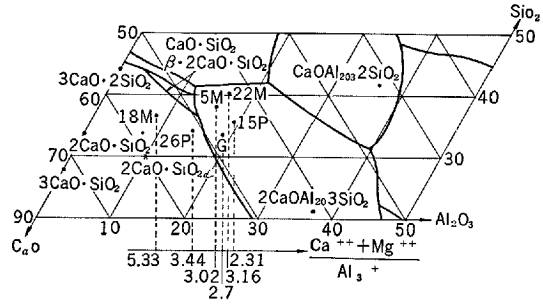

Fig. 3

When $\frac{Ca^{2+} + Mg^{2+}}{Al^{3+}}$ decreases, the representative point of the slag, placed on a Rankin Diagram, considering only the 3 elements Si, Ca, Al, is displaced from the primary stability field of α C_2S to that of C_2AS, passing through the eutectic line (Fig. 3).

The analogy with the preceding case leads us to suppose that the observed correlation results from this transition.

In practice and considering that blast furnace slags high in alumina content are valued, the θ°C knowledge should be one of the basis on which to predict their hydraulic properties.

This observation which wanted explaining concurs with the conclusions of F. Keil and F. W. Locher (4) about the hydraulic properties of glass in the C–A–S. system.

The authors show in fact that the activation with clinker of MgO containing slags, pushes the field of high resistance values of compressive strength up to elevated values of Al_2O_3.

Oral Discussion

R. R. Hattiangadi

Dr. Schröder's paper had brought out that portland blast furnace cement had extraordinary good properties in respect of sulphate resistance and was highly recommended. Dr. Hattiangadi asked if there was any correlation between the sulphate resistance of portland blast furnace cement and the alumina content of the slag. In his own experience in India where the blast furnace slag had a very high alumina content, (over 22%), they had found that the sulphate resistance as measured by standard methods was hardly as good as the parent portland cement itself. Dr. Hattiangadi added further that he would be glad to furnish such information as was necessary in this connection. In the general reply to the various points, he got the impression that Dr. Schröder did not touch upon this particular point.

Oral Discussion

Udo Ludwig
Peter A. Otto
Hans E. Schwiete

Some interesting facts during hydration of supersulphated cement are shown in the following Fig.

1. The decrease in anhydrite is corresponding with the increase in heat liberation and strength development. That means that ettringite formation will give in this special case of supersulphated cement a part to strength.
2. In context we measured a decrease in open porosity by means of O_2-diffusion.

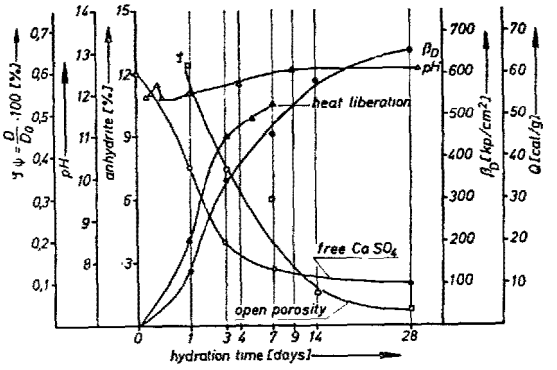

Fig. 1. *Hydration of SHZ*

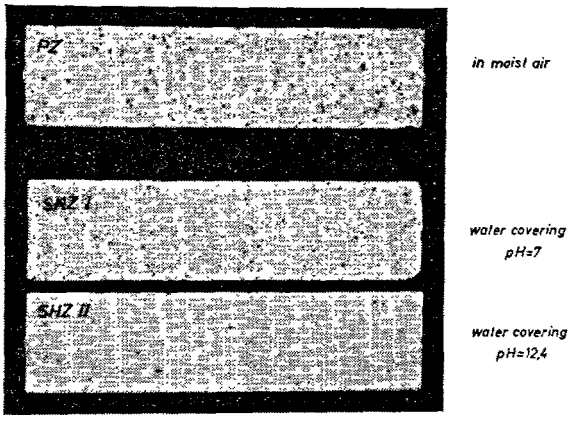

Fig. 2. *Surface abrasion of mortar specimen*

3. The pH-value firstly rises up to 4 hours hydration than decreases and rises again. At least the value lies in the range of 12.6.
4. The following Fig. 2 shows three motar surfaces with portland and supersulphated cement after 3 days hardening brushed with a steel brush.

SHZ I was covered with normal water during the one-days moulding time whilst SHZ II was covered with lime solution of pH = 12.4 by which the surface abrasion was put to zero. This means that by the water fixation during the first hydration and the resulting contraction of volume the open surface becomes poor in lime solution so that only slight hydration reaction can start. Open porosity remains large and CO_2 from air will neutralize the cement.

5. By the carbonation of ettringite ($d = 1.75$ g/cm³) under formation of calcite ($d = 2.71$ g/cm³), gypsum ($d = 2.32$ g/cm³), gibbsite ($d = 2.42$ g/cm³) and evaporation of free water the rest volume becomes 51% of solids and 49% of pores. This increase of porosity explains a loss in strength (3). But wet or moist stored supersulphated cement is in our opinion the best sulphate resisting cement.

Reply to A. Negro

The replacement of CaO by CaF_2 as a fluxing material for lowering the viscosity of slags has been utilized for many years. Thereby an exchange of oxygen ions by twice the number of fluorine ions takes place. It is obvious that this exchange increases the anion to cation ratio in silicate melts. This improves not only a lowering of the viscosity but it also accelerates the crystalisation.

In the case of the replacement of CaO by NaF according to the investigations by A. Negro the F-ions seem also to have acted as a mineralizer.

This can be deducted from the proof of the deformation of the gehlenite-lattice and the formation of a superstructure, and the decomposition of the gehlenite-crystals. The X-ray-diagrams by A. Negro and M. Regourd (1) show the formation and inclusion of wollastonite- and nepheline-crystalites (which was to be expected according to the investigations made by R. W. Nurse and H. G. Midgley (2)), Negro and Regourd assume moreover the inclusions of Na-silicate and Na-aluminate.

Due to these findings, one can assume, that by addition of NaF, gehlenite-lattices with a greater lot of empty sites are being built up. But the strict coordination requirements of the Si^{4+}-ions makes it difficult for silica to form vacant anion sites and therefore the alumina-tetrahedra are essentially disproportionated.

A. Negro's statement that by introducing of minor quantities of NaF the modified and microheterogenic gehlenite-crystals are more reactive than better ordered ones, is therefore not surprising. Due to the surely disturbed coordination requirements and the increased inner surface such gehlenite-crystals, if brought together with $Ca(OH)_2$ or other alkaline solutions will set and harden by capturing hydroxyl-ions and by binding water.

A. Negro's findings on hydration in water and under hydrothermal conditions of gehlenite- and melilite-glasses with an increasing akermanite content confirm some wellknown results, viz. that thereby can build up, besides tobermorite phases, gehlenite-hydrate, plazolite, xonotlite and hydrogarnets as at least I. C. Yang (3) has found under similar conditions.

A. Negro's statement that "at 50°C, glasses in gehlenite-akermanite system present a decrease of reactivity increasing the akermanite content; when this content is higher than 25%, no reaction occours" is in contradiction to F. Keil and F. Gille's (4) findings, and also to the actual experience gained over a period of many years in curing mortars and concrete at temperatures from 40 to 60°C.

Reply to N. Stutterheim

Considering the discussion remarks on Session IV-3 firstly I thank Mr. Stutterheim for his explanations.

Because of an uninteded shortening which occurred during translation, the reference text on page 64 does indeed give an inexact interpretation of F. Guye's findings.

The text in question should read: By means of a very interesting laboratory investigation, carried out at the "Centre Technique Holderbank" on request of the "Societe Anglo-Alpha, Johannesburg", F. Guye (162) proved the favorable influence of blast-furnace slag on the soundness of high magnesia cements.

The test blastfurnace cements consisted of laboratory clinkers with high MgO-content (16–25%), burned from South African dolomites, and of blast-

furnace slags from a South African iron and steel plant (ISCOR); the slags containing up to 22% MgO. The fineness of these test cements was 4000 to 4500 cm^2/g (Blaine), as usual for blastfurnace cements.

These test blastfurnace cements were found to pass the autoclave test (ASTM C151) under the following conditions: clinker content of the cement: maximum 30 vol.-%; MgO content of the clinker: maximum 17 vol.-%.

Reply to J. Forest

Further I thank Mr. Forest for informing me about his explanations concerning the estimation of the hydraulicity of slag in one of his publications (1).

Investigating a great number of slag samples, Mr. Forest found a relation between the chemical composition, expressed as an atomic ratio Ca + Mg/Al, and the devitrification temperature of slag-glasses.

Forest's relation allows it to valuate relatively well the hydraulic behaviour of granulated slag by means of the chemical analysis, or by measuring the devitrification temperature. This investigation completes the number of research-work done by other authors to estimate the hydraulic capacity of granulated slag by D.T.A. and S.T.A. analysis or by chemical formulas.

After a first review the above relation seems to allow, with the aid of the devitrification temperature, a more secure evaluation of the hydraulic behaviour of granulated slags than the "Hydraulic Potential" according to L. Blondiau (2).

I would, therefore, be glad if Mr. Forest could recheck on the slag samples—provided they are still existing in sufficient quantity—the relation between the "Hydraulic Potential" (that means the difference: solution heat of glassy slag minus solution heat of devitrificated slag) and the atomic ratio Ca + Mg/Al.

Reply to R. R. Hattiangadi

Answering to Mr. Hattiangadi I consider that a strict correlation between the sulphate resistance of portland blastfurnace cements and the Al_2O_3 content of the granulated slag used for their manufacture cannot be stated.

The Indian Standard No. 455–1968 permits only the production of PBFS cements with slag content from 25% to 65%, with a maximum percentage of 3% SO_3. Taking into account the investigations of F. W. Locher (3) (see also principal paper and Fig. 17) the low resistance to sulphate of those cements is obvious.

Since it is, however, possible—as proved by T. Tanaka, T. Sakai and I. Yamane (4) and by H. Williams and S. K. Chopra (5)—to make supersulphated cements from Indian slags (20%-30% Al_2O_3), I hold the view that it should also be feasible to produce from the alumina rich Indian slag sulphate-resisting portland blastfurnace cements with slag content >65 wt. % and somewhat higher SO_3 content. According to F. W. Locher (6) those slags should contain more than 5% MgO.

In many investigations it has again and again been ascertained that those slag rich cements are sulphate resistant without any limitation.

Reply to U. Ludwig

Mr. Ludwig has shortly presented some results from comprehensive investigations on hydration and properties of supersulphated cements (SSC). But his statement that the ettringite formation contributes decisively to the strength development is in contradiction to the results of longtime studies by F. Schröder, H. Schürmann and H.-G. Smolczyk (7).

These authors have pointed out that in general there is no direct influence of the ettringite formation. But such an influence could be seen when relating the strength values to the X-ray determined quantities of hydration products or to the unhydrated cement components. For example, an influence of the ettringite formation could result if when comparing strength values with decreasing anhydrite content the fact is not taken into consideration, that sulphate can be built into the CSH-phases, as shown by L. E. Copeland, E. Bodor, T. N. Chang and C. H. Weise (8).

According to (7) during hydration of SSC, the formation of CSH-phases starts nearly simultaneously with the formation of ettringite. Due to the composition of SSC, especially due to the anhydrite content, the quantity of the built up ettringite (12% to 14% according to our experience) remains nearly constant from the fourth, or from the seventh day latest, whilst the strength increases rapidly up to 28 days and than slower up to 12 or 18 months. Therefore, in the opinion of the a.m. authors (7) the formation of CSH-phases is the decisive factor for the hardening of the SSC.

The decrease in open porosity during hydration of SSC, as measured by Mr. Ludwig (9) is in good accordance with the above said findings, as well as the pH-values, determined by these authors correspond to the formation of CSH-phases.

The dusting of the surface-skins of lean SSC mortars and concretes due to drying out or due to the carbonation especially of the ettringite crystals, is a wellknown fact. In Germany the process of moistening or drizzeling SSC concrete structures with half-saturated lime solutions (pH $\sim$ 12.4) has been used for some 20 years.

Mr. Ludwig's assertion that in his opinion SSC is the most resistant to sulphate ion attack is very valuable, this all the more since it confirms the test results of numerous other authors. (At least see V-ISCC supplementary paper No. IV-130 by George H. Thomas.)

Closure

First of all I wish to thank all the relevent authors and general reporters who represented certain investigations and discussed them in supplementary papers, or dealed with them in written or oral discussions.

Also since 1960 (IV-ISCC, Washington) much research work was done to elucidate the useful characteristics of granulated slags and slag cements (BLFC). Many newer informations—obtained with modern scientific test methods—about the latent hydraulic properties of slags and about the characteristics of the BLFC's are now available, contributing to confirm known statements or to consolidate less secure knowledge.

Nowadays there is only a small lot of unsolved problems and of apparent contradictions.

Firstly there remains the heavy problem of comparing objectively test results, because the standards in addition to national, historic and economical aspects contain different demands and testing methods. Therefore, for laboratory studies all the involved scientists and engineers should use BLFC's corresponding to the draft ISO recommendation no. 771 and test them according to the RILEM-CEMBUREAU methods. And especially the BLFC subtype 60/80 should be used only for valuating the hydraulic capacity of the slag. Furthermore, attention must be paid to the fact that this type of cement only should be compared with an ordinary portland cement, made of the parent clinker.

For a rapid valuating of the hydraulicity of slag the use of moduli or indices—got by combining the chemical components (wt %)—are unsuitable because there is no scientific basis.

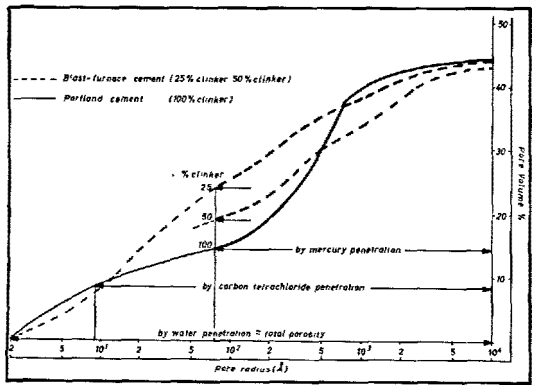
Meanwhile, there are undertaken some investigations to combine the physico-chemical properties with the chemical composition. Here the statement of S. K. Chopra and C. A. Taneja (1) and also of T. Rogozinski (2) are remarkable that in slag melts (resp. glassy slags) the Al-ion only have the coordination number 4.

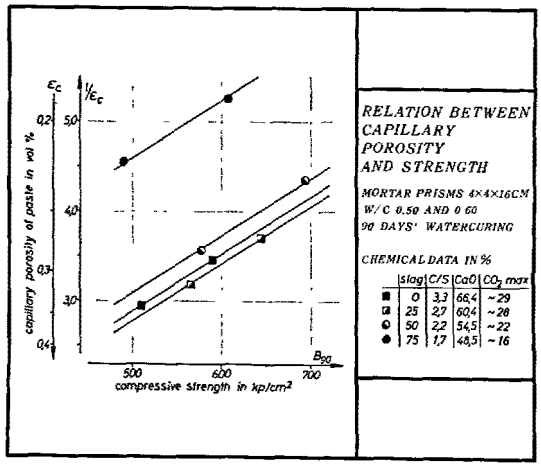
Today it can be taken for sure that for the slag metls besides from their chemical composition the height of the temperature during furnace operation and the high temperature treatment until granulation process are decisive factors. To study this influence the fluorescence radiation of the glassy slag seem to be the simplest aid. Further investigations in this field should proceed from the statements of F. Schröder (3) that there is a shifting of the fluorescence

radiation from UV or dark violet over violet-blue to pink—red for completely crystallized over badly crystallized to completely glassy slag samples of the same chemical composition, or, the release of energy of the fluorescence radiation seems to be related to the disproportioning of the crystal lattices and of the glass constitution, due to the high temperature treatment.

With regard to the strength properties—as well as others—there are no, or only minor differences between PC's and BLFC's containing less than 50% slag. On the contrary, minor slag contentes can improve certain PC properties.

To obtain an explanation for the deviating strength development of the BLFC subtype 60/80 slag we (4) have investigated—among others—the relation between open porosity and mechanical strength of mortars and concretes from different BLFC types. The results obtained from various curing conditions, for the pore size distribution show similar but clear differences depending on the slag content, resp. on the ratio C/S, as demonstrated in the two Figs.





In all test series rising slag content causes a decreasing content of capillary pores.

These results explain the steeper rising strength curves of the slag-rich BLFC and its further hardening over several years, as well as the high density of BLFC concretes and its very high resistance against chemical attack. Moreover, these results explain for what reason the BLFC concretes in spite of their lower content of free $Ca(OH)_2$ don't carbonate faster at later ages than PC concretes of the same quality. And based on these results the formula for carbonation rule

$$= \text{carbonation} \sim \sqrt{1/\text{compressive strength}}$$

—supposed by H.-G. Smolczyk (5) comparing many carbonation test results—obtains a theoretical explanation.

Further investigations about the relations between the ratio C/S, the mechanical strength and other cement properties, e.g. the carbonation, should therefore especially deal with the proportion of low-lime CSH-phases and its detailed properties among the first and the later hydration products of BLFC.

Starting from some cases of corrosion damage on prestressed prefabricated concrete made of sulphide containing high alumina cement, more recently apprehensions have expressed that the sulphide in BLFC—harmless for normal reinforcing steels—may subject to high stresses with prestressed steels leading to cathodic hydrogen embrittlement and to stress corrosion fracture. F. K. Naumann and A. Bäumel (6) clearly have pointed out that hydrogen embirttlement cannot occur within alkaline concretes. Although BLFC form the same hydration products as PC—and therefore a comparison with high alumina cement is fundamentally wrong—the development of H_2S in BLFC concretes is said to be possible due to neutralization in presence of carbonic acid. Although we do not know of any case of stress corrosion failure, since two years we are investigating whether humid carbonic acid may develope H_2S from sulphides in BLFC mortars and concretes. The first part of this investigation (7) shows that only very small quantities of H_2S will be developed by the reaction with unhydrated cement powder, resp. upon the specimen surface during the first hours after demolding. Until today it was impossible to detect any traces of H_2S inside of the partly or completely carbonated specimen.

In the second part we investigate now whether CaS, resp. $Ca(SH)_2$ will be bound during first hydration period into the solid solution compounds of the system $C_3A\bar{S}H$–C_4AH_{13}.

Equal studies in other laboratories would be desi-

rable and would enable the cement-chemists to refute scientifically unsifficient cleared up apprehensions, and would also help to solve several so far unexplained problems and apparent contradictions.

(A) Paper regarding Slag

Supplementary Paper IV-11 A Method of Utilizing Blast-Furnace Slag as a Strength-Improving Agent for Concrete

Tohru Iwai, Toru Mori, Akihiko Yoda and Masaaki Oshima*

Synopsis

Blast-furnace slag, when processed with a special treatment, can be used as an accelerating admixture for portland cement. The special treatment comprises;

a) forming a slurry which consists of water, blast-furnace slag and anhydrite,

b) grinding the slurry sufficiently in a vibrating ball mill and

c) admixing the ground slurry to the cement mix.

Accelerated strength development of cement with the admixture is brought about by rapid crystal growth of calcium sulpho-aluminate which is formed through a reaction between alumina in slag, anhydrite and calcium hydroxide consequent to the hydration of calcium silicate.

Making use of a low grade slag, of which oxides' ratio deviated considerably from the ideal one, the optimum mixing proportion of cement, slag and anhydrite to achieve the highest initial strength was found to be about 80/15/5. A part of anhydrite in the slurry could be replaced by sodium sulphate, which resulted a further acceleration of strength development.

When grinding the slurry, a ball mill of vibrating type with a large capacity was employed. Although an effective accelerating admixture could be produced through sufficient grinding, it was observed that a milling time longer than 25 minutes gave no noticeable improvement of admixture's quality.

Increased strength of cement with the ground admixture was especially in evidence at very early stage (1 to 3 days), and it was also measurable at later stage (7 to 28 days). The later stage improvement of cement strength is attributable to normal slag reaction in which silicate content of slag plays a major role.

Introduction

In construction works rapid strength development of concrete is necessary when formwork is to be removed quickly for re-use or when sufficient early strength for further works is to be obtained; the use of aluminous cement, which offers a very high rate of strength development, however, is kept within narrow bounds because of its high price.

The high rate of strength development of aluminous cement is attributable to the prompt hydration of monocalcium aluminate, while the main component of portland cement is a slow hydrating calcium silicate. Tricalcium aluminate, the secondary component of portland cement, is hydrated rather rapidly, permitting development of initial strength.

The amount of aluminate comprised in portland cement is relatively small but its effects on cement hydration make it of importance. The hydration of tricalcium aluminate itself proceeds too violently, leading to an immediate stiffening of cement paste. To control this phenomena, gypsum is added to cement clinker. Tricalcium aluminate, gypsum and water combined react by forming calcium sulpho-aluminate hydrate, of which crystal grows rapidly and develops the initial strength of cement. The rapid reaction was confirmed by Schwiete, Ludwig and Niel (1), who identified the crystal of the hydrate in a very fresh cement paste.

The initial strength of portland cement can be increased by adding a small amount of aluminous

*Research Institute, Kajima Construction Co., Tokyo, Japan.

cement and extra sulphate. The cement, however, has such defect as making setting time too short and the final strength too low. It was the recognition that pozzolanic materials or latent hydraulic materials contain considerable amount of alumina that the present authors chose them as a low cost alumina additive to portland cement. These admixing materials have been normally utilized not as an alumina source but as a silica source.

Fly ash, which is pozzolanic material, has about 25% alumina, while the alumina content in portland cement is about 5%. If portland cement and fly ash are mixed in proportion of 75 to 25, the mixed cement should contain 10% of alumina. Thus the alumina contents in cement can be doubled.

Pozzolanic materials or latent hydraulic materials are known to be hydrated slowly to release silica or alumina. Therefore, as a rule, mixed cements made of these materials gain strength very slowly. The present study deals with a method of activating these materials by employing a mechanical and chemical treatment.

Activation of Slag through Wet Grinding

As the hydration of cementitious material proceeds on the surface of the particles, it is the total surface area that represents the hydraulic properties of the material with a given composition. In other words, the activity of the material depends on the fineness of the particles, and for a rapid hydration a high degree of fineness is desired.

The conventional blast-furnace cement is made by mixing portland cement and granulated blast-furnace slag. As the usual practice dry granulated slag is fed into a grinding mill with portland cement clinker and gypsum. There is a Belgian method which is called as the Trief process, in which wet-ground granulated slag is fed in the form of a slurry direct into the concrete mixer, together with portland cement and aggregate. Grinding in the wet state results in a greater fineness than would be obtainable with dry grinding.

There are various mills in existence for wet grinding, which are being classified into two types, rotary ball mill and vibrating ball mill. Rotary ball mill possesses a simpler mechanism but is of a lower grinding efficiency compared with vibrating ball mill. In order to obtain a great quantity of materials to be used for practical concreting works, a ball mill of large capacity is necessary. In the present study a vibrating ball mill with a capacity of 60 *l* (vibration frequency: 1,200 c.p.m., maximum amplitude: 5 mm) was employed.

Grinding efficiency of the mill was determined by observing the particle size reduction through an optical microscope. The maximum particle size of slag used for this study was about 50 microns, as seen on Fig. 1-A. When slag was treated with the mill for 30 minutes, the maximum particle size was reduced to about 10 to 15 microns, and for 90 minutes to less than 5 microns, as shown respectively on Fig. 1-B and on Fig. 1-C. In consideration of the processing speed for practical works, the present study chose the wet grinding time of 25 minutes, as will be explained later.

Activation of slag through the wet grinding was confirmed by the preliminary test, in which unprocessed slag with the maximum particle size of 50 microns and processed one with the maximum particle size of 10 to 15 microns were respectively added to rapid hardening portland cement, in which the mixing ratio of slag was 15% to the total amount of the blended cement. The compressive strength was measured in the form of mortar. All mortar specimens for strength measurement in this study were made with w/c ratio of 65% and c/s ratio of 1/2, unless otherwise specified. Up to two months, mortars having unprocessed slag gained a lower strength than mortars composed entirely of portland cement. On the other hand, the development of strength was found to be greater after one week when mortars with processed slag was used than with mortars composed entirely of portland cement. The result, however, was unsatisfactory for the present study, which aimed at an increased strength of hydrated cement in such an accelerated speed as 1 to 3 days.

Activation of Slag through Sulphate Stimulation

Slag, a waste product in the manufacture of iron, is composed of lime, silica and alumina; i.e., the same oxides which make up portland cement, but not in the same proportion. It was reported by various researchers as Tanaka (2) or Locher (3) that the hydraulic properties of slag are greatly influenced by its oxide composition. The ideal slag, according to these researchers, should have the following oxide proportion; $CaO/SiO_2/Al_2O_3 = 50/30/20$. Now the slag used for the present study possessed an oxide proportion which was greatly deviated from the ideal, as shown in Table 1.

Fig. 2. *Stimulated slag*

There are two methods for activating slag chemically; sulphate stimulation and lime stimulation. In the hydration of conventional portland blast-furnace cement, slag is stimulated by calcium sulphate and also by lime which is released from calcium silicate. Hydrate formed by slag and lime consists of C–S–H phase and C–A–H phase. Reaction of slag and sulphate results in producing calcium sulphoaluminate hydrate on top of the two phases. According to the investigation of Locher (3) in which C–A–S–glasses were stimulated by anhydrite, lime or portland cement clinker, it was found out that strength development of the hydrate was most in evidence with the sulphate stimulation using slag of the ideal composition.

Figs. 2-A, 2-B and 2-C demonstrate the microscopic pictures of slag particles which were placed in solution of saturated lime, gypsum and sodium sulphate. Slag was wet-ground to bring out the maximum particle size of about 5 microns, and 1 gr of the slag sample was aged in 1 *l* of the stimulating medium for three days. As shown in the pictures, the sulphates affected slag more strongly than lime did, reducing the size of slag particles.

The present study adopted the sulphate stimulation for activating slag, using anhydrite and sodium sulphate.

Wet Grinding of Mixture of Slag and Sulphate

As a rule, when slag or cement is wet-ground, the resulting slurry becomes considerably viscous, making it difficult to handle the slurry. The increase of slurry viscosity is especially noticeable when it contains sulphate. In the present study the slurry was diluted with water to give less viscosity, the proportion of powdered mixture to water being fixed at the ratio of 1 to 1 by weight.

Proportioning of the materials was carried out by the following steps. When, for example, the final weight ratio of cement, slag and sulphate should be 70/25/5 and the w/c ratio 65%, then 25 kg of slag, 5 kg of sulphate and 30 kg of water were milled together for 25 minutes, and 60 kg of slurry thus obtained was added to 70 kg of cement together with 35 kg of water. The total weight of the mixed cement amounted to 100 kg, and the total weight of water to 65 kg.

80	16	1	3	196
80	16	0	4	194

pictures respectively of one-day-old wet-ground portland cement specimen without the admixture, of the same specimen with the admixture and of one-day-old admixing slurry. The X-ray diffraction patterns of these three specimens are presented on Figs. 4–A, 4–B and 4–C, the last two showing the ettringite formation.

Strength of cement with milled admixture could be varied with the ratio of slag/sulphate in slurry. One-day strength of mortar made of 80 parts cement and 20 parts admixture attained the maximum point when the ratio of slag/sulphate was about 15/5, as Table 2 gives.

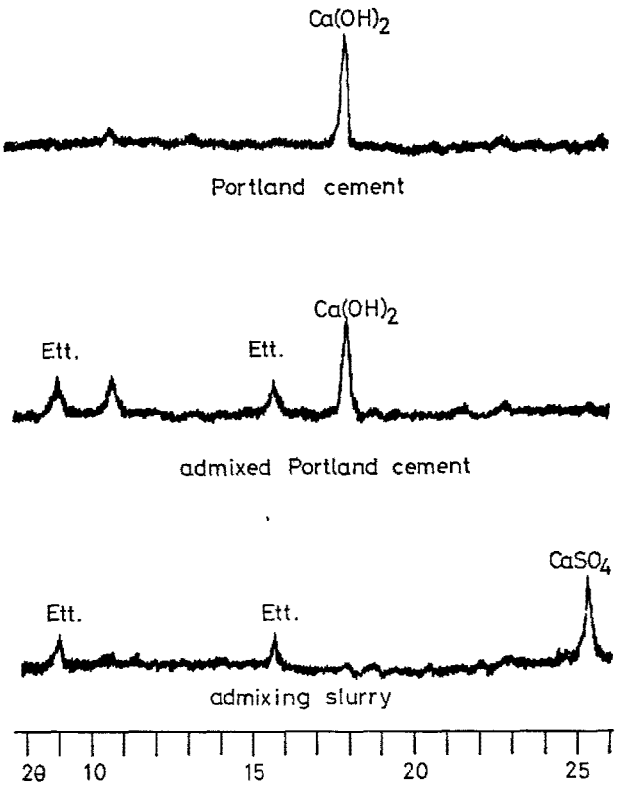

Fig. 4. *X-ray diagrams of hydrate specimens*

Cement with milled admixture gained a higher strength when a part of calcium sulphate was substituted by sodium sulphate. The amount of sodium sulfate to be added to cement, however, should not exceed 2%; for a high contents of sodium sulphate caused efflorescence on the surface of the hardened cement. Table 3 shows the effects of sodium sulfate on one-day strength of mortar.

Grinding Time, Slag Contents and w/c Ratio

Grinding time of slurry could influence the rate of strength development of the mixed cement. Slag, anhydrite, sodium sulphate and water were mixed in the proportion of 16/2/2/20, the slurry being milled for 5 to 40 minutes. Initial strength of the mortars made of 80 parts cement and 20 parts milled admixture are shown on Table 4. Although a sufficiently milled slurry gave a higher mortar strength, a milling time longer than 25 minutes gave no further improvement of mortar strength. In addition, if milling was too prolonged it produced slurry of high viscosity which deteriorated the workability of fresh cement paste.

With a given amount of sulphate to be added, strength of the mixed cement could be varied with the slag contents. Table 5 shows the blending ratio of cement/slag/sulphate, Table 6 and Fig. 5 the initial strength of mortars. The optimum slag content in cement was found to be about 15% with sulphate content of 4%, achieving an increase of initial strength by more than 100%.

Strength increase due to the milled admixture was especially in evidence at the earlier stage of cement hydration and also with the higher w/c ratio. Fig. 6 shows strength (1 to 7 days) of mortar specimens with and without admixture (No. 1 and No. 19 on Table 5). One-day strength of the two specimens with various w/c ratio is compared on Table 7 and Fig. 7.

Generally speaking, higher sulphate content in

cement increases strength at the early stage but causes decreased strength later. A suitable amount of slag in cement, on the other hand, improves the later strength. The mixed cement as presented in this study, containing sulphate and slag, solves both the problems. Pattern of strength development due to each admixture is compared on Table 8 and Fig. 8.

Supplementary Paper IV-28 Investigation of the Physicochemical Processes of Hardening of Slag Portland Cement

Vladimir I. Satarin and Yakov M. Syrkin*

Synopsis

Physicochemical investigations of the slag portland cement hardening processes are reported in the paper. Chemical methods of analysis were used for the investigation of the composition of liquid phases and of chemically bound water in hydrated cements.

The morphological structure was defined by electronic microscopy methods. X-ray and thermographic methods were used for the identification of hydrates in the cement stone hardening process.

The complex of theoretical investigations allowed it to find out the ways for the improvement of slag portland cement quality, to work out the parameters of rapid-hardening slag portland cement production technology and to study up its building and technical properties that enable wide use of this new kind of cement in concretes and reinforced concrete constructions produced by the method of hydrothermal treatment.

As a result of the investigations made in the USSR (Institute "Yuzhgiprocement", Kharkov) and aimed at the improvement of the quality of slag portland cement a new type of slag portland cement—rapid-hardening slag portland cement—was created and is now widely produced in industry. The kinetics of hardening of this new type of slag portland cement is equal to that of portland cement of grade 500–600 (in rigid mortars) (1, 2, 3, 4, 5 and 6).

As it is seen from the results of physicomechanical tests of cements (Fig. 1) rapid-hardening slag portland cement is free from the main shortcoming which is inherent to slag portland cements and which is characterized by slower, in comparison with portland cement, strength gain at early stages of hardening.

The technology of manufacturing of slag portland cement is based on finer than usual grinding of the clinker component, in due regard for mineralogical composition and gypsum additions.

For producing such a slag portland cement the following parameters were determined: clinker-slag ratio 60: 40 and 50: 50, fineness of cement grinding 4000 cm^2/g; cement components were ground as follows: clinker—up to 5000 cm^2/g, slag—up to 3000 cm^2/g, addition of gypsum—4–5%.

Investigation of the properties of rapid-hardening slag portland cement in concretes and reinforced concrete constructions had proved its suitableness for use in high-grade concretes and its advantages, in comparison with portland cement, for manufac-

turing reinforced concrete products produced by the method of hydrothermal treatment for industrial and civil construction (reduced steam-curing) (7).

For further improvements of rapid-hardening slag portland cement properties complex investigations aimed at studying principal regularities of the hardening process (8) have been carried out at the Institute. Till now nobody studied the hydration process of rapid-hardening slag portland cement. Rapid-hardening slag portland cement was investigated in comparison with portland cement and ordinary slag portland cement.

This report is dedicated to the investigation of structure-forming processes taking place in rapid-hardening slag portland cements. Investigation was carried out by the method of electronic microscopy in combination with electronographical, X-ray, thermographical and chemical methods. In addition to that phase composition and morphological properties of newly formed hydrates were determined and cement stone structure was analysed.

Portland cement and slag portland cements were investigated on the basis of the same clinker and the same granulated blast-furnace slags. For this investigation the following materials were taken: granulated blast-furnace slags from the metallurgical works in Zaporozhye (up to 90% of glass with refractive index 1.67; minerals of the mellilite row, grains C_2S); acid slags from the Novokuznetsk works (up to 95% of glass, 2% of gehlenite and 3% of calcite); clinker from the Belgorod works (65% of alite, 15% of belite and 20% of interstitial substance). The specific surface, determined by the method of air suction through mix bed, equaled: for slag portland cement and portland cement—3000 cm^2/g, for rapid-hardening slag portland cement—4000 cm^2/g. Clinker and slag batching for rapid-hardening slag portland cement was accordingly 50% and 50%; 60% and 40%, for slag portland cement was 30% and 70%. Water/cement ratio for all studied cements was 0.5. Portland cement, rapid-hardening slag portland cement and slag portland cement were also investigated at water/cement ratio which corresponded to normal paste thickness.

The phase analysis of newly formed hydrates was carried out by X-ray and electronic microscopy methods combined with electronographical and thermographical methods. The structure originated and developing as a result of the hardening process was analysed by the electronic microscopy method. As a rule the analysis was carried out after one day, 3 days, 7 days and 28 days of hydration. Besides, several samples were analysed after 4 minutes, 1 hour, 4 hours, 12 hours, 24 hours, 6 months and one year of hydration.

Investigation of Liquid Phases of the Hardening Cement Stone

For the purpose of determining liquid phases of the hardening cement stone cement samples (Table 1) were mixed up with distilled water at a water/cement ratio of 0.5. After 4 minutes, 30 minutes, one hour, 4 hours, 12 hours, one day and 3 days since mixing up liquid phases were extracted by means of a special pressform under pressure of 1500 kg/cm^2 (9, 10). Composition changes in $Ca(OH)_2$, $CaSO_4$ and in R_2O were studied in liquid phases (Fig. 2, 3, 4).

The Fig. 2 shows that after 4 minutes since mixing up the concentration of calcium hydroxide (calcium hydroxide is shown in percentage of CaO) in liquid phases of portland cement and rapid-hardening slag portland cements is much higher (1.63—1.80 g/l) than in the case of the saturated solution of calcium hydroxide. (1.23 g/l). The high concentration of calcium hydroxide is retained up to 4 hours of hydration and in some liquid phases it is retained up to one day hydration and then it falls down.

In portland cement and rapid-hardening slag portland cement containing acid slag, calcium hydroxide content decreases more rapidly because of the higher alkali concentration in the liquid phase (Fig. 3).

By 3 day hydration the concentration of calcium hydroxide in liquid phases of portland cement and rapid-hardening slag portland cements decreases up to 0.14—0.43 g/l which is the evidence of actively proceeding processes of hydrolysis and hydration at

early stages of hardening.

In spite of that clinker/cement ratio equals 50: 50 in rapid-hardening slag portland cements, the latter as well as portland cement is characterized by substantial activity of hydration processes at early stages (Table 2). This fact is obviously attributed to the high

fineness of the clinker fraction of rapid-hardening slag portland cement.

In difference from portland cement and rapid-hardening slag portland cement the concentration of calcium hydroxide in liquid phases of slag portland cement, produced either with basic or acid granulated slags, after 4 minutes since mixing up with water is much lower (0.75—0.82 g/l) than in the case of the saturated solution of calcium hydroxide. The saturation is reached only in about 4 hours of hydration. The high calcium hydroxide concentration in liquid phases is retained up to one day of hydration, then by 3 days it falls down to 0.64—0.72 g/l.

As above-mentioned experimental data show hydrolysis and hydration processes in slag portland cements at early stages of hydration are somewhat inhibited because of rougher grinding of cement clinker, on the one hand, and because of less clinker content in cement, on the other hand, in comparison with rapid-hardening slag portland cement.

The gypsum concentration in liquid phases of portland cement, rapid-hardening portland cement and slag portland cement produced either with basic or acid granulated slags is high (1.56–1.89 g/l of $CaSO_4$) after 4 minutes since mixing up with water, but however it is lower than that of the saturated solution

(2 g/l of $CaSO_4$) (Fig. 3). The exception to this fact is the rapid-hardening slag portland cement with the acid granulated slag where the gypsum concentration after 4 minutes of hydration is 2.06 g/l of $CaSO_4$.

In portland cement and rapid-hardening slag portland cements gypsum disappears from the liquid phase in one day of hardening and in slag portland cements it disappears in 3 days of hardening. The disappearance of gypsum from the liquid phase is the evidence of completing the reaction with forming a high-sulphate form of calcium hydrosulphoaluminate. Thus, hydration and hardening processes are somewhat inhibited in slag portland cement in comparison with portland cement and rapid-hardening slag portland cements.

The concentration of alkalies in liquid phases increases with the increase of the sample age and by 3 days reaches 1.79–4.40 g/l of R_2O (Fig. 4). With the increase of the quantity of alkalies in liquid phases the solubility of calcium hydroxide decreases. The alkalies, passing into the solution, limit the calcium hydroxide solubility.

Determination of Chemically Bound Water in Rapid-Hardening Slag Portland Cement

Till now there is no single technique of determining chemically bound water; probably it is attributed to inhomogeneous properties of newly formed products of hydration and to complication of dividing chemically bound and non-bound water in hydrated cement.

The determination of chemically bound water in rapid-hardening portland cements is complicated by the proceeding of oxidizing processes combined with the presence of protoxydic compounds (in slag fraction of cement). Our technique of determining chemically bound water is described below.

At the earliest stages including 4 minute, 30 minute, one hour, 4 hour hydration when the cement paste has not yet hardened for determining chemically bound water, 8–10 grammes of cement paste are poured with 30–40 ml of absolute alcohol and are mixed well up, then the alcohol is filtered out.

The hydrated cement is washed in a funnel for 3–4 times with 10–15 ml of absolute alcohol. Such a treatment is quite enough for removing non-bound water from the hydrated paste as the alcohol is mixed with water very well and removes it from the reaction. In order to give constant weight to the dehydrated cement powder this powder is double treated in a funnel with 10 ml of ethyl ether. Thus more easily volatilized other vapours are substituted for heavy alcohol vapours and the drying process of hydrated cement powder is accelerated. The powder is dried up to the constant weight in a chamber at room temperature 22–25°C by means of suction of dried air free from carbon dioxide through it.

After the drying of hydrated cement powder to its constant weight chemically bound water is determined. In portland cement this determination is simple. One gramme of hydrated cement powder is calcinated in a muffle furnace at the temperature of 1000°C up to the constant weight. At the same time the original unhydrated cement is also calcinated and the correction is introduced while determining the percentage of chemically bound water.

The calcining temperature of 1000°C was chosen for portland cement on the basis of great experimental material on the dehydration of individual hydrated clinker minerals and portland cement clinkers.

The calcining temperature for determining chemically bound water in cements containing slag was defined more exactly while studying hydrated rapid-hardening slag portland cements and slag portland cements.

Chemically bound water was determined in rapid-hardening slag portland cement and slag portland cement produced with the same basic slag from the Zaporozhye works at the ages from 4 minutes to 3 days of hardening. Chemically bound water was determined at temperatures of 800–1000°C.

The Table 2 shows that chemically bound water content at 800°C reaches its maximum; at 1000°C it decreases both in rapid-hardening and slag portland cements. At early stages of hardening the difference in chemically bound water content at temperatures of 800 and 1000°C is greater by slag portland cement than by rapid-hardening slag portland cement because the slag content in slag portland cement is greater.

Chemically bound water was determined at the temperature range from 100°C to 1000°C in hydrated slag portland cement and rapid-hardening slag portland cement at the age of 28 days of hardening (Table 3).

As the table data show the quantity of chemically bound water in slag portland cement and rapid-hardening slag portland cement increases with the increase of calcination temperature. In this case we do not observe the decrease of chemically bound water which is caused by the oxidation process of slag protoxydic compounds.

Table 3. *Changes in chemically bound water content with the temperature*

900	17.83	900	12.53
1000	17.83	1000	12.53

Above-mentioned phenomena permit to recommend successive calcination at temperatures of 600°C, 700°C and 800°C etc. while determining chemically bound water in slag portland cements. Maximum weight losses are considered as the weight of chemically bound water as in the case of portland cement.

The quantity of chemically bound water in cement paste increases with the increase of the sample age (Fig. 3). This fact is the evidence of the activity of hydration processes at different cement hardening periods because the chemically bound water content in the cement paste is an indirect evidence of the quantitative increase of newly formed products of hydration in the hardened cement paste.

The quantity of chemically bound water in portland cement and rapid-hardening slag portland cement containing acid slags is much higher than in slag portland cement with the same slag (Fig. 5). This fact proves once more a great activity of hydration processes proceeding in rapid-hardening slag portland cement.

As rapid-hardening slag portland cement and slag portland cement are composed of clinker and slag let us to examine the reaction chemism of producing high-sulphate form of calcium hydrosulphoaluminate in the process of hydration and hardening of these cements.

As it is known, this reaction for portland cement can be expressed as follows:

$$3CaO \cdot Al_2O_3 + 3CaSO_4 \xrightarrow{nH_2O} 3CaO \cdot Al_2O_3 \cdot 3CaSO_4 \cdot 31H_2O \quad (1)$$

This reaction proceeds differently for cements containing slag (11).

According to petrographical data, granulated slags from the Zaporozhye and the Novokuznetsk works contain more than 90% of glass. Proceeding from the chemical analyses and assuming that slags are entirely composed of glassy phase we can express their empirical formulae respectively:

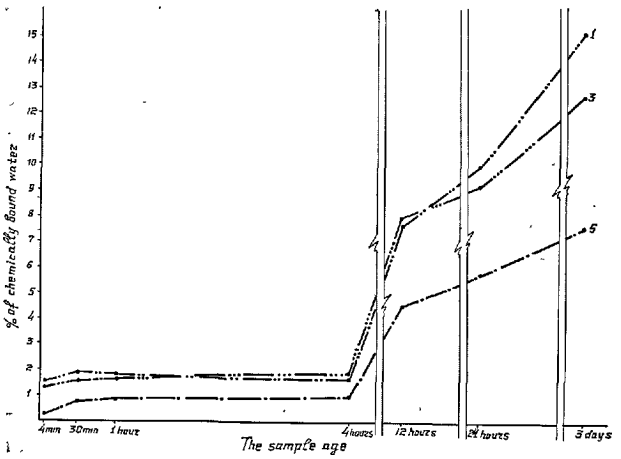

Fig. 5. The chemically bound water content in

Fig. 5. *The chemically bound water content in cement aged up from 4 minutes to 3 days of hardening.*

1—portland cement; 3—rapid-hardening slag portland cement with the acid slag; 5—slag portland cement with the acid slag.

$16CaO \cdot 13SiO_2 \cdot Al_2O_3$ and $6CaO \cdot 5SiO_2 \cdot Al_2O_3$

As appears from formulae above there is no equimolecular ratio C: A = 3: 1 in both of them. Electronic microscopical investigations show that hydrosilicates in hydrated rapid-hardening slag portland cements and slag portland cements are represented in the form of minute low-basic newly formed products of hydration of tobermorite type.

As follows from the above, the reaction chemism of hydration of cements containing slag can be represented as follows.

The clinker fraction of cement is first subjected to hydrolysis and hydration processes and as a result of this calcium hydroxide, gypsum, alkalies and quite small quantities of calcium hydroaluminates, calcium hydrosilicates and calcium hydroferrites are dissolved in the liquid phase. Under the influence of calcium hydroxide and alkalies the slag fraction of cement is excited and glassy slag acquires the reactivity and reacts with gypsum and calcium hydroxide:

$$16CaO \cdot 13SiO_2 \cdot Al_2O_3 + 3CaSO_4 \xrightarrow{nH_2O} 3CaO \cdot Al_2O_3 \cdot 3CaSO_4 \cdot 31H_2O + 13CaSiO_3 \cdot pH_2O \quad (2)$$

$$6CaO \cdot 5SiO_2 \cdot Al_2O_3 + 3CaSO_4 + 2Ca(OH)_2 \xrightarrow{nH_2O} 3CaO \cdot Al_2O_3 \cdot 3CaSO_4 31H_2O + 5CaSiO_3 \cdot pH_2O \quad (3)$$

Hence, the high-sulphate form of calcium hydrosulphoaluminate and calcium hydrosilicate which resembles tobermorite are the reaction products of hydration of slag fraction of cement.

Electronomicroscopical and Electronographical Investigations

While making preparations for direct electronomicroscopical investigations small quantity of cement (0.2–0.3 g) was placed in a test-tube with 2—3 ml of absolute ethyl alcohol. The resulting suspension was dispersed by means of supersound (frequency 2 megs, power—60–70 wt, time of sound action—one minute) and a drop of this suspension was placed on the carbon specimen supporting film located on the objective grid. After evaporation of alcohol the sample was placed either into the column of the electronic microscope for immediate examination or into a vacuum-post where Al as a standard for microdiffraction investigations was sprinkled on it.

The method of electronic microscope replicas was used at the investigation of cement stone structure too.

Together with generally used methods (13, 14) a new method for examination of early stages of structure formation, offered by A. G. Kholodnyi (12), was used. It consists of getting a print from a cement layer stuck to a glass-slide during hardening. The investigations were carried out by means of electronic microscope EM-5.

Electronic microscope analysis of portland cement at 0.5 water/cement ratio showed that at the intial stages of hydration (up to 7 days inclusive) the main hydrate phases were calcium hydrosulphoaluminates of ettringite type and needle-shaped hydrosilicates. The calcium hydrosulphoaluminates were identified by their characteristic elongated and prismatic shape.

The attempts to get diffraction patterns of ettringite crystals have not succeeded as under the influence of electronic eradiation and vacuum the crystals lose water and the inner crystalline structure of the compound gets disordered. The analogous phenomenon was observed by other investigators too (15).

The electronographs of calcium hydrosilicates contain only some wide reflections, the strongest of which lying in the range of 3.0 and 1.8 Å. In connection with it we did not succeed in precise defining of the composition of the needle-shaped calcium hydrosilicates. The diffraction character shows that the hydrosilicates are similar by composition to low-basic calcium hydrosilicates and are characterized by slightly amorphous structure.

As the investigations showed, in the period of portland cement paste setting an intensive formation of crystals of calcium trisulphoaluminate and needle-shaped silicates and also of hexagonal crystals of $Ca(OH)_2$ is observed.

It is characteristic that newly formed products of hydration cover the most of the initial cement grains with a film of hydrates predestining a diffusive character of the solution process and evening by it the rates of hydration of separate phases of portland cement clinker. Thus, it is possible to suppose that to a certain stage of hydration, namely to the stage of the intensive formation of hydrate particles on the surface of the initial clinker grains, the process of hydration of clinker minerals goes at different rates. Thereafter the rates of hydration get equal as a result of formation of hydrate films on the surface of the initial grains. These data agree with the conclusions made by H. Lehmann and V. Roesky (16).

In the process of hardening the structure of portland cement stone gets denser. Crystals of ettringite get localized and the areas appear, formed by the minute particles of calcium hydrosilicates the shape of which resembles the scales of montmorillonite (Fig. 6).

Further the dense hydrosilicate gel becomes the prevailing component of the structure. The process of calcium hydrosilicates formation is accompanied by the development of newly formed hydrosulphoalumi-

Fig. 6. *Portland cement at 0.5 w/c ratio, age-7 days. X 10000*

nates. In portland cement and in rapid-hardening slag portland cements gypsum disappears from the liquid phase in a day hardening, in slag portland cements—in 3 days (Fig. 3). Disappearance of gypsum from the liquid phase shows the completion of the formation of a high-sulphate form of calcium hydrosulphoaluminate.

It is characteristic that hydrosilicate gel and plate-shaped phases of hydroaluminate—hydrosulphoaluminate compounds differ sharply in their morphological characteristics. Therefore the electronic microscope investigations by the method of replicas allow to follow the process of changing of these phases during the hardening process.

The study of portland cement stone at various water/cement ratio (0.5; 0.25) showed that the structure of portland cement stone aged up to one year at higher water/cement ratio was characterized by considerably higher inhomogeneity and by lower desity (Fig. 7, 8).

Crystalline phases occupy considerable volume of the structure both at 0.5 water/cement ratio and at 0.25 water/cement ratio. It is noticed that in the first case the crystals of ettringite having prismatic shape are more frequently met in the structure of cement stone than in the second case (Fig. 8, a). At 0.5 water/cement ratio areas of the structure with considerably lower density than the whole mass of hydrogel are observed. The formation of large crystals is noticed in such areas of the structure (apparently the crystals of calcium hydroaluminate). May be, the pores and areas of less dense hydrosilicate gel are the areas where the large plate-shaped crystals, frequently met in cement structure, arise (Fig. 8, b). The size of these newly formed products of hydration increases in the process of hardening. Evidently the inner tension appears in the places of contact between the large, increasing in their size, plate-shaped crystals and hydrosilicate gel (as a result of pressure of crystalization). Thus the process of hardening of portland cement is accompanied by the rise and development of destructive phenomena finally leading to decrease of strength characteristics of cement stone. The improvement of the material properties comprises the decrease of influence of these phenomena during the process of cement stone hardening. From this point of view it is particularly interesting to follow the hardening process of rapid-hardening slag portland cement and slag portland cement.

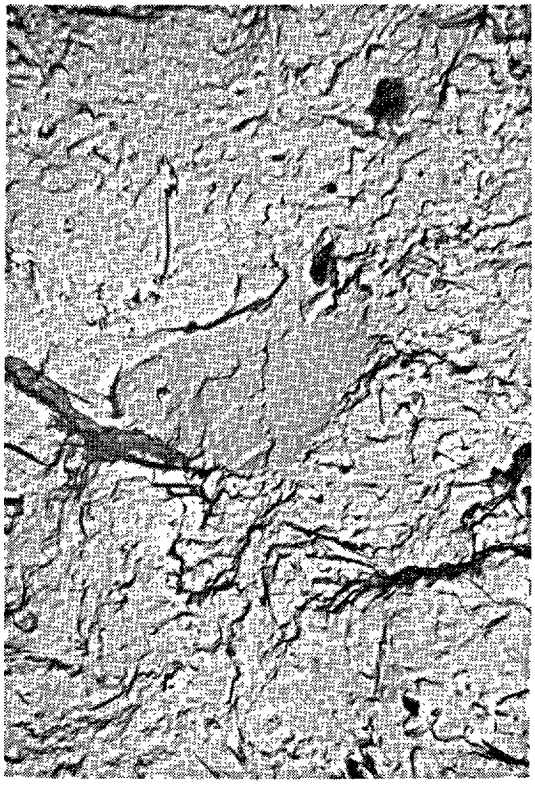

Fig. 7. *Portland cement at 0.25 w/c ratio, age-1 year. X 10000*

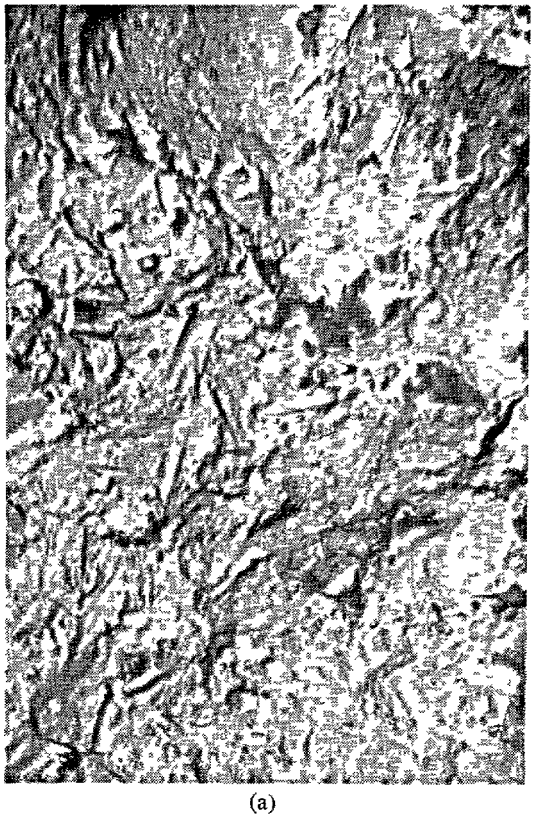
The early stages of hydration of these cements are characterized by arising of the same newly formed products of hydration as in the portland cement.

Thus even in the 4-minute samples the particles of calcium hydrosulphoaluminates of ettringite type are observed, but further the calcium hydrosilicates are fixed too. It is characteristic that the content of $Ca(OH)_2$ crystals is smaller comparing with portland cement, what is evidently connected with CaO absorption from the solution in the process of slag excitation. Composition and morphological features of above-mentioned newly formed products of hydration are similar in all studied cements. It is witnessed for example by the fact that the hydrosilicates as a rule give the diffraction of the same type. (2—3 wide reflections in the range of 3.0; 2.8; 1.8 Å). Only in a case of examination of a slag portland cement sample aged up to 28 days and based on the slag from Zaporozhye it was possible to get electronograph with bigger quantity of more distinct reflexes (Fig. 9). The identity of newly formed products of hydration in cement stone of various mineralogical composition, noticed by other scientists too (17), allows it to suppose that the strength charactersistics and other properties of cement stone depend on the intensity of hydration processes and structure formation. From this point of view it is possible to interpret some properties of rapid-hardening slag portland cement.

It is known that slag cements are characterized by



(a)

(b)

Fig. 8. *Portland cement at 0.5 w/c ratio, age-1 year. X 10000*

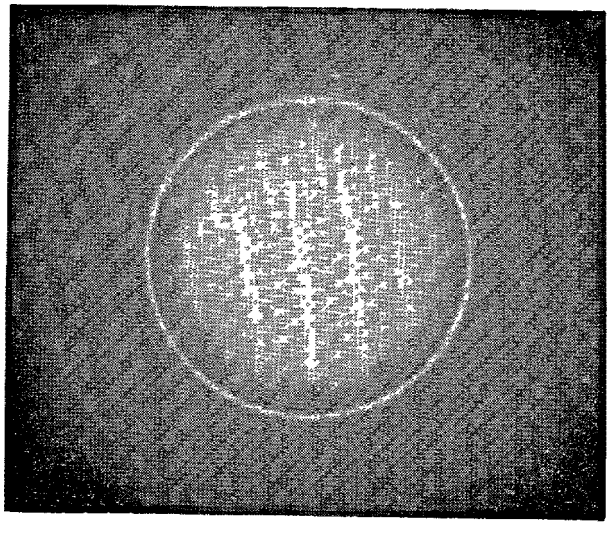


Fig. 9. *Slag portland cement with the slag from the Zaporozhye works at 0.5 w/c ratio, age-28 days.*

considerable strength only after long hardening. Rapid-hardening slag portland cement is characterized by accelerated strength gain at early stages. Electronic microscope examinations indicate that it is caused by intensive formation of calcium hydrosulphoaluminate of ettringite type and lowbasic calcium hydrosilicates.

The processes of structure formation in rapid-hardening slag portland cement and in portland cement proceed similarly, but at early stages a main role of ettringite is marked (Fig. 10). Further, as the investigations of cement stone aged up to a year showed, the calcium hydrosilicates play the main role in the structure of rapid-hardening slag portland cement (Fig. 11). The crystals of ettringite type are observed only episodically. It is characteristic that the size of plate-shaped newly formed products of hydration of hydroaluminate-hydrosulphoaluminate phases in rapid-hardening slag portland cement aged up to a year is considerably smaller than in portland cement. Density of hydrosilicate gel in the samples of rapid-hardening slag portland cement at 0.5 water/cement ratio corresponds approximately to density in the portland cement samples at 0.25 water/cement ratio.

On the basis of the above-mentioned data it is possible to conclude that fineness of clinker component influences the properties of slag portland cement mainly at early stages of hydration when it is necessary to intensify the rise of newly formed

Fig. 10. *Rapid-hardening slag portland cement with the slag from the Almaznyansky works at 0.5 w/c ratio, age-3 days. X 10000*

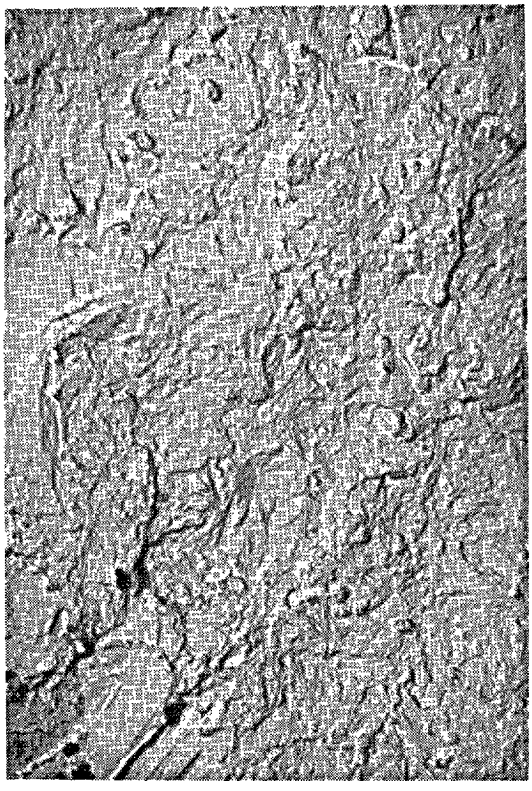

Fig. 11. *Rapid-hardening slag portland cement with the slag from the Novokuznetsk works at 0.5 w/c ratio, age-1 year. X 10000*

hydrates from slag material. Further the hydrosilicate hardening inherent even to the slags without additions proceeds, and probably due to that the influence of destructive phenomena, taking place at the interaction between the hydrosulphoaluminate and hydrosilicate structures of hardening, decreases.

Thus rapid-hardening slag portland cement is a binding material in which the property of portland cement to harden rapidly and the ability of slag cements to form hydrosilicates during a long time luckily combine.

The results of electronic microscope examinations are completed and confirmed by our thermographic and X-ray investigations.

The Thermographic and X-ray Investigations

Differential thermal analysis was carried out by means of automatic thermoweighting device ATVU–8 at a rate of heating 10°C per minute.

Thermographic analysis allowed it to get the average characteristics of hydration process of studied cements. The investigations showed that the character of DTA curves of various cements was identical.

DTA—curves contain mainly 3 endothermic effects connected with the rise of the newly formed hydrates in the process of hydration: the first is in the region of 100–200°C, the second—about 500°C and the third is within the limits of 700°C and 800°C (Fig. 12). The low temperature endothermic effect is the most interesting one (100–200°C). According to the data of our investigations it is a summary effect and is conditioned by water losses by a number of principal minerals of cement stone such as calcium hydrosilicates, hydroaluminates and hydrosulphoaluminates.

According to Midgley's data (18) it is conditioned by water losses by calcium hydrosilicates and high-sulfate form of calcium hydrosulphoaluminates (in the absence of non-bound water in the sample). Our data agree with Midgley's results with the only difference that dehydration temperatures of the above-mentioned hydrate phases coincide in all the cements studied by us.

Intensive increase of the low temperature endothermic effect is characteristic for portland cement at the

initial stages of hardening (up to 7 days at 0.5 water/cement ratio). The increase is mainly attributed to the decomposition of increasing quantity of the calcium hydrosulphoaluminate of ettringite type, being formed in cement stone (Fig. 12). However the growth of low temperature endothermic effect on DTA curves slows up with the increase of sample age what is connected with the decrease of intensity of ettringite formation and its changing into monosulphoaluminate containing smaller quantity of combined water. Then the increase of endothermic effect in the region of 100–200°C is observed again, it is connected with the process of formation of a large quantity of calcium hydrosilicates taking place in this period of hardening. Thus, DTA curves reflect to a certain degree the process of structure formation of portland cement stone. The received DTA curves (Fig. 12, 13) allowed it to find out that in portland cement the process of slowing up of the reaction of ettringite formation and the modification changings of calcium hydrosulphoaluminate in cement stone at 0.5 water/cement ratio took place after about 7 days; in slag portland cement the process is expressed less distinctly and is defined by 1—3 days.

The main feature of the DTA curves of slag portland cements comparing with the curves of portland cement is a smaller value of the endothermic effect caused by the decomposition of $Ca(OH)_2$ (Fig. 13). Evidently the calcium hydroxide is spent on the formation of calcium hydrosilicates.

The question about the nature of the third endothermic effect (700–800°C) has been studied insufficiently. It is characteristic that this effect is especially well expressed on the DTA curves of slag portland cements.

In our opinion the third endothermic effect (700–800°C) is mainly caused by the decomposition of low-basic calcium hydrosilicates and not by that of calcium carbonate. In fact in the opposite case its value would depend on the value of the effect of $Ca(OH)_2$ that is easily carbonated (500°C). However it has not been observed.

It is characteristic that the strength characteristics of rapid-hardening slag portland cements both at the early stages and at the further stages of hardening are higher than the analogous characteristics of portland cement.

The DTA data indicate that this phenomenon is mainly interpreted by more intensive development of hydrosilicate structure of hardening. Thus, the comparing of DTA curves of portland cement and rapid-hardening slag portland cement samples shows that the first endothermic effect in the region of 100–200°C,

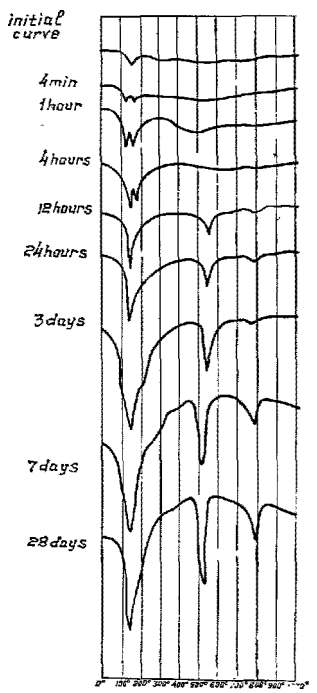

Fig. 12. *DTA-curves of portland cement at 0.5 w/c ratio*

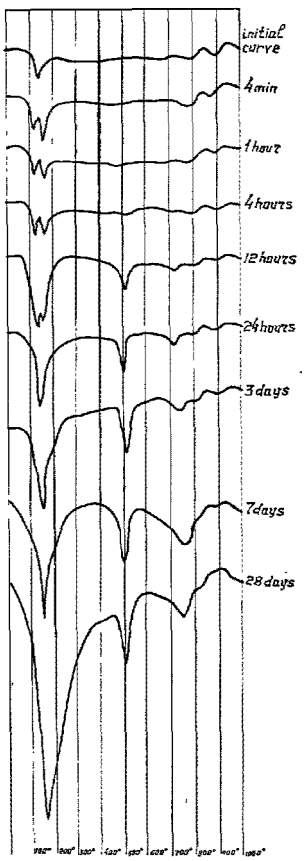

Fig. 13. *DTA-curves of rapid-hardening slag portland cement at 0.5 w/c ratio.*

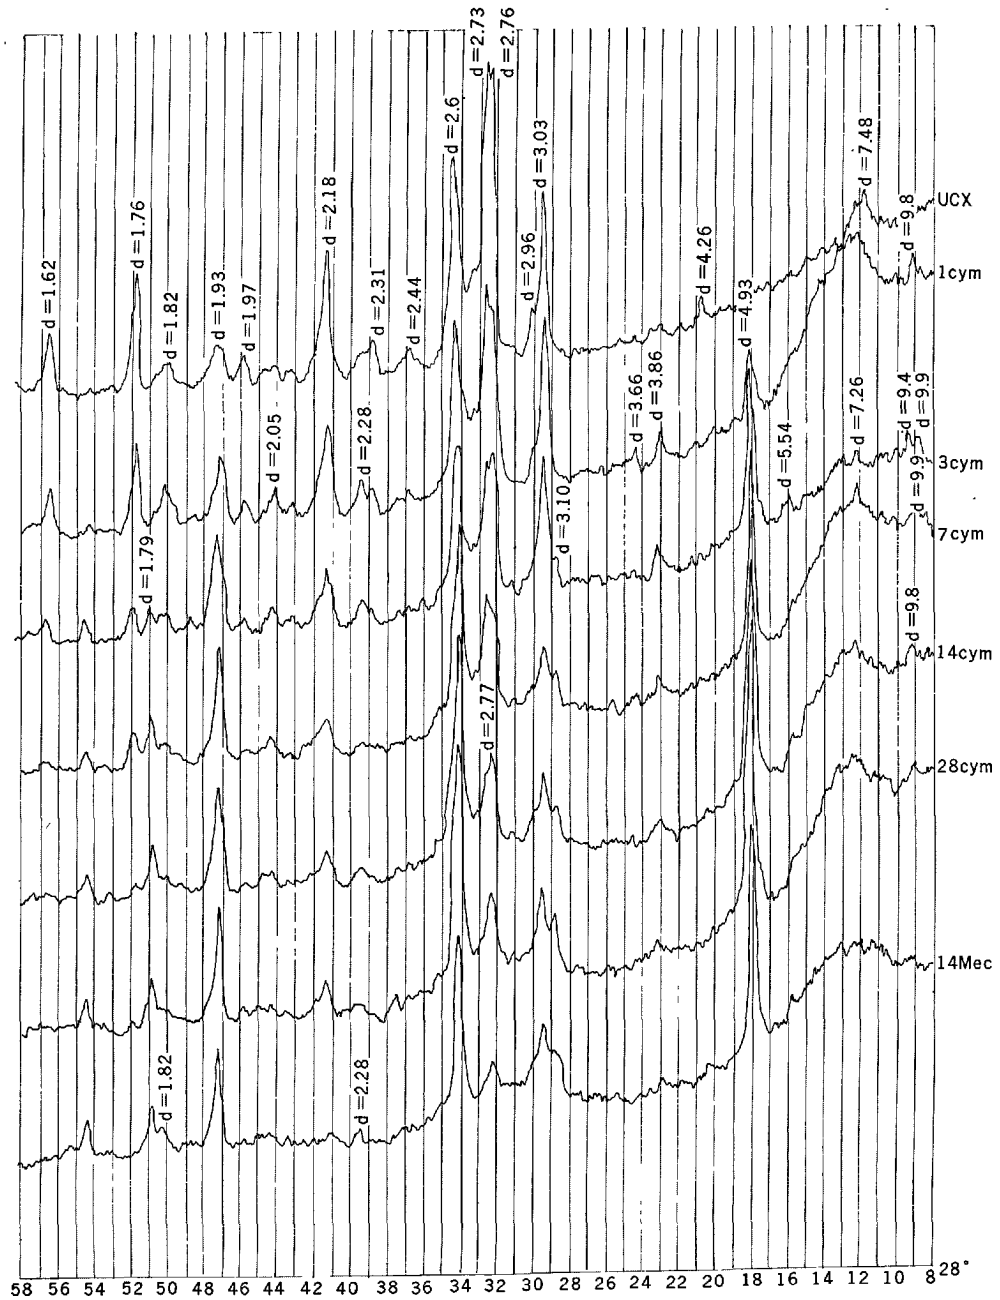

Fig. 14. *X-ray diffraction charts of portland cement at 0.5 w/c ratio.*

characterizing the decomposition of hydrosilicates, is much better developed in rapid-hardening slag portland cement.

X-ray examinations of cement stone samples, together with the data obtained by other methods allowed it to follow the changes in phase composition and in quantity of newly formed products of hydration proceeding in the process of hardening. X-ray examination of the phase composition of the hydrate phases of cement stone is however hindered because of chiefly colloidal character of the greater part of the newly formed products of hydration. It is especially evident at the attempt to estimate the quality and quantity of calcium hydrosilicates produced in the process of hardening; besides the reflexes from them are overlapped by the reflexes of clinker minerals.

The analysis of X-ray diffraction charts obtained from portland cement (Fig. 14) shows that gypsum

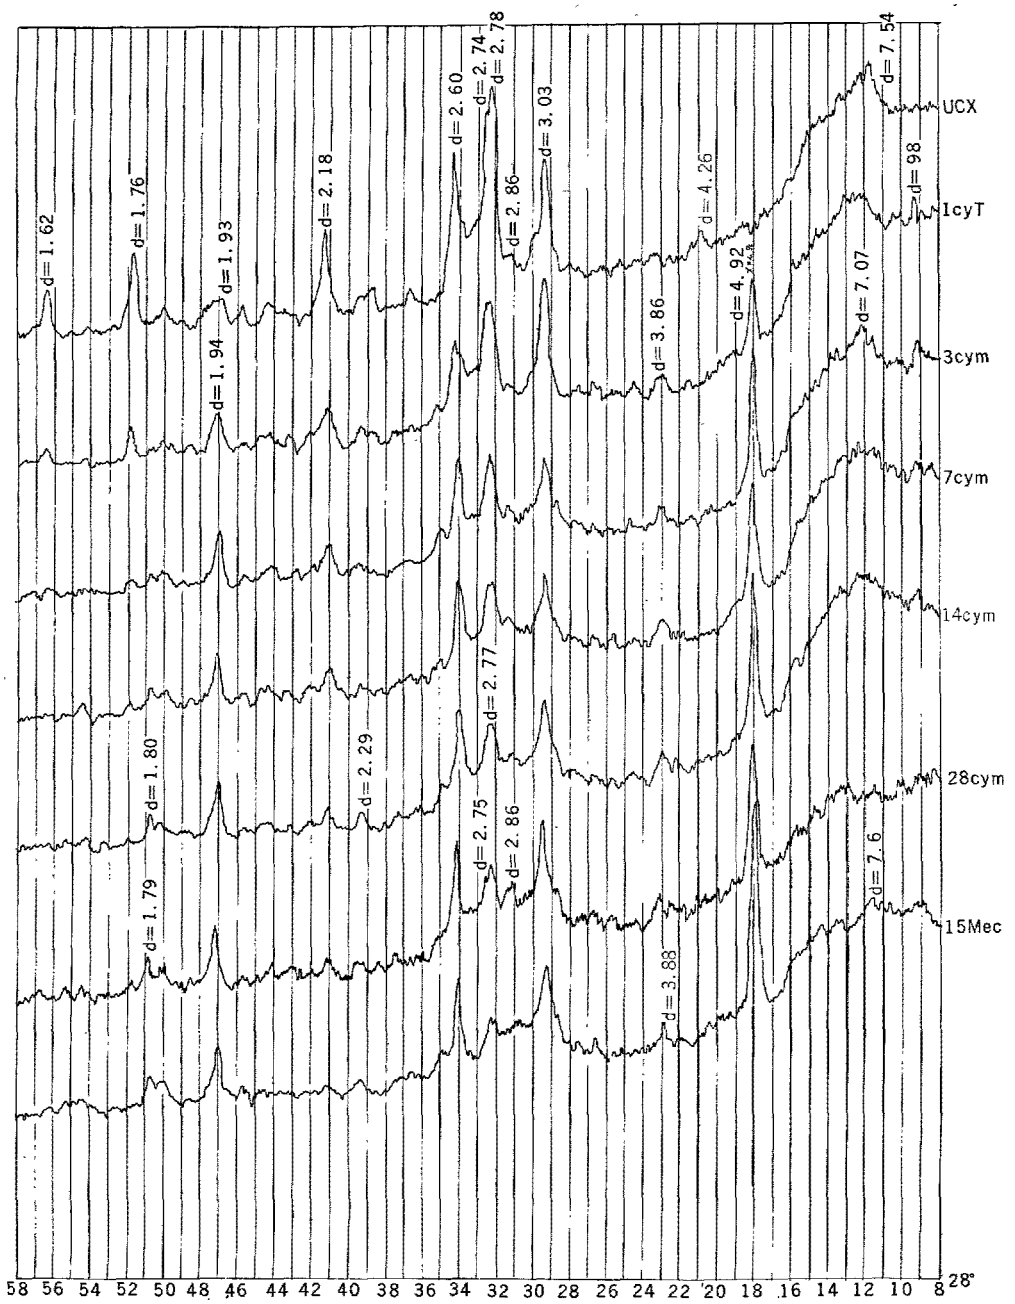

Fig. 15. *X-ray diffraction charats of rapid-hardening slag portland cement at 0.5 w/c ratio.*

aged up to 1—3 days which is present in composition of an initial sample ($d = 7.48$; 4.26 Å) reacts with the aluminate phases of clinker producing a high-sulphate form of calcium hydrosulphoaluminates (hydrosulphoferrites) (reflection with $d = 9.8$; 5.54 Å). In this period the increase of reflex with $d = 4.9$ Å, characterizing crystalline $Ca(OH)_2$, is observed too. The rise and development of this peak show the intensive proceeding even at early stage process of hydrolysis of C_3S, but the produced hydrosilicates don't give distinct reflections on the X-ray diffraction charts because of their amorphous structure and the presence of reflections from the initial clinker phases.

In the process of hardening the X-ray diffraction charts of corresponding samples are characterized by decrease of reflections from the anhydrite phases of clinker and by gradual decrease of reflexions from high-sulphate calcium hydrosulphoaluminates (hydro-

sulphoferrites). The reflection with $d = 3.86$ Å tends to decrease too. In connection with it the reflection should be considered as belonging to the crystals of ettringite type and not to calcium carbonate.

In the samples aged up to 14 months the expansion of reflection is well seen in the region of angles $2\theta = 28–30°$. It may be explained by the going on of hydration process of by that time remaining initial clinker phases and by intensive formation of colloidal compounds of C–S–H gel. To a certain degree this summary reflex is caused by the presence of $Ca(OH)_2$ ($d = 3.10$ Å) in the sample.

The X-ray diffraction charts obtained from rapid-hardening slag portland cement samples (Fig. 15) are similar to the corresponding X-ray diffraction charts of portland cement. Gypsum intensively reacts with aluminates of the initial cement components and is spent on the formation of high-sluphate compounds of ettringite type ($d = 9.8$ Å; 5.6 Å).

The changing of reflection value (401) of tricalcium silicate is characteristic.

Both in portland cement and in rapid-hardening slag portland cement this reflex decreases quite intensively in the period from 3 to 7 days. Consequently, the clinker that is a component of rapid-hardening slag portland cement is hydrated with almost the same intensity as the intensity of hardening of portland cement. However, the calcium hydroxide produced as a result of hydrolysis process partially combines with slag components into colloidal calcium hydrosilicates. That accounts for a smaller value of reflections of $Ca(OH)_2$ on the X-ray diffraction charts of rapid-hardening slag portland cement ($d = 4.9$ Å; 2.61 Å) in comparison with portland cement.

Supplementary Paper IV-48 Co-Ordination State of Aluminium, Magnesium and Maganese Ions in Synthetic Slag Glasses

Surinder K. Chopra and C. A. Taneja*

Synopsis

The states of co-ordination of aluminium, magnesium and manganese ions were determined in slag glasses in the systems $CaO–Al_2O_3–SiO_2$, $CaO–Al_2O_3–SiO_2–MgO$ and $CaO–Al_2O_3–SiO_2–MnO$ respectively by a combination of techniques such as specific volume, molar refractivity, fluorescence and differential thermal analysis. In glasses of composition $10CaO \cdot 8SiO_2 \cdot nAl_2O_3$, where n was varied from 1 to 7 moles (about 9 to 41 percent of Al_2O_3 by weight), the partial molar refraction of alumina ($K_{Al_2O_3}$) was found to be 12.7 which indicates four-fold co-ordination of aluminium ions. This conclusion was also supported by the differential thermal analysis of the glasses $10CaO \cdot (10–n)SiO_2 \cdot nAl_2O_3$ wherein Al_2O_3 replaced SiO_2 in four equal increments. The average partial molar refraction of magnesia (K_{MgO}) was found to be 5.08 and 5.05 in the two glass series having compositions $10CaO \cdot 8SiO_2 \cdot 4Al_2O_3 \cdot nMgO$ and $(12–n)CaO \cdot 8SiO_2 \cdot 4Al_2O_3 \cdot nMgO$ respectively and n varying from 1 to 4 moles (about 2 to 11 percent of MgO by weight). The K_{MgO} values indicate that magnesium ions are also present in four-fold co-ordination. This was confirmed by the fluorescence under UV of glass wherein MgO was replaced by NiO. The data also indicated four-fold co-ordination of magnesium ions. However, in glass compositions $9CaO \cdot 8SiO_2 \cdot 3.5Al_2O_3 \cdot nMnO$ where n was varied from 0.5 to 1.5 moles (about 2 to 7 percent of MnO by weight), the partial molar refraction values of manganese oxide showed six-fold co-ordination of manganese ions. The magnetic suceptibility measurements further revealed that though manganese was present in these glasses both in di- and trivalent states, the former was predominant, being more than 75 per cent.

Introduction

According to the random network theory, glass constituents can be divided into two classes, network formers and network modifiers (1). Oxides such as SiO_2, Al_2O_3, B_2O_3 and P_2O_5 belong to the former class because they are known to provide cations which link together appropriately by sharing of oxygens to form randomized three-dimensional networks of tetrahedra. The oxides of sodium, potassium and calcium are classified as network modifiers because they provide cations which occupy voids in the network. Though this theory is not universally accepted, Parker and Nurse (2), Tanaka, Sakai and Yamane (3), Keil and Locher (4), Kondo (5) and Mchedlov-Petrosyan (6) have employed it successfully to interpret the behaviour of hydraulic glasses corresponding to the blastfurnace slag system.

Granulated blastfurnace slag used commercially for the manufacture of slag cements consists predominantly of $CaO–Al_2O_3–SiO_2–MgO$ glass with a small amount of oxides of manganese and iron. Its hydraulicity is known to be influenced primarily by CaO/SiO_2 ratio and content of each of the oxides of aluminium, magnesium, and manganese etc. (7). Since the stability and the rate of solution of slag glasses, which are so important for hydraulic hardening, are dependent upon glass constitution (4), it is important to know how aluminium, magnesium and manganese oxides are present in the glassy structure. The states of co-ordination of aluminium, magnesium and manganese ions were therefore determined in low-lime synthetic slag glasses, corresponding to the compositions of the Indian blastfurnace slags, in the systems $CaO–Al_2O_3–SiO_2$, $CaO–Al_2O_3–SiO_2–MgO$ and $CaO–Al_2O_3–SiO_2–MnO$ respectively and the main findings of this study are reported in this paper.

*Central Building Research Institute, Roorkee, India.

Experimental

Preparation of Glasses

The synthetic slag glasses were prepared from analytical reagents of highest purity by the Dyckerhoff method (8). Precipitated silica, aluminium oxide, and carbonates of calcium, magnesium and manganese formed the raw materials in this study. Microscopic and X-ray techniques were employed to ensure that each sample was a pure glass. Six different series of glasses of the molecular formulae given below were prepared.

Series	Glass compositions in moles	Variation of 'n' in moles
A	$10CaO \cdot 8SiO_2 \cdot nAl_2O_3$	1 to 7
B	$10CaO \cdot nSiO_2 \cdot 3Al_2O_3$	7 to 10
C	$10CaO \cdot (10-n)SiO_2 \cdot nAl_2O_3$	1 to 4
D	$10CaO \cdot 8SiO_2 \cdot 4Al_2O_3 \cdot nMgO$	1 to 4
E	$(12-n)CaO \cdot 8SiO_2 \cdot 4Al_2O_3 \cdot nMgO$	
F	$9CaO \cdot 8SiO_2 \cdot 3 \cdot 5Al_2O_3 \cdot nMnO$	0.5 to 1.5

Methods of Study of Glass Constitution

The density determinations were made by the displacement method in which samples were weighed in air and in xylene at 27°C and referred to water at 4°C. The refractive index of powdered glass (passing a No. 100 B.S. sieve) was measured by the immersion method employing liquids of known refractive indices and examining the movement of the Becke line under a microscope. The total molecular refractivity of a glass was calculated with the help of Lorentz-Lorenz equation (9).

The synthetic glasses of the series C, D & E were also examined by differential thermal analysis as the latter has been used to deduce information on constitution of slag glasses (10). A heating rate of 10°C per minute was employed to heat the glass sample to about 1100°C. The heating was done in a ceramic holder and the thermocouple used was chromel/alumel. Ignited alumina (α-Al_2O_3) was used as an inert reference material. The glass sample was diluted with an equal amount of periclase of the same fineness (–B.S. Sieve No. 100). The weight of the diluted sample and that of the reference material were equal for each run. Periclase, which is considered to be physically and chemically unreactive (11), was added to prevent sticking of glass at softening temperature to the thermocouple wires.

Of the other methods recommended in the literature X-ray technique was not employed because of its limitations in interpreting complex glasses (12). Infra red absorption spectra was tried but it failed to reveal anything more than the position of Si–O absorption band at 9—10Å in glasses of series A and this did not prove of any help in this study. However, colour fluorescence indicators were found useful and NiO was used on the basis of earlier experience (13).

Magnetic Susceptibility

Magnetic susceptibility measurements were made for determining the state of valence of manganese in glasses of series F. A semi-micro aperiodic balance was used for this purpose. The powdered glass was packed uniformly in a sample holder made of glass of about 0.35 cm diameter and 16 cm length. The sample holder was suspended vertically between the poles of the electromagnet so that its bottom was in uniform field of maximum intensity and the upper portion nearly out of the magnetic field of the electromagnet. Weight of the sample along with the holder was taken before and after exciting the electromagnet with a known rate of current (3 amps.), and the change in weight was noted at 29°C. Ferrous ammonium sulphate was used for calibrating the instrument (29°C). The magnetic susceptibility was calculated from the equation

$$\lambda g = \frac{l}{W}(K_H \Delta W + AK_a)$$

where

λg = the magnetic susceptibility per g of sample in cgs units,
l = the length of the glass sample in cm,
W = the weight of the glass sample in g,
ΔW = the change in weight of the glass sample at a field strength of H Gauss,
A = cross sectional area of the glass sample in sq cm
K_H = the instrument constant for a field strength of H gauss,

and

K_a = the magnetic susceptibility per cc of air in cgs units.

The magnetic susceptibility of ferrous ammonium sulphate per g is $9500 \times 10^{-6}/(T° + l)$ where T is absolute temperature (14). At 29°C, this was found to be 31.35×10^{-6} cgs units. The value of K_H at 29°C was 0.14181×10^{-2}.

Results and Discussions

Co-Ordination State of Aluminium Ions

Aluminium ions can be present in tetrahedral state of co-ordination just like silicons or in octahedral co-ordination just like sodium, potassium or calcium ions. Density, refractive index and molecular refraction (K) are sensitive to a change in the co-ordination state of Al ions. The molecular refraction for visible light is a measure of the deformation of electronic shells in the structural unit. Since aluminium is a small cation of high charge and essentially non-deformable, its contribution to the molecular refraction, ($K_{Al_2O_3}$), is almost entirely due to the refractions of the large and easily deformable oxygen ions. For aluminium in the four-fold co-ordination state, the cation-anion distance is less than that for six-fold co-ordination and the inter-ionic forces are more intense. This causes a greater deformation of oxygen ions and therefore greater molecular refraction than when aluminium is in six-fold co-ordination. Safford and Silverman (15) and Day and Rindone (16) employed the determination of molecular refraction (K) to determine the state of co-ordination of the Al ions in soda-lime-silica glasses containing varying amounts of Al_2O_3.

Keil and Locher (4) maintained calcium oxide at a constant level and studied the effect of increasing alumina contents on the specific gravities and refractive indices of synthetic glasses in the system CaO–Al_2O_3–SiO_2. The molar CaO/SiO_2 ratio was therefore variable. Since the composition of the calcium silicate hydrate phase formed on hydration and activation of slag glasses depends to a great extent on the CaO/SiO_2 ratio in the original slag glass, in the present study the CaO/SiO_2 ratio was maintained constant in glasses prepared with varying alumina content in the part of the CaO–Al_2O_3–SiO_2 system corresponding to Indian slags (17). The results under column 2 in Table 1 show that the glasses cover the entire range of alumina content present in slag glasses. The values in column 3 show that the Zachariasen number of glasses varies from 0.34 to 0.50 thus covering the entire range of compositions which can form glasses (18).

Since the molecular refraction of the parent glass (sample 1) increases in a regular manner (Fig. 1) on incorporating six moles of alumina in six equal increments, it is obvious that the state of co-ordination of aluminium ions remains unchanged in the entire series (A). A similar trend was observed in the corresponding results for samples 8–11 of series B wherein different amounts of silica (7—10 moles) had been added to a glass of CaO/Al_2O_3 ratio of 1.83: 1. The values of density and refractive index decreased as expected because Si^{4+} is known to take up four-fold co-ordination and is a 'network former'.

The partial specific volume of Al_2O_3 in series A was found to be on the average 0.3673 cc/g. The specific volume of α-Al_2O_3 in which Al^{3+} is known to be present in six-fold co-ordination (19) is reported as 0.2525 cc/g (Table 1) and shows no agreement with the observed partial specific volume of this study. Hence, it is inferred that Al^{3+} in the glasses studied does not exist in six-fold co-ordination.

The slope of the linear curve in Fig. 1 represents the partial molar refraction ($K_{Al_2O_3}$) of alumina which

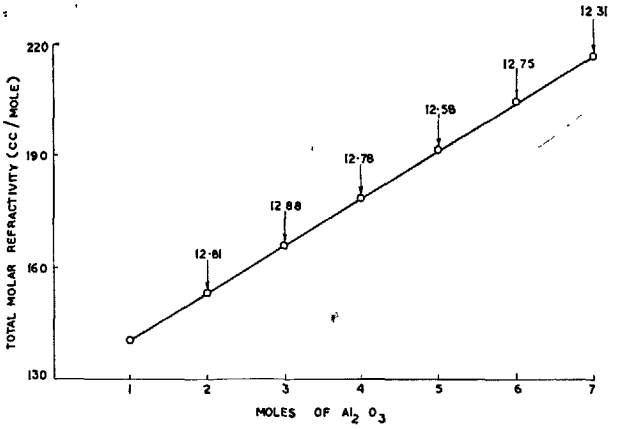

Fig. 1. *Partialmolar refractivity of Al_2O_3 in glasses of composition $10CaO \cdot 8SiO_2 \cdot (1\text{–}7)Al_2O_3$ numerals indicate $K_{Al_2O_3}$ values (average 12.70)*

was found to be 12.70. According to Safford and Silverman (15), Al^{3+} in four-fold co-ordination in glass has a molar refraction contribution of 12.55 (calculated for Al_2O_3), whereas in six-fold co-ordination it is 10.53. Since $K_{Al_2O_3}$ of the glasses of the present study is close to the former value, it is concluded that Al^{3+} in the $CaO–Al_2O_3–SiO_2$ glasses exists only in four-fold co-ordination.

Keil and Locher (4) had believed that aluminium ions existed in six-fold co-ordination in low-lime slag glasses. Chopra and Taneja (20) have examined Keil and Locher's data and calculated the average value of $K_{Al_2O_3}$ for the glasses of CaO/SiO_2 ratio of either 1.06 or 1.24: 1. $K_{Al_2O_3}$ was found to be 12.80 showing four-fold co-ordination. This value should have been between 10.63 and 12.55 if part of Al^{3+} had been present in six-fold co-ordination as believed by Keil and Locher.

Vitreous blastfurnace slags devitrify on heating to temperatures of the order to 800 to 1000°C and the heat evolved during devitrification can be recorded on a differential thermal analysis curve as a single or a set of multiple exothermic peaks. It has been observed that the exothermic effect of devitrification is many a time preceded by a small endothermic peak (21). Yamauchi and Kondo (10) have studied the thermal behaviour of glasses in the $CaO–SiO_2$ and $CaO–Al_2O_3$ systems and have reported correlations between slag compositions and its constitution in terms of peak temperatures in the range 800 to 1,000°C (5). The differential thermal analysis of the synthetic slag glasses of the present study was therefore carried out (Fig. 2). For this purpose glass series C was prepared. In this series increasing amount of SiO_2 was substituted by Al_2O_3 on molar basis. The data show that the peak temperatures of the endothermic effect,

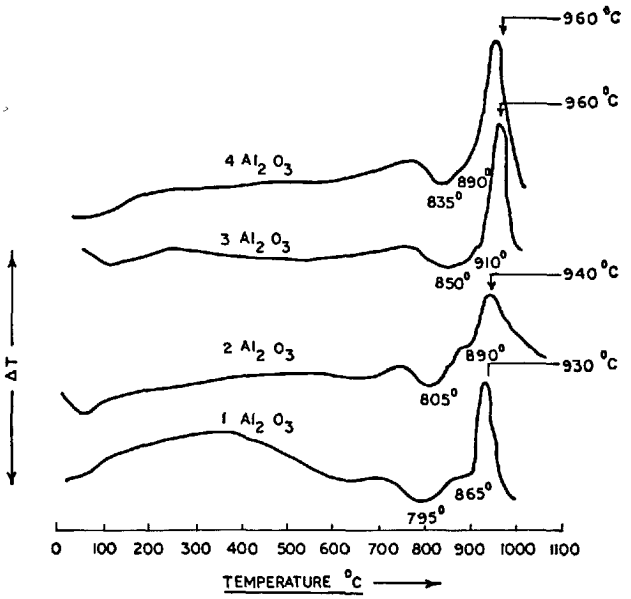

Fig. 2. *DTA curves of synthetic slag glasses of composition $10CaO \cdot (10\text{–}n)SiO_2 \cdot nAl_2O_3$ n varying from 1 to 4*

temperatures of the beginning of the exothermic effect and the exothermic peak temperatures generally show an increase as the number of moles of Al_2O_3 in glass increase. According to Kondo (4) the above mentioned rise in peak temperature indicates tightening of the glass structure by the replacement of silicon-oxygen tetrahedra by unsaturated oxygen in AlO_4 tetrahedra. It may therefore be concluded that the differential thermal analysis support the earlier conclusion of tetrahedral state of co-ordination of aluminium ions in slag glasses in the system $CaO–Al_2O_3–SiO_2$ based on the molecular refractivity data.

Co-Ordination State of Magnesium Ions

Chemical composition and physical characteristics of magnesium glasses of series D and E are reported in table 2.

Magnesium (Mg^{2+}) is a medium size cation having Goldschmidt radius of 0.78Å. It is known to exist in six-fold co-ordination in enstatite ($MgO \cdot SiO_2$) and diopside $CaO \cdot MgO \cdot 2SiO_2$, and four-fold in spinel ($MgO \cdot Al_2O_3$). Roy (22) calculated the molar refractivity of minerals of enstatite and diopside from the published data and determined the same for glasses of the same compositions by employing the Lorentz-Lorenz equation and found an increase of molar refractivity of the glasses by about 0.65. He concluded that the increase was due to a lower state of co-ordination i.e. four-fold assumed by Mg^{2+} ions in the glasses. Galent (23) has also shown that Mg^{2+} ions exist in

* This difference is for two moles of CaO;
**This difference is for one mole of CaO

four-fold co-ordination in melilite (including akermanite) glasses.

The difference in the total molecular refractivity of spinel ($MgO \cdot Al_2O_3$) and corrundum (α-Al_2O_3) gives the partial molar refractivity of MgO in four-fold co-ordination as magnesium in spinel exists in four-fold co-ordination. This value turns out to be 5.05 against a value of 4.54 for six-fold co-ordination of magnesium ions in periclase (Table 2).

The total molecular refractivity of magnesium glasses of series D was plotted against the number of moles of MgO present in each glass (Fig. 3). The slope of the resulting linear curve represents the partial molar refractivity (K_{MgO}) of magnesia. Since the latter value (K_{MgO}) was found out to be 5.08, it is concluded that Mg^{2+} exists in four-fold co-ordination in these glasses.

In the glass compositions of the series E, CaO was partially replaced by MgO (Table 2c). The maximum percentage of MgO in the substituted glasses is about 10 percent. The data show that the values of density, refractive index and total refractivity decrease on substitution of CaO by MgO. If co-ordination of calcium ions in both the glass series D and E is assumed to be six-fold, the partial refractivity due to CaO can be calculated from the differences in the values of the total refractivity of individual glasses, say No. 6 and 1, 7 and 2, 4 and 9, and 5 and 10. The average K_{CaO} was thus found to be 6.82 (Table 2d) against the reported value of 6.75 (24). If the average differ-

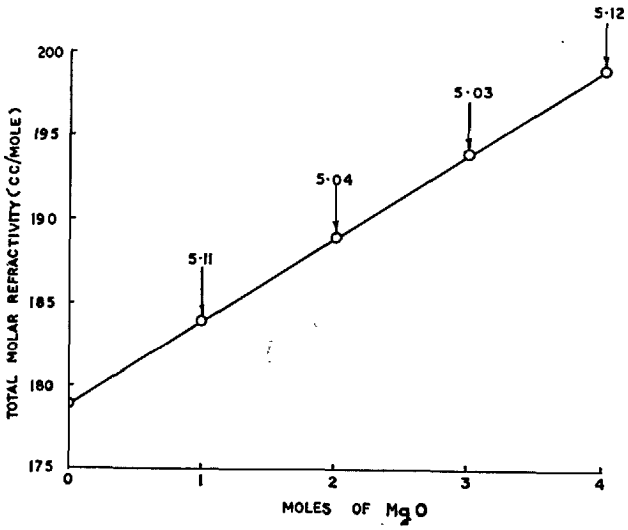

Fig. 3. *Partial molar refractivity of MgO in glasses of composition* $10CaO \cdot 8SiO_2 \cdot 4Al_2O_3 \cdot (0\text{–}4)MgO$ *numerals indicate* K_{MgO} *values (average 5.08)*

ence between K_{CaO} and K_{MgO} is 1.775 (Table 2c), K_{MgO} by difference from glasses of the series E equals 5.045 as against the value of 5.08 for the glasses of the series D. In other words, Mg^{2+} ions exist in four-fold state of co-ordination in the substituted glasses of series E also, thus confirming the earlier conclusions.

Differential thermal analysis of the glasses (series C and D) was also carried out and the pattern of the curves was similar to those given in Fig. 2. The thermal effects were recorded mostly in the range 800 to 1000°C and data are reported in Table 3.

With the addition of 4 moles of MgO to the parent glass of composition $10CaO \cdot 8SiO_2 \cdot 4Al_2O_3$ in four equal increments (series D), a fall was noticed in the temperatures of the endothermic peak, beginning of the exothermic effect and also the exothermic peak due to devitrification. A similar but less pronounced trend was observed in glasses of the series E wherein magnesium oxide substituted CaO in increasing amounts. The data in Table 3 show that the introduction of MgO loosens the structure, and is contrary to expectations on the basis of analogy with tetrahedral state of co-ordination of aluminium ions (Fig. 2).

Weyl and Marboe have reported the work of Petzold Wishman & Kamptz, who had correlated the hardness of glasses with other properties such as softening temperature and molar refractivity, and had found that the molar substitution of MgO for CaO did not fit into a simple pattern (25). Instead of increasing the hardness, as they had expected, the substitution of MgO for CaO on molar basis produced softer glasses. This discrepancy was explained by

Petzold, Wishman and Kamptz on the basis of tetrahedral state of co-ordination of magnesium ions. According to them, the substitution of MgO_4 groups for CaO_4 groups causes the tetrahedral structure to become weaker, because some Si^{4+} ions are replaced by Mg^{2+} ions and the average co-ordination of O^{2-} ions is lowered because the glass structure can accomodate Mg^{2+} but not Ca^{2+} ions in tetrahedral co-ordination. Similarly, the substitution of MgO_4 groups for CaO_6 groups in the slag glasses of series D and E causes the tetrahedral structure to become weaker because tetravalent silicon and trivalent aluminium ions are probably replaced by divalent magnesium ions of bigger size and the average co-ordination of O^{2-} ions is lowered and the structure thus gets loosened as is evident from the data in Table 3.

Mg^{2+} and Ni^{2+} ions are both divalent and have almost equal ionic radii (Goldschmidt). Ni^{2+} has been found to take up a bridging position in the network, and exists in four-fold co-ordination in high alkali borosilicate glasses and in $CaO\text{–}Al_2O_3\text{–}B_2O_3$ and $CaO\text{–}B_2O_3$ glasses containing high CaO (13). The colour of glass under ultraviolet light is purple when Ni^{2+} occurs in four-fold co-ordination. In view of this a part of MgO in glasses No. 8 and 10 was replaced by an equivalent amount of NiO. The glasses when examined under ultraviolet light showed purple colour thus confirming that Mg^{2+} ions exist in four-fold co-ordination in both the series of glasses in the system $CaO\text{–}Al_2O_3\text{–}SiO_2\text{–}MgO$.

Co-Ordination State of Manganese Ions

Since blastfurnace slags are known to contain a small amount of manganese, a few samples of the synthetic slag glasses of the general formula $9CaO \cdot 8SiO_2 \cdot 3.5Al_2O_3 \cdot nMnO$ were prepared in a reducing flame by the Dyckerhoff method. These glasses correspond to the compositions of the Rourkela slag

Table 4. *Characteristics of CSAMn* glass samples (Series F)*

													av. = 7.66

*C = CaO S = SiO_2 A = Al_2O_3 Mn = MnO

(17). The value of n in these glasses (series F) was varied from 0.5 to 1.5 and the corresponding variation of MnO content in the glass was 2.58 to 7.36 percent by weight. The state of co-ordination of manganese ions in these glasses was studied by the partial molar refractivity method and also by investigating fluorescence under UV radiation.

The values of densities, refractive indices and molecular refractivities of the glass samples are reported in Table 4. The average value of partial molar refractivity works out to 7.66 against a value of 7.2 for six-fold co-ordination of manganese reported in the literature (24). The higher experimental value therefore indicates that part of manganese exists either in four-fold state of co-ordination or in trivalent state of valence. According to Weyl and Marboe (26) red fluorescence in manganese glasses under UV radiation is attributed to manganese ions present in interstitial position in the glass network when they are surrounded by six oxygens. The slag glasses of the series containing manganese oxide up to 7.5 percent, when exposed to UV radiations, exhibited red fluorescence thus confirming a six-fold state of co-ordination of manganese ions. This may be presumably due to its greater ionic size. It was therefore inferred that the higher value of partial molar refractivity is probably due to part of manganese occuring in a higher state of valence. This was confirmed as reported below.

It is well known that atoms and ions of transition elements in the free state have unfilled electron shells and hence possess magnetic moments. The magnetic properties of glasses, whose framework is usually slightly diamagnetic, will change substantially by the incorporation of ions of transition elements. It, therefore, follows that measurement of magnetic susceptibilities of the glass samples of the series F could throw light on the state of valence of manganese ions.

The magnetic susceptibility λg of a glass sample can be taken to be the sum of diamagnetic susceptibility $\lambda_0(1 - C_{Mn})$, due to the base glass and the paramagnetic susceptibility, $\lambda_{Mn} \cdot C_{Mn}$, due to the concentration C_{Mn} of manganese present in the glass (27)

Table 5. *Magnetic properties of CSAMn glass samples (Series F)*

Sl. No.	Glass formula C: S: A: Mn				Manganese total percent by wt.	Magnetic susceptibility $\lambda_{Mn} \times 10^{-6}$ in cgs units	Magnetic moment (μ) (Bohr magnetons)	Manganese present in manganic state percent
1	9	8	3.5	—	0	—	—	—
2	9	8	3.5	0.5	2.0	228.24	5.52	18
3	9	8	3.5	1.0	3.9	244.42	5.71	24
4	9	8	3.5	1.5	5.7	232.48	5.58	20

and can be expressed by the equation (1)

$$\lambda g = \lambda_{Mn} \cdot C_{Mn} + \lambda_0(1 - C_{Mn}) \qquad (1)$$

The magnetic susceptibility value λ_{Mn} (at 29°C) for Mn in the synthetic slag glasses of the series F are reported in Table 5 column 4. From λ_{Mn} the paramagnetic moment μ (in Bohr magnetons) due to the manganese in glass was calculated from the equation (2)

$$\mu = 2.83\sqrt{T\lambda_{Mn} \cdot M} \qquad (2)$$

where

M is the atomic weight of Mn (54.93) and
T the absolute temperature.

The magnetic moments due Mn in the synthetic slag glasses are from 5.52 to 5.71 Bohr magnetons (Table 5 column 5). Since the theoretical moment due to spin only, are 5.92 and 4.90 Bohr magnetons for Mn^{2+} and Mn^{3+} respectively, it may be concluded that manganese is predominantly present in the manganous state. The values of $\lambda_{Mn^{2+}}$ and $\lambda_{Mn^{3+}}$ as calculated from equation (2) are 26.38×10^{-5} and 18.07×10^{-5} cgs units respectively.

The relative amounts of divalent (Mn^{2+}) and trivalent (Mn^{3+}) in the glass samples can be calculated from equation (3).

$$\lambda_{Mn} = \lambda_{Mn^{2+}} \cdot C_{Mn^{2+}} + \lambda_{Mn^{3+}}(1 - C_{Mn^{2+}}) \qquad (3)$$

where $\lambda_{Mn^{2+}}$ and $\lambda_{Mn^{3+}}$ are the magnetic susceptibilities and $C_{Mn^{2+}}$ and $(1 - C_{Mn^{2+}})$ are concentrations of the Mn^{2+} and Mn^{3+} ions respectively. By substituting the magnetic susceptibility value, λ_{Mn} in the above equation (3) and the calculated values of $\lambda_{Mn^{2+}}$ and $\lambda_{Mn^{3+}}$

from the equation (2) using the theoretical moments for Mn^{2+} and Mn^{3+} ions, as 26.38 $\times 10^{-5}$ and 18.07 $\times 10^{-5}$ cgs units respectively at 302°K, the amounts of manganous and manganic ions were calculated (equation 3) and are expressed as percentage of total manganese in Table 5. The data indicate that manganese in the synthetic glass sample is predominantly present in bivalent state i.e. from 76 to 82 percent. This is in accord with the knowledge that high temperatures and reducing atmosphere in blastfurnaces promote bivalent manganous state.

Conclusions

The state of co-ordination of aluminium ions in synthetic slag glasses in the system $CaO–Al_2O_3–SiO_2$ was studied by determining the effects of varying the alumina content (from 1 to 7 moles) on the density and refractive indices of glasses of composition $10CaO \cdot 8SiO_2 \cdot nAl_2O_3$ having a CaO/SiO_2 ratio of 1.17: 1. The partial molar refractivity of alumina indicated that aluminium ions are always present in four-fold co-ordination. This was also supported by the value of the partial specific volume of Al_2O_3 and the rise in temperature of the exothermic peak due to devitrification on substituting increasing amounts of Al_2O_3 (moles) for SiO_2 in the glass compositions $10\,CaO \cdot (10–n)\,SiO_2 \cdot nAl_2O_3$. Similarly, the partial molar refractivity of magnesia in glass compositions of general formulae $10CaO \cdot 8SiO_2 \cdot 4Al_2O_3 \cdot nMgO$ and $(12–n)\,CaO \cdot 8SiO_2 \cdot 4Al_2O_3 \cdot nMgO$ where n was varied from 1 to 4, indicated a four-fold state of co-ordination of magnesium ions. This was also confirmed by the purple fluorescence of Ni^{2+} ions in glasses where part of MgO was substituted by NiO. But the average value of partial molar refractivity of manganese oxide in glass compositions of $9CaO \cdot 8SiO_2 \cdot 3.5Al_2O_3 \cdot$ (0.5 to 1.5) MnO showed that manganese ions were present in six-fold co-ordination. This was also indicated by the red fluorescence of manganese glasses in ultraviolet light. The partial molar refractivity data (K_{MnO}), however, indicated further that a part of manganese was present in a higher state of valence and the magnetic susceptibility measurements confirmed that about 18 to 24 percent of manganese was present in trivalent state in the manganese bearing glasses.

Supplementary Paper IV-100 A Contribution to the Study of the Physical Properties of Hardened Pastes of Portland Cements Containing Granulated Blast-Furnace Slag

Cesare Cesareni and Giuseppe Frigione*

Synopsis

This paper wants to bring up a contribution to the study of some fundamental physical properties of the hardened pastes of cement containing granulated blast-furnace slags with the precise intent to put in evidence analogies and differences of the slag under hydrated stage in comparison with the portland cement.

The properties studied, adopting the different methods indiceted by Powers and other Collaborators are:

—Sedimentation process of the fresh pastes.
—Contents of non-evaporable water at a normal temperature.
—Development of the surface area of the pastes.
—Porosity of the pastes.

It has been tempted to find, besides, a relation among the above mentioned properties and the other fundamental physico-mechanical characteristics of the cements for their use.

The experiment has been conducted on a series of cements obtained by mixture of different clinkers, differentiated from the ratio C_3A/C_4AF; and of different industrial samples of slag coming from different blast-furnaces and differentiated by the content of the three fundamental oxides SiO_2-CaO–Al_2O_3.

Clinkers and slags have been mixed in proportions that vary from 10 to 70% and compared with portland cements obtained from the same clinker.

Storage time of 7–28–180–365–630 days and water-cement ratio of 0.30 and 0.50 have been considered.

Introduction

The study of hardened pastes made with portland blast-furnace slag cement acts as a bridge between the chemistry of these cements and their technological application in concrete.

The set of variabilities (chemical composition of the clinker, composition of the slags, physical condition of the same, fineness of the two components, centesimal composition of the mixtures, percentages of gypsum content and of other activating or regulating products) is so vast that a systematic experiment would require many years of work.

It has to be taken into consideration, in particular, that any study on cements containing blast-furnace slag, involves two basic components (clinker and slag) of which one (slag) is in a metastable condition and therefore its behaviour will never be able to be perfectly defined until physico-chemical parameters and therefore an unequivocal consent to the classification of slags are found.

This paper is limited to the illustration of the results obtained by us and a general review on the subject is postponed for later date in order to improve the results by other evidences, to be found in the present experiment.

The main purpose of the work is the enrolment in great lines of the physico-chemical phenomena which charaterizes the process of hydration of hardened cement pastes containing blast-furnace slag.

Since the purpose was to study industrial cements, the slags have been associated with clinkers as they are actually used for the production of blastfurnace cements, i.e., clinkers characterized by high contents of C_3S (1). It follows that since this constituent is in an almost constant quantity, it is possible to study the influence of the other constituents (C_3A and C_4AF) on the hydration of blast-furnace slags.

*Cementir-Cementerie del Tirreno S.p.A. Roma, Italy.

Characteristics of Cements Tested

The clinker and slag used are of ordinary industrial products and have the chemical analyses listed in Table 1.

The slags, by products of three different basic blast-furnace process are granulated directly by pouring in a pit containing sea-water, and located near the furnace.

The values assumed for the three slags from the various formulae in order to evaluate the hydraulic properties of the blast-furnace slags, may be found in Table 2.

Thirty-nine types of cement formed by different percentages of clinker-slag mixture, in ratio of 100/0, 70/30, 50/50, 30/70 and 10/90, from three types of clinker and three types of slag, have been prepared.

The various mixtures have been obtained by mixing in an appropriate mixer the two main components having been ground in a laboratory mill with the addition of a fixed quantity of 4% gypsum, and to a fineness characterized by a Wagner specific surface of about 1850 cm^2/g.

Sedimentation Test on Fresh Pastes

The experiment has been conducted according to the method realized by Valore, Bowling and Baline

(2), (3).

We have verified that the phenomenon has a common procedure for all tested slags, that is, the capacity and bleeding velocity increase continuosly with the increase of slag content.

We have investigated more thoroughly the phenomenon of a group of mixtures, which constitutes clinker A and slag 1.

The characteristics of bleeding tests are listed in Table 3 and shown in Fig. 1.

On the basis of above mentioned characteristics, it has been calculated the value of immobile water W_i: it decreases by increasing the slag content.

The bleeding rate increases with the slag content not only for the decrease of W_i but also for the variations of the fluid density and the fluid viscosity (with an increase of about 2.5% and 6% respectively for the mixture 10/90) which result remarkably enough; and such that they influence, in a great way, the above parameter, as it can be confirmed by the Kozeny-Karman equation adapted for this particular case by Powers (4).

(°) The hydraulic radius is calculated from the formula $W/C\sigma$ where W is the water present in the sediment after bleeding and the volume of water corresponds to the porosity of sediment.

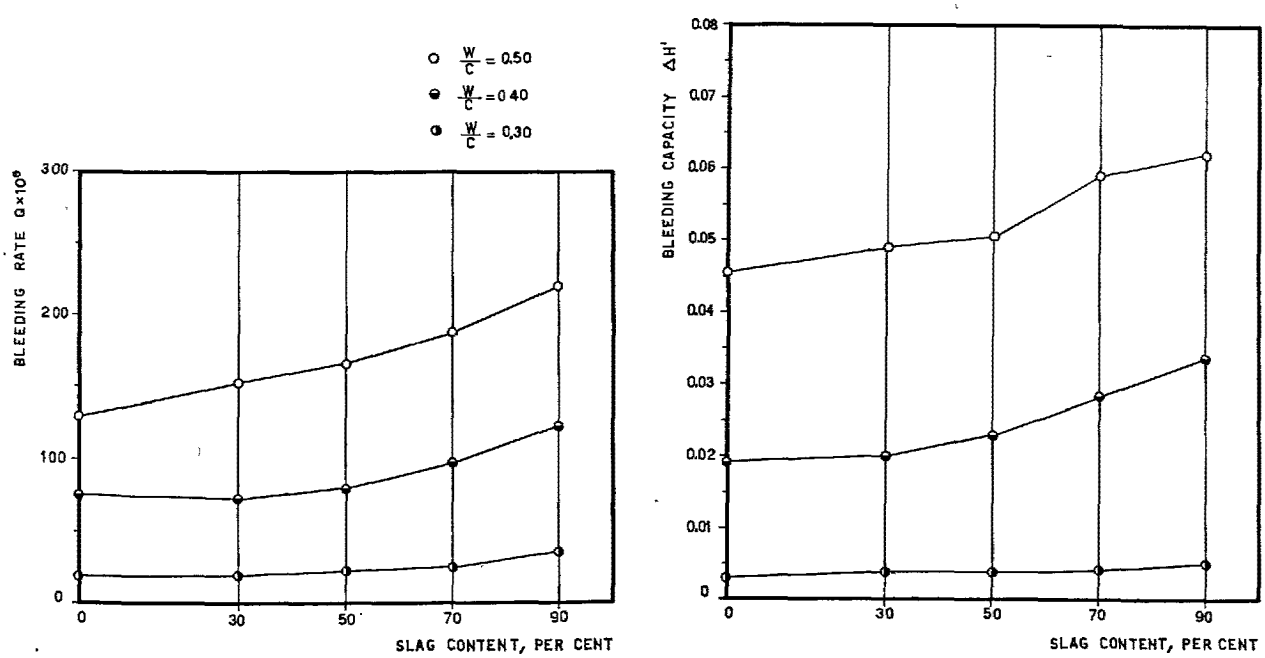

Fig. 1. *Bleeding characteristics as a function of slag content of the cement*

We still ought to consider the flocculation effect which probably is decreased in higher slag mixtures, where the amount of hydrated lime from the clinker, is quite small.

Besides, hydraulic radius have been calculated (already reported in table 3), considering the content of water in fresh pastes equal to the presence of water after the bleeding or, in other words, corresponding to the porosity of the paste sedimentation. From value of hydraulic radius it is possible to evaluate the mean pore size of the paste.

It must be observed that, the hydraulic radius and therefore the mean size of pores, decreases with the increase of the slag content. Such a result does not agree with what was found by Chopra (5).

Tests on Hardened Pastes

Tests on all mixtures were conducted employing two ratios W/C, i.e., 0.30 and 0.50.

The pastes used in this research were mixed free from air as described by Powers, Copeland, Hayes and Mann (6).

The mixtures were immediately poured in test tubes which were accurately corked so that no air could remain between the paste and the cork. Immediately after, the test tube was held in continuous motion attached in a radial position, to a vertical disc rotating at a slow velocity (7 r.p.m.) until the cement has completed its setting. In such a way the bleeding has been avoided obtaining so, for a more vigorous comparison, with pastes having an equal ratio W_0/C.

Successively the test tube was cured in water at $20 \pm 1°C$ until the date of the determinations of the different periods of curing.

The periods of curing considered were: 7–28–180–365 and 730 days.

To appear more evident in the graphic description, in the various diagrams we have limited ourselves in relating the values corresponding to the curing periods of 7–28 and 730 days.

Non-evaporable Water and Free Calcium Hydroxide

Non-evaporable water has been determined by the method described by Copeland and Hayes (7).

The free calcium hydroxide has been determined according to the "time variation method" described by Pressler, Brunauer, Kantro and Weise (8), and following modification (9).

All the mixtures were tested only for the curing periods of 7 days and 2 years.

For the mixture with W_0/C 0.30, the determinations seem, though, affected by a noticeable experimental error, and therefore are not taken into consideration.

In Figs. 2 and 3 are reported the variation bands of Wn/C for the various cement mixture ratios.

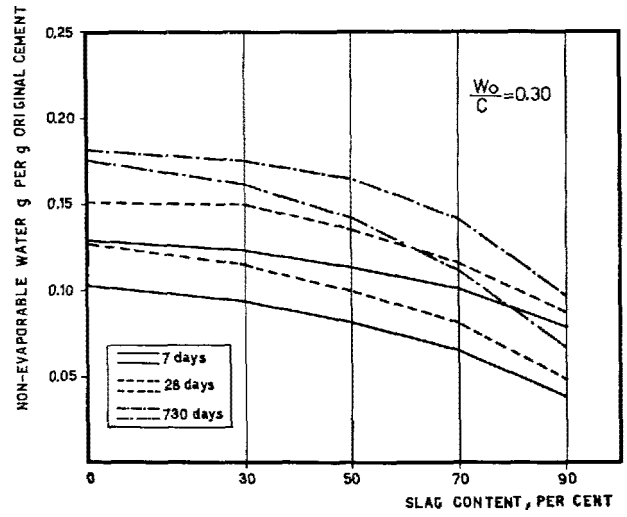

Fig. 2. *Bands of non-evaporable water as a function of slag content of the cement (Wo/C 0.30)*

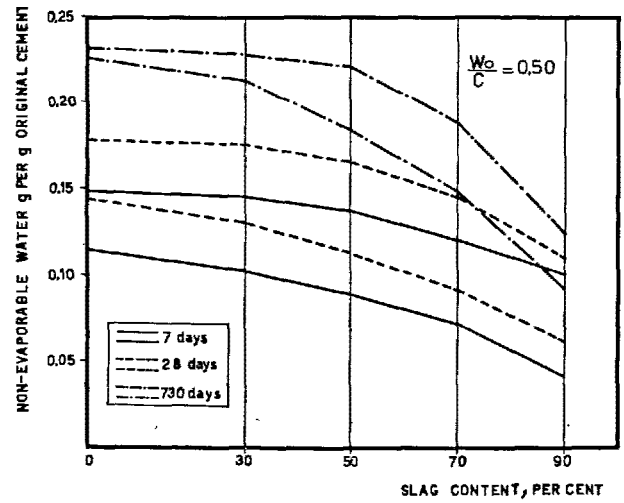

Fig. 3. *Bands of non-evaporable water as a function of slag content of the cement (Wo/C 0.50)*

It is noted that until a cement mixture ratio at 50/50 the values of nonevaporable water are of the

same order as those of portland; while for cement mixtures with 70% to 90% of slag, the values of Wn/C are much inferior and the difference is accentuated with hydration during the time process.

In Fig. 4 are reported the variation bands of CaO extracted. Still in Fig. 5 are reported the bands of CaO absorbed (calculated as a difference between that liberated by the corresponding pure portland cement at the same curing period and the CaO extracted) expressed in grams of lime based on 100 grams of anhydrous slag.

It is observed that the quantity of CaO absorbed for the mixtures 70/30, is of the same order (or even higher) as that of the same slag capable of absorbing if kept in contact and in constant agitation with saturated calcium hydroxide solution; for the mixtures richer in slag, the CaO absorbed is very limited.

In order to evaluate how much non-evaporable water is attributable to water combined in gel, we have also calculated for a series of mixtures the contribution given to Wn/C by the calcium hydroxide and we have obtained the new values of the non-evaporable water (Wn^g/C) always based on 1 g of anhydrous cement (mixtures clinker A—slag 1).

	% clinker	% slag	Wn^g/C
7 days	100	—	0.0634
	70	30	0.0703
	50	50	0.0669
	30	70	0.0604
	10	90	0.0493
730 days	100	—	0.1584
	70	30	0.1767
	50	50	0.1597
	30	70	0.1320
	10	90	0.1099

It is still underlined here that up to 50% of slag, non-evaporable water contained in hydrated products-exclusive of calcium hydroxide-is higher than that of pure portland, and the maximum non-evaporable water content is attained with a cement mixture containing 30% of slag. While the mixtures with higher slag content show an accentuated and progressive Wn^g/C diminution.

The explanation of the above evident phenomena does not appear clear, considering the interaction of the variable; it can be, anyway, hypothesize that with higher slag content:

a) the minor quantity of lime present absolutely in the mixture gives place to more impermeable gel which slows down the hydration reaction and those of "pozzolanic" action; and this occurs due to a topochemical absence of lime.

b) The reaction products have a minor basicity and combine with a minor water quantity.

The confirmation of the validity of both hypotheses or more, probably of the two, requires, according to us, a further experimentation with other and different research methods.

(°) We have indicated non-evaporable water combined with gels with Wn^g/C.

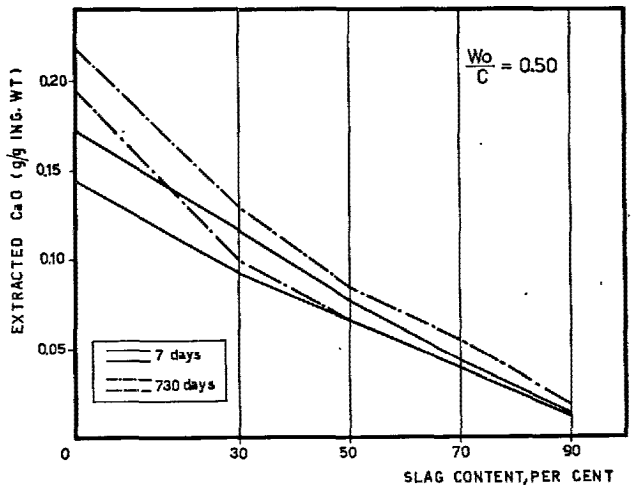

Fig. 4. *Bands of CaO extracted as a function of slag content of the cement (Wo/C 0.50)*

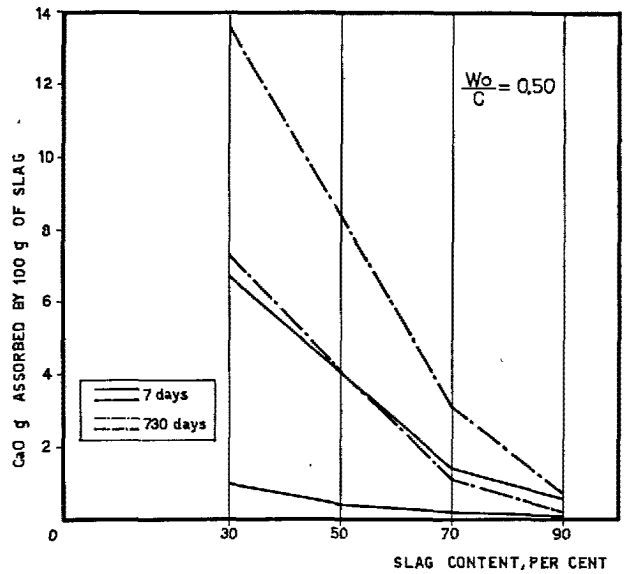

Fig. 5. *Bands of CaO absorbed by 100 g of slag as a function of slag content of the cement (Wo/C 0.50)*

Specific Surface Areas

The specific surface areas and in particular Vm, characteristic parameter of the surface areas to which

it is directly proportional, were evaluated with the method described by Kantro, Brunauer and Weise (10).

The variation bands of the specific surface areas, always relative to 7–28–730 days, are reported in Figs. 6 and 7 (respectively ratio Wo/C 0.30 and 0.50).

This curve trend confirms that the slag hydration products are prevailingly colloids and they contribute significantly to the total surface areas.

In particular it is observed that mixtures of low slag content have areas of the same size as those of pure portland; and attaining a progressively higher surface

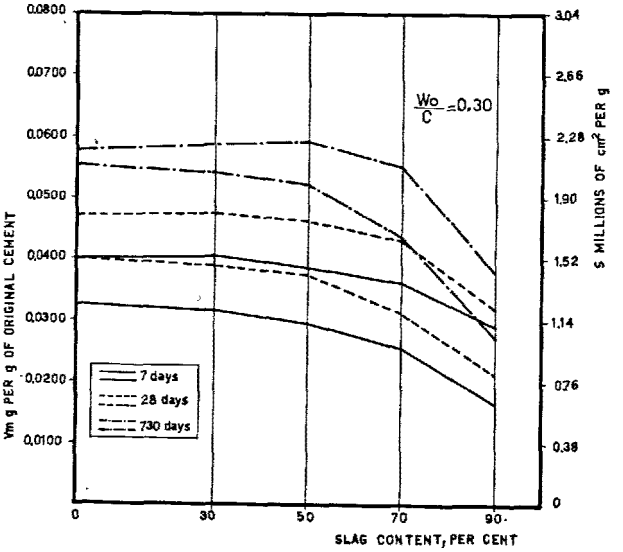

Fig. 6. *Bands of Vm and specific surface area S as a function of slag content of the cement (Wo/C 0.30)*

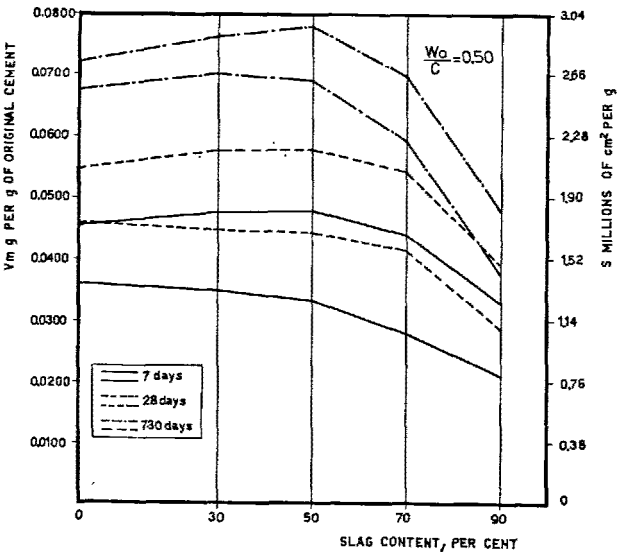

Fig. 7. *Bands of Vm and specific surface area S as a function of slag content of the cement (Wo/C 0.50)*

area during the curing period; and also because of the minor content of calcium hydroxide.

The physico-mechanical characteristics of these cements therefore will be quite similar to the clinkers from which they have been derived and during the curing period these cements have more colloidal new-formations in hardening products; and all those characteristics due to higher quantity of gel will be more conspicuous.

In relation with the above hypothesis, concerning the explanations of the different non-evaporable water content in the cements rich of slag, the surface areas would also show the formation of more compact products and consequently reduced velocity of reaction.

This could give value to Locher's hypothesis (11) according to which the remarkable sulphate resistance of this cement is not due to the chemical properties of the reaction products, but to the capacity of the

hardened cement to avoid the formation of sulphoaluminate, richer in sulphate, in accordance with its particular physical structure.

We have reported in Table 4 the values of Vm in grams developed by one cubic centimeter of paste (Wo/C 0.50).

By such results it appears evident that the chemical characteristics of the clinker have a great influence on the development of the specific surface areas and consequently on the whole hydration process of the cements containing slag and that this influence is practically uniform with the three slags.

Remembering that the content of C_3S and C_2S is almost the same in the three experimented clinkers, it seems quite true that the characteristics which differentiates their actions in the hydration process of the slags are given by the C_3A content.

The different behaviours of the three slags are evident in Fig. 8, where making the value of Vm for one cubic centimeter of portland cement paste equal to 100, the corresponding values of the different mixtures of various curing periods is reported.

By these diagrams, it can be extablished a qualitative classification of different slags which appear independent from the quality of the activating clinker -in decreasing order slag 3, slag 2, slag 1-; which classification, according to the actual experiment, is not capable of having relations with the slag characteristics in spite of the premise about the necessity to find sure parameters for the classification of the slag.

$$K = Vm/Wn$$

Powers and Brownyard (12) put in evidence that the specific surface area BET of gel formed by portland cement pastes as shown in the diagram with respect to the content of non-evaporable water, gives a straight line through the origin, and concludes that this indicates the equality of hydration products in different hydration stages.

The characteristic ratio for each type of cement between specific area and non-evaporable water was indicated with K.

Verbeck and Foster (13) determined the K constant

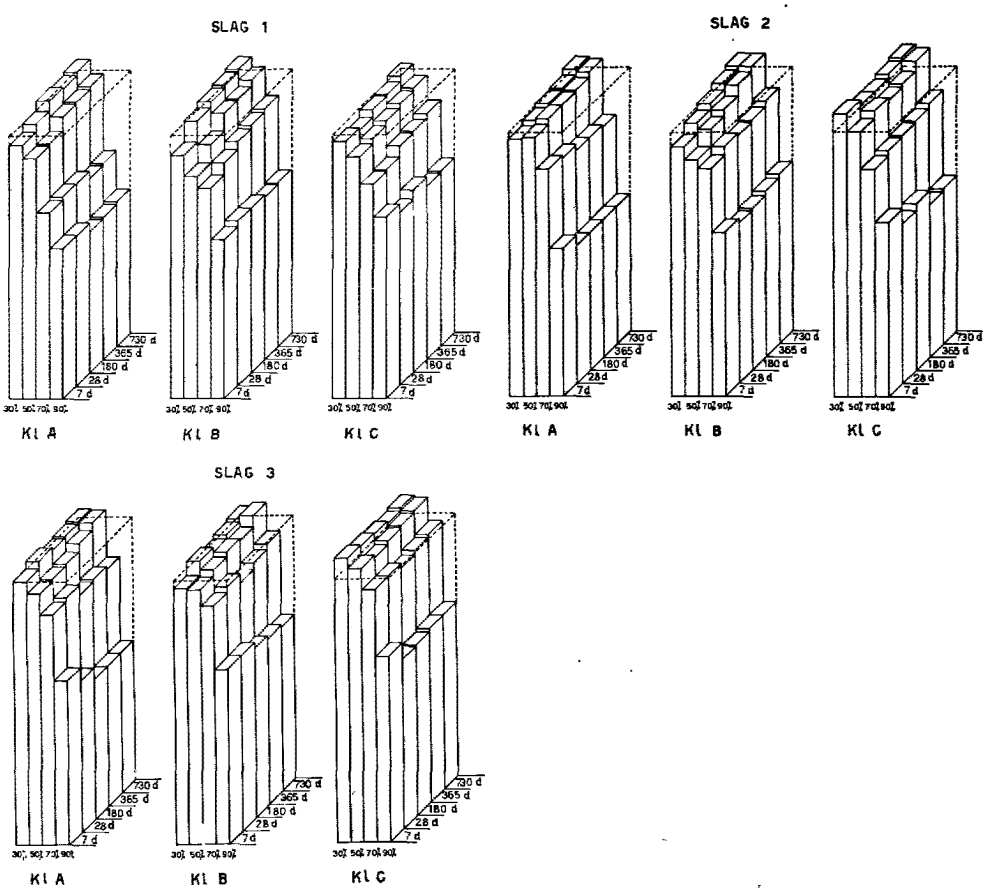

Fig. 8. *Values of Vm (g per cc of paste) expressed in per cent of value of portland cement*

for any given cement with determinations of the heats of hydration, at different curing periods, which were showed to be proportional to the quantity of non-evaporable water (Wn).

Later it was found (8), (14) that K constant applies only for type I ASTM cements.

The constancy of K implies, as already said, that to equal the quantity of non-evaporable water (Wn), one must have equal formation of hydrated compounds. However this is not strictly true with cements containing slags regarding the new-formation of $Ca(OH)_2$, as shown in Fig. 9, and where the calcium hydroxide (expressed as CaO/g ignited cement) is reported in function with Wn/C for a mixture of 70% slag.

For comparison, the correlating line found by Pressler, Brunauer, Kantro and Weise (8) for a cement type I ASTM has also been reported.

It has been observed that in the time interval between 7 to 730 days, although the points are on a straight line, the intersecting line does not pass through the origin.

Anyway the deviation is very little and while it explains why the inconstancy of K is hardly pointed out by the adsorption measurements, it allows to adapt the mean values to K to characterize the cements. The mean characteristics of K in the clinker/slag ratios is shown in Fig. 10.

On the other hand, Lehmann and Roesky (15) have also found for cement containing slag practically a constant ratio between heat of hydration and non-evaporable water quantity along the time interval between 1 to 90 days, and does nothing else but show the modest entity of variation of K.

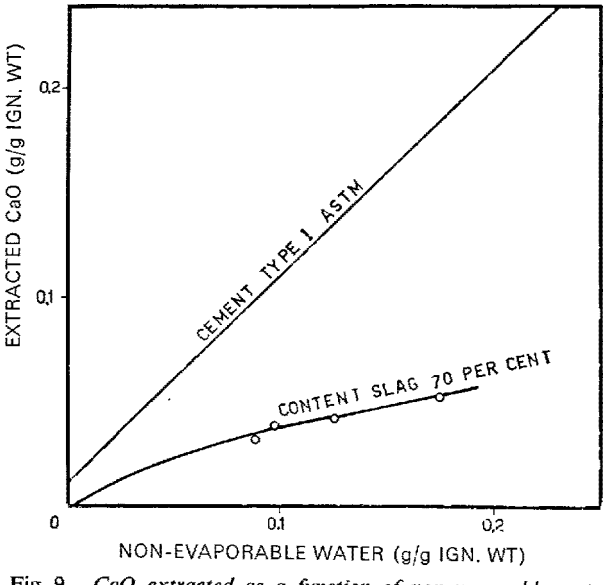

Fig. 9. *CaO extracted as a function of non-evaporable water for hydrated cement containing 70% slag and for hydrated Type I ASTM cement*

Compressive Strength

In Table 5 are shown the values of compressive strength obtained by the various mixtures, in tests done according to the RILEM-Cembureau method, limiting to the curing periods of 7–28–180 days.

Agreeing with what was said by Locher (11) and with what was said by us concerning the variable Vm,

Table 5. *Values of compressive strength (kg/cm²)(Rilem-Cembureau)*

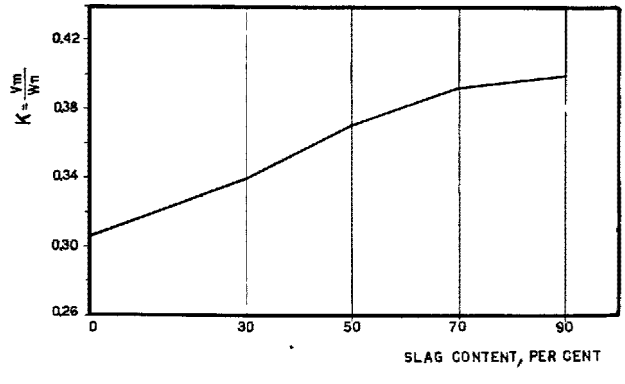

Fig. 10. *The characteristic relationship between Vm and non-evaporable water (Wn) as a function of slag content of the cement*

we confirm that the higher quantity of C_3A contained in the clinker influences positively the slag hydration.

In Fig. 11, the proceeding of Vm referred to cubic centimeter of the paste volume in relation to the compressive strength, has been reported.

Concerning the portland cements, we confirm what was said by Powers and Brownyard (12), i.e., for cements with high C_3A content, you can obtain a deviation of the points from the correlated line.

It is noted that increasing the slag content up to 50%, the slope of the line decrease and i.e., at equal values of Vm, resistances are less.

On the basis of what was found by Powers and Brownyard (12), it can be deemed that adding suitable gypsum in cements, these lines would attempt to put themselves above those of pure portlands.

For mixtures richer in slag, the ratios between strength and surface area become clearly higher, and this would admit once more that we are in front of a hydration characterized by chemical and physical phenomena of different nature.

For these mixtures, however, we have not thought of tracing a characteristic line, being, according to us, necessary to make a further thorough test for clarifying the reason of such a dispersion.

Volume of Capillary Pores

The volume of capillary pores has been calculated according to determinations of total water (16).

In Figs. 12 and 13 are reported the variation bands of the volumes of the capillary pores for the two Wo/C ratios and the curing periods of 7–28–730 days.

It is noted how the volume of capillary pores remains practically constant up to 50% slag content while starting from such value, it denotes a higher increase.

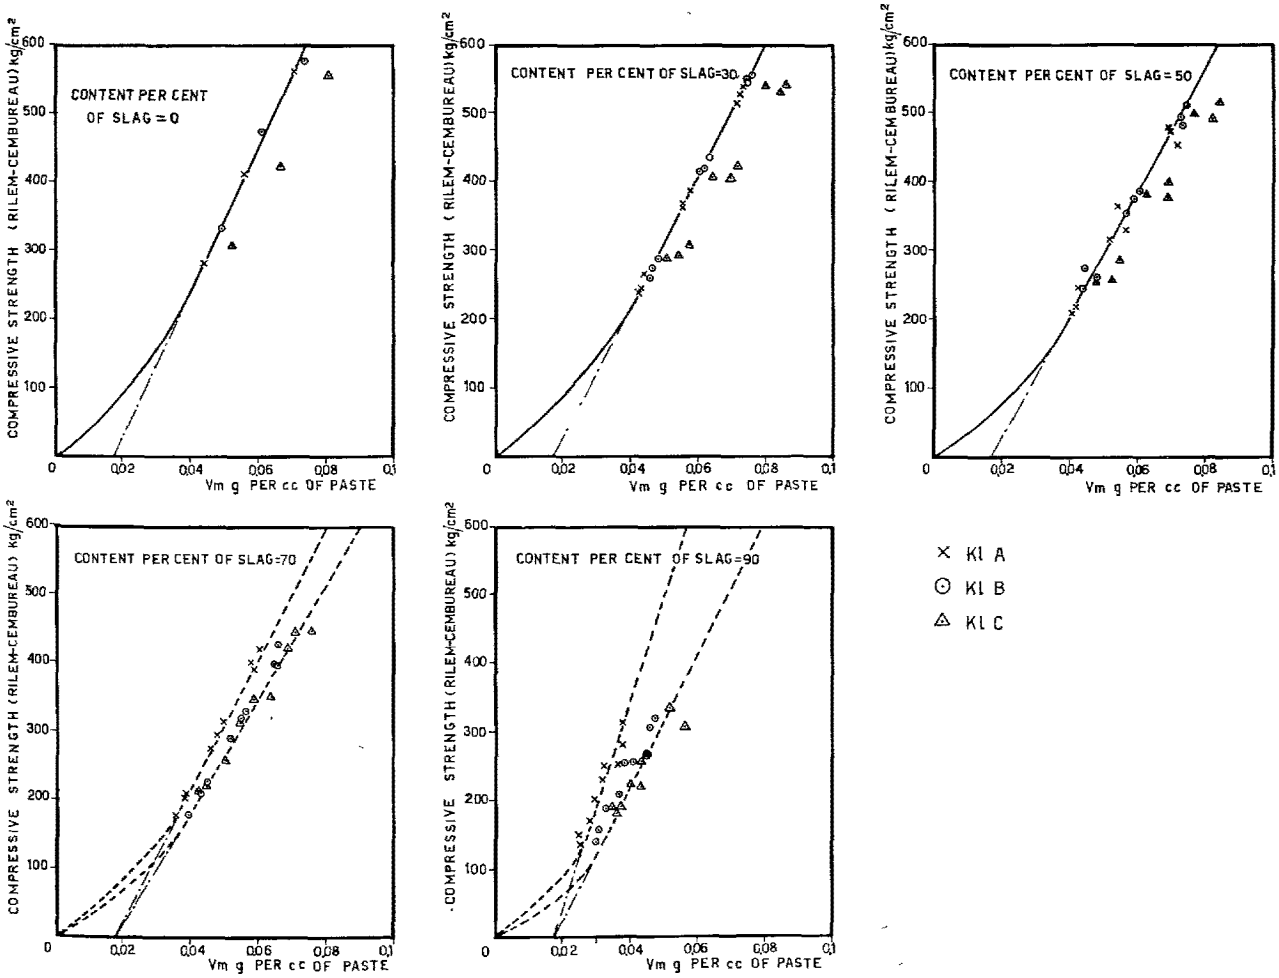

Fig. 11. *Compressive strength versus Vm (g per cc of paste)*

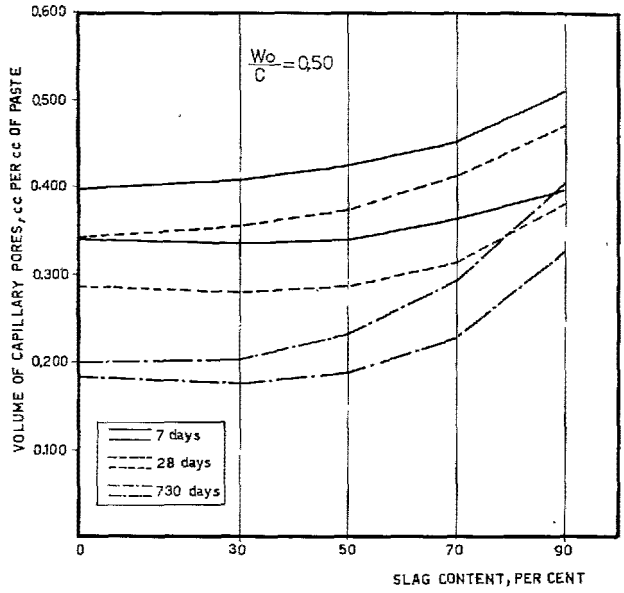

Fig. 13. *Bands of the volume of capillary pores as a function of slag content of the cement (Wo/C 0.50)*

Conclusion

From the entire experiment, it is noted that hydrated pastes of the mixtures containing slag although they give place to a quantity of gel equal or also slightly superior to those produced in clinker portland pastes are, though, all characterized by a small amount of non-evaporable water.

While for the mixtures containing up to a maximum of 50% slag content, the phenomenon can be perfectly explained by the small amount of calcium hydroxide present in relation with the small amount of C_3S in anhydrous cement and of the "pozzolanic" activity of slag. The same explanation is not valid for mixtures richer in slag content whose non-evaporable water content attributed to gel is clearly inferior.

It is also evident that the chemical characteristics of the clinker have a secure influence on the phenomena which characterize the hydration of cements containing slags; and this influence is almost uniform on the three experimented slags.

We can, no doubt, affirm that between the chemical characteristics of the clinker which contribute to differentiate the action on the hydration of slag process the content of C_3A is highly prevailing, naturally at equal contents of C_3A and C_2S.

It is more difficult to find a valid explanation on different behaviours of different types of slags with a same clinker.

Concerning compressive strength, the correlation between the hardening degree measured by the size of mechanical resistance and the hydration degree measured by the physico-structural characteristics of the pastes seem very close; and it is also a fact that the positive action is exerted on the slag hydration by the C_3A content in the activating clinker.

Concerning the properties of fresh pastes, we have realized a behaviour common to all slags namely, that the velocity and the bleeding capacity increase, with an increasing slag content.

From this is derived an effective minor porosity of pastes containing slag in comparison with cements of pure clinker which, practically, brings a lower volume of capillary porosity of pastes containing slag in respect to that noticed by us working for experimental necessities of Wo/C ratio constant.

From the series of tests made on 39 experimented cements, we can convince ourselves that the pace of the physico-chemical phenomena which characterizes the hardening of cement pastes containing granulated blast-furnace slag, are similar to the corresponding portland clinker, at least up to 50% of clinker.

The cements containing high slag percentages seem to form, instead, a type of cement differentiated enough by portland.

In fact, as many times underlined, physical and chemical parameters which characterize hydration do not present congruent values with the mixture arrange-

ments.

If hydration and therefore also the compressive strength have a slower development-that can be corrected, no doubt, industrially, increasing the fineness with the grinding- the different chemical and physical structures of the pastes of these cement exalt its characteristics of sulphate resistance, and render it a cement of election for special uses.

Supplementary Paper IV-102 Reactive Slag-Like Glasses of the S-A-F-C-M System

V. N. Pai and R. R. Hattiangadi*

Synopsis

The principal and strength-giving product of the portland cement hydration is tobermorite gel with a Ca/Si ratio lower than that of the main ahydrous compounds, C_3S and C_2S. As a result $Ca(OH)_2$, which does not contribute to strength, is also formed during hydration. The less basic crystalline silicates and aluminosilicates are inert, but the lower basicity compositions in the vitreous state are reactive in the presence of portland cement.

This seemed to point to a way of utilizing low-grade limestone (high in silica and magnesia contents) unsuitable for portland cement manufacture.

Since such raw materials ordinarily contain iron and since the processing contemplated is of melting the materials in an oxidising atmosphere, for the sake of fuel economy, Fe^{3+} is a constituent of these glasses.

In order to make the process economical, such compositions were chosen for tests as would melt at temperatures below 1350°C, and strength tests were carried out after intergrinding the same with portland cement clinker.

These experiments prove the feasibility of utilization of these low-grade raw materials to manufacture a cementitious product.

Introduction

Portland cement clinker is a material of high basicity, since its principal mineralogical constituents are tricalcium silicate and dicalcium silicate. As a consequence, the raw mix used in its manufacture must have a high lime saturation value.

It is necessary to start with such a highly basic composition because C_3S and C_2S are perhaps the only crystalline calcium silicates with have an irregular coordination and which have the capacity to chemically react with water and give rise to strength-producing hydrous compounds. These hydrates however have a Ca/Si ratio even lower than that of C_2S. All other crystalline calcium silicates such as merwinite C_3MS_2, akermanite C_2MS_2, monticellite CMS, rankinite C_3S_2, etc. are inert towards water, and their non-reactivity has been explained in terms of the regular coordination of atoms in their crystal structures.

The structure of the hydrous phase, tobermorite gel, obtained by the hydration of the two silicate phases in portland cement has been studied inter alia, by Taylor (1), Kalousek and Roy (2), Brunauer, Kantro and Copeland (3) and others and has been shown to have a variable Ca: Si ratio and it is now generally agreed that a ratio between 1.5 and 2.0 is desirable from the point of view of the mechanical strength of the hardened paste. Bearing in mind the basicity of the tobermorite, one would not start with such a highly basic material as C_3S as a component of the anhydrous cement, were it not for the fact that the C_3S alone reacts with sufficient speed to give commercially acceptable strength at early ages. The rest of the lime, not combined in the tobermorite, forms plates of $Ca(OH)_2$ which make no contribution to mechanical strength. While its presence is required to give a high pH environment for protecting the reinforcing steel, it is at the same time a source of weakness when sulphates are present. It would therefore appear that the use of less basic anhydrous materials could be an advantage, and since this is not possible with crystalline materials, the use of materials in the vitreous state offers a possible solution.

It is indeed well-known that a vitreous or glassy material such as granulated blast-furnace slag containing a lower proportion of lime and a higher proportion of silica than cement clinker can, in conjunction with the latter, hydrate to give similar strength-giving products. Since the product under consideration will be processed from naturally occurring low grade raw materials (such as high-silica, high-magnesia limestone together with bauxite or laterite, where

*Central Research Station, The Associated Cement Cos., Ltd., Thana, India.

necessary) containing iron oxide, it will differ from blast-furnace slag in this respect that whereas only small proportions of iron as Fe^{2+} are present in the slag, this product will contain considerably higher proportions of iron in the Fe^{3+} form. This would be so because the processing method contemplated is one of maintaining an atmosphere with a small excess of O_2, for obtaining maximum fuel effiency, unlike the reducing atmosphere of the blast furnace. An additional difference will be the absence of any sulphide sulphur. The hydraulic properties of such Fe^{3+} containing slag-like glasses are not known, and this investigation was undertaken to study their behaviour when interground with portland cement clinker.

The economic importance of this investigation stems from the fact that in India there are several occurrences of low-grade limestones interspersed among high-grade bands, which are unsuitable for portland cement manufacture, and this appeared to be a means of making cementitious materials out of them.

Experimental

Furnace

A furnace employing butane gas as fuel and castable refractory as furnace material was developed for this purpose. The furnace developed 1550°C in a matter of three hours. The clean hot blue gas flame played directly on the material as in a glass tank or open hearth furnace and served similar function.

The hearth was a shallow dish with smooth surface capable of collecting the molten material. A charge of about 3 kg could be molten at a time and poured out for quenching through a lip provided for the purpose.

A part of the burner equipment reached deep into the wall of the furnace. The burner block was cast out of castable refractory, and the butane and air mixture burnt within the cone of the burner block. The burner head entered the furnace dipping at an angle of 45° and thus facilitating the heating up of the material directly.

Preparation of the Quenched Melts

Nodules of the precalcined raw mix were molten in the furnace and quenched in water. The glass content was estimated with the optical microscope and was generally well above 90%. The quenched melt was interground with portland cement clinker along with 5% gypsum. The clinker had a potential C_3S content of about 35%.

Compressive Strength Tests

The compressive strengths were tested on 2" mortar cubes prepared according to the American Society of Testing Materials Method of Test No. C 109–64 when small quantities of glass were available. Where larger quantities were prepared, 4" concrete cubes made according to British Standard 12–1958 were tested in addition to the mortar cubes above.

Choice of Compositions

Several investigators, notably Osborn et al (4) have carried out studies on blast furnace slag and have reported on the optimum conditions for low liquidus temperature, low viscosities and high desulphurization potential, characteristics that are important in blast-furnace operation. There have also been studies from the point of view of the utilisation of the vitreous slag to produce the highest mechanical strengths when interground with portland cement clinker, and mention should be made of the work of Tanaka (5, 6), Keil (7), Locher (8), Solacolu (9). Solacolu has shown that there is a close relation between the hydraulic activity of vitreous slags and the paragenesis of thermal equilibrium in the completely crystallized state. Mention should also be made of the studies of Nurse and Midgley (10), Gutt (11, 12) on quenching experiments in the system Gehlenite-Akermanite-Merwinite, etc. and of Steyn and Watson (13) on the liquidus properties of high-magnesia blast furnace slags.

The results of Tanaka and Solacolu giving an indication of the compositions where high strengths are to be expected and the equilibrium diagrams of Nurse, Gutt and others showing the liquidus temperatures were utilised in designing mixes, with the difference that Fe_2O_3 is an additional constituent.

The choice of the compositions in the present study was in addition dictated by the requirement that the fusion point should not be in excess of 1350°C so that the actual temperature of the material is not required to be raised beyond about 1450°C which is the temperature ordinarily attained in a cement rotary kiln or in a furnace similar to a glass melting tank furnace with oil or pulverized coal firing. A temperature higher than the liquidus by about 100–150°C was considered desirable to prevent crystallization during the tapping of the melt and quenching with water. Another higher temperature requirement would be more expensive from the point of fuel requirement as well as from the point of the life of the refractories due to the severity of conditions of exposure.

With the above in view more than 30 compositions were chosen around the known low liquidus temperature compositions, and the glasses prepared for strength tests.

Results

A large number of different compositions were tried to investigate as to which among these would be optimum. A few of the results are discussed in the following.

A) Osborn and Schairer (14) have reported a lowest fusion temperature of about 1390°C in the binary system gehlenite-akermanite at 75 mole % akermanite. This composition would have a high MgO content of 11%. Nurse & Midgeley (15) also studied the ternary system C_2AS–C_2MS_2–$C_2A_{1/2}F_{1/2}S$ with iron-gehlenite as the third component. In this system, starting from the above proportion of gehlenite to akermanite, if the iron-gehlenite is increased, the fusion temperature is reduced, and the zone of these lower fusion temperatures is increased. The composition A roughly in this range was tried (Table 1).

The 2″ mortar cube compressive strengths on 75: 25 melt: portland clinker blend ground to 4100 cm²/g (Blaine) are as follows:

3 days	82 kg/cm²
7 〃	181 〃

The strengths were thus rather low.

B) In another experiment the Fe_2O_3 content was reduced, as well as the basicity ratio also was reduced by incorporating a fourth component viz. anorthite (CAS_2) in the system roughly with the composition B (Table 1).

The compressive strengths on 2″ mortar cubes were as follows:

3 days	43 kg/cm²
7 〃	49 〃
28 〃	80 〃

C) Since this gave poor strengths, the Fe_2O_3 was reduced, and CaO and MgO increased (composition C, Table 1).

This composition C gave much higher strengths on 2″ mortar cubes.

3 days	119 kg/cm²
7 〃	171 〃
28 〃	275 〃
91 〃	288 〃

D) If the SiO_2 were increased at the expense of Al_2O_3 as in D (Table 1) roughly corresponding to

C_2MS_2	2 moles
C_2AS	1 mole
$C_2A_{1/2}F_{1/2}S$	0.15 mole

This composition is not far removed from the low melting high magnesia compositions reported by Steyn & Watson (13).

The 2″ mortar cube strengths of a 60: 40 blend of melt: clinker ground to 3800 cm²/g are given in the following along with those for the portland cement alone:

	Melt D blend.	P.C.
3 days	103 kg/cm²	122 kg/cm²
7 〃	129 〃	154 〃
28 〃	219 〃	243 〃

The 4″ concrete cube strengths also are given in the following along with those for the portland cement alone.

	Melt D blend.	P.C.
3 days	147 kg/cm²	155 kg/cm²
7 〃	202 〃	209 〃
28 〃	256 〃	296 〃
3 months	295 〃	

E) Another melt near the ternary system gehlenite-akermanite-iron-gehlenite was:

C_2AS	3 moles
C_2MS_2	2 〃
$C_2A_{1/2}F_{1/2}S$	1 mole
with C_3MS_2	1.1/2 mole

Table 1. *Chemical composition of various quenched melts (%)*

	A	B	C	D	E	F
SiO_2	31.8	30.1	28.2	35.4	26.7	38.8
Al_2O_3	11.6	22.4	19.4	13.3	18.8	18.9
Fe_2O_3	} 10.2	} 6.2	} 3.0	1.4	3.8	1.4
FeO				1.1	1.6	1.9
CaO	39.9	30.6	38.4	39.5	40.4	30.1
MgO	6.0	5.0	10.3	8.6	8.0	7.5

By having merwinite, the acid to base ratio of the composition would increase from 1.5 to 1.6 .(In gehlenite 1/2 the Al^{3+} are tetrahedrally coordinated and considered as acid, while the other half are considered as base).

The actual composition is given under E (Table 1).

The 2" mortar strengths on 60: 40 blend of melt: clinker ground to 3280 cm^2/g are given below:

3 days	91 kg/cm^2
7 "	136 "
28 "	182 "

The corresponding 4" concrete cube strengths were found to be:

	Melt E blend	P.C.
3 days	90 kg/cm^2	96 kg/cm^2
7 "	138 "	138 "
28 "	252 "	238 "
3 months	300 "	353 "

1 year	354 "	430 "

F) De Wys and Foster (16) have reported a binary eutectic between anorthite and akermanite at 1234°C and further reported a ternary eutectic of the above with diopside at 1226°C at the weight proportions 47: 44: 9 of akermanite, anorthite and diopside respectively. This composition works out to

SiO_2	44.7%
Al_2O_3	16.1
CaO	30.5
MgO	8.6

Here the silica is rather high. The alumina may be increased and partly replaced by Fe_2O_3. An increase in the liquidus temperature of the system can be tolerated since the eutectic temperature is rather low. Such a change would be equivalent to having a composition:

CAS_2	1 mole
C_2MS_2	1 mole
$C_2F_{1/2}A_{1/2}S$	1/4 mole

The blend readily melted at a low temperature and was free flowing. The actual composition was found in Table 1.

It was found that the iron had partly reduced to the divalent state.

The melt was interground with portland cement clinker 75: 25 to 4200 cm^2/g with 5% gypsum. The 2" mortar strengths were

3 days	85 kg/cm^2
7 "	130 "
28 "	169 "

This melt F was rather low in lime. The D.T.A. curves of the hydrated cement did not show the presence of free $Ca(OH)_2$. It was therefore felt that this would give better results with a higher clinker content. Therefore another blend was made with melt to cement as 40: 60 ground coarser to 3270 cm^2/g.

The concrete strengths were

	Melt F blend	P.C.
3days	74 kg/cm^2	95 kg/cm^2
7 "	111 "	138 "
28 "	245 "	252 "

The strength thus appears to pick up by 28 days.

A composition around melts C or E was thus regarded as suitable. The following composition was now regarded as the base composition.

SiO_2	29.0%
Al_2O_3	19.0
Fe_2O_3	3.0
CaO	41.3
MgO	7.7

Mixes were prepared by changing the percentage of these oxides by pairs by roughly 2%. These finely powdered mix blends were heated at 1000°C for 2 hrs. rolled into sticks with water, the sticks were melted in an oxy-acetylene flame according to the method of Dyckerhoff and quenched in water. These were ground to 3100 cm^2/g and blended with ground clinker (3100 cm^2/g) and gypsum in the weight proportion 50: 50: 5 and tested for compressive strength according to ASTM 2" mortar cubes (Table 2). The liquidus temperature of these was determined on a hot stage microscope and the values are given in the same table.

The aim of this part of the work was to ascertain the effect of variations in the melt composition on the significant properties, viz. the fusion temperature and the compressive strengths. This should serve as a guide for large scale manufacture.

Products of Hydration

The products of hydration were identified by D.T.A.

Table 2.

Chemical composition %					Liquidus temp.	Compressive strength kg/cm²		
SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	°C	3 day	7 day	28 day
28.3	20.1	2.7	42.0	7.1	1360	100	138	197

and X-ray diffraction. Fig. 1 shows the D.T.A. curves of the melt-cement blends, hydrated for 14 days.

Melt A-cement which contained lower Al_2O_3 and high Fe_2O_3 showed ettringite up to 7 days in addition to tobermorite. C and E which were higher in Al_2O_3 gave monosulphate instead at these ages.

Melt A-cement, which gave poor strengths shows larger exotherm due to the unreacted glass, as well as a fair amount of $Ca(OH)_2$ which has not been taken up by the melt due to its slow hydration.

The other two show only a trace of lime, if at all, indicating that the lime released by the portland clinker has been immediately fixed up by the reactive melt.

Melt cement E, and especially C show some $Mg(OH)_2$. The autoclave tests in all these cements showed an expansion less than 0.3% showing that this

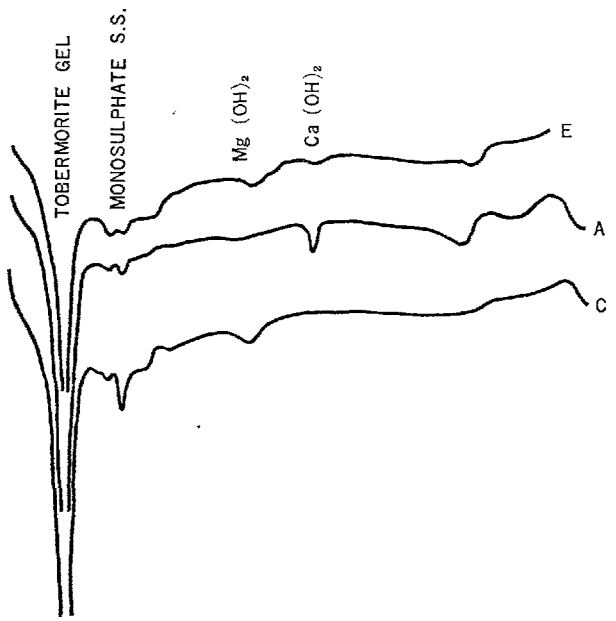

Fig. 1. *D.T.A. curves of melt cements A, C, and E hydrated for 14 days*

$Mg(OH)_2$ had not arisen out of the expansive component viz. periclase, and that these glasses did not contain any periclase as a crystalline component.

Nevertheless $Mg(OH)_2$, similar to $Ca(OH)_2$ is not likely to contribute to strength.

Therefore melts containing MgO greater than 8–10% may not be too desirable.

Discussion

In the present article, some of the results obtained on the iron oxide containing melts, in the S–A–C–M–F system have been reported.

As regards the compositions of these melts the following observations were made from a number of experiments.

1) SiO_2 content much above 30–31% would be undesirable since some compositions with silica content as high as 40% gave low strengths.

2) Al_2O_3 was added to the extent of 20% since much lower Al_2O_3 content was found to give lower early strength, confirming the observations of earlier workers.

3) Fe_2O_3 was a necessary constituent of the melts since it is present in all naturally occurring raw materials used for cement manufacture.

4) CaO as high as in portland cement was considered unnecessary for the reasons given earlier as well as since it increases the fusion temperature. In fact the CaO content was limited to a maximum of about 43% in order to have a reasonably low point of fusion of the raw materials. The optimum composition in the system S–A–C given by Tanaka (6) and by Locher (8) with 50% or more of CaO would require fusion temperatures of about 1500°C and operating temperatures of over 1600°C which are not easy to attain.

5) MgO should give rise to lower fusion temperature. Besides this, the addition of MgO can, in certain composition ranges, yield better strengths. However, the MgO should not be too high so that $Mg(OH)_2$ becomes a product of hydration; since $Mg(OH)_2$—like $Ca(OH)_2$—is not expected to contribute to strength. Again a high MgO content would cause problems of corrosion of refractories during melting. The MgO was therefore limited to a maximum of about 8–10%.

These results have demonstrated that it is possible to process low grade limestone with proportions of

silica and magnesia in excess of those tolerated in portland cement manufacture in order to produce melts which after quenching have properties similar to those of granulated blast furnace slags.

By judicious choice of the compositions it is possible to reduce the fusion point to about 1300°C so that the process can be economical.

Oral Discussion

Mitsuo Hanada

(1) What are the reagents used for the experiments?
(2) The test results are extremely good. Are there any plans for industrial production, and if so, what is the economical outlook?

Author's Closure

R. R. Hattiangadi

Replying to the first of the two questions by Mr. Hanada, Dr. Hattiangadi first of all stated that he had already ascertained from Mr. Hanada, that by reagents he had meant raw materials used. He assured Mr. Hanada that the raw materials used were representative samples of naturally occurring limestone from some of the quarries obtained in his company's factories in India. The portland clinker used was also commercial clinker. It was explained that there were large quantities of substandard limestone (in terms of calcium values), available in India, which could not be harnessed into use for the manufacture of cement. In soms cases even beneficiation by froth flotation was not possible on account of the very fine crystalline structure of the oxides available. The idea was to find a way of making direct use of this substandard stone for producing a cementing material of suitable quality.

2. Answering to Mr. Hanada's second question, Dr. Hattiangadi stated that it was precisely because there was an urgent economic commercial problem to be solved that the work was undertaken. Based on studies

in reactive slag of SAC and SACM systems by Taylor, Kalousek and Roy, Brunauer, Kantro, Nurse and others, an experimental furnace was erected to carry out pilot scale experiments and it would appear from the results obtained that the economic possibilities of exploitation of this process were good.

Supplementary Paper IV-106 Studies on a Method to Determine the Amount of Granulated Blastfurnace Slag and the Rate of Hydration of Slag in Cements

Renichi Kondo and Shigenari Ohsawa*

Synopsis

A method of quantitative determination of granulated blastfurnace slag not only in unhydrated slag cement but also in hydrated paste as an unreacted part was established by using a salicylic acid, aceton-methanol solution. In this solution, slag hardly dissolves, but most of the hydrated slag, clinker minerals and their hydrates dissolve. By making use of this principle, it is possible to determine the amount of unreacted slag. But in the case of determination of the amount of unreacted slag, it is preferable to make corrections so that most part of aluminate, ferrite and gypsum contained in portland cement also hardly dissolve in this solution.

The experiment to determine the quantity of unhydrated slag on the hydration of portland blastfurnace cement paste and super sulphate slag cement paste were carried out.

The amount of unreacted slag contained in these cement pastes was determined by using the salicylic acid, aceton-methanol solution. The accuracy of this measurement was found to be satisfactory. Unreacted C_3S was quantified and the hydration products were detected by X-ray diffraction. Non-evaporable water, free $Ca(OH)_2$, and free $CaSO_4$ were also determined by chemical analyses, and the hydrated phases were observed under a microscope.

The chemical compositions of the products and the rate of reaction of each component such as slag, C_3S and $CaSO_4$, and the depths of the reacted layer on the particles of slag and C_3S were calculated from the experimental data.

The rate of reaction of slag contained in every type of slag cement was unexpectedly slow. The rate of reaction of slag and also of C_3S was reduced remarkably after about 3–7 days in hydration.

Introduction

The determination of blastfurnace slag is comparatively easy if the slag is in crystalline state, but it is very difficult with glassy slag. The granulated blastfurnace slag is generally in a glassy state and is highly reactive, as it is used for the main constituent of portland blastfurnace cement and super sulphate slag cement. It is necessary to determine the amount of slag when we want to know either the slag content in these cements or the rate of reaction of slag and also the chemical composition of hydration products. In the determination of granulated blastfurnace slag, however, it is difficult to distinguish slag from other cement minerals and their hydrates by an extraction method or the X-ray diffraction method.

Several attempts, listed below, have been proposed to determine the slag content in the protland blastfurnace cement since the beginning of this century.

(1) Dissolution method using acetic acid as the extracting agent (1, 2).
(2) Dissolution method using ammonium chloride-ammonia (3, 4).
(3) Observation under an optical microscope (5).
(4) Separation by using heavy solutions (5).
(5) Determination of Mn content by chemical analysis with sample separated by heavy solution (5).

The experimental error in each of these methods is great and it is impossible to determine the slag content especially in the presence of hydrates. If we would follow the methods (1), (2) and (5) listed above, it is necessary to examine every components of the test cement in isolated forms before blending as reference samples.

Here we found that the determination of granulated blastfurnace slag is possible by an extraction method using salicylic acid, aceton-methanol solution. In this

*Research Laboratory of Engineering Materials, Tokyo Institute of Technology, Tokyo, Japan.

method slag hardly dissolves but most of the hydrated slag, clinker minerals and their hydrates do dissolve. By making use of this phenomenon, with certain corrections if necessary, it is possible to determine the quantity of unreacted slag in cement either unhydrated or hydrated.

This study was made to elucidate the rate of hydration of slag and the chemical composition of the hydration products by a quantitative determination of slag, which has not yet been investigated.

Experiments to Determine the Required Conditions for an Extraction Method

Experiments were carried out as described below to determine the required conditions in which unhydrated slag is practically undissolved, while most of the hydrated slag, clinker minerals and their hydrates are dissolved.

A method established by Takashima and his collaborator (6) utilizes the conditions in which the selective dissolution of such silicates as C_2S and C_3S occurs. These conditions are as follows:

The entirety of a 1 g sample, 6 g of salicylic acid and 40 cc of methanol are put into a beaker and stirred by a magnetic stirrer for 3 hours at room temperature. The filtered residue is then washed with methanol, dried and heated at 850°C for 10 minutes in an electric furnace. Heating conditions were selected by us to avoid a weight increase due to the oxidation of S, Mn and such in the slag.

It was found that 82.7% of slag is insoluble by this method, and that it could not be greatly improved by decreasing the amount of salicylic acid or reduction of treating time.

Another method also established by Takashima (7), is improved by the addition of aceton.

In this method, 0.5 g sample is put into a beaker together with 2.5 g of salicylic acid, 35 cc of aceton and 15 cc of methanol and stirred at room temperature for 1 hour. After being kept motionless for 1 day, it is filtered, and then treated as previously described.

With this method, 99.3% of slag was insoluble. On the basis of the experimental results, the latter method is adopted for the determination of unreacted slag. The tests were made on various samples by this method with results as shown in Table 1.

Table 1. *The amount of inroluble part on various samples treated in a salicylic acid, aceton-methanol solution*

$$\text{Insoluble } \% = \frac{\text{Insoluble part}}{\text{Sample} - \text{Loss on ignition}} \times 100 \text{ (wt.)}$$

Sample	Loss on ignition %	Insoluble %	Remarks

Al_2O_3	0.52	99.7	

Preparation of Hydrated Samples

Hydration of Low Slag and High Slag Portland Blastfurnace Cements

The compositions of portland cement and granulated blastfurnace slag used are shown in Table 2.

Low slag and high slag portland blastfurnace cements, abbreviated as LC and HC in this paper, were prepared from granulated blastfurnace slag (Blaine

4000 cm^2/g) and portland cement abbreviated as PC (Blaine 3100 cm^2/g). They were blended in the weight ratios of 40: 60 and 70: 30 respectively and hydrated at 20°C in paste form with W/C = 0.4, for 3, 7, 28 and 90 days in glass bottles. The original slag and portland cement were also separately hydrated under the same conditions. The hydration was stopped in such a way that the hydrated samples were ground in an aceton-ether solution in a 1: 1 volumetric ratio for 5 minutes. After the samples were evacuated to eliminate the remaining aceton and ether, they were dried in a condition called P-drying.

Hydration of C_3S-Slag Cement

C_3S-Slag cement was prepared from C_3S and granulated blastfurnace slag in which the particle radii were 1.3–5.8 μ (Blaine 2480 cm^2/g) and 1.35–6 μ (Blaine 4730 cm^2/g) respectively. This powder was obtained with a "Bahco" micro particle classifier. The slag is the same as used in LC and HC. The blended ratio was 50: 50 in weight. The conditions of hydration of this cement were the same as those of LC and HC except the ratio of W/C = 0.5.

Hydration of Super Sulphate Slag Cement

Super sulphate slag cement, abbreviated as SC in this paper, was composed of granulated blastfurnace slag, $CaSO_4$ and C_3S in the weight ratio of 80: 15: 5. The sizes of these components were 1.35–6 μ, 1.35–6 μ and 1.3–5.8 μ in radii, respectively. $CaSO_4$ was obtained by heating gypsum at 750°C. The preparation of hydrated samples was the same as that of C_3S-slag cement.

Experimental Results

Results of the Extraction Treatment

The conditions of the treatment were followed by the method described above. The results obtained from this treatment are shown in Fig. 1. The data were corrected by the method described in the discussion.

Fig. 2 shows the percentage of reaction of slag in the hardened paste of various types of slag cements.

Determination of Unreacted C_3S by X-ray Diffraction

HC and SC were not examined for the content of C_3S.

MgO as an internal standard was added to the extent of 5% of the samples on an ignited base. The peaks selected for the determinations are 2.10 Å ($2\theta = 43.1°$) for MgO, 1.77 Å ($2\theta = 51.8°$) for alite in LC and 2.19 Å ($2\theta = 41.2°$) for C_3S in C_3S-slag cement. The conditions in the X-ray diffraction were the usual. The area of these peaks was measured with

in the hardened paste of various types of cements.

Determination of Free $CaSO_4$

Free $CaSO_4$ in the hardened paste of SC was deter-

mined by the method suggested by Forsén (8).

In this experiment 1 g of a powdered sample and 300 cc of half saturated lime water were stirred in a beaker with a magnetic stirrer for 1 hour, at room temperature, and then filtered. The residue was washed with lime water, and then with aceton. As unreacted free $CaSO_4$ dissolves, it was determined by gravimetric analysis with the filtrate, while the residue was P-dried and used for the determination of the unreacted slag. Fig. 4 shows the percentage of reaction of $CaSO_4$ in the hardened paste of SC.

The quantity of formed ettringite was calculated from the data on free $CaSO_4$, and shown in Fig. 5. In this calculation it was assumed that all of the reacted $CaSO_4$ forms ettringite.

Determination of Non-Evaporable Water

Non-evaporable water (9) is that retained in the P-dried sample, and abbreviated as Wn. Wn was determined by ignition of the dried sample at 700°C for 1 hour. The obtained results are shown in Fig. 6.

Determination of Free $Ca(OH)_2$

Free $Ca(OH)_2$ was determined according to the modified Franke method by using ethyl acetoacetate and isopropyl alcohol as the solvent. Fig. 7 shows the results obtained.

Identification of Hydration Products by X-ray Diffraction

In the X-ray diffraction, scanning was operated from 14.7 Å ($2\theta = 6°$) to 1.70 Å ($2\theta = 54°$). Detected phases were described in the discussion.

Microscopic Examination

Observations were made under a polarizing microscope on the polished thin sections of hydrated pastes of slag cements.

In comparison of the number and grain size of $Ca(OH)_2$ in the pastes of PC, LC and HC, both of them were in the same order mentioned above. As for the C_3S–slag cement paste, the diameter of $Ca(OH)_2$ crystals reached about 100 μ even by 24 hrs.

Inner hydration products of C_3S with a lower refractive index were difficult to be observed in the cases of HC and C_3S-slag cement, however, clearly observed in the case of portland cement. While remarkable changes on the surface of slag particles were not observed except the formation of cracks on the large particles

Discussion

The Accuracy of the Extraction Method

The accuracy of the quantitative determination of slag by the extraction method was quite excellent in reproducibility as shown in Table 3, and the coefficient of variations lies within 0.1 to 2%, though this value seems to depend upon the type of slag cement.

It has become clear as the result of this experiment that the determination of slag by this method is, after all, sufficiently effective for estimating the rate of hydration of slag. Moreover, this method can be used for determining the amount of slag contained in unhydrated blastfurnace cement, and further, a similar method may also be adoptable for the pozzolanic reaction.

Corrections in the Determination of Unreacted Slag

The data were corrected in order to quantify a certain reactant such as slag, because a little part of slag is dissolved and a part of the insoluble matter originates from the other phases.

The corrections were made in such a way that 0.7% of unreacted slag is dissolved, and 4.1% of C_3S and 3.4% of C_3S hydrate are insoluble in the extracting solvent. The corrections on C_3S were not made on HC and SC.

In the case of LC and HC, C_3A and C_4AF are almost insoluble so that these amounts should be subtracted from the insoluble matter. Nevertheless, consistent results in the amount of unreacted C_3A and C_4AF could not be obtained by X-ray quantitative analysis. The insoluble part coming from portland cement can be regarded as a constant to be 0.211 at any time of hydration as seen in Fig. 1. Thus the adopted correction is based on this fact instead of the determination of C_3A and C_4AF. Unreacted slag in the hydrated portland blastfurnace cement can now be determined in application of the following relation.

Table 3. *The standard deviations on the mean values obtained by the extraction method*

A. The values are % of insoluble part in the paste of LC

Time in day / Repetition	3	7	28	90
1	44.6	39.9	37.2	40.0
2	46.5	41.1	39.0	38.3

Unreacted slag = Insol. part
− Portland cement × 0.211

In the case of SC paste, correction is made on the amount of ettringite which is the main hydration product of this cement and insoluble in the extraction treatment. Therefore, the quantity of ettringite was calculated from the chemical analysis of free $CaSO_4$, and the results are shown in Fig. 5. The amount of unreacted slag in SC paste can be estimated as follows.

Unreacted slag = Insol. part
− Formed ettringite × 0.615

Non-Evaporable Water (Wn)

Concerning non-evaporable water (Wn), Cesareni and others (10) reported that the Wn content of HC is lower than that of PC. On the other hand the content of Wn is formed to be well proportioned to the percentage of reaction of slag, as seen in comparison of Figs. 2 and 6. The Wn content of SC is very large in the early stage, but hardly increases thereafter.

The increase of Wn is remarkable both in LC and HC, but especially so in HC, during the period from 28 days to 90 days.

In case of C_3S-slag C, the increase of Wn in the period between 28 days and 90 days, is seemingly caused by the reaction products of slag, because in this period the hydration of C_3S hardly progresses, and as seen in Fig. 2 the reaction of slag has progressed.

Free $Ca(OH)_2$

The content of formed $Ca(OH)_2$ increases with the time of hydration in case of LC, but in case of HC it gradually decreases as shown in Fig. 7. This result, coinciding with the research of Smolczyk (11), reveals the fact that the $Ca(OH)_2$ produced by hydrolysis of of C_3S is consumed by the pozzolanic reaction of slag.

The $Ca(OH)_2$ content of C_3S-slag C hardly increases on and after 3 days. This is natural because as seen in Fig. 3, the reaction of C_3S has not yet progressed. In case of SC the amount of $Ca(OH)_2$ produced is larger than the theoretical content, though SC contains only 5% of C_3S. A similar tendency has been shown also in Locher's experiment (12).

This fact may have some relation to the fact that the solvent and ettringite react slightly with each other in the modified Franke method, as is referred to by Schwiete and others (13). The present authors, however, could not find the above phenomenon on purely synthesized ettringite. This difference perhaps comes from the fact that the synthesized ettringite grows to a larger crystal than that formed in cement paste.

Effect of Gypsum

In the case of SC containing gypsum anhydrate as the main activator, the hydration of slag is at a high rate in the early stage, but tends to slow down more in the later stage than in other cements. Cesareni and others (10) expected that gypsum, when added to high slag blastfurnace cement, would accelerate the reaction, but the result was contrary to their expectation. And the cause of this was thought to lie in chemical factors so that the amount of lime in the liquid phase is not sufficient in case of HC to complete the hydration of slag.

Formation of Ettringite

From slag comes the Al_2O_3 that composes ettringite rapidly formed in the hydration of SC at early stage. Moreover, judging from the relation between the amount of the reacted slag and the amount of the ettringite thus formed, it is clear that almost all the Al_2O_3 in the reacted slag forms ettringite. Further,

during the first 3 days SC has the highest rate of slag reaction, but on and after 7 days, LC has the highest reaction rate.

If the composition of slag can be simplified as C_4AS_3, SC must produces low lime silicate hydrate such as CS_3Hn besides ettringite in hydration. After consumption of $CaSO_4$, the reaction becomes inert, and thus not a little slag remains unreacted.

The presence of a little alkaline exciter is necessary for Al_2O_3 to dissolve out of slag, but the presence of too much lime renders the product layer on each slag particle denser and so rather hinders the reaction. Nevertheless ettringite is to be dehydrated into an amorphous state when P-dried, the X-ray diffraction peak of ettringite was sharp in our experiment. Thus, the ettringite formed in SC seems to be rather difficult to dehydrate.

Hydration Products Detected by X-ray Diffraction

In the hardened paste of LC, detected hydration products are in addition to C–S–H and $Ca(OH)_2$, C_4AH_{13} and a trace of ettringite after 28 days and C_4AH_{13} and monosulphate hydrate after 90 days.

In the case of HC, monosulphate hydrate is detected as early as after 3 days and both C_4AH_{13} and ettringite are detected on the 90th day.

In the case of C_3S-slag cement, C–S–H, $Ca(OH)_2$ and C_4AH_{13} are detected as early as after 1 day, and unreacted C_3S is clearly detected even after 90 days.

In the case of SC, ettringite and C–S–H are detected on the 3rd day. The shape and height of ettringite peaks are nearly the same regardless of the time of hydration.

Size of Formed $Ca(OH)_2$

There is not much difference between C_3S-slag C and LC in the content of slag, but concerning the other components and particle size distribution. The fact that LC has a higher rate of hydration than C_3S-slag C can be partly explained by the difference in size of $Ca(OH)_2$ formed. Microscopic observation shows that $Ca(OH)_2$ scattered in C_3S-slag C paste is as large as 100 μ in diameter and generally uniform in size, and that on the other hand it is smaller and uneven in size in the case of LC. Thus, a part of particles of slag or of C_3S are surrounded by $Ca(OH)_2$ crystals.

Thickness of the Reacted Layer

Since the rate of reaction of such solid powder as cement largely depends upon the particle size, it is appropriate to compare the reactivities of such reactants as C_3S or slag on the basis of the thickness of the reacted layer. The relationship between the percentage of reaction and the thickness of the reacted layer was determined in accordance with the method already mentioned by Kondo (14). Fig. 8 shows the thickness of the reacted layer of C_3S or slag particles in the hardened paste of various types of cements. The percentage of reaction was obtained by the extraction method for slag, by the X-ray diffraction method for C_3S and by a chemical analysis for $CaSO_4$.

As shown in Fig. 2, slag is hydrated at a high rate during the first 3 to 7 days, but thereafter the reaction is extremely delayed. The thickness of the reacted layer of slag should be a little lowered from the values indicated in Fig. 8, as the original surface area of slag is nearly twice higher than that of C_3S. Simultaneously with this delay, the hydration of C_3S also tends to be delayed as shown in Fig. 3. In the hydration of C_3S alone, the rate of hydration and the thickness of the reacted layer are examined and separately reported by Kondo and Yoshida in this Symposium (15).

According to Cesareni and Frigione (10) one might suggest, concerning the hydration of blastfurnace cement of high slag content, that a sheath of some very compact hydration products wraps around the slag particles and prevents water from penetrating into the particle cores, therefore delaying the reaction.

But this delay in hydration seems to occur not only to HC, but also to various kinds of slag cements investigated. The delay of hydration starts suddenly when this compact sheath has grown to a certain thickness after 3 to 7 days reaction. The thickness of the reacted layer at the beginning time of the reaction

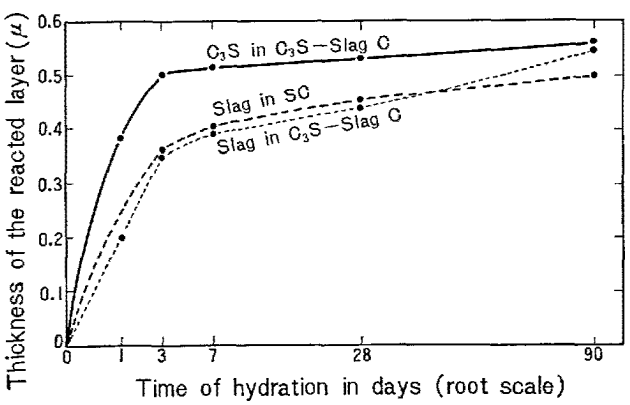

Fig. 8. *Thickness of the reacted layer of slag or C_3S in slag cements vs. time of hydration.*

delay was 0.35 μ and 0.50 μ in cases of the slag and C_3S each contained in C_3S-slag C, and 0.36 μ in case of the slag contained in SC. It seems that also on the surface of C_3S, compact sheath is similarly formed.

Compared with the case of LC, the reaction of C_3S in C_3S-slag C is very slow even before starting of the delay. The reason for this seems to be due to the formation of ettringite in hydration of LC, and because of its comparatively porous quality, the reaction progresses at much the same rate as that of PC until the beginning of the delay.

C_3S in LC as the activator has a higher reaction rate during the first 28 days than in PC. But after 90 days, C_3S in PC has a higher reaction rate. The insoluble part shown in Fig. 1 appears to increase during the period from 28 days to 90 days. This phenomenon seems to be caused by the fact that the hydrates change into less soluble materials, for non-evaporable water and $Ca(OH)_2$ are increased and the reaction having progressed in this period.

Rate of Hydration

As the particles of C_3S and of the slag are coated with the hydration products, the hydration seems to be controlled by the diffusion of the ingredients through the layer of the products. The relationship between the thickness of reacted layer of reactant particles and the reaction rate constant was examined in conformity with the following formula in which $1 - \sqrt[3]{1-\alpha}$ implies the ratio of the thickness of the reacted layer to the radius.

$$(1 - \sqrt[3]{1-\alpha})^N = kt$$

The rate of hydration of slag in C_3S-slag C is expressed as $N = 1.5$ during the first 1 to 3 days, but $N = 7$ in the decay period from 3 to 90 days. As for C_3S, $N = 4$ during the first 1 to 3 days, but indeed $N = 32$ during the period from 3 to 90 days. Concerning the slag in SC, $N = 9$ during the period from 3 to 90 days.

When the reacted layer becomes denser or the pore size smaller, the value N is thought to rise to more than 2 with increasing the resistance to the diffusion (14). Thus it is characteristic that the hydration products formed around the slag particles and the coexistent C_3S particles become denser and denser with lapse of time, and also that the rate of hydration slows down correspondently.

Supplementary Paper IV-110 Mineral Composition of Blast-Furnace Slag

Hideo Minato*

Synopsis

There is two types in blast-furnace slag. One is water quenched one and the other is slow cooling one, and range of chemical composition in the slag is as follows; SiO_2 30–35, Al_2O_3 13–20, MgO 2–6, CaO 40–50%. Slow cooling blast-furnace slag was constituted with melilite, dicalciumsilicate, pseudowollastonite, anorthite and glass, and had porphyritic texture with phenocrysts of melilite, dicalciumsilicate and pseudowollastonite. Water quenched slag was composed of fine glass bubbles and accompanied with small quantity of minute melilite. In the course of cooling of the molten slag, iron, manganese, alkalies and sulphur were concentrated in the residual liquid, and the melilite crystallized out from these liquid had iron, manganese and alkalies in its components.

Melilite phenocrysts display a characteristic zonal structure under the polarizing microscope. The optical property of the melilite implies that its nucleus is highest in the content of gehlenite molecule, while the rim is lowest. Small idiomorphic crystals of melilite are found in cavites of the slag, in some case. It shows short prismatic shape consisting of a tetragonal prism and the base.

Crystallization on melilite in the course of cooling of molten slag was investigated, also. The chilled margin of slow cooling slag was polished in smooth plane and etched by dilute hydrochloric acid. Globules with diameter of 5–10μ, which were composed of fine short prismatic melilites were observed on the plane under the electron microscope. These globules were the nucleus of dendritic aggregates of melilite needles and the dendrite turned to melilite phenocryst.

Kind of Blast-Furnace Slag

Blast-furnace slag is a by-product of smelting of iron and is classified into two types. One is water quenched slag, the other is slow cooling one. The former is used for raw material of cement and etc., and the latter is used for slag ballast and etc. Mineralogical investigations on these two kinds of slags have been carried out and reported in this paper by this writer.

Water Quenched Slag

Water quenched slag is formed by quenching of molten slag with large amounts of water and used for cement. It has pumice-like appearance and with yellowish gray colour. It was tested its crystalline phase by means of X-ray powder method, observed its texture under the polarizing microscope and analysed by chemical method.

Texture

Thin section of the slag was investigated under the polarizing microscope, many fine glassy bubbles with diameter of 0.05–0.1 mm were observed and in a part of the glassy film, minute crystalline material was observed under crossed nicols. The crystalline material might be fine melilite crystals.

Crystalline Phase

Six powdered slag specimens were tested by means of X-ray powder method and their X-ray powder profiles were shown in Fig. 1. All specimens take glassy phase and two specimens of them are associated with small amounts of melilite crystals. In Fig. 1, X-ray powder pattern of 2.8 Å is derived from melilite. The results of X-ray investigation agree well with that of the observation under the polarizing micro-

scope.

Chemical Composition

Chemical analyses of six slag specimens are listed in Table 1. Alkalies, sulphur and water were not determined.

Slow Cooling Slag

Slow cooling slag is formed by slow cooling of molten slag in slag yard, and mainly composed of crystalline material. Chemical and mineralogical investigation on the slag have been carried out by the present writer.

Chemical Composition

Chemical compositions of two slags from foundry pig iron and one slag from steel making pig iron are listed in Table 2. Specimens of No. 3 and 4 in the Table 2 are specially made slags of high MgO component. SiO_2, Al_2O_3, MgO and CaO are main components of the slag.

Differentiation of Some Elements in the Course of Cooling of Molten Slag

Differentiation of elements in the course of cooling of molten slag is investigated. Stalactitic glassy bodies were found in a large cavity of throwed slag (Figure 2B). The stalactitic slag was composed of glassy material and associated with small amount of melilite crystals, and formed from the residual liquid of molten slag. The chemical analysis of the slag is listed in No. 5 of the Table 2, and manganese, alkalies and sulphur are concentrated to compared with the chemical analysis of other slags.

Texture

Texture of slow cooling slag was observed under the polarizing microscope and shown in photograph 2. Porphyritic texture is characteristic appearence in slow cooling slag, and melilite and calciumsilicate minerals are phenocrists.

Mineral Composition

Melilite

i) Crystal growth of melilite.

Growth of crystalline material from the molten slag was investigated also. Slow cooling slag mass in a iron ladle was used for this investigation. The chilled margin of the mass was composed mainly of glassy material and associated with minute amount of crystalline material (melilite). By the observation under the polarizing microscope with thin section, minute dusty bodies are in glassy material (photograph 3), and the same part is polished to smooth surface and etched by dilute hydrochloric acid, after the process, it is tested under the electron microscope, globules with diameter of 100–150 μ were observed and the globules were composed of minute short prismatic crystal aggregate (Fig. 3 A and photograph 8). The marginal part of crystalline body is composed of dendritic aggregate of elongated melilite crystals. It is observed under the polarizing microscope and the electron microscope (Fig. 3B and photographs 3 and 9). In the core of crystalline body, dendritic aggregate of melilite had same orientation in small area (Fig. 3C), and in the center of the mass, the dendritic mass turn to compact crystal of melilite and is covered with melilite film which is rich in akermanite molecule than that of the center of crystal (Fig. 3D and photograph 4). The early stage of growth of melilite is compared with the crystalline material of water quenched slag and large melilite crystal suggest the growth of zonal structure in melilite.

ii) Zonal structure in melilite crystal.

Zonal structure is characteristic texture in well crystallized melilite and was observed under the polarizing microscope (Fig. 5B and photograph 5). The core (Fig. 5B1) has the highest content of gehlentie molecule and the rim (Fig. 5 B 3) the lowest content of the same molecule. The chemical analyses of the two zones of melilite (Fig. 5 B 2 and 5 B 3) are cited in Table 2–6 and 7, respectively.

iii) Chemical composition of melilite crystal.

Pure melilite grains are separated from slag powder by means of magnetic separater and the method of heavy liquid. Purified materials were analyzed by means of micro method. The results are listed in Table 2 and their molecular ratios of gehlenite and akermanite are calculated too.

iv) Melilite crystals in the cavity of slag

Small idiomorphic crystals of melilite in cavity of the slag which had been left in a ballastyard had been found (Fig. 2 C_1).

Although zonal structure is not so distinct in the melilite crystal from cavities, a thin layer with higher content of gehlenite molecule (Fig. 2A 1) prevails along the border of groundmass, and another layer with lower content of gehlenite molecule (Fig. 2A 3) covers the top of the crystal. The pure material of the melilite in cavities, was easily obtained by hand-picking under the binocular microscope. Clear part of the melilite phenocryst corresponding to 2 in Fig. 5B was obtained from 200–250 mesh fraction of powder slag by using magnetic separator, heavy liquid and binocular microscope.

Both 1 and 2 samples had been examined under the polarizing microscope and they were analysed. The results were listed in 1 and 2 in Table 3.

Crystallization of melilite in cavities. The composition of the melilite crystal in cavities of blast-furnace slag is higher in gehlenite content than the melilite phenocryst from the neighbouring massive part, while the zonal structure of the latter indicates the crystallization course from gehlenite rich to aker-

1 and 2 are derived from same slag.

manite rich melilite, which is reasonable in those range of melilite series from the viewpoint of phase diagram. So, the melilite in cavities cannot be the product of later stage or fractional crystallization of the slag. Possibly, the gas, which had been released from cooling slag to form bubbles played an important role in mineralization in cavities.

Small idiomorphic melilite crystals with brownish colour were found in the cavity of slag collected from the other ballastyard. The chemical analysis of the melilite crystals was listed in 3 of Table 3. This melilite crystals is rich in manganese, alkalies and water. And this characteristic in chemical composition resemble to that of stalactitic glassy slag (5 in Table 2). It may be crystallized out from residual liquid in the course of cooling on molten slag, and will be occurred in a cavity shown in C_2 in Fig. 2.

Dicalciumsilicate and anorthite

The dense fraction of powdered slag which separated by heavy liquid, is investigated by means of X-ray powder method. It is composed of β-dicalciumsilicate and associated with small amount of γ-dicalciumsilicate and anorthite, occasionally. And minute crystals of β-dicalciumsilicate are observed under the polarizing microscope, also.

Pseudowollastonite

There are prismatic minerals which have higher birefringence than that of melilite (photograph 6). This mineral is pseudowollastonite. X-ray powder patterns of 3.24, 2.83 and 1.98 Å are derived from pseudowollastonite.

Perovskite

Minute octahedral crystals with very high refractive index is observed in thin section of slag (photograph 7). This mineral is perovskite and rarely found in slag.

Supplementary Paper IV-113 Portland Blast-Furnace Cements-A Case for Separate Grinding of Slag

Niko Stutterheim

Synopsis

Portland blast-furnace cement is normally manufactured by grinding together clinker, granulated slag and gypsum. In his review of slag cements for the 1960 Symposium, Kramer dealt, inter alia, with the then current knowledge concerning separate grinding of clinker and slag. He did not deal specifically with blending of the two products in the factory or, with the more novel process of blending at construction site.

In 1948–1952 the author carried out laboratory and pilot plant studies on separate grinding, and blending in the concrete mixing process. He established important advantages for this procedure compared to integral grinding. Separate grinding on an industrial scale was started in South Africa in 1953; although some difficulties were experienced initially by the users due to the novelty of the idea and also because the construction industry was not familiar with portland blast-furnace cements, the demand for the product, and for separately ground slag, has grown impressively. Of the slag more than half was separately ground.

Advantages of separate grinding:—

1. The grinding process is more efficient;
2. Product quality is under better control;
3. Ground slag has much better storage properties than portland cement;
4. Proportions of portland cement and slag is at discretion of user;
5. Workability can be significantly improved or water: cement ratio reduced.

Of special technical and economic interest is the freedom to choose the proportions of slag in the final cement; Portland cement and slag have different properties and by this choice optimum combination for any job can be decided by the user; since slag costs less to produce, this can also yield material economies.

There is therefore a case for all slag intended for use in hydraulic cements to be ground separately and blended with portland cement at construction site. Modern methods of mix design, proportioning and control make this readily possible.

Introduction

In his excellent summary of the state of knowledge of blast-furnace slags and slag cements presented to the Fourth Symposium on the Chemistry of Cement in 1960, Kramer referred, inter alia, to practices then current concerning the grinding of cements containing slag. He pointed out that the great bulk of portland blast-furnace cements were integrally ground, a satisfactory procedure provided that the separate components, cement clinker and granulated slag, had suitable grinding characteristics. This is seldom the case: particularly slag tends to vary considerably in grindability, depending on composition and granulation conditions; moreover, it is generally much harder to grind than portland cement clinker as a result of which the slag component of an integrally ground cement tends to be coarser than the clinker component. As the reactivity of slag is much lower than that of clinker, strength development particularly at early ages is partially inhibited. In fact poor use is made of the latest hydraulicity of the slag.

Consequently cements containing slag like portland blast-furnace cements are commonly regarded as second-grade products which would not be selected where high quality was a prerequisite.

In order to improve quality and reduce variability the possibilities of separate grinding have begun to receive more attention and some manufacturers use separate grinding with subsequent blending before delivery as standard production procedure to ensure greater uniformity of end product. As pointed out by Kramer, each component can then be ground to yield an optimum combination of properties. Developments in the field of mixing of dry powders have made it

*South African Council for Scientific and Industrial Research, Pretoria, South Africa.

possible to ensure intimate blending at no great cost.

In terms of the quality of the product therefore, separate grinding can lead to more economical production.

In the course of experimental studies carried out between 1947 and 1954, reported elsewhere, (1) (2) (3) the author used separate grinding of slag as standard procedure for the preparation of experimental cements containing slag, since only by this procedure could one ensure that fineness of the slag was a controlled variable. This was carried through to the pilot plant stage of the preparation and testing of granulated slags, the blending in this case being done in a concrete mixer, as part of the routine concrete mixing operations. Check tests demonstrated that adequate intermixing could be achieved in this way.

As a result of this pilot plant study it was realized that there were promising possibilities in supplying the construction industry with separately ground granulated slag for on-site mixing with portland cement and the other ingredients of concrete. Such a procedure brought with it two possible disadvantages. Firstly, there was an additional component, viz., the slag, which had to be handled, measured and blended into the concrete. Secondly, there was a risk that users, unacquainted with the necessity to add an activator (such as portland cement) to a finely-ground slag before the latter would develop hydraulic properties, might deliberately or through negligence use the finely-ground granulated slag as sole cementing medium, with possible disastrous results. During the last fifteen years separately ground granulated slag has been used extensively in South Africa without these disabilities having been of any practical consequence. On the contrary, the performance of cements containing separately ground slag as a major constituent has been such that it is now widely accepted as a quality product, as proved by its use in some major construction projects.

Separate grinding and supply of slag has a number of advantages, the most important of which are discussed under the following heads.

Separate Grinding

As already referred to above, separate grinding gives control over fineness and uniformity of quality. There are, however, other advantages; for instance, since the raw materials required for portland cement manufacture are not derived from the same source as granulated slag, the latter being a waste product of blast-furnace operation, there are invariably advantages in grinding products like clinker and slag in geographically separated plants, particularly if there is no case for blending them prior to use on the job. A slag grinding plant should be located in a position which is optimal with respect to the source of the raw slag on the one hand and the consumption centres of the finished product, ground slag, on the other.

Storage

The susceptibility to deterioration in storage of portland cement is well known. Ground granulated slag in the absence of any additive has remarkably good storage properties. In fact, there are cases where this material has not deteriorated after storage in paper bags for three years.

Proportioning

With the integrally ground portland blast-furnace cements the manufacturer pre-determines the proportions of portland cement and slag for the user. Since on most construction works a variety of types of concretes are required, there are obvious advantages in being able to select the proportion of portland cement and of slag to be used for a particular application since this will lead to a more effective utilization of the properties of each component, which can lead to better performance and greater economy. For instance, on many construction works concretes of different quality involving different mix designs and therefore different specifications for instance for strengths, shrinkage, permeability and cost are often required. Blending can be done as part of the concrete mixing operation. Since weigh-batching is now almost universal for well-controlled construction works, batching of an additional component is a simple matter.

Mix Design

If the properties of portland cement and of mixtures of portland cement and slag were identical, the use of mixtures would not affect mix design. However, slag does affect the characteristics of a concrete mix, particularly if it is finely-ground, as should be the practice with separately-ground slag to allow for its lower reactivity. In particular there are two properties which should be taken into account when using portland blast-furnace cements instead of portland cement. The first is that such mixed cements tend to have a lower initial rate of strength gain, leading to lower strengths in the period two to four weeks after casting. It is fairly common experience, at any rate for South African materials, that the mixed cements thereafter develop strengths higher than those for ordinary portland cements. This dictates that if early strengths are important, portland blast-furnace cement concretes should be designed at a lower water-cement ratio, but that if strength at later ages is the important criterion, concretes with a lower cement content could prove acceptable.

The second factor concerns the effect of the use of finely-ground slag on workability or placeability, particularly when using vibrators. It is common experience that these concretes are appreciably more workable as a result of which it is possible to reduce water content compared to the case for portland cement, so leading to higher strengths and lower shrinkage.

These effects are sufficiently large to justify mix design changes.

Two special applications of separately ground slag must be mentioned. The one concerns stabilization of soil for road construction. It has been established that for certain groups of soil types excellent results are achieved by mixtures of ground granulated slag and lime. This is not only a cheaper stabilizer but it has setting properties more suited to the forming and consolidation operations inherent in road foundation construction; experience has shown that the use of this stabilizer leads to reduction in shrinkage cracking of the stabilized soil layers. By having the slag in separately ground form available on the construction site, its rate of application and the proportions of lime to be added can be varied at the discretion of the consulting engineer.

The other special case refers to the process of cementation of rock formations to reduce water penetration and seepage. Under certain circumstances such as for instance those found on the Rand Gold Mines excellent cementation can be achieved with mixtures of 99 parts ground granulated slag and one part calcium chloride, with no addition of any other cementing agent.

Economics

The ex-factory cost of ground granulated slags is appreciably lower than that of portland cements. If all the factors given above are used to best advantage, yielding a concrete in which the slag content is at optimum, the cost will be at a minimum.

In this respect Van Dÿk (4) has done an interesting study; he determined the cost of cement per cubic yard of concrete for different strength levels. The cements used in the study were:—

1. Ordinary portland cement (OPC). (60.1 cent/pocket).
2. High early strength portland cement (HE). (66.4 cent/pocket).
3. Portland blast-furnace cement (interground) (PBFC). (54.7 cent/pocket).
4. 50-50 mixture of OPC and separately ground granulated slag.
5. 50-50 mixture of HE and separately ground granulated slag.
6. Separately ground granulated slag (39.0 cent/pocket).

(Prices are quoted in South African cents. 1 S.A. cent = 1.4 U.S. cent).

The variables were: type of cement and strength at particular ages. No advantage was taken of the greater workabilities possible with cements containing finely ground granulated blast-furnace slag. Some of his results are shown in Fig. 1.

Van Dÿk concludes that the combinaton of 50 percent high early cement and 50 percent slag generally gave the most economical mixes for moist-cured concrete tested at 3, 7 and 28 days.

On the other hand the ordinary portland cement and the portland blast-furnace cement gave the highest costs per unit of strength.

He adds that if concretes of equal placeability had been made for each comparative group, these cost differences would have been accentuated. The ques-

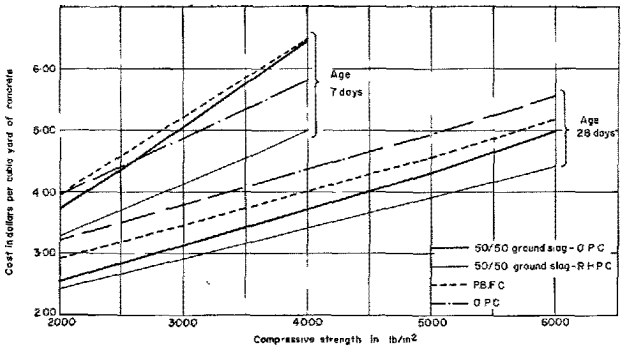

Fig. 1. *Comparative costs of different cements*

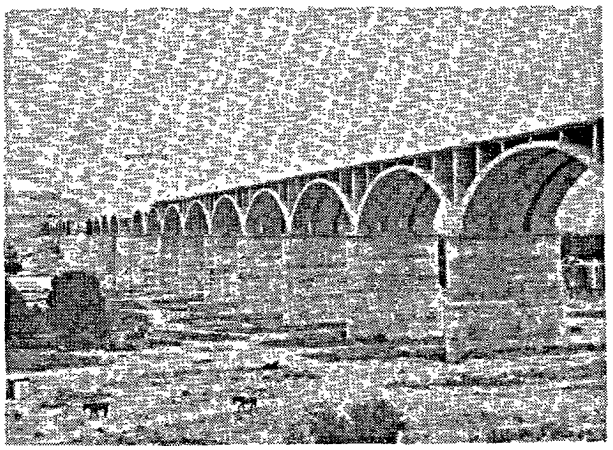

Fig. 2. *Bethulie bridge over Orange River 1,200 metres long.*

toin of the effect of workability is rather complex as it depends upon the criteria of workability to be used. Static workability tests like the slump test are not satisfactory in an age when most concrete is placed by vibration. Moreover, when comparing the workability of concretes made with portland cements on the one hand and portland slag mixes on the other, it becomes particularly important that the workability test used should somehow relate to the placeability obtained in practice with the use of internal vibrators. A start has been made on such studies.

Typical examples of the practical application of concrete mixes designed specifically for combination of portland cement and separately ground granulated slag mixed in the concrete-making operation, are shown in Figs. 2, 3 and 4.

Conclusion

Blast-furnace slags, being by-products, vary tremendously in quality from place to place. By far the greater bulk of slag produced in the world is not suitable for cement manufacture. Where, however, this product does have physical and chemical properties which allow it to be converted to a potentially hydraulic material, there is scope for using it for constructional purposes. Industries in many countries

have taken advantage of this fact and some have been producing cements containing granulated slag as a major constituent for decades. Most of this cement has been marketed in the form of a product interground with portland cement to give one of the various varieties of portland blast-furnace cements. Recently separate grinding of the slag has become more common but generally only as a preliminary to factory blending to yield a ready-mixed product for sale.

Experience in South Africa with separately-ground granulated high-magnesia slag marketed as such and blended with portland cement or other activator at the point of final use, has shown that this procedure can give very staisfactory results, both technically and from the economic point of view. The resultant product compares favourably with portland cements for certain classes of construction, in particular civil engineering works.

Oral Discussion

Mitsuo Hanada

What are the hydration products when high-MgO slag (such as 15% MgO) is used, especially those of the MgO hydration?

Oral Discussion

Steven Gottlieb

Dr. Stutterheim must be congratulated for strengthening the case for separate grinding of slag, and as this recommendation has far reaching qualitative and economic consequences, I would like to make some comments.

Certain types of blast furnace slags are ground together with portland cement clinker for decades:—in fact, the German cement industry for instance, would hardly exist economically without the substantial quantity of blast furnace cement produced. However, not much has changed in the method of producing blast furnace cements during the past 50 years, though great advances in grinding and classifying technology, particularly during the past 15 years, would have justified such changes for the betterment of quality and economy.

Dr. Stutterheim points out that the higher fineness of the harder slag as achieved by separately controlled grinding, produces more active surface. This is correct, but there is another, perhaps even more important possibility of improvement in regard to the grinding of the clinker constituent, provided that the blast furnace cement is produced at the cement works. With the intended use of blast furnace slag, the clinker can be ground much finer than usual;—utilizing new classifier technology even as high as 7000 cm^2/g Blaine-which normally would be an unreasonable thing to do, not only because of prohibitive costs, but also for many other considerations such as excessive shrinkage and potential instability due to particle attraction leading to agglomeration. However, in a properly designed blending system blending between the very finely ground cement and the finely ground slag is accomplished immediately after the very finely ground clinker and gypsum leave the classifier,—then the disadvantages of excessive fineness disappear, as intimate blending with the slag with increase the average distances between the very small portland cement clinker particles and thus reduce, or even totally eliminate the nuisance attraction forces between these particles.

Surface wetting in such system becomes more uniform due to the absence of particle agglomeration. This could open up ways for further improvement of qualitative and economic performance of clinker and blast furnace slag mixes.

Oral Discussion

Herman Kaiser

I fully agree with Dr. Stutterheim in that separate grinding of slag rather than intergrinding of slag and clinker has a great many advantages.

I understand that one plant here in Japan grinds the slag separately. In Venezuela a plant now under constructon will also grind slag separately, and then blend it with finished portland cement shipped in from another plant.

However, I wonder what the advantages are of leaving the blending to the cement user because quality control can probably better and more reliably be achieved in the cement plant rather than on the construction site.

Furthermore, different customers may require, or want slags ground to different finenesses. This, I fear, might complicate an otherwise quite simple manufacturing process.

Oral Discussion

R. R. Hattiangadi

Congratulating Dr.Stutterheim for bringing to the pointed notice of the delegates that there was, both technically and commercially, a case for separate grinding of granulated blast furnace slag and portland clinker and thereafter blending the same as and when necessary. Dr. Hattiangadi gave a brief resume of his own experiences in India. Dr. Hattiangadi gave figures in respect of a factory where commercial scale experiments had revealed by separate grinding and blending of slag and cement the net saving in power consumption alone, was of the order of 7 to 8 units per tonne of portland blast furnace cement, after making due allowances for power consumption for conveying and blending of the two separately ground materials. In this country (India) the slag which was granulated at some distance from the site of the blast furnace was very much harder to grind than portland clinker and it seemed obvious that it was not correct to intergrind two materials of different grindabilities and of different average diameters.

Dr. Hattiangadi also asked if it was necessary to grind the slag to a greater degree of fineness than the parent portland clinker to which Dr. Stutterheim seemed to say that it would be desirable but not quite necessary.

Author's Closure

Niko Stutterheim

Reply to M. Hanada

"Except in the improbable case for which the high magnesia slag contains some periclase, the hydrates are free of brucite. Searches e.g. by Nurse, Yang, van Aardt, have failed to identify any products other than gel indistinguishable physically from CSH gel. Earlier in this Symposium Prof. Tayler made a case for naming the gel product of portland cement hydration CSH gel, presumably until more is known about. It would therefore be logical to call the product of hydration of a high magnesia slag CMSH gel."

Reply to S. Gottlieb

"I find Dr. Gottlieb's statements about the effect of electrical charges on separately ground slag particles very interesting but must confess lack of knowledge on my part regarding the practical implications of this charged state on blending with portland cement. There may be scope for further study of these phenomena.

As I envisage it, however, separate grinding of slag may well take place at plants geographically distant from portland cement plants; several such plants exist in South Africa. Then blending soon after grinding is of course out of the question. In fact, from other points of view, as set out in may paper, there are overriding technical and economic advantages in blending only at construction site, which may be weeks or months after grinding."

Reply to H. Kaiser

"It is interesting to find confirmation in the experience of Mr. Kaiser in Venezuela for the advantages of separate grinding of slag. Our reasons for believing that separate marketing of the finely ground slag and blending only at the construction site are partly dealt with in my paper. I may add that this procedure allows the user to decide what blend ratios he will use on the job, whereas intergrinding or factory blending puts this decision in the hands of the manufacturer who does not know the requirements for the specific application.

In South Africa about 500,000 tons p.a. of finely ground slag is supplied direct to construction works, and blended with portland cement on site, mostly in the concrete mixer. It is used mainly for large works, e.g. civil engineering constructons; such works are generally under good supervision. We have not had any serious problems with separately marketed slag."

Reply to R. R. Hattiangadi

"The fullscale production trials on integral and separate grinding, respectively, mentioned by Dr. Hattiangadi is further clear indication of the favourable economies of separate grinding. From their work,

Locher *et al* have concluded that the influence of slag fineness on its performance in concrete is decisive; Kayser has stressed the importance of grain size distribution; Birthelmer established that separately ground slag and portland cement attain strengths equal to those for interground cements of higher surface areas. These findings quoted in Dr. Schröder's principal paper to this Symposium reinforce the case for separate grinding."

Supplementary Paper IV-121 The Role of Magnesia and Alumina in the Hydraulic Properties of Granulated Blast-Furnace Slags

Marcel Cheron and Claude Lardinois*

Synopsis

The authors compare the incidence of the Al_2O_3 and especially the MgO content on the hydraulic activity of the iron slags. These slags were prepared from industrial blast-furnace slags to which pure oxides were added covering a large area of chemical compositions limited by the following characteristics:

$$C/S = 0.85 - 1.45; \quad Al_2O_3 = 8.0 - 21.0\%; \quad MgO = 5.0 - 15.0\%.$$

The mixtures were fused at temperatures exceeding 1500°C and quickly cooled, to obtain an almost complete vitrification, which was controlled by X-ray diffraction. These slags were separately ground with gypsum and cements prepared by mixing them with the same proportion of previously ground portland cement. The mechanical strengths of these cements were determined according to the RILEM Cembureau Method.

The representation of the results on triangular diagrams (S-A-M) at constant level of Al_2O_3 showed the beneficial influence of the Al_2O_3 and MgO on the mechanical strengths.

A linear relation between the mechanical strengths and the chemical composition was established and the hydraulic index

$$I_h = \frac{CaO + 1.4MgO + 0.56Al_2O_3}{SiO_2}$$

was proposed.

Tests made on industrial slags showed a good agreement between the hydraulic index of the slag and the mechanical strengths of the corresponding cements.

Introduction

Ten years ago, the cement industry in Belgium, used granulated slags characterized by a CaO/SiO_2 ratio exceeding 1.4 and an almost constant alumina and magnesia content varying between 15-16% for Al_2O_3 and 4-5% for MgO. These slags gave a relatively fair granulation.

During the last ten years, the iron industry of our country as well as of the countries outside, progressed considerably, even regarding the process (preparation of the charge, increase of the blast-furnace size, LD-process), as respecting the raw materials now mostly imported from beyond the seas. This evolution involved many consequences for the slag quality (decrease of the C/S ratio, increase or decrease of the Al_2O_3 percentage, increase of the MgO percentage). Table 1 gives some examples of slags produced currently in 1963-1964. The largest part of the production had a composition similar to that of slags B and C. Slags A, D and E are examples of the extreme compositions encountered. In the same time a fair improvement of the slag vitrification was observed.

The incidence of the qualitative evolution of the slags on its hydraulic value is very important for the cement industry in Belgium and other neighbouring countries such as the Netherlands and the north-east of France, where the average incorporation rate of slag in blast-furnace cements reaches 60–70%.

Table 1.

Slag	CaO/SiO_2	% Al_2O_3	% MgO	% MnO
A	1.65	13.4	4.2	0.7
B	1.27	14.1	4.9	1.2
C	1.21	13.5	7.6	0.9

Literature Survey

All authors agree to consider the non-crystallized state of slags as a strictly necessary condition to their hydraulic activity.

Keil (1) and Kramer (2) synthesized, in 1952 and 1960 respectively, the essential opinions thereabout. L. Santarelli, G. Goggi (3), and more recently H. E. Schwiete and F. C. Dölbor (4) pointed out that strength development appeared as a linear function of the "glass content". S. Solacolu (5) has proposed an explanation of the influence of the vitreous state of slag based on quasi-crystallized phases, namely a molecular preorganization recalling the crystalline phases which should be formed, at equilibrium, by slow cooling of the slag. The hydraulic properties of the slag consequently depend only on the chemical composition within the field of crystallization and there is a discontinuity of properties when passing from one field to the other.

Although some authors, as R. Kondo (6), do not entirely agree with this point of view, it seems self-evident, to admit a certain organization within the glass which is rather difficult to reveal experimentally. But its action on the hydraulic activity is superposed to other essential factors such as the chemical composition of the vitrified part.

According to this last aspect, which has had our full attention in this study, and in the case of basic slags whose composition belongs to the melilite group, the hydraulic activity increases according to the C/S ratio and the alumina content, the part played by the MgO being contested (5) (7) (8) (9).

H. E. Schwiete and F. C. Dölbor (4) obtain a fair statistical concordance between the hydraulic activity and a chemical index where Al_2O_3 is partially associated to SiO_2 as denominator, and partially associated to the lime (% Al_2O_3-10) as numerator.

Other well-known chemical indices (10), more particularly these proposed by F. Keil, C. de Langavant, L. Tetmayer and others consider that the total amount of alumina must be considered as favourable for the hydraulic activity of the slag.

The amphoteric character of alumina cannot be contested; it surely depends on the silica content of the slag and its effect will be more favourable on the hydraulic activity when the C/S ratio of the slag is lower. This point of view has been developed by Hüettemann (8).

The hydraulic value of MgO is accepted by some authors, contested by others. F. Keil and F. W. Locher (9) consider that the slags containing 5% MgO are more active than the slags of similar composition without MgO excepted if the activation is obtained with lime.

E. F. Osborn, R. C. De Vries, K.H. Gee and H. M. Kraner (7) determined the optimum slag compositions with various alumina percentages and pointed out that the optimum magnesium content varied between 16 and 12.5% when the C/S ratio increased from 1.20 to 1.54 and the Al_2O_3 content raised from 5 to 15%. Other authors affirm that until 8%, MgO may replace CaO (1). N. Sutterheim and R. W. Nurse (11) estimate that if MgO reaches 15–16% the slag is less hydraulic; this is probably due to the partial devitrification (spinel); the slags containing a high MgO percentage crystallize fast.

On behalf of structural considerations, H. E. Schwiete and F. C. Dölbor (4) propose a formula of hydraulic index where the magnesia appears as denominator and has an effect opposite to that of the lime.

$$\frac{CaO + (x - 10\,Al_2O_3) + CaS + Na_2O + K_2O}{SiO_2 + 10\,Al_2O_3 + TiO_2 + MnO + MgO}$$

This formula seems however not to have been tested experimentally.

Object of the Study

The main object of this paper will be to specify the incidence of the MgO content for increasing amounts of Al_2O_3 on the hydraulic activity of granulated industrial slags. These slags are characterized by a relatively low C/S ratio and a degree of vitrification higher than 90%. The field of chemical composition covered will be

C/S	from	0.85	to	1.45
Al_2O_3	from	8	to	21%
MgO	from	5	to	15%

The choice of a "quality factor" which permits the evaluation of the hydraulic value of the iron blast-furnace slag is our principal aim; it will be based on the following method as previously proposed (6):

—measure of the degree of vitrification by estimating the crystalline phase amount by X-ray diffraction

—estimation of the hydraulic value by the chemical composition (made for example by the X-ray fluorescence method).

Experimental Part

Industrial Slags

Industrial slags were collected whose chemical characteristics varied in the following way

C/S =	0.72	to	1.65
Al_2O_3 =	13.4%	to	22.7%
MgO =	3.8%	to	16.3%
MnO =	0.2%	to	2.2%
FeO =	0.2%	to	1.0%

The degree of vitrification was controlled by X-ray diffraction and was in all the cases higher than 90%.

The following method was used for this control. First of all were established calibration curves applicable to each group of slags characterized by the same primary crystalline phase e.g. the gehlenite phase. The calibration curve is obtained from mixtures of the vitreous and the crystallized variety of the same sample. The crystallized sample was prepared by heating the slag at 1000°C during 1 hour followed by a very slow cooling. The percentage of the crystallized phase was determined by measuring the intensity of the proper diffraction line (gehlenite at 2.84 Å spacing e.g.).

The Fig. 1 gives an example of the calibration curve. Although the precision of this method is better than 3% we divided for simplicity the examined slags in classes containing 0 to 5, 5 to 10 and 10 to 15% of crystallized material.

The slags with a crystallized phase greater than 10% were discarded. The hydraulic activity of the other slags was measured from cements prepared in the following way

—separate grinding of the slag with gypsum in a laboratory mill to obtain a fineness of 3500 or 4500 cm²/g Blaine and a SO_3 content at 3%.

—separate grinding of a sufficiently large sample of clinker with gypsum to attain a SO_3 content at 3% and a specific surface of 3300 cm²/g Blaine.

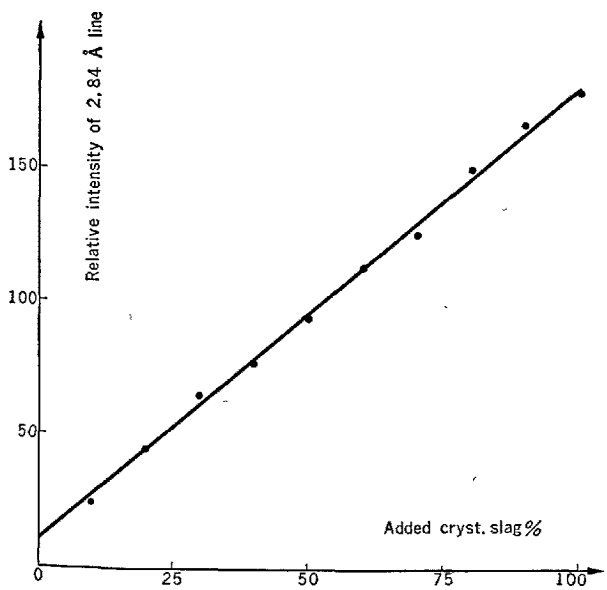

Fig. 1. *2.84 Å line of gehlenite*

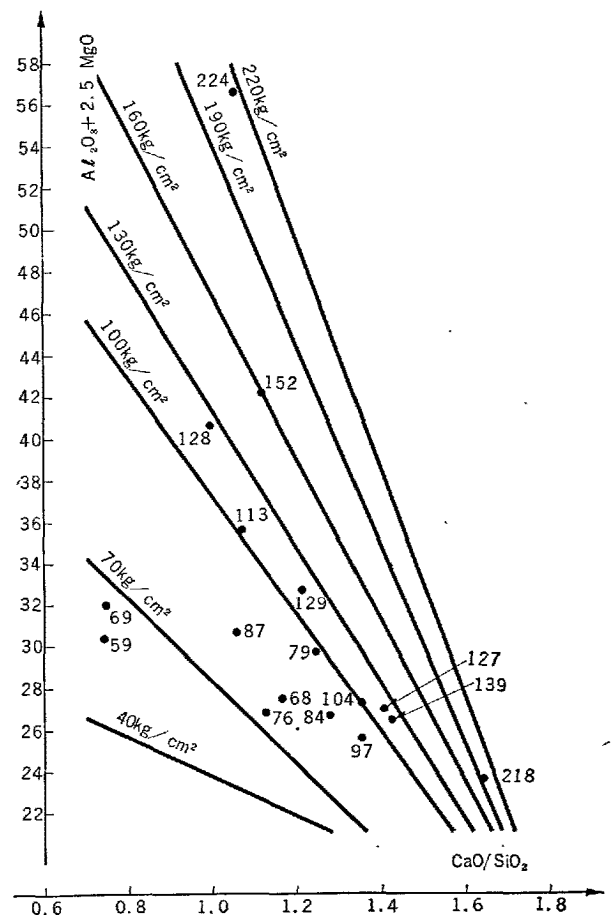

Fig. 2. *Comp. strength of industrial slags at 3 days*

—preparation of the slag/portland cement mixture in three different proportions containing 30–50 and 80% of portland cement.

—test of the mixed cements obtained according to the "RILEM Cembureau" standard testing method for cements (12).

Fig. 2 gives the compressive strengths at 3 days for the cements corresponding to a 70% slag content with a fineness of 4500 cm^2/g Blaine. This graph represents striaght lines of equal mechanical strengths in function of the parameters CaO/SiO_2 and $(Al_2O_3 + 2.5MgO)$. The best correlation was obtained by the choice of a 2.5 coefficient for MgO.

Similar diagrams were established at the ages of 7 and 28 days and for a slag fineness of 3500 cm^2/g Blaine, and tend to the same conclusions.

Nevertheless, the chemical area covered by the industrial slags was rather small; therefore the composition of some of them was modified in the laboratory to enlarge the investigated field.

Corrected Industrial Slags

We made a choice of four industrial slags with a

Table 3. *Hydraulic index of laboratory modified slags and compressive strengths of cements-mortars made from them.*

Slag No.	Hydraulic index I_h	Compressive strengths after (kg/cm²)

54	1.89	134	264
55	1.98	170	334
56	2.18	216	377

(a) $I_h = \dfrac{CaO + 1.4\,MgO + 0.70\,Al_2O_3}{SiO_2}$

C/S ratio between 1.16 and 1.41, a Al_2O_3 content of 15%, a MgO content of 5% and a MnO content between 0.6 and 1%.

The chemical composition of these slags were modified by addition of pure oxides, then fused and granulated. The chemical composition of the slags so obtained and their crystalline phase content are given in table 2.

The industrial slags were first ground at 2500 cm²/g Blaine and then intimately mixed with the pure oxides to obtain definite compositions; the mixture was fused by portions of 2 kg, at a temperature exceeding 1500°C, in a graphite crucible protected against oxidation by an outer silimanite crucible and heated in a rotary gas flame furnace.

The fused mass was quickly poured in water to obtain a fine division of the melt. The degree of vitrification was controlled as previously described.

Laboratory cement were prepared by mixing 70% slag separately ground with gypsum to a fineness of 4500 cm²/g Blaine and 30% standard portland cement. These cements were tested according to the RILEM Cembureau method (12). The compressive strength obtained from these samples are reported in Table 3. The compressive strengths at 3 and 7 days are plotted in ternary diagrams (Figs. 3 to 8) resulting from the quaternary diagram ($CaO–SiO_2–Al_2O_3–MgO$) by maintaining the Al_2O_3 content constant at the levels 9–12 and 15%. The slags were divided in three classes according to their Al_2O_3 content: from 7.5 to 10.5, from 10.5 to 13.5 and from 13.5 to 16.5. The first class was projected on the 9% Al_2O_3 level diagram. The second on the 12% level diagram etc . . .

Some of the points of these diagrams correspond to partially crystallized slags; those single-underlined are characterized by a crystalline content lower than 5%, those double-underlined are characterized by a crystalline content between 5 and 15%.

These diagrams prove undoubtedly that an increase in the MgO content improves the mechanical stregnths of the blast-furnace slag cement at least for the area taken on account.

Choice of a Chemical Index for the Hydraulic Activity of the Slag

The chemical index I_h giving the best correlation with the experimental values Figs. 9 and 10 was cal-

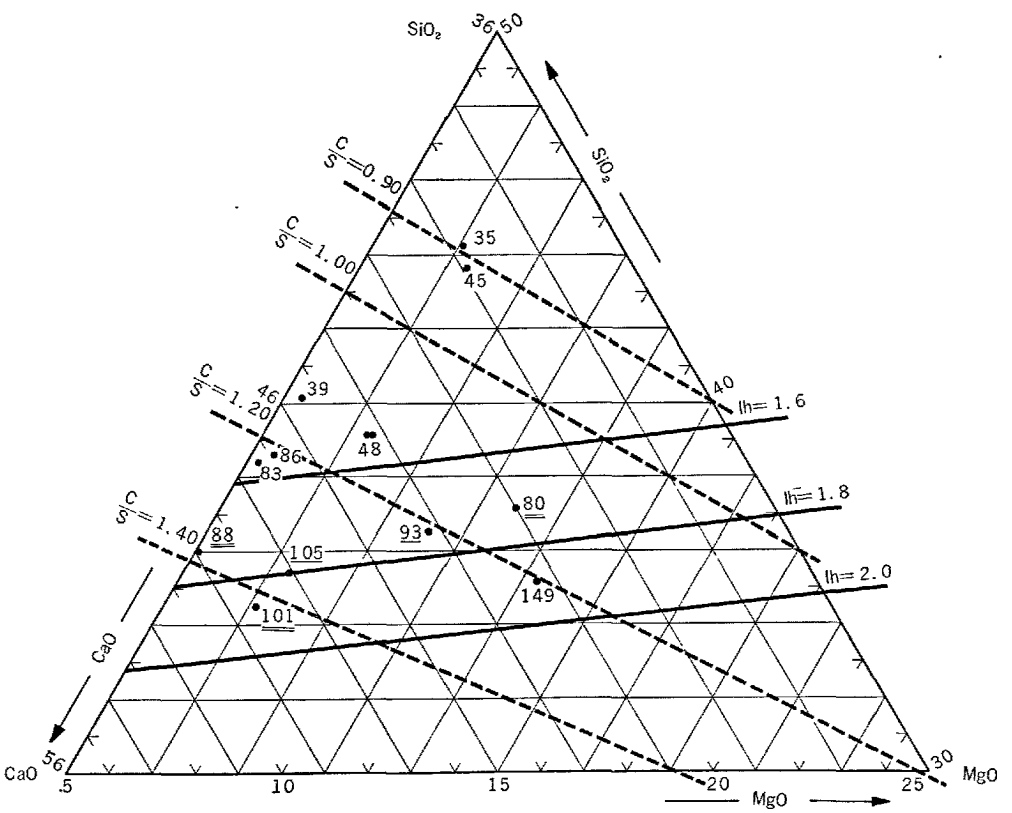

Fig. 3. *9% Al_2O_3 Comp. strength at 3 days*

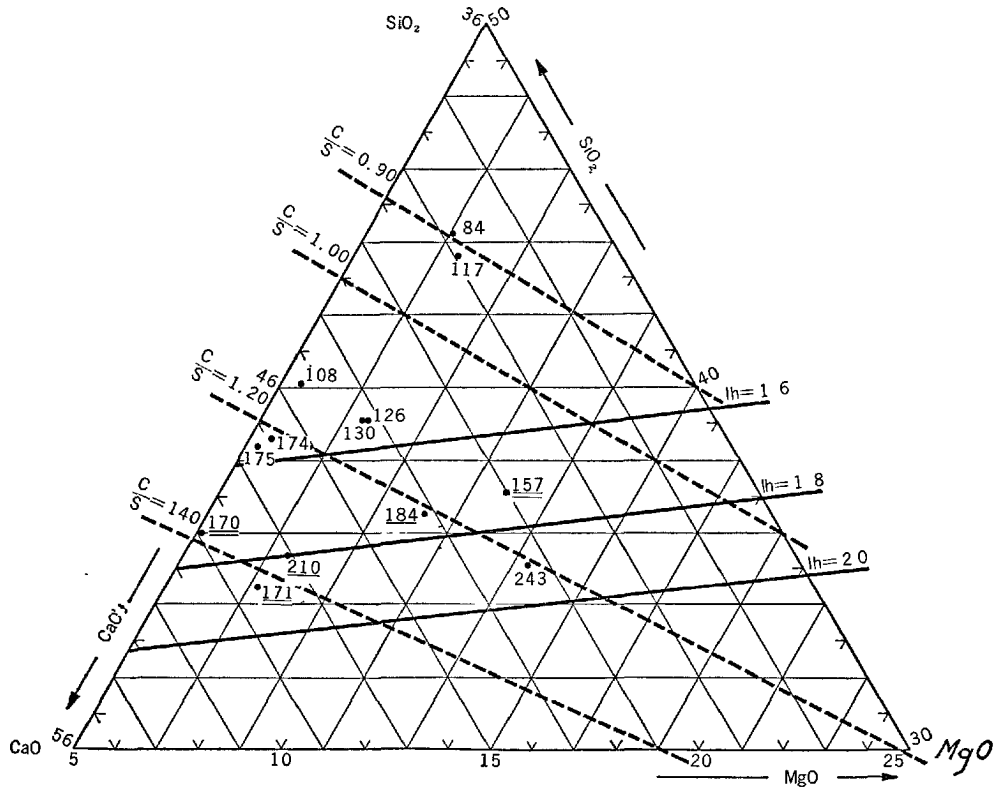

Fig. 4. *9% Al_2O_3 Comp. strength at 7 days*

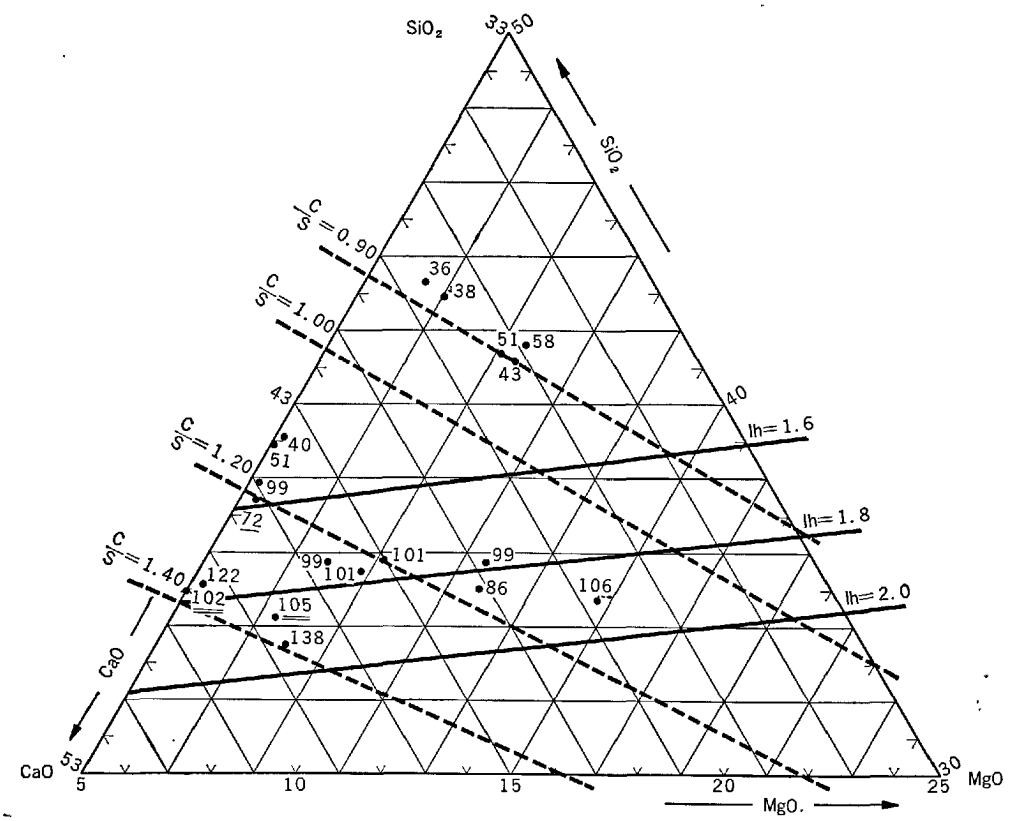

Fig. 5. *12% Al_2O_3 Comp. strength at 3 days*

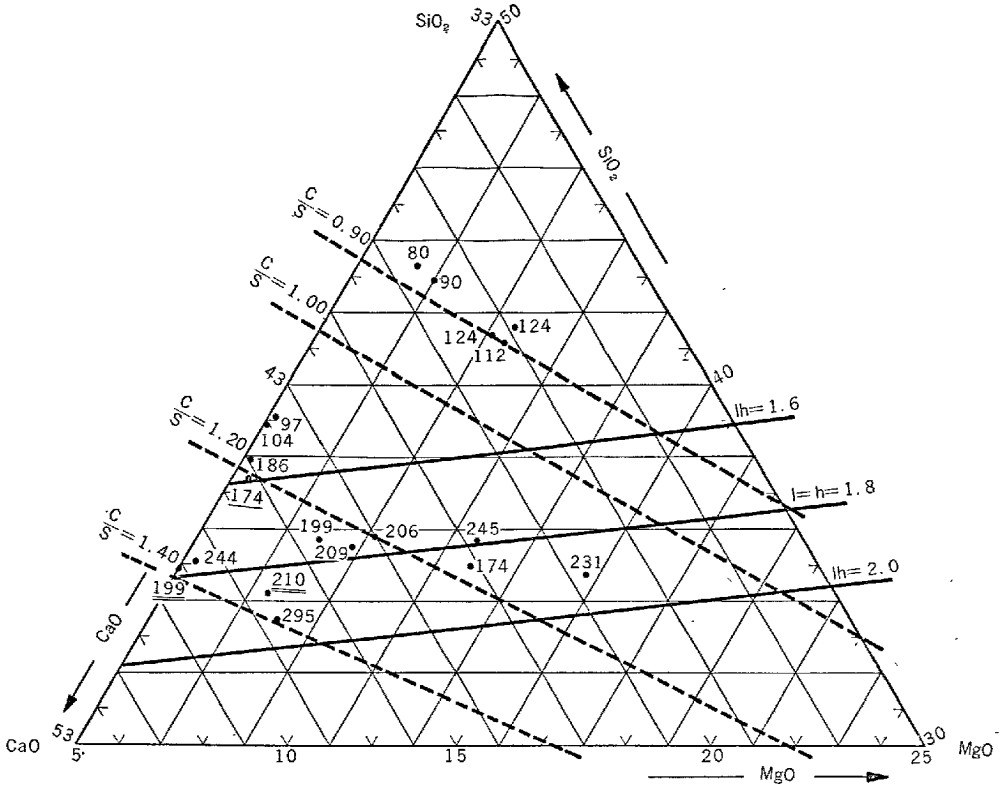

Fig. 6. *12% Al_2O_3 Comp. strength at 7 days*

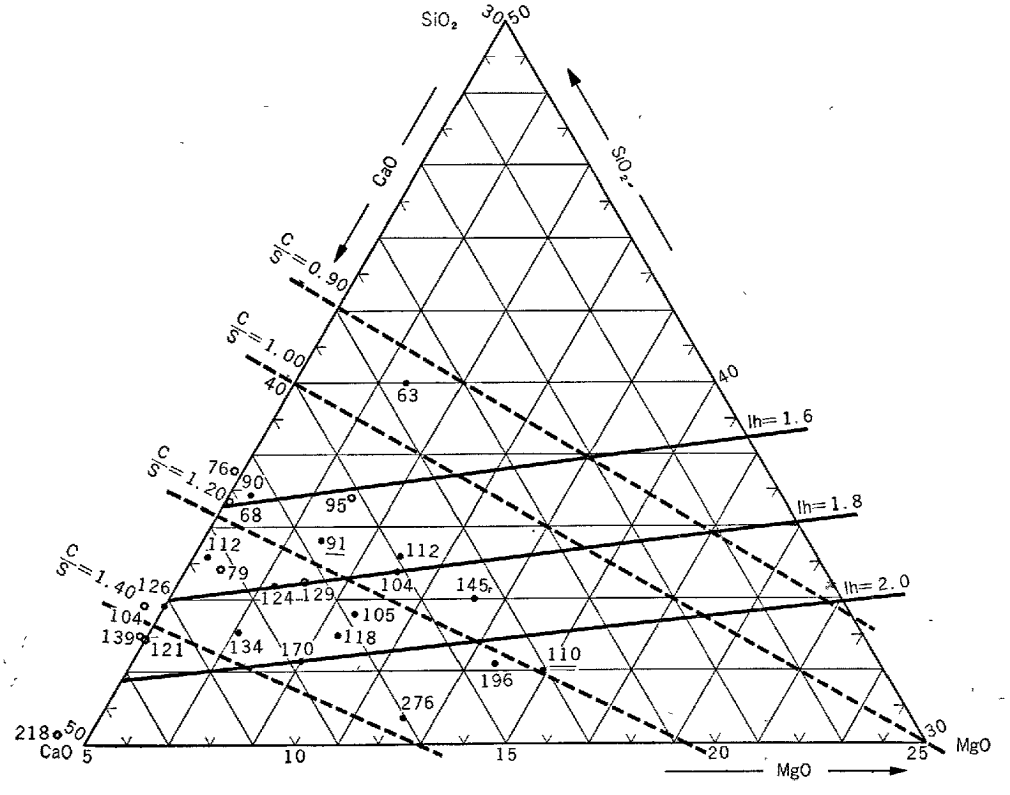

Fig. 7. *15% Al_2O_3 Comp. strength at 3 days*

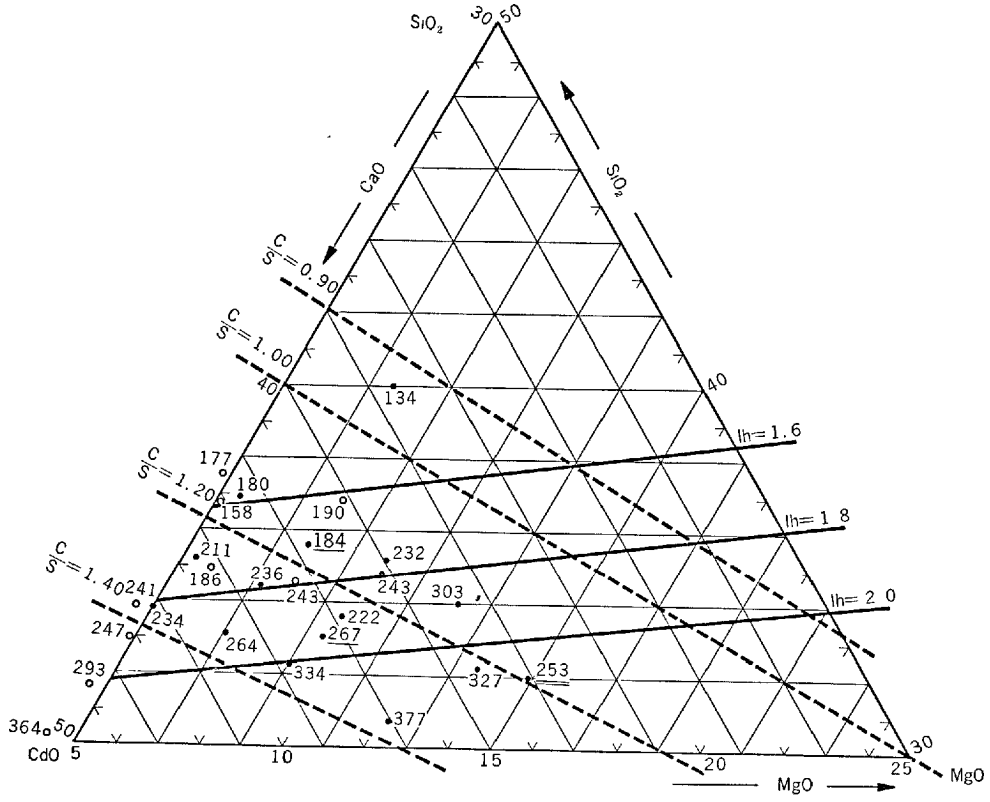

Fig. 8. *15% Al_2O_3 Comp. strength at 7 days*

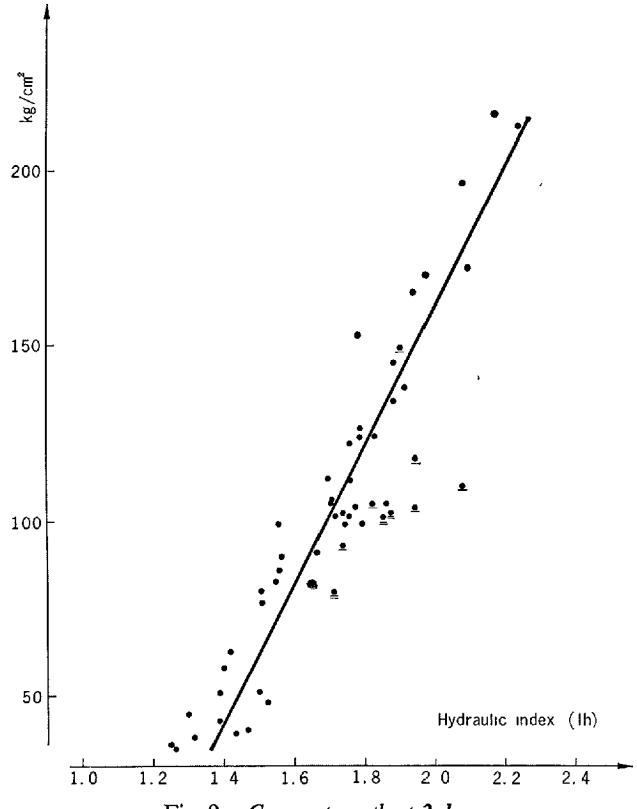

Fig. 9. *Comp. strength at 3 days*

culated and may be expressed as:

$$I_h = \frac{CaO + 1.4\,MgO + 0.56\,Al_2O_3}{SiO_2}$$

For values of I_h lower than 1.4 a better correlation is obtained when the coefficient 0.56 for the Al_2O_3 is replaced by the value 0.70. This formula which was deduced experimentally is in good agreement with the one proposed by Tetmayer for the characterization of the hydraulic vaule of the slags:

$$\frac{\frac{CaO}{56} + \frac{MgO}{40} + \frac{Al_2O_3}{102}}{\frac{SiO_2}{60}} \geqslant 1$$

We plotted on the same figures a certain number of of points corresponding to industrial slags and found a good agreement between the value of the index I_h and the related mechanical strengths. Some of the points coresond to partially crystallized slags and are indicated as previously noted.

On the Figs. 3 to 8 are drawn straight lines corresponding to a constant C/S ratio or to a constant value of the hydraulic index (I_h). These last lines are also the loci of equal mechanical strengths.

(B) Papers regarding High-Sulphate Slag

Supplementary Paper IV-21 Anhydrite Cement

André A. Van Haute*

Synopsis

Anhydrite cement is a synthetic cement composed of anhydrite obtained from residual gypsum and slag. In itself an anhydrite-slag mixture gives a cement of insufficient strength and with too long a setting time. Research aimed at improving this cement will therefore have to be centered on finding the anhydrite-slag ratio producing the greatest strength, on the one hand, and seeking the nature and quantity of components to provide greater strength and to shorten the setting time (catalyst), on the other hand.

A new catalyst has been developed: it consists of a mixture of aluminous cement, K_2SO_4 and $Ca(OH)_2$. After hundreds of tests it has been found that the strongest anhydrite cement is obtained with a 50/40 anhydrite/slag ratio, $\pm 10\%$ catalyst mixture being used. The composition of the mixture can be varied according to whether the purpose is to obtain a cement having the greatest possible compressive strength after 3 days or else after a longer period, say 28 days. Flexion and compression tests were carried out in accordance with the standardized Rilem-Cembureau method; the results are shown in table form in terms of the catalyst composition (3, 7 and 28 days).

From these tests it emerged that the specimens which gave the best results after three days (80 kg/cm² compressive strength) consisted of 6 to 7% aluminous cement, 1.5% $Ca(OH)_2$ and 1.2% K_2SO_4 (that is to say, in all 8.7 to 9.7% catalyst). This anhydrite cement has a normal consistency of 37%; setting begins after 5.15 hours and ends after 7.35 hours; the compressive strength after 28 days attains a value of 400 kg/cm².

On the long term strong specimens require more aluminous cement (8%), less hydrated lime (1.1%), a similar anhydrite/slag ratio (50/40) and the same quantity of potassium sulphate (1.2%). After 28 days a specimen such as this produces a compressive strength of 580 kg/cm².

Anhydrite Cement

This study contains the results of a research to prepare a synthetic cement using anhydrite as the main component. Only the anhydrite obtained by calcining the waste gypsum from the phosphoric acid industry has been used: so that, at the same time, a possible solution to the problem of disposal of waste gypsum from this industry has been found.

Of course, one is immediately faced with the slow setting and the instability to water of the anhydrite. To realize a faster reaction and a waterproof crystal structure a blast furnace slag as well as a mixture of catalyst consisting of K_2SO_4, $Ca(OH)_2$ and aluminous cement has been added.

To be acceptable as a binder, the properties of this new kind of cement must be near those of portland cement and even better: the search for the "optimum composition" of the anhydrite cement to reach the highest possible mechanical resistance, while the other physical properties still conform to the standard specifications of portland cement, has been the main object of this study. At the same time we tried to determine the relative influence of the different components.

*Institute of Industrial Chemistry, University of Louvain, Heverlee, Belgium.

Basic Components

Anhydrite

As raw material residual gypsum was taken from the phosphoric acid industry using Morocco rock. The average composition of the (dry) gypsum waste is as follows:

$CaSO_4$	76%
water	20%
P_2O_5 total	1%
P_2O_5 insoluble	0.15%
Fe_2O_3	0.1%
Al_2O_3	0.15%
F	1%
MgO	0.1%
SiO_2	1%
organic components	rest

This residual gypsum was calcined at a temperature of 850 to 900°C in order to obtain anhydrite II, which was ground to a fineness smaller than 63μ (230 mesh). The specific weight of this anhydrite is 3.04 g/cm^3 and the specific surface (Blaine) 1900 cm^2/g. The porosity of the anhydrite is 0.53.

Because of the already mentioned slow setting of the anhydrite II, an accelerator is needed. The following materials can be considered:

—neutral or weakly acid sulphates: K_2SO_4, Na_2SO_4, $(NH_4)_2SO_4$, $CaSO_4 \cdot 1/2H_2O$, $MgSO_4$, $CdSO_4$, $ZnSO_4$, $FeSO_4$, alum, $CuSO_4$.

—bisulphates: $NaHSO_4$, $KHSO_4$.

—bases: CaO, $Ca(OH)_2$, MgO, $Mg(OH)_2$.

—cement, basic slags . . .

The quantity of accelerator which can be added is mostly restricted from 0.1 to 3% because it can influence the crystal structure and therefore decrease the mechanical strength.

Since the concentrations of the impurities are different according to the rock (apatite), from which the waste gypsum is produced, it ought to be checked in what way these impurities influence the flexural and compressive strengths. It is always preferable not to be dependent on one sole distributor. In nature apatite rock is not found which gives a waste gypsum with larger concentrations of impurities than:

F (in the form of Na_2SiF_6)	4%
Fe_2O_3	3%
P_2O_5 (in the form of H_3PO_4)	2%
Na_2O (in the form of Na_2SO_4)	1%
K_2O (in the form of K_2SO_4)	1%
MgO (in the form of $MgSO_4$)	1%

To conform as much as possible to reality, supplementary tests have been carried out, in which the above mentioned impurities, even in quantities to the maximum possible concentrations in the anhydrite, were recalcined with the latter, and then ground to the above mentioned fineness. We have carried out a series of tests with a well determined composition of the anhydrite cement, which, although it does not completely conform to the "optimum composition" to be found later, is very close to it: we never noticed a drop of more than 10% of the mechanical strength, whereas by adding sulphates and phosphates the final strength even slightly increases.

Slag

Blast furnace slags were used with the following compositions (dry):

CaO	41.60%
SiO_2	31.70%
Al_2O_3	16.70%
MgO	5.70%
MnO	1.10%
FeO	0.80%
S	1.00%
$K_2O + Na_2O$	1.40%

After drying these slags, they were ground also to a fineness smaller than 63μ (230 mesh). The specific weight of the ground slag is 3.0 g/cm^3 and the specific surface (Blaine) 2460 cm^2/g; the porosity has a value of 0.50.

Of course, only "quenched" slags have hydraulic properties. The setting of these slags can be accelerated by adding $Ca(OH)_2$ or portland cement (which liberates $Ca(OH)_2$ during setting). During the setting of the slag the liberated alumina reacts with the hydrated lime, which will therefore be absent in the end product.

Tests have shown that slags for the production of anhydrite cement should have the following composition:

CaO	35 to 45%
SiO_2	preferably 30 to 33%, not more than 35%
Al_2O_3	not less than 15%
S	not more than 1.5 to 1.8%

Catalyst

A mixture of K_2SO_4, $Ca(OH)_2$ and aluminous cement, also ground to a fineness less than 63μ, is used as catalyst.

As mentioned above, K_2SO_4 and a part of the hydrated lime are added as an accelerator for the an-

hydrite: the other part of the lime activates the slag. Also several other sulphates (see above) were tried as accelerators for the anhydrite in the anhydrite cement, but with not so good a result.

As aluminous cement a cement of the English firm "Lafarge Aluminous Cement Co. Ltd.", was used, with the following composition:

Al_2O_3	40%
CaO	37.5%
SiO_2	4.5%
FeO	7%
Fe_2O_3	9%
TiO_2	2%

Crystallographically aluminous cement (with $SiO_2 >$ 5%) consists of $\pm$60% $CaO \cdot Al_2O_3$, the hydration of which will be strongly activated by portland cement, lime and calciumsulphate; it is also composed of 15 to 20% gehlenite, $2CaO \cdot Al_2O_3 \cdot SiO_2$, which sets very slowly, and of 10 to 15% $2CaO \cdot SiO_2$. Furthermore, fibrous structures of $4CaO \cdot Al_2O_3 \cdot Fe_2O_3$ and of $6CaO \cdot Al_2O_3 \cdot 2Fe_2O_3$ are found, and also $CaO \cdot TiO_2$. Not more than 0.5% alkalis may be present, otherwise the setting will be too fast and the full strength will never be developed. The same remark applies to the use of lime.

The main purpose of adding aluminous cement to the catalyst mixture is to increase the final strength of the anhydrite cement.

The optimum composition of the catalyst mixture has to be worked out precisely as a function of the anhydrite-slag ratio, in order to reach the highest mechanical strength of the anhydrite cement, whereas the other physical properties still conform to the standards of portland cement.

Other aluminous cements (for instance the German "Rolandshütte" cement) have a larger percentage of alumina and a lower percentage of ironoxide: the optimum composition will have to be slightly adapted, but tests carried out with "Rolandshütte" show a larger final strength of the anhydrite cement.

Standardization and Accuracy of Tests

Standardization

In order to obtain reliable and reproducible results the following Belgian specifications were accurately used:

—for testing anhydrite cement:

NBN 178.21 for the determination of the fineness. As already mentioned earlier all components were ground to a fineness less than 63μ (230 mesh). Some tests were also carried out with finenesses less than 88μ (170 mesh): the properties of the samples were practically identical.

NBN 178.22 for the determination of the specific weight (approximately 3.0 g/cm^3).

NBN 178.30 for the determination of the consistency of standard cement paste.

NBN 178.31 for the determination of initial and final setting times.

NBN 178.32 for the determination of soundness.

—for testing the corresponding plastic mortars ("Rilem-Cembureau" method):

NBN 178.51 for the preparation and the mixing of the samples.

NBN 178.52 for the curing of the samples

NBN 178.53 for th determination of the flexion and compression strengths.

Two deviations from the specifications have to be noted:

—first of all it was necessary to use only 45% of water for the preparation of the plastic mortars instead of 50% as NBN 178.52 prescribes: indeed, the plastic mortars showed the same plasticity with 45% of water as they did with 50% for plastic mortars made of portland cement.

—secondly, all the samples were cured in saturated humid air at 20°C instead of in water saturated with lime as NBN 178.52 prescribes. Some comparative tests were carried out and we noticed that the two methods of curing were almost equivalent.

Accuracy of Flexion and Compression Tests

In order to have an idea about the accuracy of the whole experiment (going from weighing and mixing of the components to the testing of the mortars) some samples with identical composition were made at different times, following exactly the Belgian specifications mentioned above. The deviations noticed point to inaccuracies inherent to the testing method.

From these "reference" tests the average and the standard deviation were determined. These calculations show on one hand the spreading of the results; on the other hand they offer a criterion for the real meaning of a difference in strength between samples made at different times.

In order to determine the *absolute* standard devia-

tions (S) for each group of results (flexural strengths after 3, 7 and 28 days, and compressive strengths after 3, 7 and 28 days) the differences (d) between each result (n per group) and the corresponding group average are calculated according to the following formula:

$$S = \sqrt{\frac{\sum d^2}{n}}$$

The following *proportional* standard deviations (S') were found:

	3d	7d	28d
flexion	17.7%	10.9%	10.7%
compression	6.9%	8.6%	9.7%

Systematic Investigation about the Influence of the Different Components and about the Optimum Composition

Several introductory tests have shown that the optimum composition has to be found between the following values of the different components:

Anhydrite/slag ratio between 45/45 and 50/40
$Ca(OH)_2$-percentage between 1.0 and 1.5
K_2SO_4-percentage between 0.9 and 1.2
Aluminous cement between 5 and 9%

In order to determine narrower and more precise limits for the optimum composition and to have at the same time a clear picture of the influence of the different components on the strength, the principal combinations of the compositions of the different components, mentioned above, were tested:

A/S: Anhydrite/Slag ratio: 45/45 and 50/40
C: $Ca(OH)_2$-percentage: 1.1%, 1.2%, 1.3% and 1.4% (+1.5% for the A/S ratio 50/40)
K: K_2SO_4-percentage: 0.9%, 1.0% and 1.2%
Al: Aluminous cement: 6%, 7% and 8%.

The samples are numbered X1 to X48 for the A/S ratio 45/45, and X49 to X108 for the ratio 50/40.

Results: Flexion and Compression Strengths (after 3, 7, and 28 days)

Flexural and compressive strengths of the smaples X 1 to X 108 are listed in 9 tables.

Some other tests were made after 56 days: the average increase of the compressive strength with respect to the strength after 28 days was of the order of magnitude of 10%.

Discussion of the Influence of the Different Components

Influence of the Quantity of Aluminous Cement

From the Tables 1 to 9 we can conclude:

Table 1.
A/S: 45/45
$Ca(OH)_2$: 1.1%

No	Composition					Flexural strength kg/cm²			Compressive strength kg/cm²		
	A(%)	S(%)	C(%)	K(%)	Al(%)	3d	7d	28d	3d	7d	28d

—at short term (after 3 days) the best results are obtained with 6% Al, especially in the presence of much lime.

—at long term (after 28 days) the best results are obtained with 8% Al, especially in the presence of not too much lime.

—at medium term (after 7 days) the samples do not show any significant difference in strength according to the content of aluminous cement.

Influence of the Quantity of Hydrated Lime

The effect of the lime seems to be influenced by the anhydrite-slag ratio, so that two cases have to be discerned:

a. 45/45 ratio:

—at short term a maximum strength is obtained

Table 2.

with 1.3% $Ca(OH)_2$. Less lime is worse, and also more lime has a weakening effect.

—at long term, no important differences have to be noted, unless a small increase of the strength with decreasing $Ca(OH)_2$-content.

b. 50/40 ratio:

Now, the differences are bigger, but always in the same direction.

—at short term 1.4% $Ca(OH)_2$ gives the best results, particularly in the presence of much K_2SO_4 (1.1 to 1.2%).

—at long term, the use of much lime seems to be fatal. Samples with 1.1% $Ca(OH)_2$ give the best results. The following conclusion can hence be taken: much lime causes high mechanical strengths after 3 days, and small quantities of lime do the same after 28

days.

Influence of the Quantity of K_2SO_4

Here also, the effect is somewhat different according to the anhydrite-slag ratio:

a. 45/45 ratio:

—at long term, the strength increases with the K_2SO_4-content.

—at short term, the strength also increases with the K_2SO_4-content, but this time a maximum strength is obtained for 1.1% K. 1.2% K gives worse results.

b. 50/40 ratio:

—at short term 1.2% K is the best percentage to be used, especially in the presence of a high $Ca(OH)_2$-content.

—at long term, there seems not to be an influence of

the K_2SO_4-content in the presence of 1.1 to 1.2 $Ca(OH)_2$. However, stronger mortars are obtained with increasing K_2SO_4-content in the presence of 1.3 to 1.4% $Ca(OH)_2$.

Conclusion: a large quantity of K_2SO_4 is always favourable, except for an A/S ratio 45/45, tested after 3 days.

Influence of the Anhydrite-Slag Ratio

First of all there is the influence of this ratio on the effect of the other components, as discussed in the previous paragraphs.

On the other hand, we can establish that about 90% of the samples made with a 50/40 anhydrite/slag ratio are stronger than the corresponding samples

made with a 45/45 ratio. The superiority of the 50/40 samples with respect to the 45/45 samples goes from 20% for a lime content of 1.1% to 5% for a lime content of 1.3%, as can be seen in Fig. 1, which shows the mean value of the compressive strengths after 3, 7 and 28 days as a function of the A/S ratio and the $Ca(OH)_2$-percentage.

The Optimum Composition

If we want to conclude from the previous paragraphs as to the optimum composition, we are faced with two difficulties:

—first of all, the influence of a specific component can not be predicted without taking into account the quantities of the other components in the cement. In other words, as to the strength of the sample, the complete composition has to be seen as a whole.

—secondly, the conditions to have a strong sample at short term contradict those to have a good sample at long term. Very rare are the samples which give good results after 3 and after 28 days. For these reasons, the optimum compositions at short and at long term will be discussed separately.

The Optimum Composition for Strong Samples at Short Term

The highest mechanical strengths after 3 days are obtained with a 50/40 anhydrite/slag ratio, independently of the other components.

—secondly it has been noticed that a small percentage of aluminous cement gives the best results after 3 days. In the systematic research about the influence of the different components not less than 6% aluminous cement has been used. Therefore, later on, some samples with only 5% aluminous cement were made: unfortunately, the mechanical strength decreased at short term, whereas at long term the samples could only be considered equivalent to those with 6% Al.

—by using a 50/40 anhydrite/slag ratio, it has been found advantagous to add up to 1.5% $Ca(OH)_2$. Even compressive strengths of 80 kg/cm² were obtained, which are the highest ones ever gotten during our study of anhydrite cement.

—it can hence be stated that a strong sample at short term should have the following composition:

Anhydrite-slag ratio:	50/40
Aluminous cement:	6 to 7%
$Ca(OH)_2$:	1.5%
K_2SO_4:	1.2%

(the compressive strength after 28 days has a value of 400 kg/cm²).

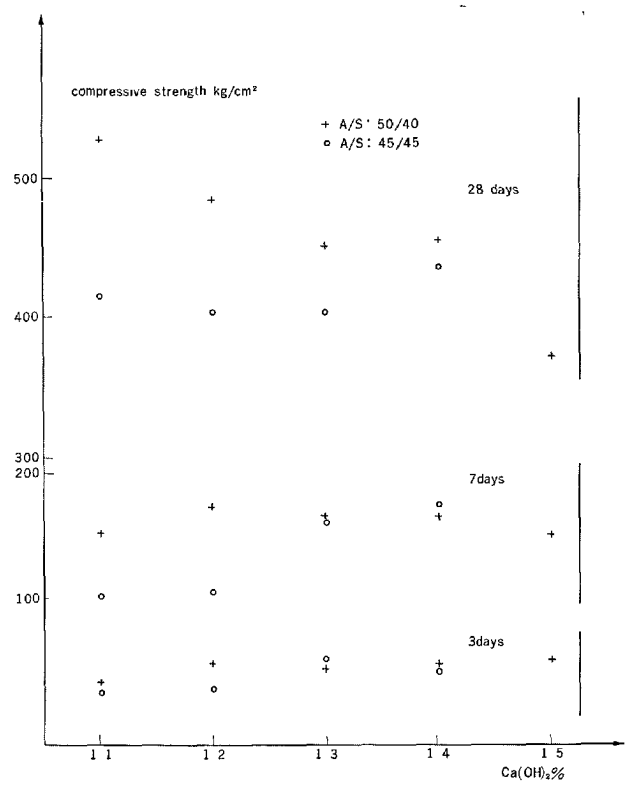

Fig. 1. *Mean value of the compressive strength as a function of the composition of the anhydrite cement.*

The Optimum Composition for Strong Samples at Long Term

According to the tests compressive strengths higher than 550 kg/cm² after 28 days can be obtained with the following composition:

Anhydrite-slag ratio:	50/40
Aluminous cement:	8%
$Ca(OH)_2$:	1.1%
K_2SO_4:	1.2%

The Optimum Composition for Strong Samples after 7 Days

Out of the tables it can be seen that, after 7 days, the compressive strength is higher than 180 kg/cm² for the optimum composition after 3 days, mentioned above, and for the following one:

Anhydrite-slag ratio:	50/40
Aluminous cement:	6%
$Ca(OH)_2$:	1.2%
K_2SO_4:	1.0 to 1.2%

(after 28 days the compressive strength amounts to 540 kg/cm²)

Standard Specifications and Comparisons with Portland Cement

Flexion and Compression Strength

The Belgian standard specifications for flexural and compressive strengths (NBN 178.53) of plastic mortars (Rilem-Cembureau method) on a base of portland cement are formulated for final approval as follows:

	3d	7d	28d
Flexion strength kg/cm²	—	30	50
Compression strength	—	160	300

The following compositions meet the standards: with an A/S ratio of 45/45:

—some with a $Ca(OH)_2$-content of 1.3%, when the K_2SO_4-percentage amounts to 1.2%

—all with a $Ca(OH)_2$-content of 1.4%.

with an A/S ratio of 50/40:

the largest part of the compositions with $Ca(OH)_2$-contents equal to 1.2, 1.3 and 1.4%.

Our results after 7 days are up to 30% higher than the standards as far as the flexural strength is concerned, and up to 20% as far as the compressive strength is concerned; after 28 days the percentages can even reach the values of 50% and 90%, respectively.

Setting Times (NBN 178.31) and Soundness (NBN 178.32)

The proposed Belgian standards stipulate that the initial setting time of portland cement should not be less than 90 minutes, but not be more than 10 hours. As far as the soundness is concerned, the increase of distance separating the indicator points of the apparatus for conducting the "Le Chatelier" test may not exceed 3 mm.

Some figures for anhydrite cement are given below:

	sample X 28	sample X 104 (much lime)
standard consistency		
NBN 178.30: % water	38	37
setting times		
NBN 178.31: initial	5h	5.15h
final	9.35h	7.35h
soundness		
NBN 178.32		
Le Chatelier test	0.9 mm	1.7 mm

Anhydrite cement also conforms to these standards of portland cement.

Supplementary Paper IV-128 Chemistry of Slag-Rich Cements

Julie C. Yang*

Synopsis

The hydration studies of slag-rich cements has been studied with emphasis on the effect of cement composition and curing conditions on strength properties and chemical stability of cement products. Blast furnace slag cement, composed of about 75 per cent finely ground granulated slag powder and 25 per cent portland cement is suggested for structures cured either under high-humidity atmospheric pressure or autoclave conditions including asbestos-cement building products, whereas supersulphated cement is recommended for air-cured massive structures or other applications requiring good sulphate resistance.

Introduction

Granulated blast furnace slag is known to have hydraulic activity. When it is finely ground and mixed with activators, it can be made into a cement for construction work. Slag-rich cements consist of a finely powdered mixture of a high percentage of granulated blast furnace slag, and alkaline activators such as portland cement clinker, portland cement, or calcium hydroxide. In the case of supersulphated cement, dehydrated gypsum (anhydrite) is added with the alkaline activators.

Because of its excellent resistance to chemical attack (1–9), and its low heat of hydration (10–12), many successful structures have been constructed with slag cements in Europe during the past fifty years. Slag-rich cements are claimed to be more resistant to sulphate attack than Type V portland cement (13–15). Its resistance to inorganic acids and food wastes makes it particularly suitable for sewers which carry such effluents, and it also affords some protection against the action of bacteria. Its low heat of hydration makes it particularly suitable for structures requiring large masses of concrete, such as dams, and thick dock walls.

It is intended in this paper to provide basic information on the setting properties and hydration products of slag-rich cements under various curing conditions and an evaluation of its potential in the manufacture of autoclaved building products.

Experimental

Composition

Slag cements employed in this investigation consist of at least 65 per cent by weight granulated blast furnace slag. Two main classes of slag cements are discussed: (a) blast furnace slag cement composed of granulated slag and portland cement, and (b) supersulphated cement. The latter is a mixture of at least 75 per cent of granulated slag, anhydrous calcium sulphate and up to 5 per cent of an activator such as lime, portland cement clinker, or portland cement.

The granulated or quenched slag must consist almost entirely of glass and must have a suitable chemical composition in order to have hydraulic activity. Numerous investigations have been made to correlate the chemical composition and hydraulic activity of slags (16–24). The hydraulic activity of a slag generally rises with increasing contents of CaO and Al_2O_3 and with decreasing contents of SiO_2 and MnO. Parker and Nurse (17) have adopted a formula to determine the quality of slag by a factor M, wherein:

$$M = \frac{CaO + MgO + Al_2O_3}{SiO_2 + MnO} > 1.0 \qquad (1)$$

The oxides are in weight per cent, and the amount of CaO must be corrected for Ca present as CaS. Knowledge of the extent to which MgO can replace

*Research and Engineering Center, Johns-Manville Products Corp., Manville, New Jersey, U.S.A.

CaO and yet maintain a satisfactory cement is rather limited. Stütterheim and Nurse (25) and Stütterheim (26, 27) found that it is possible to make a good hydraulic cement with high-magnesia slags containing 13 to 21 per cent MgO with little or no risk of forming free periclase which might cause disruptive expansion.

Blondiau (28) suggested the composition of a suitable slag for supersulphated cement as one having a CaO/SiO_2 molar ratio of 1.45/1.0 to 1.54/1.0 and a SiO_2/Al_2O_3 ratio between 1.8/1.0 to 1.9/1.0. A SO_3 content of 6 to 9 per cent, corresponding to 10.4 to 15.3 per cent of anhydrite is also desirable for a good supersulphated cement.

Four commercial supersulphated cements and six experimental slag cements made from domestic and foreign slags also were investigated. The commercial supersulphated cements were obtained from Belgium, England, and Germany, respectively. With the exception of the Belgian cement, 3.5 to 5.0 per cent of portland cement was detected in all of the cements. The identification of calcite ($CaCO_3$) and of hydrated lime in trace quantity in the Belgian cement led to the assumption that calcium oxide or hydroxide was the activator.

The experimental blast furnace slag cement was prepared by mixing calculated amounts of preground glassy slag (65 to 95 per cent) and the balance of portland cement. The supersulphated cement composition was 83 per cent slag, 12 per cent anhydrite and 5 per cent portland cement, unless specified. The granulated slags were from Homestead, Pennsylvania; South Works, Illinois (U. S. Steel); Woodward, Alabama (Birmingham Slag Division, Vulcan Materials Company); St. Louis, Missouri (St. Louis Slag Products Company); and Pretoria, South Africa*. These slags were ground to a Blaine fineness of 4200 to 6000 cm^2/g, much finer than regular portland cement, to promote hydration and the development of early strength. The analysis of these slags and of the commercial cements are listed in Tables 1 and 2, respectively.

Sample Preparation for Hydration Studies at Atmospheric Pressure

Slag cement pastes with a water/solid ratio of 0.60 were prepared with boiled distilled water to minimize the contamination by CO_2. Twenty gram samples were sealed in polyethylene bottles and allowed to hydrate for 24 hours to 60 days at 23 ±2°C in a tumbling device. Other samples were hydrated at various temperatures and times in a CO_2-free atmosphere. After the reaction periods had been completed, the materials were filtered, washed with acetone, and dried in a vacuum desiccator over Ascarite and calcium chloride.

*Courtesy of Dr. N. Stütterheim, South African Council for Scientific and Industrial Research, Pretoria, South Africa.

Sample Preparation for Hydration Studies under Hydrothermal Conditions

A water suspension of 2 grams of slag cement in 40 ml distilled water was placed in a 100-ml capacity stainless steel autoclave. The assembly was closed and the cement was allowed to hydrate at room temperature for 24 hours. Then the assembly was heated to the desired temperature for the required time and quenched. The product was filtered and dried in the same manner as described in the case of atmospheric pressure.

Sample Examination and Identification

X-ray diffraction diagrams of the partially or completely hydrated samples were obtained with a Norelco diffractometer, using copper Kα radiation. The microscopic examinations were made with a Zeiss polarizing microscope. These methods included examination of thin section by transmitted light and with cross-polarization, and similar examination of powders in oil immersion. In addition, polished sections etched in sulphur were examined by reflected light.

Strength Determinations

Compressive Strength

Compressive strength tests were made on 1-in. cube specimens, each of which initially contained 28 grams of solids. Both room-temperature-cured and autoclaved products were formed from 50 per cent by weight slag cement and 50 per cent silica flour (2600 cm^2/g Blaine fineness). The water/cement ratio was 0.60. The procedure for molding the cube specimens was similar to that of ASTM method C109 for 2-in. cubes. The ASTM method was also employed in some tests.

The room-temperature-cured cubes were kept in a humidity chamber at 90 per cent relative humidity for 28 days at 23 $\pm$2°C; the autoclave-cured cubes were kept under the same conditions for 24 hours and then treated hydrothermally for 16 hours at either 170°C or 182°C and their corresponding saturated steam pressures. The specimens were saturated by immersion in water for 24 hours at 23 $\pm$2°C and then broken for their compressive strength on a 60,000-lb Baldwin universal testing machine. Each value was the average of ten cubes.

Flexural Strength

Flexural strength was determined using asbestos-cement specimens 3 × 8 × 1/4-in., prepared from a mixture containing a special chrysotile asbestos fiber blend (from Johns-Manville Jeffrey mine, Quebec, Canada); pulverized sand flour (2600 cm^2/g Blaine); and either portland cement (Type I, 3650 cm^2/g Blaine fineness) or slag-rich cement.

The formulation usually consisted of 20 per cent by weight fiber with the balance varied in composition as specified, but expressed in terms of silica/cement ratio. For example, for a composition with 20 per cent fiber, 30 per cent silica, and 50 per cent slag cement, the silica/cement ratio is 0.60. The weight of the original solids per sample was 150 grams.

A liter of water was added to the premixed dry blend and stirred vigorously for one minute at 500 rpm. The slurry was filtered, tamped, and pressed in a confined mold at 10,000 psi for 10 seconds. The samples were cured in the same fashion as the cubes and tested for flexural strength according to ASTM C223–55 method. For each composition, the modulus of rupture (in psi) was computed from the average of four samples.

Strength Determinations of Asbestos-Cement Pipe

Methods covering the strength tests of asbestos-cement pipe are described in detail in ASTM method C500.

For a 6-inch diameter, 10-ft class 150 pipe, flexural strength was determined on a 9-ft span with third point loading for a 5-second dwell period. Hydrostatic strength was tested to an internal pressure of 525 lb for a 5-second dwell time, and crush strength was determined by crushing 1-ft section under load on a 60,000-lb Baldwin testing machine.

Setting Property Determinations of Asbestos-Cement Compositions

Rate of setting of hydraulic cement is determined by measuring the plasticity of an asbestos cement specimen. The measurement is also an indicator of the shape-retaining characteristics of a product, and is employed to determine the effectiveness of accelerators.

In the laboratory, oblong specimens 3 × 8 × 1/4 inches were prepared as described in the section of flexural strength. An accelerator solution, if needed, was poured over the sample prior to pressing. The pressed sample was then transferred immediately to test equipment which measures the deviation from

horizontal under a given load at a specific time. A span of 6 inches and a load of 140 grams were employed for all the determinations.

For large-diameter pipe, the linear deformation (out-of-roundness) was measured when a 1-ft pipe section of about 2-hour age was placed between two steel plates of a press to which a given load was applied.

Results and Discussion

Cement Hydration and Setting at Atmospheric Pressure

When blast furnace slag cement is in contact with water, glassy slag particles release Ca^{++} ions to the solution. Calcium hydroxide, liberated also from the hydration of the activator portland cement, reacts with the colloidal acid hydrates on the surface of the slag grains to form hydrated calcium aluminates, silicates, and hydrogarnets (29–32). Composition of the calcium silicates depends upon the CaO concentration in the solution. At low CaO concentration, CSH-I* (0.8–1.5 $CaO \cdot SiO_2 \cdot XH_2O$) will form, and if the CaO content exceeds 0.020 mol/liter according to Taylor (33), CSH-II (1.7–2.0 $CaO \cdot SiO_2 \cdot XH_2O$) will be obtained.

Hydration of supersulphated cement takes place when the colloidal acid hydrates react with the available $CaSO_4$ in a high Ca^{++} ion concentration to form calcium sulfoaluminates (31, 32, 34).

X-ray diffraction and microscopic identification of the hydrated products of experimental blast furnace slag cement and a British supersulphated cement at atmospheric pressure are presented in Tables 3 and 4, respectively. In a slag-rich cement concrete or mortar, whether it is composed of a blast furnace slag or a supersulphate cement, if sand or fine quartz powder is added as filler or aggregate, there is no evidence of chemical reaction between the cement components and quartz at room temperature. The data of Table 4 are typical for all the supersulphated cement investigated including the experimental cements.

The main hydration products of the blast furnace slag cement containing 25 per cent portland cement are found to be CSH-I and C_4AH_{13} or its solid solution with 3 $CaO \cdot Al_2O_3 \cdot CaCO_3 \cdot 12H_2O$ at ambient conditions; tobermorite and some hydrogarnet phases at elevated temperatures. The slag cement made with high magnesia slag content of 14.6 per cent (Pretoria Slag) showed no detectable free MgO or $Mg(OH)_2$ upon hydration.

Hydration of supersulphated cement yielded a very poorly crystallized ettringite (3 $CaO \cdot Al_2O_3 \cdot 3CaSO_4 \cdot 31H_2O$) after 15 to 20 minutes which was developed subsequently into a well-crystallized material, probably a mixture of ettringite and its solid solution in which Al^{+3} ions were isomerically replaced by Fe^{+3} ions or $CaSO_4$ replaced by $Ca(OH)_2$ or $CaCO_3$. The monosulphate salt (3 $CaO \cdot Al_2O_3 \cdot CaSO_4 \cdot 12H_2O$) was found in some samples, especially when the hydration was carried out at 75 to 80°C, but not consistently. Gypsum ($CaSO_4 \cdot 2H_2O$) was also found in small quantities in short-term hydrated products. In a 28-day hydrated sample, ettringite was present in fine needle-like crystals, exhibiting a low birefringence, a mean refractive index of 1.48, and a CSH-I binding gel. (Fig.1). An increased amount of ettringite with improved crystallinity was obtained with prolonged reaction time or with increasing temperature up to about 50°C. Unreacted slag particles were still quite abundant in this temperature range.

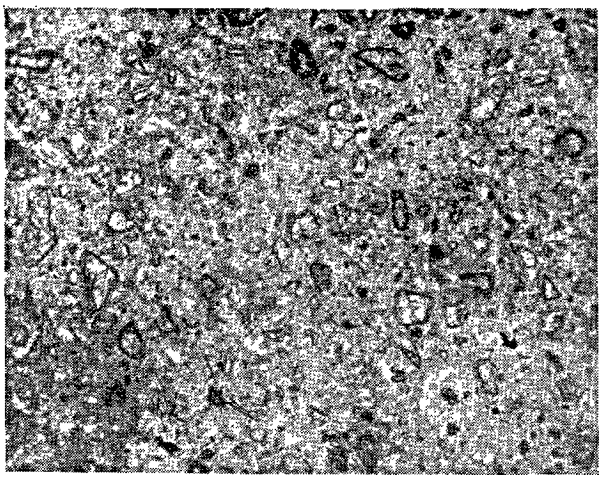

Fig. 1. *An English supersulphated cement hydrated at 23 ± 2°C, 90% RH for 35 days (thin section)* (×200)

Increasing temperature above 50°C resulted in a gradual decomposition of ettringite to calcium aluminate hydrates, probably C_3AH_6 and anhydrous calcium sulphate ($CaSO_4$); no gypsum was detected. Hydration at 95°C resulted in the formation of tobermorite ($C_5S_6H_5$) and also the appearance of poorly-defined hydrogarnets presumably in the solid solution series of C_3AH_6–$C_3AS_nH_{2(3-n)}$ where $0 < n < 3$. Strätling compound (35–37), or gehlenite octahydrate (C_2ASH_8) was not detected in any of the hydrated pastes.

The rate and extent of hydration reactions are determined by the characteristics of the calcium sulphate present (a predominant factor in supersulphated cement), temperature, and rate of release of acid hydrates (hydrated alumina and silica) and other components from the slag cement (38–40).

The good sulphate resistance of the slag-rich cement product is attributed to the absence of free $Ca(OH)_2$ in the set cement and the low C_3A content in the minor portland cement component. Furthermore, the low heat of hydration of the slag cement permits the construction of water-impervious massive structures which are free of cracks—an important feature for structures exposed to sea water or underground aggressive surroundings (41).

Structures made of slag-rich cement should be cured under highly humid conditions, especially the first 2 to 3 days, to prevent surface carbonation and drying out which cause "dusting" (42) and low strength. Most of the well-cured specimens were very dark, usually bluish grey in color when they were freshly cured; and, in aging, the color of these products lightened as a result of oxidation of colored polysulphides to corresponding sulphates.

Blondiau and other researchers (3, 5, 6, 7, 13, 14 and 15) have independently carried out long-term corrosion tests with an air-cured slag-rich cement specimen. They found that in aggresive solutions, such as 2 to 5 per cent solutions of Na_2SO_4, $MgSO_4$ or $(NH_4)_2SO_4$, triple-strength sea water and 0.25 per cent sulphuric acid at a pH of approximately 1.3, slag-rich cements (with slag content greater than 65 per cent) showed better chemical resistance than the portland cement specimens used in the studies. However, the reactivity of ettringite, one of the main hydration products of air-cured, supersulphated cement, in contact with weak inorganic mineral acid of 0.5 per cent concentration or more, or on long period exposure of more than eight years (43), or to high concentration of organic acid generated from food and waste, cannot be ignored.

Previous findings by the author (44) showed that a synthetic ettringite reacted with these media slowly to form insoluble calcium salts such as gypsum ($CaSO_4 \cdot 2H_2O$); calcium citrate tetrahydrate [$Ca_3(C_6H_5O_7)_2 \cdot 4H_2O$]; or partially soluble acetate

$[Ca(C_2H_3O_2)_2]$ and lactate $[Ca(C_3H_5O_4)\cdot 5H_2O]$.

Cement Hydration Reactions under Hydrothermal Conditions

The hydration of slag-rich cements under hydrothermal conditions up to 300°C was investigated to determine the possibility of accelerating the rate of setting, of providing adequate strength in a short period of curing, and of forming compounds of high chemical stability.

When the supersulphated cement paste was subjected to temperatures above 100°C at saturated steam pressure, ettringite and calcium monosulphoaluminate could not be detected by an instrumental method. The slag particles in the cement autoclaved at 170°C, 100 psi or higher temperature and pressure exhibited some thin reaction rims, as shown in Fig. 2. The mean index of refraction of the gel matrix was 1.54. X-ray diffraction examination revealed the presence of $CaSO_4$, tobermorite and a weak pattern of hydrogarnets.

Blast furnace slag cement hydrated under similar hydrothermal condition to form tobermorite and hydrogarnets as shown in Table 5.

Anhydrite ($CaSO_4$), which was originally present in the supersulphated cement, probably reacted partially when the cement was in contact with water to form ettringite prior to the hydrothermal treatment. When the product was autoclaved, ettringite decomposed to yield fine crystalline $CaSO_4$, which recrystallized during the hydration process and grew to crystals up to 20 microns, as observed by microscopic methods.

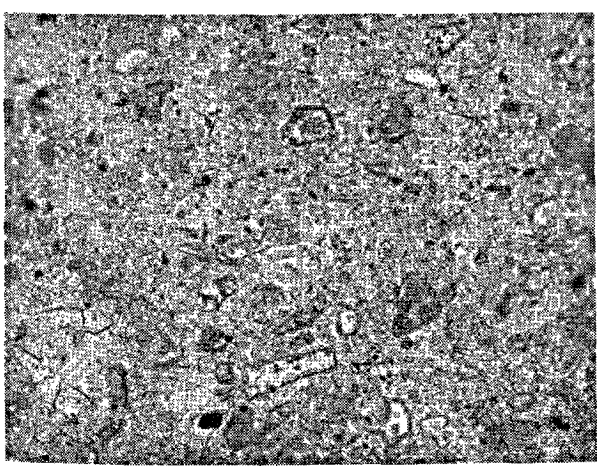

Fig. 2. *An English supersuphated cement autoclaved 5 days at 225°C, 345 psi (thin section)* (×200)

Since anhydrite is not a strength-contributing binder by itself, and ettringite is neither stable nor formed under hydrothermal conditions, the presence of a large amount of $CaSO_4$ in a cement is not desirable if the cement will be subjected to an autoclave cure. In addition, the free $CaSO_4$ present in a set product may slowly react with the hydrated slag components to form ettringite which results in volume expansion and cracking with age. Consequently, blast furnace slag cement is preferred for autoclave-cured products to the supersulphated cement

Hydrogarnet formation is highly desirable for sulphate resistance and high resistance to carbonation (13, 43, 45). The diffraction peaks of the hydrogarnets gradually shifted, indicating a lower cell constant, at higher temperature autoclaving in addition to the improved crystallinity, presumably attributable to a lower water content and higher silica content (46, 47).

The unit cell dimensions of the hydrogarnets were computed and are listed in Table 6.

As autoclaving temperature approaches 225°C, the gel matrix of the product became coarser and more granular than that of the low-temperature treated specimen. Noted difference in the appearance of the binding gel was observed in Figs. 1 and 2, and the slag grains of the higher pressure autoclaved products were surrounded by thicker reaction rims. X-ray examination showed a distinctive hydrogarnet pattern in the specimen of Fig. 2 which has been reacted 5 days at a temperature of 225°C. The hydrogarnet formed resembled plazolite, $3CaO \cdot Al_2O_3 \cdot 2SiO_2 \cdot 2H_2O$, (48, 51) a cubic mineral which has a unit cell dimension a = 12.14 Å and a refractive index of 1.675. Synthetic plazolite with the same unit cell constant was prepared hydrothermally as a standard for comparison from a pure C_3AS_2 glass autoclaved at 250°C, 580 psi for 12 days.

Few unreacted slag grains remained after autoclaving for 24 hours at 225°C or above. At 300°C and its saturated steam pressure the hydrogarnet formed resembled hibschite, especially at long reaction periods of 10 to 14 days, a natural mineral which has the same theoretical composition and crystal habit as plazolite, but differs in optical properties and unit cell dimensions. The lattice constant of hibschite has been reported as 12.00 $\pm$0.02 Å, the refractive index is (n) = 1.681 (48). Pabst (52) and Cornu (53) observed independently that the cloudy nuclei of hibschite crystals had a higher refractive index than the crust and had slight birefringence. This suggested that the nucleus of hibschite probably contains some iron; otherwise the mineral is nearly identical in composition to plazolite. The chemical analysis by Belyankin and Petrov (54) indicated the presence of about 4 per cent Fe_2O_3 in hibschite. In autoclaving slag-rich cements in this p-t range, it is probable that a small amount of iron, from either the slag or the added portland cement, entered into the hydrogarnet structure and promoted the formation of a hydrogarnet of low unit cell dimension resembling hibschite. Without iron, the hydrothermal treatment of a pure C_3AS_2 glass, even at a higher temperature (354°C, 2500 psi) for 15 days, yields a product with a unit cell dimension a = 12.07 Å (55).

In autoclaved-cured portland cement products, it is a common practice to add silicon flour (quartz) to reduce the free calcium hydroxide content by forming calcium silicate hydrates and to increase strength. Even though the slag-rich cements contain a small amount of free calcium hydroxide which is released by the activator upon hydration, addition of silica to the cement increased strength as well as lowered cost.

Data in Table 5 show that increasing the amount of silica flour of 2600 cm²/g Blaine fineness added to the cement reduced the tendency of forming hydrogarnets. The molar ratio of CaO/Al_2O_3 in the hydrated binding gel decreased gradually with increasing amount of silica because of the ease of interaction of calcium hydroxide and the silica to form CSH compounds. When the added silica exceeded about 30 per cent of the total weight, no hydrogarnet was detected by X-rays, and the CSH compounds were in predominant quantities. The X-ray pattern of the "CASH" gel was very similar to tobermorite; a noted decrease in intensity of 2.81 Å and a shift of 11.1 Å to 11.6 Å were observed. This indicated the introduction of Al_2O_3 into the tobermorite lattice (56), the presence of Al_2O_3 inhibited the formation of xonotlite. Petrographic examination of thin sections of an 100psi, 16-hour autoclaved blast furnace cement mortar showed a very fine-grained binding gel surrounded the quartz and glass particles. The mean refractive index of the binding gel was in the range of 1.53 to 1.56.

Effect of Cement Composition and Curing Conditions on Strength and Possible Applications

The strength of supersulphated cement cured under atmospheric pressure has been discussed in many technical articles, the general consensus indicated that even after seven days moist air and under water curing at 18 to 25°C, the compressive strength of concrete cubes made with supersulphated cement was about 20 to 35 per cent lower than that of the corresponding portland cement specimens, but at the end of 28 days, the supersulphated cement mortar showed high strength (57–60). Our evaluation, as shown in Table 7(a) indicated that even at 28 days, the compressive strength of portland cement is still considerably higher. If the slag with high magnesia content (such as Pretoria slag) is employed to make supersulphated slag cement, it has to be ground to about 6000 cm²/g Blaine fineness in order to have a product of comparable strength to those cements composed of slags of low magnesia content (<6 per cent MgO) at 4500 to 5000 cm²/g, and to pass the ASTM Specification for Type IS portland-blast furnace slag cement (C 205) or (C 358) for Type S cement, or (C 150) for portland cement, since no specification has been set for supersulphated cement

by ASTM.

The possibility of employing supersulphated cement compositions in autoclaved products was also investigated to secure the advantage of a shorter curing period and less storage space for the in-process material. The compressive strength data of Table 7(a) show that for all the mortar tested. the autoclaved products exhibit better strength than the air-cured specimens, but is still 25 per cent or more lower than the corresponding autoclaved portland cement products. This is assumed due to the presence of a considerable amount of non-strength contributing $CaSO_4$.

Compressive strength of 2-in. blast furnace slag cement cube specimens were also evaluated. A composition of 75 per cent slag and 25 per cent portland cement cured for 7 and 28 days showed equal or better strength than that of portland cement. Accelerators can be employed to promote early strength of the slag product and ease of handling in replacing superfine grinding (61–63). Results in Table 7(b) indicate the effectiveness of calcium chloride. Autoclaving of blast furnace cement of the same composition is

definitely favored, as shown also in Table 7(b); a high-strength product can be achieved.

The application of slag-rich cements in autoclaved asbestos-cement building products was studied. In these products, asbestos fibers are employed for reinforcement and to impart a measure of flexibility to the material. No chemical reaction could be detected by any instrumental means between asbestos fiber and the slag cement, either under air-cured or under hydrothermal conditions, up to 200°C for 24 hours.

Flexural strength was measured for specimens consisting of 20 per cent chrysotile fiber blend, 40 per cent silica flour, and 40 per cent slag-rich cements. The composition was chosen on account of strength properties (as shown in Table 8(a)) and cost considerations. The autoclave conditions studied were in the saturated steam pressure range of 100 to 150 psi. The reference sample was composed of 20 per cent fiber blend, 30 per cent silica and 50 per cent Type I portland cement, (an established optimum formulation for autoclaved product evaluation at Johns-Manville Products Corporation), which has been autoclaved for 16 hours at 100 psi. A photomicrograph, Fig. 3, shows a thin section of an 150-psi autoclaved product. The majority of the slag particles had reacted and disappeared in the gel, and the remaining slag grains showed very distinctive interfacial reaction. By means of point-count determinations, it was estimated that about 75 to 80 per cent of the slag present was reacted in the autoclaved

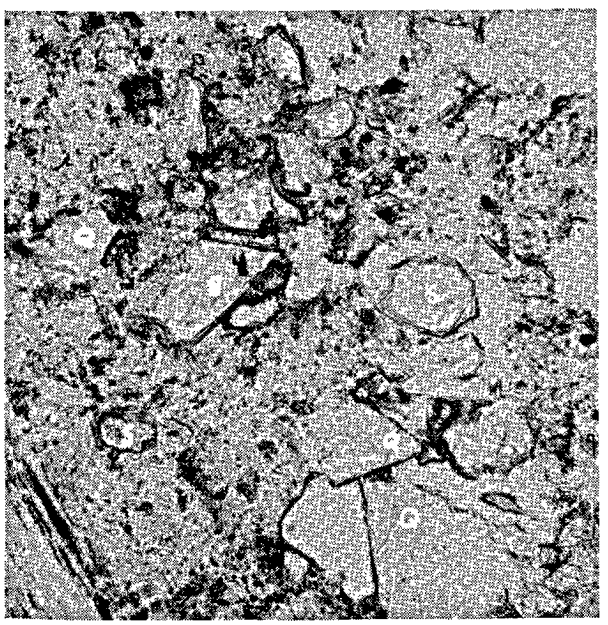

Fig. 3. *An autoclaved asbestos-blast furnace cement product cured for 16 hours at 172°C, 111 psi*
In the thin section unreacted slag grains (S) and quartz (Q) and fiber (F) are noted (×500)

asbestos-cement specimens, and only about 25 to 30 per cent reacted in the 28 day air-cured products.

The data tabulated in Tables 8(b), 8(c), and 8(d) indicated that optimum strength can be achieved with a cement consisting of 75 per cent blast furnace slag powder (4500–5000 cm^2/g) and 25 per cent portland cement at autoclaving pressures 100 to 125 psi. As curing pressure approaches 150 psi, the composition with more portland cement (around 35 per cent) is favored.

* Blast furnace slag cement composition:
75% St. Louis slag (5200 cm^2/g Blaine) + 25% Type I portland cement (3650 cm^2/g)
**Na_2SiO_3 was sprayed on the wet sheet of asbestos-slag cement-silica furnish at 2.5 gal/min corresponding to 0.8% Na_2SiO_3 based on dry solid. Excess entrained water was removed under reduced pressure prior to the accumulation and integration of rolling layers of materials upon themselves on a mandrel under pressure to form pipe (61).

Effect of intergrinding slag and portland cement clinker was studied. However, due to the abrasiveness and hardness of the granulated slag, portland cement clinker was ground to a much finer size in the process than the slag. As a result a slag cement will have poor hydraulic strength in comparison with a slag cement composed of separately ground components.

The slag-rich cements were further evaluated in pilot plant and production as in an actual asbestos-cement pipe product. The mechanical strength data, as shown in Table 9, and setting property determinations (Table 10) demonstrated that satisfactory autoclaved formulation can be achieved when portland cement is replaced by a blast furnace slag cement.

Chemical abrasion-corrosion tests for soft water and dilute sulphuric acid were conducted. Results in Table 11 and Fig. 4 showed the soundness of using

Table 11. *Abrasion—corrosion resistance of autoclaved asbestos-cement pipe products*

Test group	Asbestos cement pipe composition (%)				Testing condition				Rate of abrasion (inch/24 hr)	X-ray and microscopic identification of inner surface (1-2mm)
	Class	Asbestos fiber	Cement	SiO_2/Cement	Sample	Solution	Time (hr)	Rolling rate (rev/hr)		
1	6 in. 150 Pressure	20	Portland	0.6	Sections cemented together	0.5 N H_2SO_4	336	4800	—	High gypsum content, some swelling

blast furnace slag cement in an asbestos-cement product.

Summary

The hydration of supersulphated cement and blast furnace slag cement under atmospheric pressure

and hydrothermal conditions has been investigated. Ettringite and tobermorite-like CSH-I are found to be the main binders in the supersulphated cement hydrated at atmospheric pressure and temperatures below 75°C, whereas tobermorite-like CSH-I and hydrated calcium aluminate (C_4AH_{13} or its solid solutions) are the main hydration products in blast furnace slag cement under the same conditions.

Under hydrothermal treatment or curing temperature above 75°C ettringite decomposes to $CaSO_4$, a non-strength contributing material. Therefore, supersulphated cement is recommended only for air-cured products requiring good sulphate resistance and massive structures. Blast furnace slag cement, with an optimum composition of 70 to 80 percent granulated slag of around 4500 cm^2/g Blaine fineness and the remainder portland cement, yields hydrogarnets and calcium silicate hydrates (tobermorite or xonotlite or a mixture of both depending upon the autoclaving condition) and is recommended for both air-cured and autoclaved products.

The choice of aggregates employed in these systems depends upon the end applications. In the autoclaved compositions hydrogarnets are formed only when the aggregates do not provide an appreciable amount of active silica.

The presence of hydrogarnets presumably improves chemical stability but does not have beneficial effects on strength of the finished material. For high strength requirements, reactive aggregates are preferable. The main binders in the product with the reactive aggregates are hydrated calcium silicates and a tobermorite with aluminum substituted in the lattice.

The results demonstrated the possibility of employing blast furnace slag cement in autoclaved asbestos-cement building products.

Acknowledgement

The author acknowledges Mr. R. L. Blaine of the National Bureau of Standards for providing the German supersulphated cements and to Dr. N. Stütterheim of the South African Council for Scientific and Industrial Research for the supply of high-magnesia slags. Gratitude is expressed also to Dr. W. C. Hansen for his constructive criticisms and to the St. Louis Slag Product Company and Johns-Manville Products Corporation for their permission to make this publication possible.

Supplementary Paper IV-130 A Comparative Assessment of the Resistance of Super Sulphated, Sulphate Resistant Portland, and Ordinary Portland Cements to Solutions of Various Sulphates and Dilute Mineral Acids

George H. Thomas*

Introduction

The study of the resistance of concrete made with various cements to aggressive solution attack has been the subject of numerous studies which have frequently led to differing conclusions.

The present paper records the results of a specific investigation to determine the relative merits of a supersulphated cement based upon a United Kingdom blast furnace slag so as to assess its value in the manufacture of concretes for use in aggressive environments.

Results from three groups of tests are considered:—

Group 1—A laboratory assessment using concrete specimens.

Group 2—An "on site" assessment in an expermiental sewer exhibiting severe acidic conditions.

Group 3—A laboratory study employing miniature microconcrete techniques.

Group 1 Program

The programme required the comparative assessment of the resistance of three different cements to a range of aggressive solutions. The cements used were:—

(1) A supersulphated cement.

(2) An ordinary portland cement with a relatively high C_3A content.

(3) A "low C_3A" sulphate rsistant portland cement.

All three cements were commercial brands made in the north of England. Some difficulty was experienced in selecting a suitable batch of sulphate resisting portland cement for the tests. Two separate consignments exhibited unusually rapid falling off in workability in preliminary testing and were rejected. The batch finally selected behaved normally.

Chemical analyses of all three cements are recorded in Table 1. "Bogue" constitutions were calculated for the two portland cements and these are listed in Table 2. From the values obtained it was con-

Table 1. *Chemical analysis of cements used in the aggressive solution tests*

*Swinden Laboratories, United Steel Co., Ltd., Rotherham, United Kingdom.

cluded that the ordinary portland cement was of high quality but with an estimated C_3A conttent which would render it susceptible to sulphatic attack. The sulphate resistant portland cement results indicated that it was a good quality product in its category.

Aggressive Solution Testing Procedure

As concrete made to resist severe aggresive attack is usually of a fairly rich mix, an aggregate cement ratio of $4\frac{1}{2}$:1 was employed. Owing to the differing water requirements of the various cement, it was decided to use a fixed workability and to adjust the water/cement ratio accordingly. The water/cement ratios used were:—

Supersulphated cement— 0.423
Ordinary portland cement— 0.460
Sulphate resisting portland cement—0.455

All the concretes were machine mixed and hand tamped into four inch steel cube moulds. Specimens were damp air stored in the usual way for the first 24 hours and then water cured for a further 27 days prior to immersing in aggressive solutions or water for control.

The solutions used were:—

(1) Na_2SO_4 (3.5% SO_3)
(2) 〃 (0.35% SO_3)
(3) $MgSO_4$ (3.5% SO_3)
(4) 〃 (0.35% SO_3)
(5) $(NH_4)_2SO_4$ (3.5% SO_3)
(6) 〃 (0.35% SO_3)
(7) H_2SO_4 (2.0% W/V)
(8) 〃 (0.25% W/V)

Assessment of attack was by compressive strength supplemented by visual observation. Four specimens from each solution were tested at each test age. To provide an accurate basis for comparison, twelve water control specimens were also tested at the same intervals.

Originally, it was planned to test the concretes at 3 months, 6 months, 12 months, 2 years and 5 years after immersion. After the two years tests had been completed, however, it became clear from visual observation of the specimens that testing beyond 5 years would be necessary in order to establish the relative merits of the two sulphate resisting cements. Final testing of some specimens were, therefore, delayed until after eight or ten years immersion. Results are summarised in Table 3.

In order to facilitate statistical processing of results, selection of concrete specimens for immersion in the various solutions was made on a statistically random basis as was the selection at each age for testing.

The sulphate and acid solutions were prepared from pure chemicals and were replaced by fresh solutions each month. The ratio of solution/concrete at the commencement of the test was approximately 1: 1 by volume but increased as cubes were removed to a maximum of around 9: 1. The cubes were maintained

Table 3. *Summary of mean compressive strengths for group 1 tests*

	Age of test (Years)	Water	Na_2SO_4		$MgSO_4$		$(NH_4)_2SO_4$		H_2SO_4

in solution in sealed glass tanks to eliminate problems arising from evaporation.

Attack by Sulphate Solutions and Sulphuric Acid

Statistical Analysis

The compressive strength results obtained at all ages up to ten years were subjected to statistical analysis. This consisted of three separate operations:—

(1) The removal of "outliers" from water control results by statistical processing (1). It was found to be theoretically unsound to apply this technique to the removal of outliers from the groups of four cubes immersed in aggressive solutions. However, it proved sound and helpful to use the technique on the groups of twelve water cured "control" specimens. Only one test value out of 180 was, in fact, processed out.

(2) An analysis of each cement was carried out separately and a comparison of the results in each aggressive solution at each age was obtained. The method of statistical comparison employed was the Student test. Figs. 1 to 8 illustrate the results of this

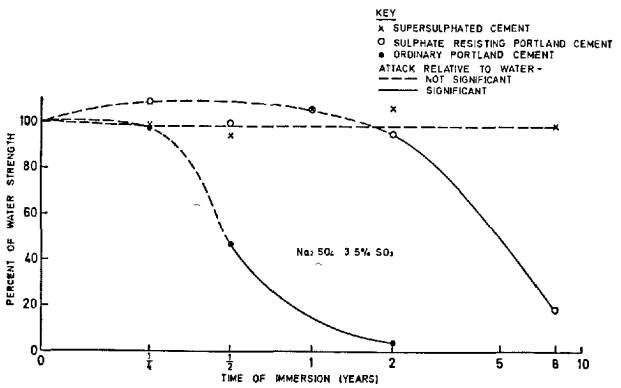

Fig. 1.

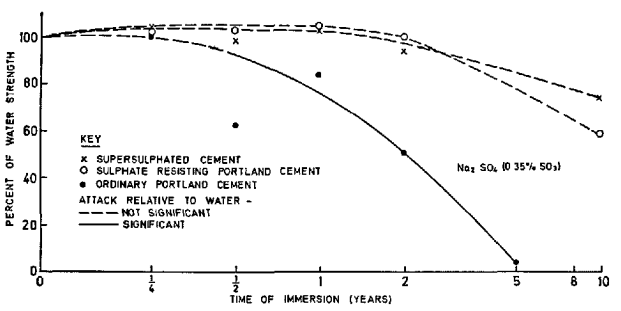

Fig. 2.

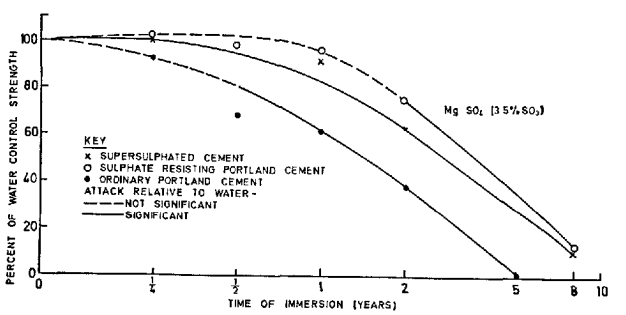

Fig. 3.

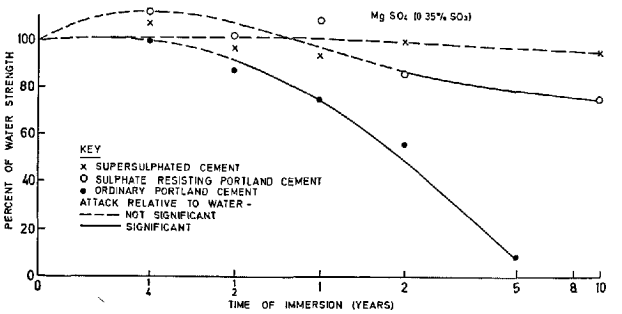

Fig. 4

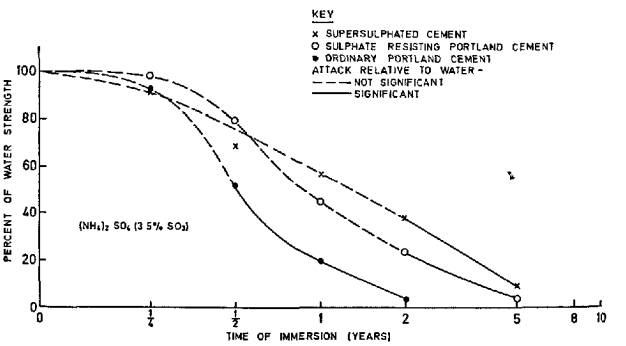

Fig. 5

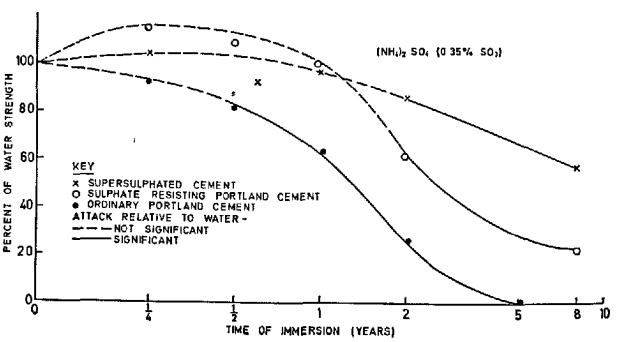

Fig. 6

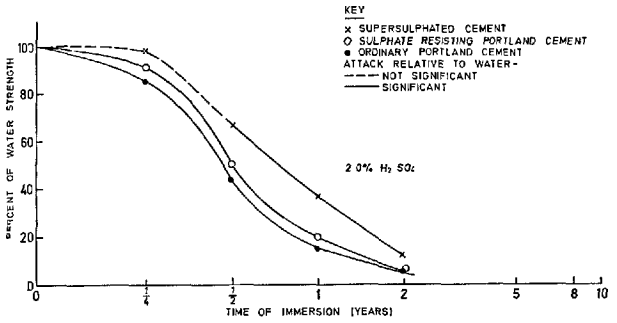

Fig. 7

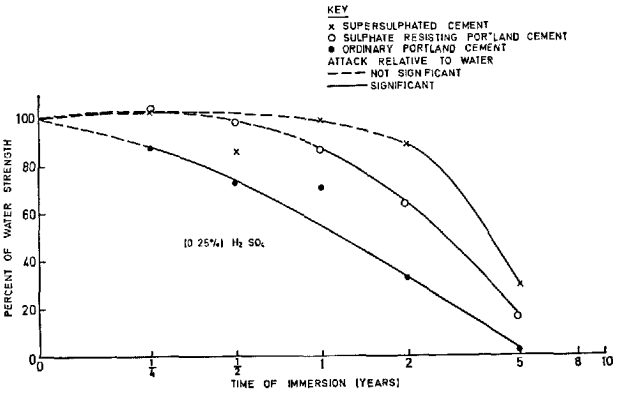

Fig. 8

analysis, the concrete strength in each solution being expressed as a percentage of the equivalent water control strength. The degree of attack expressed in this way is plotted against time on a logarithmic scale and the time at which the attack became significant is indicated.

The comparison is taken one stage further in Table 4. In the first of each pair of columns, symbols are used to indicate when, and to what degree, the attack has become statistically significant. After two consecutive instances of significant attack, the comparison is changed to establish whether or not the attack is continuing and progressive. This is assessed by comparing the respective strengths as a percentage of the water control with the equivalent value for the preceding test age. The results of these statistical tests are summarised in the second of each pair of columns.

(3) For each aggressive solution a comparison was made between the performance of the supersulphated cement and each of the portland cements. The results are summarised in Table 5—a negative sign indicating that supersulphated cement gave an inferior result.

Comparisons within Cements

The main conclusions indicated by analysis of the results may be summarised as follows:—

(1) Ordinary portland cement concrete was attacked by all solutions, in most instances after only a short period of immersion. In each solution the attack had become statistically significant at six months at the latest. In some instances, with the most aggressive conditions, less than half the water control sterngth remained in the solution immersed specimens.

This rapid rate of concrete deterioration was expected and underlines the basic need for cements with a high degree of resistance to sulphates and dilute acidic conditions.

(2) Sulpahte resisting portland cement gave a very much better performance, showing a relatively high degree of resistance to many of the solutions.

Up to two years immersion only the acids and the stronger ammonium sulphate solutions were showing a significant degree of attack but from two years onwards, deterioration became more general and ultimately the concrete was shown to have suffered a significant loss in strength in all test solutions.

(3) The supersulphated cement also demonstrated a high degree of resistance to attack in the early stages. Up to two years, deterioration was only statistically significant in the stronger ammonium sulphate solution and the 2.0 percent W/V acid. Attack by the weaker acid concentration only became significant at two years. It should be noted that although the latter acid concentration may be weak in general chemical terms, it is very much stronger than would normally be encountered in civil engineering.

Again, as with the sulphate resisting portland cement, deterioration became more general after two years immersion. However, even after eight years in the stronger sodium sulphate solution and ten years in the weaker magnesium sulphate solution, no statistically significant attack on the concrete had been recorded.

Comparison between Cements

Supersulphated Cement vs. Ordinary Portland Cement

As may be observed from Table 4, the supersulphated product was significantly superior in resistance to ordinary portland cement in all solutions. After two years immersion and in most instances much earlier, the superiority of the slag based product was obvious.

Supersulphated Cement vs. Sulphate Resisting Portland Cement

Here the position is less clear cut. The main conclusions may be summarised as follows:—

Table 4(1). *Statistical comparison of strengths in solutions versus water control (group 1)*

Key: — As in 4(1).

(1) At early ages in three of the solutions, sulphate resisting portland cement displayed a marginal advantage over supersulphated cement. However, in each case, the situation was reversed with time.

(2) In seven out of the eight solutions, supersulphated cement proved to have, sooner or later, significantly superior durability to the sulphate resisting protland product.

(3) In one instance, the stronger magnesium sulphate solution, sulphate resisting portland cement demonstrated superior resistance to the supersulphated cement when assessed by statistical techniques.

Group 2

Acidic Testing in an Experimental Sewer at Burton-on-Trent, the Acidic Resistance of Supersulphated Cements

Acidic conditions in civil engineering environments are usually of a very low concentration. Ground waters rarely reach pH4 unless industrial pollution increases the acidic concentration (2).

Supersulphated cement is generally considered to have an excellent resistance to these conditions, being recommended to give a good life down to at least pH3.5. Laboratory confirmation of such claims is difficult. An acidic concentration of pH3.5 would be neutralized by concretes very quickly. On the other hand, the constant maintenance of an acidic level by the use of pH control equipment is probably creating conditions which are equally far from practice as the acid levels are almost certainly being replaced at a rate far more frequently than is normal in common usage.

The use of higher concentrations such as in the 'Group 1' tests may give results of some comparative value, but clearly the most valuable test for the acidic resistance of a cement is in the kind of environment for which it may be employed.

At Burton-on-Trent the existing sewerage system has been badly attacked and extensive rebuilding is in progress. The attack is usually attributed to dilute sulphurous and sulphuric acid conditions arising from effluent containing waste materials from the brewing industry. As is common in these situations, corrosive conditions are worst above the water level. pH values of below 3.5 are common and values as low as 1.9 have been recorded on the walls (3).

Prior to redesigning the system a testing programme was organised by the Burton-on-Trent Borough Engineer's Department to evaluate materials which might be included in the programme and three different batches of supersulphated cement concrete were subjected to attack below and above the effluent level in an experimental section of the sewer.

Evaluation of test results were again on the basis

Table 6. *Percent of water control strengths of cubes tested in the burton-on-trent experimental sewer*

		Period of immersion (Months)											
		Over the effluent							Below the effluent				
		11	12	19	30	42	64	79	11	12	19	24	30
Supersulphated cement concrete	*Series 1*	96.2		96.2	84.4		75.1	49.0	98.3		95.2		99.8
	Series 2												
	Series 3												
	(a) Gravel					73.6							
	(b) Limestone					78.2							
Ordinary portland cement			72.0							96.0			
Sulphate resisting portland cement			70.0	58.0						92.0		87.0	

of percent of water control and the results are summarised in Table 6.

The results compare very favourably with the portland cement values carried out independently (3) and confirm the superior resistance of supersulphated cement to either ordinary portland or sulphate resisting portland cements. It must be emphasised that the conditions in the experimental sewer are worse than would be expected in applications for which supersulphated cement would normally be specified. However, the superiority in life over both the portland cements tested is definite and confirms the reported applicability of this cement in weak acidic environments, particularly where acid concentrations are at a more typical level than those experienced at Burton.

Group 3

A method of assessing aggressive solution resistance of cements by the use of microconcrete techniques is being developed based on procedures used at the Cement and Concrete Association's Laboratories. These techniques have the following advantages over larger scale testing:—

(i) Smaller quantities of materials are employed.
(ii) Less storage capacity is required.
(iii) Less time is required to prepare specimens.
(iv) Aggressive solution deterioration is more rapid.

The microconcrete techniques have the following disadvantages:—

(i) A higher degree of skill is required in the preparation of specimens.
(ii) The reproducibility of the test is of a lower order and hence more replicate specimens are required.
(iii) The use of half-inch microconcrete cubes is more remote from practice than the conventional four inch concrete cubes.
(iv) The testing of the specimens requires both more time and more precision on the part of the testing machine operator.

One of the reasons for developing the technique is that it promises to provide a rapid means of assessing aggressive solution resistance of cements.

A series of $\frac{1}{2}$" microconcrete cubes made of cements from the same source but of different batches to those recorded in the full scale test have been made. Sufficient specimens were manufactured for testing 5 replicas at each of 3 ages.

The test procedure involved the mixing by hand manipulation of a microconcrete mix consisting of graded washed silica sand, cement and water in a polythene bag. The microconcrete mix was then compacted by vibration into a 10 gang stainless steel precision mould.

The specimens were demoulded after 24 hours and subjected to the same curing procedure as the full scale specimens before immersion in sulphate solutions.

The aggregate cement ratio was 3: 1 and the water/cement ratio fixed as before, by adjusting for constant workability. The workability level was measured by a dropping ball test and the level of penetration fixed at 3 mms.

The water/cement ratios used were:—

Supersulphated cement	0.433
Sulphate resisting portland cement	0.465
Ordinary portland cement	0.465

As a preliminary examination into the possibilities of the test only 2 solutions were employed:—

Na_2SO_4 at 0.5% SO_3
$MgSO_4$ at 0.5% SO_3

To date results have been obtained up to six months and the results are analysed in Tables 7 and 8. Some initial difficulty was experienced in establishing a satisfactory order of test reproducibility. Subsequently, it was found that the use of "soft" tap water for the water control specimens could lead to

Table 7. *Statistical significance of attack with respect to water control*

	Na_2SO_4		$MgSO_4$

*Specimens in solution completely destroyed.

Table 8. *Statistical significance of attack between cements*

	Na_2SO_4		$MgSO_4$	
	3 months	6 months	3 months	6 months
Supersulphated cement v. ordinary portland cement	*	*	$S^{0.1}$	$S^{0.1}$
Supersulphated cement v. sulphate resisting portland cement	N.S.		N.S	$S^{5.0}$

*O.P.C. specimens compl etely destroyed.

a considerable reduction in strength with time, presumably due to leaching of lime. The latter effect only occurred with the portland cements.

The procedure would appear to be promising as a fairly rapid test of sulphate susceptibility. It is unlikely, however, to be able to define accurately, degrees of resistance.

General Conclusions

In assessing the detailed results, use has been made of statistical techniques in an attempt to differentiate between real effect and experimental variation. It should be noted, however, that statistical superiority or inferiority does not imply satisfactory or unsatisfactory performance or life. In attempting to arrive at the value of a cement for a particular application it is necessary to make use of general trends indicated by the detailed results and to bear in mind not only whether the concrete will be attacked but also its likely residual strength and the rate at which it will deteriorate. From the analysis of results recorded it would appear that the following general guide lines can be drawn as to the applicability of the cements tested:—

(1) In sodium sulphate solutions supersulphated cement gives by far the best performance. It is particularly noteworthy that in the stronger solution, no significant attack was registered even after eight years of continuous immersion. Over the same period the sulphate resisting portland cement had been almost completely destroyed.

(2) In the 0.35% SO_3 Na_2SO_4 solution the advantage for supersulphated cement is less marked but still significant. Clearly either of the two sulphate resistant cements would give a good life.

(3) In strong magnesium sulphate, although the sulphate resisting portland cement gave a statistically significant better performance, in real terms neither cement would appear suitable for use in such high concentrations of this salt.

(4) Magnesium sulphate solution at the 0.35% level is resisted by both cements. Again, the supersulphated cement appears to have a slight advantage in resistance.

(5) In both concentrations of ammonium sulphate, all cements were attacked. Again supersulphated cement gave superior resistance to both the portland cements and in the case of the weaker solution, the order of difference would certainly indicate a considerably extended life.

(6) The reputed superiority of supersulphated cement in weak sulphuric acid concentrations sometimes encountered in civil engineering is confirmed by the results recorded in both Group 1 and 2 tests.

SESSION IV-4 EXPANSIVE CEMENT

Principal Paper Expansive Cements

Peter P. Budnikov and Irina. V. Kravchenko*

Synopsis

The existing expanding cements can be divided into those obtained on the base of aluminous cement and on that of portland cement. In respect to their composition and technology of production they differ both as to the form in which exist the compounds of issue necessary to form calcium hydrosulfoaluminate in the hardening cement paste, and to the technology of producing it. Most investigators are inclined to explain the aptitude of cements to expand by the formation in the hardening cement stone of complex compounds having a complex molecule with a great amount of crystallisation water bound with it and by a directed growth of crystals, in particular of calcium hydrosulfoaluminate. But some authors are inclined to see the cause calling forth an expansion of the cement stone during hardening in the action of osmotic forces or in the swelling of solvable films of the hydrate gels.

We are of the opinion that the phenomenon of expansion is inherent to a certain stage of hardening not only of expanding, but also of ordinary cements, but this expansion is distinguished by its intensivity and time of duration. The hydration products form during the hardening of cement first in the shape of finest crystallisation centres which, as they accumulate, grow out into larger semirigid formations. During further hydration the interstices between the particles are filled up by the hydrates formed, what leads on the one part to a condensation of the cement stone, and on the other to an extension and partial destruction of the crystalline semirigid skeleton. This is why a fine expansion of hardening cement is always accompanied by a certain decrease of its strength.

The technology of expanding cements must secure an intensive formation of a quickly growing expanding component during a certain period of hardening of the cement stone which is characterised by the presence in it of a semirigid structure formed by hydrate new formations. The process of expansion of cement can be controlled by acting on all the factors influencing: 1) the velocity of cessation of hydration reactions, 2) the number of crystallisation centres that appear in a volume unity of the hardening cement, and 3) the rate of growth of the expanding components. Such factors are for instance the composition of the cement, the fineness of grind of its components, the temperature of the surrounding medium, the additions-modifiers of structure of hydrate new formations, etc. Practically the period of extensive expansion of cement stone is 1 to 7 days for different variaties of expanding cements. The practice of many years standing of the production and use of expanding cements in construction work in the U. S. S. R. has shown a great perspectivity of the cements suggested by us.

Introduction

When mixing portland, blast-furnace and alumina cement with water, the dissolution of non-aqueous mineral compounds of a cement takes place at first. This is followed by the formation of hydrates, this providing the binding qualities of the cement paste.

During this process the change of the volume of the hardened cement paste takes place (Fig. 1). The primary contraction of the hardened cement on the section of the curve "$a-b$" takes place due to the sedimentation and dissolution of the non-aqueous clinker minerals. Then, on the section "$b-c$" some growth of the volume of the hardening cement takes place, this being connected with the formation of some hydrates (this process will be discussed below). And,

*Moscow Academy of Science, Moscow, U.S.S.R.

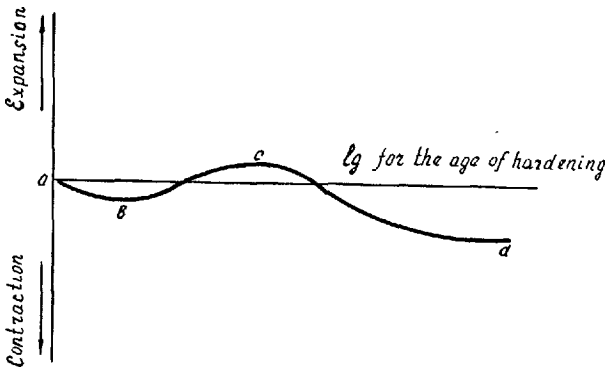

Fig. 1. *The change of volume of cement when hardening*

at last, on the section "$c - d$" the shrinkage of the hardened cement takes place, this being connected with the evaporation of water and consolidation of the geleous mass of the new formations of the hardened cement (1).

As a result of the abovesaid phenomena in mortars and concretes made on ordinary cements, pores, macro- and microcracks form, this worsening the technical qualities of the constructions. The waterproofing of the concrete or mortar, protective features of the concrete layer coating the steel bars, durability and corrosion resistance lower. All this oftenly makes it impossible the use of ordinary shrinking hydraulic cements for monolithic waterproof projects, for rendering joints, hydroisolation, clogging of holes in constructions. Or it brings to the lowering of the quality of construction works.

Therefore it is of no wonder that during the last twenty years a lot of attempts have been made in many countries to develop cements free of the shortage aforesaid, to develop cements not only "non-shrinking" but even expansive ones.

At present there has been a constant, commercial-scale production of three following kinds of expansive cements in the Soviet Union: waterproofing expansive cements (ВРЦ), gypsum-alumina cement (ГГЦ) and expansive portland cement (РПЦ) these having wide spread in construction engineering*.

As far as we know there are two kinds of expansive cements on the U.S. market and deep explorations have been conducted to improve their qualities. In some other countries periodical production of expansive cements and their use in construction takes place as well.

Interesting building qualities of expansive cements, absent in common hydraulic ones, make it profitable for more close consideration of the physiochemical processes taking place during the hardening of these cements and more close study of their features.

Technical Requirements to the Expansive Cements

Various workers in various countries have offered a lot of ways to make expansive cements (3–45). However, the biggest part of these ways has not been commercially introduced through the unreliability and not sufficient reproduction of their technical data, complication of their technology etc.

Principally, the cheapest compounds able to secure the volume increase of the hardened cement paste of expansive cements are the following ones: calcium sulphoaluminate hydrate, magnesium oxide hydrate and calcium oxide hydrate. However, there has not been yet obtained any sound and reliable results when using CaO and MgO as an expansion stimulant and most of the ways offered are based on the formation and rapid growth of the crystals of high sulphate form of calcium sulphaouminate hydrate at the interaction of calcium sulphate with calcium aluminate hydrate.

Various proposals as to the compositions and the ways of making expansive cements differ from each other both by the form the primary compounds exist (these being necessary to form calcium sulphoaluminate hydrate in hardened cement paste) and by the technology of making these cements.

To exemplify this, one may mention that in expansive cements offered in France, Hungary, USA and in some other countries, calcium sulphoaluminate hydrate forms through adding the so called "expanding admixture" in the form of a specially prepared anhydrous calcium sulphoaluminate to the expansive or non-shrinking cement.

One of the expansive cements made in the USSR—is the so called waterproofing expansive cement (ВРЦ), which is obtained by mutual grinding of some components, these containing specially prepared highly basic calcium aluminate hydrate and gypsum hemihydrate. Other kinds of the Soviet expansive cements have no special pre-treatment of their components, this simplifying their technology and lowering the cost.

The method of making expansive cement offered by P.P. Budnikov and B.G. Skramtaev (10) distincts

*Russian letters denote the abbreviations used by the Soviet National Standard—the GOST (ГОСТ)

from the aforementioned methods, this distinction being as follows: alumina cements are ground or blended with either estrich-gypsum or anhydrite cement obtained by mutual grinding of anhydrite with burned dolomite.

W.E. Leyrich has offered the way of making an expansive cement by mutual grinding of alumina and blast-furnace slags with anhydrite and air-slaked lime. Further he, in co-authorship with W. H. Prohorov (7), offered to add the expansive cement of the aforementioned composition to the portland cement and through this process to obtain an expansive portland cement.

V. V. Mikhailov and his co-workers (33), besides his aforesaid waterproofing (hydrophobic) expansive cement (BPLI) have developed a stressing cement, which is made by mutual grinding or blending in a ball mill a mixture containing gypsum, alumina cement and portland cement. The combination of the expansion and the strength growth controlled by the hydrothermal treatment and followed by water curing at normal temperature brings to the stress of reinforcement.

K. Kutateladze, E. Zedhiedze and N. Mamulashvili (44) have offered an expansive cement containing the mixture of the portland cement, gypsum and alunite bearing rock, this mixture burned at 800–900°C.

A. E. Sheikin and T. Yu. Yakub (46) have offered a nonshrinking cement made on the base of a hydrophobized hydrophobic portlanc cement with 5–10 per cent of CaO added.

A. Guttman (3) has offered the way of making of an expansive cement by adding to the cement being ground the admixtures of sulphates and chlorides, i.e.—salts which due to the formation of complex aluminate hydrate bring to the expansion.

G. Bukenbach (25) has offered the making of an expansive cement by the mutual grinding of portland cement clinker with aluminium sulfide.

P. P. Budnikov (USSR) and I. Arens (Poland) have offered the way of making and expansive cement in which, as the source of alumina to form calcium sulfoaluminate hydrate, kaolin burned at 800°C is used.

Keil and Gille (15) have obtained an expansive cement by adding to the mixture of portland cement and blast furnace slags some estrich-gypsum and up to 10 per cent of alumina cement.

A. Lossier (5, 8) has offered some expansive cements contining portland cement, sulphoaluminate cement and blast furnace slags. The amount of the expansion of hardening concrete made with these expansive cements can be, as Mr. Lossier reports, controlled by means of the composition and the dosage of the cement in the concrete and by the curing condition of this concrete.

An expansive cement, containing portland cement and an expansive admixture, this admixture being composed from anhydrous calcium sulphoauminate and gypsum, has been obtained in the University of California (USA). The amount of both the expansive admixture and gypsum is 15–20 per cent.

The U.S. Portland Cement Association (PCA) recommends to make expansive cements by blending various proportion of portland cement, calcium aluminates and gypsum. As distinct from the USSR, where expansive cements are made by mutual blending the PCA recommends the mixing in a concrete mixer some fabricated products: portland cemnt, alumina cements and gypsum—just before the adding of aggregates and water when making the concrete mix.

The authors of this report do not aim to give a comprehensive survey concerning all the patents and proposals as to the compositions and technological layouts for the manufacture of expansive cements. The examples given above should but just outline the main directions of this work which is being intensively conducted in various countries.

The existing expansive cements can be divided those based on alumina cement and those based on portland cement.

The mortars and concretes on expansive cements after the end of the expansion and further drying, give approximately the same contraction as the mortars made with ordinary cements—i.e. 0.1–0.2 per cent. But so far as the expansion taking place before this contraction can reach some per cents, the resulting expansion makes it possible to avoid the harmful consequences of shrinking deformations and—even at the sufficient rate of expansion—to use a considerable resulting expansion for making the prestressing of the concrete reinforcement.

As to the amount of expansion, the expansive cements fall into those ones having a minor value of linear expansion—in the order of some tenths of a per cent—and those with the linear expansion reaching some per cents.

The expansive cements of the first kind are intended for cases where it is necessary to compensate the shrinkage of ordinary concrete; these cements are usually called either "the cements with compensated shrinkage" or "non-shrinking cements".

The cements of the second type are intended to provide for some higher degree of an expansion of the hardened concrete in order to obtain the prestressing of the steel reinforcement. These cements are called

"selfstressing cements". The cements of the first kind prevent the development of shrinkage cracks and pores in concrete while the second ones give concrete providing for the prestressing of the reinforcement. Both the cements have been worked out in the USSR and in the USA as well.

The practice of using expansive cements in construction has shown that, when keeping all the standards, expansive concrete can have quite definite, practically sufficiently stable and reproducible qualities. All this can be achieved without any serious change of the common concrete technology and without any serious deviation from the common practice of construction.

On the base of the experience in production and using expansive cements in construction one can formulate the next basic requirements to the commercial expansive cements:

1. The amount of expansion should be equal or greatly exceed the amount of shrinkage of a common shrinking cement. In the first case there would be a non-contracting cement, while in the second case it would be an expansive one.

2. The expansion of a cement should completely end during the first period of its hardening—without bringing any further stresses in the concrete or in the mortar.

3. The construction qualities of an expansive cement, including its guaranteed amount of expansion, should be sufficiently reliable and completely reproducible.

4. The manufacturing layout of an expansive cement should be simple and commercially expedient.

The Nature of the Expansion of a Hardened Cement Paste

The most of research workers tend to explain the ability of cements to expand by the formation in a hardening cement paste of some complex compounds, these having a complicated molecule with a great amount of combined water and with a definitely directed growth of crystals—particularly calcium sulphoaluminate hydrate (4, 6, 9 et al). However, some authors tend to regard the expansion of a hardening cement paste as a result of either osmotic forces or swelling of the solvable layers of hydrate gels (46).

A. LeChaterier, H. Lafuma, A. A. Baikov and V. V. Mikhailov think that, depending from physicochemical conditions, the formation of calcium sulphoaluminate hydrate in hydrated cement can occur in two ways. At the concentration of CaO in liquid phase above 1.08 g per liter, calcium sulphoaluminate forms as a result of the interaction of the SO_4'' ion with the insoluble solid phase. During this process calcium sulphoaluminate hydrate crystals, forming through the linking to the solid phase of three gypsum moleculae and 19–20 moleculae of water, occupy a greatly larger volume than that of initial compounds, this resulting the expansion of the cement. At the concentration of CaO less than 1.08 g per liter, calcium sulphoaluminate hydrate forms as a result of reactions in the liquid phase—among the compounds dissolved in. During this process the volume, occupied by the calcium sulphoaluminate hydrate, is a little bit less than the sum of the volumes the primary compounds occupied, and thus the expansion of the cement does not take place.

On the base of this conception V. V. Mikhailov has introduced into the technological layout of his waterproof expansive cement which is widely used in the USSR for more than 25 years, the preliminary preparation of highly basic calcium aluminate hydrate and its interaction with gypsum at the high concentration of CaO in liquid phase.

The authors of this work have some other opinion as to the nature of the expansion. The results of the experiments we have conducted make it possible to formulate the following opinion concerning the mechanism of cement expansion phenomenon and of the factors causing to.

First of all it is necessary to say that the expansion, of the first sight a specific phenomenon, is inherent, on a definite stage of hardening, not only to expansive cements but as well to all the other ones. The process taking part at the hardening of expansive cements arises also at the hardening of ordinary contracting cements differing from those ones in expansive cements just by their intensity and duration.

After the mixing a cement with water anhydrous compounds of cement clinker interact with water and convert into hydrates. The products of hydration while hardening of cement paste, at first appear in the form of extremely fine nuclei of crystallization, these nuclei appearing both in liquid phase surrounding a hydration grain and on the surface of such a grain, since the concentration of the solution there is the largest one.

As far as the number of these crystallization nuclei increases, their coalescence into larger formations takes place. It is necessary to point out that in hardened cement paste the crystals of newly formed

compounds do not make a rigid, single whole crystallic coalescence. Along with the microareas where such a rigid frame forms, there are some areas where no rigid coalescence of separate crystals took part. Moreover, if a hardened cement paste were a rigid, single whole crystallic frame, it would break down as a result of continued hydration of the inner part of cement grains, since the newly formed hydration products, during the growth of their crystals, would inevitably assert some pressure on the already formed crystallic coalescence and would, at last, break it down.

It is necessary to say that the break down of the crystallic coalescence formed over some areas of the hardened cement paste do arise and it is due to such "break-downs" that temporary strength drops take place, these drops occuring in all cements-without exception-though in various degree. And the more intensive the cement hydration is, the more probable and the more appreciable these strength drops are.

It is also possible that essential role in these drops to form, take the recrystallization processes: the transition of metastable crystallic hydrates into stable ones and the dissolution of thermodynamically unstable crystallic contacts between separate crystals forming coalescences of crystals. These processes are described by E. E. Segalova and P. A. Rebinder (47).

After the semi-rigid frame in hardened cement paste has been formed, the further hydration of cement brings to both the consolidation of the hardened cements paste, this resulted from filling up the newly formed compounds into the spaces between the cement particles and previously formed hydrates and the moving apart and partial deterioration of the semi-rigid crystallic frame. And it is due to such phenomenon according to the scientists working in the field of expansive cements, a non restricted expansion of hardened cement paste is always followed by some decrease of its strength.

The volume of a hardened cement paste results from the two contrary phenomena occuring in, the first one being the growth of its volume under the influence of continuing crystallization in hydrated newly formed compounds, while the second one being the contraction under the influence of capillary forces.

The ability of a compound to crystallize is mainly defined by two factors: by its ability to spontaneous crystallization (i.e. the number of crystallization nuclei, formed for a unit of time in a unite of volume), and by the linear speed of crystals' growth.

If the number of crystallization nuclei in a unit of the volume is very large or if the speed of the crystals'-growth in newly formed compounds is small, then the dimension of the rigidly framed microareas of the hardened cement paste would be very small—despite a great number of these areas. This is featured by the consolidation of the hardened cement paste accompanied with the full absence or a very small expansion.

On the contrary, if the number of crystallizing nuclei is a little bit less, while the growth of crystals is either having greater speed or is more prolonged, then the dimensions of the areas having rigid crystallation frame would be relatively bigger. Then the growing crystals of newly formed compounds should more often meet some obstacles and move apart surrounding crystallic "Buildups".

On the base of such a conception concerning the nature of cement expansion, the composition and manufacturing layout of any expansive cement should be so designed as to provide for an intensive formation of quickly growing crystals of an expansive compound during a definite period of the paste hardening, this period being characterized by the presence in the hardened paste of a semi-rigid frame formed by the hydrated newly formed compounds.

It also results from this conception that the expansion process can be controlled by regulating all the factors influencing:

1) speed of hydration reactions,
2) the number of crystallization nuclei formed in a unit of volume of the hardening cement per unit of time and
3) the speed of growth of crystals in the expansive compound.

Such factors are, for example, the following ones: the composition of an expansive cement, the fineness of a cement and of its components, the temperature of the environment, the admixtures modifying the structures of newly formed hydrate etc.

The most rapidly crystallized component of the most commonly known expansive cements, able to form quickly growing crystals, is calcium sulphoaluminate hydrate. However, as it was mentioned above, the expansion of a cement depends not only on the amount of this compound in the hardened cement but on the time of its formation as well.

Practically the period for vigorous expansion of the hardened cement paste of various expansive cements lies between one and seven days (see Fig. 2).

If the formation of crystals of calcium sulphoaluminate hydrates occurs too quick (as for example in the case of a very fine expansive cement)—and mainly ends at the first period of hydration, when the hardening cement paste is not yet hard enough, then the amount of expansion would be a small one. At the

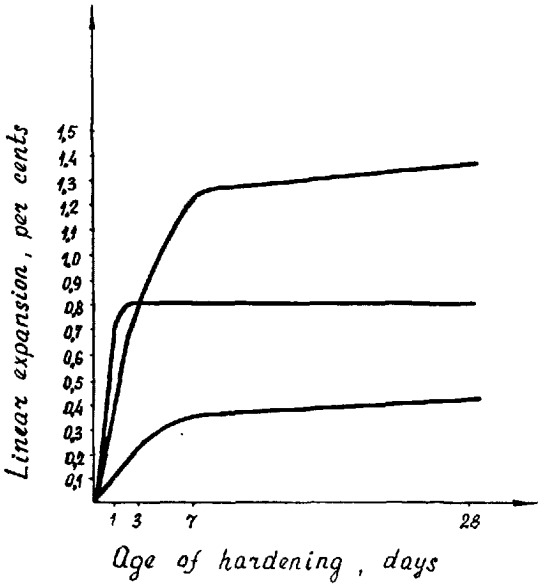

Fig. 2. *The expansion of various expansive cements*

coarser cement the growth of crystals of calcium sulphoaluminate hydrates slows down, this resulting to some greater expansion amount of the cement when hardening. Table 1 below contains the data of the amount of the expansion of alumina expansive cement (ГРЦ) made in the USSR depending on its fineness.

According to our data (20, 38, 45) the control of the amount of the cement expansion when hardening is also possible through the change of CaO concentration in the liquid phase. Increasing the CaO concentration in liquid phase accelerates the crystallization of calcium sulphoaluminate hydrate thus decreasing the amount of the cement expansion. This has been proved by our study of the binding of calcium sulphate into calcium sulphoaluminate hydrate in the systems where the alumina compound is highly basic calcium aluminate $C_{12}A_7$ and less basic one CA.

We have found that the binding of calcium sulphate into calcium sulphoaluminate hydrate in systems containing highly basic calcium aluminate ($C_{12}A_7$), which is hydraulically more active, ends 60–70 times quicker than in systems containing a less basic calcium aluminate (CA). Fig. 3 shows the data concerning the speed of binding of calcium sulphate with various calcium aluminates which we have synthesized.

At the more rapid interaction of highly basic calcium aluminate with calcium sulphate in the liquid phase, the crystals of the formed calcium sulphoaluminate hydrate are of smaller dimensions than those at the slow interaction and it brings to some decrease of the linear expansion. (See Table 2).

Table 1. *The amount of expansion, depending on its fineness*

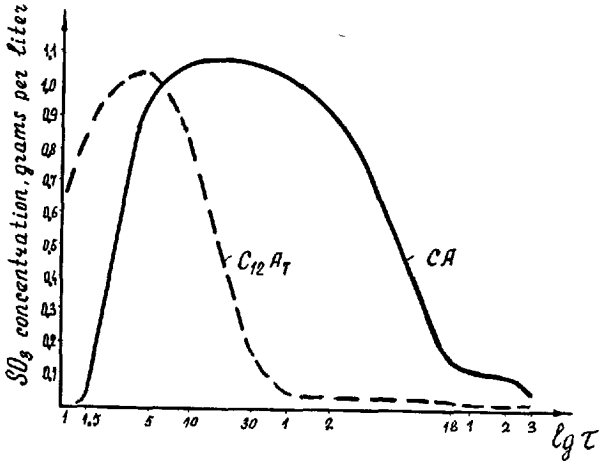

Fig. 3. *The binding of gypsum with various calcium aluminates*

As it is known, the environment temperature makes a serious influence on the hydration processes. We have studied the influence of the temperature of the environment on the speed of the growth of calcium sulphoaluminate hydrates crystals. Fig. 4 shows the photo of calcium sulphoaluminate hydrates formed in the hardened expansive cements at the various temperature of the environment. Table 3 contains the strength data of expansive cements hardened at normal and elevated temperatures.

Our data concerning the influence of the temperature and humidity on the speed of growth of calcium sulphoaluminate hydrates crystals have been used as a basis for designing of a third kind of expansive cement made in the USSR—The expansive portland cement (РПЦ) (27).

We have found that the formation of calcium sulphoaluminate hydrate at the interaction of cal-

on the formation of calcium sulphoaluminate hydrates, is considerably higher than the rate of strength of cements, whose hardening to a great extent is based on the formation of calcium sulphoaluminate hydrates, is considerably higher than the rate of strength growth of portland cements. On the base of these tests we have designed an expansive portland cement (РПЦ) in which the accelerated strength growth at the steam curing is accounted for a more intensive formation of calcium sulphoaluminate hydrates. After the steam curing is ended, the strength growth continues this accounted for common reactions occuring when hardening portland cements at the common temperature.

Fig. 5 shows the pictures of the crystals of calcium

sulphoaluminate hydrate formed in hardening expansive portland cement (РПЦ) at the normal and elevated temperatures. Fig. 6 contains the data on the strength change of both the ordinary and expansive portland cements at the steam-curing.

The linear expansion of expansive portland cement (РПЦ), that obtained by means of mutual grinding of starting materials, which provide the formation of calcium sulphoaluminate hydrate at the first period of cement hardening, amounts to 2–3 per cent. This expansive portland cement is used in construction technics as a common expansive cement. It is more widely used, however, as a special cement for making reinforced concrete articles in order to speed up their hardening when steam-cured (45). The concrete made of this cement makes no contraction cracks; moreover, it is of high water-proofing values.

The Technical Features of Expansive Cements

Commercial manufacture of expansion cements in the USSR and their wide use was preceeded by the long study of their technical features and numerous tests which have proved the reproduction of the results obtained.

For example, the stability of technical features of the alumina expansive cement (ГРЦ) has been studied by us for twenty years. The strength of cement has been tested in standard mortars of 1: 3 composition in both lean and plastic consistency with normal sand and with common sand used in building in mortars of 1: 2.5 composition; we have also tested cements in concretes of various composition and plasticity. Table 4 contains compression and tensile strength tests data for samples made from alumina expansive cement (ГРЦ) depending on the conditions of five years hardening.

Fig. 7 shows the crystals of calcium sulphoaluminate hydrates extracted from the alumina expansive cement hardened during 11 years.

Alumina expansive cement as well as common alumina cement is a rapid hardening one. The hardening in alternate moisting and drying conditions makes no appreciable adverse influence on it. Its compressive and tensile strength values are higher than those for alumina cement.

Fig. 8 shows the change of linear expansion for expansive alumina cement when hardening in water, in air and at the alternate pattern of hardening. As seen from the data reported, the expansion of an

3—in air

expansive aluminous cement (ГРЦ) hardened in water during the first day amounts to 50 per cent of the final expansion, this process practically ending at the age of three days. Table 5 contains data concerning the relationship between the expansion amount of a hardened cement and the mortar composition. These data show that the expansion of expansive alumina cement (ГРЦ) decreases proportionally to the decrease of binding agent content in it and inversely proportional to the W/C ratio increase.

The heat release when hardening of alumina expansive cement starts quickly and runs smoothly. The

1:8	1.00	0	0.01	0.01	0.01	0.01	0.01	0.01

maximum temperature of its heating is lower than that of alumina cement.

Tests for both the adhesion of expansive alumina cement with reinforcement steel and the safety of the steel were conducted for five years. These tests show that the hardening of concrete and mortars at the constant humidity, expansive aluminous cement bears no corroding action on the reinforcement. At the air hardening, however, when gypsum contained in expansive aluminous cement has no time enough to completely bind into calcium sulphoaluminate hydrate the corrosion of the steels surface takes place.

The studies have shown that concretes and mortars on expansive alumina cement are waterproofing ones at 10 atm. pressure after three days of hardening.

Rich mortars of 1: 2.5 composition and concretes with cement consumption of 350 kg per cubic meter, having W/C = 0.45 and made on expansive alumina cement (ГРЦ) suffer more than 200 alternate freezing-thawing cycles.

The mortars and concretes made from expansive alumina cement are quite stable at alternate watering and drying but cannot be used at temperatures above 80°C since at these temperatures calcium sulphoaluminate hydrate decomposes.

Expansive aluminous cement (ГРЦ) can be used for jointing separate concrete articles into a single unit and for strengthening of articles, for pouring base-plate bolts, for making joints and sockets in water supply tubes having pressure up to 10 atm and sewage in tubes for making hydroisolation and plastering, for building, reservoirs, for jointing large parts of machines and metallic works.

Expansive aluminous cement (ГРЦ) is widely used in the form of gel cements for oil wells and gas wells when sinking into cavernous and cracked rocks.

The study of the technical features of waterproofing expansive cement (ВРЦ) and the inspection of constructions made of this cement have been continued for over twenty five years. This cement is of quick

strength growth value, of short setting time and of high waterproofing value. Table 6 contains the data featuring the technical values of this cement. The widest use of this cement is the joint making of city subways cast sections. The long year service of various Soviet subways has proved high values of the waterproofing expansive cements.

This cement has also been used for repair and restoration, hydroisolation coating, for jointing separate concrete articles into a single unit etc.

Table 7 contains data featuring technical values of expansive portland cement (РПЦ). The study of its features and inspection of construction projects made of this cement have been conducted for thirteen years.

This kind of cement is of high strength, waterproofing and of anticorrosive values. Numerous floating, precast and reinforced construction projects made of this cement some thirteen years ago are still in good service conditions.

This cement has been widely used for making common precast reinforced articles made of precast unit factories since it makes possible to spend half the time for isothermal curing of units when hydrothermally treated as to compare with ordinary portland cement of equal strength.

To add that this cement is of some lesser cost than ordinary portland cement of equal strength.

So, the manufacturing and use of expansive cements in the Soviet Union and in other countries reveal wide prospects for these kind of cements.

To conclude it is necessary to state however, that, despite the broad promise of expansive cements as a building material, their output and their use has not yet attained the volume necessary. And, for their further development, following research work and accumulation of practical experience are necessary concerning:

1. More strict framing of the building features and composition of expansive cements.
2. Working out the optimum compositions and manufacturing layout for expansive concretes of the strictly shaped quality.
3. More strict framing of the optimum areas for use of expansive concretes, specifically for self-stressed one.
4. Finding out the amount of the stress loss in reinforcement work under the influence of the shrinkage and the creep in a long aged concrete.
5. The study of still unexplored features of expansive concretes in order to broaden their use.

Written Discussion

Otar P. Mchedlov-Petrosyan and Dmitrijs A. Ugінčius

The excellent Principal Paper "Expansive Cements" by P. P. Budnikov and I. V. Kravchenko is of great interest for everybody who works in this field of cement and concrete technology. However, the authors say that they do not try to give a complete survey of all the works in this field. That is the reason why we wish to pay attention to some aspects of this problem about which the authors say nothing.

From our point of view the production of expansive compositions on the base of commercial portland cement directly at the construction site or at prefabricated concrete plant, using the simplest technological operations, is a good idea. H. Lafuma backs this idea (1).

Such a composition, in particular, is the same composition which has been already mentioned at this Symposium in connection with other problems (7).

Besides the patent mentioned by the authors of Principal Paper there are some publications giving theoretical basis, ingredients of the compounded additive, structure and properties of materials, obtained while using it (2, 3, 4, 5, 6, 8).

The introduction of this inexpensive additive "reaction accelerator + expander + retarder" in the moment of mixing commercial portland cement proved to provide higher density, strength of cement stone and to reduce its permeability without using manufactured expansive cements.

The using of the action of compounded additive is an example of chemical way of the directed concrete structure formation.

In addition to this we give some data about cement stone structure of expansive compositions on the basis of portland cement.

As thermographic, petrographic and physico-mechanical investigations have shown that cement stone with compounded chemical additive acquires greater density and strength not only during hardening at room temperature but also as the result of steam curing.

The application of additive at the normal (3, 4, 5) and high (2, 6) temperatures proved to be successful and has widely been used during more than seven years.

The additive in consideration may be an example of effectiveness of a radical new trend—the transformation of the expansive composition preparing process from cement technology element to concrete technology element.

Written Discussion

Albert Joisel

Introduction

Cement expansions may looks as rather mysterious phenomena. However we intend to indicate that their essential principles are simple; they are based on universally admitted physico-chemical laws; they are strengthened by numerous published results, which we will suppose well known by the readers.

The LeChatelier theory (1887) expresses that the hydraulic constituents of the cement grains go into solution in the mixing water and precipitate as a less soluble hydrated form; it may be stated as follows:

In an *hydraulic cement*, which may be wrote B — X, at least one of its constituents X forms, with the mixing water, an hydrate X — H *molarly less soluble* than the anhydrate in this water.

A solid constituent Y of the concrete (belonging or not to the cement) which forms with the mixing water a hydrate Y — H *molarly as much soluble or much soluble* than the anhydrate in this water, gives an *expansion* (or obviously a simple dissolution, if it is sufficiently soluble and diluted).

Hydraulic Cement

Let us consider (Fig. 1a) the aqueous space between a cement grain B – X, containing a soluble constituent X, and an inert aggregate G.

The X constituent passes into solution in water (Fig. 1b). Its concentration in this water, at first stronger near the cement grain, tends to get more uniform and to reach saturation.

The first precipitation $\boxed{X - H}$ *takes place far*

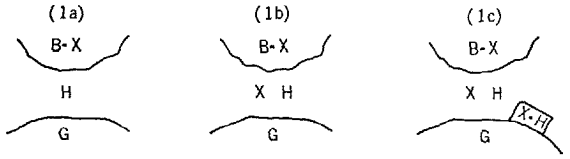

Fig. 1.

from the B — X grain (Fig. 1c). In fact, if it had taken place near the B — X grain, it would mean that a molecule (or an ion) X of the solution could precipitate as an hydrated form $\boxed{X-H}$ in presence of a X, remained anhydrous in the B — X grain. This is not possible as the X constituent is more soluble when anhydrous than hydrated, that is to say: the anhydrous constituent X has a greater affinity for water than has the same X constituent in solution.

The precipitation goes on from the first germs and progressively binds the grains, and particularly the inert grains, each other.

The X constituent is, for instance, a part of the lime of the tricalcium silicate C_3S, which goes into solution almost alone during the hydration. This lime is molarly more soluble than the lime in solution, as we can observe a sursaturation of the mixing water. The initial crystallisation of the portlandite $\boxed{CH}$ is done *at a certain distance from the alite grain.* It goes on afterwards in aqueous interstices.

The X constituent is also the calcium hydroxide of the "fat limes" which is molarly more soluble in water charged with carbonic gas, than the calcium carbonate which precipitate in the interstitial water.

The X constituent is also the part of the silica of a pozzolana which, in the presence of portlandite, goes into solution in the basic water of the interstices and precipitate at a distance from the pozzolana grain in a relatively low calcic form, that is to say, relatively scarcely soluble.

Expansive

Let us consider now an expansive grain Y (Fig. 2a). The Y constituent goes into solution in water (Fig. 2b).

The first precipitation $\boxed{Y-H}$ *takes place near the* Y *grain* (Fig. 2c), as it is there that the concentration is stronger, and as Y has at least as much affinity for water H when it is in solution as when anhydrous.

The Y grain is thus progressively surrounded by a solid layer $\boxed{Y-H}$ (Fig. 2d). At the surface of this layer in contact with water, the interchanges between the water of the (Y, H) liquid and the $\boxed{Y-H}$ solid are possible, if this solid is *somewhat soluble* in the mixing water: the water may enter this hydrate layer, towards the Y anhydrous grain.

On the contrary, the constituent of the Y solid grain, not molarly more soluble in water than the $\boxed{Y-H}$ solid one (that is to say, having no more water affinity when anhydrous than hydrated) cannot take out some water molecule from this solid and so, it cannot go into solution in the aqueous interstice through the Y — H layer. This solid $\boxed{Y-H}$ layer behaves, as we can see, as a *semi-permeable membrane* between the Y solid and the mixing water. (That is what Le Chatelier expressed when saying that the hydration of an expansive constituent is done without dissolution).

The Van't-Hoff's law, derived from the gases's law, applies to the *water osmotic pressure*. This water enters into the membrane, hydrates in situ the Y

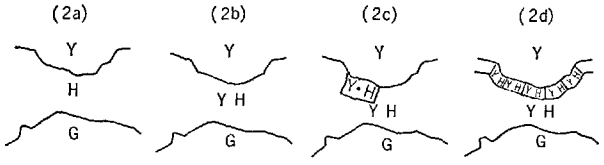

Fig. 2.

constituent, causes high pressures, as it is easy to compute, and breaks out the peripheric part. We are than brought back to the previous process.

The smaller the expansive grain dimension, and the larger Y surface, the lower is the expansion and less dangerous for strength, since the Y part forming the semipermeable membrane is gone into solution and so has not caused expansion.

The expansive constituent Y is, for example, free lime CaO, since we may consider that CaO and $Ca(OH)_2$ have the same molar solubility, or free magnesia MgO. (CaO and MgO are dissolved in water without sursaturation).

Heating at 100° or 200°C, which reduces the lime and magnesia solubilities, but which increases their *dissolution rate*, accelerates the expansion of these two constituents.

Every addition to the portland cement susceptible to form, with the lime (or magnesia) gone into solution,

a lower lime molar solubility product tends to precipitate the lime, for example as an hydrated calcium silico-aluminate, far from the grains, and so to reduce expansion. It is the case for relatively low additions of pozzolana or slag to a cement, which would be unstable because a free lime excess.

The lime and magnesia which are a part of the constitution of vitreous silico-aluminates of slags and pozzolanas cannot promote expansion.

Alkali-Aggregate Reaction

The reactive silica of certain grains, which goes into solution in the alkaline mixing water, leads to local expansions on the peripheral part of these grains, since it forms hydrated mixed silicates or silico-aluminates of alkaline earths and alkalines, which are molarly at least as soluble as the original silica.

The expansion can be reduced either by reduction of alkali content, or largely increasing the reactive surfaces in order to divide the mixed silico-aluminates on thin films through the concrete mass, by the addition of fine pozzolana or grounded slag (Those alkali salts are almost insoluble). For this reason, the grinding of a reactive aggregate reduces the concrete expansion.

Expansion due to Reinforcement Oxidation

Iron, as all metals, is molarly more soluble in the ionised state than in metallic state. If it oxidises, it is then with expansion, unless it dissolves entirely, for example, in acid water.

Hydration of Aluminates

The richer in lime, the more water soluble are the hydrated calcium aluminates; but on the contrary for silicates, the anhydrous aluminates go into solution in their stoechiometric ratio. They form in the aqueous interstices hydrated aluminates with varied molar ratios C/A and *the most stable is the hydrated tricalcium aluminate* C_3AH_6.

The tricalcium aluminate, if used alone, would give an hydrated tricalcium aluminate having the same solubility as the anhydrous one. It would then be expansive. It is effectively observed that the pure tricalcium aluminate hydrates efficiently with expansion; it is not an hydraulic cement; its strength is null.

For the protland cement, in presence of lime freed by the silicate hydration, an aluminate with more than 3 lime molecules may precipitate which is more soluble than tricalcium aluminate and expansive. The final strengths of high tricalcium aluminate cements are then relatively low, chiefly if they are steamed. Autoclave expansion of these cements is frequent; it is diminished if the clinkers are rapidly cooled, because tricalcium aluminate crystals are then smaller (see what is formerly said of the alkali-aggregate reaction).

On the contrary, for an aluminous cement with a C/A ratio <3, a less calcic hydrated aluminate precipitates, then less soluble; it is observed in fact that it remains more lime than alumina in solution. The aluminous cement is not then expansive.

However, if we add a small amount of lime (or of portland) to the aluminous cement, lime richer hydrated aluminate can precipitate in the aqueous interstices (moreover promoting a rapid setting). There is then expansion and the strengths are weakened.

Sulphates Addition to Cements

The tricalcium aluminate, though it is not favorable for final strengths of portland cement, is favorable for early strengths, because it fixes a relatively high amount of water and so contributes to the "squeezing" of the silicates which are the veritable hydraulic constituents of this cement. But for the normal setting cements, we must delay this aluminate hydration by calcium sulphate. This sulphate forms with the alumi-

nate a hydrated *sulphoaluminate which is more soluble, the richer in sulphate.*

If, at the end of the setting, some free calcium sulphate remains, it forms, with the scarcely sulphated hydrated aluminate or sulphoaluminates, *more soluble* hydrated sulfoaluminates, and it promotes an expansion. Therefore, the SO_3 content of portland cement is limited, for example to 3.5%. We can note that this data corresponds for a usual portland cement (with about 12% C_3A), nearly to the potential formula $C_3A\bar{S}CH_n$, that is to say, to the monosulphate.

A raising of temperature at 100°C largely hastens the sulphates dissolution and the silicates hydration (but almost does not change the aluminates hydration rate). The initial distribution of the sulphates against the aluminates is then more *homogenous.* As a result, the expansion due to a high amount of sulphate is less for warm than for cold curing.

We know that at the beginning of hydration, it is a very sulphated hydrated aluminate (trisulphated) that precipitates. Its ulterior transformation into a less sulphated aluminate (monosulphated), then less solu ble, may take place without expansion.

For silico-aluminous cements, alumina richer than portland cements, containing basic slag or certain pozzolanas, the proportion of sulphate may and must be increased (with the high slag content cements and particularly sursulphated cements).

Expansion due to Sulphated Agents

We have just seen that a cement, containing initialy tricalcium aluminate, gives hydrated aluminous or sulphoaluminous products, the mean composition of which is about $C_3A\bar{S}CH_n$. In the presence of sulphate, particularly sulphated waters, it is known that it trisulphated sulphoaluminate that tends to form. Now it is more soluble than the already formed aluminous or sulphoaluminous hydrates of the cement; then it leads to an expansion.

Expansive Cements

As expansive product, free lime CaO, free magnesia MgO, and chiefly varied sulphoaluminates were used. Lime and magnesia must be calcined and ground in definite conditions: particularly the temperature and the duration of calcining have a great influence on the dimension of the expansive grains (and consequently on their porosity). As for the expansion of sulphoaluminates, it should happen or continue after the cement setting (obtained, for instance, through a certain proportion of portland clinker), by the action of a sulphate on hydrated aluminates or sulphoaluminates that are already formed or that are forming. It is then necessary that the sulphate or aluminate does not enter too quickly into solution: high temperature calcined anhydrite and aluminous cement (which must be relatively lime rich, so that the C/A ratio be between 1 and 3), or stoechiometrically analogous mixes, or most often a sulphoaluminous cement, have been used.

The expansion, for a well distribution in the mass, needs a sufficient fineness of the cement, which moreover confers on it a good workability, but which may lead to a relatively important hydraulic shrinkage after expansion, when drying.

At last, it is necessary that the cement contains a high proportion of sound constituents, even in the presence of sulphates. They hydrate relatively slowly and lately consolidate the expanded zones: blast furnace slag, pozzolana, clinker with a low lime saturation rate and low C_3A content.

It can be seen that these principles, concerning in fact:

1)—setting,

2)—time, duration and distribution of expansion,

3)—hardening,

might lead to a large variety of expanesive cements.

As for the structures cracking, if the hydraulic shrinkage is the major cause, the "without shrinkage" cements or "with compensated shrinkage" cements would be of great interest, but the hydraulic shrinkage is never the essential cause of cracking . . .

Oral Discussion

José Calleja

In connection with the Principal Paper Expansive Cement presented by Prof. Budnikov and Prof. Kravchenko, from the Soviet Union, I want to emphasize the interest which the original points of view of the authors should have for future interpretation of expansion phenomena.

Following ideas of the authors, it may be said that, in general variations of volume in the cement paste will cause the weakening of its structure and, consequently, will lower its strength and its durability. These are particularly affected by external and internal microcracking and cracking due to shrinkage.

In this respect, every action which will tend to reduce shrinkage, will equally tend to improve the mechanical strength and the chemical resistance. This is the origin of the so-called "non shrinking cements", or "shrinkage compensated cements", or even "controlled expansion cements".

Spanish research work on such types of cements has been carried out at the "Eduardo Torroja" Institute for Cement and Concrete Research in Madrid, from the year nineteen fifty onwards (1 to 4).

Portland cements were prepared starting from clinkers with a high content of highly basic calcium aluminates and from both, gypsum stone and (or) anhydrite as retarders. A certain amount of free lime was also present in the clinkers, so that conditions were the most favourable for the formation of expansive tricalcium aluminate sulphate hydrates.

Results showed that minimum shrinkage, maximum strength and maximum durability were achieved when the gypsum or anhydrite contents in the resulting portland cements were close to those corresponding to the formation of tricalcium aluminate monosulphate hydrate as final stable sulphated aluminous phase, according to Forsen's point of view (5).

Such amounts of calcium sulphate corresponded also closely to those present in the portland cements called "correctly retarded" by Lerch, years ago (6).

Then, maximum strength in such conditions is most probably the direct or indirect consequence of a minimum change involume (shrinkage compensated as much as possible by expansion), and it seems therefore that the involved calcium sulphate content, i.e., that corresponding to the formation of $C_3A \cdot CaSO_4 \cdot 12H_2O$ from the C_3A of the clinker (leaving aside other influences such as that of the fineness and of the alkali content, etc. in the cements), may provide a limit for separating "shrinkage compensated cements" or "non shrinking cements" from actual "expansive cements" made with the same clinker, as far as the manufacture of such cements is concerned.

I would much ppreciate to know if the authors or any other delegates have had a similar experience and their opinion on this matter.

Oral Discussion

Kozo Sugiura

Of the three types of expansive cements industrially produced in the Soviet Union it is stated that expansive portland cement is used mainly for manufacture of precast reinforced articles. Has this type of expansive cement been used for cast-in-situ concrete such as pavements?

For such uses, it is thought that retarding of set would require replacement of gypsum with anhydrite or addition of a retarder. Have such measures been taken?

Supplementary Paper IV-66 Nature of Hydration Products in the System $4CaO \cdot 3Al_2O_3 \cdot SO_3$-$CaSO_4$-CaO-$H_2O$

Alexander Klein and Povindar K. Mehta*

Synopsis.

Commercially made expansive cements in the United States are presently based on the inclusion of an expansive complex in portland cement. The expansive component consists of suitable proportions of $C_4A_3\bar{S}$, $C\bar{S}$ and lime. The hydration products in the systems $C_4A_3\bar{S}$-CS-C-H contain several calcium sulfoaluminate hydrates. Only calcium trisulfohydrates (ettringite) is known to cause expansion under conditions of restraint. For a better understanding of the chemistry of expansive cements, a thorough investigation is undertaken to determine the nature of hydration products from a wide range of anhydrous compositions containing $C_4A_3\bar{S}$, $C\bar{S}$ and lime.

Mixtures of $C_4A_3\bar{S}$, $C\bar{S}$ and lime were made corresponding to $A/\bar{S}$ ratios of 0.25, 0.50, 0.75, 1.00, 1.25 and $C/\bar{S}$ ratios of 2.0, 2.5, 3.0, 3.5, 4.0, 5.0, 6.0, 7.0, 8.0. The hydrating mixtures were studied by X-ray diffraction analysis at 6, 24, 72 and 168 hours.

The results are compared with theoretical predictions, and a phase diagram has been constructed to show the nature of final hydration products in the system.

The utilisation of expansion based on the formation of ettringite has been successfully demonstrated in the U.S.S.R. by Mikhailov(1, 2) and in the United States by Klein and his associates(3, 4, 5, 6). The expansive cements developed at the University of California by Klein and Troxell(3) are blends of portland cement with an expansive component which consists of appropriate proportions of $C_4A_3\bar{S}$, $C\bar{S}$ and lime.

Portland cements containing the "expansive complex" are also being produced commercially from portland cement clinkers containing all the constituents of the "expansive complex". The American Concrete Institute's Committee on Expansive Cements has designated these cements as Type K expansive cements.

Kalousek(7) Jones(8) and D'Ans(9) have made important contributions to our knowledge on the formation of calcium sulfoaluminate hydrate from aqueous solutions of C_3A, $A\bar{S}$, $C\bar{S}$, CH etc., but Mehta and Klein(10) have reported on calcium sulfoaluminate hydrates formed by solid state hydration in the system $C_4A_3\bar{S}$-$C\bar{S}$-C-H.

Mehta and Klein(10) confined their preliminary investigation to reaction mixtures having 2.0 and 4.0 $C/\bar{S}$ mole ratios, and corresponding to $A/\bar{S}$ mole ratios between 0.2 to 1.25. For a better understanding and control of the chemistry of expansive cement, the scope of the present investigation has been enlarged to include mixtures with wider range of $C/\bar{S}$ mole ratios.

Materiais and Experimental Procedure

High-purity $C_4A_3\bar{S}$ was made by intergrinding stoichiometric proportions of reagent grade $CaCO_3$, $CaSO_4 \cdot 2H_2O$ and $Al_2O_3 \cdot 3H_2O$, and thereafter sintering the material at 1350°C in a Globar furnace. High-purity $C\bar{S}$ and lime were made by calcining at 1300°C reagent-grade gypsum and chalk respectively. All the three anhydrous components thus prepared were ground to 3000–4000 cm^2/g Blaine and stored in air-tight bottles.

In Tables 1, 2 and 3 are shown molar compositions of mixes investigated in the present study. In every case weight proportions for a 75 g mix were calculated corresponding to molar proportions of the constituent components. For hydration purposes, 30 g (0.4 water-cement ratio) of chilled distilled water was placed in a porcelain dish, and weighed CaO was the first component to be mixed with water before the weighed portions of other constituents were added. This procedure was adopted in order to offset any detrimental effects of excessive heat of hydration of CaO on the products of hydration. Otherwise the casting,

*University of California, Berkeley, California, U.S.A.

Standard abbreviation used in cement chemistry are followed. Abbreviation $\bar{S}$ stands for SO_3.

curing and XRD analysis procedures remained essentially the same as described in Appendix A of the earlier paper by Mehta and Klein (10).

The ingredients after thorough mixing with water were cast in plastic vials which were properly covered to prevent access of atmospheric carbon dioxide. After six hours, a small sample of the hydrating material was taken for XRD analysis while the rest

of the hardened specimen was exposed to moist curing in airtight plastic containers lined with cotton pads soaked in distilled water. Samples were regularly withdrawn for XRD analysis at 24, 72 and 168 hours.

For XRD analysis, a Philips Norelco XR generator with Cu target (40 KV, 35 mA) and 0.0007″ nickel filter was used in conjunction with a Philips Norelco Diffractometer scanning at 0.5 deg. 2θ/min. The diffraction pattern was recorded at 1000 counts per second full scale deflection by a Bristol recorder.

Identification of anhydrous compounds as well as of hydrated phases presented no difficulty by XRD analysis technique except for AH_3 which, due probably to very poor crystallinity, yielded broad peaks in the diffration patterns of the specimens. The presence of AH_3 was, therefore, confirmed by solubity test in dilute HCI (1: 5). The solutions exhibiting turbidity in this test were assumed to contain AH_3.

Results and Discussion

The predicted hydration products from the theoretical molar compositions as well as the hydration products actually determined at 168 hours are shown against the respective anhydrous mixtures listed in Tables 1, 2 and 3. The XRD data for earlier ages of hydration are not given in this paper because its inclusion is not considered necessary for the purposes of this report. The reuslts shown in Tables 1, 2 and 3 are plotted in Fig. 1. The following abbreviations are used in the Figure and Tables:

E —Ettringite

M_{18}—Monosulfate hydrate with 18 moles of water (10)

M_{12}—Monosulfate hydrate with 12 moles of water

M_x —Monosulfate hydrate with unknown moles of water. The basal spacing on the XRD pattern indicates that the number of moles of water should be somewhere between 12 and 18 (perhaps 15)

$C_xA_yH_z$—Calcium aluminate hydrates

S. S. Phases—Solid solution phases present probably as a result of interaction of monosulfate hydrates, calcium aluminate hydrates, and calcium hydroxide.

In the Figure at point E which represents "Ettringite", the molar ratio of $C/\bar{S}$ is 2.0 and $A/\bar{S}$ is 0.33. Point M which represents "Monosulfate hydrate" corresponds to a $C/\bar{S}$ ratio of 4.0 and $A/\bar{S}$ ratio of 1.0.

Since unconsumed $C\bar{S}$ is present in all compositions

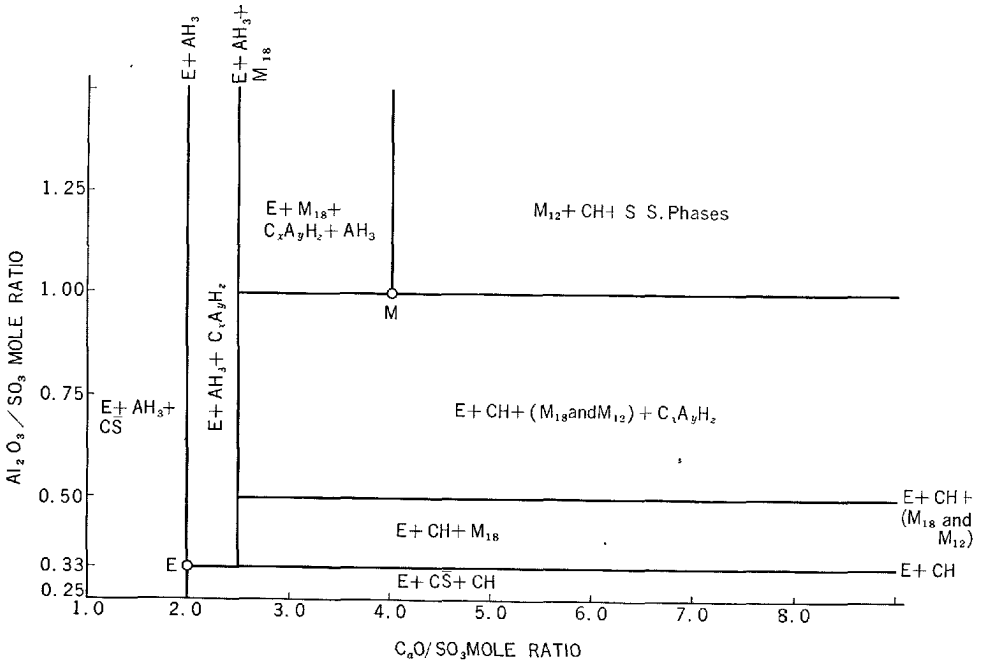

Fig. 1. *Nature of final hydralion products obtained from hydration of mixtures containing* $C_4A_3\bar{S}$, *and* $C\bar{S}$ *lime*

having 0.25 $A/\bar{S}$ mole ratio (regardless of C/S ratio), on theoretical grounds it can be concluded that for all composition below 0.33 $A/\bar{S}$ mole ratio, the alumina content is too low and the sulfate content is too high for depletion of all the available $C\bar{S}$. Similarly from theoretical calculations it can be proved that for compositions below 2.0 $C/\bar{S}$ mole ratio, the lime content is too low and the sulfate content is too high for depletion of all the available $C\bar{S}$, hence there will always be unconsumed $C\bar{S}$ for compositions with $C/\bar{S}$ less than 2.0 (regardless of $A/\bar{S}$ mole ratio).

Regarding compositions having less than 2.0 $C/\bar{S}$ mole ratio, the hydration products always contain ettringite, $C\bar{S}$ and AH_3, the proportion of the latter being increasingly more as the $A/\bar{S}$ ratio is raised in the original mix. At 2.0 $C/\bar{S}$, only ettringite and AH_3 are present in the hydration products except in compositions with lower than 0.33 $A/\bar{S}$. Similarly at 0.33 $A/\bar{S}$, only ettringite and $Ca(OH)_2$ are present in the hydration products except compositions with lower than 2.0 $C/\bar{S}$.

For compositions with $C/\bar{S}$ between 2.5 and 8.0, it can be observed that M_{18} appears in hydration products as soon as $A/\bar{S}$ mole ratio of the mix crosses 0.33. At 0.50 $A/\bar{S}$, M_{12} begins to exist side by side with M_{18}. Beyond 0.5 $A/\bar{S}$, the alumina content becomes high enough to form $C_xA_yH_z$ phases in addition to ettringite and monosulfate hydrates.

Regarding compositions with 0.33 and higher $A/\bar{S}$, $C/\bar{S}$ is raised slightly above 2.0 (but below 2.5) it is observed that $C_xA_yH_z$ phases begin to exist along with ettringite and AH_3. At 2.5 $C/\bar{S}$, the conditions become favourable for the appearance of M_{18} in the system, therefore here M_{18} exists along with ettringite and AH_3.

It can be seen from the Figure that corresponding to A/S ratios of 1.0 and 1.25, and $C/\bar{S}$ ratios between 2.5 and 4.0, the $C_xA_yH_z$ phases again co-exist with ettringite, M_{18} and AH_3. Comparison of theoretically predicted results with actually determined products of hydration shows that $C_xA_yH_z$ phases were readily detectable when CH/AH_3 ratio in the reaction products was between 1.0 and 8.0. When CH/AH_3 was 1.0 or less, (as in the case of the last two mixes in Table 1), free AH_3 was invariably present in the products. Furthermore, at 1.25 $A/\bar{S}$, and 5.0 and above $C/\bar{S}$, when formatoin of $C_xA_yH_z$ phases could be expected on the basis of theoretical equations, no such phases were actually detected due probably to formation of solid solution phases with the monosulfate hydrate.

At 4.0 $C/\bar{S}$ and 1.0 $A/\bar{S}$ (point M) where the theoretical equation predicts the presence of monosulfate hydrate only, both types of the monosulfate hydrate i.e., M_{18} and M_{12} were detected along with a trace of ettringite. At 4.0 $C/\bar{S}$ and 1.25 $A/\bar{S}$, however, no M_{12} and ettringite were detected, only M_{18} and AH_3 being present. On the other hand, at 1.0 $A/\bar{S}$ and greater than 4.0 $C/\bar{S}$, both types of the monosulfate hydrate (M_{18} and M_{12}) along with traces of ettringite continued to exist, CH being an additional product formed in accordance with the theoretical expectations. But as soon as the $A/\bar{S}$ ratio is raised above 1.0 and $C/\bar{S}$ ratio above 4.0, ettringite and M_{18} ceased to be stable phases. Only M_{12}, CH and certain solid solution phases (probably M_{12}—$C_xA_yH_z$—CH) were found capable of existing in this region. This shows that for $C/\bar{S}$ ratios of 4.0 and less, the stability of M_{18} in compositions having 1.0 and more $A/\bar{S}$ may be associated with the presence of ettringite or AH_3 in the hydrated system. Similarly in low alumina mixes, i.e. between 0.33 and 0.5 $A/\bar{S}$ (and corresponding to 2.5 and above $C/\bar{S}$), the stability of M_{18} took place in presence of ettringite and CH. From both the above mentioned cases, ettringite being the common denominator, appears to be the stabilizing influence on the monosulfate hydrate having 18 moles of water.

For compositions above 5.0 $C/\bar{S}$ and between 0.33 — 1.0 $A/\bar{S}$, another monosulfate hydrate M_x (strong peak at 9.6° 2θ) was suspected to be present along with M_{18} and M_{12}. On the basis of basal d-spacing, the number of water moles in M_x are probably 15. The occurrence of M_x is shown in the tabulated data, but is not shown in the Figure.

Conclusions

It can be concluded from the results of this investigation that theoretical equations alone are not adequate to deal with the products of hydration actually formed in the system $C_4A_3\bar{S}$-$C\bar{S}$-C-H.

Among the calcium sulfoaluminate hydrates present, in addition to the trisulfate hydrate at least three types of monosulfate hydrates were found to exist in hydration products, namely, $C_4A\bar{S}H_{12}$, $C_4A\bar{S}H_{18}$ and C_4ASH_x. The hydrate with 12 water moles is well known. The nomosulfate hydrate having 18 moles of water was discussed in an earlier paper by the authors. It appears that the stability of this hydrate is dependent on the presence of the trisulfate hydrate in the system.

Regarding $C_4A\bar{S}H$, it was found present along with other monosulfate hydrates in compositions having greater than 5.0 $C/\bar{S}$ and corresponding to 0.33 – 1.0 $A/\bar{S}$. On the basis of basal d-spacing, the number of water moles in this hydrate are suspected to be 15.

The trisulfate hydrate as well as the monosulfate hydrates having 18 and 15 moles of water were not stable when $A/\bar{S}$ exceed 1.0 and $C/\bar{S}$ exceeded 4.0, hence anhydrous mixes corresponding to these compositions are not expected to be useful in making expansive cements.

It may be pointed out here that the results of this investigation are not adequate for the purpose of designing Type K expansive cements having desired properties. The present investigation has been confined to the study of hydration products in the expansive complex system alone, whereas the expansive cements contain constitutens of the expansive complex as well as of the portland cement (C_3S, C_2S etc). Integration of knowledge of the two independently hydrating systems, namely, the portland cement—water system and the expansive complex—water system will not be appropriate because of the possible interaction caused by simultaneous presence of both the systems in the hydration process.

Oral Discussion

Kozo Sugiura

Plotting the chemical composition of the expansive cement being manufactured in the U.S.A. under your guidance on Fig. 1, most of them will be slightly above the line for $Al_2O_3/SO_3 = 1$. Supposed the value were lowered, more trisulfate is made to be produced, I think. Is there any special reason for selecting the composition described above?

Authors' Closure

Alexander Klein and Povindar K. Mehta

The research reported in our paper deals with the nature of hydration products corresponding to different $A/\bar{S}$ and $C/\bar{S}$ molar ratios in the expansive *component* system only. The discusser's question relates to expansive *cements*, and is therefore, beyond the scope of this paper. The information on compositions of Type K commercial expansive cements is of a proprietary nature, and cannot be discussed here. However, it may be pointed out that our phase diagram regarding nature of hydration products in the expansive component system will not hold good for similarly computed $A/\bar{S}$ and $C/\bar{S}$ values from chemical composition of integral expansive cements, because the distribution of aluminate and sulphate ions amongst compounds present there is of a more complex character.

Supplementary Paper IV-69 Fundamental Studies on the Expansive Cement

Nobue Fukuda*

Synopsis

Fundamental studies have been made on Lossier's expansive cement.

The constitution of sulphoaluminate clinker, was investigated by experiments of system CaO-Al_2O_3-SO_3. From the results it was made known that the existence of a ternary compound $3CaO \cdot 3Al_2O_3 \cdot CaSO_4$ (or $3C \cdot 3A \cdot CaSO_4$) was certain. In usual sulphoaluminate clinker, the formation of $3C \cdot 3A \cdot CaSO_4$ is considered to be completed practically, and excess of $CaSO_4$ remains as free $CaSO_4$. And the compound composition is to be calculated, for example, that of a sulphoaluminate clinker prepared by similar method to Lossier's became as follows.

$3CaO \cdot 3Al_2O_3 \cdot CaSO_4$	43.5%
free $CaSO_4$	28.2%
C_2S	20.3%
free CaO, ferrite, etc	8.0%

In order to make clear the hydration mechanism of expansive cement, the author made a basic hydrating experiment of $3C \cdot 3A \cdot CaSO_4$ to which $CaSO_4 \cdot 2H_2O$, calcined $CaSO_4$, and $Ca(OH)_2$ was added. According to the results, without additives, $3C \cdot 3A \cdot CaSO_4$ formed low sulphate hydrate $C_3A \cdot CaSO_4 \cdot 12H_2O$ but no high sulphate $C_3A \cdot 3CaSO_4 \cdot 30\text{-}32H_2O$. In order to form high sulphate, addition of gypsum is necessary.

$3C \cdot 3A \cdot CaSO_4 + 2CaSO_4 \cdot 2H_2O + xH_2O = C_3A \cdot 3CaSO_4 \cdot 30-32H_2O + 2Al_2O_3$ hydrate. In order to increase further the yield of high-sulphate greater amount of gypsum must be given with addition of CaO. The components, i.e. $3C \cdot 3A \cdot CaSO_4$, free $CaSO_4$ and free CaO, contained in the clinkers might possess more effective nature or condition, than that of simple mixtures of these components. When the system is rich in CaO and lacking in $CaSO_4$ for Al_2O_3 to change into high sulphate completely, the formation of $C_2A \cdot 8H_2O$ occurs, besides high- or low-sulphate hydrate. The formation of $C_2A \cdot 8H_2O$ seems to be closely related to the setting.

Introduction

Lossier's expansive cement (1) of sulphoaluminate type has received much attention. Following applications have been studied and carried out; manufacture of non-shrinking cement; production of self-stressed concrete; and other practical uses. But the industry of this sort of cements is still in the course of development, there remains many unsolved problems about the manufacturing process and the properties. And in laboratory, the rate and extent of expansion have been often irregular and unpredictable. Thus, for practical use, fundamental studies should be advanced.

In this paper, following problems have been investigated; the constituents of clinkers obtained by burning the raw mixture of system CaO–Al_2O_3–SO_3; the hydrating behaviors of the constituents of the clinkers; and the relations between these items and the characters of expansion and setting of the cements.

*Cement Division, Tokuyama Soda Co., Ltd., Tokuyama, Japan.

$3CaO \cdot 3Al_2O_3 \cdot CaSO_4 (3C \cdot 3A \cdot CaSO_4)$

Ternary Compound of System $CaO-Al_2O_3-SO_3$

In another experiment (2), replacing the various amount of $CaCO_3$ of portland cement raw mixtures with $CaSO_4$, the clinkers shown in Table 1 were prepared. It has been reported (3) that SO_3 in portland cement clinker forms alkali-sulphate and that excess SO_3 enters into combination with CaO to form $CaSO_4$. Also in this experiment, these reactions were observed. In these clinkers, assuming that all the alkalies formed sulphates and that excess SO_3 formed $CaSO_4$, the mineral composition was calculated by Bogue's method as in Table-1. The contents of C_3A and C_4AF were about 8.0 and 9.6%, and that of $CaSO_4$ was 0.6–5.5%. But X-ray powder diffraction of the clinkers revealed following remarkable facts. When SO_3 content was small just as in clinker So, the formation of C_3A and C_4AF was clear. As SO_3 content increased, the diffraction patterns of C_3A and C_4AF became weak. In the clinkers S_3 and S_4, the patterns could not be observed any longer. As for $CaSO_4$ in clinkers, only when SO_3 content was excessively large as in clinker S_8, the pattern of $CaSO_4$ could be detected. These facts suggested that, in the course of burning, $CaSO_4$ might be lost by the reaction with Al_2O_3 forming a compound (probably ternary compound) and that, on account of the lack of Al_2O_3, C_3A and C_4AF could not be formed.

From the above results, the presence of a ternary compound of system $CaO-Al_2O_3-SO_3$ was predicted.

Experiments of System $CaO-Al_2O_3-SO_3$

If an anhydrous ternary compound could be formed in the system $CaO-Al_2O_3-SO_3$, it might be the main compound of Lossier's sulphoaluminate clinker prepared from the system $CaO-Al_2O_3-SO_3$. In order to confirm the presence of the compound, following experiments of system $CaO-Al_2O_3-SO_3$ were made.

For the solid phase reaction, six series of mixtures were devised from synthesized C_3A and chemical reagents.

i) $C_3A-nCaSO_4$, $n = 0.1, 0.3, 0.5, 1.0, 3.0$
Mixtures were burned at 1,400°C for 10 min.

ii) $3CaO-3Al_2O_3-CaSO_4$
The mixture was burned at 900°C—6 hrs, 1000°C—6 hrs, 1,100°C—3 hrs—3 hrs (repeatedly), 1,200°C—3 hrs, 1,350°C—6 hrs, and 1,400°C—4.5 hrs.

iii) $3Al_2O_3-4CaSO_4$
The mixture was burned at 1,300°C for 3 hrs. Decomposition of $CaSO_4$ was measured.

iv) $5CaO-3Al_2O_3-CaSO_4$
The mixture contained excessively large amount of CaO. It was burned at 1,350°C for (3 + 3) hrs, repeatedly.

v) $4CaO-3Al_2O_3-SO_2$ (gas)
Instead of using $CaSO_4 \cdot 2H_2O$, the mixture $4CaO-3Al_2O_3$ was burned at 1,200°C for 3 hrs in air current containing 5% SO_2 gas.

vi) $n(CaO-Al_2O_3)-CaSO_4$ $n = 1 - 5$
In order to determine the mol ratio $CaO \cdot Al_2O_3/CaSO_4$, the mixtures were burned at 1,350°C for 6 hrs.

The ground and blended mixtures were burned in an electric furnace. After burning they were quenched in air. The products were examined by chemical analysis and X-ray powder diffraction. The contents of free CaO and free Al_2O_3 were determined by chemical analysis, and the contents of the ternary compound and free $CaSO_4$ were measured by X-ray quantitative analysis (internal standard method). And the reaction at high temperature was observed with high temperature X-ray diffractometer.

By X-ray diffraction, all the products showed the same unknown pattern. Products of series ii), showed weak peaks of this pattern at 900°C, and remarkable peaks in coexistence of those of $CaO \cdot Al_2O_3$ at

S_8	10.0			15.8			S

1,000°C. The patterns of $CaO \cdot Al_2O_3$ and uncombined material became weak at 1,100°C. At 1,200°C, only the pattern of the unknown compound was observed distinctly. At 1,300°C the formation seemed to finish, but small amount of Al_2O_3 remained. At 1,400°C, the formation seemed to have already been completed. The calculated composition of the unknown compound became nearly equal to $3CaO \cdot 3Al_2O_3 \cdot CaSO_4$, in all the products of this series. Products of series iii), (mixture of $3Al_2O_3$–$4CaSO_4$) showed the decomposition of $CaSO_4$ in accordance with the formation of the compound $3CaO \cdot 3Al_2O_3 \cdot CaSO_4$. Products of series v), (mixture of $4CaO$–$3Al_2O_3$ burned in SO_2 containing current) showed the formation of $CaSO_4$ and remarkable amount of the above ternary compound. Products of series iv) ($5CaO$–$3Al_2O_3$–$CaSO_4$) contained small amount of C_3A due to excess of CaO and Al_2O_3. The excess of Al_2O_3 was caused by the decomposition of $CaSO_4$. Of course, the main compound was the above ternary compound. Products of series vi) gave the results shown in Table 2. Besides the ternary compound, the products of n = 1 and 2 contained 23% and 6% of free $CaSO_4$ respectively, and the products of n = 4 and 5 contained 22.3% and 35.6% of $CaO \cdot Al_2O_3$ respectively. As for free CaO, the content was small in n = 1 and 2 and extremely small in n = 4 and 5. No free CaO was found in n = 3. The product of n = 3, had remarkable amount of the ternay compound and only 0.2% of free Al_2O_3 was detected. The mixture n = 3 gave maximum yield of the ternary compound, namely 94.8%.

The obtained results are summerized as follows: A sole ternary compound with definite crystalline form exists in the system CaO–Al_2O_3–SO_3. This ternary compound begins to form at about 900°C and is stable at least up to 1,400°C. At the initial stage of this reaction, the formation of $CaO \cdot Al_2O_3$ was often observed. From the results of chemical analysis and X-ray diffraction, the composition of this ternary compound is estimated as $3CaO \cdot 3Al_2O_3 \cdot CaSO_4$.

The compound gives following X-ray powder diffration data.

dÅ	3.75	3.24	2.91	2.65	2.46	2.30	2.17	1.62	1.58
int.	100	7	6	29	7	4	24	7	4

Halstead and Moore (4) made an advanced study of the synthesis and the crystallography of the above ternary compound. They have reported that $3CaO \cdot 3Al_2O_2 \cdot CaSO_4 (4CaO \cdot 3Al_2O_3 \cdot SO_3)$ is the only ternary compound occurring in the system CaO–Al_2O_3–SO_3 below 1,350°C, and the above formula is reasonable and correct judging from the results of chemical analysis and X-ray diffraction. And from the crystallographic investigation, they showed that the compound is an end member of sodalite-noselite-haüynite series with all the Si replaced by Al and all Na by Ca. R. Kondo (5) also described that the above ternary compound is one of the compounds belonging to haüyne type structure and could be obtained by substitution of all of Na and Si of haüyne by Ca and Al.

Constitution of Sulpho-Aluminate Clinker

The Experiments on Sulphoaluminate Clinker

Presuming that $3CaO \cdot 3Al_2O_3 \cdot CaSO_4 (3C \cdot 3A \cdot CaSO_4)$ should occur in Lossier's sulphoaluminate clinker, following experiments were made.

Changing the amount of gypsum, raw mixtures of gypsum-bauxite-lime were prepared. They were ground to the fineness of minus 88μ, and after burning at 1,300°C for 30 min, they were quenched in air. Thus six clinkers with various mol ratio Al_2O_3/SO_3 were obtained (Table 3). In all of them, the formation of $3C \cdot 3A \cdot CaSO_4$ was made clear by X-ray diffraction. The content of $3C \cdot 3A \cdot CaSO_4$ was calculated on the base of SO_3 in the case of $Al_2O_3/SO_3 > 3$, and on the base of Al_2O_3 in the case of $Al_2O_3/SO_3 < 3$. On the other hand, the content was determined by X-ray internal standard method. Both of the values were nearly equal, so that the calculated value could be useful. On the change of Al_2O_3/SO_3 mol ratio from 8.2 to 6.0, the content of $3C \cdot 3A \cdot CaSO_4$ increased, reached maximum at $Al_2O_3/SO_3 = 3.5$–2.0, and decreased at $Al_2O_3/SO_3 = 2.0 - 0.8$. The clinker of

$Al_2O_3/SO_3 = 0.8$ is the most similar one to the sulphoaluminate clinker reported by Lafuma. (1)

Then, considerable amount of the clinker having similar composition to Lafuma's, was prepared by the above method (Table 4), and examined. X-ray diffraction revealed that this clinker was mainly composed of $3C\cdot3A\cdot CaSO_4$ and free $CaSO_4$, and that $\beta-C_2S$ was formed clearly. The compound composition was calculated; $3C\cdot3A\cdot CaSO_4$ from Al_2O_3, free $CaSO_4$ from excess SO_3 and C_2S from SiO_2. The calculated composition became as follows.

$3CaO\cdot3Al_2O_3\cdot CaSO_4$ 43.5%
free $CaSO_4$ 28.2%
$\beta-C_2S$ 20.3%
free CaO, Fe_2O_3, TiO_2 etc..... 8.0%

Lossier's sulphoaluminate clinker burned at 1,300°C for 30 min, contains $3C\cdot3A\cdot CaSO_4$ as the principal constituent and comparable amount of free $CaSO_4$, which play an important role in expanding reaction. And SiO_2 seemed to form $\beta-C_2S$. In industrial products, calcium aluminate and considerable amount of free CaO may be contained besides the above constituents.

Lafuma reported that his sulphoaluminate clinker was a mixture of free $CaSO_4$, calcium aluminate probably C_5A_3 and $\gamma-C_2S$, and not a ternary compound. Probably, the burning temperature might be too low to form the ternary compound, as Halstead and Moore (4) have described.

Klein and Troxell (6) propared clinkers by burning the mixture of $Ca(OH)_2$ or $CaCO_3$, gypsum and bauxite or aluminium sulphate at 1,350°C. They deduced that they had synthesized two ternary compounds, estimating composition as $5CaO\cdot2Al_2O_3\cdot SO_3$ and $9CaO\cdot4Al_2O_3\cdot3SO_3$. But it seems that the composition reported by Klein and Troxell must be the composition of a mixture of $3C\cdot3A\cdot CaSO_4$ and free $CaSO_4$ or calcium aluminate. In the experiment of the present auther, only $3C\cdot3A\cdot CaSO_4$ was detected as stable ternary compound.

The Effect of SiO_2 on the Formation of $3C\cdot3A\cdot CaSO_4$

In the manufacture of expanding cement, raw materials of Al_2O_3-source often contain considerable amount of SiO_2. In order to make clear the effect of SiO_2 on the formation of $3C\cdot3A\cdot CaSO_4$, following fundamental experiments were made. Raw mixtures were prepared from chemical reagents.

Series (1) $3CaO-3Al_2O_3-CaSO_4-nSiO_2$

Sample No.	S-0	S-0.5	S-1	S-2	S-3
n	0	0.5	1	2	3

Series (2) $(3+m)CaO-3Al_2O_3-CaSO_4-nSiO_2$

Sample No.	CS	2CS	3CS	2C2S	4C2S	6C2S	7.5C2S
m	1	2	3	2	4	6	7.5
n	1	1	1	2	2	2	2

Series (1) was made by changing the amount of SiO_2, while series (2) was made by changing the amount of SiO_2 and CaO. After moulding, the mixtures were burned at 1,300°C or 1,350°C for 30 min. The products were examined by chemical analysis and X-ray diffraction. The results are shown in Table 5 and summerized as follows. Series (1); when the mixtures were burned, the decomposition of $CaSO_4$ occurred depending upon the amount of SiO_2, therefore the content of $3C\cdot3A\cdot CaSO_4$ was reduced. SiO_2 formed C_2AS($2CaO\cdot Al_2O_3\cdot SiO_2$, gehlenite) in the reaction with CaO and Al_2O_3. With the increase of SiO_2, the formation of C_3A_5 and probably of CAS_2 was observed. Series (2); when CaO content was enough to form C_2S, i.e. in the case of molar ratio of extra $CaO/SiO_2 > 2$, no decomposition of $CaSO_4$ occurred, and SiO_2 had no effect on the formation of $3C\cdot3A\cdot CaSO_4$. But in the case of extra $CaO/SiO_2 < 2$, decomposition of $CaSO_4$ occurred and the content of $3C\cdot3A\cdot CaSO_4$ decreased. It can be concluded that SiO_2 has no effect on the formation of $3C\cdot3A\cdot CaSO_4$, only when the mol ratio extra CaO/SiO_2 is greater than 2.

Hydration of Sulphoaluminous Cement

Hydration of $3CaO\cdot3Al_2O_4\cdot CaSO_4$

In order to study the expanding properties of sulphoaluminate type expansive cement, examination was made on the hydrating behaviors of expansive material and sulphoaluminous cement. It has been confirmed that the main constituent of sulphoaluminous cement is $3C\cdot3A\cdot CaSO_4$. The hydration mechanism of this compound has not yet been made clear, and there have been some different points of view about $3C\cdot3A\cdot CaSO_4$ and its hydrated product i.e. $C_3A\cdot3CaSO_4\cdot30\text{-}32H_2O$ which is said to cause expansion. In order to investigate the hydration of sulphoaluminous cement, the basic hydration experiments (7) were made about the following four systems.

(1) $3C\cdot3A\cdot CaSO_4-H_2O$
(2) $3C\cdot3A\cdot CaSO_4-CaSO_4\cdot2H_2O-H_2O$
(3) $3C\cdot3A\cdot CaSO_4-CaSO_4$(calcined)$-H_2O$
(4) $3C\cdot3A\cdot CaSO_4-Ca(OH)_2-H_2O$

System (1)—represents the hydration of only $3C\cdot3A\cdot CaSO_4$, namely hydration with pure water, system (2)—the hydration with coexistence of gypsum, system (3)—the hydration with coexistence of calcined $CaSO_4$ corresponding to free $CaSO_4$ in sulphoaluminate clinker, and system (4)—the hydration with coexistence of free CaO. Varying the amount, the additives i.e. $CaSO_4\cdot2H_2O$, $Ca(OH)_2$ and $CaSO_4$ (calcined at 1,300°C) were mixed with $3C\cdot3A\cdot CaSO_4$. The hydration was carried out in a rotating porcelain pot mill with mixing water (five times in weight of the solid sample) at 20±1°C for 6, 24 and 48 hrs. Then the slurry was filtered rapidly. After washing with absolute alcohol and drying, the solid phase was examined by chemical analysis and X-ray diffraction. At the same time, the extracted substances in the liquid phase were analysed. The results are shown in Fig. 1 and Table 6, and summerized as follows.

In the hydration of $3C\cdot3A\cdot CaSO_4$ and H_2O the

high s. = $C_3A\cdot3CaSO_4\cdot30$–$32H_2O$ low s. = $C_3A\cdot CaSO_4\cdot12H_2O$

low sulphate of calcium aluminium sulphate hydrate, $C_3A\cdot CaSO_4\cdot12H_2O$ was formed, and high sulphate was hardly observed. The reaction seems as follows.

$$3C\cdot3A\cdot CaSO_4 + xH_2O = C_2A\cdot CaSO_4\cdot12H_2O + 2Al_2O_3 \text{ hydrate}$$

In the hydration of $3C\cdot3A\cdot CaSO_4$, gypsum and H_2O, high sulphate of calcium aluminium sulphate hydrate $C_3A\cdot3CaSO_4\cdot30$–$32H_2O$ was formed and low sulphate was hardly observed. Fig. 1 shows the relation between the amount of added $CaSO_4$ and the concentration of Al_2O_3, CaO and SO_3 in the liquid phase. At the amount of added $CaSO_4$ 44.6%, Al_2O_3 in the liquid phase began to decrease, on the contrary SO_3 and CaO began to increase sharply. It indicates that, until the added $CaSO_4$ reaches this point (44.6%), it takes part in the formation of high sulphate hydrate, beyond this point excess of $CaSO_4$ dissolves according to its solubility, and remains in the liquid phase. The value 44.6% corresponds to the mol ratio $CaSO_4/3C\cdot3A\cdot CaSO_4 = 2$.

The reaction seems as follows.

$$3C\cdot3A\cdot CaSO_4 + 2CaSO_4\cdot2H_2O + xH_2O = C_3A\cdot3CaSO_4\cdot30\text{-}32H_2O + 2Al_2O_3 \text{ hydrate}$$

In the hydration of $3C\cdot3A\cdot CaSO_4$ with calcined $CaSO_4$ (corresponding to free $CaSO_4$ in the clinker) both low-and high-sulphate hydrates were formed, probably because of low solubility of calcined $CaSO_4$. The reaction seems as follows.

$$3C\cdot3A\cdot CaSO_4 + CaSO_4 \text{ (calcined)} + xH_2O \longrightarrow \begin{cases} C_3A\cdot CaSO_4\cdot12H_2O + 2Al_2O_3 \text{ hydrate} \\ C_3A\cdot3CaSO_4\cdot30\text{–}32H_2O + 2Al_2O_3 \text{ hydrate} \end{cases}$$

From the results, it seems that calcined $CaSO_4$ or free $CaSO_4$ in the clinker is less available than gypsum.

In the hydration of expansive cement, $3C\cdot3A\cdot CaSO_4$ is in contact with considerable amount of free lime, i.e. free CaO in the clinker, and $Ca(OH)_2$ separated by the hydration of portland cement. When $3C\cdot3A\cdot CaSO_4$ was hydrated under the coexistence of $Ca(OH)_2$, the low sulphate hydrate was formed, while high sulphate was not observed. Besides, small amount of $2CaO\cdot Al_2O_3\cdot8H_2O$ was formed. The reaction is considered as follows.

$$3C\cdot3A\cdot CaSO_4 + 4Ca(OH)_2 + 24H_2O = C_3A\cdot CaSO_4\cdot12H_2O + 2(C_2A\cdot8H_2O)$$

When $3C\cdot3A\cdot CaSO_4$ reacts on H_2O only, low sulphate hydrate and probably Al_2O_3 hydrate are formed. By addition of gypsum to this system, high sulphate is formed. Until the mol ratio $CaSO_4/3C\cdot3A\cdot CaSO_4$ reaches 2, $CaSO_4$ is useful to form high sulphate, beyond this point, the excess of $CaSO_4$ is not useful because of the lack of CaO. Beside high sulphate, Al_2O_3 separates probably as hydrate. With addition of more than 8 and 6 mol of $CaSO_4$ and CaO against one mol of $3C\cdot3A\cdot CaSO_4$, the formation of high sulphate can be completed. Calcined $CaSO_4$ is not so useful as $CaSO_4\cdot2H_2O$ to form high sulphate, because of its low solubility. But this fact does not mean that free $CaSO_4$ in clinker is not so useful as mixed gypsum. Compared with simply mixed gypsum, free $CaSO_4$ contained in clinker often shows favorable results in expansion. When the system is poor in $CaSO_4$ and rich in CaO, low sulphate is formed, and Al_2O_3 separates as $C_2A\cdot8H_2O$. This reaction should be paid attention, because it has something to do with the setting.

Hydration of Expansive Cement

Samples

$3C\cdot3A\cdot CaSO_4$ was synthesized from reagents, and sulphoaluminous cement was prepared from bauxite, lime and gypsum. They were mixed with portland cement, gypsum and blast-furnace slag in the proportion shown in Table 7 and ground to the specific surface of 3,150–3,200 cm^2/g. These cement samples were examined as follows.

Length Change

Cement mortar specimens were prepared in the mixing ratio, cement: sand: water = 1: 2: 0.60 (0.64 or 0.68). The specimens were demolded 2 days after molding. After curing in water (20±1°C) for 0, 3, and 7 days, they were stored in air (20±1°C, RH

76%). The length at each period was measured with comparator of JCEA, TYPE II. The results are shown in Fig. 2, 3, and summerized as follows:

Expansive cement containing 10% of sulphoaluminous cement, did not show any expansion, and the addition of 1.0% gypsum had no effect. Expansive cement containing 20% of sulphoaluminous cement continued to expand for the first 2 weeks, then the expansion began to decrease. But the addition of 0.5 or 1.0% gypsum caused remarkable expansion during the first week of curing, and the expansion was kept up to the end of this test, i.e. for 13 weeks after demolding. A similar tendency was observed, also in the case of curing only in air. When the added gypsum reached 6.0%, the specimen expanded extremely and cracked. But when 1.0% gypsum was added to cement sample containing 10% of sulphoaluminous cement, the effect did not appear. There should be a definite range for useful addition of sulphoaluminous cement.

The cement, prepared by mixing synthesized $3C \cdot 3A \cdot CaSO_4$ and portland cement, showed shrinkage instead of expansion. With increased $3C \cdot 3A \cdot CaSO_4$ content, the degree of shrinkage increased. Addition of 3 or 6% gypsum caused a slight decrease in shrinkage but no expansion. When more slag was added, the shrinkage decreased remarkably, but no expansion occurred. Paste specimens also had a similar tendency in the length change at early age of curing.

Hydrated Products in Paste Specimens

Paste specimens (water/cement = 27%) were cured up to 8 weeks. Samples for each period were pulverized and washed with absolute alcohol. After drying at low temperature, they were examined by X-ray diffraction. The results are shown in Table 8, and summerized as follows:

Paste specimen of expansive cement containing sulphoaluminous cement, cured in air for 2 days and in water for a week, showed obviously the formation of high sulphate hydrate. With the increase of mixed sulphoaluminous cement, the content of high sulphate increased. Expansive cement mixed with 20% of

sulphoaluminous cement, is estimated to contain 8.3% $3C \cdot 3A \cdot CaSO_4$ and 8.0% free $CaSO_4$. It is considered that the free $CaSO_4$ is effective to form high sulphate hydrate.

Paste specimen of cement sample containing synthesized $3C \cdot 3A \cdot CaSO_4$, showed the formation of low sulphate but high sulphate was scarcely observed. Even with addition of 6% gypsum, the formation of high sulphate was not clearly observed. It seems that, much greater amount of gypsum is necessary to form high sulphate. Even with curing of longer age, there was not any appreciable change in the hydrates.

Hydrating Characters

Expansive cement prepared by mixing with sulphoaluminous cement, contained sufficient amount of $3C \cdot 3A \cdot CaSO_4$ and free $CaSO_4$, from which considerable amount of high sulphate was formed in the hydration. From the hydrating experiment of system $3C \cdot 3A \cdot CaSO_4$–$CaSO_4$ (calcined)–H_2O, it was clarified that calcined $CaSO_4$ was not so effective as ordinary gypsum in the formation of high sulphate. Nevertheless, in the hydration of the above expansive cement, the content of high sulphate was observed to be sufficient. Therefore, it seems that $3C \cdot 3A \cdot CaSO_4$ and free $CaSO_4$ contained in sulphoaluminate clinker must be in a particularly activated state.

In the case of cement sample, prepared by mixing with synthesized $3C \cdot 3A \cdot CaSO_4$, its paste showed the formation of low sulphate hydrate, but high sulphate was scarcely observed, and its mortar specimen showed shrinkage. With addition of 6% gypsum (or 4.7% $CaSO_4$) to the cement sample containing 6% of synthesized $3C \cdot 3A \cdot CaSO_4$, high sulphate could hardly be observed, and its mortar specimen did not show any expansion. Addition of much greater amount of gypsum would be necessary to cause the formation of high sulphate and expansion. On the other hand, from the hydrating experiment of system $3C \cdot 3A \cdot CaSO_4$–$CaSO_4 \cdot 2H_2O$–H_2O, the effect of gypsum to form high sulphate has been confirmed. These facts indicate that expansive cement prepared by mixing with sulphoaluminous cement is much more reactive, compared with cement sample prepared by mixing with synthesized $3C \cdot 3A \cdot CaSO_4$ and $CaSO_4$ (gypsum or calcined). It will be necessary to make further studies on the dispersion of components and the effect of portland cement, etc. R. Kondo and N. Nawata (8) also described that a simple mixture of $3C \cdot 3A \cdot CaSO_4$, CaO and $CaSO_4$ could not hydrate or expand so rapidly as the sulphoaluminate clinker, in which $3C \cdot 3A \cdot CaSO_4$ crystals were surrounded by a matrix containing free lime with or without $CaSO_4$.

Setting of the Cements Containing $3C \cdot 3A \cdot CaSO_4$

By J.I.S. method, setting test was made for the mixtures, prepared from $3C \cdot 3A \cdot CaSO_4$, gypsum, blastfurnace slag, $Ca(OH)_2$, and portland cement in the proportion shown in Table 9. The results are summerized as folllws:

$3C \cdot 3A \cdot CaSO_4$ itself showed normal setting. When it was mixed with normal portland cement, the mixture showed quick setting. And addition of 6% gypsum could not retard the setting. When 20% slag was further added, the setting became normal at last. The mixture of $3C \cdot 3A \cdot CaSO_4$ and $Ca(OH)_2$, showed flash setting. Under the presence of $Ca(OH)_2$, the hydration of $3C \cdot 3A \cdot CaSO_4$ seemed to proceed as follows:

$$3C \cdot 3A \cdot CaSO_4 + 4Ca(OH)_2 + 24H_2O = C_3A \cdot CaSO_4 \cdot 12H_2O + 2(C_2A \cdot 8H_2O)$$

Besides low sulphate, $C_2A \cdot 8H_2O$ was formed. With

addition of gypsum to this system, high sulphate is formed. But, when the amount of gypsum is not enough for Al_2O_3 to change into high sulphate completely, the formation of $C_2A \cdot 8H_2O$ should continue. In the hydration of $3C \cdot 3A \cdot CaSO_4$, as in the experiment of system $3C \cdot 3A \cdot CaSO_4 - H_2O$, $C_2A \cdot 8H_2O$ could not be formed because of the lack of CaO, though the system contained considerable amount of Al_2O_3 separated from $3C \cdot 3A \cdot CaSO_4$. When $C_2A \cdot 8H_2O$ was not formed in the hydration, the setting became normal, on the other hand, when $C_2A \cdot 8H_2O$ was formed, quick or flash setting occurred under other conditions. In this way, the setting may be changeable depending upon the extent of formation of $C_2A \cdot 8H_2O$ and other conditions. Thus, the formation of $C_2A \cdot 8H_2O$ is considered to be related closely to setting.

Summary

By the solid phase reaction of system $CaO-Al_2O_3-SO_3$, the author confirmed the presence of a sole ternary compound, which is stable at high temperature. The composition was estimated as $3CaO \cdot 3Al_2O_3 \cdot CaSO_4$. The formation begins at 900–1,000°C, and this compound is stable up to 1,400°C at least. According to Halstead and Moore, the melting point of the compound was indicated between 1,590°C and 1,600°C by a rough differential thermal analysis. The compound gives following X-ray powder diffraction data.

dÅ	3.75	3.24	2.91	2.65	2.46	2.30	2.17	1.62	1.58
int.	100	7	6	29	7	4	24	7	4

In the industrial sulphoaluminate clinker, apart from the variation attributable to manufacturing process, the formation of $3CaO \cdot 3Al_2O_3 \cdot CaSO_4$ is considered to be completed practically. The excess SO_3 in the clinkers can be considered to exist as free $CaSO_4$. Thus, the compound composition of the clinkers can be calculated; the content of $3C \cdot 3A \cdot CaSO_4$ from Al_2O_3, because the mol ratio Al_2O_3/SO_3 is usually less than 3, free $CaSO_4$ from excess of SO_3, and C_2S from SiO_2. The calculated value is thought to be practical.

When the raw mixture contains sufficient amount of CaO, SiO_2 has probably no effect on the formation of $3C \cdot 3A \cdot CaSO_4$.

In the hydration of $3C \cdot 3A \cdot CaSO_4$ by itself or with insufficient amount of $CaSO_4$, low sulphate hydrate $C_3A \cdot CaSO_4 \cdot 12H_2O$ is formed. In the experiment, the low sulphate does not cause any expansion but shrinkage. Without the formation of high sulphate $C_3A \cdot 3CaSO_4 \cdot 30-32H_2O$, expansion can not occur. In the hydration of $3C \cdot 3A \cdot CaSO_4$ with $CaSO_4$ (gypsum), high sulphate is formed and excess of Al_2O_3 is considered to separate as hydrate. In this case, the limit of useful amount of $CaSO_4$ is 2 mol for one mol of $3C \cdot 3A \cdot CaSO_4$.

$$3C \cdot 3A \cdot CaSO_4 + 2CaSO_4 + H_2O = C_3A \cdot 3CaSO_4 \cdot 30-32H_2O + 2Al_2O_3 \text{ hydrate}$$

In order to further increase the yield of high sulphate greater amount of gypsum must be used with CaO added thereto. For one mol of $3C \cdot 3A \cdot CaSO_4$ to change into high sulphate completely, addition of 8 mol $CaSO_4$ and 6 mol CaO is necessary in theory. Lossier's sulphoaluminous cement, usually contains sufficient amount of $3C \cdot 3A \cdot CaSO_4$ and free $CaSO_4$, and some free CaO. In the reaction with sufficient amount of $Ca(OH)_2$ separated from portland cement, those constituents could form enough amount of high sulphate to cause expansion. Probably, free $CaSO_4$ in the sulphoaluminate clinker, is not so reactive, like the gypsum calcined at high temperature, and shows less effect to form high sulphate in the hydration of $3C \cdot 3A \cdot CaSO_4$, compared with ordinary gypsum. But as above mentioned, free $CaSO_4$ in the sulphoaluminous cement is effective in the formation of high sulphate. On the other hand, cement sample prepared by simply mixing synthesized $3C \cdot 3A \cdot CaSO_4$ and gypsum with portland cement, forms low sulphate but scarcely high sulphate. From these facts, it is gathered that, the components, i.e. $3C \cdot 3A \cdot CaSO_4$, free $CaSO_4$ and free CaO contained in sulphoaluminate clinker might possess very effective nature or condition for the hydration. After all, $3C \cdot 3A \cdot CaSO_4$ and free $CaSO_4$ are the principal components of Lossier's sulphoaluminous cement and should play an important role in expansion.

In the hydration with paste state, synthesized $3C \cdot 3A \cdot CaSO_4$ showed normal setting. However, the mixture of pure $3C \cdot 3A \cdot CaSO_4$ and normal portland cement showed quick setting. Even when gypsum was (6%) added, the setting could not be retarded. Sulphoaluminous cement which contains free CaO in some degree, shows quick setting sometimes. In the paste of synthesized $3C \cdot 3A \cdot CaSO_4$, the reaction is considered as follows:

$$3C \cdot 3A \cdot CaSO_4 + xH_2O = C_3A \cdot CaSO_4 \cdot 12H_2O + 2Al_2O_3 \text{ hydrate}$$

And in the paste of the mixture of $3C \cdot 3A \cdot CaSO_4$ and portland cement, the reaction is considered as follows:

$$3C \cdot 3A \cdot CaSO_4 + 4Ca(OH)_2 + 24H_2O = C_3A \cdot CaSO_4 \cdot 12H_2O + 2(C_2A \cdot 8H_2O)$$

With addition of gypsum to this system, the formation of high sulphate begins. But when the amount of gypsum is not enough for Al_2O_3 to change into high sulphate completely, the formation of $C_2A \cdot 8H_2O$ should continue. In the paste specimen of synthesized $3C \cdot 3A \cdot CaSO_4$, because of absence of free CaO or $Ca(OH)_2$, $C_2A \cdot 8H_2O$ is not formed, and the setting is normal. In the pastes of the mixtures of $3C \cdot 3A \cdot CaSO_4$ and portland cement containing $CaSO_4$ (gypsum) or not, $C_2A \cdot 8H_2O$ is formed besides low- or high-sulphate, on account of the presence of $Ca(OH)_2$ separated from portland cement and the paste specimen shows quick or flash setting. Thus, the formation of $C_2A \cdot 8H_2O$, is considered to be related closely to the setting.

Supplementary Paper IV-74 Mineralogical Composition of Expansive Cement Clinker Rich in SiO_2 and Its Expansibility

Takanori Nakamura, Giichi Sudoh and Shigeo Akaiwa*

Synopsis

The authors experimented on the manufacture of expansive cement clinker by the use of kaolin clay as an aluminous material to be mixed with lime-stone and gypsum.

The mineralogical composition of the burned clinker varied with the mixing ratio of limestone, clay and gypsum, but it was roughly divided into the following three cases; 1) as the principal mineral, anorthite CAS_2 is formed, 2) gehlenite C_2AS is formed, 3) $C_4A_3(SO_3)$ is formed. Conditions of mixing raw materials for good expansive cement clinker were presented. In this case, SiO_2 occurred as $2(C_2S)\cdot CaSO_4$ or β-C_2S; Al_2O_3 entered $C_4A_3(SO_3)$ and ferrite phase. When the raw material contained P_2O_5, wilkeite was occasionally produced.

$2(C_2S)\cdot CaSO_4$ is a prismatic crystal, and was decomposed into C_2S and $CaSO_4$ at 1285°C. This compound showed poor hydraulicity and contributed very little to the initial expansion. Appropriate temperature for burning clinker was determined as 1150–1200°C. The rate of expansion became slow with a rise in the burning temperature.

For good expansion behavior due to hydration, the most desirable mineralogical composition of the clinker was as follows: The quantity of $C_4A_3(SO_3)$ should be large enough; free CaO should be 6 moles or more, and free $CaSO_4$ around 8 moles, per 1 mole of $C_4A_3(SO_3)$. Setting of the experimentally prepared expansive cement was retarded by adding gypsum to it. Additional gypsum was apt to cause abnormal expansion and lowering of strength, but these defects were solved by intermixing blast-furance slag.

It was revealed that the expansion of $C_4A_3(SO_3)$ was controlled by the type of formation of ettringite, rather than by the total amount of produced ettringite. The ettringite produced under high concentration of lime caused expansion, whereas the ettringite produced under low lime concentration did not contribute to expansion.

Introduction

This paper is a report of the results of experiments carried out for the purpose of utilizing the widely distributed kaolin clay as an aluminous material for the manufacture of expansive cement clinker.

When an alumina-rich material, such as bauxite, is used, the burning of expansive cement clinker is generally understood as a reaction of the CaO–Al_2O_3–SO_3 system. But, if the material used was comparatively rich in SiO_2, the behavior of the SiO_2 would present a problem, causing difficulties in manufacturing expansive cement clinker. Information is scarce on reactions of the CaO–SiO_2–Al_2O_3–SO_3 system, and reports on the effects of SiO_2 upon the formation of $C_4A_3(SO_3)$, a compound of the CaO–Al_2O_3–SO_3 system, are very few, except those by the present authors, (1) Fukuda and Kiyoku (2) and Budnikov et al (3). Thus, the knowledge pertaining to the use of clay as raw material has hitherto been very poor.

The authors pursued the behavior of SiO_2 in the clinker during the burning of limestone-clay-gypsum mixture, and established the optimum condition, such as the mixing ratio of raw materials and the burning temperature, for manufacturing expanisve cement clinker.

*Chichibu Cement Co., Ltd., Tokyo, Japan.

In the present paper, following notations are used:
E. C. clinker = Expansive cement clinker rich in SiO_2.
O. P. C. clinker = Ordinary portland cement clinker.

Experimental Procedures and Results

Raw Materials, Burning of Clinker and Measurement of Basic Length

In the present experiments, widely distributed kaolin clay, containing 40–45% SiO_2 and 24–30% Al_2O_3, was used as an aluminous material. As a limy material, limestone of a high purity was used, and chemical by-product gypsum was used as an SO_3 material. The gypsum contained about 0.5% P_2O_5. Clay, limestone and gypsum were mixed in the given proportion; the mixture was made into pellets of 10–15 mmϕ, which were burned in a small test rotary kiln at 1050–1300°C. The best temperature for burning varied with the mixing ratio of raw materials. The clinker for each test was pulverized into 3000–4000 cm^2/g of Blaine specific surface area. The clinker was more easily pulverized than the O.P.C. clinker. Chemical properties of the typical clays and the burned clinkers are given in Table 1.

The measurements of starting basic lengths in the expansion tests were all carried out on the test pieces immediately when they were demolded after one and half hours of their molding.

Mixing Ratio of Raw Materials and Mineralogical Composition of Clinker

The minerals formed in the clinker were identified by means of X-ray diffraction analysis. In the lime-rich mix proportion of raw materials, Al_2O_3 of the clinker occurred as $C_4A_3(SO_3)$ and calcium aluminoferrite, even when a large quantity of SiO_2 existed. In the lime-poor mix proportion, however, gehlenite C_2AS or anorthite CAS_2, both being unhydraulic compound, was formed, but occurrence of $C_4A_3(SO_3)$ was not recognized, in spite of the presence of abundant $CaSO_4$, as shown in Fig.1. In other words, E.C. cliker containing $C_4A_3(SO_3)$ was obtained when the chemical composition of the raw mix was more than 1.0 in the $CaCO_3/(Al_2O_3 + 2SiO_2 + 3Fe_2O_3)$ molar ratio; when the molar ratio was below 1.0, C_2AS or CAS_2 was formed and the obtained clinker was not expansive.

It was revealed that the SiO_2 component in the E.C. clinker, in which $C_4A_3(SO_3)$ is formed, occurs as β-C_2S or calcium silicosulphate, *i. e.*, a double salt of dicalcium silicate and $CaSO_4$. As will be mentioned later, the stable temperature range of calcium silicosulphate varies more or less with the condition of raw material mixing, but it was normally found that calcium silicosulphate is formed in the E.C. clinker burned at lower than 1150–1250°C, an when the burning temperature was higher than this, β-C_2S occurs. The chemical composition of this calcium silicosulphate was determined as $2(C_2S)\cdot CaSO_4$.

The calcium aluminoferrite that was formed in the E.C. clinker had the composition of $C_{10}A_2F_3$ which is somewhat Fe_2O_3-rich. Lime and gypsum, which did not contribute to the formation of $C_4A_3(SO_3)$, calcium aluminoferrite, β-C_2S or $2(C_2S)\cdot CaSO_4$, existed as free and unreacted CaO and β-$CaSO_4$. In the use of chemical by-product gypsum, containing a small quantity of P_2O_5, wilkeite $Ca_{10}O[(Si, S, P)O_4]_6$ was occasionally produced. Any aluminate phase, such as C_3A, $C_{12}A_7$ and CA, was not observed to form, and all Al_2O_3 was fixed as $C_4A_3(SO_3)$ and calcium

aluminoferrite.

Mixing Condition of Raw Materials for E.C. Clinker

As stated above, the constituent minerals of the E.C. clinker were chiefly $C_4A_3(SO_3)$, $2(C_2S)\cdot CaSO_4$ or β-C_2S, $C_{10}A_2F_3$ solid solution phase, free $CaSO_4$ and free CaO. Quantities of these minerals to be formed were dependent upon the chemical composition of clay and the consequent ratios of limestone, clay and gypsum, as well as upon the burning temperature. Quantities of the principal minerals to be fomed can be expressed by the following equations, taking the formation process of each mineral into consideration:

$$\%\, C_{10}A_2F_3 = 2.60 \times \%\,\overline{Fe_2O_3}$$

$$\%\, C_4A_3(SO_3) = 2.00 \times (\%\,\overline{Al_2O_3} - 0.426 \times \%\,\overline{Fe_2O_3})$$

$$\%\, 2(C_2S)\cdot CaSO_4 = 4.00 \times \%\,\overline{SiO_2}$$

$$\%\, \beta\text{-}C_2S = 2.87 \times \%\,\overline{SiO_2}$$

In the above, the mean chemical composition of the ferrite phase is represented by $C_{10}A_2F_3$; $\%\,\overline{SiO_2}$, $\%\,\overline{Al_2O_3}$ and $\%\,\overline{Fe_2O_3}$ are the contents of the respective components of the raw mix on the ignited base.

Based on these equation, the proportion of raw materials to be mixed, in order to obtain E.C. clinker having the aimed mineralogical composition, can be calculated by the equations given below. Assuming that the weight of clay is 100 on the dry base, $\%\,SiO_2$, $\%\,Al_2O_3$ and $\%\,Fe_2O_3$ as the respective contents in the clay, and the purity of limestone and gypsum as 100%, the following calculation is made:

$$\text{Clay (dry base)} = 100 \quad \ldots\ldots(1)$$

$$\text{Limestone (dry base)} = 1.78\{0.550(\%\,Al_2O_3 - 0.426 \times \%\,Fe_2O_3) + 1.17 \times \%\,Fe_2O_3 + 1.87 \times \%\,SiO_2 + n \times 0.183 \times (\%\,Al_2O_3 - 0.426 \times \%\,Fe_2O_3)\} \quad \ldots\ldots(2)$$

$$\text{Gypsum (dry base)} = 1.13\{0.445(\%\,Al_2O_3 - 0.426 \times \%\,Fe_2O_3) + 1.13 \times \%\,SiO_2^* \times m \times 0.445(\%\,Al_2O_3 - 0.426 \times \%\,Fe_2O_3)\} \quad \ldots\ldots(3)$$

The term marked with asterisk is the quantity of gypsum consumed in formaton of $2(C_2S)\cdot CaSO_4$. Since the SiO_2 in the E.C. clinker burned at high temperature occurs as β-C_2S. the quantity of consumed gypsum was unnecessary to consider. Coefficients m and n represent the molar ratio of free $CaSO_4$ and free CaO, which are to be retained in the E.C. clinker to the quantity of $C_4A_3(SO_3)$ to be formed. As will be mentioned later, the molar ratio is an important factor to control the expansibility of E.C. clinker.

This calculation of the proportion of raw materials to be mixed was an approximate calculation, ignoring SiO_2, Al_2O_3, Fe_2O_3 and P_2O_3 of small quantities existing in limestone and gypsum, and also ignoring TiO_2 and other components contained in clay. It was revealed that in the use of a SiO_2-rich clay, careful attention should be paid to the mixing ratio of raw materials, since an inadequate proportion would cause formation of C_2AS or CAS_2, resulting in unexpansive, poorly hydraulic clinker.

Properties of $2(C_2S)\cdot CaSO_4$

The result of synthesis test on pure chemicals showed that calcium silicosulphate which is formed in E.C. clinker is a double salt of dicalcium silicate and calcium sulphate, having the chemical composition of $2(C_2S)\cdot CaSO_4$. In preparing the synthetic, the prescribed mixture of chemicals was placed in the air-tight platinum capsule, and was heated in the electric furnace at 1170°C for 300 hours. The synthe-

sized material took the form of light green prismatic crystals, the growth of which was slow and the maximum length attained to only 30–40μ. The result of X-ray diffraction analysis showed that this synthetic smaple was identical with the $2(C_2S)\cdot CaSO_4$ phase to be formed in E.C. clinker, without any great differences in X-ray patterns. Table 2 is X-ray powder data of the purely synthetic $2(C_2S)\cdot CaSO_4$.

In the pure synthesis from $CaCO_3$, SiO_2 and $CaSO_4$, this compound was formed in the region of $CaCO_3/2SiO_2$ molar ratio ≥ 1. In the region of $CaCO_3/2SiO_2$ molar ratio < 1, volatilization of SO_3 occurred and formation of rankinite C_3S_2 or pseudowollastonite α-CS was observed. In the case of $CaCO_3/2SiO_2$ molar ratio ≥ 1, volatilization of SO_3 was scarce at temperature below 1250°C, and decomposition of excessive $CaSO_4$, which remained after the formation of $2(C_2S)\cdot CaSO_4$, was not particularly accelerated.

The results of DTA and high-temperature X-ray analysis revealed that pure $2(C_2S)\cdot CaSO_4$ was decomposed at about 1285°C, and after cooling down to room temperature it was recognized as β-C_2S and β-$CaSO_4$. When β-C_2S and β-$CaSO_4$, which are the products of decomposition, were heated they combined with each other again and formed $2C_2S\cdot CaSO_4$. The DTA curve of $2(C_2S)\cdot CaSO_4$ showed a large endothermic peak starting at about 1285°C and a small endothermic peak above 1300°C, as illustrated in Fig. 3. In synthesizing $2(C_2S)\cdot CaSO_4$ from $CaCO_3$, SiO_2 and $CaSO_4$, formation of $2(C_2S)\cdot CaSO_4$ progressed rapidly from about 1220°C and large endothermic peak starting at this temperature was observed in DTA.

The heat of hydration of purely synthetic $2(C_2S)\cdot CaSO_4$ was measured with a twin type conduction calorimeter and by the heat of solution method. The obtained value was somewhat lower than that of β-C_2S and slightly higher than that of a $2(\beta\text{-}C_2S) + CaSO_4$ mixture. $2(C_2S)\cdot CaSO_4$ is slow in the rate of hydration and is poorly hydraulic. It was noticed that extrication of SO_4^{2-} into liquid phase due to hydration is difficult to take place. Table 3 shows the heats of hydration of $2(C_2S)\cdot CaSO_4$ and β-C_2S.

Burning Temperature and Fusibility of E.C. Clinker

The degree of sintering was found to be dependent upon the mixing ratio of raw materials as well as upon the burning temperature. In a mixture where free CaO and free $CaSO_4$ remain abundantly, the E.C. clinker began to fuse at a relatively low temperature. The temperature of decomposition of $2(C_2S)\cdot CaSO_4$ in the clinker was lower than that of a purely synthetic sample, and the decomosing temperature was dependent upon the value of n in equation (2).

From the measurement by DTA, the following result was obtained: When $n = 0$ the decomposing temperature of $2(C_2S)\cdot CaSO_4$ was 1250–1260°C, whereas in the case of $n = 3 - 8$ the decomposing temperature lowered by 20–30°C. Fig. 3 shows the relation between the value of n and the temperature of endothermic peak due to decomposition of $2(C_2S)\cdot CaSO_4$. When the temperature was high, $CaSO_4$ was extricated due to decomposition of $2(C_2S)\cdot CaSO_4$. Therefore, the content of free $CaSO_4$ in the E.C. clinker increased, and SiO_2 occurred as β-C_2S.

Fusibility of E.C. clinker in burning process became a problem from about 1220°C. When the raw mix is such that enables much of free CaO and free $CaSO_4$ to remain in the E.C. clinker, fusion occurs easily even if the burning temperature is low, so that the E.C. clinker is apt to agglutinate during the burning. The variations of raw mix during the burning were studied by means of DTA and TGA, and an endothermic reaction was observed to start at about 1120–1150°C. The quantity of endothermal heat at this temperature increased when the value of m in equation (3) became larger. During this endothermic period the E.C. clinker was sintered, and the degree of

sintering was higher with larger quantity of endothermal heat. When later endothermic reactions took place accompanying decomposition of $2(C_2S)\cdot CaSO_4$, the E.C. clinker became much better sintered, and especially when the value of n was large the clinker began to fuse.

Microstructure of E.C. Clinker

The internal structure of E.C. clinker was examined with the optical microscope and the electron probe X-ray microanalyzer. The E.C. clinker burned at temperatures lower than 1100°C was low in the degree of sintering, and the minerals formed in burning were so fine-grained that it was difficult to identify them under the optical microscope.

In the E.C. clinker which was sintered better at 1150–1200°C, the principal minerals $C_4A_3(SO_3)$ and $2(C_2S)\cdot CaSO_4$ were recognized, but the size of crystals was still small, about 5–10μ. $C_4A_3(SO_3)$ was enclosed by $2(C_2S)\cdot CaSO_4$ of the small prismatic crystals

Table 4. *Relation between mix proportion of raw materials and degree of sintering.*

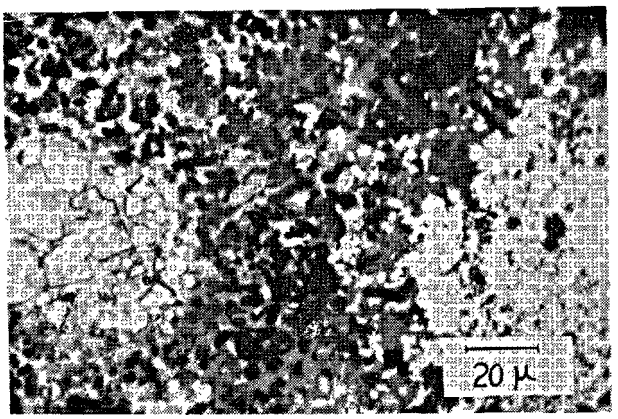
Note. The degrees of sintering are as follows: X, insufficiently sintered, o, well-sintered; ◎, partly fused, F, completely fused.

and both were included in $CaSO_4$ which, under crossed niclos, could be seen to exist as large crystals of euhedral. However, by observation with reflected light on the polished surface etched with a solution of HNO_3 in alcohol, $CaSO_4$ was recognized as an irregular-shaped phase, without showing any distinct outline of crystals. In the case of fused clinker, in particular, $CaSO_4$ was found to enclose more tightly the $C_4A_3(SO_3)$ and other compounds. In the E.C. clinker burned at temperatures below 1200°C, the ferrite phase had the appearance of groups of minute crystals, but in the fused clinker it was dispersed chiefly in irregular shapes.

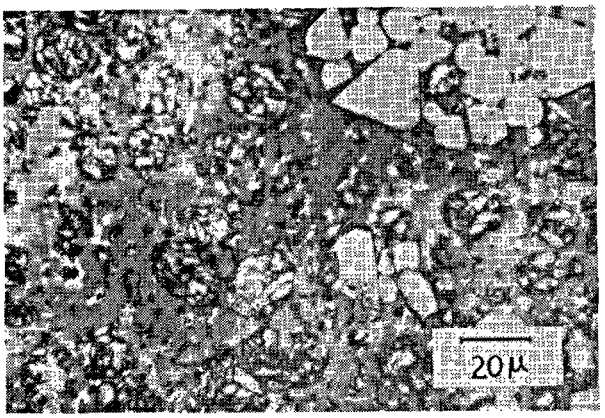
In the E.C. clinker sintered well or in the fused clikner, CaO occurs as groups of relatively large crystals. The CaO is surrounded chiefly by $CaSO_4$, and in many cases it does not contact directly with $C_4A_3(SO_3)$, $2(C_2S)\cdot CaSO_4$ or β-C_2S. β-C_2S, produced by decomposition of $2(C_2S)\cdot CaSO_4$, occurred as fine grains at the outset, but it gradually grew larger and finally became globular. As the $2(C_2S)\cdot CaSO_4$ in the E.C. clinker can be colored blue or reddish brown with HNO_3, its identification was easy.

Expansibility of $C_4A_3(SO_3)$

In order to know the characteristic of expansion of SiO_2–rich E.C. clinker, the expansion behavior of mixtures of $C_4A_3(SO_3)$, $Ca(OH)_2$ and $CaSO_4$ was examined as a first step, by making them into paste of W/solid = 0.5, which was kept under air-tight condition at 20°C, and were measured the changes in length. Expansion of $C_4A_3(SO_3)$ occurred only when ettringite was formed, and shrinkage was noticed when other calcium aluminate hydrates, such as calcium monosulphoaluminate hydrate and $C_4A_3\cdot CaSO_4\cdot 18H_2O$ (M phase) (5), were formed. The condition of formation of ettringite from $C_4A_3(SO_3)$ in hydration of pure mixture of $C_4A_3(SO_3)$–$Ca(OH)_2$–$CaSO_4$ system seemed to be dependent upon concentration of SO_4^{2-}



(1)



(2)

Fig. 4-1. *Microstructure of E.C. clinkers. Etched with 2% HNO_3 in alcohol. Reflected light. (1) E.C. clinker-4a; (2) E.C. clinker-4b.*

ions around $C_4A_3(SO_3)$, irrespective of existence or absence of $Ca(OH)_2$. With the presence of sufficient SO_4^{2-} ions, ettringite was readily formed and remained stable. When unhydrated $C_4A_3(SO_3)$ remained and SO_4^{2-} ion concentration lowered below a certain value, calcium monosulphoaluminate hydrate, M phase and other calcium aluminate hydrates were formed.

The reaction by which ettringite is formed out of $C_4A_3(SO_3)$ can be expressed stoichiometrically as follows:

$$C_4A_3(SO_3) + 2CaSO_4 \xrightarrow{aq} C_3A \cdot 3CaSO_4 \cdot 32H_2O + 2AH_3 \quad \ldots\ldots(4)$$

$$C_4A_3(SO_3) + 6Ca(OH)_2 + 8CaSO_4 \xrightarrow{aq} 3C_3A \cdot 3CaSO_4 \cdot 32H_2O \quad \ldots\ldots(5)$$

Owing to the presence of $Ca(OH)_2$, the reaction of (5) proceeds in $C_4A_3(SO_3)$, prior to the reaction of (4). The reaction of (5) was active for several hours after water-pouring, and a large quantity of ettringite was crystallized out rapidly, thus giving rise to quick setting and exothermal phenomenon. When $Ca(OH)_2$ was absent, as exemplified by equation (4), there was a tendency that, after the dormant period of several hours after water-pouring, the reaction progressed rapidly and ettringite crystallized out.

It was revealed, however, that the expansion of pure mixture of the $C_4A_3(SO_3)$–$Ca(OH)_2$–$CaSO_4$ system was not necessarily dependent upon the amount of ettringite that was formed. Under the condition shown in Fig. 5-1, where $CaSO_4$ is sufficient ($m = 8$) and only ettringite is formed, the volume of expansion increased with increasing amount of $Ca(OH)_2$ existing simultaneously. When $Ca(OH)_2$ was not added ($n = 0$), formation of ettringite was observed but it was not accompained by expansion.

Successive processes of expansion of $C_4A_3(SO_3)$–$Ca(OH)_2$–$CaSO_4$ system (W/solid = 5.0) at 20°C were studied under the optical microscope, and it was noticed that ettringite was largely developed in the form of acicular crystals when Ca^{2+} ions were relatively scarce. Especially in the case of low concentration of Ca^{2+} ions, as represented by equation (4), formation of ettringite occurred following the solution of unhydrated particles, and ettringite took the form of relatively large crystals in the liquid phase (Fig. 6-(1), (2)). Under high concentration of Ca^{2+} ions, ettringite crystallized as fine grians, coating the surface of $C_4A_3(SO_3)$ particles. This coating develops with progress of hydration, and begins to act on the adjacent particles (Fig. 6-(3), (4)).

The pure mixture of $C_4A_3(SO_3)$–$Ca(OH)_2$–$CaSO_4$ was intermixed with powder of O.P.C. clinker and made into neat paste of expansive cement (W/C = 0.25). Then, the paste was shut off from the air by a vinyl sheet, and its expansion behavior under the sealed condition was studied. It was recognized that, within an hour after water-pouring and kneading, the paste began to set and harden, and continued to expand for more than ten hours. In this early stage reaction, however, the expansion of the pure mixture of $C_4A_3(SO_3)$–$Ca(OH)_2$–$CaSO_4$ was different from that of the pure mixture of ($C_4A_3(SO_3)$–$Ca(OH)_2$–$CaSO_4$) + O.P.C. clinker powder. In the former, expansion attained to maximum when $n = 6$ or larger, whereas the latter's expansion was larger when $n = 2$ than when $n = 6$, and even when $n = 0$ it continued to expand for several hours after hardening. The result is shown in Fig. 5-2.

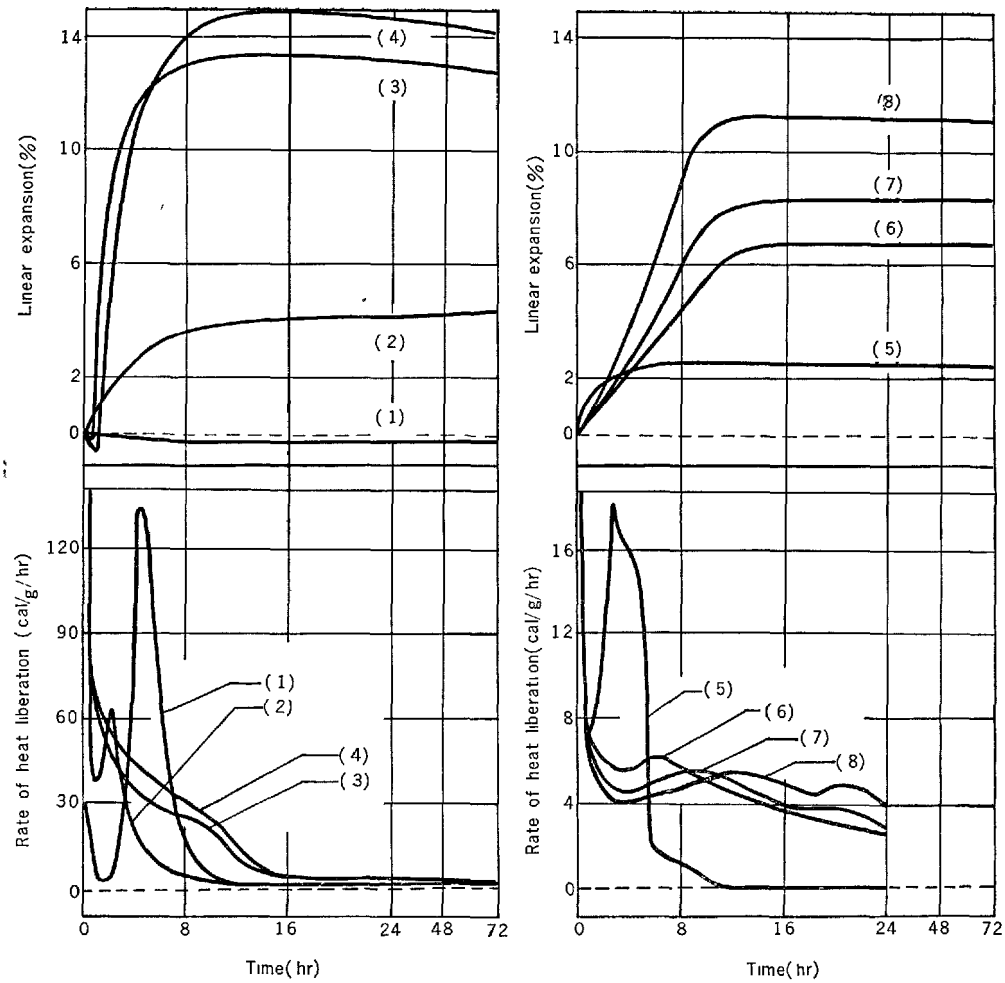

Fig. 5. *Expansibility and rate of hydration of pure $C_4A_3(SO_3)$–$CaSO_4$–$Ca(OH)_2$ mixture as a function of $Ca(OH)_2$ content. (1) $C_4A_3(SO_3) + 8CaSO_4$; (2) $C_4A_3(SO_3) + 8CaSO_4 + 2Ca(OH)_2$; (3) $C_4A_3(SO_3) + 8CaSO_4 + 6Ca(OH)_2$; (4) $C_4A_3(SO_3) + 8CaSO_4 + 10Ca(OH)_2$; (5)–(8) Prepared expansive cements containing 30% of (1)–(4), respectively.*

hydration was considerably slower than that of pure mixture of the $C_4A_3(SO_3)$–$Ca(OH)_2$–$CaSO_4$ system. But, the relation between the expansibility and the quantitative proportion of $C_4A_3(SO_3)$, free CaO and free $CaSO_4$ in the E.C. clinker was similar to that of the pure mixture shown in Fig. 5-1. In general, the expansibility of E.C. clinker was better when a large quantity of $C_4A_3(SO_3)$ was poduced, with $m = 8$ and $n \geq 6$. As indicated by Fig. 8, the SO_3 component in $2(C_2S)\cdot CaSO_4$ contributed very little to the initial expansion.

Using the paste (W/C = 0.25) of a powder mixture of E.C. clinker + O.P.C. clinker, its unrestrained expansion under sealed condition at 20°C was measured (Fig. 7-2), and it was noticed that the expansion started at about the time the paste began to set and harden. The expansibility after hardening was chiefly influenced by the mineralogical composition and hydration behavior of the E.C. clinker, the amount of added E.C. clinker, the amount of mixing water, the curing condition, and by other materials that were added.

The hydration behavior of the clinker was influenced not only by the fineness but also by the amount of free CaO (n-value) against $C_4A_3(SO_3)$ in the clinker, so that the rate of expansion increased as the value of n became larger. In the case of free CaO = 0 (n = 0), expansion was also due to the presence of $Ca(OH)_2$, which was formed by hydration of the O.P.C. clinker, after the paste had set and hardened.

But, the effect diminished as the hardening of the paste advanced, and after two days it contributed very little to expansion, even in the water curing.

Compared with the sealed curing, the water curing showed better expansion after one to two days, and the larger the value of n the more effective. With increasing fineness of E.C. clinker, the hydraion reaction became intense right after the kneading, and expansion was remarkable for 24 hours after setting and hardening, but after one day the expansibility became somewhat lower. Fig. 9 shows an example of the relation between the expansibility and the amount of intermixed E.C. clinker.

Effects of Burning Temperature on the Expansibility of E.C. Clinker

Degree of sintering of E.C. clinker at any temperature was dependent upon the value of m and n, if the materials used were identical, as mentioned already. In the E.C. clinker made of the same materials and with definite values of m and n, the expansibility due to hydration was influenced by the degree of sintering, *i.e.*, burning temperature. The relation is shown in Fig. 10, taking an example of clinker-4. Hydration of the E.C. clinker with the same fineness became lower as the burning temperature rose. In the fused clinker (corresponding to a clinker in which $2(C_2S)\cdot CaSO_4$ was decomposed, when n is large), the rate of expansion was much slower.

By the apparent degree of sintering, the E.C. clinker was divided into three stages; (a) insufficient-sintered clinker (clinker burned at about 1050–1100°C), (b) well-sintered clinker (clinker burned at about 1150–1200°C), and (c) fused clinker (burned above 1220°C). The E.C. clinker of stage (a) began to expand imme-

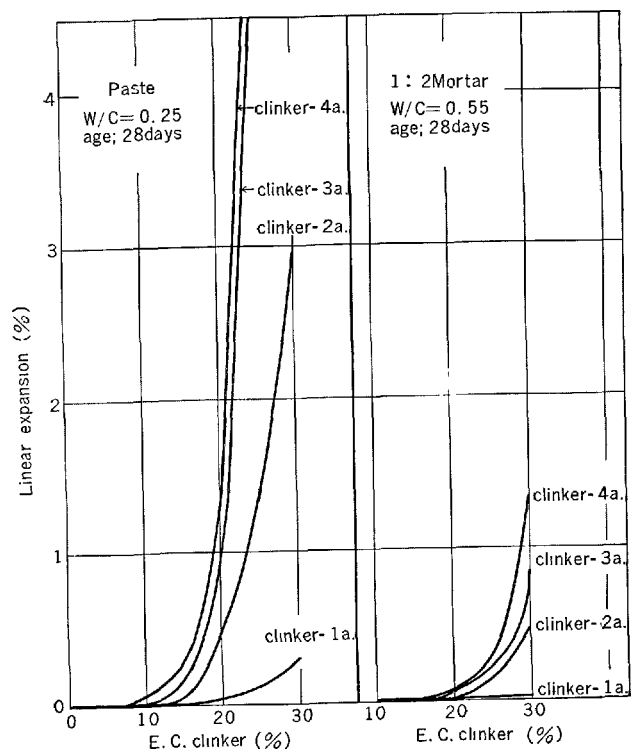

Fig. 9. *Amount of E.C. clinker intermixed and expansibility of prepared cement.*

diately after setting and hardening, and the expansion was almost completed within 24 hours in the sealed curing. After that, it showed little expansion even in the water curing. The E.C. clinker of (b) began to expand gradually after several hours since setting and hardening. After 24 hours the rate of expansion in the sealed curing was slow, but in the water curing the

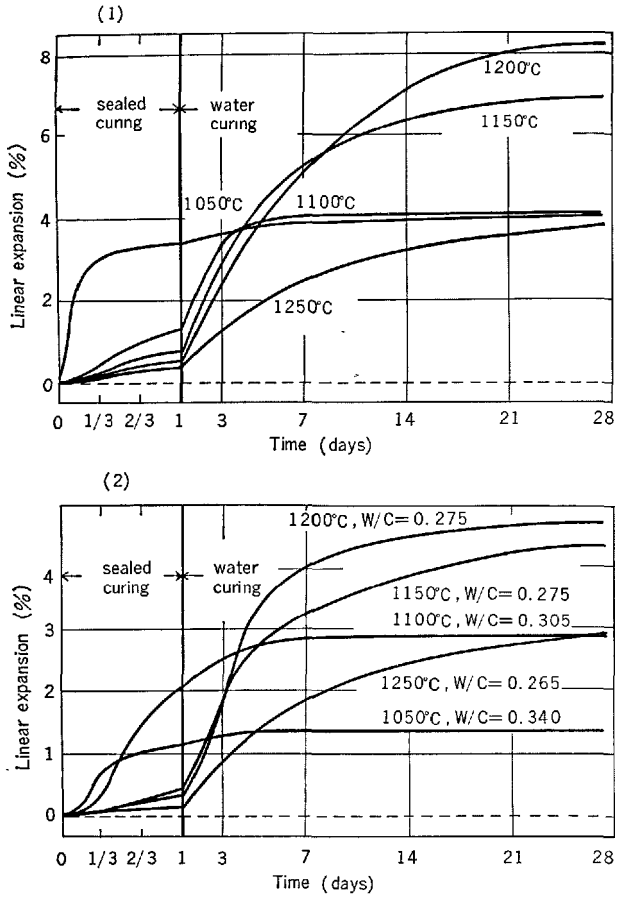

Fig. 10. *Burning temperatures of E.C. clinker and expansibility of prepared cements. E.C. clinker-4, 20°C curing. (1) W/C = 0.25; (2) Normal consistency.*

expansion became much better and was completed in a relatively short time. In the E.C. clinker of (c), the rate of expansion even in the water curing was slower than (b), and it took a long time to complete the expansion.

In the clinker of (a), the grains of produced minerals were very fine on account of the low degree of sintering, and the clinker was porous or fragile. In (b), the sintering is better so that relatively well developed crystals of $C_4A_3(SO_3)$ and $2(C_2S)\cdot CaSO_4$ were seen. The clinker of (c) was in a fused state as decomposition of $2(C_2S)\cdot CaSO_4$ occurred, and the clinker was characteristically dense in texture.

Effects of Gypsum and Blast-Furnace Slag Added to Prepared Expansive Cement

Setting of the experimentally prepared expansive cement was fairly quick, and the setting became quicker with increase in the added amount of E.C. clinker.

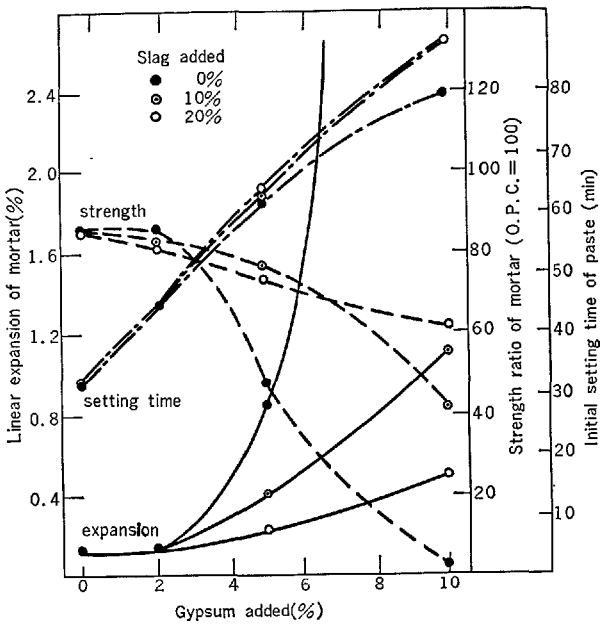

Fig. 11. *Effects of gypsum and blast-furnace slag on property of prepared cement. Mortar: 1: 2 cement-sand, W/C = 0.65, mold storage 24 hrs, 20°C water curing. Paste: normal consistency.*

To retard the setting, addition of gypsum proved effective. However, more than 2% addition of gypsum caused abnormal expansion and, at the same time, the cement strength was lowered. This enormous expansion and the lowering of cement strength were prevented by adding the blast furnace slag, without obstructing the setting retardation effect of gypsum. These cases are illustrated in Fig. 11.

Relation Between the Amount of Absorbed Water and Expansion of the Prepared Expansive Cement

In general, the expansibility of expansive cement after hardening was larger in the water curing or moist curing than in the dry curing. The characteristic of such expansion was that the volume expansion of the test piece was in a linear relation with the amount of water absorbed, as expressed by the following equation, denoting the increased volume by $(1 + \Delta l)^3$ and the total amount of absorbed water by ΔW (%):

$$(1 + \Delta l)^3 = a(\Delta W - \mu) \quad \ldots\ldots\ldots (6)$$

where Δl is the change in length (m/m) and μ is the amount (%) of absorbed water unrelated to the expansion. Using the paste in the range of W/C = 0.23 – 0.32, which was molded under restraining condition in the moist curing for one day, the expansion in the

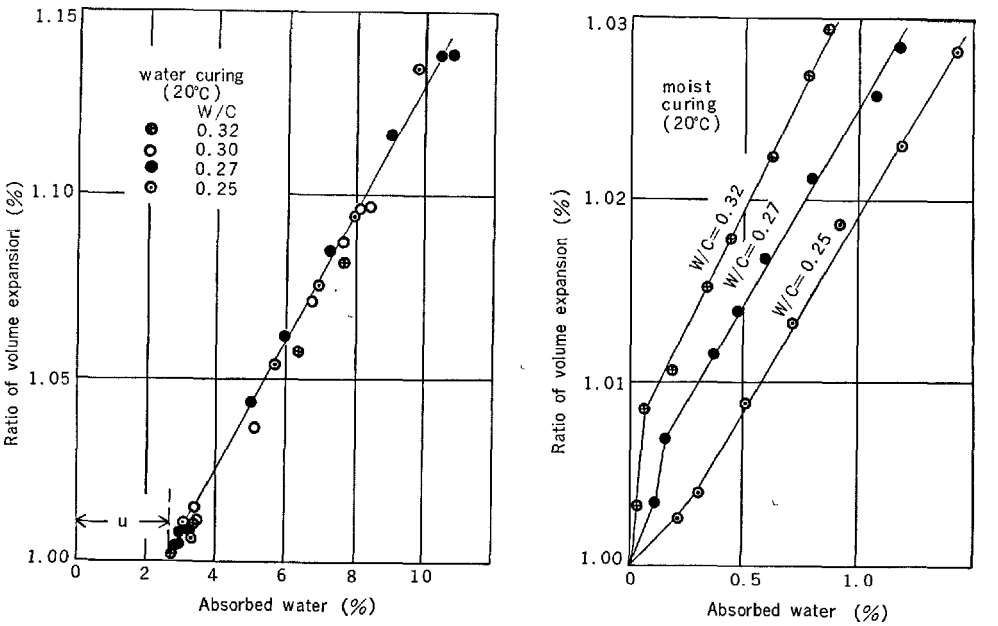

Fig. 12. *Amount of absorbed water and ratio of volume expansion.*

later water curing was measured and a linear relation as expressed by (6) was obtained, irrespective of the amount of water used in kneading.

In the moist curing with 90% in relative humidity, the paste absorbed moisture also from the air and showed expansion, but the mode of expansion varied with the amount of water used in kneading. In the case of the sealed curing or dry curing, where moisture cannot be supplied from outside, the paste expanded for one or two days, but later the expansion became very small even by the use of the E.C. clinker having a large value of n.

Discussion

Mineralogical Composition of E.C. Clinker

Even when the SiO_2-rich aluminous material was used, there was a region in which $C_4A_3(SO_3)$ can be formed stably if the mixing ratio of limestone and gypsum was appropriate. Within this region no other calcium aluminates, such as C_3A, $C_{12}A_7$ and CA, are coexistent. This is probably on account of the presence of gypsum. C_3S, too, is not produced on account of the presence of a large quantity of gypsum.

$2(C_2S)\cdot CaSO_4$ was the only compound of the CaO–SiO_2–SO_3 system, and no other three-component compounds were found to exist at normal temperature. Gutt and Smith (4) also synthesized this compound and reported its X-ray diffraction data. In the E.C. clinker, $C_4A_3(SO_3)$ is easier to form than $2(C_2S)\cdot CaSO_4$, so that the formation of the former seems not to be obstructed by the latter.

Expansibility of E.C. Clinker

The initial hydration of E.C. clinker is controlled chiefly by the content of $C_4A_3(SO_3)$ and by the ratios of $CaSO_4$ and CaO to the former. $2(C_2S)\cdot CaSO_4$ contributes very little to expansion. This was becuse SO_4^{2-} ions were not liberated into liquid phase in the early stage, on account of the slow rate of hydration of $2(C_2S)\cdot CaSO_4$. Accordingly, by raising the burning temperature to let the SiO_2 component occur as β-C_2S, without fixing it as $2(C_2S)\cdot CaSO_4$, an E.C. clinker having the same value of m can be obtained even when the amount of $CaSO_4$ was small in mixing the raw materials at the outset. Thus, the relative content of $C_4A_3(SO_3)$ would become larger and the expansibility should turn better. However, in high temperature burning, which allows β-C_2S to exist, the E.C. clinker is easy to fuse, and the internal structure of the

clinker becomes dense, retarding the rate of expansion.

Expansion of $C_4A_3(SO_3)$ due to hydration depends upon the type of formation of ettringite. The variance of the type of formation of ettringite according to the concentration of Ca^{2+} ions is not discontinuous; the type is considered to change successively, depending on the degree of concentration of Ca^{2+} ions around the unhydrated particles.

When the pure mixture of the $C_4A_3(SO_3)$–$Ca(OH)_2$–$CaSO_4$ system is intermixed with the portland cement, the paste expands rapidly within several hours after kneading and the expansion is completed in a short time, because of the better hydration of the pure synthetic system than the E.C. clinker. In such expansion within a day after kneading, the $Ca(OH)_2$, which is liberated from the cement, accelerates the expansion. Therefore, rather by lessening the amount of $Ca(OH)_2$, which would result in a relative increase in the amount of $C_4A_3(SO_3)$, the volume of expansion can be enlarged. however, a dormant period of O.P.C. clinker occurs at two to three hours after water was poured into the expansive cement, and in and around this dormant period the liveration of $Ca(OH)_2$ is not sufficient, so that the reaction of (4) would progress rapidly in the case of absence of $Ca(OH)_2$ added, unabling further expansion. Therefore, in order to obtain large expansion it wold be necessary to add a small amount of $Ca(OH)_2$ in advance.

On the other hand, E.C. clinker is slow in the rate of expansion, probably because $C_4A_3(SO_3)$ in the clinker is enclosed by other compounds. The expansive cement, composed of portland cement added with powder of E.C. clinker, expands larger when the value of n is large, unlike the case of the pure mixture system. In the sealed curing or dry cruing, where little or no moisture can be supplied from the outside, the expansibility of the cement lowers remarkably within one or two days after kneading, even when the n-value is large, and the expansion comes almost to a standstill. If the n-value is small, or when the E.C. clinker powder is coarse, the cement even shrinks though slightly. It is considered that in the sealed curing the hardening of the cement progresses, and the expansibility lowers with a decrease in the amount of free water. The expansibility is improved by the water cruing, and the difference in the value of n begins to appear. If the value of n is small, for example $n = 2$, the water curing cannot improve the expansibility of the cement in one or two days after its hardening. In other words, the expansion-accelerating effect of $Ca(OH)_2$, which is liberated from the hardened cement, is small in this case.

The fact that free CaO in the E.C. clinker is effective to improve the expansibility may be explained by breakdown of the $C_4A_3(SO_3)$-bearing matrix of the structure, caused by hydration of CaO, as was maintained by Kondo and Nawada (6). But, it can be considered also that the proportion of CaO around $C_4A_3(SO_3)$ particles becomes larger with increasing value of n, so that the expansion is still effective after the hardening.

In the experimentally prepared expansive cement, which was added with gypsum later, fine grains of ettringite began to form on the surface of unhydrated particles of $C_4A_3(SO_3)$ right after the water-pouring, differing from the case of only $CaSO_4$. It is presumed that by this coating of ettringite the later reaction was restrained and setting was retaded.

That the hydration behavior of E.C. clinker varies with brning condition is attributable to the clinker's structure, because the structure becomes harder with rising temperature of burning and the breakdown of the matrix due to hydration would be retarded. In the clinker burned at temperatures below 1100°C, the grains of the respective minerals are minute and the structure is easily broken in water, so that the hydration advances.

Supplementary Paper IV-83 Prevention of Drying Shrinkage Crack by Use of the Expansive Cement with Calciumsulphoaluminous Cement Clinker

Kazuo Ohmo*, Sin Nakamura** and Taiji Saji***

Introduction

Cement mortar or concrete is liable to cause crack due to its drying shrinkage. In this paper, are presented some results of experiments on the problem of how far the shrinkage crack can be prevented by use of the expansive cement which is blended Calciumsulphoaluminous Cement Clinker (CSA) to ordinary cement clinker. The first half deals with mortar while the latter half with concrete.

Takashige Hattori, Assistant of Hokkaido Univ. Kohichi Yano, Assistant of Tokyo Metropolitan Univ.; Tohei Horishima, Hirokazu Hashimoto, Eiichi Tazawa, and Kuniomi Suzuki, Research members of Taisei Construction Co., Ltd.'s Technical Research Division. Yoshizo Ono, Tsutomu Mizunuma, and Satoru Furui, Research members of Denkikagaku-Kogyo Co. Ltd. All these persons cooperated in the studies.

In the Case of Mortar

Restricted Cracking Test

Expansive cement was prepared by mixing C.S.A. cement with normal portland cement by weight ratios of 0%, 3%, 5%, 7%, 11%, 13%, 15% and, to make test pieces for restricted cracking test, which are shown in Fig. 1 was used using mortar, cement: sand: water = 1: 2: 0.65 by weight, and the occurrence of shrinkage created in those test pieces was observed. The restricted cracking test pieces of Fig. 1 are, $4 \times 4\ cm^2$ in section at the center part and 18 cm in length, tapered toward both ends to enlarge their section and anchored to the steel frame with screw bolts and supported between two sheets of steel plate, $1.2 \times 4\ cm^2$ in section to restricted them from expansion or shrinkage.

Other test pieces were prepared with the same kinds of mortar to be used for measurement of free length change as well as the tests of compressive and flexural strength.

All tests were performed in a curing room, where the temperature was kept approximately at 20°C and the humidity about 70 ~ 80%. None of the test pieces were subjected to cure in water, while the sand used for mortar was Toyoura standard sand f.m. ≒ 1.60. The results are given in Fig. 2 and Fig. 3, occurrence of crack and change of crack width in Fig. 2 and rate of free expansion and shrinkage in Fig. 3. The cracking test results show that the time elapsed from the occurrence of crack was gradually prolonged with the increase of the mixing rate of expansive admixture, as shown in Fig. 2. That is the 0% test piece cracked at the 16th day, and that of 3% addition at the 36th day, 5% at the 63rd day, 7% at the 84th day and addition of 11%, 13% and 15% almost at the same time, that is at the 175th day, 182nd day, 185th day respectively.

It is appreciated from the above-mentioned results, that the occurrence of crack is considerably delayed by the addition of expansive admixture, but in the case of calcium sulfoaluminate adopted in the present experiment, the author could not completely prevent shrinkage cracks from occurring in every kinds of mortar.

What is noteworthy is that, in the case of test pieces, which was mixed with more than 7% expansive admixture, shrinkage cracks developed even when the measured value of free length change was still on the

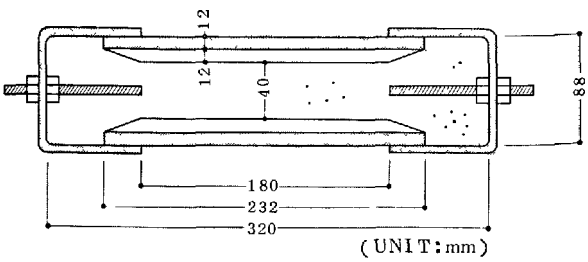

Fig. 1. *Shrinkage crack apparatus*

*Hokkaido University, Sapporo, **Tokyo Metropolitan University, Tokyo and ***Kyushu University, Fukuoka Japan.

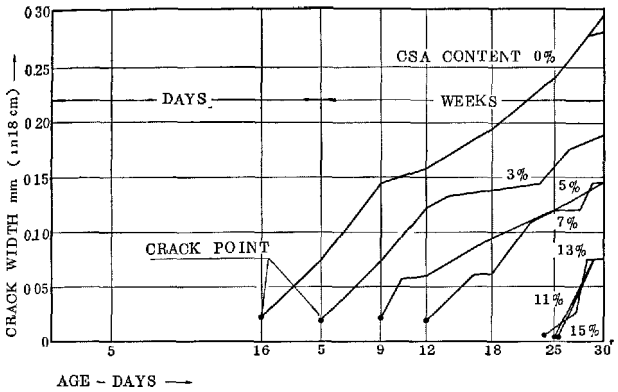

Fig. 2. *Occurrence of crack time and crack width*

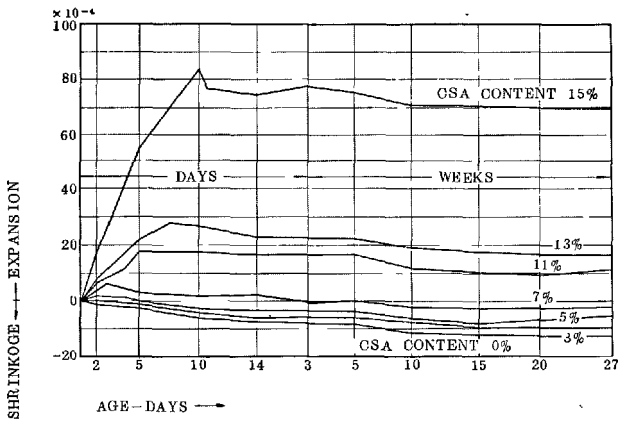

Fig. 3. *Free expansion and shrinkage*

expansion side. This can be explained from the fact the expansion comes to an end rather early time, and thereafter shifts to drying shrinkage.

Even in case of 15% admixture being added, expansion lasts only about the 10 days, thereafter occurs shrinkage, and with the decrease of the amount of addition of admixture, expansion comes to terminate gradually earlier.

Now, tentatively, if the shrinkage rate is calculated for a duration from the time of maximum expansion to the crack occurring time, the result will be about as follows; with 10^{-4} as unit, 0% = 5.44, 3% = 6.25, 5% = 7.00, 7% = 8.14, 11% = 8.10, 13% = 8.52, and 15% = 10.00.

The above values show that the larger the rate of expansion is, the larger the rate of shrinkage becomes and show the effect of expansion to a certain extent.

In the case of more than 11% addition, crack has occurred after about the same number of days had elapsed, which is associated with the decrease of strength due to the increase of addition of expansive admixture.

Reconsidering the effect of expansion at this stage, it is probable that a greater part of expansion has disappeared as compressive creep due to the comparatively earlier expansion as stated before, and besides that the expansion may escape simultaneously in horizontal direction because of the restriction of lengthwise expansion. Dr. K. Shirayama has measured the expansion pressure of concrete under a uniaxial restriction, and reported that the expansion pressure diminishes about the time when the expansion is replaced by shrinkage.

It has been observed that, by the expansive admixture used in this experiment, we cannot prevent shrinkage cracking to the perfection when it is completely restricted in the lengthwise direction. However, with a real structure, restricting force is not so completely effective that the shrinkage crack is expected to be considerably prevented by the use of expansive admixture (C.S.A.)

Application to Plastering Mortar, for Wall

Since portland cement mortar for the use of plaster is liable to crack when it is richly mixed, so that as a method of preventing crack usually considerable amounts of sand mixing in mortar is generally followed. Accordingly, if we can prevent drying shrinkage crack by use of expansive cement, we shall be able to finish up nearly as well as plaster by reducing mixing amount of sand in mortar.

The authors have carried out an experiment here to find out whether comparatively rich mixed mortar is practically applicable to plastering by expansive cement.

As the first test, preliminary experiments were carried out using thirty kinds of mortars with several ratios of sand mixing, and the ratios of water to the whole mixtures added with some % of expansive admixture (C.S.A.) in portland cement, and then on the basis of these experiments, the possibility for plastering was investigated by applying expansive cement mortar to an actually erected building.

The physical properties of tested mortar, are given in the later table Table 1, and an outline of the wall used for the plastering experiment are given in Fig. 4.

For each mix in Table 1 about 10 ± 1 mm consistency was chosen, as the appropriate consistency for plastering. While the consistency adopted was obtained from the Vicat apparatus of JIS R5201, for physical test of cement 9-4, with necessary modifications, penetration-needle was using a 19mmϕ steel bar, and adjusting the total weight of its descending part to 400 gr. Then the value of 100 mm penetrated by this method will be called as consistency of 10 mm.

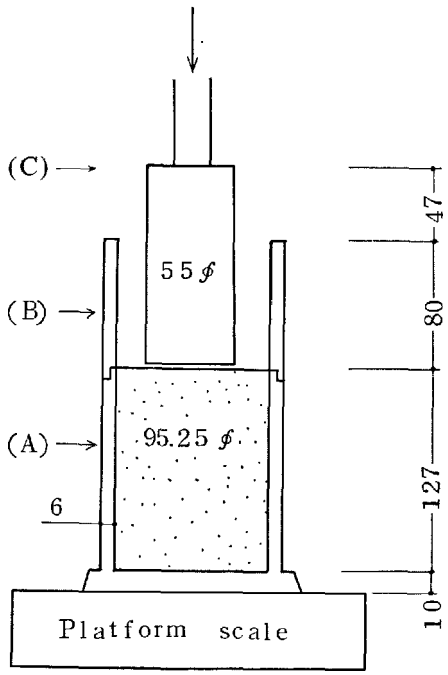

Fig. 5. *Penetration resistance test apparatus*

In the next place, as the method of estimating the suitability of plastering mortar, penetration-resistance test was carried out on each kind of mortars.

Above-mentioned test method is shown in the later Figure (Fig. 5), the mortar being filled in two layers in (A) vessel. The process of filling mortar was to set the vessel (A) on the flow table of cement and move the flow table 5 times for each layer. After the two layers were filled up the collar (B) was set and by penetrating the plunger (C) into the mortar at a constant speed (20 mm/sec), then the penetration resistance corresponding to the depth was measured.

There are shown Fig. 6 and Fig. 7 the values of some typical figures of penetration resistance measured at each depth.

Where the two straight lines represent the range of appropriate values of plastering work, the sand used for this experiment was approximately f.m., 2.09, and the sieve test result is given in Table 2.

Next water holding capacity test was performed. The test was based upon A.S.T.M. with force of absorption set at 50 mm Hg, the water-holding rate was calculated at each elapsed time by the following equation:

$$\text{Water holding rate} = \frac{\text{water ratio after test}}{\text{water ratio before test}} \times 100\%$$

The water holding capacity was apt to decrease when the expansive admixture C.S.A. was added, while that of the material tested with dolomite plaster

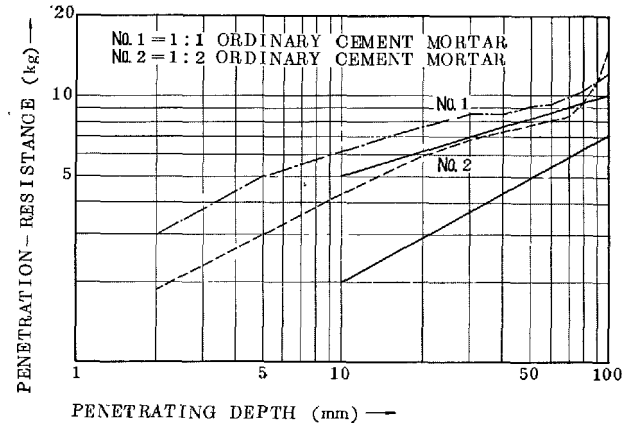

Fig. 6. *Penetration-resistance at each depth*

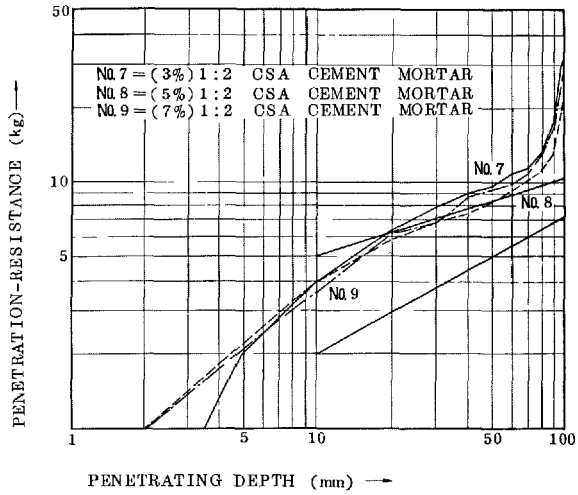

Fig. 7. *Penetration-resistance at each depth*

Table 2. *The sieve analysis of sand*

Sieve (mm)	5.0	2.5	1.2	0.6	0.3	0.15	f.m.
Pass-ratio (%)	100	98.9	94.6	73.5	27.7	0.4	2.09

brought about exceedingly good result. Furthermore, weight decrease rate, drying shrinkage rate Fig. 8 and Fig. 9, and flexural strength were tested. The shrinkage rate showed the minimum in case of (No. 10) gypsum plaster. In the case of C.S.A. cement mortar, shrinkage rate was less than that of ordinary portland cement mortar, but all measured values remained on the shrinkage side. However, the test piece was cured in a curing room where the temperature was 20°C and humidity 50%.

Based on the above-mentioned preliminary experiments each kind of materials given in the foregoing

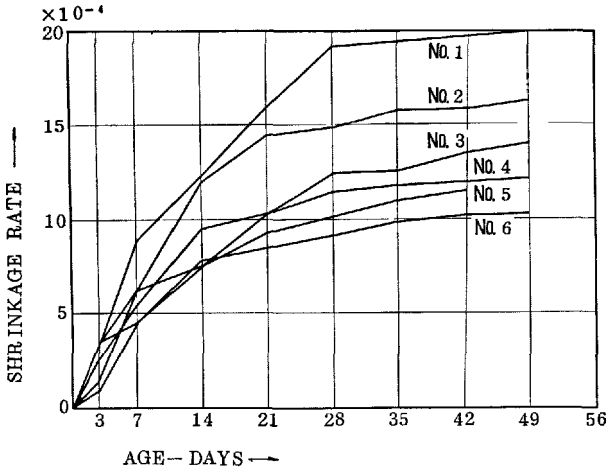

Fig. 8. *Shrinkage rate*

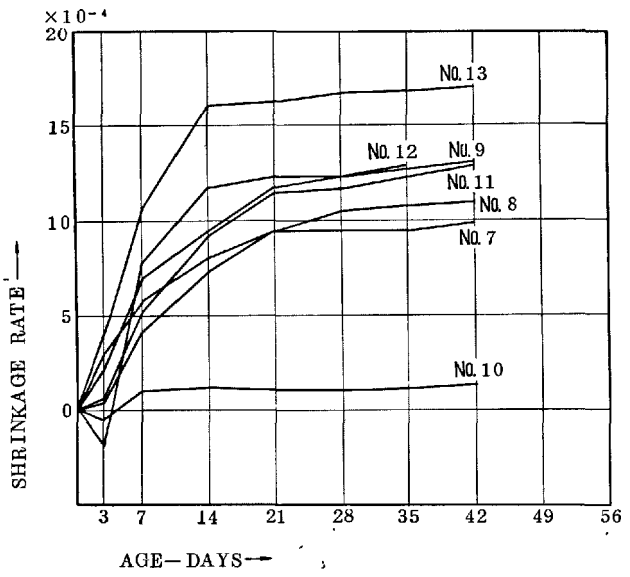

Fig. 9. *Shrinkage rate*

Table 1 was subjected to the field test, in which the thickness of test plastering was about 1.5 cm and the base concrete surface was painted with cement paste, containing 0.2% methyl-cellulose. The finishing up of plastering was also done on the same day. The plan of test house, and the observed crack pattern is shown in Fig. 4.

In this field test, cracks occurred in portland cement mortar of No. 1 and No. 2 in Table 1, the former appearing at the 5th day, and the latter at the 10th day.

As for the expansive cement, crack was found in No. 7 of 3% mixing rate after 23 days, but the surfaces of wall plastered with other expansive cement mortar caused no cracks. Judging from this field experiment,

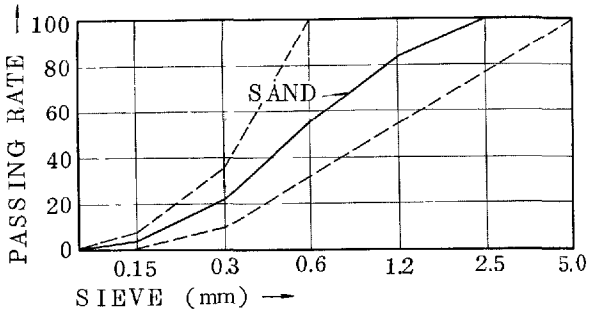

Fig. 10. *Sieve analysis of sand*

it is safe to estimate that mortar mixed with 7% expansive admixture (C.S.A.) will not so easily yield shrinkage cracks.

Application to Plastering Mortar for Floor

It is essential for floor mortar to be endowed with a quality to stand abrasion, since rather high strength of mortar is required, hence rich mixed mortar is to be used, and this fact naturally involves the condition leading to shrinkage crack more easily. Then the authors tried to find out by use of expansive cement (C.S.A.) floor mortar, abrasion-proof and free from shrinkage-cracking.

The experiment is carried out by changing the rate of cement and sand in referred to in the foregoing chapter (for wall), while the amount of water to be added was chosen by the penetration resistance test, and consistency was measured by 19 mmϕ needle penetration test. The sand used in this experiment was passed through 2.5 mm sieve, the result of sieve test being given in (Fig. 10).

The notation of each kind of mortars and the mixing tables are shown in the Table 3. In the next place, water-holding capacity test was performed based on "JIS A6904 Gypsum plaster". It has been clarified from this water holding test and penetration test that there is little difference in quality between expansive cement and ordinary portland cement, provided that mixing rate is the same. Also with a viscosity improving agent such as methyl-cellulose, its effect was found to be very little in the case of rich-mixed mortar.

Flexural strength was also evaluated using $2 \times 4 \times 16$ cm^3 test piece at 10 cm span and by center loading. The results of this test showed nearly the same values in strength between A-3 and P-3, but in the case of A-2 and P-2, A-2 decreased strength as 70% of P-2. Therefore, in the case of expansive cement, we cannot obtain abrasion-proof mortar unless we make cement ratio richer than 1: 1.5 as shown in Fig. 11.

In the next place, the rate of expansion and shrin-

C and M = Consistency improving agent. (Methyl-cellulose) adding this agent 0.1% of cement. +AC − 3 = 0.2%.

kage was measured, using a test piece of 1 × 4 × 16cm³. For comparison two cases of tests, i.e. The one at temperature of 20 ± 3°C and humidity of 80~85%, the other in water curing of 20 ± 3°C, were partly carried out simultaneously.

According to Fig. 12 the rate of drying shrinkage expansive cement mortar is invariably less than that of portland cement mortar, which is however on the shrinkage side when cured in the air, but the one subjected to water curing shows considerable expansion and the richer the mixing, the more conspicuous the expansion.

With reference to the above-mentioned fundamental experiments, field tests were carried out on the plastering of the floor of a real building. The sketch of field plastering test is shown in Fig. 13 while mix of mortar is as shown in Table 3.

On August 24, 1966 the plastering works of P-3, A-05, A-1 and A-1.5 were performed, of which A-0.5 was replaced afterward by A-1, the formers viscosity being too large for plastering. The expansive cement mortar showed considerable expansion corresponding to the condition of water curing or water sprinkling for a week after its placement, and caused expansion fracture. The swollen-up amount was about to 4 cm at the maximum on the floor line.

As indicated in Fig. 13 plastering work was applied several times, on September 29 (5th time), November 18 (6th time) and November 28 (7th time). At the 5th time ratios of cement to sand 1: 2 and 1: 3 were used, and at the 6th time and 7th time expansive admixture (C.S.A.) added in cement was only 5% in cement. After recoating, no conspicuous cracks occurred except for small hair cracks at several portions. The main results obtained from these experiments on floor

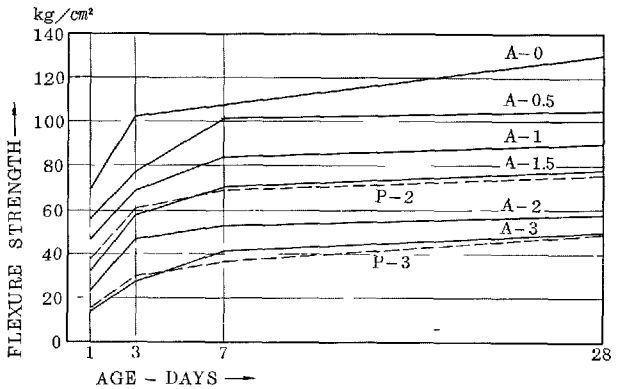

Fig. 11. *Flexural strength*

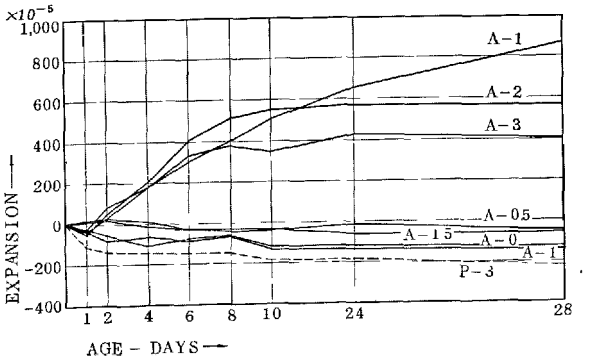

Fig. 12. *Change in length on non-constraint*

mortar are;

*There is little difference in workability between expansive cement and portland cement.

*In order to obtain abrasion-proof mortar, rich mixing mortar more than (1: 1.5) should be chosen in the case of expansive cement (5% C.S.A. mixed).

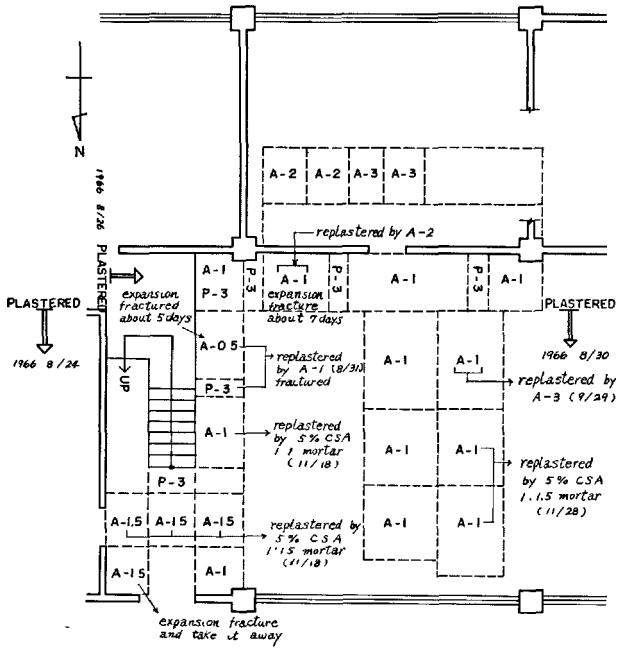

Fig. 13. *Field plastering test*

It is, however, important not to mix too much expansive admixture, for there are some points yet to be thoroughly investigated.

*The fact that this expansive cement considerably varies in its rate of expansion in curing in water or in the air is a problem of great importance in the plastering work, since the damage due to expansion is much worse than that of shrinkage. We have to study further, the mixed amount of expansive admixture (C.S.A.) in portland cement, by use of plastering work.

Mortar Lining for Steel Pipe and Cast Iron Pipe

There is a construction use for which expansive cement consisting of C.S.A. as expansive agent is particularly advantageous.

It is mortar lining for steel pipe and cast iron pipe. There have been considerable troubles with cracking and separation in the lining mortar.

They were due to drying shrinkage of the cement, generally ordinary portland cement used.

As drying shrinkage introduces tensile stress to the lining mortar, the cement that would shrink on hydration cannot be used for mortar lining.

Success in precluding the formation of shrinkage crack and separation was achieved by blending C.S.A. with ordinary portland cement, slag cement or flyash cement.

The proportion in which C.S.A. is mixed with cement is different with the kind of the base cements.

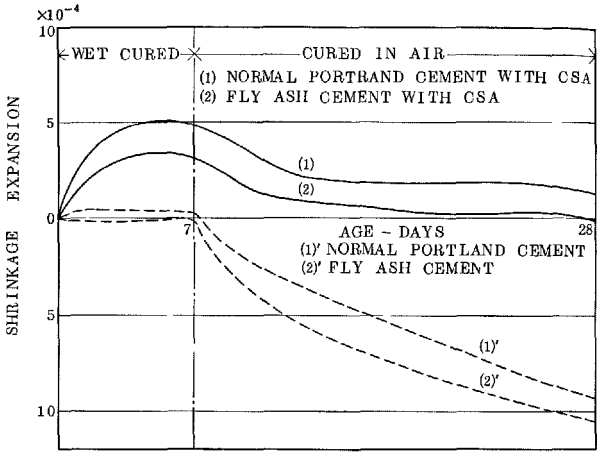

Fig. 14. *Free expansion of non steam curing*

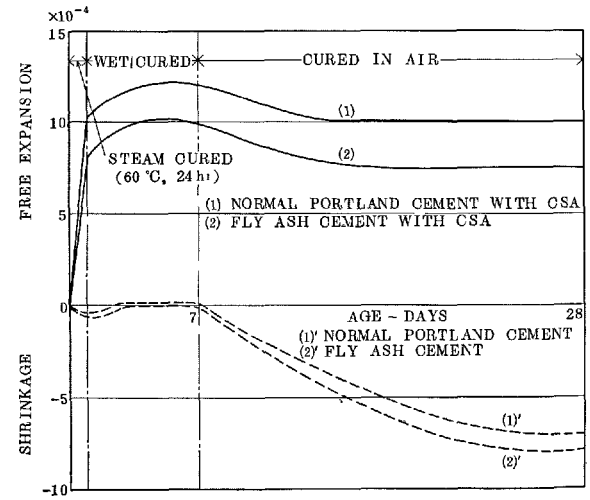

Fig. 15. *Free expansion of the water steam curing*

For instance, C.S.A. has been used by a company for mortar lining in a mix proportion of 8:92 by weight to flyash cement and by another company in a mix proportion of 11:89 by weight to ordinary portland cement. Free expansion of these mortar is shown in Fig. 14. From Fig. 14, it can be seen that free expansion of flyash cement mortar mixed with C.S.A. is less than that of ordinary portland cement with C.S.A. However, these mortar shrinkages after maximum free expansion which occurred at an early age of mortar are the same and enough to prevent the shrinkage crack and separation formation.

The mortar-lined pipe is cured in water or steam on the manufacturing process.

As the expansion of lining mortar is larger in steam curing than in water, and mortar shrinkage is smaller after maximum free expansion, the effect of preventing crack and separation is larger. These facts are shown in Fig. 15.

Table 4. *Chemical analysis of water*

Kind of water*	Smell	pH	M. O. alkalinity ppm	Total hardness ppm	Evaporated residue ppm
Normal portland cement mortar	Normal	11.7	143.5	68.0	180.0
Normal portland cement with CSA mortar	Normal	9.7	45.1	68.0	119.0
Non-immersed	Normal	7.1	39.0	68.0	104.0

*Immersed water of each mortars

On the other hand, researches in the influence of lining mortar containing C.S.A. on soundness and solubility to water were prosecuted by immersing a piece lining mortar vertically in water (60°C) for 1000 hrs. From this test, we could get satisfactory results shown as follows:

*The soundness of the cement with C.S.A. is equivalent to ordinary portland cement.

*Chemical analytic results of the water in which each living mortar is immersed (Table 4) indicate that in the case of the cement with C.S.A. it has lower alkalinity as compared with normal portland cement but almost the same content in other elements.

In the Case of Concrete

Dry Shringkage of Reinforced Concrete Mixed with CSA-Cements

Here are presented the result of two series of observations on the change in length and crack distribution of reinforced concrete mixed with CSA-cements and usual aggregates.

In the first series, a CSA-cement of 13% CSA was tested with the specimens of rectangular plates for the convenience of observing cracks which would be caused by dry shrinkage.

The second series was a test of a CSA-cement with 10% CSA consisting of two parts. The first part was the repetition of the foregoing test with this cement and the second part was a study on the change in length by beam type specimens which enabled to observe the change in length from the first stage of hardening of of concrete. Each series of tests included some comparisons of CSA-cement concrete with the ordinary portland cement concrete.

Test Series I

The purpose of this study was to observe the influence of steel reinforcements on the change in length and the crack distributions for reinforced concrete mixed with a CSA-cement.

Specimens

Type and size. A rectangular plates of 50 × 50 × 10 cm³ was adopted as the specimen.

Reinforcements. Four kinds of double meshes made of deformed bars of 10mm in diameter were applied, as shown in Fig. 16.

Cements. Three kinds of cements were tested—that is, which contained 13% CSA (noted by C), a portland-cement made by the same plant (noted by P) and a certain other manufacturer's portland cement (noted by A). (Table 5)

Aggregates. Sand and gravel from the same river were used. Their physical properties are shown in Table 6.

Mixtures. The mixtures were selected as described in Table 7, where w/c was 0.6 and the slump was controlled to be about 21 cm.

Concrete form. Wooden forms were used. Vinylchloride plates of 1 mm in thickness were lined inside the forms, which gave so smooth surfaces to the specimens that inspection of hair cracks on the surfaces

Normal portland cement A	0.60	295	844	985	177	250	170

was very easy.

Casting of concrete and curing. The wooden forms were set up edgewise like the walls, and the concrete was casted in the upper edge and covered with polyethylene films. The forms were removed after 48 hours and the specimens were also set up edgewise in the room air of about 18°C and 70% R. H. for one week. Then, R.H. was dropped to 45% for three weeks. After 4 weeks the temperature was controlled to be 16°C, but the relative humidity gradually rose to 70%.

Measurement of the Change in Length

Small steel screws were inserted to the concrete surface and on the ends of reinforcement bars, as are pointed in Fig. 16. The distance between a pair of screw heads, which were placed on the contrary edges of the specimen, was measured by a simple apparatus with a couple of 1/1000 mm dialgages. The accuracy of measurement was calculated to be about 2×10^{-6} mm/mm.

The measurement was started immediately after removing the wooden form, and was continued for 15 weeks.

Change in Length of Plain Concrete

The CSA-cement concrete C_0 expanded remarkably in its early age, although the ordinary concrete P_0 and A_0 showed almost no expansion, as shown in Fig. 17. The maximum expansion of C_0 reached over 45×10^{-5} mm/mm at the ninth day. Then, C_0 showed dry shrinkage similar as the ordinary concrete. The magnitude of these shrinkage reached about 50×10^{-5} mm/mm after 15 weeks. Consequently, the amount of change in length became nearly zero compared with the initial length observed in this test.

There can be seen some difference between the change in length of the CSA-cement concrete in the vertical direction and that in the horizontal direction; the former was smaller than the latter. The reason for this phenomenon would be attributed to the constraint against expansion of young concrete by its own weight.

On the other hand, the magnitudes of dry shrinkage of P_0 and A_0 were $54 \sim 61 \times 10^{-5}$ mm/mm compared with their initial length.

Change in Length of Reinforced Concrete

There were some troubles with the measurement of

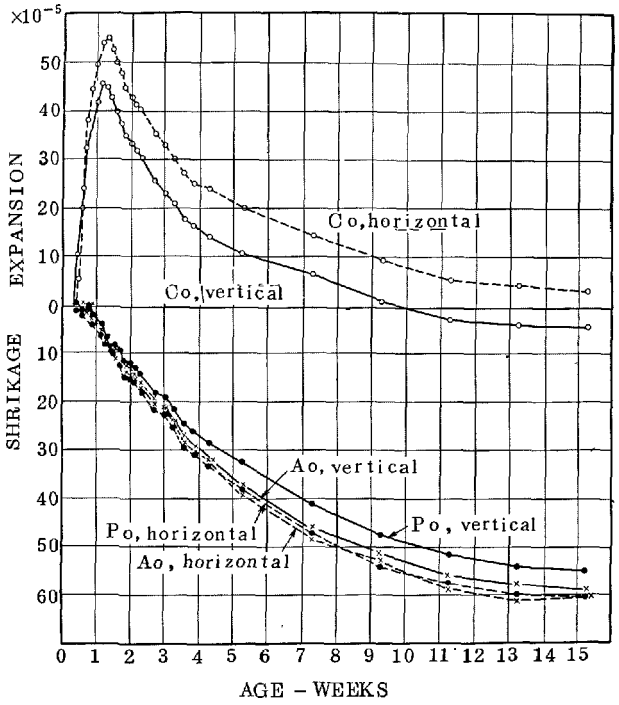

Fig. 17. *The change in length of non-reinforced concrete*

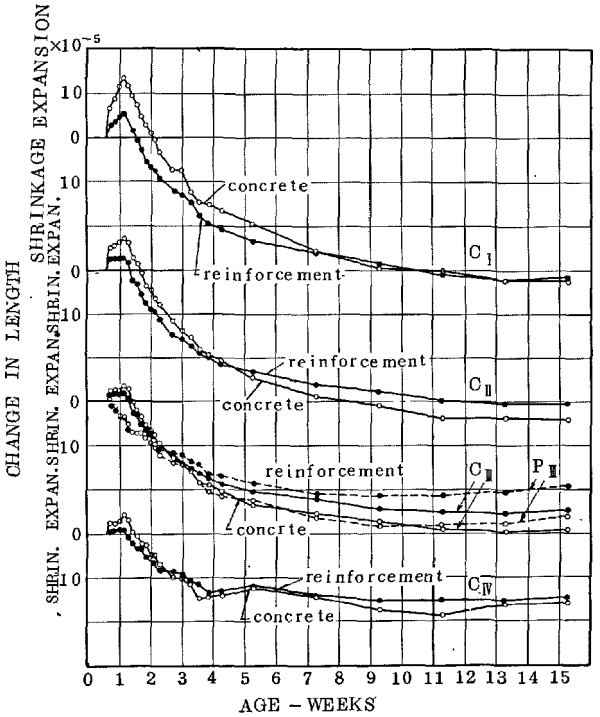

Fig. 18. *The change in length of reinforced concrete*

change in length for the first two days. Therefore, the data were conveniently arranged by taking the length at the fourth day after casting concrete as the standard. The test result are plotted in Fig. 18.

There were some differences between the change in length of reinforcing bars and those of concrete body. The former was less than the latter in both cases of expansion and contraction. It may be supposed that these differences would be caused by the plastic deformation of bond between the concrete and bars, and perhaps by the warp of concrete surface constrained by the bars.

Speaking of the change in length of concrete body, the tendency of expansion was also observed in the early stage of hardening of concrete. However, the magnitudes were considerably smaller than those of plain concrete and the maximum expansion decreased when the reinforcement ratio increased.

As the dry shrinkage of concrete was also constrained by the existence of reinforcement bars, the specimens which had a higher reinforcement showed a smaller shrinkage and the magnitudes of shrinkage after the primary expansion at a certain age decreased almost linearly with the increase of reinforcement ratios.

Fig. 19 shows the relation between the reinforcement ratios and the amount of change in length, when the length at the 4th day after casting concrete

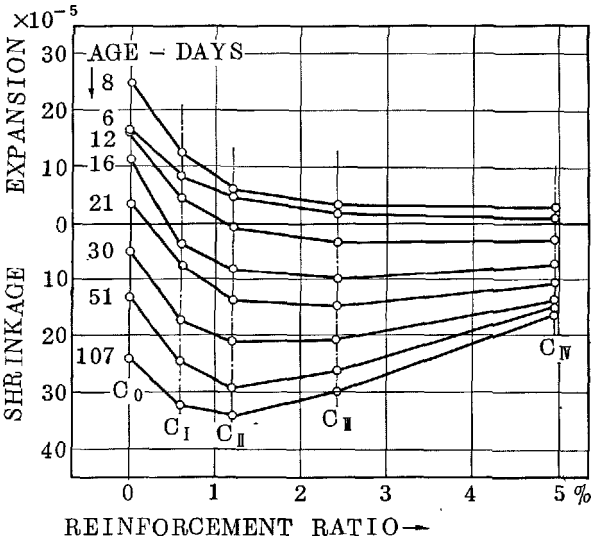

Fig. 19. *The relation between the change in length and the reinforcement ratio*

was taken as the standard. It is very interesting that the specimens with moderate reinforcement ratio showed the largest shrinkage at the 15th week.

Observation of Cracks

An observation of cracks on the surfraces of specimens was proceeded by a magnifying glass.

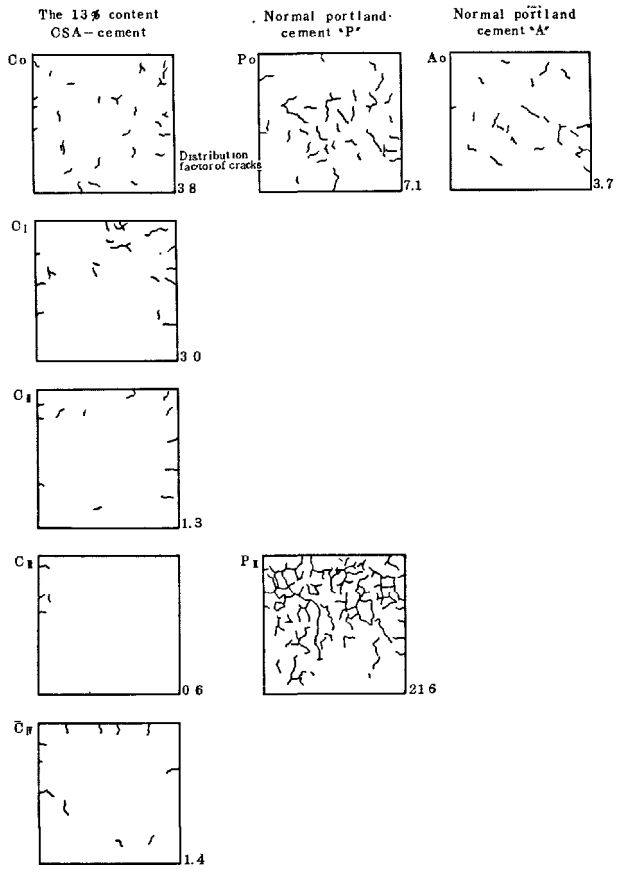

Fig. 20. *Cracking map at the age of 3 weeks*

A_0	Normal portland cement A	0	6.5	7.0	10.6	10.1	9.6	10.7	9.1

The first hair cracks were observed on every specimen at the age of 16 days, when the relative humidity of test room was about 42%. It looks likely that there was no difference between the age of initial cracking of concrete and the kinds of cements as well as the quantity of reinforcement, in the range of such a low humidity. Fig. 20 and Fig. 21 show the sketch of crack distribution at the age of 3 weeks and 15 weeks respectively, and Table 8 shows the distribution factors of cracks, i.e., the mean length of crack per unit area. Both data indicate that there were not so much difference on the crack distribution for every specimen, in spite of the variation of cement, mixtures and reinforcement ratios, excepting the specimens of P_{III} hardly cracked notwithstanding the same grade of shrinkage. If the crack distributions were the same, the width of crack should theoretically increase with the increase of reinforcement, but any remarkable

difference could not be found in this CSA-cement concrete. Every crack had the width of 0.02–0.04 mm. It was very difficult to distinguish the deep cracks from hair cracks on the surfaces of specimens.

Test Series II-1

The purpose of this test was to compare a CSA-cement with an ordinary portland cement from the viewpoint of crack distribution of reinforced concrete. The testing method of Series 1 was followed in this study by using a CSA-cement with 10% CSA and the portland cement "A".

Specimens

Type and Size, Aggregates, and *Concrete Forms.* These were the same as the foregoing test.

Reinforcements. Two kinds of double meshes, as shown in Fig. 22

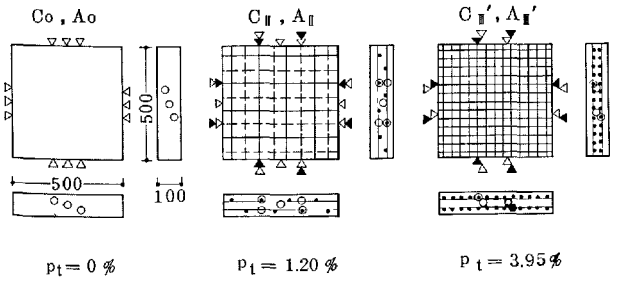
Cements. Two kinds of cements, above-mentioned.

Mixtures. The mixtures were selected as shown in Table 9, where w/c was 0.7 and the slump was controlled to be about 18 cm.

Curing. The wooden forms were removed 48 hours after casting concrete and the specimens were cured in the room air of 16°C and 75% R. H. for three weeks, and then of 16°C and 55% R. H.

Measurement of Change in Length

The results of measurement are plotted in Fig. 23.



▽ shows the position of the measuring point for concrete.
▼ shows the position of the measuring point for bars

Fig. 22. *Kinds of reinforcements*

Table 9. *Mix proportion of concrete*

Kind of cement	w/c	Slump cm	Cement kg/m³	Sand kg/m³	Gravel kg/m³	Water kg/m³	Compressive strength kg/cm²
CSA-cement	0.70	18.3	275	990	850	193	179
Normal portland cement A	〃	16.8	〃	〃	〃	〃	255
CSA-cement*	0.55	17.6	335	900	911	184	269

*This mixture was used in test series II-2.

The expansions of CSA-cement were very little, even in the case of plain concrete C_0, and there was not so much difference of change in length between C_0 and the ordinary concrete A_0 for the first week. However, A_0 showed thereafter somewhat larger shrinkage than C_0. The magnitudes of dry shrinkage are given in Table 10. It shows that the shrinkage of reinforced concrete at the end of the 7th week almost linearly decreased with the increase of reinforcement ratio for both kinds of cements.

Observation of Cracks

The crack distributions on the surfaces of specimens which were sketched in the 7th week and after 50 weeks are shown in Fig. 24 and Fig. 25 respectively, and their distribution factors are calculated in Table 11.

These results were somewhat different from those in test series I. Both figures show that few cracks were observed on the specimens of plain concrete C_0 and A_0, even after 50 weeks, and that cracks of reinforced concrete mixed with the CSA-cement increased considerably after 7th weeks, although the cracks did not extend so much in the earlier age.

It would be notable that the dry shrinkage of ordinary reinforced concrete with the high reinforcement ratio showed some relaxation after a certain age. It means that some deep cracks reached to the reinforcement bars and the compressive stress of steel bar

had partly been released.

Test Series II-2

The aim of this test was to start the measurement of change in length immediately after casting concrete because the CSA-cement concrete in the foregoing test did not show a remarkable expansion.

Specimens

Type and size. A modified beam with the cross section of 20 × 20 cm² and the length of 200 cm was adopted for the specimens of reinforced concrete, as shown in Fig. 26. A beam with the same cross section and the length of 50 cm was adopted for the specimens of plain concrete. Each beam had steel end plates of 9 mm in thickness, where the measuring points made of small screws were installed. These end plates would serve to prevent the drying of concrete from the ends of beams.

For the specimens of reinforced concrete, the end plates were previously welded to the both ends of reinforcement bars; four deformed bars of 16 mm in diameter. The reinforcement ratio became 1.96%. For the specimens of plain concrete, four small bolts were attached to the inside of the end plates in order to secure the bond strength between the plate and concrete body.

Wooden forms were used for manufacturing the specimens. The above-mentioned end plates were fitted as the parts of form.

Aggregates, Cements. These were the same as those referred to in the first part of this test series.

Mixtures. For CSA-cement concrete, two kinds of w/c were applied, i.e., 0.70 and 0.55. For ordinary concrete w/c was 0.70. The mixtures were selected as shown in Table 5 by controlling their slumps to be about 18 cm.

Curing. The wooden forms were removed at the age of 5 days. Then, the specimens were cured in the room air of 18°C and 70% R. H.

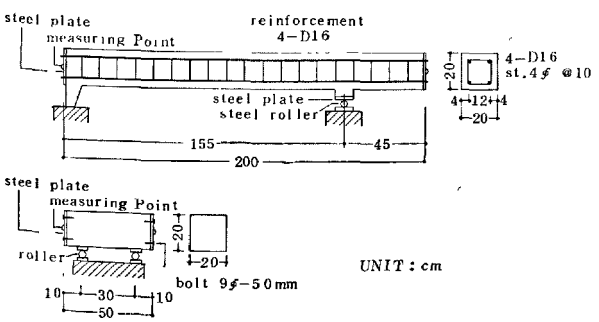

Fig. 26. *The specimens of beam type*

Measurement of Change in Length

The measurement was started at 6–8 hours after casting the concrete. Similar measuring apparatuses as used in Series I were used by providing exclusively one apparatus to one specimen. The results are shown in Fig. 27.

Change in Length in Young Age

All of the specimens of CSA-cement concrete showed a tendency of expansion in the period of one or two days after casting concrete, although the specimens of the ordinary concrete did not show any expansion nor contraction in this period. The magnitudes of expansion in the plain concrete were about 60% of the test results in Series I. The reason could mainly be attributed to the difference of CSA content of 13% and 10%. Besides, the forms would constrain the concrete against free expansion as the reinforcement bars do.

According to Table 12 which indicates the magnitude of the maximum expansion of each specimen, C_5(w/c = 0.55) showed somewhat larger expansion than C_7(w/c = 0.70), in both cases of plain concrete and reinforced concrete. And the expansion of reinforced concrete was only 37 and 38% compared with plain concrete for corresponding w/c of 0.7 and 0.55 respectively.

Dry Shrinkage and Crack

After the primary expansion, both of plain concrete and reinforced concrete mixed with CSA-cement showed dry shrinkage. The behaviors of these dry shrinkage were not so much affected by the difference

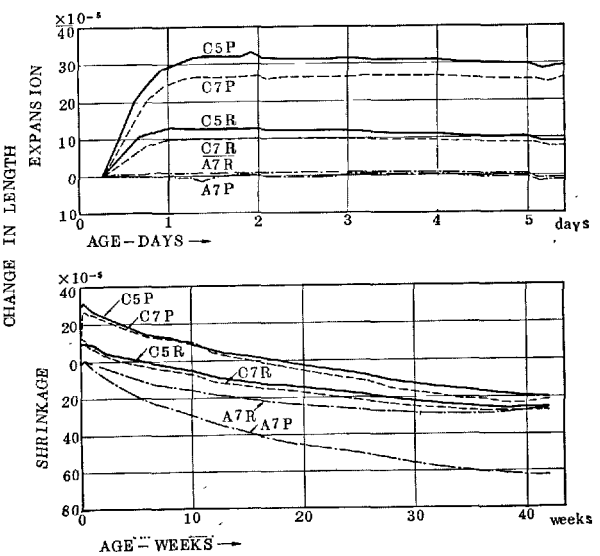

Fig. 27. *The change in length*

Table 12. *The influence of reinforcements on the shrinkage*

× 10^{-5} mm/mm

Symbol	Kind of cement	w/c	Reinforcements ratio %	Max. expansion	Ratio	Max. shrinkage	Ratio

of water-cement-ratios.

According to the observations on the cracks of the specimens many cracks transverse to the longitudinal axis of the specimens were found in the pitch of about 10 cm for the ordinary concrete, but very few cracks were found on the CSA-cement concrete.

Summary of this Section

The change in length and crack distribution of plain concrete and reinforced concrete mixed with CSA-cement were studied. Two kinds of CSA-cements which contained 13% and 10% of CSA were used in the separate test series.

In the case of CSA-cement with 13% CSA (w/c = 0.6)

*The plain concrete expanded remarkably in the first week after manufacturing the specimens. The maximum expansion was observed at the 9th day and the magnitude reached over 45×10^{-5} mm/mm. However, after these primary expansion, the CSA-cement concrete showed a large dry shrinkage similar to that of the ordinary concrete. Consequently, the amount of change in length became nearly zero after 15 weeks, when the length at 48 hours after casting concrete was taken as the standard.

*The reinforced concrete showed a similar tendency of primary expansion and successive shrinkage. However, the magnitudes were considerably small and the magnitude of dry shrinkage after the primary expansion decreased almost proportionally with the increase of reinforcement ratio.

*According to the observation of crack distribution on the surfaces of specimens, very little difference could be found between the plain concrete and the reinforced concrete with various kinds of reinforcement ratios. It is uncertain whether this phenomenon was proper to the CSA-cement with 13% CSA or it would be attributed to the low humidity of testing room.

In the case of CSA-cement with 10% CSA (w/c = 0.7)

*Any expansion was hardly observed after removing the concrete form. The observation of crack showed that plain concrete mixed with CSA-cement and the ordinary portland cement had a few cracks in a similar degree, and that the crack distribution increased with the increase of reinforcement ratio for both concrete, less cracks being found in the CSA-cement concrete than in the ordinary concrete.

A study on the CSA-cement concrete with 10% CSA by a special testing method gave the following results.

*For plain concrete, a considerable expansion was observed in the first one or two days and the magnitude of maximum expansion was about 60% of the CSA- cement concrete with 13% CSA. There was not so much difference of the primary expansion and successive shrinkage between two kinds of water-cement-ratios (w/c = 0.55 and 0.70), although the smaller water-cement-ratio gave somewhat larger expansion. The magnitude of dry shrinkage after the primary expansion was about 50×10^{-5} mm/mm at the age of 42 weeks. The corresponding shrinkage of the ordinary concrete was about 60×10^{-5} mm/mm.

*In the case of the reinforced concrete (reinforcement ratio = 1.96%), the magnitude of the primary expansion was less than 40% of the plain concrete for both water-cement-ratios. The shrinkage after the primary expansion was about 70% of the plain concrete at the age of 42 weeks and the amount of the change in length became almost equal to that of the ordinary reinforced concrete. However, very few cracks were observed on the specimens of the CSA-cement concrete, although considerably much cracks were found on the ordinary concrete.

Application to Field Concrete

Up to the present, CSA has been applied in some construction works, including the experimental building (Aug. to Dec. 1964), Nagano Prefectural Office (Apr. 1966 to Mar. 1967), the experimental

paving (Mar. to Apr. 1964) and Noheji By-pass, Aomori Prefecture (Nov. to Dec. 1966), etc. From the above examples, CSA-cement concrete decreased cracks in building and made it possible to perform 60 meters long paving without expansion joints. Also, many other desirable results were obtained. The experimental building and paving that has been metnioned above will be briefly reported hereinafter.

Test 1. Example of Application to Building Works (Experimental Building)

The experimental building and dummy slabs were prepared for measurement of the difference between the 13% content CSA-cement concrete and normal portland cement concrete. The experimental building was composed of two one-storied buildings connected by expansion joint at the central part as shown in Fig. 28.

Dummy slabs were comprised with or without reinforcement. The effects due to expansion of CSA were observed by making comparative studies of inner stresses caused in roof slabs and dummy slabs, and cracks occurred in roof slabs and wall panels. Mixing-ratio of concrete used is shown in Table 13.

Measurement of change in length of roof slabs and dummy slabs was made by using Carlson type extensometer and that of constrained deformation by Carlson type strainmeter. The location of measurement of roof slabs are shown in Fig. 29.

Temperature and humidity during measuring period are shown in Fig. 30. The condition of weather involving rain, snow or sleet during the first 3 months was similar to that in case of wet curing, and the slow appearance of compressive strength seemed due to the effect of low temperature at the beginning of that period.

The compressive strength of concrete is shown in Table 14. Addition of CSA has not a tendency to reduce compressive strength in case of field curing.

Fig. 31 shows the change in length of dummy slabs, and also clearly indicates expansive effect due to CSA.

Fig. 32 shows the inner stresses of concrete. It is clear that there exists inner compressive stresses due to reinforcement constraint. On the other hand, tensile stresses occurr in normal portland cement

Table 13. *Mix proportion of concrete*

Ingredient / Kinds of concrete	Cement kg/m³	CSA kg/m³	Water kg/m³	Sand kg/m³	Gravel kg/m³
Normal portland cement concrete	350.0	0	200	805	1061
The 13% content CSA-cement concrete	304.4	45.6	200	805	1061

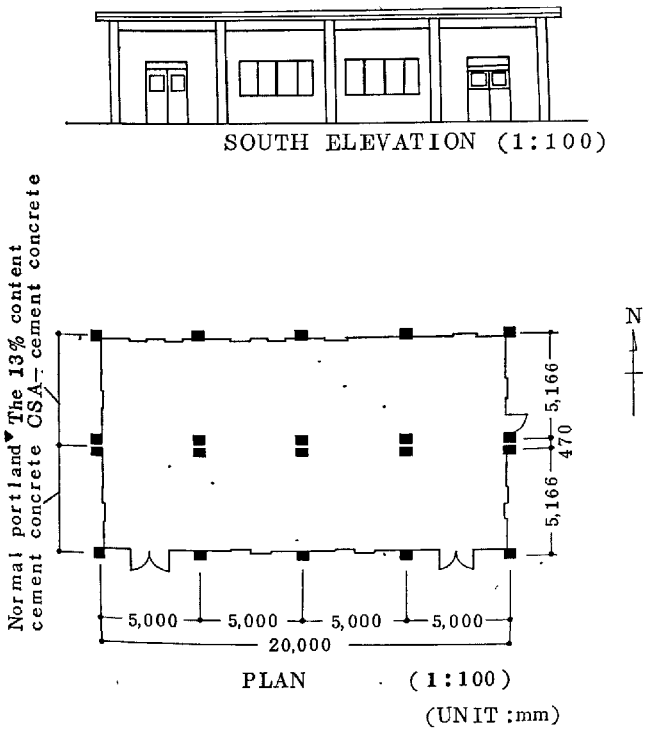

Fig. 28. *Plan and south elevation*

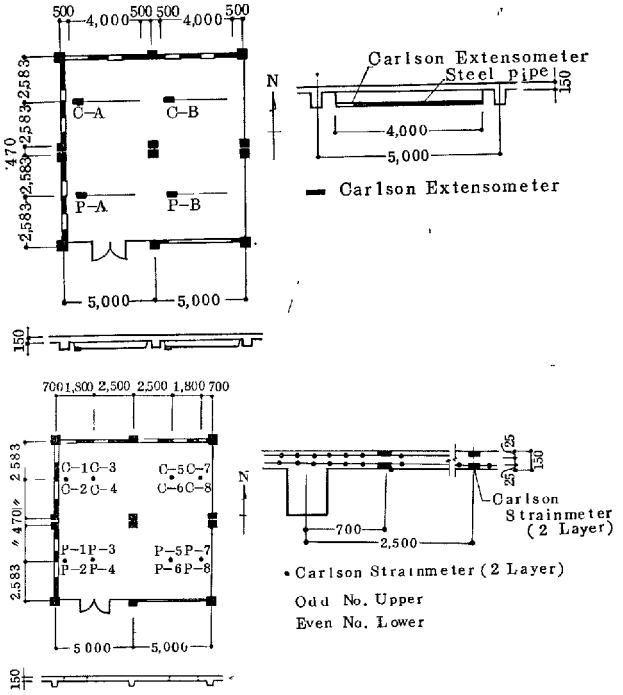

Fig. 29. *The location of measurement of roof slabs (Unit: mm)*

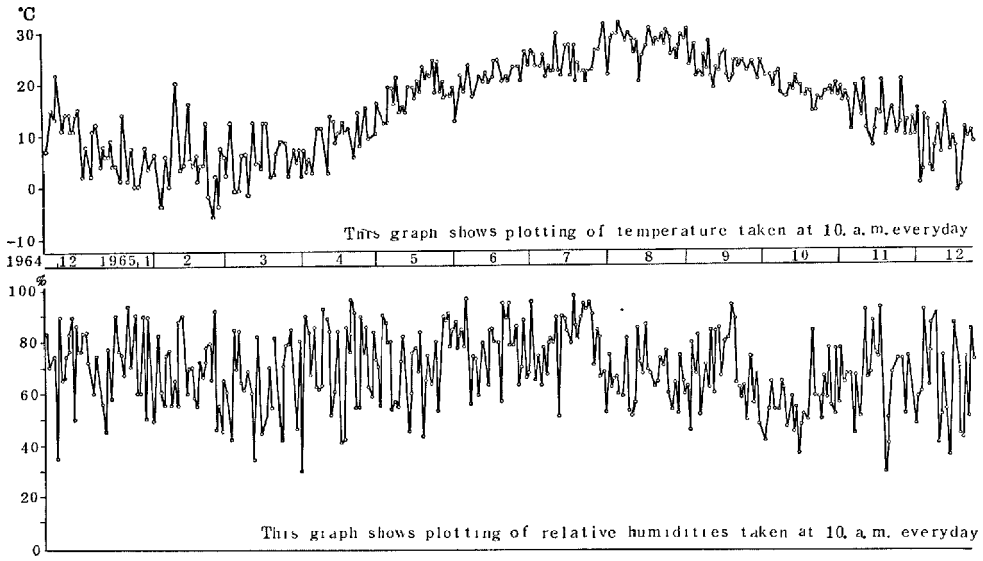

Fig. 30. *Temperature and relative humidity during measuring period*

Table 14. *Compressive strength of concrete*

Kind of concrete / Method of curing	Age-days	Compressive strength kg/cm²			
		7 days	28 days	270 days	400 days
Normal portland cement concrete	Air curing	—	327.1	—	—
	Field curing	86.2	181.2	278.5	398.7
The 13% content CSA-cement concrete	Air curing	—	278.1	—	—
	Field curing	99.9	185.9	303.1	341.3

Air Curing = Air curing (20°C 80% R.H.) after 3 days water curing (20°C)

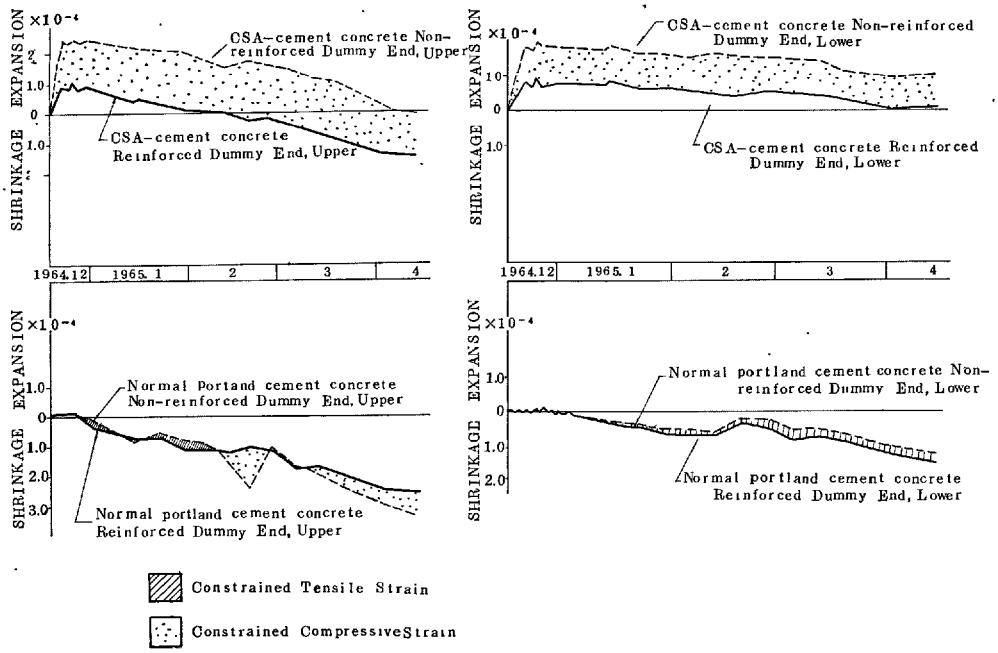

Fig. 32. *Camparison of inner stresses of concrete due to reinforcement constraint by carlson strainmeter*

concrete.

Fig. 33 shows change in length of roof slab at end span, and the 13% content CSA-cement concrete expands by approximately 0.5 mm (1.0×10^{-4}) and is restored to the original length after 1 year. Normal portland cement concrete shrinks by approximately 0.6 mm (1.2×10^{-4}) after 1 year.

Fig. 34 shows the results of the inner stresses of roof slab at end span. It is noted from these results that the 13% content CSA-cement concrete shows larger expansion rate on the upper side and normal portland cement concrete always shows larger shrinkage rate on the upper side.

Fig. 35 shows the condition of cracks that occurred on wall surface after 1 year. Cracks began to occur at the 5th month. During the period from 5th to the 8th month, the occurrence and growth of cracks were prominent probably because of the summer season, However, any change was hardly observed during the following 4 months.

No distinct cracks, however, were observed on the roof slabs.

By the use of CSA, it is possible to create compressive stresses, although in small amounts, within concrete through constraint due to reinforcement, and therefore, it is considered advantageous to use it for building. And, it is also considered to have distinct effect in decreasing shrinkages and cracks. However, the occurrence of a crack as large as 1.2 mm at a certain spot yet remains for us to be studied.

Test 2. Example of Use in Paving (Experimental Paving)

The experimental paving and dummy pavement were prepared for measurement of the difference with the 10%, 13% content CSA-cement concrete and normal portland cement concrete. And, the possibility of increasing the distance between expansion joints and decreasing the thickness of paving were studied. Dummy pavement that avoid surface friction from botton were placed on grease coated steel plate. The experimental paving was approximately 50 meters long and 2 lanes wide as shown in Fig. 36. Mixing-ratio of concretes are shown in Table 15.

On experimental paving, changes of joints width were measured by Carlson type extensometer, con-

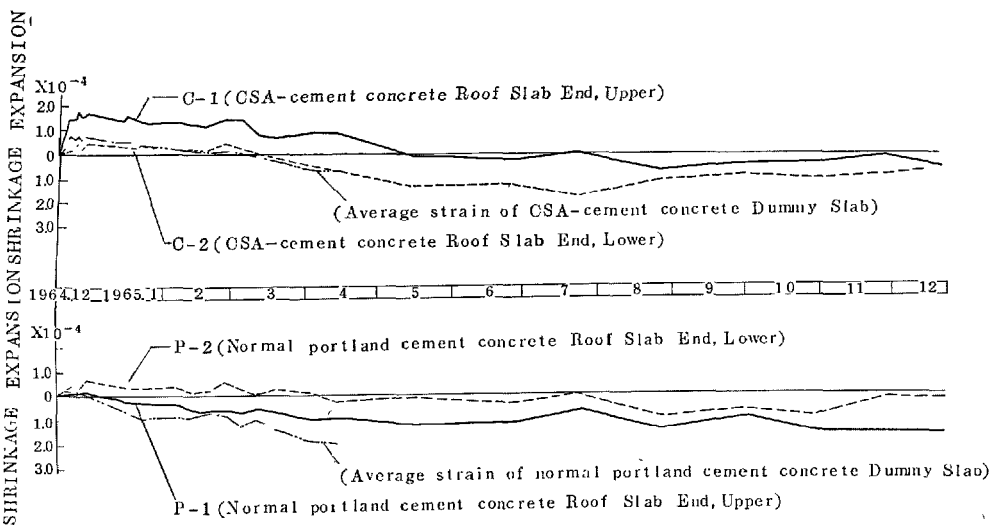

Fig. 34. *The results of measurement by carlson strainmeter on roof slabs*

strained strain by Carlson type strain meter, warping deformation by dial gage and inner temperature of concrete by thermocouple. And on dummy pavement, the changes in length were measured by contact strain meter, and inner temperature of concrete was measured.

Temperature and humidity during measuring period are shown in Fig. 37.

Table 15. *Mixproportion of concrete*

Ingredient / Kind of concrete	Cement kg/m³	CSA kg/m³	Water kg/m³	Sand kg/m³	Gravel kg/m³	Pozzolith No. 8 kg/m³

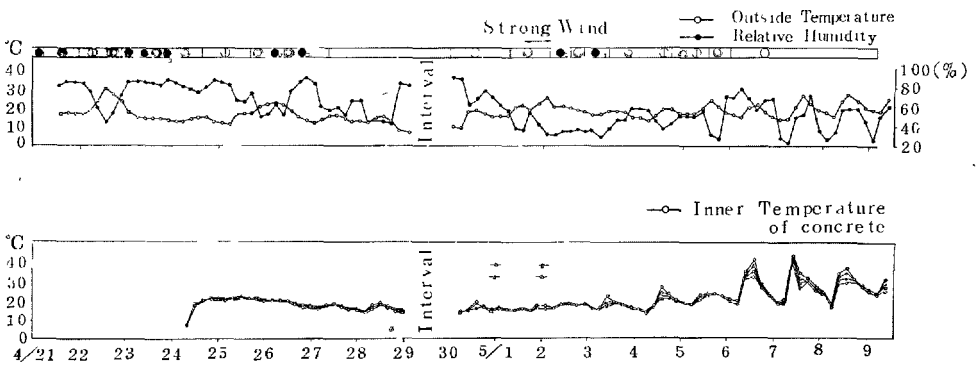

Fig. 37. *Outside temperature and relative humidity and inner temperature of concrete*

tween normal portland cement concrete and the 10%, 13% content CSA- cement concrete. However, in case of field curing, addition of CSA increases compressive strength at 28 days.

Fig. 38 shows the comparison of changes in length of dummy pavement for the 10%, 13% content CSA-cement concrete and normal portland cement concrete. It was found that the maximum change in length is about 0.4 mm due to temperature change in a day in every cases.

An example of change in width of expansion joint of experimental paving is shown in Fig. 39. The difference between CSA- cement concrete and normal portland cement concrete is clearly observed. The results of measurement in central parts of paving by Carlson type strain meter are shown in Fig. 40. The average strain that is calculated in Fig. 39 and the strain in Fig. 40 do not correspond. This suggests a reason why the constrain at central part of paving should have been very large as compared with that of the end. The strain in opposite directions on upper and lower surfaces of paving were shown with mark "0" in Fig. 40. These phenomena are presumed to have happened due to constrained deformation. Strains were 0.5×10^{-4} or around.

Average strain is obtained by dividing the movements of paving ends measured with joint extensometer by the distance between expansion joints, and it is plotted together with the strain of dummy pavement in Fig. 41. According to Fig. 41, the maximum

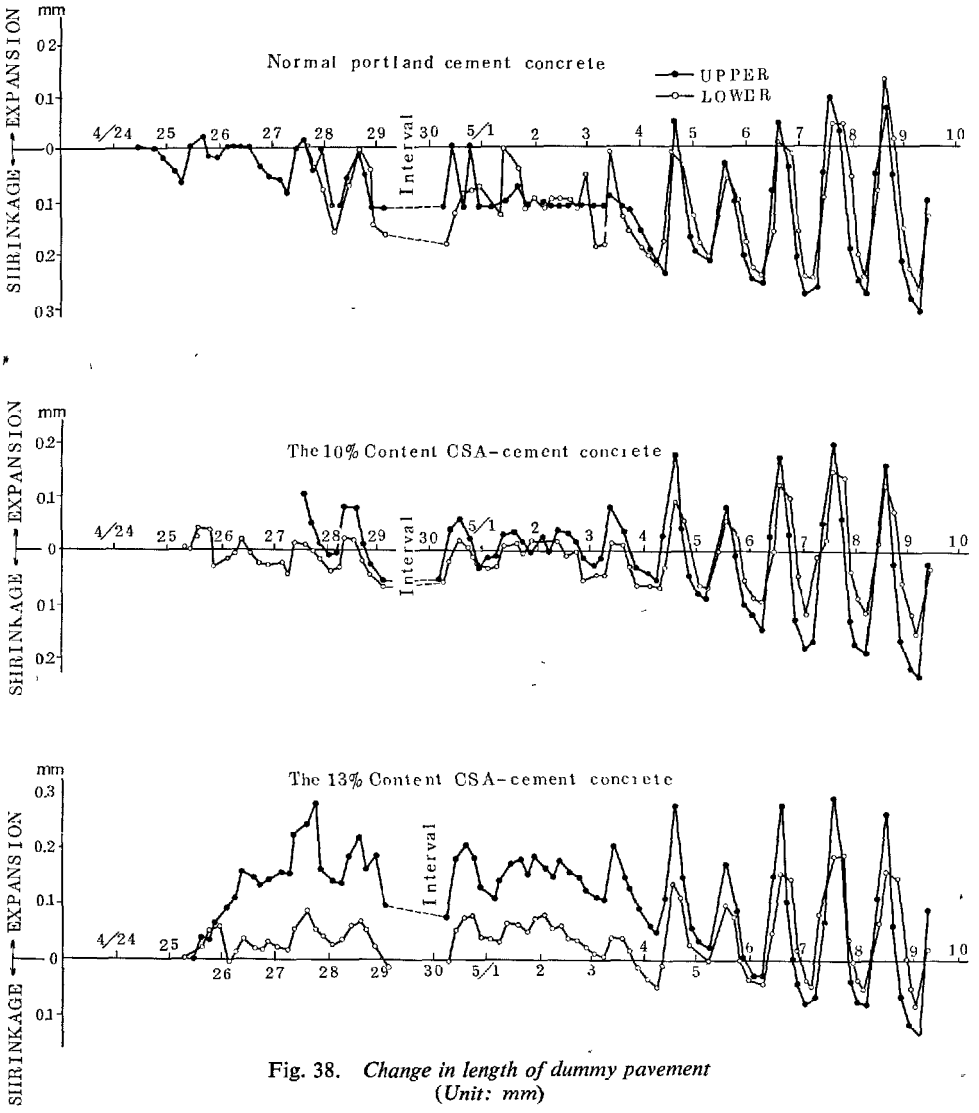

Fig. 38. *Change in length of dummy pavement*
(Unit: mm)

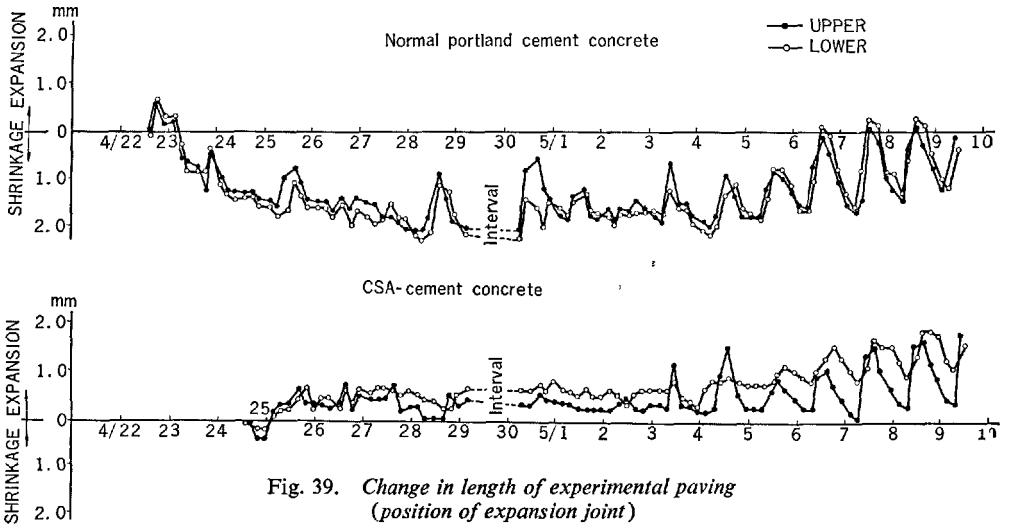

Fig. 39. *Change in length of experimental paving*
(position of expansion joint)

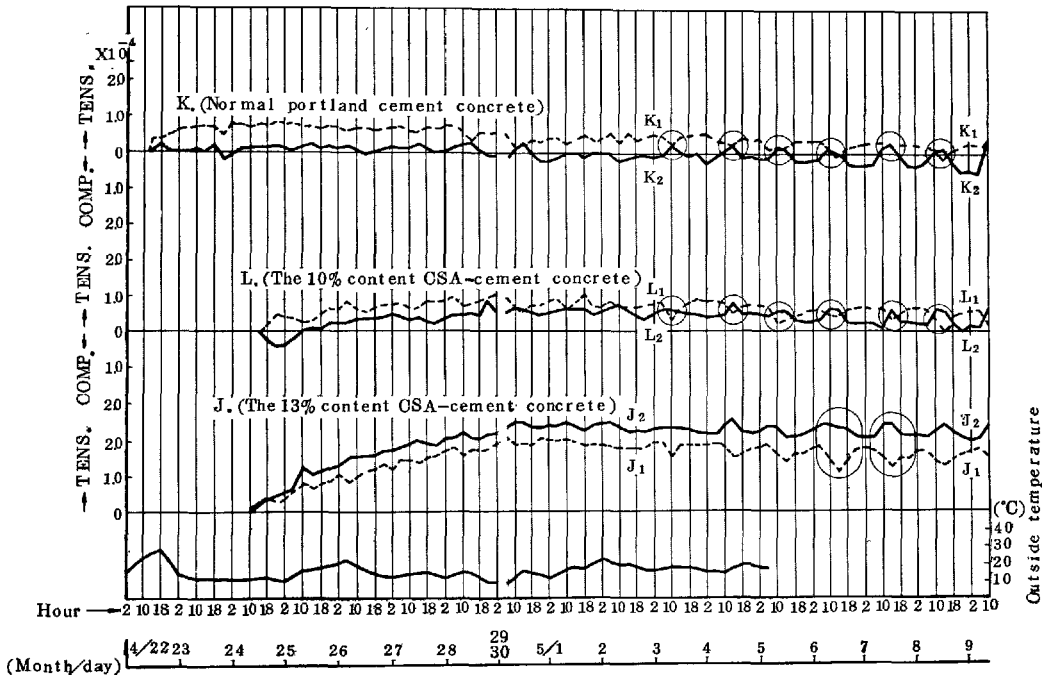

Fig. 40. *Strain of experimental paving by carlson strainmeter*

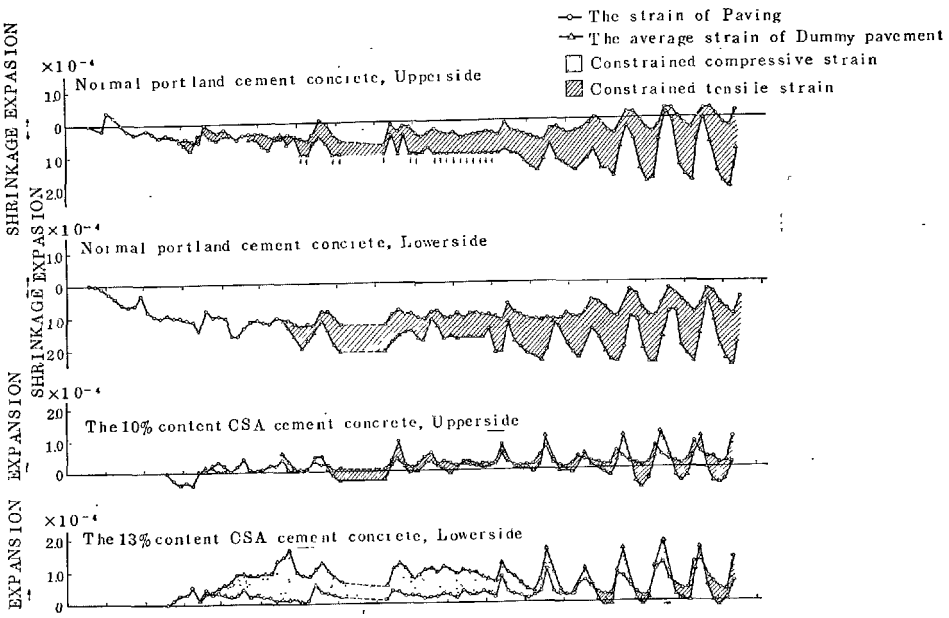

Fig. 41. *Inner constrained stresses*

constrained tensile strain of normal portland cement concrete is 1.6×10^{-4}. If "3/4 of constrained shrinkage deformation remains to be creep and 1/4 as tensile stress"*, then it must be considered that, by taking modulus of elasticity for 2.5×10^{6} kg/cm² along its total length, and in view of this value being an average one, there are some local parts where the value are higher than the average one.

No crack has so far been observed in any of paving, although there were differences in inner stresses as mentioned above. It is common practice to provide a construction joint in every 8 to 10 meters in ordinary

*N.B. Opinion of Mr. Taiji Saji, Kyushu University.

concrete paving. The reason for observing no crack in this experiment may be that the job site was in rainy area and that traffic over the road was not so busy. However, as far as the use of expansive concrete was able to decrease greatly the inner stresses that had occurred within the paving, and with the use of 13% content CSA cement concrete, it was possible to decrease tensile side constrained deformation down to 1/10 approximately.

Supplementary Paper IV-85 General Behavior of Mortar and Concrete Made of Expansive Cement with Calcium Sulphoaluminous Cement Clinker

Tadao Nishi,* Tamotsu Harada and Yoshiro Koh*****

Synopsis

In this paper are reported the results of various experiments which were carried out for the purpose of checking inspection on general behaviors of the expansive cement mortar and concrete, on length change effects, strength, creep, modulus of elasticity, effect of steam curing, effect of resistance to rusting of steel, carbonation (neutralization) of concrete using the expansive cement, thermal properties of the expansive cement concrete, resistance to chemical attack (containing sea water attack) and resistance of the concrete to its frost action, and so on.

These tests for check were carried out with concrete or mortar which used cement containing various contents of calcium sulphoaluminous cement clinker, and the main results obtained were as follows:

Concrete of cement with about 10% content of the expansive agent showed good effects on compressive strength, bond strength and showed that the tendency of carbonation and steel rusting of the concrete with expansive cement of this content was a little larger than that of ordinary cement concrete, but it will be reduced to the same rate as that of ordinary concrete by adding dispersion admixture.

Intensity of expanding pressure reached to maximum at 7 days after reaction and decreased when cured in water.

Effect of steam curing on expansive cement concrete was recognized.

Thermal properties such as effect of high temperature on strength, or thermal conductivity of the expansive cement concrete were observed.

The strength of the expansive cement concrete was rather promoted in alkali solution, but in the solution containing dilute sulphuric acid solution, its strength was reduced as much as the ordinary portland cement concrete.

The sea water resistance of the expansive cement concrete was good.

The result of freezing and thawing test showed that there was not much difference between the expansive cement mortar and the ordinary cement mortar.

This paper is based on a number of test results carried out by Tadao Nishi*, Tamotsu Harada**, Yoshiro Koh***, Kazuo Gotoh[1], Kazuyoshi Hirai[2], Touhei Horishima[3], Kyubei Kizawa[4], Hiroshi Kuriyama[5], Hiroshi Muruguma[6], Syoichi Okushima[7], Yoshizo Ono[8], Taiji Saji[9], Toyokazu Shiire[10], Kazuhisa Shirayama[11] and Eiichi Tazawa[12].

Introduction

The purpose of this paper is to clarify the general behavior of CSA-cement mortar and concrete, among others the effects of the contents of CSA and the curing conditions on the physical properties of mortar and concrete compared with ordinary mortars and concretes.

The durability and thermal properties were also tested in the light of every possible usage of the cements.

Two types of expansive cements with different calcium sulphoaluminous cement clinker were used in our experiments. The molar-ratios CaO: Al_2O_3: $CaSO_4$ of calcium sulphoaluminous cement clinkers were adjusted to 3: 1: 3 and 4: 1: 3.

The meanings of following abbreviations used in this paper are as follows.

CSA:	Calcium sulphoaluminous cement clinker
CSA-cement:	Expansive cement with calcium sulphoaluminous cement clinker
CSA-cement mortar:	Mortar made of CSA-cement
CSA-cement concrete:	Concrete made of CSA-cement
3–1–3 CSA:	The molar-ratio CaO: Al_2O_3: $CaSO_4$ of CSA is 3: 1: 3
4–1–3 CSA:	The molar-ratio CaO: Al_2O_3: $CaSO_4$ of CSA is 4–1–3
10% CSA:	Expansive cement with 10% content of CSA

Effects of Mixing Contents and Curing Conditions on the Expansion-Shrinkage Characteristics

Influence of Various Factors

Procedure and Results

In the factorial experiment shown in Table 1, the effects of a number of different factors on the expansion-shrinkage characteristics are investigated simultaneously.

The concretes were made with the normal portland cement and 3–1–3 CSA and were cast in 10 × 10 × 40 cm prisms. Results of the experiment with all factors were shown in Table 2.

In the analyses of variance for the expansion-shrinkage values at the age of 180 days, the relative efficiency of all factors were estimated in Table 3.

Table 1. *Factors and levels*

Factor	Level			
	1	2	3	4
CSA content*	0%	13%	—	—
Cement paste content	30%	25%	—	—
W/C-ratio	70%	50%	—	—

Initial curing	stored in room	cured in water	—	—
Relative humidity	70%	80%	—	—

* Normal porltand cement + CSA
**Artificial light-weight aggregate

Concluding Remarks

Concluding remarks obtained are as follows.

(1) Among these factors which affect the expansion-shrinkage of concrete, the mixing content of CSA is most significant.
(2) The effect of admixtures is great following the mixing contents of CSA.
(3) As the conditions of the initial curing differ, the difference of the expansion-shrinkage of concrete is recognized.
(4) The effect of cement paste contents can be found, but is relatively low.

Effects of another factors have the same tendency as in the case of the ordinary concrete.

Effect of CSA-Contents

Prodedure and Results

A. The effect of variation in the CSA-content on the expansion-shrinkage of CSA-cement mortar was investigated. The normal portland cement and standard sand were used as cementing material and aggregate respectively. The specimens were cast in 25 × 25 × 280 cm prisms, and cured in water at the age of 3 days, and then placed in air at 20°C and 80% R. H.

*+: Expansion
−: Shrinkage

Table 4 shows the results measured. Note that additions of 20 and 30% CSA-contents to the mortar resulted in the expansive cracks.

B. And the effect of variation in the CSA-content on expansion-shrinkage of the CSA-cement concrete was investigated, too. Normal portland cement, portland blast-furnace cement and fly ash cement were used as cementing material, and natural river sand and gravel were used as aggregates. W/C-ratio was about 0.6, and the slump was expected to be 18 to 20 cm. The specimens were cast in 10 × 10 × 50 cm prisms, and were removed from the molds at the age of 24 hours, and then stored in a room. The results obtained are shown in Table 5.

Concluding Remarks

The following conclusion will be gained.

Table 5. *Mix-proportion of CSA and expansion-shrinkage of CSA cement concrete (by T. Nishi)*

Cement type	3-1-3 CSA content %	Rate of expansion-shrinkage* $\times 10^{-5}$				
		3 days	7 days	28 days	63 days	105 days
Normal portland cement	0	+5	−2	−21	−51	−60

	10	+6	+8	0	−21	−31
	13	+24	+33	+20	−1	−11

*+: Expansion
−: Shrinkage

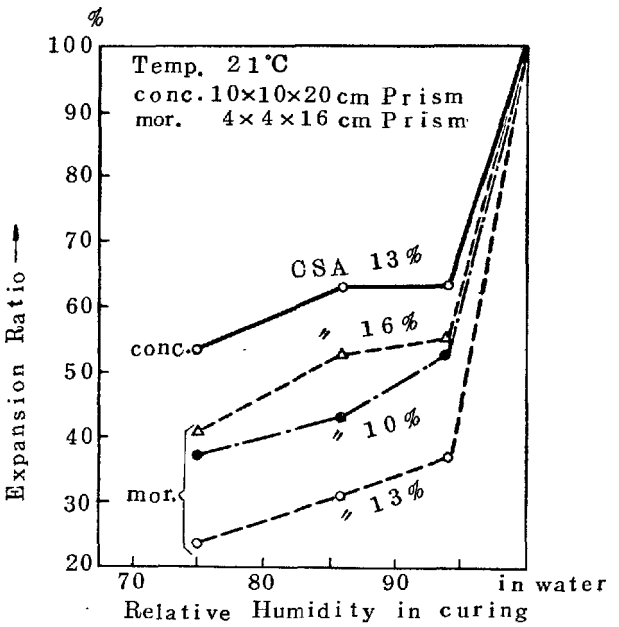

Fig. 1. *Relation between initial curing condition and the maximum expansion of the respective CSA-cement mortar and concrete (by T. Shiire)*

(1) If the CSA- content is less than 5%, the apparent effect of CSA-mixture on compensation of shrinkage is not observed.
(2) If the CSA-content is more than 20%, even expansion cracks are markedly observed.
(3) The rate of drying shrinkage after finishing the initial expansion of CSA-cement mortar and concrete is little different from that of the ordinary cement mortar and concrete.

Effect of Curing Condition

Procedure and Results

A. The relation between the initial curing humidity and the expansion of CSA-cement mortar and concrete is shown in Fig. 1.

In this experiment, the normal portland cement, 3–1–3 CSA and natural river sand and gravel were used as the mixing materials of the concrete. The mixing ratio of cement to fine aggregate and W/C-ratio for the mortar specimens were 1: 3.75 and 0.65 by weight respectively. For the concrete specimens, the proportion of cement: fine aggregate: coarse aggregate and W/C-ratio were 1: 2.58: 2.44 and 0.6 by weight respectively. All specimens reached to arbitrarily constant expansion value at the age of around 7 days.

B. The expansion value of 13% CSA-cement mortar which was, prior to water curing, dried in air at 70% R. H. at the various ages is shown in Fig. 2. The mixing proportion of cement: fine aggregate and W/C-ratio were 1: 1.5 and 0.45 by weight respectively.

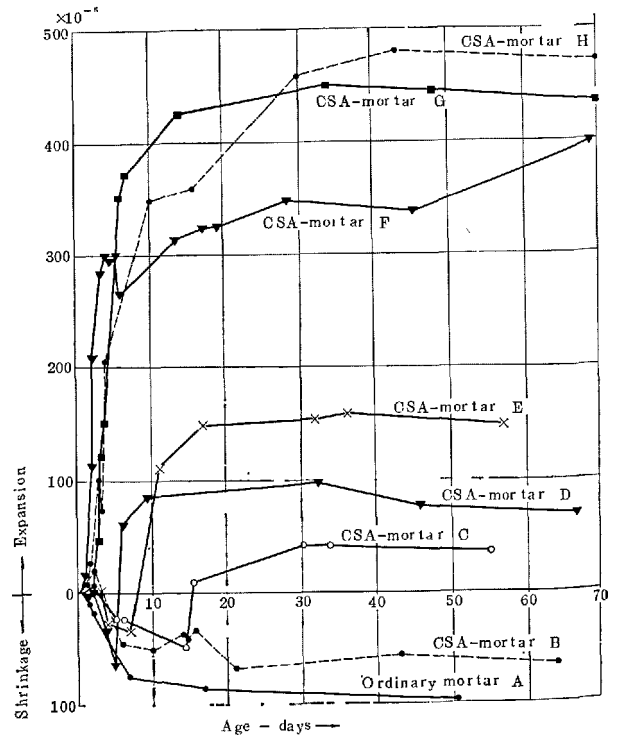

Fig. 2. *Expansion-shrinkage value of CSA-cement (3-1-3, 13% CSA) mortars effected by various initial curing conditions (by H. Muguruma)*

*+: Expansion
−: Shrinkage

C. The concrete specimens were cured in either of four ways for a long time. Some were placed in water, some in a room, some in the open air, and the others were placed in polyethylene bags. The expansion data in these cases were shown in Table 6.

In this experiment, the ordinary portland cement, 3-1-3 CSA and natural river sand and gravel were used as cementing materials and aggregate respectively. The cement contents of concrete specimens were 340 kg per cubic meter, and slump was 21–23 cm. W/C-ratio was 0.60. The specimens were cast in 15 × 30 cm cylindrical mold.

D. The expansion values of mortars cured in water at 20°C and 40°C were shown in Fig. 2. And the expansion values of mortars cured in water at 20°C and 5°C were shown in Table 7.

In this experiment the ordinary portland cement, 4-1-3 CSA and the standard sand (Japanese standard sand conforming to JIS R5201) were used as cementing material, expansive admixture and aggregate respectively, the mixing proportion of cement to fine aggregate was 1:2 by weight. The specimens were cast in 4 × 4 × 16 cm prisms.

Table 7. *Curing temperature and expansion of concrete (by K. Kuriyama)*

4-1-3- CSA content %	Temperature of curing water, °C	Expansion value $\times 10^{-5}$		
		3 days	7 days	19 days
0	20	21	42	102
	5	5	−6*	69
10	20	105	138	204
	5	36	54	161

*Minus sign indicates shrinkage

Concluding Remarks

The concluding remarks obtained from this experiment are as follows.

(1) The expansion value of CSA-cement mortar and concrete cured in drying air was about 1/2 or less than that of the mortar and concrete cured in water.
(2) The expansion, when cured in water, ceased to grow by one or two weeks.
(3) The longer a curing in drying air was conducted before water curing, the less expansion value was obtained after water curing. In order to get the expansion of about 30×10^{-4} which might be necessary for the chemical prestressing, the concrete should be cured in air for less than 3 days.
(4) If the temperature of curing in water is 5°C or 40°C, little effective expansion is obtained as compared with 20°C.

Summary and Conclusion

(1) Effects of CSA on the expansion of mortar and concrete are produced. However, the drying shrinkage from the maximum free expansion is little different from that of ordinary mortar and concrete. The effective and stable expansion depends on the mix content of CSA.
(2) To produce the effective expansion, it is necessary to supply the sufficient water at the early age. The sooner the water supply, the better the effect is produced.
(3) If the temperature of water curing is too high or too low, the effective expansion of CSA-cement mortar or concrete does not grow.

Mechanical Properties of Mortar and Concrete Made of CSA-Cement

Mechanical Properties of CSA-Cement Mortar

A number of flexural and compressive strengths tests were made on CSA-cement mortar specimens. Following six test series mainly on the effect of curing conditions were carried out by four research institutions.

M 1: Effect of curing conditions on flexural and compressive strength of mortars (Ono).

M 2: Effect of curing conditions on flexural and compressive strength of mortar (Shirayama).

M 3: Effect of curing temperature on compressive strength of mortars using diluvial sand and 3–1–3 13% CSA-cement (Koh and Gotoh).

M 4: Effect of curing temperature and content of CSA on compressive strength of mortars using diluvial sand and 3–1–3 CSA-cement, made in 1964 and 1965 (Koh and Gotoh).

M 5: Effect of curing temperature on compressive strength of mortars using diluvial sand and 4–1–3 10% CSA-cement (Koh and Gotoh).

M 6: Effect of proportion and flow of mortars on flexural and compressive strength of mortars using river sand and 4–1–3 10% CSA-cement (Kuriyama and Hirai).

Series M1

This is a part of fundamental test series to decide the amount of addition of CSA to normal portland cement. Three curing conditions, water curing, air dry conditions and air dry after 3 days water curing, were compared with each other, from the viewpoint of the drying condition at building site which causes the drying shrinkage.

Specimens in this series were 4 × 4 × 16 cm beam according to JIS for testing the strength of cement. Standard and a river sand were used for making mortars and their water cement ratios were 0.65 and 0.45 respectively. The mixing proportion of cement and sand was fixed to 1: 2 by weight. Both 3–1–3 and 4–1–3 CSA were tested and the content of CSA were varied from 0 to 15%.

Series M2

In the test for measuring creep of mortar, the flexural and compressive strengths were tested after curing in water or air for 7 days to 1 year. 4 × 4 × 16 cm beam were made of 3–1–3 13% CSA-cement and standard sand (w/c = 0.60).

Series M3, M4 and M5

Four kinds of mortar mix, with their water cement ratio varied over arange of 0.45, 0.55, 0.65 and 0.75, were tested after curing at 5 and 20°C for planned periods varying from 3 days to 1 year as shown in Table 8. Curing at 0°C was also applied only in M 3 series. The mortar mixes, in which definite diluvial sand was used, were always fixed to compare the effect of low temperature with that of definite ordinary portland cement of Hokkaido district, which is selected as a standard for making our chart[1] for selecting water cement ratio to get required strength, established by Koh by using maturity according to Saul-Bergström.

The specimens were 4 × 4 × 8 cm square column, and most of them were wrapped with polyethylene sheet and cured in air. Curing in water or air is also carried out. The compressive strength was tested at definite ages from 3 days to 1 year as shown in Table 8. The results obtained are shown in Figs. 3 and 4 the series M 3 and M 5 respectively.

Series M6

Nine kinds of river sand mortar were used for the tests of flexural and compressive strength by using 4 × 4 × 16 cm beam specimens made of 4–1–3 10% CSA-cement. The results obtained are shown in Fig. 5.

Table 8. *Experimental scheme of series M3-M5 (by Y. Koh, T. Gotoh)*

Mechanical Properties of CSA-Cement Concrete

Nine series of compressive strength tests and two series of tensile strength tests were carried out and elastic moduli were measured by four different research institutions to learn mainly on the effects of curing conditions on the mechanical properties of concrete.

Compressive Strength and Elastic Modulus of CSA-Cement Concrete

Followings are main object of test series.

CC 1: Effect of curing condition and content of 3–1–3 or 4–1–3 CSA as compared with that of normal portland cement (Ono).

CC 2: Effect of curing and testing condition in view of moisture conditions (Tazawa).

CC 3: Gain of strength at building site (Horishima).

CC 4: Effect of moisture condition, as supplementary test for drying shrinkage (Shirayama).

CC 5: Effect of curing temperature (Koh).

CC 6: Long term test to study the effect of curing condition (1) (Shiire and Kawase).

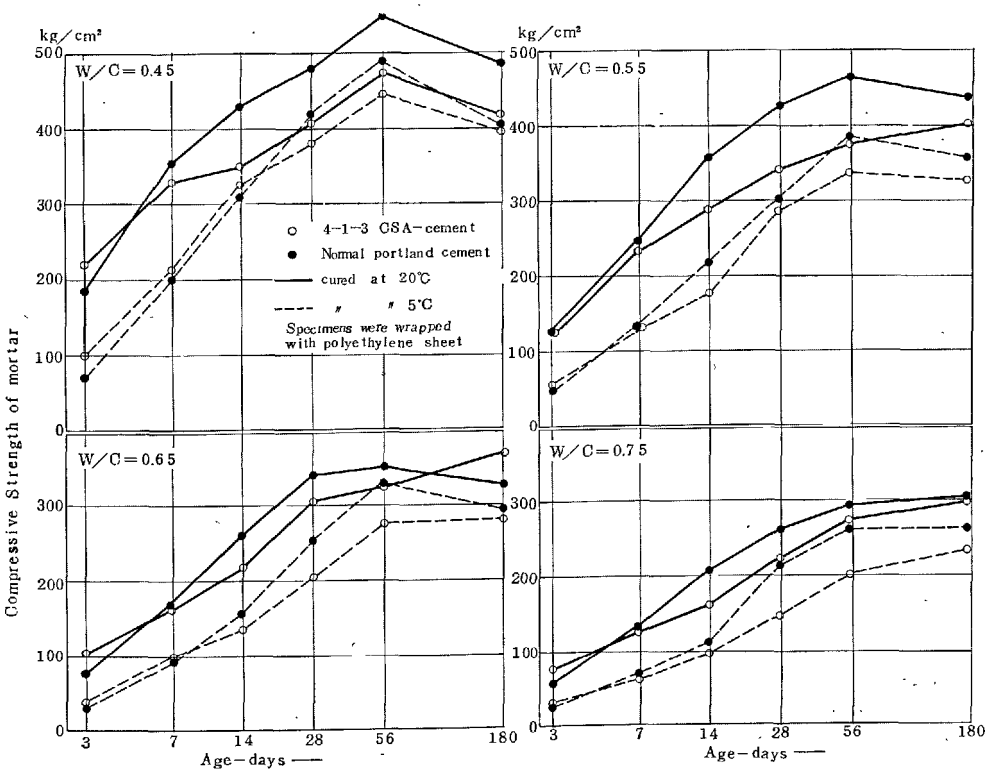

Fig. 4. *Test results of series M5 (by Y. Koh, T. Gotoh)*

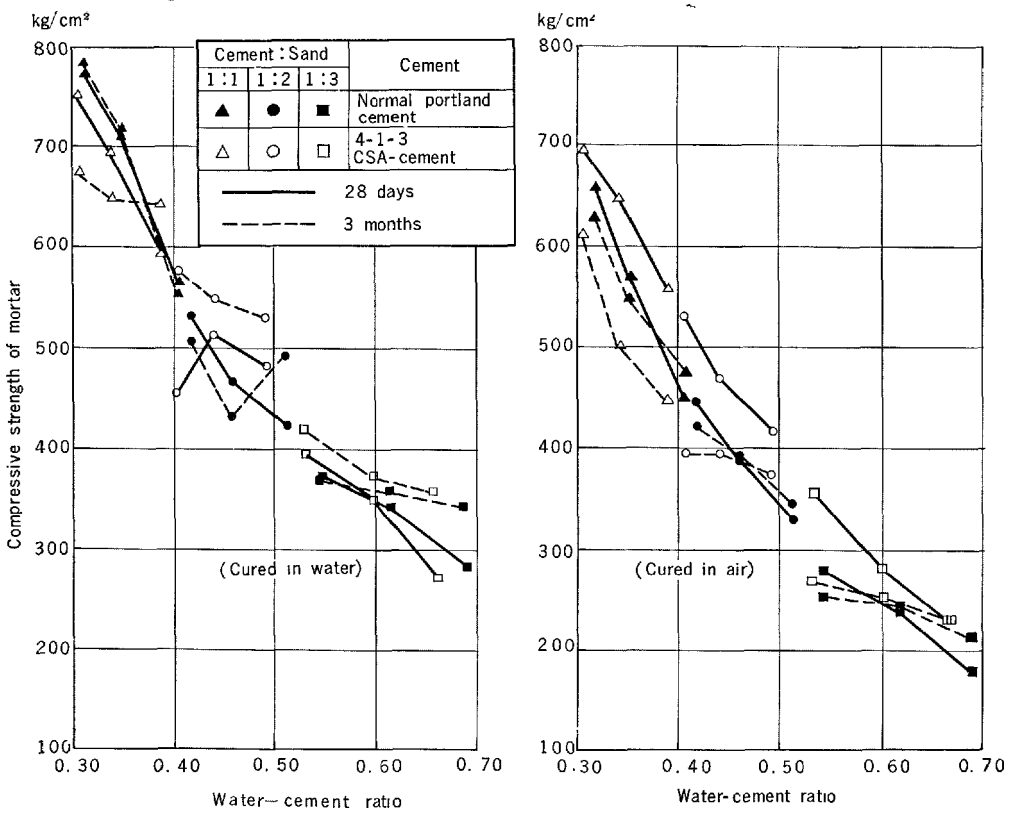

Fig. 5. *Compressive strength of mortars made of 4-1-3 10% CSA-cement and river sand (by H. Kuriyama, K. Hirai)*

CC 7: Long term test to study the effect of curing condition (2) (Koh, Gotoh and Kamada).

CC 8: Effect of curing temperature (1); differences between concrete mixes (Koh, Gotoh and Kamada).

CC 9: Effect of curing temperature (2); differences between two consistency grades (Koh, Gotoh and Kamada).

In the series CC 2–7, 3–1–3 CSA-cement, mainly 13% content of CSA, was used for test, however, 4–1–3 10% CSA-cement was used in series CC 8 and 9.

Series CC 1

This is a part of fundamental test series to decide the amount of addition of CSA to normal portland cement. Three curing conditions, the same with mortar test, were applied to $10\phi \times 20$ cm cylinder specimens made of a definite concrete mix, in which the cement content was maintained at 317 kg/m³ and water cement ratio was fixed to 0.60. River sand (<5 mm, F.M. = 2.65) and river gravel (<25 mm, F.M. = 6.65) were used as aggregates. A part of results is shown in Fig. 6.

Series CC 2

To learn the effect of moisture conditions in curing and testing of concrete, $15\phi \times 30$ cm cylinder specimens were stored and tested under four conditions, i.e., water curing and testing in a saturated condition, water curing but dry test (3 days in air before test), exposed to dry air (20°C and 50% R.H.) and dry test, and exposed to dry air but saturated prior to test. Content of CSA was 0, 6 and 12% by weight.

Series CC 3

3–1–3 13% CSA-cement was used and $10\phi \times 20$ cm cylinder concrete specimens were tested after curing in water or storage at building site.

Series CC 4

Strength and elastic modulus were tested by 3–1–3 13% CSA-cement or portland cement.

Series CC 5

Effect of curing temperature on concrete strength were compared with each other by using 4 kinds of concrete mix. Cylinder specimens measuring $10\phi \times$

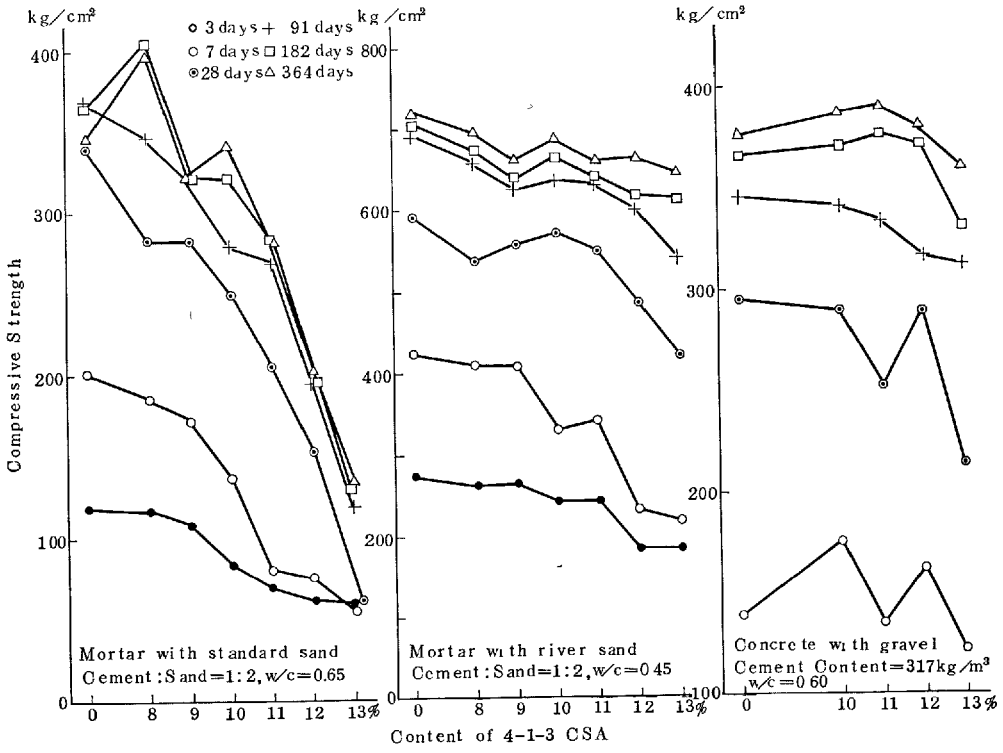

Fig. 6. *Compressive strength of mortar and concrete made of 4-1-3 CSA-cement (water curing) (by Y. Ono)*

20 cm and 15 $\phi \times 30$ cm respectively were made from 3–1–3 13% CSA-cement or normal portland cement with or without air-entraining agent and cured at 20 and 5°C. Test results obtained are shown in Figs. 7 and 8.

Series CC 6 and CC 7

In these series, we intended to clarify long term behavior of concrete strength. In the former, 3–1–3 13% CSA-cement were used and the test was carried out in Tokyo, while the latter was carried out in Sapporo and used cement was changed to 3–1–3 10% CSA-cement, in view of rather large decrease of strength by the former cement, based on the results of other series, e.g., CC 1 and CC 5. Static and dynamic moduli of elasticity were measured in the latter series.

Series CC 8 and CC 9

Effect of temperature and its difference between various mix proportions were compared with each other. 10 $\phi \times 20$ cm cylinder specimens were mainly used. Concrete mixes of these series are shown in Table 9 and results are shown in Fig. 9.

Tensile Strength and Elastic Modulus of Concrete

Direct tensile test and splitting tensile test methods were applied in following two series.

CT 1: 3–1–3 CSA-cement concrete. Content of CSA was varied as 0, 7, 13 and 16% (Shiire).

CT 2: 4–1–3 10% CSA-cement concrete (Shiire).

A part of test results are shown in Fig. 10 and Table 10.

Conclusion on Mechanical Properties of Mortar and Concrete

From all the test above mentioned, it seems that 13% content of CSA is rather excess as the loss of strength is comparatively large, however, 10% addition of CSA, either 3–1–3 or 4–1–3, will be suitable without considerable sacrifice of strength either compressive or flexural strength of both mortar and concrete, because 10% CSA- cement gives nearly the same result as ordinary portland cement either cured at 20°C or 5°C.

In case of tensile strength of CSA-concrete, however, the strength will be little affected when cured in water, and the more the content of CSA, the less the modulus of elasticity.

Creep and Expansive Force of Expansive Cement Mixture

For practical application of expansive cement, it is essential to characterize the expansive force of the cement mixture. Earlier results have shown that mechanical behavior of expansive cement mixture depends to a large degree on the availability of water. Therefore, effect of storage conditions on the expansive force was mainly investigated and other mechanical behaviors related to it, such as creep, volume change, strength etc. were also tested. This report consists of two experiments, that is, mortar test carri-

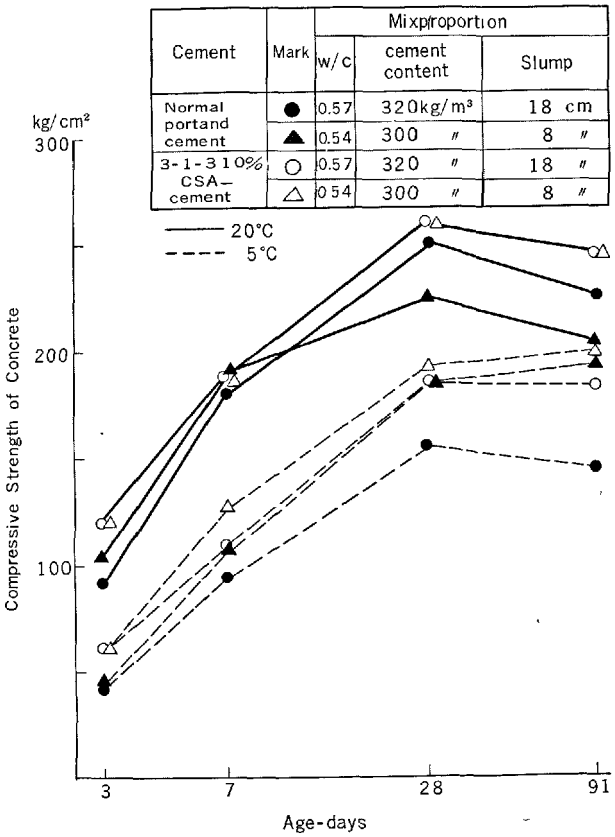

Fig. 9. *Test results of series CC9. Specimens were wrapped by polyethylene sheet and stored in air (by Y. Koh, E. Kamada)*

ed out by K. Kizawa's group, and concrete test carried out by K. Shirayama's group.

Expansive Force of Expansive Cement Mortar

Scope

The principal objective of this study is to find out how advantageous the expansive cement with calcium sulphoaluminous cement clinker (CSA-cement) is, when applied to grouting materials for embedding the anchor of pier.

For this purpose, the expansive force and other mechanical properties, such as strength and volume change were determined for the mortar with CSA-cement and for the mortars with other cementing materials for comparison.

Materials

Cementing materials: As the base of cementing materials, ordinatry portland cement was used. The expansive cements were composed by adding the

following expansive agents to the base cement; a calcium sulphoaluminous cement clinker (4–1–3 CSA), a compound of gypsum and pulverized limestone: two compounds of iron powder and chemicals. Aggregate: The aggregate was natural sand having the fineness modulus of 2.78. Mortar: The mixing proportion of mortar is shown in Table 11.

Specimens and Measurement

Mortar was placed in 75-by 500 mm cylindrical mold, and the expansive force was determined based on the strain of the mold. Longitudinal expansion of each specimen was also restrained by the end plate set up and fastened to the cylindrical mold after placing concrete, by tightening the nuts at the end of the rods, fixed to the bottom plate at another ends.

Two types of molds were prepared, the one being air-tight to prevent the water evaporation from mortar and the other being not air-tight having many small holes to allow the mortar to dry.

Test Results

Test results were shown in Fig. 11 and it demonstrates the following:

(1) The expansive force of CSA mortars was much larger than that of other mortars. CSA mortar No. 4 casted in the air-tight mold showed the highest expansive force, i.e. 49.5 kg/cm² at the age of about 4 days.

(2) The expansive forces of CSA mortars casted in perforated molds were not determined accurately after the age of 38 hours, because the molds were broken, but it seemed that about half or one-third of the expansive force developed in the air-tight mold.

Table 11. *Mix-proportion of mortar*

*Determined according to JIS R 5201: "Method of Test for Physical Properties of Cement."

Creep and Expansive Force of CSA-Cement Concrete

Scope

The program of the test was concerned with determining creep and expansive force of CSA-cement concrete kept in different storage conditions, that is, under water, in the wrapping of plastic sheet, and in the laboratory air. Compressive strength and volume change of concrete were also determined.

Materials

Cement: Ordinary portland cement and expansive cement with 10% content of 3–1–3 CSA both delivered as common sample to the laboratories concerned, were used. Aggregate: The aggregates were ordinary river sand and river gravel having the maximum size of 20 cm. Concrete: The mix proportion was exactly the same for portland cement concrete and CSA-cement concrete. Both concretes had the cement content of 340 kg/m³, W/C-ratio of 0.6, and their consistensies measured by slump were also nearly the same.

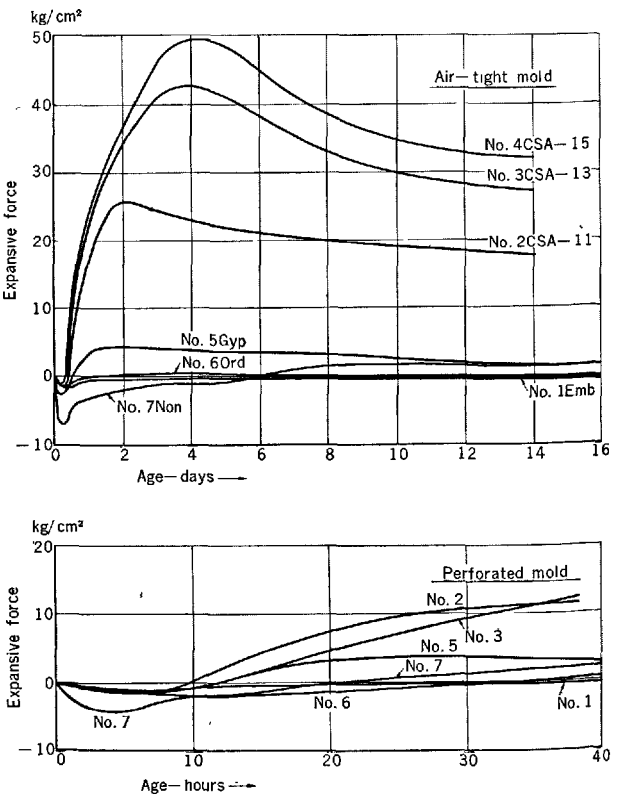

Fig. 11. *Expansive force development of mortar as affected by addition of expansive agent (by K. Kizawa)*

Specimens and Measurement

The concrete specimens were cylinders 15 by 30 cm. They were removed from the mold one day after casting, and then initial readings of the longitudinal length were taken by means of Whittmore gauge. After that, the specimens were stored in different conditions as follows:

(1) Curing in water: The specimens were placed in the sacks of plastic sheet, filled with water.

(2) Air-tight sealing: The specimens were wrapped by plastics sheets.

(3) Exposing to laboratory air: All specimens were stored and tested in the laboratory, maintained at the temperature of 20 ± 3°C and relative humidity of 60 ± 3%. The longitudinal expansive forces of concretes without restraint of transverse expansions, were determined by measuring the load need to maintain the concrete length between the gauge points equal to the initial reading.

At the age of 28 days, the specimens destined for creep tests were subjected to compressive stress of 30 percent of the 28 day compressive strength, and maintained under a constant stress from 2 to 22 months.

Test Results

Test results are shown in Fig. 12, Fig. 13, Fig. 14 and Table 12. The expansive force was highest and lasted for longest time in case of the specimen cured in water, as expected from its large expansion, that is, it attained to more than 27 kg/cm² (about 15% of 28-day compressive strength) at the age of 7 days, and 9.5 kg/cm² of expansive force was still remained at the age of 60 days.

Expansive forces of the specimens wrapped by

Compressive strength, kg/cm²	28 days	319	358	171	200
	12 months	—	356	—	255
	33 months	471	—	350	—
Initial elastic deformation $\times 10^{-4}$		3.2	4.2	2.4	3.0
At time under load in 8 weeks	Total deformation $\times 10^{-4}$	5.8	13.0	9.2	11.6
	Creep $\times 10^{-4}$	2.7	6.3	6.1	6.3
	Creep function	0.84	1.50	2.54	2.10
At time under load in 22 months	Total deformation $\times 10^{-4}$	12.6	—	16.0	—
	Creep $\times 10^{-4}$	7.1	—	11.4	—
	Creep function	3.94	—	4.75	—

plastic sheet or in the laboratory air were about 12kg/cm² at their maxima, and disappeared in 30 days.

The CSA-cement concrete showed higher creep values than the portland cement concrete, perhaps owing to their lower strengths. However, the differences in creep values get smaller with the time, for the increase of strengths of the CSA-cement concretes was larger than the portland cement concretes.

Conclusions

These two experiments again showed the importance of curing conditions of CSA cement mixture. It seems possible to keep the expansive force of CSA-cement mixture for a considerably long period, if the curing condition is carefully taken.

Bond Strength between Concrete and Reinforcement

Pull out Bond Test

Pull out bond tests were carried out by T. Shiire. Round reinforcing bar, 13 mm in diameter, was embedded vertically in center of 15 × 15 × 15 cm concrete specimens. Concrete mix and the results obtained are shown in Table 13. Specimens cured in air show better values than that cured in water.

Beam Type Bond Test

M. Okushima investigated the effect of CSA-cement on the bond strength of reinforcement by

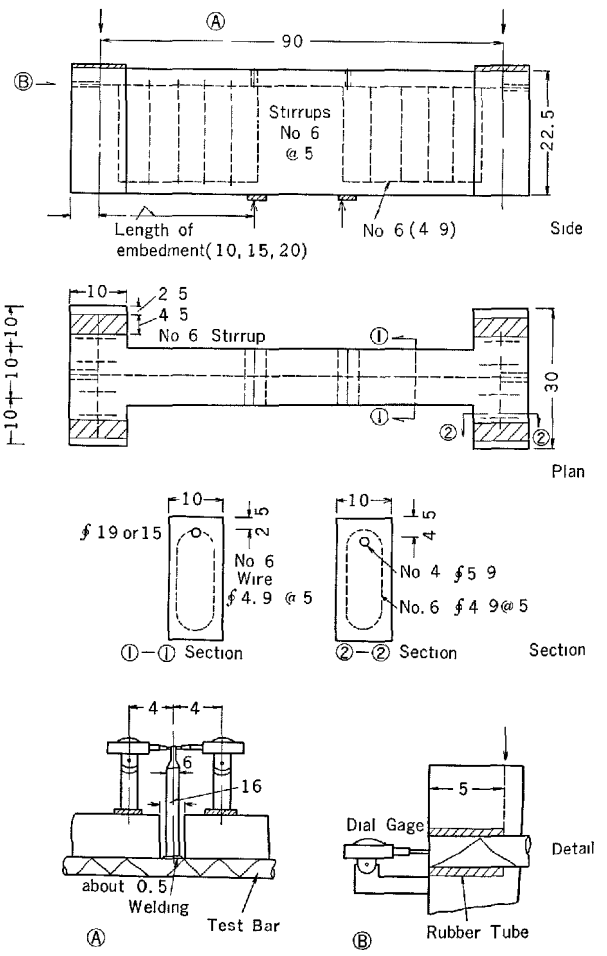

Fig. 15. *Beam type bond strength specimens (Unit: cm)*

beam type bond test shown in Fig. 15 from the viewpoint of factors such as the length of embedment of bars, use of the deformed bars and horizontally placed top or bottom bars.

Concrete mixes are shown in Table 14.

Normal portland cement	0.63	18	45.9	180	285	845	1014

Specimens with 16 mm diameter reinforcement of round and deformed respectively, and length of embedment of 10, 15 and 20 cm, were tested at age of 28 days.

The results are shown in Table 15 and Fig. 16, 17, that can be summarized as follows:

(1) Bond strength of reinforcement in 4–1–3 CSA-cement concrete is generally larger than that of normal portland-cement concrete.

(2) Both in CSA-cement concrete and ordinary concrete, the bond strength decreases as increasing the length of embedment of bars.

(3) Deformed bar is also effective in bond strength for CSA-cement concrete as for ordinary concrete.

(4) Bond strength of the bottom reinforcement is larger than that of the top reinforcement in both CSA-cement concrete and the ordinary concrete, and it is especially remarkable that in

CSA-cement concrete there is a little difference of bond strength between top and bottom.

Bond Test under Restriction

K. Gotoh investigated the bond strength of reinforcement in CSA-cement mortars under restriction for the purpose of jointing precast concrete panels. The round bars, 16 mm in diameter, were vertically placed in a steel pipe, 48.6 mm in diameter and 2.3 mm in thickness, and CSA-cement mortars were grouted into the pipe (Fig. 18).

The length of embedment of bars were 320 and 480 mm. Mortar mix and strength are shown in Table 16.

Pull out test results of specimens at 28 days are shown in Table 17 and Fig. 19.

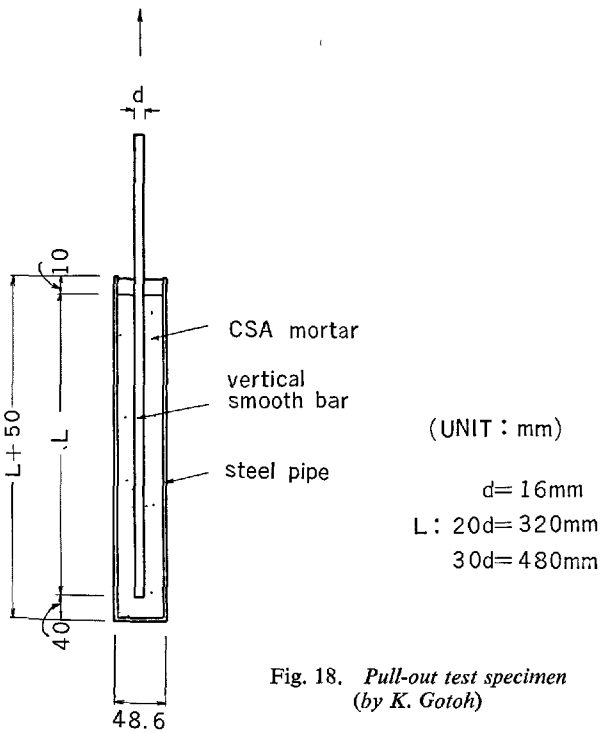

Fig. 18. *Pull-out test specimen (by K. Gotoh)*

Table 17. *Pull-out test results (by K. Gotoh)*

No.	Length of embedment mm	Content of CSA %	Maximum load Kg
A	320 (20 d)	0	2500 3000 2780

D′		40	6650 6800 6930

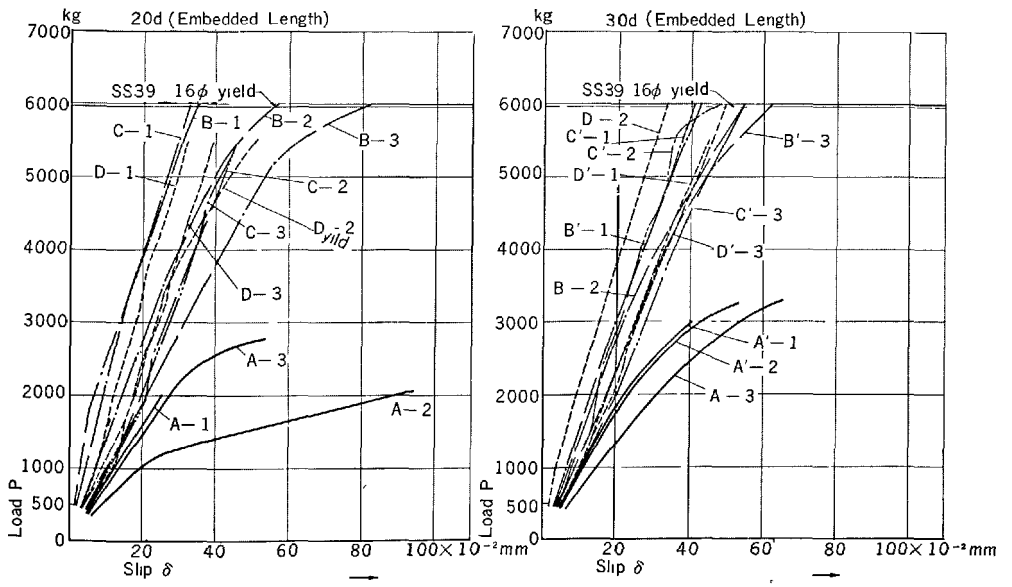

Fig. 19. *Bond slip at loaded end for 20d and 30d length of embedment (by K. Gotoh)*

The results show that the bond strength of round bars in CSA-cement mortars under restriction are much the same value of yield point of steel, and about twice of the bond strength in plain mortars.

Effects of Steam Curing upon the General Behavior of Calcium Sulphoaluminous Cement Mortar and Concrete

Procedure of Experiment

Materials

The expansive cement used for this study carried out by Y. Ono, is composed of blended cement that is mixed with content of 0–17% calcium sulphoaluminous cement clinker.

Aggregates used are river sand and gravel produced in Himekawa River, and they are as shown in Table 18.

Procedure

Table 19 shows measuring items, varieties of specimen and curing conditions.

Results Obtained

Results obtained are shown in Figs. 20–25: Fig. 20 shows that when contents of calcium sulphoaluminous cement clinker in portland cement is less than 13% by weight, the higher the steam curing temperature goes, the larger the expansion grows. When concrete

		b) Long period steam curing. Demolded at 24 hrs. after molding in test room, and cured at: 40°C ... 32 hrs 60°C ... 19 hrs 70°C ... 11 hrs and cured in water (20°C)	13 15 17	do

1) Initial gauge length was measured by comparator when demolded at 24 hrs. after moulding.
2) Dimension of specimen for compresive strength is ϕ10 × 20cm
3) Dimension of specimen for tensile strength is ϕ15 × 20cm
4) Steel bar used for reinforcement is SS41 (ϕ18mm, conformed to JIS G 3101).

is restrained by reinforcement bars, the maximum expansion coefficient reaches to 11×10^{-4} at temperature of 70°C, 7×10^{-4} at temperature of 60°C, and 4×10^{-4} at temperature of 40°C.

The general tendency of this result is akin to that of non-reinforced concrete. This fact will be seen in Figs. 20, 21 and 22.

Fig. 22 shows length change curves of reinforced concretes cured by steam for a comparatively long period.

Effect of steam curing times and temperatures on CSA-cement concrete will be seen in Fig. 23.

Fig. 24 and 25 show compressive strength and tensile strength respectively.

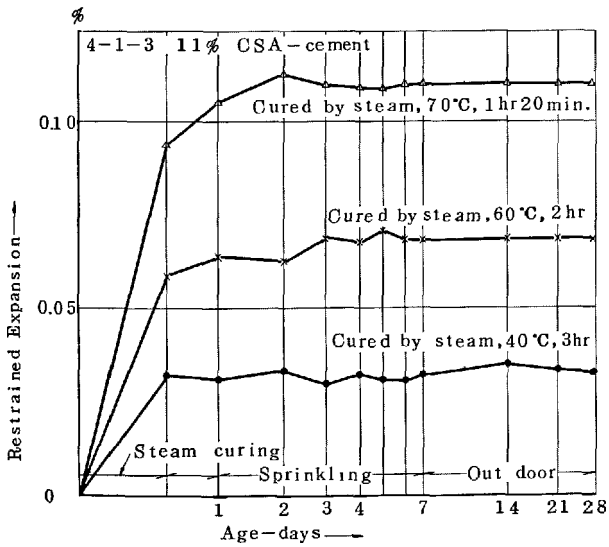

Fig. 21. *Restrained expansion of CSA-cement concrete (short period steam curing) (by Y. Ono)*

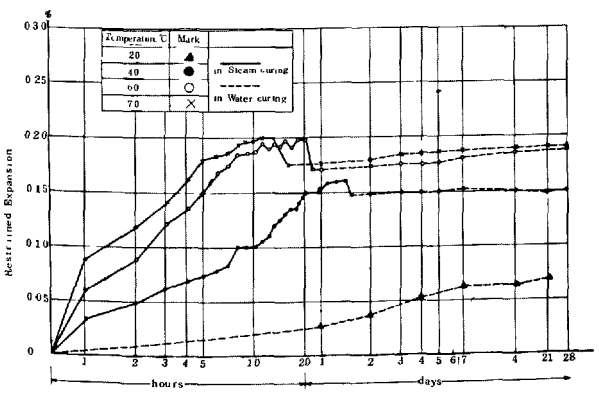

Fig. 22. *Restrained expansion of 4-1-3 11% CSA-cement concrete (long period steam curing) (by Y. Ono)*

Summary and Conclusion

(1) Expanding behavior of calcium sulphoaluminous cement mortar and concrete shows that the higher the curing temperature goes, the swifter the ascending coefficient of expansion ratio becomes and the more rapidly it reaches to the maximum expansion.

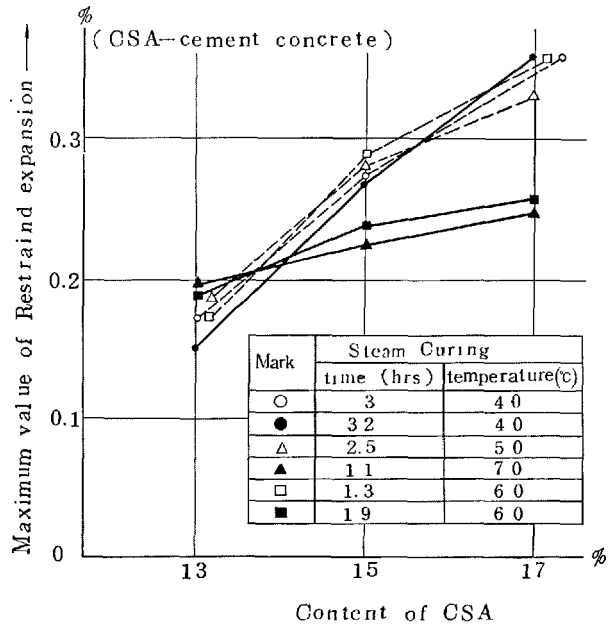

Fig. 23. *Effect of steam curing times and temperatures at different contents of CSA (by Y. Ono)*

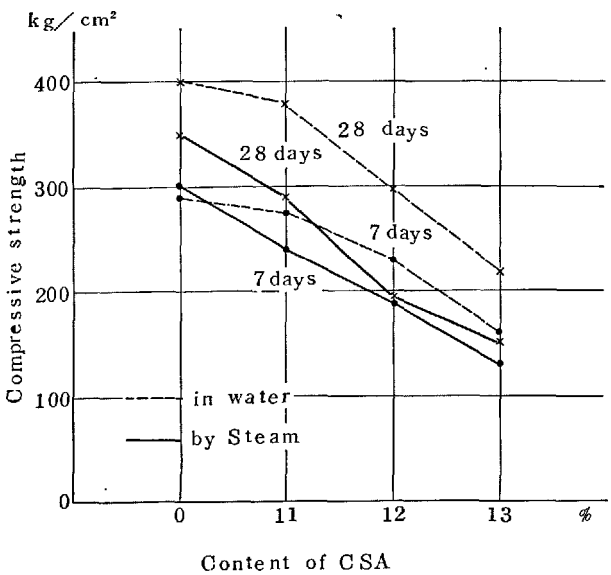

Fig. 24. *Compressive strength of CSA-cement mortar cured in water or by steam (by Y. Ono)*

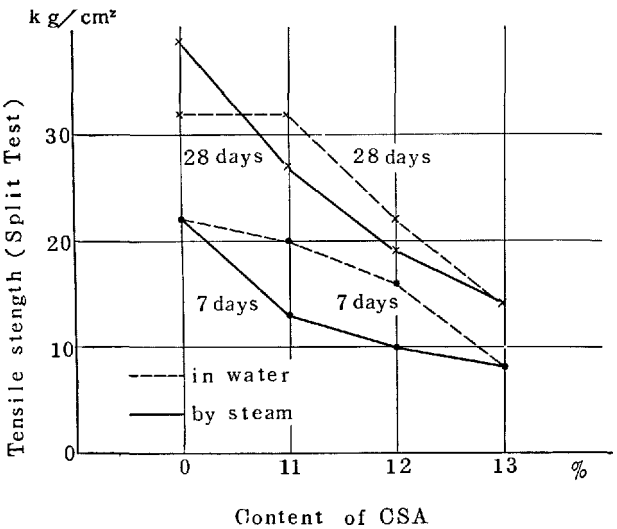

Fig. 25. *Tensile strength of CSA-cement mortar cured in water or by steam (by. Y. Ono)*

(2) Eventhough the curing period is short, if water sprinkling would be done after curing, expansive cement concrete will expand more effectively than in the case of long period steam curing.

(3) The relation between strength and expansion is in inverse proportion independently of their curing temperatures.

Durability

Carbonation of CSA-Cement Concrete and Corrosion of Reinforcing Steel

A. Carbonation of CSA-Cement and Rust of Embedded Steel Reinforcement

Procedure

In this study carried out by T. Horishima et al, the 5, 10 and 13% CSA-cement concrete and normal portland cement concrete were used. Kinds of concrete, their mixing-ratio and dimension of specimens are shown in Table 20 and Fig. 26.

Test specimens were cured in water (20°C) for 3 days and then in dry room (20°C R. H. 50%) for 12–15 months. And then, specimens were cut off by a quarter, and the depth of carbonation was measured by means of spraying phenolphthalein alcoholic liquid on the cut surface. Measuring method of carbonation are shown in Fig. 27.

Next, the remaining specimens were placed in a CO_2 gas chamber (gas concentration 10%, 25°C, R.H. 50%). After 24 days the depth of carbonation was measured again, and the embedded steel bar was observed.

Results Obtained

The results of test are shown in Fig. 28.

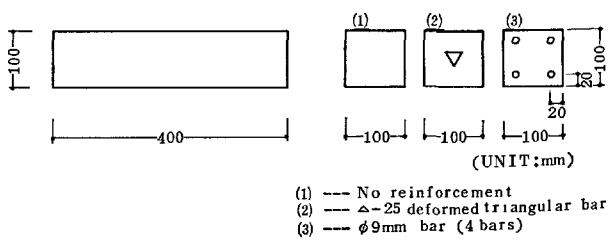

Fig. 26. *Dimension of specimens (by T. Horishima)*

Table 20. *Kinds of concrete and mixing-ratio*

	CSA content %	Materials (per m³)						Slump cm	Unit weight kg/l	Air content %	Compressive strength kg/cm²	Reinforcement
		Cement kg	CSA kg	Water l	Sand kg	Coarse aggregate kg	Pozzolith No. 8 %, cwt					
1	0	325	0	193	840	952	0	21.0	2.307	—	198	△-25
2	5	308	16.2	199	838	950	0	20.9	2.314	—	247	△-25
3	10	293	32.5	210	841	953	0	20.3	2.305	—	216	△-25
4	0	290	0	202	824	941	0.25	22.3	2.170	5.7	—	4-9φ
5	13	252.3	37.7	202	824	941	0.25	21.9	2.160	5.7	—	4-9φ

The depth of carbonation of all specimens reached to 5–15 mm after 15 months. There was no significant difference in the depth of carbonation between normal portland cement concrete and the 5% CSA-cement concrete, but in case of the 10% CSA-cement concrete it was slightly deeper than that of the former. The depth of carbonation after accelerated test reached to 15–25 mm and this tendency was the same as that in the previous case. Also, it was found that the depth of carbonation could be reduced considerably by using water reducing agent.

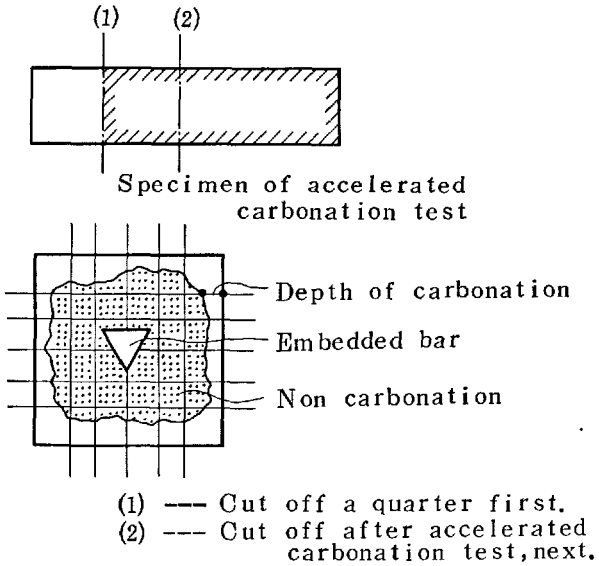

Fig. 27. *Measuring method of carbonation (by T. Horishima)*

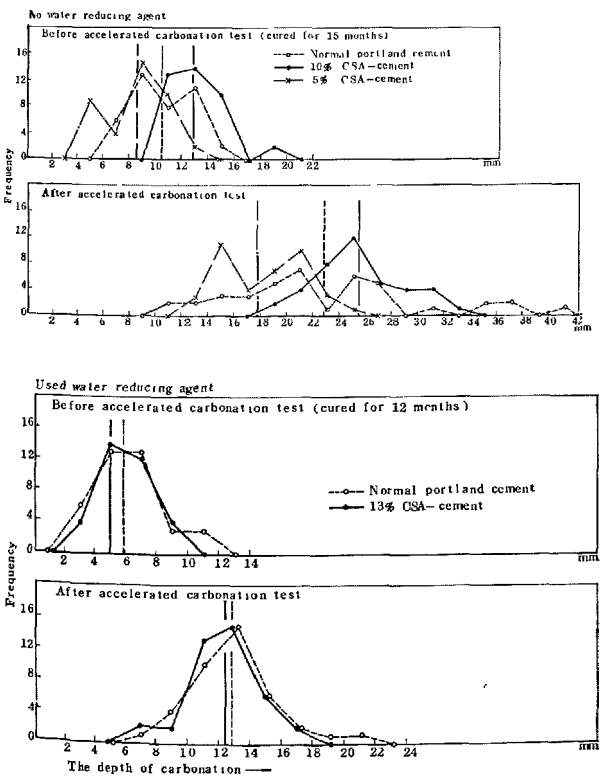

Fig. 28. *Frequency of the measured depth of carbonation (by T. Horishima)*

B. Corrosion of Steel Plates

This study was carried out by Y. Ono.

Procedure

The solutions of CSA, the 10% and 13% CSA-cement, normal portland cement and lime were prepared, and in each of these solution, polished steel plates were dipped and were kept in conditions of 10, 20 and 30°C. A change of pH value of solutions and increase of corrosion on steel plates (by weight) were measured for a month.

Results Obtained

The results of these tests are shown in Fig. 29 and Fig. 30.

pH value of CSA solution changed from 12 to 9 after a month, whereas the others were remained equally 12. The tendency was same in every tempera-

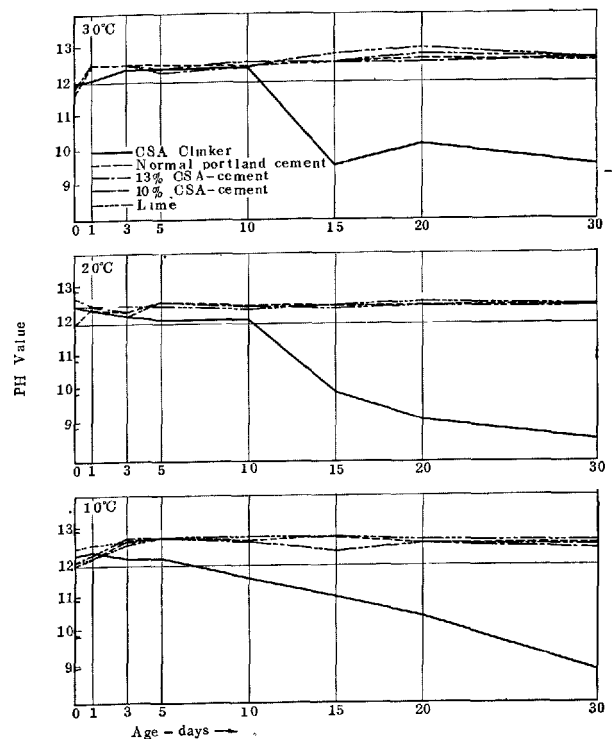

Fig. 29. *pH value change (by T. Horishima)*

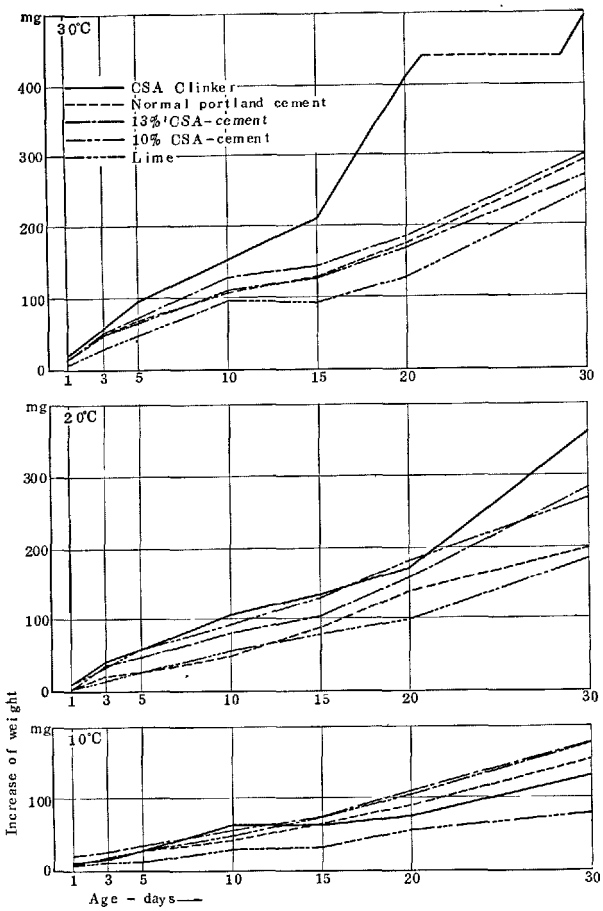

Fig. 30. *Increase of corrosion (by T. Horishima)*

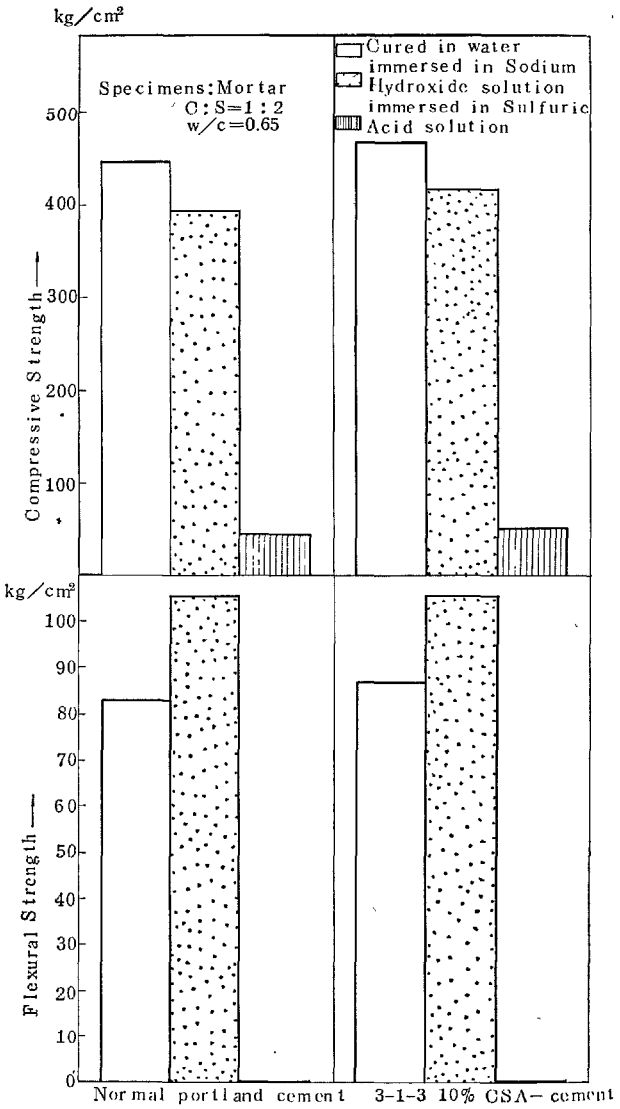

Fig. 31. *Test results of mortar specimens at age of 1 year (by Y. Ono)*

ture. With regard to the corrosion of steel plate, rust began to form at the boundary line between the solution and the air. And the increase of weight by rusting was measured in the order of lime<normal portland cement<the 10% CSA-cement<the 13% CSA-cement <CSA only. This tendency became larger in high temperature.

Resistance of CSA-Cement Mortars and Concretes to Sulphuric Acid Solution, Sodium Hydroxide Solution and Sea Water

Procedure

For the purpose of studying the resistance of CSA-cement to sulphuric acid solution, sodium hydroxide solution and sea water, mortar and concrete specimens were made. These studies were carried out by Y. Ono et al.

After curing for 28 days in water, these specimens were immersed in different solution of 0.2% sulphuric acid solution, 0.2% sodium hydroxide solution and sea water. The change in compressive and flexural strengths of these immersed specimens were measured at the ages of from 4 weeks to 2 years, to estimate the rate of attack by these solutions against water curing strength.

Results Obtained

The results obtained are shown in Fig. 31—Fig. 34.

The test results are summarized as follows.

(1) When immersed in 0.2% solution of sodium

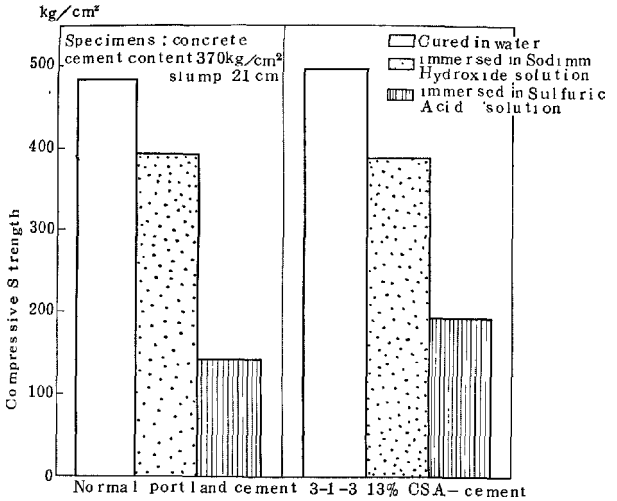

Fig. 32. *Test results of concrete specimens at age of 1 year (by. Y. Ono)*

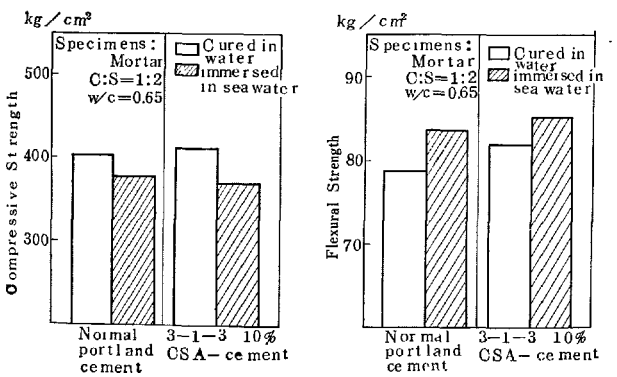

Fig. 33. *Test results of mortar specimens at age of 2 years (by Y. Ono)*

hydroxide, the compressive and flexural strengths of CSA-cement mortar and concrete were as same as the case of ordinary portland cement.

And either specimens reduced slightly the compressive strengths comparing with that of water cured specimens, but the case of flexural strengths were vice versa.

(2) The compressive and flexural strength of mortar and concrete specimens immersed in sulphuric acid solution were very low comparing with the case of water curing.

(3) When immersed in sea water, the flexural strength of the CSA-cement mortar and concrete increased largely as those immersed in 0.2% solution of sodium hydroxide.

(4) Hardly any mark of change was observed in strength of mortar and concrete by replacement

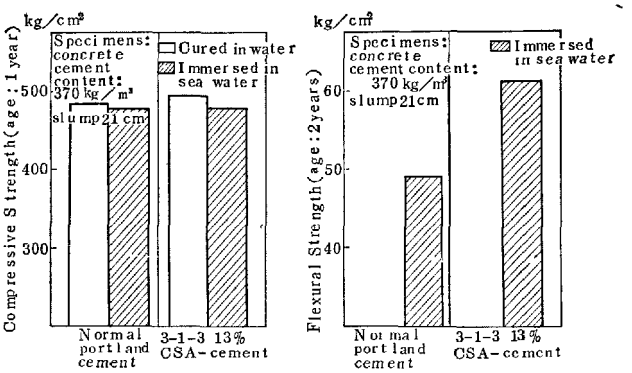

Fig. 34. *Test results of concrete specimens at age of 1 year or 2 years (by Y. Ono)*

Table 21. *Conditions of freezing-thawing test and factors of mortar applied to the test. (by H. Kuriyama, K. Hirai)*

Series	Freezing	Thawing	
FTM 1	−16～−18°C × 22 hours	20°C × 2 hours	Slow

For both test series, 27 kinds of mortar mixes altogether were used.

of ordinary portland cement by 10–13% of CSA.

Durability to Frost Action

Freezing-Thawing Test of Mortar

Following two series of freezing-thawing tests were carried out by Kuriyama and Hirai on mortars made of 3–1–3 CSA-cement and river sand.

Series FTM 1: slow freezing in air and thawing in water.

Series FTM 2: rapid freezing-thawing in water.

The specimens were 4 × 4 × 16 cm beam and were cured in water for 90 days at 20°C or stored in air (20 ± 1°C, 70 ± 10% R. H.) after 3 days water curing and stored in water for 9 months at 20°C, for series FTM 1 and FTM 2 respectively. Results obtained are shown in Table 21–24.

Freezing-Thawing Test of Concrete

Following two test series were carried out by Koh, Gotoh and Kamada on concrete made of 3–1–3 and

4–1–3 CSA-cement and diluvial aggregates.

Series FTC 1: 3–1–3 13% CSA-cement concrete.

Series FTC 2: 4–1–3 10% CSA-cement concrete.

After 28 days curing in water at 20°C, the freezing-thawing tests were started by using 7.5 × 7.5 × 40 cm beams. Eight kinds of concrete mixes were compared with ordinary cement concretes, i.e. four water cement ratios and with or without air-entraining agent (Table 25), by applying the slow freezing-thawing in water to all test series, however, the rapid freezing-thawing in water was also applied to series FTC 1.

The decrease of relative dynamic modulus of elasticity was shown in Figs. 35–38.

Bond Strength of Mortar Rendering as a Reference to Winter Work

Considering the mortar rendering of walls in winter, the bond strength between base mortar and rendering was tested after freezing for 24 hours in early age.

The bond strength at normal temperature is affected mainly by the content of CSA, however, when damaged by freezing in early age the mortar mix or the time of start to freeze has large effect on the bond strength between rendering and base mortar. It seems that there is no significant differences of effect on bond strength between 10 or 13% CSA-cement and normal portland cement.

Conclusion

The following conclusion will be gained.

(1) The result of freezing-thawing test showed that there was not so much difference between the CSA-cement mortar and normal portland cement mortar having rich proportion and small flow, however, the CSA-cement mortar having poor proportion and large flow was a little weaker in its property, except excess content of CSA.

(2) Considering the bad results on mortar and concrete obtained by using 3–1–3 13% CSA-cement, it seems that 13% content of CSA is excess.

(3) For general use 10% content of CSA should be recommended, as the resistance against freez-

Thermal Properties

Fire Resistance

The compressive strength and the modulus of elasticity of concrete vary with the temperature. Effects of heating on properties of CSA-cement concrete and in comparison with them, those of the ordinary concrete were described in this paper.

Procedure

CSA-content of the expansive cement was 13% by weight. Aggregates were natural river sand and gravel. The mix of concrete is shown in Table 26.

The specimens of these concretes, prior to the test, were cured in water for 4 weeks and then placed in a room for a month. They were heated to a temperature up to 600°C at the rate of 1.0°C–1.5°C per minute and kept at the same temperature for about an hour. They were then cooled in air gradually to the room temperature. Further 4 weeks after cooling, compression tests were conducted. Numerous specimens heated at 500°C and 600°C showed marked cracks. Figs. 39 and 40 show variations in the strength and in the modulus of elasticity with the temperature.

Results Obtained

The results obtained are as follows.

Table 26. *Mix-proportion of concrete (by Harada)*

No.	Cement	Mix-proportion (by weight)				Slump cm
		Cement	Sand	Gravel	W/C	
F-7	CSA-cement (13%)	1	2.6	2.7	65	15.3
F-8		1	2.3	2.3	55	15.3
F-9	Normal portland cement	1	2.6	2.7	65	16.8
F-10		1	2.3	2.3	55	16.9

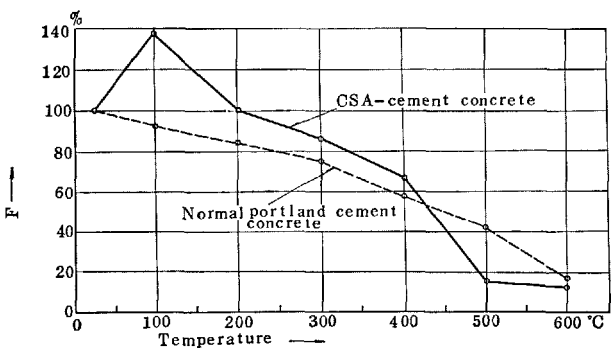

Fig. 39. *Temperature and residual strength, F*

(1) In general, strength changes of the two different type concrete are about the same. The rates of their residual moduli of elasticity change also similarly with the temperature.

(2) Fig. 41 shows the effect of temperature on the stress-strain curve of CSA-cement concrete. As the temperature rises, the elasticity of concrete decreases, indicating the increase of the plasticity of concrete.

Heat Insulation

Procedure

Values of the heat conductivity of CSA-cement mortar and concrete and of their thermal diffusivity at high temperature were measured. As compared with these values, those of ordinary portland cement concrete were also measured.

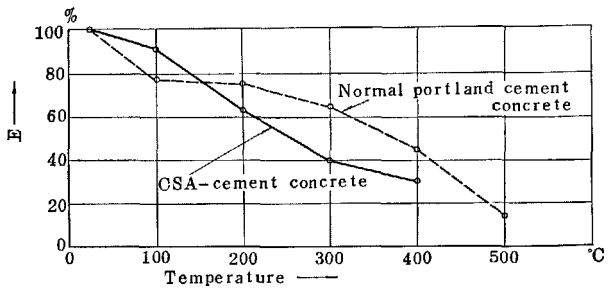

Fig. 40. Temperature and residual elasticity, E

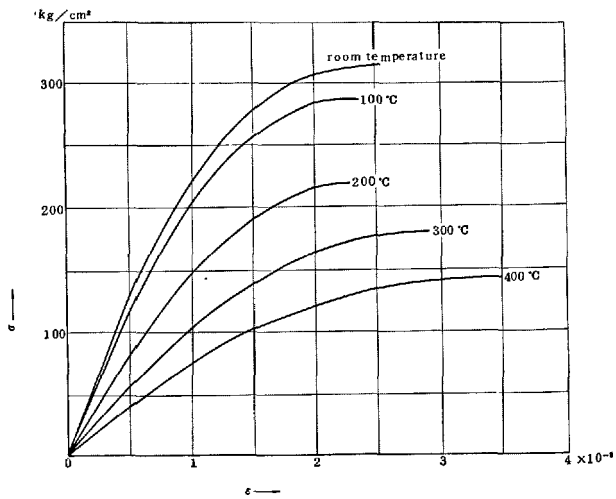

Fig. 41. *Characteristic stress-strain curves of CSA-cement concrete in the temperature range from room temperature to 400°C.*

The content of the expansive material to CSA-cement was 10%. Mix proportion of the CSA-cement concrete was 1: 2: 2.5 by weight, as well as the ordinary concrete. W/C-ratio of the CSA-cement concrete was 0.75, and that of the ordinary concrete was 0.55. As to CSA-cement mortar, the cement sand ratio was 1: 3 by weight. Aggregates used in the two type concretes and the mortar were also natural river sand and gravel. The thermal coefficients were measured in the temperature range up to 600°C. (see Fig. 42 and 43)

Results Obtained

The results obtained are as follows.

(1) Variations in the coefficients of the CSA-cement mortar and concrete with temperature are quite similar to those of the ordinary concrete. As the temperature rises, especially from 100°C to 150°C, these values are markedly reduced. However, it is inclined to somewhat increase in the temperature range to 600°C. This tendency of the variable coefficients with the temperature differs slightly from the common informations.

(2) In general, the thermal properties of the CSA-cement concrete are almost the same as those of the CSA-cement mortar, just as the relation of the ordinary concrete to the ordinary portland cement mortar; mortar is just a little superior to concrete in its insulating property.

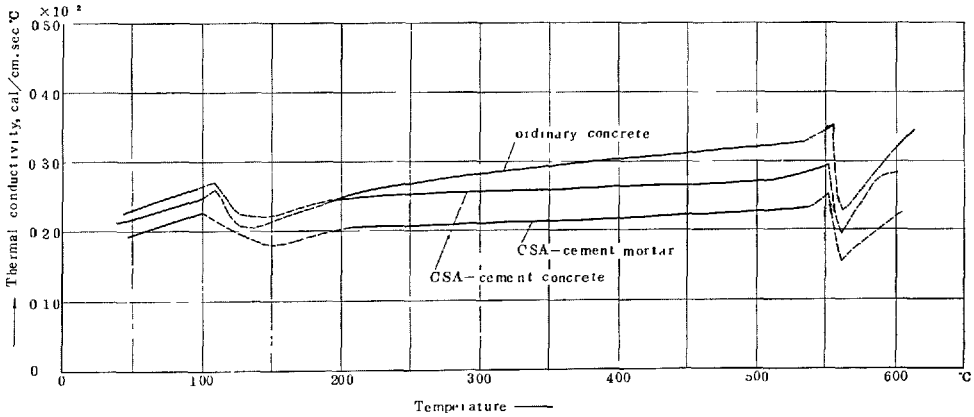

Fig. 42. *Variations of the thermal conductivity according to temperature change*

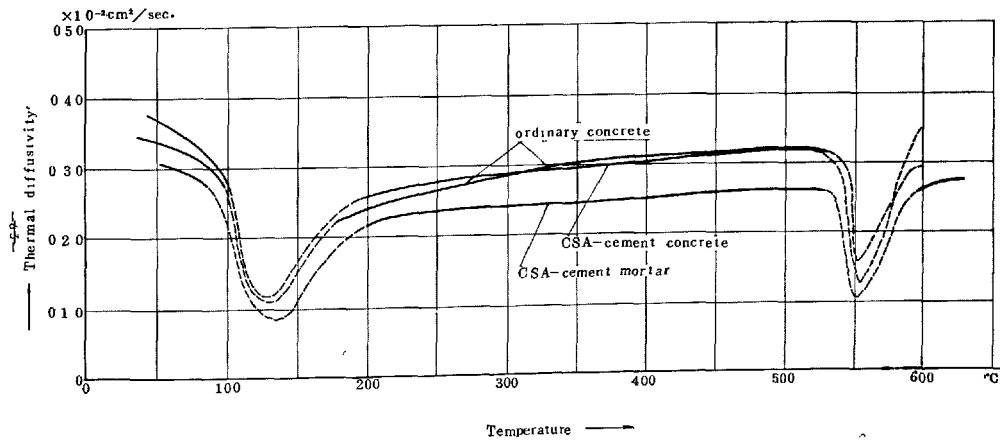

Fig. 43. *Variations of the thermal diffusivity according to temperature change*

Summary and Conclusion

Following conclusion was gained.

1. Calcium sulphoaluminous cement clinker will work for effective expansion by being mixed in cement mortar and concrete, and then it can compensate for their shrinkage of early time.
2. The content of calcium sulphoaluminous cement clinker is in a well mixed condition at about 10% by weight. In this case, final shrinkage of the cement mortar and concrete will be decreased less than the case of ordinary cement ones without sacrificing strength.
3. Wet curing condition is necessary, especially at initial period, for calcium sulphoaluminous cement mortar and concrete.
4. As the molar-ratio, $CaO: Al_2O_3: CaSO_4$ of CSA raw materials, it seems that 4–1–3 is generally better than 3–1–3 for CSA mortar and concrete uses.

Supplementary Paper IV-86 Development of Expansive Cement with Calcium Sulphoaluminous Cement Clinker

Masaichi Okushima* Renichi Kondo,** Hiroshi Muguruma*** and Yoshizo Ono****

Synopsis

Expansive cement is generally used for two purposes; for preventing the shrinkage cracks of mortar or structural concrete and for chemical prestressing of concrete elements. In the first part of this paper, the fundamental expansion-shrinkage characteristics required for expansive cement will be generally discussed from the viewpoint of shrinkage crack prevention. The results show that crack prevention directly depends on the reduction of drying shrinkage after finishing the expansion and not always on the intial expansion.

Several fundamental problems concerning chemical prestressing are also discussed and the fact that limitations for the economical use of materials, especially the prestressing steels, should be considered in comparison with ordinary prestressed concrete elements is pointed out.

Expansive cement with unique characteristics fulfilling the requirements of concrete engineering has been successfully developed in Japan because of chemical research on synthesis, phase equilibrium, crystallography and chemical engineering data analysis.

The above-mentioned expansive cement is composed of portland cement with an amount of special expansive cement clinker limited to 10%. This clinker has characteristics that allow the composition to be adjusted to a ratio of $CaO: Al_2O_3: CaSO_4 = 4:1:3$, to be heated sufficiently in a rotary kiln under such conditions that the grain size of the crystals is as large as possible, and to be very coarsely ground.

Expansive cement composed of such a clinker makes it possible to minimize the drying shrinkage after finishing the expansion without the sacrifice of mechanical strength.

In order to elucidate the mechanisms of the hydration, hardening, expansion and shrinkage of mortar and concrete, physicochemical investigations are also carried on by means of optics, electron microscopy, X-ray diffraction, determination of capillary pressure, pore size distribution, and so on.

Introduction

One of the greatest disadvantages in concrete structure is shrinkage cracking under drying conditions. The development of the expansive cement, which shows the expansion to overcome or to exceed the shrinkage of portland cement, has theoretically enabled to prevent the shrinkage crack formations. Research on the practical use of expansive cement was mainly carried out in Europe and the U.S.A., especially by H. Lossier (1), H. Lafuma (2), M. E. Perre (3), V. V. Mikhailov (4) and A. Klein (5). However, concerning the expansion-shrinkage characteristics of expanisve cement, basic study (for example, studies on how expansion-shrinkage curves are the most suitable or most appreciable for preventing the shrinkage cracks) has been quite insufficient to this date.

Another active use of expansive cement is to produce prestressed concrete by chemical prestressing. Although at present sufficient data are available for chemical prestressing (5–7), the important thing is to find a reasonable limitation for the economical use of materials, especially from the viewpoint of making the best of concrete and steel strengths.

In the first part of this paper, the fundamental expansion-shrinkage characteristics of expansive cement that are reasonable for the prevention of shrinkage cracks as well as for the economical use of materials for chemical prestressing with expansive concrete were theoretically discussed with reference to some test results.

Much research on expansive cement has been carried out in Japan as in other countries since Lafuma's (2)

report.

The expansive cement developed in France was composed of portland cement, calcium sulphoaluminous cement clinker (abbreviated as CSA in this paper) as the expansive agent and granulated blastfurnace slag as the stabilizer.

At that time, the mineral composition of CSA was not very well known, but it has been elucidated by degrees (10). The crystal structure (11 ,12) of the main component of CSA and the hydration mechanism (13, 14) of expansive cement have also been clarified. As a result, the expansive agent has been improved, so that it is now possible to produce an expansive cement of high quality by the addition of an amount of CSA that is only 10% of the cement (expansive cement composed of portland cement and CSA is abbreviated as CSA cement in this paper).

The investigation of expansive cement has been rapidly promoted by mutual exchanges of information between specialists both in basic research and engineering since the CSA Research Group was orgainzed in 1964.

Expansion-Shrinkage Behaviours to be Required to Expansive Cement

Current Concept for Shrinkage Crack Prevention by Expansive Cement

The expansive cements recently used in practice generally consist of mixtures of portland cement and sulphoaluminate additives as the expansion ingredient. Fig. 1 shows the typical expansion-shrinkage curves of expansive cement paste in comparison with that of portland cement. (1) As shown in Fig. 1, the expansive cement shrinks upon drying, just like ordinary portland cement, but by undergoing an initial free expansion of a controlled amount before drying begins, the net free expansion after drying may be any desired amount within limits. That is, it has been considered so far in much research that the formation of shrinkage cracks can be prevented by using expansive cement when the net strain of initial free expansion and the subsequent drying shrinkage becomes sufficiently smaller than the shrinkage strain of ordinary cement.

However, in practice the shrinkage crack formation can not be prevented even if the net free strain of expansive cement remains in expansion even after drying. This fact has been showed by many laboratory or field tests. Fig. 2 shows typical test results on free expansion-shrinkage strains of lining mortars for steel water pipe, where the calcium sulphoaluminous cement clinker (simple substitute CSA) as the expansive agent is blended with Type B blast-furnace slag cement in a mix proportion of 11: 89 by weight. Also Fig. 3 shows the test results on reinforced concrete slabs made of normal portland cement concrete and expan-

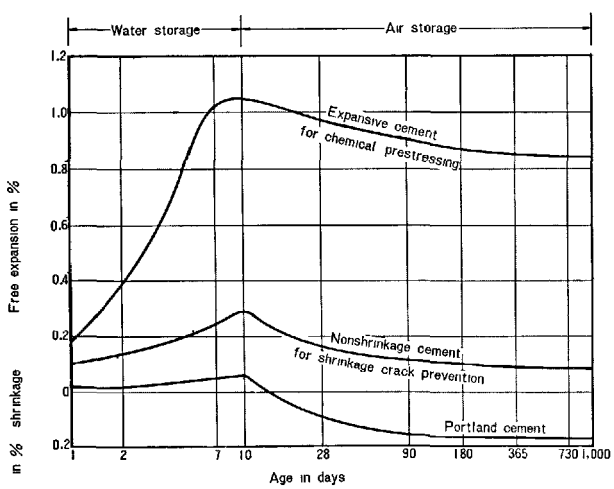

Fig. 1. *Volume changes of neat cement pastes*

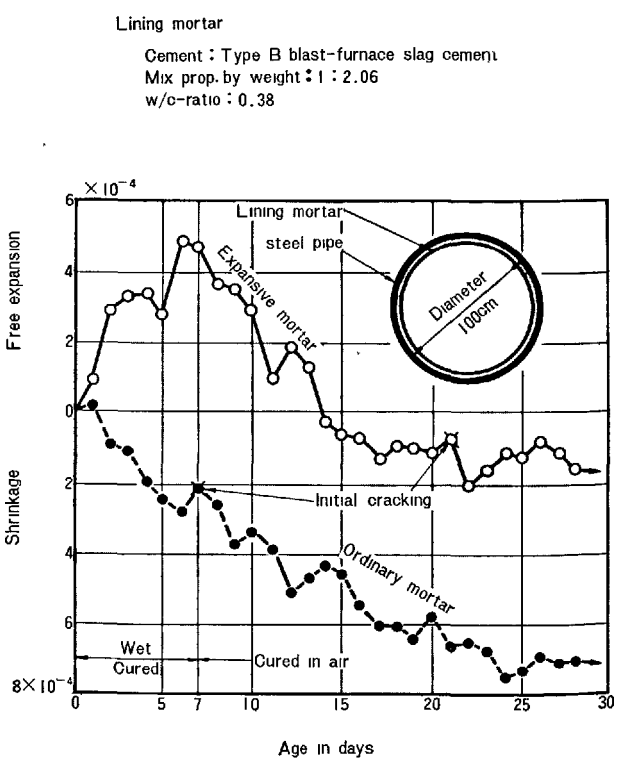

Fig. 2. *Example of shrinkage crack tests on expansive lining mortar of steel pipe (tested by H. Muguruma and Y. Ono)*

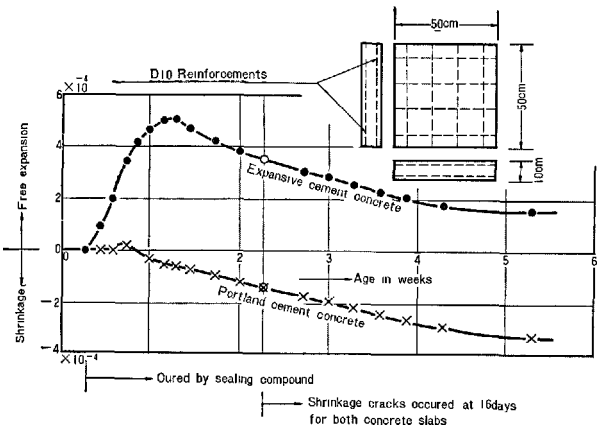

Fig. 3. *Example of shrinkage crack tests on reinforced concrete slabs made of expansive concrete (tested by K. Ohno, Hokkaido University).*

sive cement with calcium sulphoaluminous cement clinker (simple substitute CSA-cement concrete). Thus, from these results it seems that the absolute conditions for the purpose of preventing shrinkage crack formation are not to compensate the shrinkage by initial free expansion, in order words, not to keep the net free strain after drying in expansion.

Ideal Expansion-Shrinkage Curve for Shrinkage Crack Prevention

Considering that the shrinkage cracks do not really take place without the external restraint of free shrinkage of mortar or concrete and also that the easiness of crack formation will be goverened by the degree of restraining, the problem of shrinkage crack prevention can not be discussed without respect to the effects of external restraint. When the initial expansion of expansive mortar or concrete is externally restrained, the inner compressive stress is induced according to the degree of restraint. And, with the lapse of time after finishing the expansion, it is reduced due to creep and shrinkage. Although the larger restraint results in a larger inner compressive stress, the reduction of stress also becomes larger with an increase in the degree of restraining.

To discuss the ideal expansion-shrinkage characteristics for shrinkage crack prevention, the model with elastic restraint shown in the upper part of Fig. 4 is considered by H. Muguruma (8, 9). When the maximum free expansion takes place at an early age in concrete, the corresponding inner compressive stress σ_e induced in the concrete element due to the longitudinal elastic restraint can be written as

$$\sigma_e = \alpha' \frac{E_c S_e}{2} \tag{1}$$

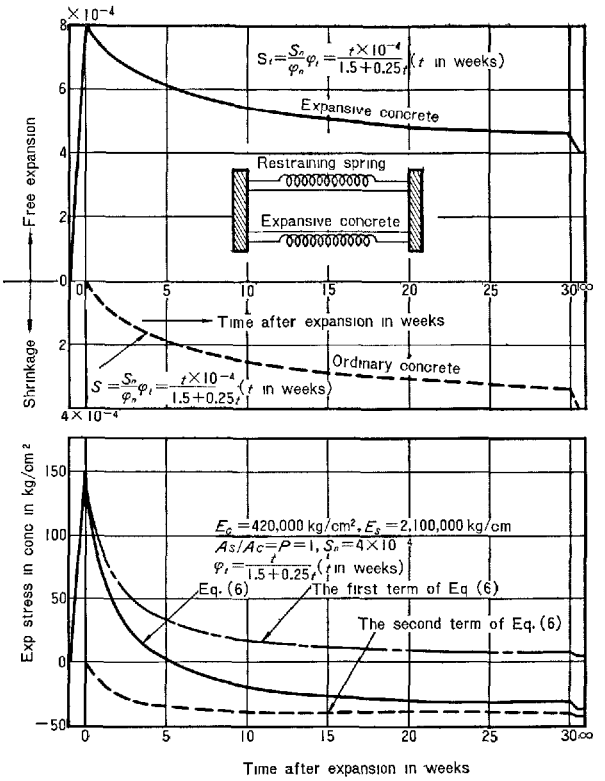

Fig. 4. *Numerical example of expansion-shrinkage stress in concrete due to external restraint of free expansion-shrinkage strain (calculated by H. Muguruma)*

$$\alpha' = \frac{2E_s A_s}{2E_s A_s + E_c A_c} \tag{2}$$

where

E_c and A_c: Elastic modulus and sectional area of concrete specimen,

E_s and A_s: Apparent elastic modulus and sectional area per unit length of elastic spring restraint.

In eq. (1), taking the reduction of stress due to creep during the expansion of the concrete into consideration, the apparent elastic modulus of concrete is assumed to be half that at the age of maximum expansion. After finishing the expansion, the inner compressive stress is released due to creep and shrinkage. Assuming the creep strain of concrete proportional to the applied stress (Davis-Glanville's law), the superposition of creep strains (Whitney's law) and the increase of shrinkage strain linear to creep strain, the following equation concerning stress reduction $\Delta\sigma_t$ can be obtained:

$$\frac{\sigma_e}{E_c}\varphi_t - \frac{\Delta\sigma_t}{E_c} - \int_0^t \frac{\Delta\sigma_t}{E_c} d\varphi_t + \frac{S_n}{\varphi_n}\varphi_t = \frac{A_c \Delta\sigma_t}{E_s A_s}, \quad (3)\,(8, 9)$$

where

φ_t: Creep factor of concrete,
φ_n: Final value of creep factor,
S_n: Final value of shrinkage strain measured from the maximum expansion strain.

Solving eq. (3) under the initial condition of $\Delta\sigma_t = 0$ at the time $t = 0$ (the time when the expansion strain reaches its maximum), we obtain

$$\Delta\sigma_t = \left(\sigma_e + E_c\frac{S_n}{\varphi_n}\right)(1 - e^{-\alpha\varphi_t}), \tag{4}$$

where

$$\alpha = \frac{E_s A_s}{E_c A_c + E_s A_s}. \tag{5}$$

Thus, the remaining stress becomes

$$\sigma_t = \sigma_e - \Delta\sigma_t = \sigma_e e^{-\alpha\varphi_t} - E_c\frac{S_n}{\varphi_n}(1 - e^{-\alpha\varphi_t}), \tag{6}$$

where the compressive stress of σ_t is assigned positive.

The first term of the right hand side in eq. (6) presents the reduction of expansive stress due to creep. Considering that the value of α is nearly unitary under such a stiff restraint as absolute rigidity and also that the final value of φ_t will be 4 for usual concrete, it vanishes rapidly to almost null. As a result, only the tensile streess due to the shrinkage strain subtracted from the maximum expansion given by the second term of eq. (6) finally remains in the concrete. Therefore, if the dropping difference between the maximum expanding strain and the shrinkage strain of expansive concrete is quite the same as that of ordinary concrete, the tensile stress similar to that induced in ordinary concrete could result, even in expansive concrete. That is, the initial expansion does not contribute to the prevention of shrinkage cracking, excepting the possible role of delaying the age of crack formation. This can be seen more evidently from Fig. 4, where the expansion-shrinkage stresses corresponding to the free expansion-shrinkage curves shown in the upper part of this figure are obtained from eqs. (1) and (6) for a concrete specimen having a restraining of $\alpha' = 0.909$ and $\alpha = 0.833$.

Consequently, the necessity for preventing the shrinkage crack formation is not always to compensate the drying shrinkage by initial expansion, but also to reduce the shrinkage strain after finishing the expansion. The net free expansion or the remaining free expansion defined as the sum of initial expansion and subsequential shrinkage has no direct effect on the prevention of shrinkage cracks, excepting the closure of some voids in concrete or mortar by external restraint, which results in superior quality with respect to permeability and strength.

Expansion for Chemical Prestressing

Another use of expansive cement is for chemical prestressing. Much of the past research showed the possibility for the expansion of concrete to produce automatically the prestressed concrete element (3–7). However, no discussions have been given on such a fundamental problem as whether the prestress as required in ordinary prestressed concrete members can be simultaneously induced or not in concrete and embedded steels of the element having an ordinary percentage of prestressing steels. Assuming that the apparent elastic modulus of concrete is half that at the age of maximum expansion, the prestressing force P induced in the concrete section by free expansion S_e can be obtained from

$$P = \frac{E_s \cdot A_s \cdot S_e}{1 - 2np(1 + e^2 A_c/I_c)} \tag{7}$$ (8, 9)

where

n: Modular ratio ($= E_s/E_c$),
p: Percentage of prestressing steels ($= A_s/A_c$),
e: Eccentricity with respect to the center of gravity of the section,
A_c and A_s: Sectional areas of concrete and prestressing steels, respectively,
I_c: Moment of inertia of the concrete section with respect to the center of gravity of the section,
E_c and E_s: Elastic moduli of concrete and prestressing steels, respectively.

Numerical example was made on the rectangular section having elastic moduli of $E_c = 420{,}000$ kg/cm² and $E_s = 2{,}100{,}000$ kg/cm², respectively, and an eccentricity of $e = D/6$ (where D denotes the height of the section). The results obtained for the various percentages of embedded steels are shown in Fig. 5.

From Fig. 5 it can be seen that the steel stress created by initial expansion varies only a little with the increase of steel percentage, while the compressive stress induced in the concrete section becomes larger approximately in proportion to the percentage of steel. In ordinary prestressed concrete members, the average compressive stress (P/A_c) that must be introduced into a rectangular concrete section is from 50 kg/cm² to 75 kg/cm², which corresponds to concrete strengths of 300 kg/cm² to 450 kg/cm². On the other hand, the ordinary percentage of prestressing steels is 0.5 to 1%. Thus, from Fig. 5 it can be seen that the prestressing steels adequate for producing the average concrete stress of 50 to 75 kg/cm² with a steel percentage of 0.5 to 1% are of a type having the allow-

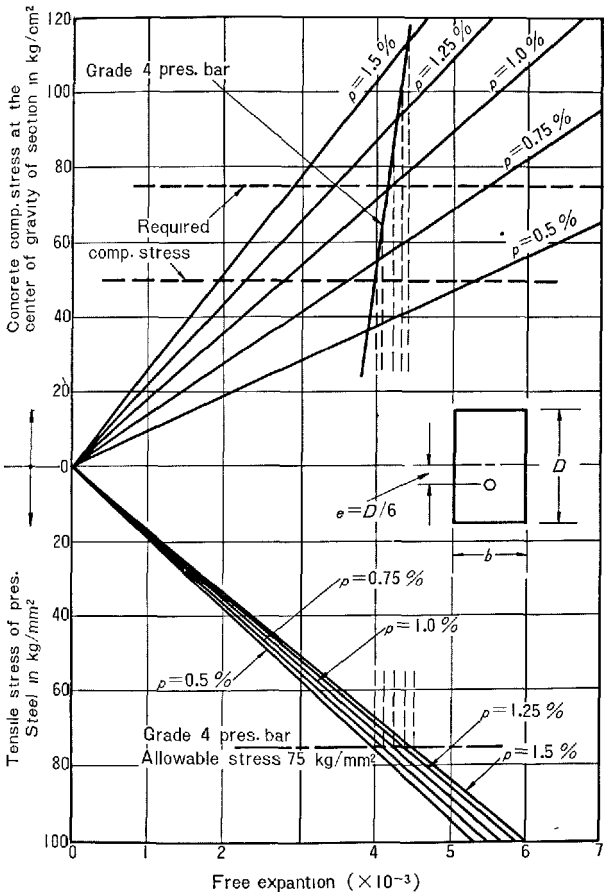

Fig. 5. *Relations between free expansion of concrete and stresses induced in concrete and embedded steels by chemical prestressing (calculated by H. Muguruma)*

able tensile stress of approximately 50 kg/mm² to 90 kg/mm². The corresponding expansion of concrete effective enough to produce such prestressing stresses thus becomes 2.75×10^{-3} to 5×10^{-3}. These results can also be approximately applicable to T or I-section concrete members. (8, 9)

Consequently, it can be stated that prestressing steels satisfying the above requirements are the so-called high tensile prestressing steel bars with relatively lower strength, and the use of piano wires or 7-wire strands having strengths of 150 kg/mm² or more would not always be economical from the viewpoint of the utilization of their higher strengths.

Possibility of Chemical Prestressing by Using CSA-Cement

As can be seen from Fig. 5, the concrete expansion effective for the production of adequate prestressed concrete members by chemical prestressing is from 0.275% to 0.5%. While the free expansion of concrete can be controlled within some limits by increasing the contents of the expansive agent in ordinary cement, the entire amount of free expanding strain is not always effective in creating the tensile stress in steels and the corresponding compressive stress in concrete under the restraining conditions of embedded prestressing steels. Therefore, for the purpose of discussing the possibility of chemical prestressing, the expanding strain effective for the creation of prestress in concrete should be predicted from test on restrained expansive concrete specimens. In this report, such expanding strain is called the effective expansion.

Fig. 6 shows typical results for the expanding strains of CSA-cement concrete specimens restrained longitudinally by embedded prestressing steel bars. Three different mix proportions of CSA and normal portland cement, that is, 10: 90, 13: 87 and 15: 85 by weight, respectively, were used. The degrees of restraining were 0, 0.46, 0.93 and 1.61%, respecitvely, in the percentage of embedded prestressing steel bar. After casting and curing the specimens were removed to the storage room with 100% relative humidity and 20°C room temperature to measure the longitudinal expanding strains. The strain measurements were made for 28 days, while the expansion reached its steady state by 7 days.

From Fig. 6, it can be seen that, although the free expansions (expansions of no restraining specimen) of the concrete having 13% and 15% CSA content were very large, those of restrained specimens were considerably smaller. The effective expansions predicted from Fig. 6 are as follows:

Age	CSA-contents	Free expansion	Predicted effective expansion
	10%	0.03%	0.03%
3 days	13%	0.30%	0.15%
	15%	0.59%	0.18%
7 days	13%	0.54%	0.23%
	15%	3.0 %	0.35%

From the above results, it can be stated that 15% CSA content is not always adequate for chemical prestressing because of the larger decrease in the 28 day compressive strength, as shown on the right side of Fig. 6. 13% weight content seems to be a reasonable limit within the test results reported here. However, as can be seen from Fig. 7, such a content is evidently insufficient to get the adequate effective expansion mentioned in this section (or to induce the adequate prestress of 50 kg/cm² or more in concrete). That is,

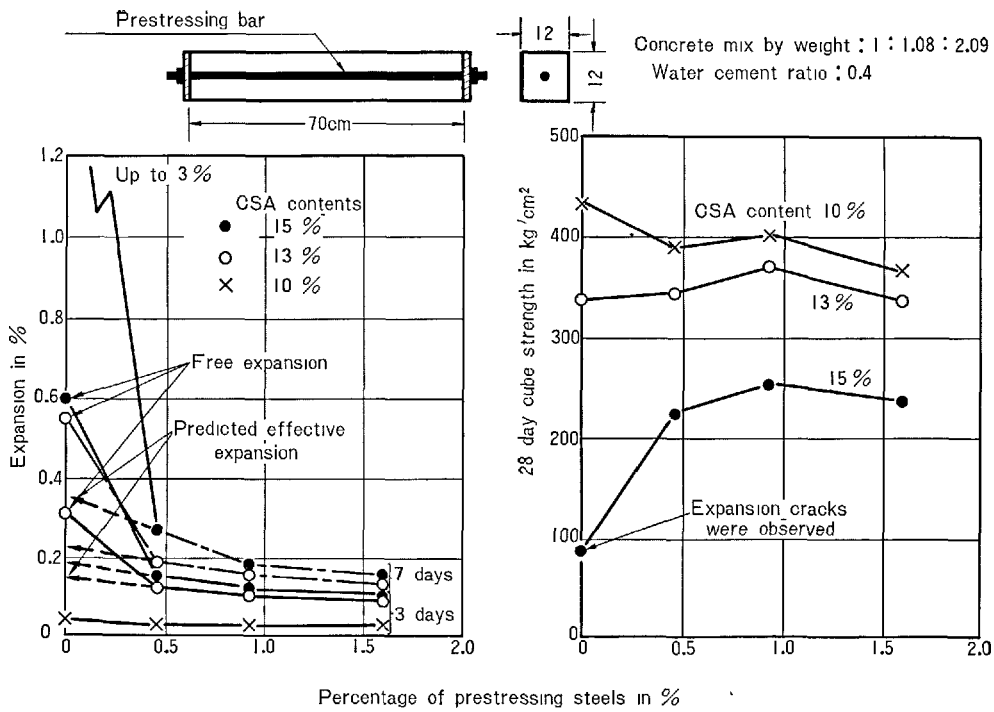

Fig. 6. *Effective expansion and compressive strength of expansive cement concrete with various calcium sulphoaluminate contents (tested by H. Muguruma).*

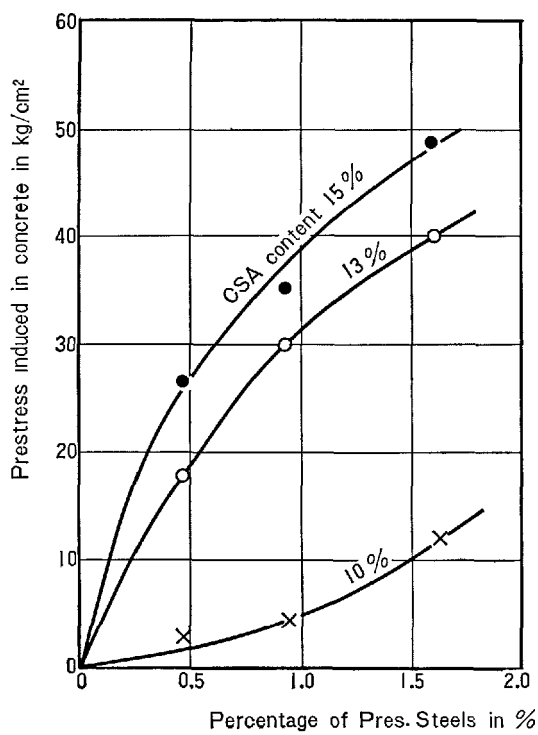

Fig. 7. *Prestress induced in concrete specimen by chemical prestressing (Tested by H. Muguruma)*

in the specimen of 13 % CSA content only 30 kg/cm² prestress was induced in the concrete section having 1 % prestressing steels.

In practice, even if only 30 kg/cm² prestress is induced in the concrete by chemical prestressing, it will be very valuable for increasing the cracking capacity of concrete members. For instance, when applying the chemical prestress in the ordinary reinforced concrete piles, which have quite insufficient flexural cracking capacity, the prestress of 30 kg/cm² in concrete is enough to increase their cracking capacity to more than twice that of ordinary piles and consequently the formation of cracks during transportation or driving in the field would be avoided entirely. (M. Okushima and H. Muguruma)

Basic Studies on Production and Properties of Expansive Cement

Calcium Sulphoaluminous Cement Clinker

The composition of CSA was originally designed to have a molar ratio of $CaO: Al_2O_3: CaSO_4 = 3:1:3$ for the purpose of forming ettringite (trisulphate hydrate TSH) as much as possible by hydration of CSA cement. It was then improved to a ratio of 4:1:3, after the beneficial effect of CaO on expansion—shrinkage characteristics was found.

The CSA is approximately composed of 50% $CaSO_4$, 30% $C_4A_3\bar{S}$, and 20% CaO. In addition, it contains a small amount of glassy phase.

According to Kondo (11), a group of new compounds of the haüyne structure type, $(Ca_2Na_6)Si_6Al_6O_{24}(SO_4)_2$, can be synthesized by the substitution of Ca and Na by Ca, Sr or Cd, Al by Be, all of Al and Si by Al, as well as SO_4 by CrO_4, MoO_4 or WO_4. $C_4A_3\bar{S}$ is a typical member of this group. Furthermore, the hydraulic property of $C_4A_3\bar{S}$ can be explained by the existence of 4-fold coordinated Al^{+++}, asymmetrically coordinated Ca^{++}, and isolated SO_4^{--} in the structure.

The crystal structure of $C_4A_3\bar{S}$ (11) is shown in Fig. 8, and the infrared absorption spectra in Fig. 18.

$C_4A_3\bar{S}$ is formed by either a solid state reaction between $CaSO_4$ and mixtures or compounds composed of CaO and Al_2O_3, or an SO_3 gas reaction with the above-mentioned mixtures. The $C_4A_3\bar{S}$ crystal is well grown in the presence of a melt containing $CaSO_4$.

By means of the Griffine hot-stage microscope, it was found that eutectics exist between $C_4A_3\bar{S}$ and CA or $CaSO_4$. However, $C_4A_3\bar{S}$ and $CaSO_4$, and especially a mixture of them, decomposes rather rapidly to give SO_3 gas when heated in open air. It was also found that CSA began to melt at 1180–1230°C. The higher the heating temperature, the greater the crystal size of either produced $C_4A_3\bar{S}$ or of residual CaO and $CaSO_4$.

Necessity of developing a high level of technology confronted at the outset in order to fulfill the requirements for the characteristics that would permit the growth of the crystal components of CSA, even though the heating temperature range of CSA is very small. In addition, it was improved to reduce the loss of SO_3 vaporization during the heating stage of production to a negligibly small amount. The CSA is heated in a rotary kiln these days, it can also be produced by electric furnaces, etc. (15) Fig. 9 shows a microphotograph of CSA industrially produced.

$CaSO_4$ is a colorless anisotropic crystal. CaO is an isotropic spherical pale yellow particle with a distinctive outline because of its high refractive index. $C_4A_3\bar{S}$ is a colorless isotropic crystal having a little

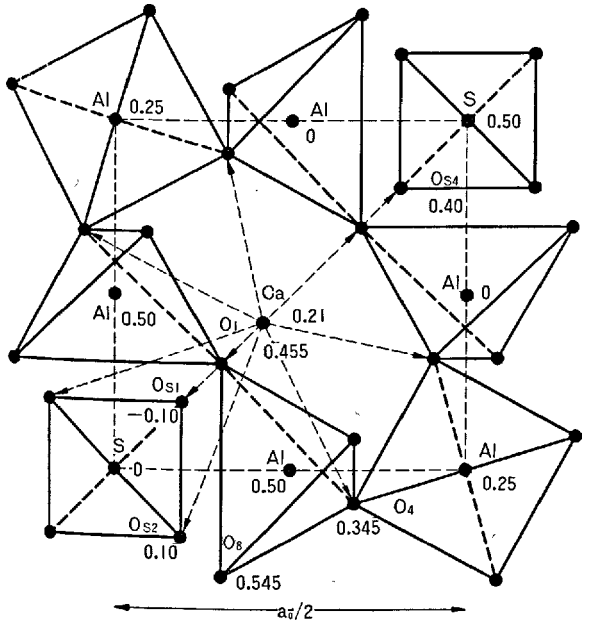

Fig. 8. *Positions of atoms in $a_0/2$ cube of $Ca_8Al_{12}O_{24}(SO_4)_2$, projected on (001) plane.*

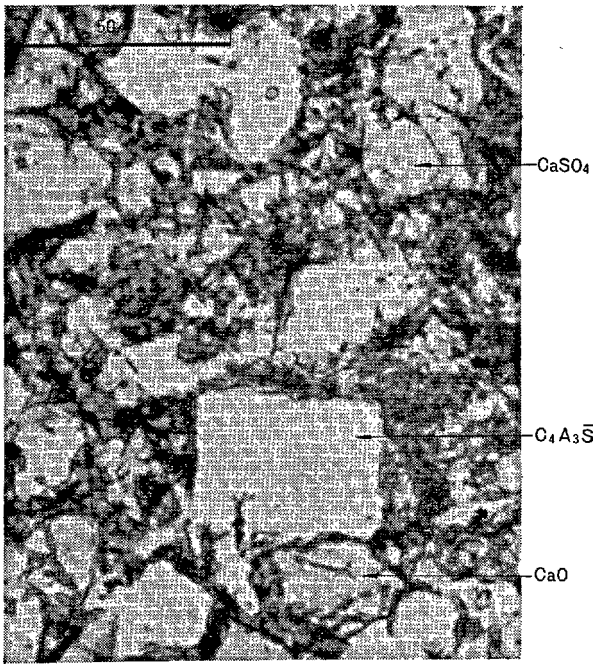

Fig. 9. *Micrography showing the main components of CSA clinker (open nicol)*

lower index than $CaSO_4$. The mean diameter of $C_4A_3\bar{S}$, CaO, and $CaSO_4$ is 50, 15 and 8μ each in the clinker produced by the sintering process, and 120, 40 and 20μ by the melting process.

Silicates and ferrites are scarcely detected among the interstitial materials, but these materials are generally in a glassy phase. By means of a Shimazu electron micro-probe analyzer, the composition of these materials was found to be rich in Al_2O_3, Fe_2O_3, SiO_2 and TiO_2 were also present, but the amount of CaO was comparatively low and there was almost no SO_3. During the cooling of the CSA, a part of $C_4A_3\bar{S}$ crystallizes out of the melted state at the periphery of the glassy material to form a fringed layer, as shown in Fig. 10.

The rate of hydration of CSA powder with a diameter of 15–43μ in the paste form was quantified by X-ray diffraction. It was found that CaO is consumed within 2 days, and the fraction of hydration of $CaSO_4$ and $C_4A_3\bar{S}$ is as shown in Table 1. The reaction of $CaSO_4$ is slower than that of $C_4A_3\bar{S}$, which is similar to the results of the case of J and S described in the paper presented by Mehta and Klein (14).

To preserve the potential force of expansion for an extended period of time by gradual hydration, the crystal growth of CSA must not only proceed properly, but the CSA must also be ground in such a way that the range of particle size is small and the particles are remarkably coarser than those of ordinary cement (16).

Hydration Process of $C_4A_3\bar{S}$ and Morphology of Hydrates

The hydration process of $C_4A_3\bar{S}$ alone, or with $Ca(OH)_2$ and/or $CaSO_4$, were observed by optical and electron microscopes. For comparison, the hydration processes of C_3A were also observed in the same way (17).

Each component used in these experiments was a powder of 5–10μ in diameter.

When the mixture of C_3A and 3 moles of $CaSO_4$ is hydrated, the surface of C_3A begins to be covered with needle-shaped crystals of TSH, after which they will coexist with monosulphate hydrate(MSH or $C_3A\cdot C\bar{S}\cdot H_{12}$) or a solid solution of the latter and C_4AH_{13}.

Fig. 11 shows the electron diffraction pattern of the solid solution. Grudemo (18) has described the formation of hexagonal plate crystals under similar conditions.

TSH is formed either on the surface of C_3A particles or in the solution, but scarcely on the surface of $CaSO_4\cdot 2H_2O$ particles.

In the case of $C_4A_3\bar{S}$ alone, a complex layer of $C_3A\cdot C\bar{S}\cdot H_{12}$ and $Al(OH)_3$ form as the inner product of

(c) Characteristic X-ray image of S: K_α.

$C_4A_3\bar{S}$, and this reaction is completed in 12–24 hrs. As shown in Fig. 12, it is remarkable that the outer shape and dimensions of each grain are almost unchanged throughout this hydration, and TSH, as an outer product, crystallizes out of the solution.

$C_4A_3\bar{S}$ hydrates quickly in the presence of CaO, and the outer shape of its grain is almost unchanged. When $C_4A_3\bar{S}$ is hydrated with $CaSO_4$, the particles of the former are rapidly covered with needly-shaped crystals of TSH.

On the one hand, when a mixture of $C_4A_3\bar{S}$, $CaSO_4$, and CaO adjusted to a molar ratio of $CaO: Al_2O_3: CaSO_4 = 4:1:3$ is hydrated, $C_4A_3\bar{S}$ particles are covered with a thick coating composed of fine crystals of TSH. This coating begins to expand after about 6–8 hrs., and becomes 2–3 times larger than at the beginning at about 24 hrs., as shown in Fig. 13.

On the other hand, when the molar ratio of $CaO: Al_2O_3: CaSO_4$ is 4:1.25:1, a solid solution of $C_3A \cdot C\bar{S} \cdot H_{12}$–$C_4AH_{13}$ crystallizes into a hexagonal plate.

It seems that the expansion due to hydration of $C_4A_3\bar{S}$ in the presence of much $CaSO_4$ and CaO is closely related to the formation of TSH by the reaction between SO_4^{--}, permeating from outside, and

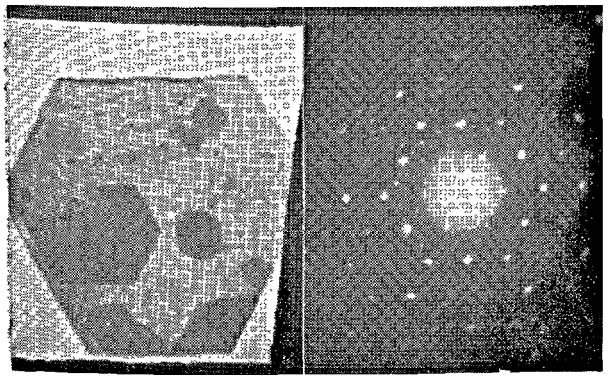

Fig. 11. *Single-crystal diffraction pattern of* $C_3AC\bar{S}H_{12}$–C_4AH_{13} *solid solution*

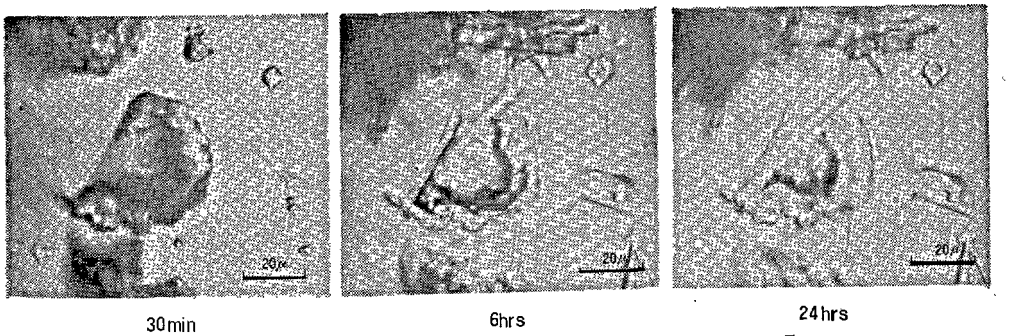

Fig. 12. *Formation of inner products in hydration of* $C_4A_3\bar{S}$ *grain with water*

$C_3A \cdot C\bar{S} \cdot H_{12}$ or its solid solution formed on the interface of each particle of $C_4A_3\bar{S}$.

If we assume that the hydration of CSA powder produces TSH alone, $CaSO_4$ and $C_4A_3\bar{S}$ should decrease accordingly, but the consumption of $CaSO_4$ is delayed as shown in Table 1. This suggests the possibility of the formation of at least a part of MSH.

Fig. 14 shows the results of a semi-quantitative analysis (by means of X-ray diffraction) of the hydration process of CSA cement paste in comparison with that of portland cement.

In this experiment the W/C ratio of paste was 0.4 and the curing temperature was 20°C.

In the case of portland cement, C_3A is eliminated within 7 days, In consumption of $CaSO_4 \cdot 2H_2O$, and at the very early stage it forms TSH, which then converts into MSH after about 3 dyas.

The hydration of C_3S, C_3A, and C_6A_2F in CSA cement is slower than that of C_3S, C_3A, and C_6A_2F in portland cement. After $C_4A_3\bar{S}$ is consumed in 1 day to form large amounts of TSH, C_3A reacts gradually.

$CaSO_4$ is not only expended in the reaction, but independently hydrated to form $CaSO_4 \cdot 2H_2O$. When the CSA cement clinker content is low, TSH partially changes into MSH after 3 days.

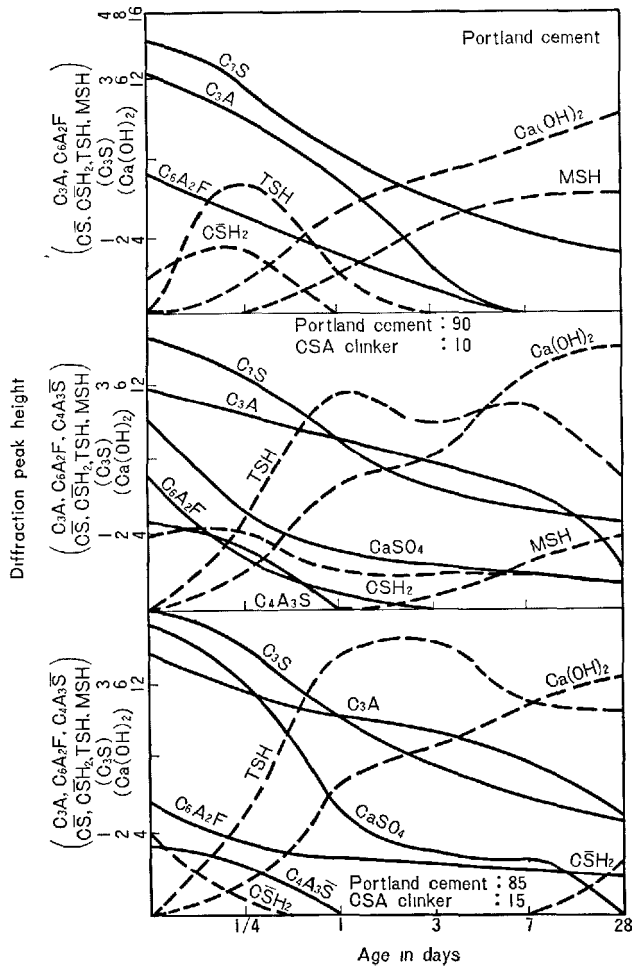

Fig. 14. *Variation of quantity in progress of hydration of CSA cement and portland cement*

The Location of the Deposition of Hydrates in the Hydration of $C_4A_3\bar{S}$ or C_3A

The location of the deposition of hydrates in the hydration of $C_4A_3\bar{S}$ or C_3A with CaO and/or $CaSO_4$ should be closely related to the hydration velocity and the irreversible expansion due to hydration.

First of all, a couple of pastes with different components, such as $C_4A_3\bar{S}$ and $CaSO_4$, were put together with 17 sheets of filter paper between them. The consistency of the pastes was kept constant at about W/C = 0.5–0.6, and they were hydrated for 3, 7, and 28 days at 20°C. On the above days, the filter papers were peeled off to measure the pH of each piece and to be dried for 12 hrs. at R.H. 4 % for examination by X-ray diffration, etc.

Furthermore, the surface of the hardened paste containing $C_4A_3\bar{S}$ or C_3A was repeatedly ground to remove the top 0.2–0.3 millimeters at one time. The surfaces and powders of each paste were examined by X-ray diffraction, and the powders were also analyzed by DTA and TGA.

In addition, the expansion was measured for compacts composed of either $C_4A_3\bar{S}$ or C_3A with CaO and/or $CaSO_4$ after moistening at 20°C and then being immersed in saturated solutions of CaO and/or $CaSO_4$.

The series shown in Table 2 were examined for hydration and expansion (19). The particles of each component here were adjusted by the BAHCO microparticle classifier to be $r = 11 - 22\mu$.

The peaks (2θ, CuK_α) selected for detection of hydrates by X-ray diffraction are as follows:

$C_3A \cdot 3C\bar{S} \cdot H_{32}$ (TSH) 9.0°,

Table 2. *Interaction between $C_4A_3\bar{S}$ or C_3A and additional components in hydration*

Series	Main component	Additional component
1	$C_4A_3\bar{S}$	$CaSO_4$

$C_3A \cdot C\bar{S} \cdot H_{12}$ (MSH)	9.9°,
$C_3A \cdot C\bar{S} \cdot H_{12}$–$C_4AH_{13}$ (solid solution)	10.5°,
$C_3A \cdot C\bar{S} \cdot H_{19}$ (*M* phase)	9.3°,
C_4AH_{13}	11.5°,
C_3AH_6	31.8°,
$Al(OH)_3$	20.3°,
$Ca(OH)_2$	34.1°.

Some of the experimental results for hydration are illustrated in Fig. 15. Some results of the expansion measurements are shown in Figs. 16 and 17.

Series 1 and 4: components which dissolve into the filter paper from both pastes form TSH in the pores

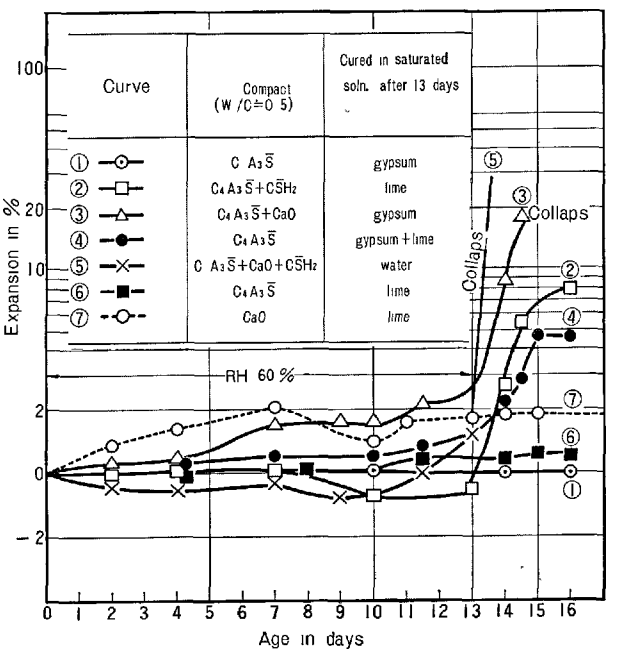

Fig. 16. *Expansion of compacts containing* $C_4A_3\bar{S}$

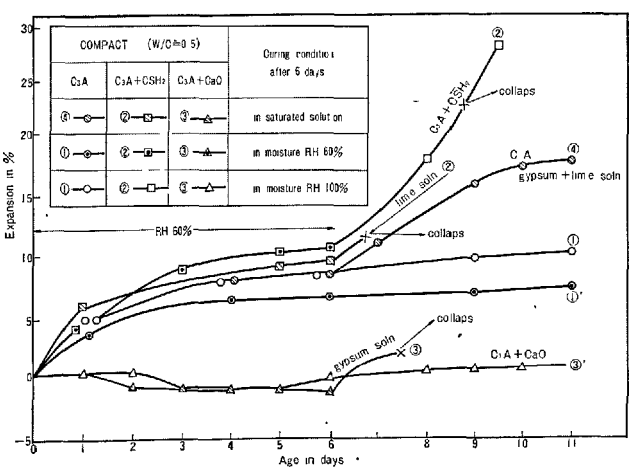

Fig. 17. *Expansion of compacts containing* C_3A.

of the filter paper. Fig. 15 (a) shows the results in the case of Series 1.

Series 2: TSH forms rapidly inside the paste of $C_4A_3\bar{S}$ and $CaSO_4$, but the expansion was very slight.

Series 3: a dense layer of TSH is finally formed along with the remarkable expansion due to the reaction between the permeated $CaSO_4$ and the $C_3A \cdot C\bar{S} \cdot H_{12}$–$C_4AH_{13}$ solid solution which has formed in the paste of $C_4A_3\bar{S}$ and CaO.

Series 5: TSH gradually forms with time and increases in the paste of $C_4A_3\bar{S}$, CaO and $CaSO_4$ along with remarkble expansion, similar to the case of Series 3. But the deposition of hydrates in the filter paper is negligible in this case.

Series 11: in C_3A paste, C_3AH_6 and C_4AH_{13} are detected, but no TSH. The latter is deposited in the filter papers, and MSH appears on the interface between the filter paper and the C_3A paste. In such a case, there is very little expansion.

Series 12: in the first stage, C_3A hydrates with $CaSO_4$ to form TSH, which reacts afterwards with the unreacted C_3A to form C_3A–$C\bar{S} \cdot H_{12}$ or a solid solution of it. In this case there is remarkable expansion.

Series 13: TSH forms only on the interface between the filter paper and paste, while C_4AH_{13}, C_3AH_6, and $Ca(OH)_2$ form on the back surface of the paste, and the solid solution forms in the paste near the filter paper. In this case there is no expansion.

Series 14: C_3A hydrates with CaO and $CaSO_4$ to form C_3AH_6 thoughout the paste, but the above mentioned solid solution in the paste is limited to the area near the filter paper. A condiderable degree of expansion occurs in spite of the limited formation of TSH in this case.

These experimental results led us to the conclusion that the hydration of $C_4A_3\bar{S}$ proceeds stepwise as follows:

$$C_4A_3\bar{S} + 8Ca(OH)_2 + 30H_2O \longrightarrow (C_3A \cdot C\bar{S} \cdot H_{12}\text{–}2C_4AH_{13}),$$

$$(C_3A \cdot C\bar{S} \cdot H_{12}\text{–}2C_4AH_{13}) + 6Ca^{++} + 8SO_4^{--} + 58H_2O \longrightarrow 3(C_3A \cdot 3C\bar{S} \cdot H_{32}).$$

Many investigators acknowledge that very little expansion occurs, regardless of the formation of TSH, if the concentration of CaO in the solution is low (13, 14, 20, 21). On the contrary, the grains of $C_4A_3\bar{S}$ are coated with hydrates at an early stage of reaction as a consequence of the lowering of the solubility of the hydrates if the concentration of CaO is high. Consequently, $C_4A_3\bar{S}$ reacts with H_2O permeated through pores to form $C_3A \cdot C\bar{S} \cdot H_{12}$ or solid solution of it with low crystallinity on the interface of $C_4A_3\bar{S}$. Remarkable expansion would take place as the result of a secondary reaction if the above hydrates with SO_4^{--} ion come from the liquid phase by diffusion to form fine crystalline TSH.

At the same time, expansion due to the formation of MSH was also confirmed when C_3A hydrates at an early stage with a limited amount of $CaSO_4$ to form crystalline TSH, which then reacts with lime to form fine crystalline MSH in the product layer.

Properties of Ettringite (TSH)

We have obtained several additional results (24) concerning the properties of TSH, especially for the state of combined water,which was investigated previously by Berman and Newman (22), and also by Takemoto and Saiki (23).

TSH was synthesized for our study by titration of $Al_2(SO_4)_3$ solution into a saturated solution of CaO and $CaSO_4 \cdot 2H_2O$ at 25°C. The precipitate was filtered by suction, and dried over 70% H_2SO_4. The resulting TSH contained 31.2 moles of combined water. It was found to dehydrate to 10.3 moles of H_2O by drying over CaO, and 6.9 moles of H_2O in the case of $MgClO_4$. TSH is however not dehydrated by portland cement used as a drying agent.

The changes in the amount of combined water of TSH with heating are as follows:

heating temp. (°C)	20	40	65	100	300	400	600	800	1000
H_2O (mole)	31.2	28.0	13.3	6.5	1.8	0.6	0.6	0.8	0.0

Fig. 18 shows the infrared absorption spectra of compounds related to TSH or CSA-cement.

The absorption of OH radical of TSH due to stretching and bending vibration appears at 3400 cm^{-1} and 1650 cm^{-1} each when caused by polymeric intermolecular hydration bond, and at 3640 cm^{-1} and 1620 cm^{-1} each when caused by monomeric OH radical. TSH changs into the amorphous state when heated above 80°C due to the dehydration of interlayer polymeric water, and the monomeric structural water is lost above 200°C. In addition, the spectrum of TSH heated above 600°C shows the existence of $CaSO_4$ and $C_4A_3\bar{S}$.

The specific surface area of TSH is slightly increased by the dehydration of interlayer water, and decreased when it becomes amorphous. Furthermore, the specific surface area of TSH increased rapidly with the destruction of the outer shape of the original crystal, and $CaSO_4$ was deposited by heating above 500°C.

The specific surface area decreased remarkably in relation to the crystallization of $C_4A_3\bar{S}$, CaO, and $C_{12}A_7$ and sintering by heating above 700°C (Fig. 19).

When the heated specimen is wetted, TSH is easily

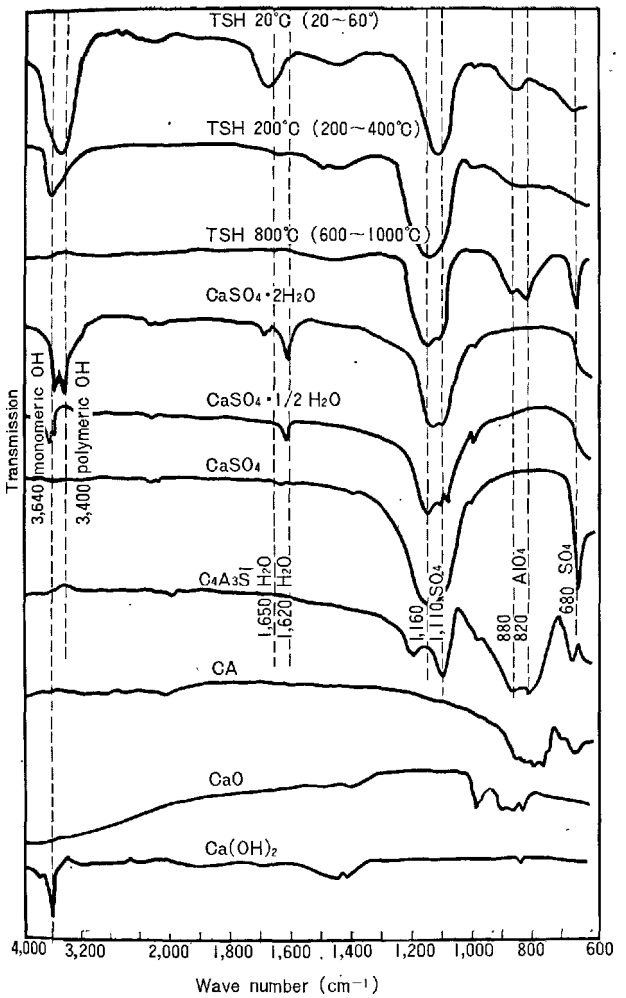

Fig. 18. *Infrared absorption curves*

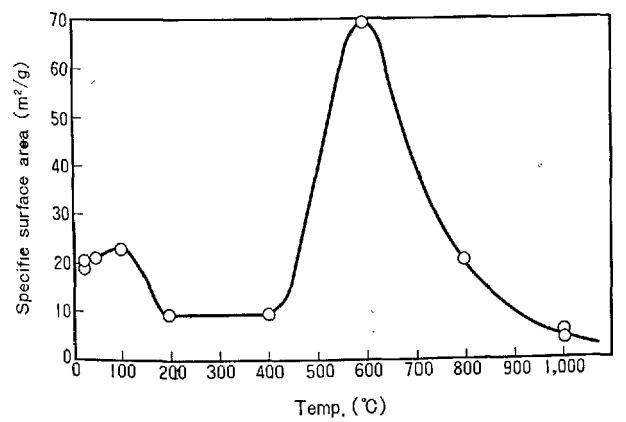

Fig. 19. *Surface area of heated ettringite measured by* N_2 *adsorption (Kept 30 min. at each temp.)*

reproduced, and the higher the heating temperature, the greater the expansion.

Pore Structure of Hardened CSA Cement

The relationship between the pore structure of hardened CSA cement and characteristics such as the expansion or drying shrinkage of CSA cement was investigated (25).

The proportion of mortar was 1:2, W/C = 0.45, and the cements used were 9–13% CSA cement and portland cement as the contrast. It was cured at 20°C in water and in the air with R.H. = 50%.

In this paper, only the results obtained with specimens cured for 18 months will be described.

The mechanical strength is not affected very much by the CSA in the case of water curing, but it decreases gradually with air curing. The strength of the mortar cured in air is about 85% for portland cement and 75% for expansive cement comprised of 13% of the amount of CSA of that in water curing. The degree of neutralization of specimens cured in air increases slightly with the addition of CSA.

According to the X-ray diffraction, the amount of TSH increases with the addition of CSA in the specimens cured in water, while a small amount of $CaCO_3$ was detected, instead of TSH and $Ca(OH)_2$, in specimens cured in air.

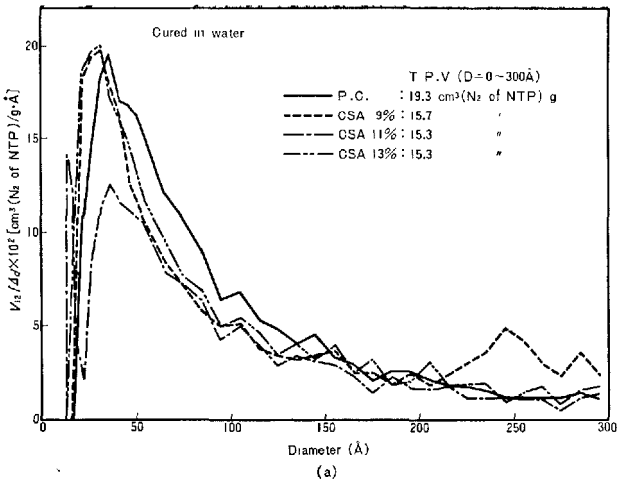
In order to examine the pore structure of mortar specimens, measurement of the adsorption and desorption of N_2 gas was carried out.

It was found that the hysteresis of the isotherm is more remarkable for the specimens cured in water than in air. The existence of hysteresis is related to the complexity of the pore structure.

The specific surface area of the specimens cured in water was about 15 m^2/g, while that of those cured in air was only about 4 m^2/g. in comparison, the specific surface area of portland cement and CSA cement were nearly the same for the specimens cured in water, but the latter had a slightly larger value than the former in the case of specimens cured in air.

In regard to the specific surface area, a value about 20% larger than the results obtained by the BET method is given by calculating under the assumption that the pore shape is a circular cylinder in the case of specimens cured in water, while in the case of air curing almost the same values are obtained by both methods.

The pore size distributions calculated by means of a digital computer are shown in Fig. 20. A large peak appears at about 15Å (in diameter) in the case of water curing. In air curing, it is shifted to about 20Å, and the total pore volume falls to lower than 30% of that of the specimens cured in water. This tendency is remarkable in the case of portland cement.



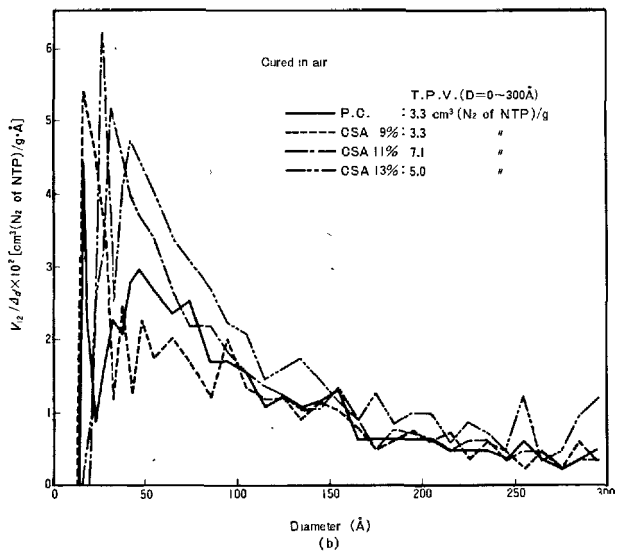


Fig. 20. *Pore size distribution curves calculated by Cranston-Inkley method*

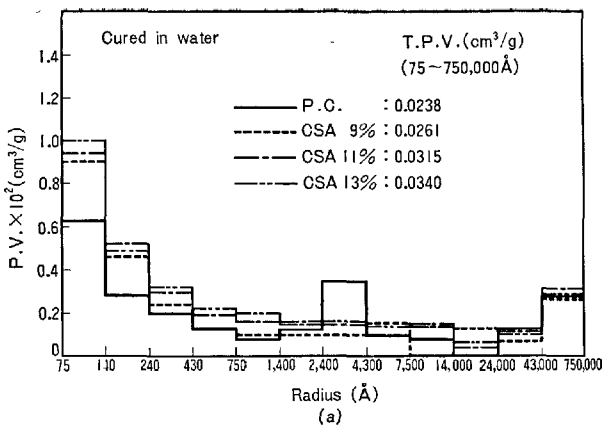
(a) Results of the mortars cured in water for 18 months
(b) Results of the mortars cured in air for 18 months



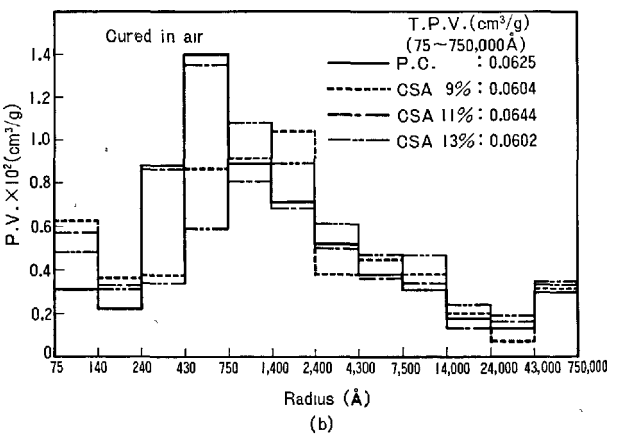


Fig. 21. *Pore size distribution curves measured by mercury pressure porosimeter*

(a) Results of the mortars cured in water for 18 months
(b) Results of the mortars cured in air for 18 months

The position of the peak is not affected by the curing conditions, but it is shifted toward a finer pore size in the case of CSA cement, compared to portland cement. This seems to be related to the formaton of TSH.

In addition, the distribution of pore sizes greater than 75Å in radius was measured by the Carlo Erba mercury pressure porosimeter, with the results shown in Fig. 21.

A peak in pore radius at 75–140Å appeared for the specimens cured in water, and the pore volume corresponding to this range of radius decreased to 60% for the specimens cured in air, for which the peak is broadened and shifted to 430–2400Å.

The pore volume in the range of 75–140Å is the lowest in the case of portland cement and increased with the amount of CSA content, but there is no relation to curing.

Since the pores are not perfectly saturated by water in the specimens cured in air, large pores remain because the pores are not completely filled up by the outer hydration product.

Furthermore, the expansion due to the hydration of CSA cement seems to be mainly accompanied by an increase in the volume of pores with a radius of 75–240Å judging from the results for the specimens at an early curing age.

The peak for the pore size is shifted towards the finer side with the progress of hydration. Also, it seems that the reason for the much lower degree of expansion in the case of curing in open air and even in moisture, compared to the case of water curing, is related to the surface tension or capillary force.

Although the above description gives a fairly clear picture, more precise analysis is being carried out to

determine more accurately the relationship between the pore structure of hardened CSA cement and such characteristics as expansion, drying shrinkage, and the rate of neutralization.

Mechanisms of Irreversible Expansion due to Hydration

When cement reacts with water, the total volume decreases but the solid volume increases. Also, the volume increases when a super-saturated solution deposits crystals. It is not exceptional for the reaction to form TSH. Therefore the expansion in CSA cement can not be explained by an increase in the specific volume due to the formation of TSH.

The reaction of C_3S, CA, C_3A, and $C_4A_3\bar{S}$, for example, with water is not accompained by remarkable expansion. In the case of such a reaction, besides the formation of an inner product, an outer product is also formed at the same time by outward diffusion owing to the high solubility of the reactant surrounded by the product layer. For instance, $Ca(OH)_2$ formed in the hydration of C_3S can only be deposited as an outer product because its solubility is not low enough for it to be deposited in the gel pores as an inner product.

However, very slight expansion occurs in the induction period because of the permeation of water into the surface of the cement grain. Also, a small amount of shrinkage is detected in the acceleratory period because of remarkable effluence.

On the other hand, in respect to the irreversible expansion of expansive cement, there is much discussion, (14, 20, 26) but many physico-chemical factors should be considered and experiments along this line should be carried out. On the remarkable irreversible expansion of expansive cement, it can be explained according to the present state of knowledge as follows (19).

In the hydration of CSA-cement, CaO and $CaSO_4$ are considered the outer reactants because their rate of dissolution is larger than that of aluminates such as C_3A or $C_4A_3\bar{S}$, and the surface of aluminate grain is covered with a less permeable layer of coating. The outer reactants permeate through this layer to the interface of the inner reactant. The inner product is rapidly formed by interaction between the diffused materials and the inner reactant, which also has a large rate of dissolution. The accumulation of hydrates begins inside of the grain because of the low solubility of the aluminate sulphate hydrates formed.

The essential problem is to decide what is the driving force of expansion in which the crystals of products can be grown under compressive stress and the structure of the product previously formed can be deformed.

As for the driving force, to be considered are (1) expansion of the crystal lattice of the hydrate by means of ion exchange, (2) the osmotic pressure produced in aluminate solution, (3) crystal growth pressure occuring at the apex of the crystal undergrowing, and (4) the surface tension which is expected on the interface between the crystal apex to be grown and another solid face.

If the first assumption is true, the conversion of C_4AH_{13} into $C_3A\cdot C\bar{S}\cdot H_{12}$ must take place by ion exchange without dissolution when the former comes in contact with calcium sulphate solution. This is believed very difficult, since the diffusion coefficients within the solid are so small.

Next, we have tried to measure the osmotic pressure in relation to the hydration of CSA cement, and found that it is not likely to be the main cause of expansion because the hydrates formed are mainly crystalline and do not form a semi-permeable membrance. However, the osmotic pressure was formerly regarded to be attributable to the expansion accompanied by the alkali-aggregate reaction.

In consideration of the crystal growth pressure, Jorgensen (27) tried to explain hydration expansion. He found, countrary to his expectation, that the degree of expansion is bigger when small crystals are formed. Nevertheless, the peripherical length was assumed as an assisting factor to effect the crystal growth pressure.

On the other hand, uniaxial pressure appears when crystal growth continues after the apex comes in contact with another fixed solid face. In order for crystal growth to continue, however, it is necessary to allow the liquid to penetrate against the pressure into the interface between the crystal apex and the other solid face.

Correns and Steinborn (28) pointed out the requisite conditions: $\gamma_{cs} > \gamma_{cl} + \gamma_{ls}$, where γ is the surface energy and C,S, and l mean the growing crystal, the other solid and the liquid, respectively. The uniaxial pressure is a function of the degree of super-saturation and also equated by them: $P = (RT/v)\ln (C_{ss}/C_s)$, where C represents the concentration and ss and s mean super-saturation and saturation.

In respect to the hydration of CSA cement, beside high concentration of SO_4^{--} ion at the outer space of aluminate grain, the concentraton of the liquid phase at the interface of unreacted $C_4A_3\bar{S}$ or C_3A should be very high in respect to the solubility of TSH, which is especially lowered by an increasing concentration

of lime. Moreover, it is probable tht TSH possesses a comparatively high surface energy and heat of wetting. Under these conditions, it is expected that significant expansion or compressive stress appears due to the formation of TSH at or near the interface of anhydrous aluminates (R. Kondo).

The Manufacturing Process and Characteristics of CSA Cement

The Manufacture of CSA Cement

Responding to the progressive requirements of concrete technology, basic research on expansive cement has been carried out, with the result that an expansive cement possessing unique characteristics was developed in Japan several years ago. CSA cement, a mixture of CSA and portland cement, can be used both for preventing shrinkage cracks and for self-stressing by means of changing the mixing ratio of CSA and portland cement.

The CSA is manufactured by a process similar to that of ordinary portland cement. Raw materials for preparing CSA are material that contain CaO,Al_2O_3, and SO_3 individually or together. Impurities such as SiO_2, Fe_2O_3, etc., are undesirable because they react with CaO and Al_2O_3 to produce less expansive components. Ordinarily, we use limestone for CaO, white bauxite for Al_2O_3 and chemically produced anhydrous gypsum for CaO and SO_3. An example of the chemical composition of the raw materials is shown in Table 3.

These raw materials are mixed in a proportion to make the ratio $CaO: Al_2O_3: CaSO_4 = 4:1:3$ in mole (CSA 4-1-3). A molar ratio of 3:1:3, which corresponds to a dehydrated TSH, was also tried (CSA 3-1-3). Weighed raw materials are ground together by a mill. The rotary kiln with a cooler is used for heating. Since the sintering degree of clinker has a great influence on the expansion characteristics of CSA, the heating temperture and cooling rate should be carefully controlled. The clinker contains three principal phases: calcium sulphoaluminate, quick lime, and anhydrous gypsum. Closed circuit type ball milling is used for grinding.

As the fineness of CSA has a remarkable influence on the expansion characteristics, two air separators are used for strict adjustment of grain size distribution. Ground CSA is mixed with portland cement at an optional ratio by an ordinary rotary mixer. The normal mixing ratio of CSA: portland cement is 10:90 for drying shrinkage prevention, and 13–17: 87–83 for selfstressing.

Characteristics of CSA and CSA Cement

Measuring Method

All the measurement described in this section were made according to the Japanese Industrial Standards (JIS) R5201, R5202, and A1125. The expansion of mortar and concrete was measured as follows.

The dimensions of the specimens were $4 \times 4 \times 16$ cm for mortar and $10 \times 10 \times 40$ cm for concrete. They were cast in the mold and cured for 24 hrs., after which the mold was removed and a lined piece of glass was affixed to both ends of the specimens.

Chemical and Physical Properties of CSA

Table 4 and Table 5 show the chemical composition and some physical properties of CSA.

Aeration of CSA Cement

The 10% CSA cement was packed in a sack made of three-fold craft paper and exposed to a temperature of 35°C and a relative humidity of 85%. The weight change of the cement, the expansion and the strength of mortar were measured for aerated CSA cement. The results are shown in Table 6. The results show that the aeration of CSA is more rapid than that of portland cement. Thus CSA cement should be tightly packed in a four-fold sack.

Table 4. *Chemical composition of CSA*

12	26.0	2—50	3—40
13	26.0	2—31	3—35

Setting of CSA Cement

In general, expansive cement has the disadvantage that it begins setting at a relatively early period. This disadvantage, however, can be overcome by proper chemical composition and the fineness of the CSA. From the data shown in Table 7, it is apparent that mixing of CSA gives little effect upon setting.

The Fluidity of CSA Cement Mortar

Fig. 22 shows the relation between the fluidity and W/C ratio of 10% CSA cement mortar. The ordinary flow test method was used. It is apparent that the fluidity of CSA cement mortar is almost the same as that of portland cement mortar. The proportion of mortar or concrete can be set in the same manner as in portland cement.

Expansion Characteristics of CSA Cement Mortar

Fig. 23 shows the curve that represents the relation between expansion and mixing amount of CSA. The curve is not linear and is rather similar to an ordinary stress-strain curve, supposing that the expansive force is proportional to the quantity of CSA. In the case of no restraint, the use of 14% or more CSA cement causes expansion cracking and destruction. If some restraint exists, it is expected that the curve will become linear one.

Fig. 24 shows relation between expansion and curing age for 10% CSA cement mortar. The expansive reaction seems to end at a relatively early age of 4–7 days. As it dries, CSA cement mortar shrinks, but the amount of shrinkage is much smaller.

13	12.8	14.8	19.7	59	55	60

Compressive and Bending Strength of CSA Cement Mortar

Table 8 shows the results of a strength test on CSA

cement mortar. Owing to the large free expansion, the compressive strength of CSA cement mortar is much lower than that of portland cement. The bending strength is also less than that of portland cement, especially 10% or more CSA cement. But the degree of decrease is not as much as that of its compressive strength. It can be considered that a little selfstress caused by internal restraint makes some contribution. If some external restraint exists, as in the general case in practical use, a certain amount of self-stress appears and the bending stength will be increased to the value of portland cement.

Expansion and Strength of CSA Cement Concrete

The mixing of the concrete is shown in Table 9. Table 10 and Table 11 show the results of the measurement of expansion and compressive strength respectively both in the case of water curing and drying condition.

Since the ratio of cement to aggregates is less than that of mortar, internal restraint is more. Consequently, the expansion is less and the compressive strength is no less than that of portland cement. Apparently, the drying shrinkage is smallest, so the resistance to cracking due to drying shrinkage is naturally great.

The Effect of Reinforcement on the Expansion of CSA Cement

An ordinal steel rod (SS41) was buried in the center of a CSA cement concrete specimen. Both ends of the specimen were restrained by two steel plates, which were connected to the internal rod. The relation between expansion and the degree of reinforcement is shown in Fig. 25. The proportion of concrete is the same as that in Table 9. The specimen was cured in

water for three days and after that at drying condition of 20°C and a relative humidity of 50%. Apparently the expansion decreased, but the drying shinkage also decreased.

Chemical Prestressing of Concrete Elements by CSA

The introduction of chemical prestress was tried with a pressure pipe. The proportions of the concrete and dimensions of the pipe are shown in Table 12, and Table 13. After about five minutes of mixing, the concrete was cast in a rotating mold. Revolution of the mold was stopped after ten minutes and the concrete pipe was left in the mold for about 24 hrs., after which the mold was removed and reinforcement bars were anchored at the end by nuts. The specimen was cured at 65°C for 2 hrs., in moisture for 7 days, and then in the open air. At the age of 15 days, the pressure pipe was subjected to an outside load ranging over the entire length. The results are shown in Table 14. The larger load required to crack the CSA cement concrete pipe suggests a contribution of chemical prestress. (Y. Ono)

Conclusions

From this study, the following conclusions were obtained.

(1) The initial free expansion of expansive cement mortar or concrete which compensates subsequent drying shrinkage is not as important for the prevention of shrinkage crack formation as was formerly thought. It is necessary to reduce the drying shrinkage after finishing the intitial expansion.

(2) Concerning the chemical prestressing of concrete elements, the limitations for the economical use of the mechanical properties of materials, especially the strength of prestressing steels, should be considered in designing the elements. In this study it can be predicted that the use of high tensile prestressing bars having the allowable stresses of 50 to 90 kg/mm² is most desirable for this purpose.

(3) In the test results on chemical prestressing by CSA-cement reported in this paper, 13% CSA content in normal portland cement is most adequate for chemical prestressing, although only about 30 kg/cm² prestress is expected to be introduced into the concrete section having 1% prestressing steels.

(4) In the manufacture of CSA cement clinker, raw materials in which the molar ratio of $CaO: Al_2O_3: CaSO_4$ equals 4: 1: 3 are heated to produce $C_4A_3\bar{S}$ crystals of the proper size at about 1200°C. Then the clinker is ground rather coarsely so that the particle size distribution is limited. The optimum mixing ratio of portland and CSA for expansive cement was found to be 90: 10 by weight.

(5) In the hydration of $C_4A_3\bar{S}$ in the presence of CaO and $CaSO_4$. the grain of $C_4A_3\bar{S}$ is at first coated with hydrates, through which the liquid phase permeates to the interface of unreacted $C_4A_3\bar{S}$ to form monosulfate hydrat or its solid solution. Irreversible expansion then takes place by the reaction of SO_4^{--} ion diffused from outside and either anhydrous or hydrated aluminates to form TSH. Remarkable expansion also occurs when C_3A reacts secondarily with the previously formed TSH that coats the C_3A grains to produce MSH.

(6) The mechanism of irreversible expansion due to the hydration of CSA cement are regarded as being related to the lack of balance of inward and outward diffusion through the product layer, the degree of super saturation of TSH, especially in the presence of lime, and the surface energy of TSH when adequate. These are most likely the essential factors in making possible the crystal growth of TSH, even under compressive stress, and in giving rise to the remarkable expansion.

(7) The manufacture of CSA cement in Japan was initially undertaken on the basis of the above-mentioned investigations, which made possible a product whose characteristics were very satisfactory. Further research will be carried out on the properties of mortar and concrete.

Supplementary Paper IV-132 Properties of Expansive Cement Concretes

Paul Klieger and Nathan R. Greening*

Synopsis

These studies provide information useful in determining the utility of expansive cement systems under a variety of conditions, thus contributing to proper engineering usage.

Earlier work at the PCA Laboratories evaluated the expansive properties of various mixtures of portland cement, calcium aluminate cement, and gypsum in mortars. This was followed by an extensive series of tests, using a particular mixture of portland cement-calcium aluminate cement-gypsum, a Klein-type shrinkage-compensating cement, and Klein expansive cement, which included an evaluation of expansive characteristics and freeze-thaw durability of relatively high cement content (729 to 752 lb/cu yd—approximately 8 U.S. bags) concretes typical of those used in the precasting industry.

The present study was directed to the evaluation of a wider range of concrete properties for air-entrained concretes typical in proportions to those used in cast-in-place structures and pavements (approximately 564 lb of cement/cu yd—6 U.S. bags). These properties include the development of compressive and flexural strength for ages from one day to one year, including the effect of initial and curing temperature; volume change in moist storage and in air, including alternations of wetting and drying; creep under sustained stress; resistance to freezing and thawing and de-icer scaling; resistance to sulphate exposure; abrasion resistance; and other aspects. With respect to durability, sulphate resistance, and abrasion, the data obtained is for both non-reinforced and reinforced (restrained) systems.

Cement formulations included in this study are: (1) portland, ASTM Types I, II, and V: (2) two shrinkage-compensating cements manufactured by intergrinding the expansive component with the portland cement clinker; (3) a shrinkage-compensating cement manufactured as an integral-burn clinker; (4) a portland cement-calcium aluminate cement-gypsum mixture; and (5) a very high C_3A portland cement-gypsum combination.

Included also is information relative to certain use aspects of such cements, including the effect of mixing time and temperature on the expansive potential.

KEY WORDS: Abrasion resistance; air-entrained concrete; aluminous cements and concretes; chemical composition; compressive strength; creep (materials); curing; deicing; durability; expansion; expansive cements; flexural strength; freeze-thaw durability; mixing time; portland cements; restraints; scaling; shrinkage; stresses; sulflate resistance

Introduction

Most studies of concretes made with expansive cement formulations have been concerned with properties such as expansive potential and strength development. Recent work in our laboratories(1)** presented the results of an extensive series of freeze-thaw and surface scaling tests of relatively high cement content concretes (729 to 752 lb/cu yd—approximately 8 U.S. bags). An earlier paper (2) reported tests on properties of mortars and concretes made with portland cement-calcium aluminate cement-gypsum blends.

This present and more comprehensive series of tests was undertaken to develop data on a wider range of concrete properties, using concretes typical in proportions of those used in cast-in-place structures, pavements, and general concrete construction (approximately 564 lb of cement/cu yd—6 U.S. bags).

**Portland Cement Association, Skokie, Illinois, U.S.A.

*Numbers in parentheses refer to list of references at end of paper.

Scope

The concretes used in this study had nominal cement contents (including the expansive materials) of 564 lb (6 U.S. bags) per cubic yard. One 752 lb of cement (8 U.S. bags) per cubic yard concrete was included to provide a comparison of performance with respect to certain properties. Slumps were of the order of 2 to 3 inches and air contents 5 to 6 percent. The maximum size of aggregate used was 3/4 inches.

Specimens were both of the unrestrained and restrained variety. In the case of the prisms, restraint to expansive force was provided by an embedded 1/4 inch diameter threaded steel rod, providing a longitudinal reinforcement percentage of 0.30. The restrained slabs contained welded wire fabric in an amount providing a reinforcement percentage of 0.89 in both directions.

A variety of curing conditions were used. These included curing at temperatures of 40, 73, and 100°F, either in a moist-room at 100% R. H. or in water. Some concretes were subjected to simulated steam curing at 160°F and atmospheric pressure, with subsequent curing at 73°F and 100% R. H. Specific details on curing procedures used are presented in subsequent discussion of various phases of the program.

These tests included (1) the effect of mixing time on unrestrained expansion, (2) the effect of curing environment on strength development of unrestrained concretes, (3) volume change of unrestrained concrete as influenced by curing history, including the effect of alternate cycles of wetting and drying, (4) freeze-thaw and de-icer scale resistance for both unrestrained and restrained concretes, (5) creep of unrestrained concretes under sustained load, (6) sulphate resistance of unrestrained and restrained concretes, (7) abrasion resistance of unrestrained and restrained concretes, and (8) the influence of amount of cementing material on unrestrained expansion in moist and water storage.

Materials

Cementing Materials

Table 1 shows the chemical analyses and finenesses of the portland cements, the calcium aluminate cement, and the various expansive (shrinkage-compensating) cements used in this study. Table 2 provides a brief description of the cements or cement formulations used in the concretes, together with a letter or letter-number designation which will be used in subsequent discussions for identification.

The American Concrete Institute's "Cement & Concrete Terminology" (SP-19) defines expansive

cements as follows:

"*Expansive cement (general)*—A cement which when mixed with water forms a paste that, after setting, tends to increase in volume to a significantly greater degree than portland cement paste; used to compensate for volume decrease due to shrinkage or to induce tensile stress in reinforcement (post-tensioning).

"*Expansive cement, Type K*—An expansive cement containing anhydrous aluminosulfate (4 $CaO \cdot 3Al_2O_3 \cdot SO_3$), burned simultaneously with a portland cement composition, or burned separately when it is to be interground with portland cement clinker or blended with portland cement, calcium sulphate ($CaSO_4$), and free lime (CaO).

"*Expansive cement, Type M*—A mixture of portland cement, calcium-aluminate cement, and calcium sulphate.

"*Expansive cement, Type S*—A portland cement containing a large computed C_3A content and modified by an excess of calcium sulphate above usual optimum content."

Referring to Table 2, Cements K-1, K-2, and K-3 are, by these definitions, Type K; Cement M-1 is Type M; and Cement S-1 is Type S.

The amount of expansive component in Cements K-1, K-2, and K-3 is not known. These are samples of commercially available shrinkage-compensating cements. The formulation for Cement M-1 is shown in Table 2. Cement S-1 was prepared in our laboratories by intergrinding a high C_3A portland cement clinker with gypsum and anhydrite to produce the composition shown in Table 1. The oxide analysis of the clinker used is shown in Table 3. Note that the computed potential C_3A content is just over 20 per cent.

Aggregates

Table 4 shows the grading of the aggregates. The sand from Elgin, Illinois is a partly siliceous and partly calcareous natural sand. The 3/4-inch maximum size natural coarse aggregate from Eau Claire, Wisconsin, is principally siliceous and contains a small percentage of crushed over-size.

Admixture

Neutralized Vinsol resin in solution, added at the mixer, was the air-entraining admixture. The solution contained 22.7 g. NVX per liter. No other admixtures were used in these tests.

Concretes

Concretes were designed to contain 564 lb of cement per cubic yard (6 U.S. bags). A few mixes made with Cement K-1 also contained 752 lb of cement per cubic yard (8 U.S. bags). Sand percentage used was 40 percent by weight of total aggregate. All concretes were air-entrained, with air contents generally in the range of 5 to 6 percent by volume. Most of the slumps were in the range of 2–1/4 to 3–1/2 inches. In those tests involving different mixing times, there were expected changes in slump and air contents.

Detailed concrete mix data are presented in Tables 5 and 15.

Fabrication and Testing

Concrete Mixing and Fabrication of Specimens

All materials were stored at the temperature at which the concrete was produced: 40, 73, or 100°F. Most of the concretes were cast at a temperature of 73°F. Aggregates were weighed in the air-dried condition (moisture content known) and inundated with a known amount of water 18 to 20 hours prior to use. Excess water was drawn off and weighed immediately prior to mixing.

Concrete batches were mixed for 2–1/2 minutes in a 1–3/4 cu. ft. capacity Lancirick mixer (horizontal open tub), except when mixing time was a variable. Unit weight, slump, and air content by the pressure method were determined immediately after mixing.

All specimens were cast in watertight steel molds, except for the abrasion specimens which were cast in watertight plastic-coated plywood molds. Consolidation of concrete in the molds was accomplished by hand rodding or on a vibrating table operating at a frequency of 4000 cycles per minute for low slump mixes and the slabs with two-way steel. Generally, specimens were made from duplicate batches, each mixed on different days.

Unrestrained prisms, 3 by 3 by $11\frac{1}{4}$-in. in size, contained stainless steel end plugs for length change measurements. Restraint in prisms was provided by a 1/4-inch diameter mild steel rod, threaded over its entire length, and embedded along the longitudinal axis of the prism. The modulus of elasticity of the steel was 27,500,000 psi. yield strength was 55,000 psi. The ends of the rod passed through 3/8-in. thick 3 × 3-inch metal end plates and protruded from the specimen ends. The rod ends were provided with stainless steel acorn nuts, in contact with the steel end plates, which served as reference points for length change measurements. The steel percentage amounted to 0.30 percent. This calculation was based on a root diameter of 0.185 inches. Restraint in the slab specimens, which were 3 by 6 by 15-in. in size, was provided by a double layer of $4 \times 4\ ^{4}/_{4}$ w.w.f. (welded-wire fabric) placed at mid-depth of the specimens. The reinforcement in the longitudinal and in the transverse directions amounted to 0.89 percent. All slabs also were equipped with stainless steel end plugs

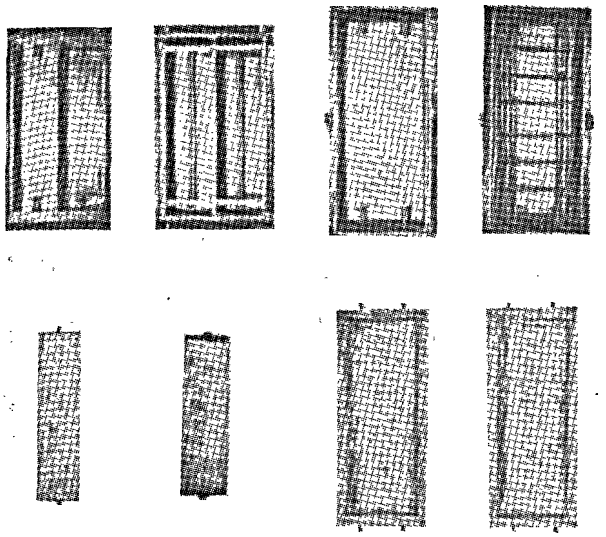

Fig. 1. *Specimen molds and arrangement of reinforcement for unrestrained and restrained prisms and slabs*

for length change measurements. Fig. 1 shows the molds, arrangement of reinforcement and specimens. Restraint in the abrasion specimens was provided by one layer at mid-depth of criss-crossed (at right angles) 1/4-in. diameter threaded rods, providing reinforcement percentages of 0.30 percent in each 12-inch direction.

Curing

Immediately after casting, specimens were covered with damp burlap kept slightly above the finished surfaces. The burlap was covered with polyethylene to retain moisture. The molds containing concretes made with portland cements were stripped at 24 hours. Those containing the various shrinkage-compensating cements were stripped at times ranging from 5 to 12 hours, depending upon the strength gain characteristics of the concrete, thus utilizing as much of the expansive potential as possible under these circumstances.

Most specimens were then cured moist at 100% R.H. at either 40, 73 or 100°F. Some were cured in water at these temperatures. Specimens for strength tests were cured continuously moist until test. Volume change specimens were made for both moist curing and water curing for 7 days at the three temperatures, followed by one day of equilibrating at 73°F in the same environment before being subjected to wetting and drying cycles. One group of volume change specimens was moist cured continuously for 6 months, while a companion set was subjected to drying at 50% R.H. after 7 days of moist curing. Specimens for freeze-thaw and de-icer scaling tests were cured 14 days moist, then 14 days in air at 50% R.H., followed by 3 days immersion in water for the prisms and 3 days with water on the top surface for the slabs, always at 73°F. Creep specimens were cured 7 days moist at 73°F prior to test, as were the specimens for sulphate resistance and abrasion tests.

The simulated steam curing cycle was essentially as follows:

1. Preset period of 6 hours after casting at 73°F. Specimens made with shrinkage-compensating cements removed from molds and measured for initial length. Specimens made with portland cement remained in molds during whole cycle, while the others were exposed directly to the curing atmosphere.
2. Heating period of about 5 hours to reach 160°F.
3. Holding period of about 11 hours at 160°F.
4. Cooling period of about 4 hours to reach 73°F. Portland cement concretes removed from molds for initial length measurement. Other specimens measured to determine expansion during curing.

Test Methods

Strength

Concrete prisms were tested in flexure, with the load applied at the third-points of a 10-inch span, as per ASTM Designation: C78–64. Prism ends were tested in compression as 3-inch modified cubes, as per ASTM Designation: C116–65T. No capping of cubes was required as the loads were applied to surfaces cast against the flat steel surfaces of the mold.

Freezing and Thawing

Concrete prisms were frozen and thawed while continuously immersed in water. Two complete cycles of freezing and thawing were obtained every 24 hours. The rate of cooling at the center of the specimens was approximately 20°F per hour. The minimum and maximum specimen temperatures attained were approximately −10°F and +55°F, respectively. Periodically during the tests, determinations were made of changes in length, weight and fundamental transverse frequency. This test method is equivalent in severity to ASTM Designation: C290–67.

De-Icer Scaling

The de-icer scaling test consisted of freezing a 1/4-inch layer of water on the top surface of the slab in a

room maintained at 0°F and then thawing the ice at about 70°F applying flake calcium chloride in an amount equivalent to 2.4 lb per sq yd of surface area. The slabs were subjected to one cycle of this procedure per day. The amount of scaling was determined by visual examination rated numerically as follows:

0 = no scale	3 = moderate
1 = slight	4 = moderate to severe
2 = slight to moderate	5 = severe

Sulphate Resistsnce

Concrete prisms were stored continuously immersed in a 10 percent sodium sulphate solution at 73°F. Exapansion was used as a criterion of performance.

Creep

Concrete cylinders were subjected to a sustained stress of 1600 psi (1200 psi for those made with Cement M-1) in a loading frame which met the requirements of ASTM Designation: C512–66T. Length change measurements were made using a 10-inch Whittemore strain gage. Companion cylinders were provided for drying shrinkage measurements. Testing was performed in a room maintained at 73°F and 50% R.H.

Abrasion Tests

Twelve-inch square by 3-inch deep slabs, restrained and unrestrained, were subjected to abrasion tests following 7 days of moist curing at 73°F and a period of at least one year of air-drying at 50% R.H. The troweled surfaces were subjected to 20 minutes of abrasion by three assemblies of dressing wheel units revolving about a horizontal axis at a speed of 170 rpm.

Discussion of Results

Table 5 shows the concrete mix data for the unrestrained specimens made for evaluating strength development and volume change characteristics. Note that the water requirements for the different cements did not vary greatly, hence the water-cement ratios are quite similar. There were, however, significant differences in air-entraining admixture requirements, with some of the shrinkage-compensating cements requiring more and some less than the portland cement.

The strength data are shown in Table 6 and are also illustrated in graphical form. Some of the 1-year data are not as yet available.

Figs. 2 and 3 show the compressive and flexural strengths of the unrestrained concretes cured continuously moist at 73°F for ages from 1 day to 1 year (1-year data not as yet available for Cements K-3 and S-1). With the exception of Cement M-1 (the portland cement-aluminate cement-gypsum blend), the strengths of the concretes made with the shrinkage-compensating cements are quite comparable to those for the protland cement concretes (Cement P-I). At 1 year, however, the difference between Cement M-1 and the others is relatively minor.

Curing temperature influences the strength development characteristics of the concretes made with the shrinkage-compensating cements in much the same manner as for the portland cement concretes. Figs. 4 and 5 show the compressive and flexural strength data for all of the concretes cast at 73°F and then stored immediately in a moist-room at temperatures of 40, 73, and 100°F for the first 7 days. After 7 days, all of the concretes were stored moist at 73°F until test. As other studies have shown, the lower the initial curing temperature, the lower the 1- and 7-day strengths. Subsequent curing at 73°F resulted in a reversal at the later ages, with the concretes cured initially at low temperatures generally showing higher strengths at 1 year. The reversal is often apparent as early as 28 days, as can be noted in Figs. 4 and 5.

In addition, Cement K-1 was used in concretes which were cast and cured moist during the first 7 days at 40, 73, and 100°F, with subsequent moist storage at 73°F. Strength data are shown in Table 6 and in Figs. 6 and 7. These changes in initial temperature of the concrete did not materially influence the strength development in comparison with the 73°F initial concrete temperature Cement K-1 strength data shown in Figs. 4 and 5.

The strength data for these same concretes subjected to steam curing at 160°F and atmospheric pressure are shown in Table 6. Again, the 1- and 7-day compressive strengths of the concretes made with Cement M-1 are significantly lower than for the other cements, but the difference is relatively small at 28 days. Flexural strengths of the Cement M-1 concretes were essentially equal, however, with the others at all ages.

These strength data indicate that concretes made with the shrinkage-compensated cements respond to curing environment in much the same manner as portland cement.

Volume Change

Effect of Mixing Time

Earlier work (1) reported that extended periods of mixing resulted in reduction of expansive potential of mortars which were wet-screened from concretes mixed for either 45 seconds or 10 minutes. It was felt that this reduction was due both to grinding and abrasion

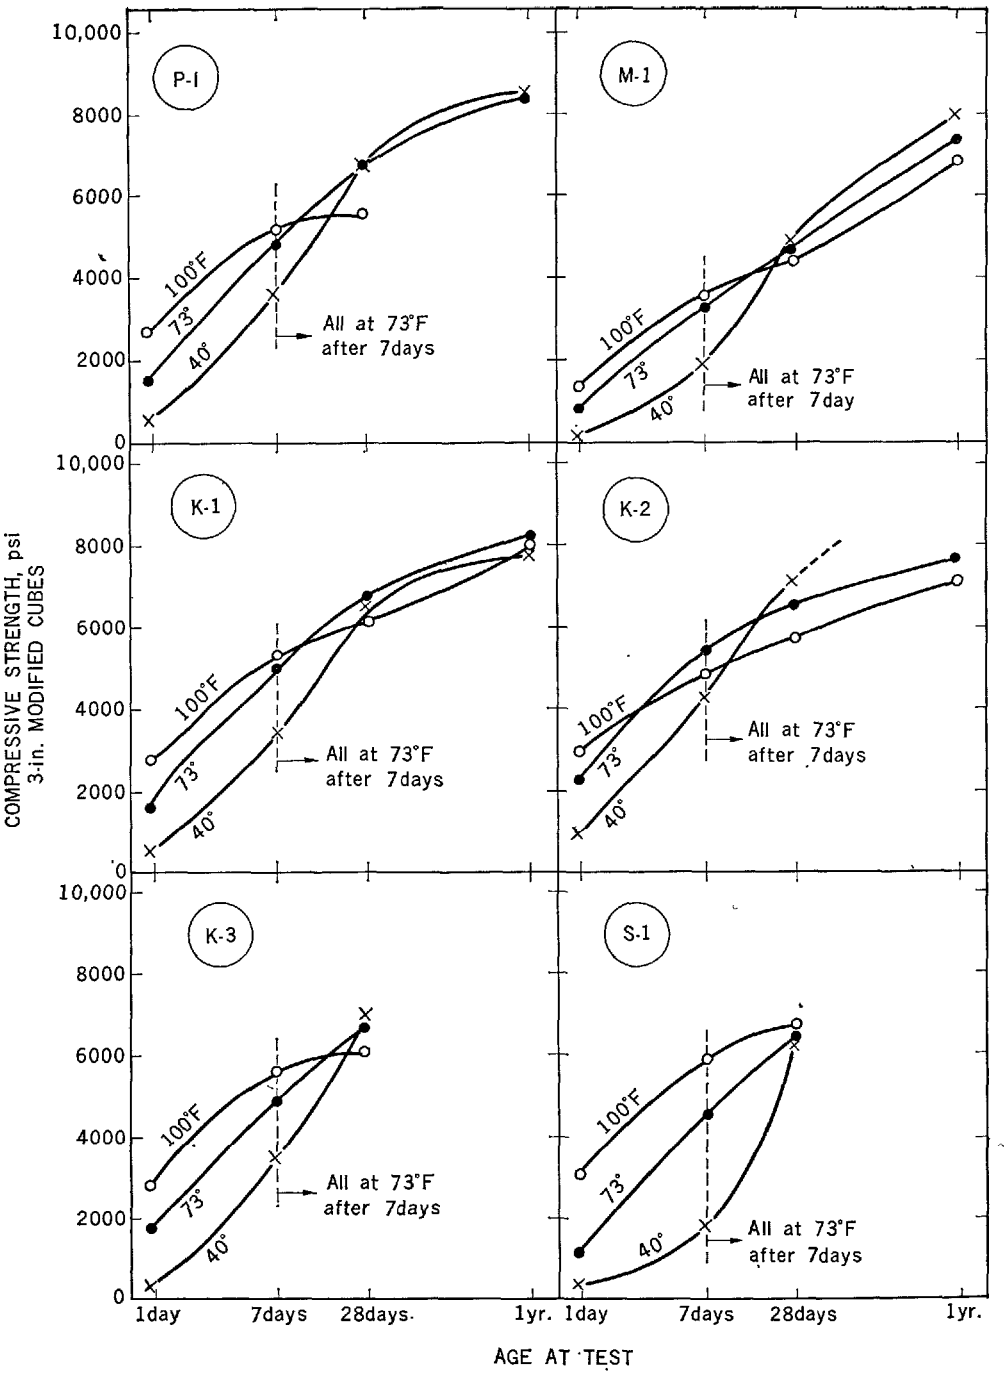

Fig. 4. *Effect of curing temperature on compressive strength*
Concretes cast at 73°F, then immediately to temperature shown for first 7 days

of hydrate coatings, thus accelerating the reaction between sulphates and aluminates (the expansive mechanism in the hardened concrete) before the concrete sets. All of the shrinkage-compensated cements were used in repeat batches which were mixed continuously for different periods of time: 1, 2-1/2, 10 and 30 minutes. Table 7 shows data on resulting slumps and air contents, on the unrestrained expansion during 28 days of moist curing at 73°F, on shrinkage on drying for the next 28 days, and on strengths at 56 days.

Fig. 8 shows the unrestrained expansions as a function of mixing time. Extension of mixing time beyond 2-1/2 minutes significantly reduces the expansive potential. In some cases, the expansions for the 2-1/2 minute mixing times were less than for the 1-minute

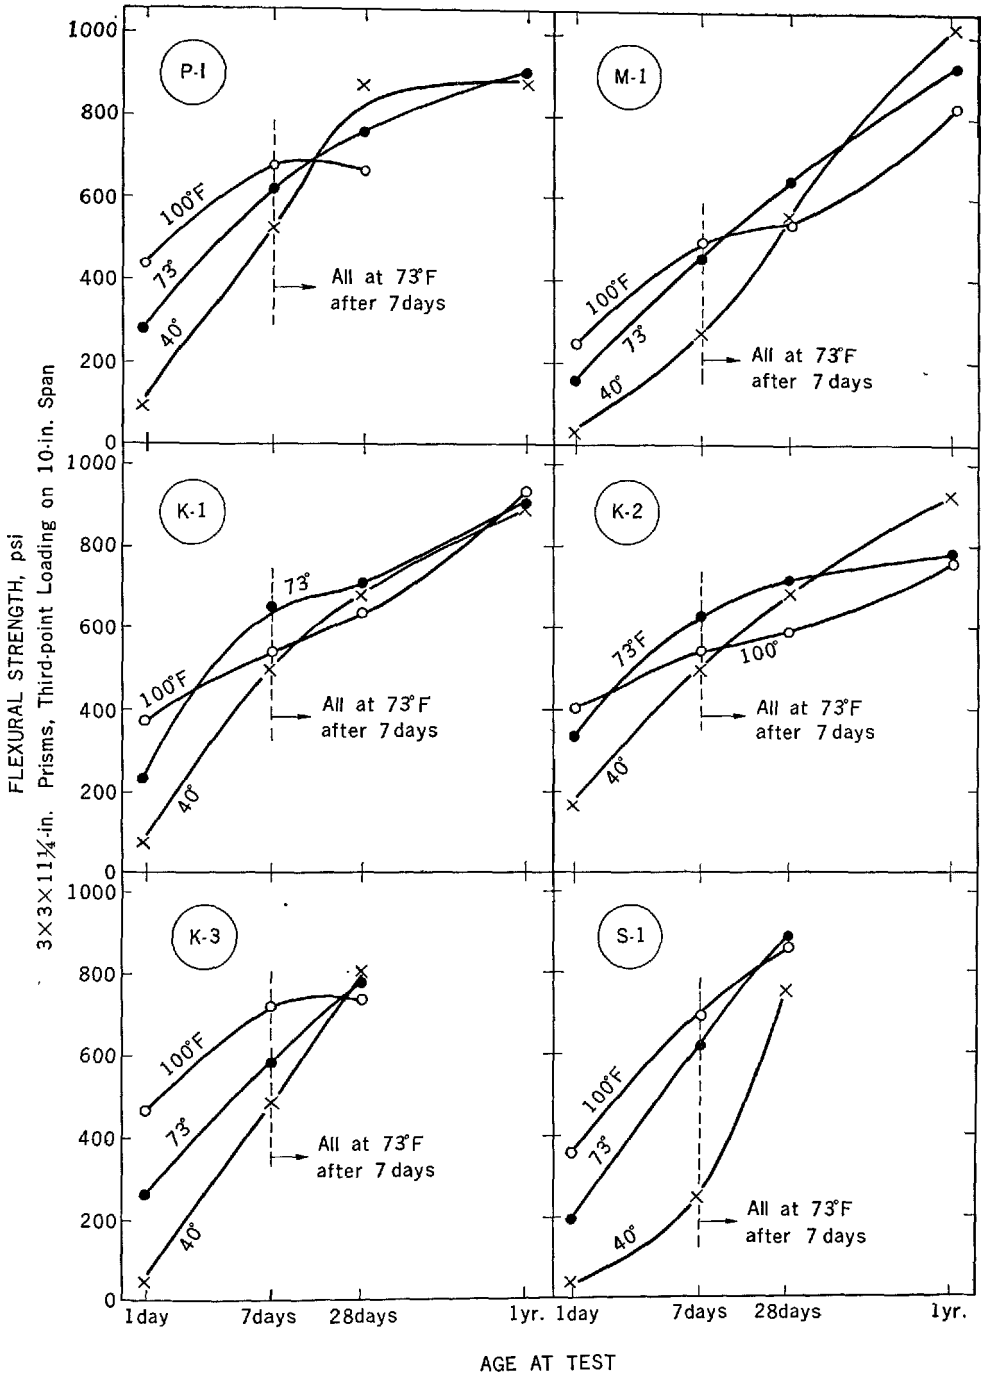

Fig. 5. *Effect of curing temperature on flexural strength*
Concretes cast at 73°F, then immediately to temperature shown for first 7 days

mixing time, in other cases the reverse was true. This latter situation might be attributable to differences in mold stripping time, since the 1-minute mix for Cement M-1 and Cement S-1 required a little more mold time to enable handling without damage, thus possibly losing some of the expansive potential. Verification of this effect is shown for Cement K-1 at 10-minute mixing time, for which two different mold times were used. Those specimens stripped at 5 hours showed significantly more expansion than those stripped at 6 hours. In the case of Cement M-1, which was a blend made at the mixer, the 1-minute mixing time may have been inadequate for uniform distribution of the ingredients.

(1)35 days.
(2)63 days.

The data indicate further that for any particular continuous mixing time, expansion reached a maximum at about 3 days, with only additional small increments at 7 days and essentially none at 28 days.

The 28-day drying shrinkages are essentially equal, showing no effect of mixing time. Strengths appeared to be influenced primarily by changes in air content which resulted from the different mixing times, i.e. increases in air volume resulted in lower strengths, and vice versa.

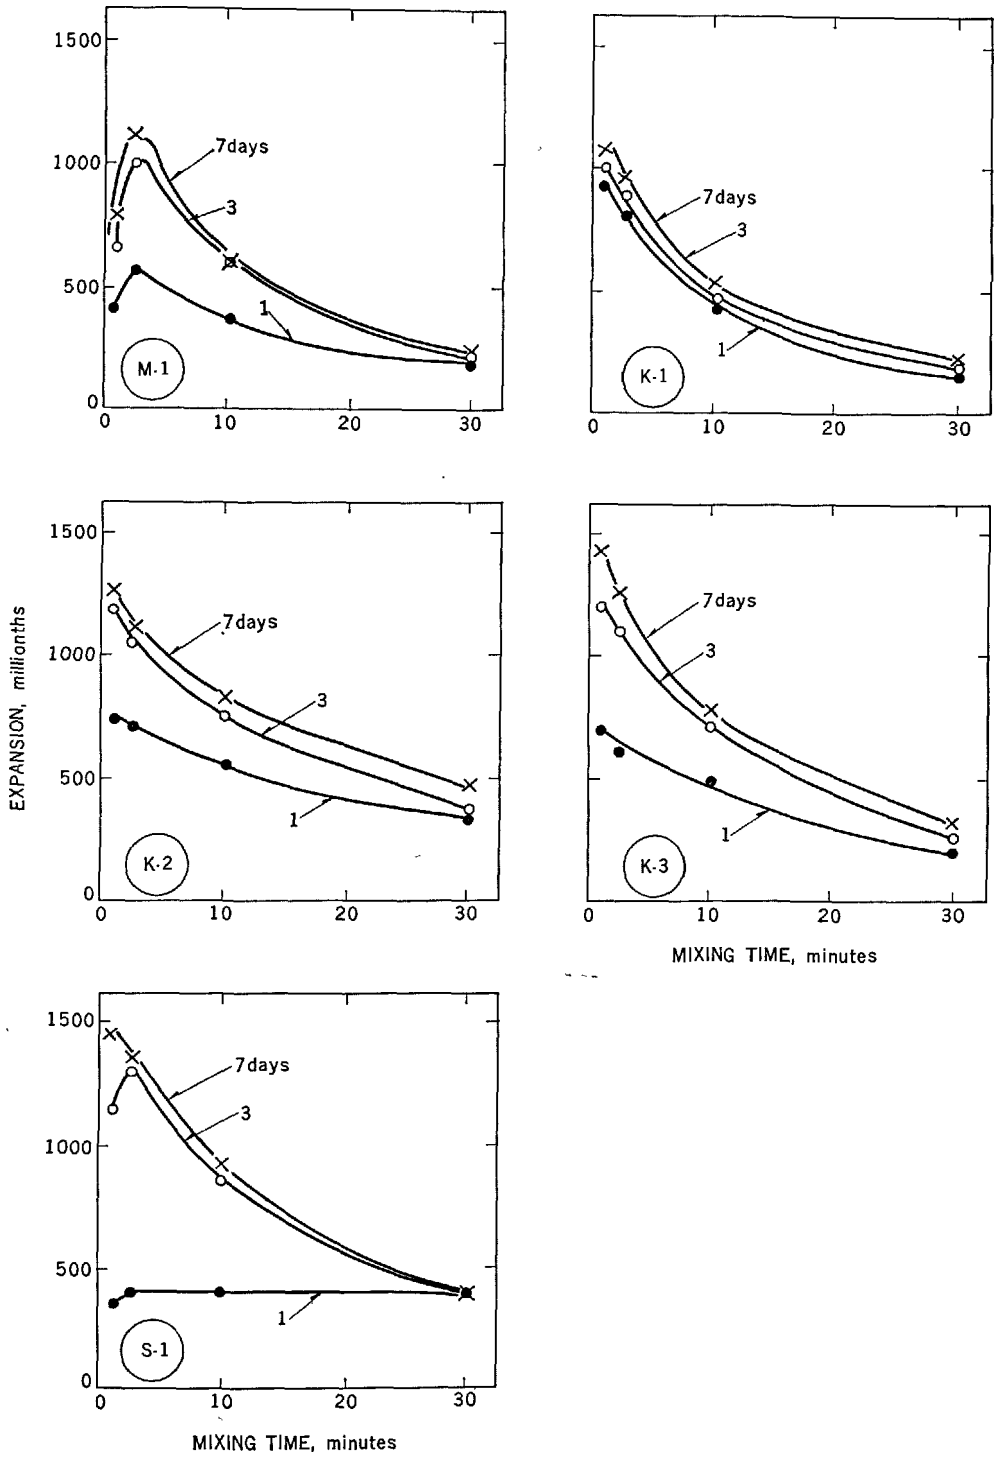

Fig. 8. *Effect of mixing time on unrestrained expansion* $3 \times 3 \times 11^1/_4$-in. *prisms*

Effect of Continuous Moist Storage and Air Drying

Fig. 9 shows the expansions of unrestrained prisms cured continuously moist at 73°F and the shrinkages of companion concretes subjected to drying at 50% R.H. after an initial 7-day moist curing period. Concrete mix data are shown in Table 5. Note that expansions during continued moist storage remain constant after 7 days, with different maxima obtained for the different shrinkage-compensating cements. The

Table 8. *Effect of curing and storage temperature on expansion and stability in wetting and drying*
Specimens are 3 × 3 × 11¼-in. unrestrained concrete prisms all cast at 73° F, cured in molds at temperatures shown, then stored in moist room or water at temperatures shown for 7 days. After an additional day to equilibrate at 73° F where required, all prisms subjected to cycles of 14 days wetting and 14 days of drying at 73° F.

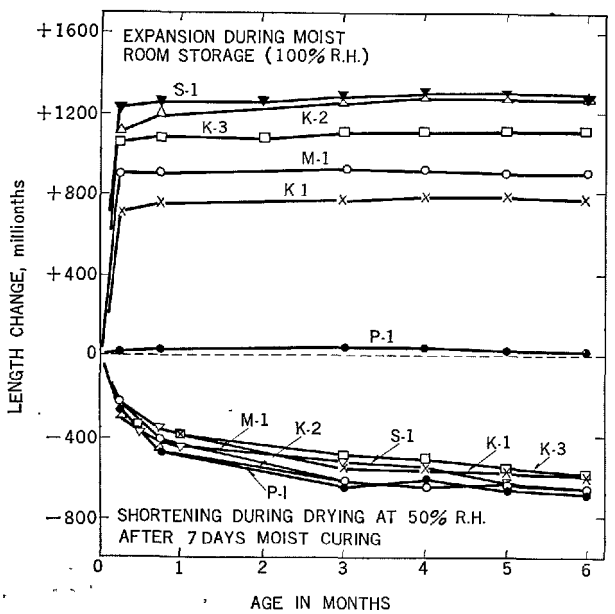

Fig. 9. *Length changes during moist storage and air drying for extended periods*
Unrestrained prisms

concretes made with Cement P-I (ASTM Type I) show the usual very low expansions during moist storage.

The magnitude of drying shrinkages for all of the concretes, including Cement P-I, are quite similar.

Volume Stability on Wetting and Drying as Influenced by Prior Curing

Unrestrained concrete prisms were cast at 73°F, kept in molds at temperatures and for times shown in Table 8, and then subjected to moist curing and to water curing at 40, 73 and 100°F for 7 days. One group was also sujected to steam curing at 160°F, followed by moist curing and water curing at 73°F. All specimens were equilibrated to 73°F on the 8th day, for both the moist and water curing environments and then subjected to alternate cycles of wetting and drying (14 days immersion in 73°F water followed by 14 days of drying at 73°F and 50% R. H.).

Table 8 shows the expansions which took place during the 8-day period described above for these concretes and the residual expansion after cycles of

wetting and drying for, in most cases, as long as 1 year. Note that all of the concretes show excellent stability to these alternate cycles of wetting and drying.

The effect of curing temperature on the level of expansions is somewhat variable. For Cements M-1, K-1, and K-2, the 7-day expansion level attained generally decreased as curing temperature increased. For Cement K-3, the 7-day expansions at 40 and 100°F were similar, but at 73°F the expansions were significantly lower. For Cement S-1, the 7-day expansions were greater at 73°F than at either 40 or 100°F. There seems to be no consistent effect attributable to the time the specimens were in the mold prior to stripping. After equilibration to 73°F on the 8th day, the residual expansions as a function of initial 7-day curing temperature show excellent correlation except for Cement K-3, with the residual expansion increasing as curing temperature decreased. This is in line with the lower strengths at lower temperatures, i.e. less "internal restraint" in these unrestrained prisms.

Resistance to Freezing and Thawing and De-Icer Scaling

Table 5 shows the mix data for the concretes used in this portion of the program. Concretes for these durability tests were cast and cured moist at 73°F for 14 days, followed by 14 days of air-drying at 50% R.H. The prisms were then soaked in water at 73°F prior to the start of freezing and thawing and the top surfaces of the slabs were covered with water for 3 days prior to the start of de-icer scaling tests.

Tables 9 and 10 show the length change data for the unrestrained and restrained prisms and slabs at various stages of this prior curing treatment. In addition, the tables show the calculated stresses in both the reinforcing steel and the concrete of the restrained specimens. At maximum expansions during moist storage (7 or 14 days), the restrained expansions of the prisms ranged from 52 percent to 72 percent of the unrestrained prism expansions. For the slabs, the range was 45 percent to 56 percent. These percentages did not appear to be influenced by the level of unrestrained expansion. Drying shrinkage during the following 14-day drying period were essentially similar for all concretes and the two types of specimens. On rewetting for 3 days, the prisms regained about two-thirds of the expansion lost during drying. The slabs regained only about 15 to 20 percent of the expansion during the 3 days with water on the top surface.

[a] Minus indicates compression in steel and tension in concrete.
[b] U = unrestrained, R = restrained, 0.89% steel, welded-wire-fabric.

The compressive stresses in the restrained concrete prisms (0.3% steel) and slabs (0.89%) were quite similar at the end of the 14-day moist curing period, ranging from 43 to 68 psi for the prisms and 83 to 149 psi for the slabs. The concrete stresses in the restrained slabs were higher than those in the restrained prisms by about 90 percent. Earlier work (1) with slab specimens and different amounts of steel ranging from 0.7% to 1.8% showed that concrete stress was relatively independent of the amount of reinforcement, at least at these percentages of reinforcement. During the 14-day drying period, a substantial proportion of this compressive stress was lost due to drying shrinkage, but for the prisms at least most of this loss was recovered on subsequent wetting.

Table 11 shows the expansion of concrete prisms, based on the 31-day length, at 100, 300, and 500 cycles of freezing and thawing in water, along with the durability factors calculated from changes in fundamental transverse frequency at 300 cycles. In addition, the weight changes of prisms after 300 cycles are shown.

The concretes made with Cement K-3 did not

perform as well as the others. Durability factors were somewhat lower, but still excellent. Weight loss, however, was quite high and de-icer scaling resistance significantly lower. All of the other air-entrained concretes, restrained or unrestrained, show excellent resistance to freezing and thawing and de-icer scaling.

Creep of Unrestrained Concretes

The mix data for the concretes used in casting 6 × 12-in. cylinders for creep and supplementary drying shrinkage tests are shown in Table 5. These cylinders were cured 7 days moist at 73°F and then loaded to a stress level of 1600 psi, except for those made with Cement M-1 which were loaded to 1200 psi due to somewhat lower 7-day strength. Creep tests were conducted at 73°F and 50% R. H.

Table 12 shows the modulus of elasticity for these concretes calculated from the immediate strain on loading and the creep strain per psi after 28 days, 9 months and 1 year of sustained loading (9-month and 1-year data for Cements K-3 and S-1 not yet available). Moduli and creep strain values are reasonably similar. Fig. 10 shows the creep strains and drying shrinkages plotted as a function of time. Concretes made with Cements K-2 and M-1 show significantly greater creep strain per psi than the other concretes. The K-2 concrete required more water and hence had a higher water-cement ratio than the others, however the 7-day strength was about equal to those for Cements K-1,

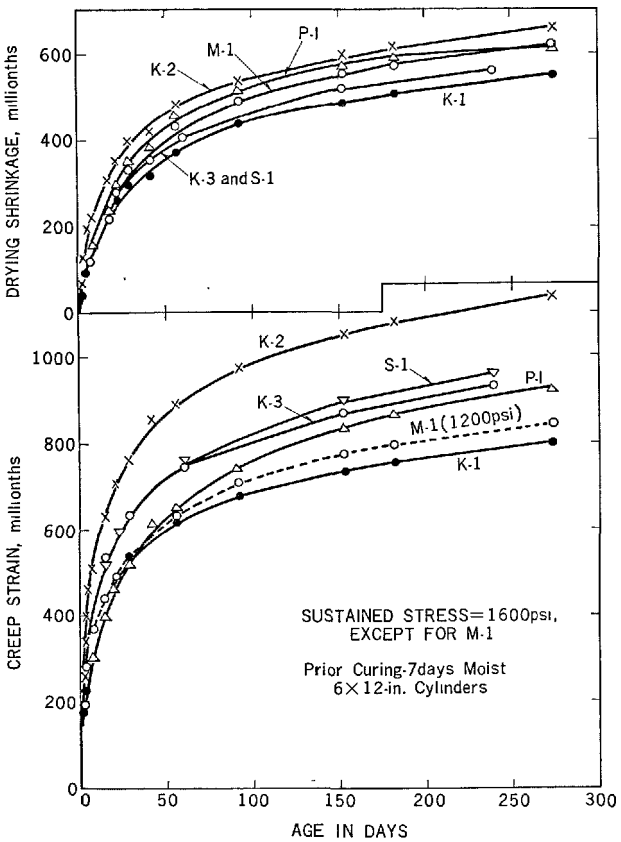

Fig. 10. *Creep and drying shrinkage of concretes*

K-3 and S-1. The 7-day strength of the concrete made with Cement M-1 was significantly lower. All of the concretes showed similar drying shrinkages, as were the case in the prism and slab tests.

Resistance to Sulphate Solution

In these tests, the performance of the shrinkage-compensated concretes was compared with concretes made with Cement P-II (ASTM Type II) and Cement P-V (ASTM Type V). Mix data for these air-entrained concretes are shown in Table 5. Concretes were cured moist at 73°F for 7 days and then kept continuously immersed in a 10 percent sodium sulphate solution at the same temperature.

Table 13 shows the expansions of unrestrained and restrained prisms during the initial 7 days of moist curing and additional expansions which occurred during immersion in the sulphate solutions. Concretes made with Cements P-II and P-V (ASTM Type II and V) showed exceedingly small expansions after 16 months' exposure. All of the shrinkage-compensated concretes show large additional expansions considerably earlier, particularly the unrestrained

concretes. Although the restraint provided by the steel reinforcement afforded marked improvement in performance, the level of additional expansions would indicate that these shrinkage-compensated concretes are not able to resist this continuous exposure to concentrated sulphate solutions. Higher percentages of steel reinforcement than that used, 0.30 percent, would probably be helpful in such exposures. In addition, a lower water-cement ratio, richer mix would also be helpful, since numerous studies of sulphate attack have shown the importance of low water-cement ratio in such exposures. Additional work in this area is planned, including also exposure to seawater.

Resistance to Abrasion

Four of the Cements (P-I, M-1, K-1, and K-2) were used in making unrestrained and restrained concrete slabs for evaluating resistance to abrasion. Table 14 shows pertinent mix data, compressive strengths at 28 days and 1 year, and the average abrasion loss for these slabs. Note that the abrasion specimens were given only 7 days of moist curing and were dried at 50% R.H. at least 1 year before being subjected to test.

Although the repeatability and accuracy of the abrasion test requires more than duplicate test specimens, the results indicate that the shrinkage-compensated concretes made with Cements K-1 and K-2 may be somewhat more resistant to abrasion than the

Table 14. *Abrasion resistance of concretes*

Specimens for abrasion tests (2 per mixture) were 12-in. square by 3-in. deep, with steel-troweled surfaces.
Curing for abrasion specimens was 7 days moist at 73°F, then to air of laboratory at 73°F and 50% R.H. until test at ages of 12 to 15 months.
Strength specimens were 3-in. modified cubes, cured continuously moist.
Restrained abrasion specimens reinforced with 1/4 in. diameter continuously threaded rods in both 12-inch directions. Percentage reinforcement in each direction = 0.30%.
Abrasion machine used dressing wheel units.

Mix designation	Net w/c, by wt.	Slump, in.	Air content, %	Comp. str., psi		Average abrasion loss after 20 minutes, mils	
				28d.	1 yr.	U(1)	R(1)
P-I	0.42	3.0	5.85	6720	8370	293	286
M-1	0.44	2.7	6.00	4730	7400	359	266
K-1	0.40	2.6	5.90	6710	8180	146	114
K-2	0.46	2.7	5.65	6540	7680	192	187

(1)U = unrestrained.
R = restrained.

concrete made with Cement P-I. The Cement M-1 shrinkage-compensated concrete showed less resistance to abrasion than the Cement P-I concrete, probably a reflection of its lower 28-day strength. In this instance, restraint was helpful in reducing abrasion loss. For Cements K-1, K-2 and P-I, restraint appeared to have little influence on abrasion loss.

Influence of Cement Content on Strength and Volume Stability

Using Cement K-1, concretes containing 564 lb (6 U.S. bags) and 752 lb (8 U.S. bags) of cement per cubic yard were prepared to compare strength and volume stability. The mix data for these concretes are shown in Table 15. Specimens were unrestrained prisms. For both cement contents, a mold stripping time of 6 hours was observed. In addition, for the 752 lb of cement/cu yd mix a mold stripping time of 18 hours was used. Those for strength tests were cured continuously moist at 73°F. Volume stability prisms were cured 7 days moist or 7 days in water at 73°F, then subjected to the wetting and drying cycles described earlier.

Table 16 shows the compressive and flexural strength data for these concretes. The 752 lb of cement/cu yd concretes showed somewhat higher strengths than the 564 lb of cement/cu yd concretes, except for the 1-year compressive strengths. The effect of mold stripping time on the higher cement content concrete

(a)lb of cement/cu yd.

strengths did not appear to be significant.

Table 17 shows the expansions during 7 days of moist storage or water storage and the residual expansions after 1 year of wetting and drying. The expansions in water storage were significantly greater than those in moist storage. For the higher cement content, the 18-hour mold stripping time resulted in large reductions in expansion. Longer time in the mold results in less total expansion remaining. This lower remaining expansion must also operate against a stronger concrete at 18 hours than one at 6 hours.

Residual expansions after 1 year of wetting and drying cycles indicate concretes of both cement contents to be quite volume stable.

Summary

This report presents data on a variety of engineering properties of air-entrained concretes made with expansive cements of the shrinkage-compensating type. These cements were used in concretes having 564 lb (6 U.S. bags) of cement per cubic yard and suitable for general cast-in-place construction work, for pavements, for precast concrete units, and for other uses of concrete as a construction material. Both unrestrained concretes and restrained concretes (internal steel reinforcement, etc.) were included in these tests.

The shrinkage-compensating cements used included three Type K cements, one Type M cement, and one Type S cement, as they are defined in the American Concrete Institute's "Cement & Concrete Terminology" (SP-19). For comparison purposes, the tests included one each of ASTM Types I, II, and V portland cements.

The tests included an evaluation of strength development as influenced by curing history, the effect of mixing time on expansive potential, the volume stability in continuous moist or air storage and after numerous wetting and drying cycles, the creep under sustained stress, the resistance to freezing and thawing and de-icer scaling, the resistance to sulphate exposure, and the resistance to abrasion.

The results of these tests showed that the strength development characteristics of these concretes in response to curing environment are similar to normal portland cement concretes, that their volumes change and creep characteristics after attaining their designed maximum expansion are comparable to those of portland cement concretes, that they are equally resistant to freezing and thawing and de-icer scaling. Where abrasion tests were conducted, abrasion resistance of restrained specimens was at least comparable to normal portland cement concrete. There was significantly less resistance to sulphate attack, however, than for the concretes made with the ASTM Type II and V portland cements. This defect might be offset by the use of a lower water-cement ratio, richer concrete and a greater percentage of steel reinforcement to provide more restraint to expansion resulting from sulphate attack.

With respect to expansive potential, the data indicate that higher curing temperatures generally resulted in lower expansions and that increased continuous mixing time markedly reduced the level of expansion.

SESSION IV-5 BY-PRODUCT GYPSUM FROM VARIOUS CHEMICAL INDUSTRIES, AS A RETARDER FOR THE SETTING OF CEMENT

Principal Paper Utilization of Chemical Gypsum for Portland Cement

Keiichi Murakami*

Synopsis

Chemical gypsums, the by-products from various industries, are regarded as a main source of gypsum for control of the setting time of portland cement and portland blastfurnace slag cement in Japan. Phosphogypsum is a by-product of phosphoric acid manufacture. The quantity of its production is the largest among chemical gypsums. Therefore, phosphogypsum is now the most important among chemical gypsums. However, it is well known that the impurities usually included in phosphogypsum injuriously affect the hydration of portland cement. The object of this paper is to clarify the characters of impurities in phosphogypsum as well as to understand the effects of impurities on the hydration of cements.

The impurities which mainly affect the hydration of portland cement are P_2O_5 substituted in the crystal lattice of gypsum, the water-soluble P_2O_5 and the water-soluble F which adhered to the surface of gypsum crystals. The analytical procedures for these impurities have been proposed and proved to be useful and successful. The impurities in phosphogypsum generally retard the setting of portland cement, but do not affect the development of three day strength of mortar.

The large quantities of phosphogypsum are now produced from the hemihydrate-dihydrate process in Japan. Since the phosphogypsum produced from the dihydrate process has a relatively large amount of impurities, it is neutralized with milk of lime after dehydration of phosphogypsum.

The grinding of portland cement clinker together with natural gypsum of a higher grade or chemical gypsum requires a larger power consumption than with natural gypsum of a lower grade. The power consumption in grinding, in particular, at a temperature of over 130°C, increases more markedly than at ordinary temperature. The clay minerals included in natural gypsum of the lower grade tend to improve the grindability at a higher as well as lower temperature.

The retarding action of the impurities in phosphogypsum was investigated by measuring the rate of heat liberation of cement hydration with calorimeter and the specific surface area of the hydration products as well as the electron microscopic observation of the hydration products. It has been consequently suggested that the insoluble compounds produced by the reaction between the impurities in phosphogypsum and the high-lime surface of cement grains or lime in the liquid phase of paste form the protective coatings on the surface of cement grains and that they retard temporarily the hydration of portland cement.

The advantages brought by the utilization of the waste products such as chemical gypsum are so great that the present success in Japan will surely become a valuable example.

*Faculty of Engineering, Tohoku University, Sendai, Japan.

Introduction

Generally, the by-product gypsum made from various industries is called "chemical gypsum" in Japan. These chemical gypsums are regarded as the valuable sources of raw material in making gypsum board, gypsum plaster, and of gypsum for control of the setting time of portland cement because the abundant sources of natural gypsum have not been found in Japan.

By the recent development of the gypsum production technique, most types of chemical gypsum have the specific properties satisfying the requirment.

Since the production of phosphogypsum is the largest among the chemical gypsums, it is regarded as a valuable source of gypsum for the portland cement industry which requires the largest amounts of gypsum. It has been demonstrated that phosphogypsum containing the impurities of over some quantities injuriously affects the early stage of the hydration of protland cement.

The purpose of this paper is to clarify the characteristics of impurities in phosphogypsum and the intrinsic features of its influence on the hydration of portland cement. The author believes that the results of these studies will be useful in the various applications of chemical gypsum.

Recent Features of Chemical Gypsums in Japan

The Kinds, Productions, Production Reactions, Consumption and Chemical Compositions of Chemical Gypsums

Chemical gypsum is by-produced from various industries. Table 1 shows the most of representative chemical gypsums and their production reactions (1–4). The content of SO_3 of natural gypsum in Japan is approximately 30% to 40%. The grade is generally poor. On the contrary, chemical gypsum has a higher content of SO_3 as shown in Table 2 (5). Table 3 shows the history of the production, the estimation of the production of natural gypsum and their consumptions respectively in Japan for the period from 1965 to 1968 (6). These data also indicate that phosphogypsum, which is the largest in production, is the most valuable source for the set control of portland cement above other chemcial gypsums.

Phosphogypsum and Wet Process in Making Phosphoric Acid

Operations of the wet process in making phosphoric acid ate closely related to the compatibility of hosphogypsum for controlling the setting time of portland cement because phosphogypsum is a by-product in making phosphoric acid. Photo 1_{-i} shows a optical microphotograph of the agglomerated phosphogypsum produced from the conventional dihydrate process. This agglomerated phosphogypsum includes the relatively large amounts of impurities in the interstice among the crystals and in the lattice of phosphogypsum crystals. It will be later clarified that the agglomerated phosphogypsum must be regenerated by the special chemical treatments to be used for controlling the setting time.

There are many reports on the dihydrate process in making phosphoric acid (7–10). Murakami and Hori (11, 12) established the hemihydrate-dihydrate process, by which the recovery of phosphoric acid is higher than by dihydrate process and the quantity of impurities in the by-produced phosphogypsum is less than that in phosphogypsum produced from dihydrate process.

At the present time many plants using this hemihydrate-dihydrate process are operating industrially in Japan (13–26) and also a plant in China. Recently, some new processes directly producing the concentrated phosphoric acid and hemihydrate or anhydrite have been investigated (27, 28).

Qualities of Chemical Gypsum as Gypsum for Control of the Setting Time of Portland Cement

It has been well known that phosphogypsum and fluorogypsum contain some amounts of impurities which unfavorably affect the hydration of portland cement. Most of the previous works have reported

Table 1. *Various chemical gypsums and their production reactions*

No. A	Chemical gypsum by reaction phosphate rock and sulfuric acid. "Phosphogypsum" $Ca_3(PO_4)_2 + 3H_2SO_4 + 6H_2O = 3CaSO_4 2H_2O + 2H_3PO_4$ (Dihydrate Process) $Ca_3(PO_4)_2 + 3H_2SO_4 + 3H_2O = 3CaSO_4 \cdot 1/2H_2O + 2H_3PO_4 + 3/2H_2O$ $CaSO_4 \cdot 1/2H_2O + 3/2H_2O = CaSO_4 \cdot 2H_2O$ (Hemihydrate-dihydrate process)
No. B	Chemical gypsum by reaction of calcium compound with sulfate in making NaCl from sea water. "Saltgypsum" $MgSO_4 + CaCl_2 + 2H_2O = MgCl_2 + CaSO_4 \cdot 2H_2O$
No. C	Chemical gypsum by reaction of fluorite and sulfuric acid in making HF. "Fluorogypsum" $CaF_2 + H_2SO_4 = 2HF + CaSO_4$ (Anhydrite) $CaSO_4 + 2H_2O = CaSO_4 \cdot 2H_2O$
No. D	Chemical gypsum by neutralization reaction of waste sulfuric acid in making TiO_2 from ilmenite. "Titangypsum" $FeOTiO_2 + 2H_2SO_4 = TiOSO_4 + FeSO_4 + 2H_2O$ $TiOSO_4 + 2H_2O = TiO(OH)_2 + H_2SO_4$ $FeSO_4$ or $H_2SO_4 + CaCO_3$ or $Ca(OH)_2 \longrightarrow CaSO_4 2H_2O$
No. E	Chemical gypsum by neutralization reaction of $CaCO_3$ and $Ca(OH)_2$ with waste sulfuric acid in pickling process of iron making. $H_2SO_4 + CaCO_3 + H_2O = CaSO_4 2H_2O + CO_2$ $FeSO_4 + Ca(OH)_2 + 2H_2O = CaSO_4 2H_2O + Fe(OH)_2$
No. F	Chemical gypsum by neutralization reaction with calcium compounds to waste sulfuric acid in refining of cuporus sulfate and zink sulfate. $H_2SO_4 + CaCO_3 + H_2O = CaSO_4 2H_2O + CO_2$
No. G	Chemical gypsum by oxidation and neutralization reaction of SO_2 in combustion gas, exhaust gas from various industries or power plant. $SO_2 + Ca(OH)_2 = CaSO_3 1/2H_2O$ $2CaSO_3 \cdot 1/2H_2O + O_2 + 3H_2O = 2CaSO_4 2H_2O$
No. H	Chemical gypsum by reaction of $CaCl_2$ with Na_2SO_4, from soda ash industry and rayon industry, respectively. "Soda-gypsum" $CaCl_2 + Na_2SO_4 + 2H_2O = CaSO_4 2H_2O + 2NaCl$
No. I	Chemical gypsum by reaction of $CaCO_3$ with aluminum sulfate from activation process of Japanese acid clay. $Al_2O_3 4SiO_2 2H_2O + 3H_2SO_4 = Al_2(SO_4)_3 + 4SiO_2 + 5H_2O$ $Al_2(SO_4)_3 + m_1CaCO_3 + H_2O = m'Al_2(SO_4)_3Al(OH)_3 + CO_2 + CaSO_4 2H_2O$ $m'Al_2(SO_4)_3Al(OH)_3 + m_2CaCO_3 = m''Al_2(SO_4)_3Al(OH)_3 + CO_2 + CaSO_4 \cdot 2H_2O$
No. J	Chemical gypsum in making phenol and humic acid. $(COO)_2Ca + H_2SO_4 + 2H_2O = (COOH)_2 + CaSO_4 2H_2O$
No. K	Chemical gypsum by reaction of ammonium sulfate with $Ca(OH)_2$. $(NH_4)_2SO_4 + Ca(OH)_2 = 2NH_3 + CaSO_4 2H_2O$

In this paper, each chemical gypsum is described as special name or numbered chemical gypsum as shown in this table.

that the impurities of phosphogypsum are the reaction products in the wet process and the impurities in phosphate rock, such as phosphoric acid, alkali silico-fluoride, monocalcium phosphate, dicalcium phosphate, some organic substances, undecomposed phosphate rock, quartz and other inorganic oxides (29–34).

The water-soluble compounds among them are likely to affect injuriously the hydration of portland cement. A large portion of impurity is found on the surface of gypsum crystals and in the interstice of

agglomerated crystals. Some portions of phosphate enter into solid solution with gypsum by the substitution of HPO_4^{--} for SO_4^{--}, because the both crystals have the similar lattice parameters and belong to the analogous space group.

Optical microphotographs of several phosphogypsums are shown in Photograph 1 by Murakami, Tanaka and Sato (35). The appearances of phosphogypsum HDS-1, 2 and 3 produced from the hemihydrate-dihydrate process show the unagglomerated single crystal or twin crystal with the smooth surface, that the impurities which adhered to the surface are easily removed by a single washing with water. Phosphogypsum HD shown in Photo 1 is also a by-product from the hemihydrate-dihydrate process. Except for phosphogypsum HD-2, however, other phosphogypsums-HD have a large amount of the agglomerated crystals which are resulted from the incomplete decomposition of phosphate rock in the digestion step of the wet process. All phosphogypsum D-1 by-produced from the dihydrate process are agglomerated crystal, the impurities of which

are impossible to be removed by a single washing with water or lime water.

Table 4 shows the both lattice parameters of dicalcium phosphate dihydrate ($CaHPO_4 2H_2O$) and gypsum ($CaSO_4 2H_2O$) (36). Maki and Suzukawa (37), using infrared spectroscopy, reported that phosphogypsum showed, besides the absorption spectrum of gypsum, weak absorption at 1015 cm^{-1} and 837 cm^{-1} in the related characteristic absorption bands of HPO_4^{--} (Fig. 1). From the study on the absorption of the system $CaSO_4 2H_2O$–$CaHPO_4 2H_2O$, these displacements can be ascribed to the formation of the solid solution of gypsum with dicalcium phosphate dihydrate equivalent to the amount of P_2O_5 in the

crystal lattice of phosphogypsum. Recent work by Dahlgren (38) also indicates that the amounts of HPO_4^{--} substituted in the crystal lattice of phosphogypsum vary with changing the concentrations of phosphoric acid and sulfuric acid during the operation of the wet process.

Kusano (33, 34, 39), through the measurement of average molecular weight, the infrared abosrption spectra, the detection of functional radicals and the spot test proposed the chemical structure of organic substance in phosphogypsum. Namely, he got the acidic and neutral substance by treating with sodium hydroxide the matters extracted from phosphogypsum by ether and ethanol. The former is a family of carbonic acids. The latter is a family of aliphatic ketons. The number of carbon atoms in a molecule of each compound is approximately from ten to thirty-five. Fig. 2 shows the infrared absorption curve of organic matter extracted from phosphogypsum by ether. The absorptions at 1710 cm^{-1} and 2900 cm^{-1} indicate that $>C=O$ or $-\underset{\underset{OH}{|}}{C}=C$ and $-\underset{|}{CH}$ is respectively included in the structure of above substance.

Analytical Procedure of the Impurities in Phosphogypsum

Gypsum contained in cement enters into water immediately after cement comes contact with water and then reacts with the components of cement. How the impurities of chemical gypsum affect the hydration of portland cement varies with the kinds, amounts and locations of impurities presenting in chemical gypsum. In order to estimate the effect of impurities on the hydration of portland cement, the appropriate analytical procedure for the impurities in phosphogypsum must be established.

The existing analytical procedure specified in JIS (40) lay some emphasis on the quantitative analysis of the main component of gypsum, such as CaO, SO_3, H_2O etc., but does not refer to the analysis of the impurities.

In large user of chemical gypsum, such as manufacturer of portland cement, gypsum plaster and

gypsum board, the arbitrary procedures devised by themselves have been used for analysis of the impurities in phosphogypsum. Some results obtained by these procedures indicated that the exact distribution of the impurities in phosphogypsum is not shown frequently and that the analytical procedures are also unfavorable.

In order to improve the existing analytical procedure of the impurities in phosphogypsum, Murakami (35), considering the varieties of crystals of phosphogypsum as illustrated in Photo 1, assumed that the impurities are in the following states; adhering to the surface of crystals of phosphogypsum, settling in the space among crystals of the agglomerated phosphogypsum, solid-soluting in the crystal lattice of phosphogypsum, and remaining in undecomposed phosphate rocks. Then the items of analysis to be accomplished are shown as follows;

1) The water-soluble P_2O_5 adhered to the surface of phosphogypsum—Aw.P_2O_5
2) The water-insoluble F adhered to the surface of phosphogypsum—Ai.F
3) The water-soluble P_2O_5 substituted in the crystal lattice of phosphogypsum —Ss.P_2O_5
4) Total P_2O_5—T.P_2O_5
5) Total F—T.F

Analytical Procedure

Samples of phosphogypsum must be previously pulverized under 325 mesh.

Aw.P_2O_5 (Sum of the water-soluble phosphates, such as phosphoric acid, monocalcium phosphate and dicalcium phosphate).

The pulverized phosphogypsum (10 g) is boiled for thirty minutes with stirring in distilled water (300 ml) saturated with pure gypsum. Then, the resultant suspension is filtered. The soluble P_2O_5 in the filtrate is determined colorimetrically by the molybdovanadophosphoric acid method.

Ss.P_2O_5 (Phosphate in the crystal lattice of phosphogypsum).

The pulverized phosphogypsum (20 g) is boiled for thirty minutes with stirring in distilled water (200 ml) with acid mixture (5 ml) consisted of one volume of concd.HNO_3 and three volumes of concd.-HCl. The resultant suspension is filtered. The residual gypsum crystals are washed with distilled water and then dried. Gypsum (1 g: accurately weighed to mg unit.) with the crystal surface which was cleaned by the aforementioned treatment is completely dissolved in distilled water (200 ml) with concd.HCl (5 ml). Then, P_2O_5 in solution is determined colorimetrically, as in the case of Aw.P_2O_5.

Ai.F (Sum of the water-insoluble F, such as calcium fluoride and undecomposed phosphate rock).

The pulverized gypsum (10 g) is boiled for thirty minutes with stirring in distilled water (500 ml to 700 ml). Then, the resultant suspension is filtered. The residual gypsum is washed and dried. The water-soluble impurities adhered to the surface of crystals of phosphogypsum will be completely removed by these treatment. The resultant gypsum (0.1 g to 0.5 g: accurately weighed to mg unit) with cleaned surface is steam-distilled in the presence of sulfuric acid and the finely powdered silica.

The vaporized silicon fluoride enters into the sodium hydroxide solution and forms sodium silicofluoride. The water-soluble F in sodium silicofluoride is determined colorimetrically by the Th-alizaline or Th-neothorine method (41–49).

T.P_2O_5 (Sum of the water-soluble and water-insoluble phosphates, such as phosphoric acid, monocalcium phosphate, dicalcium phosphate and undecomposed phosphate rock).

The pulverized gypsum is dissolved in mixed acid solution consisted of one volume of concd.HNO_3 and three volumes of concd.HCl. The solution is completely evaporated on a water both or sand bath. The residual substance is dried until the residual HCl is removed completely. This substance is dissolved again in dilute HCl. P_2O_5 in the solution is determined colorimetrically as in the case of Aw. P_2O_5 (50–52).

T.F (Sum of the water-soluble and water-insoluble F, such as fluoric acid, sodium silicofluoride and undecomposed phosphate rock).

The pulverized gypsum (0.1g to 0.5g: accurately weighed to mg unit) is steam-distilled in the presence of sulfuric acid and finely powdered silica. The subsequent procedures are similar to those of the analysis of Ai.F.

The results of chemical analysis of phosphogypsum using the aforementioned procedures are shown in Table 5. Each crystal of phosphogypsum HDS-1, 2 and 4 illustrated in Photograph 1 has the unagglomerated and relatively regular form. Therefore, when the filter cake which has been discharged from the filtration step of the wet process is simply washed again with water, the quantity of the impurities in the washed cake is reduced to under Aw.P_2O_5 0.05% and Ss.P_2O_5 0.2%. Furthermore, the thermal differential analysis of phosphogypsum was studied and its results are illustrated in Fig. 3. The endothermic curves of the first dehydration of phosphogypsums HDS-1 and 2 show a relatively regular profile which is

F-1: mixture of anhydrite and dihydrate
F-2: anhydrite
F-3: dihydrate

Ss.P_2O_5 are larger than those of phosphogypsums HDS-1, 2 and 4. The endothermic curves of their first dehydration are also broad and anomalous. In the results shown in Table 5, a value of "T.F minus Ai.F" means the water-soluble F, the amount of which is small in phosphogypsum HDS-1, 2 and 4 and large in phosphogypsum D-1. Phosphogypsum HDS-3, which was not washed once with water after removing from the filter step in the wet process, contains the large amounts of impurities. But, in HDS-3 made from the hemihydrate-dihydrate process, the amount of Ss.P_2O_5 is amsll as in the case of HDS-1. Phosphogypsum HDS-5 is the chemically treated HDS-3, in which the large portions of the water-soluble impurities have been neutralized and inactivated with milk of lime. The quantity of Aw. P_2O_5 and "T.F minus Ai.F" in HDS-5 is markedly small.

The results shown in Table 5 indicate evidently that there is a large difference among the wet processes of phosphoric acid manufacture and that the appearances of various phosphogypsums in optical microphotograph and the features of their first endothermic curves in differential thermal analysis are closely related to the quatity of impurities in phosphogypsum. Therefore, the author believes that the proposed procedure is suitable for analysis of the impurities in phosphogypsum.

Table 6 obtained by Murakami (41) shows the chemical compositions of fluorogypsums. Fluorogypsum is produced usually as an anhydrite by the production reaction shown in Table 1. Some portions of the original fluorogypsum are converted into a dihydrate by the hydration reaction while anhydrite is kept standing in the settling pond. Usually, fluorogypsum used for portland cement industry is the mixture of anhydrite and dihydrate. F-3 in Table 6 is a dihydrate which was industrially produced by the hydration of anhydrite in dilute sulfuric acid solution. The water-soluble F originated from the residual fluoric acid in fluorogypsum is different from that originated from sodium silicofluoride including in phosphogypsum. The influence of fluorogypsum on the hydration of portland cement will be later demonstrated.

Utilization of Chemical Gypsum for Portland Cement

Introduction

It has been about long years since phosphogypsum was first used for the manufacture of gypsum plaster and gypsum board in Japan. The first study of phosphogypsum for control of the setting of portland cement was attempted in 1956 by Takemoto, Ito and Suzuki. They examined the false set and the setting time of paste and the strength development of mortar. These paste and mortar were made from portland cement with each of such chemical gypsums as phosphogypsum, fluorogypsum, titangypsum and sodagypsum. When phosphogypsum produced from the dihydrate process was used, the impurities in phosphogypsum markedly retarded the set of paste and slightly lowered the strength of mortar at early stage on the hydration of portland cement. Consequently, they suggested that the setting period of portland cement can be prolonged by the retarding action of impurities into what is normally the hardening period. In addition, they also reported that the false set of paste caused by the dehydration of gypsum in cement and the aeration of cement is scarcely developed from protland cement containing phosphogypsum and sodagypsum.

The water-soluble P_2O_5 of phosphogypsum adheres to the surface of gypsum crystals and also subsitutes for SO_3 in the lattice of gypsum crystals. These water-soluble impurities enter gradually into aqueous phase of cement paste with dissolution of phosphogypsum and affect the hydration of portland cement. The water-soluble F tends to more markedly retard the setting of paste than in the case without it. Except for phosphogypsum, the effect of other chemical gypsums on the hydration of portland cement is similar to that of pure gypsum.

Takemoto, Kataoka and Suzuki (53, 54) and Yamaguchi (54) have deviced the special chemical treatment for regeneration of phosphogypsum containing a large quantity of the impurities. Phosphogypsum regenerated by this treatment did not injuriously affect the hydration of portland cement because all of the water-soluble impurities were turned into the insoluble and inactive compounds. Since this treatment pelletizes the powdered phosphogypsum, the supply of phosphogypsum to cement mill becomes easy (55). Kuzumi and Murasugi (56), in actual use of the regenerated phosphogypsum, reported that, in spite of the complete inactivation of the water-soluble impurities, the delayed set of paste accidentally occurred. The author suggests that this fact is probably due either to the residual impurities that are not neutralized or to the lime added over required for the neutralization of impurities. The results obtained by Yamaguchi (55) and Takemoto (54) et al. on the use of the regenerated phosphogypsum are shown in Table 7.

Yamaguchi, Kobayashi (57), Mori and Sudo (58) have used monocalcium phosphate, dicalcium phosphate and sodium silicofluoride as the representative water-soluble impurities in phosphogypsum and examined the influence of each impurity on the setting and the strength development of portland cement. In their experiments, each of chemical reagents corresponding to each impurity was added to portland cement in eqiuvalent quantity as found in phosphogypsum. The setting of paste is retarded markedly in proportion to the amount of reagent in cement. However, the three day-strength of mortar is not so affected, even when each chemical reagent is added to cement at relatively high concentrations. If a very large amount of each chemical reagent is added to portland cement, the development of three day-strength may be retarded. Kobayashi prepared four kinds of so called "artificial gypsum" containing water-soluble P_2O_5 in substitution for SO_3 in the crystal lattice of gypsum. The quantities of P_2O_5 in them are 0.2%, 0.5%, 1.0% and 2.0%. The retarding action of these artificial gypsum with P_2O_5 substituted in the lattice is stronger than that of gypsum with P_2O_5 which adhered to the crystal surface.

As mentioned above, hitherto, phosphogypsum

has been used for control of the setting time of portland cement only in Japan. Recently, Lejsek (59) in Czeckoslovakia has reported a similar results with Japanese investigator's on his study of the utilization of phosphogypsum.

In view of above results, only phosphogypsum among chemical gypsums has some amounts of the impurities harmfully affected the hydration of portland cement. Other chemical gypsums do not have any impurities which are likely to cause trouble on their utilization. However, their productions are far less than phosphogypsum.

A patent about making the super-sulfate cement in which phosphogypsum is used as a main component has been licenced in Germany (60).

In this chapter, the mechanism and the effective protection methods of the retarding action of phosphogypsum on the hydration of portland cement will be investigated.

It is now well known that the setting retardation is the most characteristics action of phosphogypsum and largely dependent upon the amounts, kinds and locations of impurities in phosphogypsum. If it is assumed that the retarding action is caused by the temporary suppression of the hydration with the formation of the insoluble compounds as protective coatings on the surface of cement grains, the setting time will be shortened by agitation for a longer time than specified in JIS. Namely, the protective coatings are probably consist of the reaction products between the impurities of phosphogypsum and the compounds of cement. Therefore, it is suggested that the prolonged agitation of paste or mortar is a suitable method for destroying the coatings.

Assuming that the hydration of portland cement at early stage is a chemical process predominatingly, it will be expected that the retarding action may be increased at lower temperature.

Natural gypsum produced in Japan contain, in general, a relatively large amount of clay minerals and their average SO_3 content are about 30%. On the other hand, the SO_3 content of most of chemical gypsums is usually 40% to 45%. However, chemical gypsum is generally produced in a state of powder. Such discrepancies in the feature between natural and chemical gypsum indicate that there are many important problems which should be newly investigated for the use of chemical gypsums. These problems are the grindability of cement together with chemical gypsum, the fineness of the resultant cement, the dehydration characteristics of chemical gypsum and the setting character of the resultant cement.

On the study of mechanism of the setting retardation caused by the impurities of phosphogypsum, it should be noted that phosphogypsum usually contains several impurities at the same time. Therefore, on understanding the retarding action, it is necessary to investigate the effect of each single impurity on the hydration of cement in order to exclude the complexity resulted from the multiple impurities.

Little has also been demonstrated that which of cement clinker minerals is attacked by the impurities and causes the setting retardation of portland cement.

In the last section of this chapter, the mechanism

retarding action on the hydration of portland cement will be explained with referencing to the results of the studies on the heat liberation during the hydration, the change of specific surface area of the hydration products measured by the adsorption of water vapor and on the elecrton microscopic observation of the hydrating particles of cement.

Practical Methods for Removal of the Impurities in Phosphogypsum

When phosphogypsum is used as gypsum for control of the setting time, it is necessary that the impurities of phosphogypsum are reduced as much as possible. In other words, phosphogypsum used for this purpose should be such that the impurities included in phosphogypsum are easily removed by a simple washing with water. In view of aforementioned fact, it can be said that the industrial success of the hemihydrate-dihydrate process and the utilization of phosphogypsum by-produced from that process is very significant in Japan. Phosphogypsum by-produced from the dihydrate process must be chemically treated in order to be used for control of the setting. The chemical treatment proposed by Yamaguchi and Takemoto is an appropriate one for this purpose. There are two suitable treatments for removing or inactivating the impurities of phosphogypsum produced from the hemihydrate-dihydrate process. One method is to obtain phosphogypsum, such as HDS-1, containing only the small amounts of impurities through vigoruos washing of the filter-cake of phosphogypsum which was discharged from the filter step of the wet process, while it is transported to the storage tank by the water stream. The other method is practiced at place where the sufficient quantity of water cannot be provided for washing the filter cake. Namely, Hanada (61) neutralized the water-soluble impurities in filter-cake of phosphogypsum, such as HDS-3, with milk of lime and consequently got phosphogypsum containing less amounts of impurities, such as HDS-5. When it is indispensable to minimize the effects of even small amounts of the impurities in phosphogypsum, or when it is allowed for using only a small quantity of phosphogypsum containing a large amount of impurities, the mixture containing a large amount of natural or chemical gypsums which do not contain the harmful impurities are usually used by Hanada (61).

Physical Properties of Portland Cement Containing Phosphogypsum

Setting Time and Strength Development of Portland Cement Containing Phosphogypsum

The results of the studies by Miyazawa (62), using two normal portland cement A and B (total SO_3 content 1.6%) which were mixed with each of phosphogypsums listed in Table 8, indicate that the setting time of paste is markedly retarded when portland cement is mixed with phosphogypsum No. 2 containing a larger quantity of water-soluble F than with other phosphogypsums in Table 8 (Table 9). Table 10 shows that the three day-strength of mortar containing these phosphogypsums is slightly lowered in proportion to the amount of impurities in phosphogypsum. Tables 12 and 13 are the results of tests on the setting and the development of mortar strength that was undertaken by Hanada (63) with three kinds of blast-furnace slag cement (total SO_3 content 1.8%) cntaining each kind of phosphogypsums which were neutralized with milk of lime and not. Table 11 shows the chemical compositions of the both phosphogypsums. Table 12 shows that, using the mixture of natural gypsum and

phosphogypsum, the retarding action of the untreated phosphogypsum is effectively alleviated. The results on the development of mortar strength given in Table 13 emphasizes that the appreciable reduction in the three day-strength is not observed as far as the quantity of impurities remains in the range of that contained in phosphogypsum used.

Effect of Prolonged Mechanical Agitation over Three Minutes with Hand Mixing

Since the hydration of portland cement tends to be accelerated by agitation, it is suggested that the prolonged agitation will tend to prevent the retarding action on the setting of paste with posphogypsum. In transportation of the ready mixed concrete, the prolonged agitation of concrete has already been in practice. Hanada (63) prepared nine kinds of portland

cement as well as nine kinds of blastfurnace slag cement containing five kinds of gypsums shown in Table 14 and measured the setting time of paste which was mechanically agitated by Hobert mixer for longer time, such as 3, 5, 7, 10 and 15 minutes, than specified in JIS. The results shown in Tables 15 and 16, indicate that the mechanical agitation, even for three minutes, tends to more accelerate the setting than the agitation with hand, and that also the longer the mechanical agitation the shorter the setting time. Similarly, Miyazawa (64) studied the influence of the agitation time on the flow and strength development of mortar containing several phosphogypsums as shown in Table 17. The SO_3 content in the prepared protland cement was 1.5%, 3.0% and 5.0% and the duration of mechanical agitation was 3, 5 and 30 minutes. The results illustrated in Fig. 4 reveal that, except for the case of a relatively high SO_3 content, such as 5.0%, the mechanical agitation within thirty minutes is independent of the strength development of mortar. But, the fluidity of mortar is considerably reduced by the prolonged agitation. Murakami (65) reported that the strength development of mortar containing phosphogypsum or even pure natural gypsum is markedly lowered by the prolonged agitation over thirty minutes. This results seem to support the Verbeck's hypothesis that the excess agitation of a partially hydrated concrete mixture leads to a weak product.

Effect of Increased Addition of Phosphogypsum

Aside from phosphogypsum, an attempt of adding a

w/c: water-cement ratio

In this table, setting time without parentheses is real value. Numbers in parentheses are relative value, when the setting time of paste with natural gypsum (SO_3 content 1.6%) is described as 100.

in Table 17. The SO_3 contents in the prepared cements are 1.5%, 2.0%, 3.0%, 4.0% and 5.0%. The results shown in Table 18 indicate that, for example, the setting ime in the case of SO_3 content of 2% is prolonged in comparison to natural gypsum and that the degree of prolongation is in the order of phosphogypsum No. IV > III > II > I. Therefore, it can be said that the larger the quantity of phosphogypsum

in cement, the longer is the setting time of cement. Phosphogypsum No. IV containing the largest quantity of impurities of all the other phosphogypsums in Table 17 shows a strong retarding action on the setting of cement. The results given in Table 19 show that the three day-strength of mortar containing phosphogypsum, the total SO_3 content of which is in the range of 1.5% to 3.0%, is not less than that of the mortar containing natural gypsum. The addition of a large quantity of gypsum, such as total SO_3 content 5.0%, causes the expansion of the hydrating cement to result in markedly lowered mortar strength regardless of using phosphogypsum or not. Furthermore, Miyazawa reported that the length change of the mortar after drying is reduced as the quantity of gypsum in cement increases and that the length change of the mortar is not closely related to the quantity of impurities of phosphogypsum within the limit of his experiment. The expansion-contraction test of mortar was made using the test procedure J.C.E.A.S.H (1962) under the following conditions: curing for five days in water at 20°C followed by standing for thirteen weeks in air with the relative humidity of 44%.

Mixing and Curing at Relatively Higher and Lower Temperature Than 20°C

Assuming that the hydration of portland cement at its early stage is predominated by chemical reaction, it is expected that the time of set is markedly affected by temperature during the mixing or curing of paste and mortar. In practice in cold seasons, it is feared that, on account of the decreased rate of the hydration reaction at lower temperature, the setting period of cement containing phosphogypsum can be prolonged into what is normally the hardening period. Hanada (63) prepared nine kinds of portland cements and nine kinds of blastfurnace cements containing various gypsums, namely, a natural gypsum, two kings of phosphogypsums, two kinds of chemical gypsums and four kinds of the mixtures of two of them. Then, he measured the time of set of pastes and the strength develoment of mortars at each temperature of 5, 10, 20, 30 and 40°C. Tables 20 and 21 show the results of the time of set, in which the time of set of paste containing natural gypsum is written as 100 and those of paste containing other gypsums are shown with a

W/C: water-cement ratio (%)

Setting time (hr.-min.); Numbers in parentheses are real value of setting time.
Numbers without parentheses are relative value of that of paste containing various gypsums for the setting time (100) of paste with natural gypsum.
Numbers in parentheses of the first column are the proportions of each component of the gypsum mixture contained in cement.

relative value to the former. Both time for the initial and final set of paste with natural gypsum at 5°C tend to be two times as longer as the setting time at 20°C. However, it is not observed that, at lower temperature, the setting of paste containing phosphogypsum is more markedly retarded than that of paste without phosphogypsum. Such a tendency is observed in the case of blastfurnace slag cement as well as portland

cement. Table 22 shows the strength development of mortars made from the both cement at each temperature. In view of his results, regardless of whether natural gypsum is contained in cement or not, the strength development of mortar is relatively reduced by lowering the temperature, although the tendency that the lowering in curing temperature increases the retarding action of impurities on the strength development is not observed, even on the three day-strength.

Influence of Phosphogypsum on Properties of Concrete

In view of practical point, the properties of concrete made from portland cement containing phosphogypsum should be investigated in order to be related to those of pastes and mortars obtained by laboratory test. Hanada (63) prepared concrete from portland cement and blastfurnace slag cement containing various gypsums in Table 14 and showed, as in Tables 23 and 24, the change of slump of concrete from the time just after mixing concrete up to 150 minutes. The change of slump of concrete is scarcely affected by the quantity and the kind of impurities in gypsum. Consequently, it can be said that, within the limit of his experiment, the impurities in phosphogypsum do not exert any unfavorable effects on properties of

Numbers in parentheses of the first column are the proportion of each component in the mixture of natural gypsum and chemical gypsum added to cement.

The concrete in this table was prepared from blastfurnace cement with various gypsums 4%.

The proportion of aggregate and cement in the concrete mixture is as follows;

water-cement ratio 60%
sand-aggregate ratio 41.1%

Weight of each component of concrete (per 1m³)

cement	305 kg
sand	741 kg
aggregate	1106 kg
water	183 kg
total	2335 kg

concrete. The results given in Table 25 indicate that the development of compressive strength of concrete is independent of the impurities of phosphogypsum in concrete, as mentioned previously.

Furthermore, Hanada (63), through ASTM Designation: C403-63T, measured the time of set of concrete prepared from portland cement with various gypsums. The results given in Figs. 5-1 and 5-2 show that the time of set of concrete is not considerably affected by the impurities of phosphogypsum.

Utilization of Other Chemical Gypsums for Portland Cement

There are many kinds of chemical gypsum in Japan, as in Table 1. But phosphogypsum alone is very important for portland cement industry at the stand point of the quantity and property of gypsum. The major part of this paper has been givn for the discussion on the utilization of phosphogypsum. But, some of chemical gypsums are also frequently useful for portland cement. In this chapter, the utilization of other chemical gypsums in making portland cement and the hydration of the prepared cement will be treated.

Fluorogypsum, as in Table 1, is usually produced in the form of anhydrite. After standing in storage ponds, some portions of anhydrite are converted to dihydrate through the hydration reaction. Therefore, fluorogypsum usually used in making portland cement is a mixutre of anhydrite and dihydrate. Generally,

fluorogypsums.

Miyazawa (64) prepared portland cement (total SO_3 content; 1.7% and 2.4%) containing fluorogypsum and the mixture of natural gypsum and the waste Paris mold. The results given in Table 26 show that the retarding action caused by the impurities of fluorogypsum is relatively smaller than that by the impurities of phosphogypsum. Form these results, it is supposed that there is a distinct difference in the reaction mechanism on the hydration of cement between the water-soluble F originated from hydrofluoric acid and that from sodium silicofluoride. The three day-strength of mortar containing fluorogypsum is greater than that containing natural gypsum. Mochizuki (67), using another fluorogypsum obtained from the same source, prepared portland cements containing total SO_3 contents 1.7% and 2.4% and measured the time of set of pastes and the strength development of mortars. The results obtained by him showed that the time for initial and final set is longer when the content of SO_3 was 2.4% than when it was 1.2%. In both cases, however, the strength development of mortar was not affected by the impurities of fluorogypsum.

A characteristic phenomenon in using fluorogypsum for cement is a marked increase of the power consumption for grinding of cement clinker together with fluorogypsum. Comparing with natural gypsum in Japan, the increments of the power consumption are 13% to 18% with the coarse powder of fluorogypsum and 30% to 40% with fine powder. The great increase in power consumption in grinding may be caused by the lack of clay minerals in fluorogypsum.

Takemoto (68) also prepared portland cement containing each of fifteen kinds of fluorogypsums and measured the setting time of its paste and the strength development of its mortar. The amount of the water-soluble F contained in fluorogypsum was 0.003% to 0.05% and the amount of total F was 1.00% to 1.50%. His results indicate that the amount of the water-soluble F and iron salt as well as the acidity of fluorogypsum affected the strength development of mortar. In other words, the increase of the water-soluble F results in the increase of iron salts and the lowering of the strength development of mortar.

The utilization of chemical gypsum No. D for control of the setting time of portland cement was studied by Hanada (63). Table 27 shows the chemical compositions of two kinds of chemical gypsums No. D produced from the first and second neutralization reaction in their production process. The latter has about 6% iron oxide as an impurity. The setting time of paste and the strength devlopment of mortar with these chemical gypsums is given in Tables 28 and 29. The results indicate that the both chemical gypsums do not have any adverse effects on the setting and the strength development. The properties of portland cement with two kinds of chemical gypsums No. D are similar to that of portland cement with a commercial chemical gypsum.

Table 27. *Chemical compositions of chemical gypsum No. E*

(%)

	Water	Combined water	Fe_2O_3	CaO	SO_3
Gypsum by first reaction	13	19.6	0.5	31.8	44.7
Gypsum by second reaction	25	19.2	5.7	30.8	43.1

In Tables 20–25 of last chapter, Hanada, comparing with the setting time of paste and the strength development of mortar containing phosphogypsum and natural gypsum, showed the setting time of paste and the strength development of mortar with two kinds of other chemical gypsums (63).

The work by Takemoto, Ito and Suzuki (53) on the properties of portland cement containing fluorogypsum, titangypsum and sodagypsum indicates that, except that sodagypsum slightly lowers the utilmate development of mortar strength, these chemical gypsums have scarcely the different effect from natural gypsum on the propetties of portland cement. Nakamori and Mizoguchi (69) examined the compatibility of phosphogypsum, saltgypsum, sodagypsum and chemical gypsum No. J for control of the setting time and said that these chemical gypsums can be used if they contain only a small amount of impurities.

Table 28. *Setting time of cement containing chemical gypsum No. E*

The quantity of gypsum added to the both cements is 4%

Grindability of Clinker together with Chemical Gypsum

While natural gypsums are usually produced in the form of lump, most of chemical gypsums are by-produced in state of powder, unless it is pelletized. The SO_3 content of chemical gypsum is as high as that of pure natural gypsum. Natural gypsum used generally in Japan for making portland cement contains a relatively large amount of clay minerals which may give a favorable effect on the grinding efficiency of cement.

Miyazawa, in preceding chapter, showed that the power consumption in grinding of cement markedly increases when fluorogypsum is used. He also reported that, when pure natural gypsum, pelletized phosphogypsum and powdered chemical gypsum are used, the power consumption required to obtain the cement with a definite fineness was 5% to 19% larger than that in using the relatively poorer grade natural gypsum containing some quantities of clay minerals.

Suzukawa and Kobayashi (70, 71) investigated systematically a group of problems on the grindability of cement with chemical gypsum in connection with the dehydration of gypsum caused by the temperature elevation during the grinding process and the resultant false set. They used some natural gypsums and phosphogypsums having the chemical compositions listed in Table 30.

The results of grinding tests at ordinary temperature and 160°C are given in Table 31. It is evident that at each temperature there are some differences in the grindability of cement caused by the grade of gypsums. In grinding at ordinary temperature, the grinding time required to obtain the cement with a definite fineness is minimum when the lower grade natural gypsum is used, and it is more when the ordinary natural gypsum is used and is longest when pure natural gypsum or phosphogypsum is used.

When grinding is carried out at 160°C, it is generally observed that the amount of ball coatings and the grinding time as well as the quantity of coarse particle in the sieving residue increase markedly. In particular, the grade of gypsum is closely related to the length of grinding time. Namely, using the lower grade natural gypsum, even in grinding at 160°C, it is apparently observed that the amount of ball coatings is greatly decreased, that the grinding time is relatively shortened than grinding at ordinary temperature and, however, that the amount of coarse particle in the sieving residue is unusually increased. Since the cement which is ground together with the lower grade natual gypsum has the size distribution different from that of cement ground with other gypsums, it is suggested that the abnormal acceleration of grinding has been happened only during the milling with natural gypsum of the lower grade. In view of the aforementioned results, the most reasonable conclusion is that the mineral impurities naturally included in natural gypsum are markedly effective to the improvement of grindability of cement.

Some portions of works undertaken by Suzukawa and Kabayashi in order to reconfirm the above results and to solve the problem on grinding of the cement with chemical gypsum are shown in Table 32. In this experiment, they investigated the grindability of

Numbers in parentheses of second column are the proportions of each component in the gypsum mixture added to clinker.

cements containing the mixture of the lower grade natural gypsum and one of other various gypsums at ordinary temperature and 160°C. Before the mixture of each gypsum and the lower grade natural gypsum is ground together with cement clinker, the quantity of the lower grade natural gypsum in the mixture is adjusted so as the quantity of the insoluble substance in the mixture is equal to that in the ordinary natural gypsum in order to avoid the discrepancy on the amount of insoluble substance in the resultant portland cement. These results show that the presence of the mineral impurities is effective to the remarkable reduction of the time of grinding without disturbing the distribution of particle size of the resultant cement. Moreover, the similar tendencies are observed in grinding at 160°C. Fig. 6 illustrates the grindability

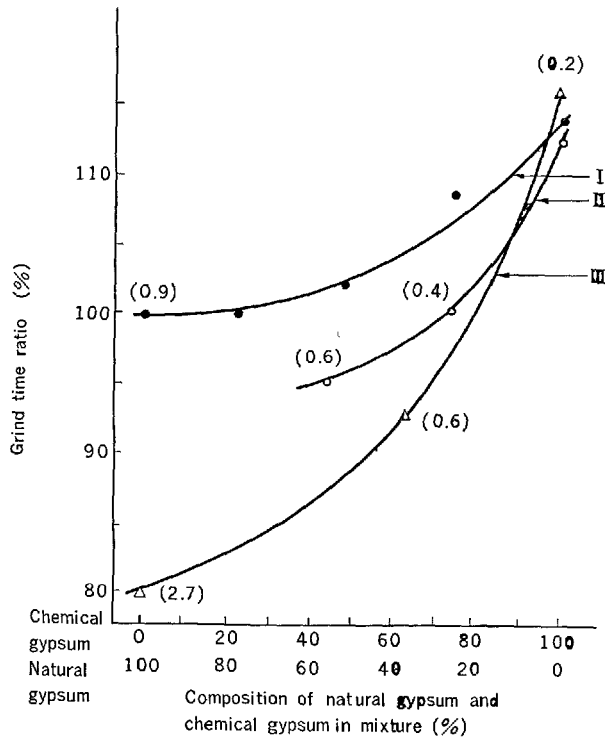

Fig. 6. *Grindability of cement with various gypsums.*
I: Natural gypsum (SO_3 35.5%)—Chemicalgypsum-mixture.
II: Natural gypsum (SO_3 28.5%)—Chemical gypsum-mixture.

In this table, ratio of setting time is relative value of the setting time of cement with other gypsum for setting time (assuming as 100) of cement with natural gypsum-No. 1 in Table 33.

Numbers in parentheses of the second column are the proportions of each component of the gypsum mixtures added to cement clinker.

scarcely affect the setting and even the development of the strength of mortar. The results shown in Table 35 indicate that the weight loss of cement on heating and the amount of SO_3 of each section of particle size of the cement ground at 160°C are approximately independent of the change of gyspum grade and, that most of gypsum in the ground cement are present as the particle under 15μ. In a previous paper, Nakamori and Mizoguchi (69) have reported that all the gypsum contained in a commercial portland cement are as fine as the particle under 15μ.

Relation between Chemical Gypsum and False Set

The purpose of this chapter is to investigate whether or not the use of chemical gypsum for portland cement is responsible for the development of a false set of fresh cement. Takemoto, Ito and Suzuki (53) reported that the false set which was caused by aeration scarcely happened in cement containing phosphogypsum or sodagypsum.

Table 35. *Loss on ignition of cements and distribution of* SO_3 *in cements ground together with various gypsums.*

Quantities of gypsums added to cement is as follows: N.G.–13.8%, N.G.–3, P.G.–23.0%, N.G.–4 and 52.7%.
All the quantity of gypsum are written as wt.% to clinker.

Suzukawa and Kobayashi studied in detail the relations between the false set of fresh cement and the addition of phosphogypsum (70, 71). Table 36 shows the chemical compositions of various gypsums used in their experiments, namely: three kinds each of natural gypsums, phosphogypsums and artificial gypsums. In two of the three kinds of artificial gypsums, some portions of SO_3 in their crystal lattice are substituted by HPO_4^{--}. Each kind of gypsums was dehydrated and mixed in the cement. False set is examined by J.A.S.S method after paste was agitated for 1.5, 3 and 5 minutes. The relation between the time of hydration versus the penetration of paste is illustrated in Figs. 7–1 and 7–2. These results show that the development of false set is not only affected by the change of grade of gypsum, but also the amount of gypsum in cement. The cement containing phosphogypsum No. 3 that is chemically untreated shows a frequent anomalous set which may be caused by the large amounts of impurities of phosphogypsum. Therefore, in cement containing natural gypsum and even phosphogypsum, a false set is a likely possibility.

False set of the cement made from two clinkers is examined in order to investigate the anomalous set mentioned above under two conditions: one of them is of a constant consistency and the other is of a constant water cement ratio. The chemical compositions of clinkers used in this experiment are given in Table 37. In both cases, the SO_3 content in the prepared cement containing phosphogypsum and natural gypsum is from 0.25% to 2.0%. From the results illustrated in Figs. 8 and 9, the optimum amount of gypsum required for normal set seems to depend on the kind or grade of gypsum. In regard to the devlopment of false set, the influence of the chemically treated phosphogypsum on settting is analogous to that of pure gypsum. It is naturally suggested that the

behavior of cement with phosphogypsum which is not chemically treated differs from that of cement with other gypsums. In addition, they prepared some cements containing various gypsums and then, examined a false set, analysed the soluble components in the liquid phase of paste and measured the solubility of gypsums.

The curves in Fig. 10 show the relation between the time of hydration and the penetration of pastes with artificial gypsums. These results indicate that the tendency to develop false set of fresh cement with artificial gypsum substituting 1.0% P_2O_5 is similar to that in the cement with phosphogypsum No. 3 in Table 36. Also, it was reported that the solubilities of SO_4^{--}, Ca^{++} and OH^- in the liquid phase of paste are obtained as the anomalous curves corresponding to the development of the false set.

Consequently, it may be generally concluded that the dehydration of gypsum during the grinding and subsequent "plaster set" caused by the dehydrated gypsum during the hydration are likely to predominate the development of a false set.

However, the mechanism mentioned above may not be supported, because the present experimental results show that a false set is scarcely developed in cement containing the ordinary or the lower grade natural gypsum. Therefore, it is natural that the false set phenomenon of fresh cement should be investigated on such many factors as the grade of gypsum, the amount of added gypsum and the quantity of impurities.

Influence of Impurities of Phosphogypsum on Hydration of Portland Cement and Its Clinker Minerals

Introduction

It is now generally accepted that the impurities of phosphogypsum have some adverse effects on the hydration of portland cement. Hitherto, the results obtained by Takemoto, Ito and Suzuki (53) showed that the several impurities picked out by them act as a retarder at concentrations 0.1% to 1.0% to gypsum in cement. These impurities are sodium silicofluoride and phosphoric acid as an inorganic substance, and humic acid and sugar as an organic substance. Also, these impurities were used respectively as a single mixture and compound mixture. The retarding action markedly increases, when the compound mixture is used. These results are given in Table 38. Kobayashi also has undertaken a similar experiment and observed the marked retarding action resulted from these compound additives. Mori and Sudo (58) prepared portland cement and blastfurnace slag cement containing monocalcium phosphate and dicalcium phosphate and they reported that the time of set was markedly prolonged with increasing concentration of each impurity in cement. Murakami has also studied the influence of phosphoric acid, monocalcium phosphate, dicalcium phosphate and sodium silicofluoride at relatively higher concentrations and, as in Table 39, he has obtained the same results with those of the preceding investigators.

Each impurity of phosphogypsum, when it is contained in the cement as a chemical reagent, does not give a slightly negative effect on the development of three day strength. These results are shown in Table 40 by Murakami and also are well identical with the previous works (53, 57, 58).

The experiments mentioned above were undertaken to clarify the influence of impurities which adhered to the surface of the crystals of phosphogypsum. However these impurities are likely to turn insoluble rapidly, owing to the neutralization reaction of lime in its liquid phase of cement paste or mortar, immediately after the cement comes into contact with water. Therefore, the retarding action may be relatively weaker than that of the impurities in phosphogypsum even if it is subjected to the same concentrations.

Consequently, it can be said that the retarding action markedly depends upon the rate of dissolution of impurities from inside or outside of the gypsum crystals. Kobayashi has already reported that the

In this table, each chemical reagent is expressed as the concentration of that in cement. The concentrations of chemical reagent to gypsum in cement is written as follows; (concentration in cement) × (33). Therefore, some portions of this experiment were undertaken at extremely high concentrations of chemical reagent.

retarding action of the P_2O_5 substituted in the crystal lattice is stronger than that of the P_2O_5 which adhered to the surface. Murakami also prepared the artificial gypsums with substituted P_2O_5 using calcium chloride, sodium sulfate and disodium phosphate. Their chemical compositions are given in Table 41. Hanada (63) prepared some portland cement containing four kinds of artificial gypsums substituting P_2O_5 and measured the time of set and the development of mortar strength at the three varied temperatures of 10°C, 20°C and 40°C. The total SO_3 content in the prepared cement is 1.0%, 2.0%, and 3.0%. The results are illustrated in Fig. 11. The cement with 1.0% SO_3 content shows a flash set, however, the retarding action in the other hand is strengthened proportionally by increasing the amount of the gypsum substituting P_2O_5 or by increasing the quantity of P_2O_5 substituted in the crystal lattice of gypsum.

Their action are relatively severe at a lower temperature, and especially a final set is characteristically retarded. In spite of the above retarding action, as in Table 42, the development of mortar strength even at early stage of the hydration is hardly lowered by the prolonged set.

In order to systematically investigate the compound action of impurities in phosphogypsum, Murakami (65) prepared the artificial pure gypsum and artificial gypsum with the water-soluble F which adhered

to the surface of crystal containing to substituted P_2O_5 in the crystal lattice. The quantity of water-soluble F added to artificial gypsum is 0.5% and 1.0%. The water-soluble F represents a fluorine content in sodium silicofluoride which adhered additionally to the surface of gypsum crystals. Hanada, again using these aritficial gypsums, prepared some portland cements with three varied SO_3 contents, such as 1.0%, 2.0% and 3.0% and he measured the time of set and the development of mortar strength at 20°C and 40°C. At 20°C, the setting is generally retarded in proportion to the amount of these gypsum. Furthermore, it is found that the development of mortar strength, in spite of the accumulation of impurities, is increased as the quantity of gypsum increases. Namely, the development of mortar strength is more closely related to the quantity of gypsum in the cement than the quantity of impurities. From the results in Tables 42 and 43, it is apparent that at 40°C the time of set is also progressively delayed in proportion to the quantity of impurities in gypsum. Consequently, the increase of impurities in the cement, resulted from the increase of either quantity of impurities in gypsum or quantity of the added gypsum with impurities, strengthens the retardation of set at 20°C and even at 40°C. But, the retardation at 40°C is less than that at 20°C. The addition of gypsum containing the substituted P_2O_5 in the gypsum lattice or the P_2O_5 which adhered to the surface of gypsum crystals does not give any adverse effect on the development of mortar strength at 40°C, within the limit of this experiment.

Sekiya (75) suggested that major part of an organic impurity in phosphogypsum may be originated from

Artificial gypsums No. 1, 2, 3 and 4 are similar to those in Table 41.
The time of set of paste and mortar made from portland cement with natural gypsum is as follows: (curing at 20°C)

	Initial set (hr.-min.)	Final set (hr.-min.)
Paste (JIS)	1–45	3–15
Mortar (ASTM)	5–50	8–45

(The quantity of SO_3 in cement is 2%)

chemical reagents which were used for the floatation of phosphate rock. In order to examine the influence of this organic impurities on the hydration of portland cement, he measured the time of set and the strength development of the cement containing oleic acid and diethylen triamine which are regarded as floating agent. But, both chemical reagents did not affect the set and strength development.

Investigation of the Retarding Action of Impurities of Phosphogypsum

Considering the various results obtained in preceding chapters, we are likely to obtain the practical evidence that most of chemical gypsums, especially even phosphogypsum, can be safely used for control of the time of set of portland cement. When a large

quantity of impurities is contained unfortunately in these gypsums, they will be inactivated by the chemical treatments mentioned above. Furthermore, in view of the character of impurities, it will be worth emphasizing that the impurities of phosphogypsum should rather be utilized than be avoided. Before reaching such conclsuion, however, it is necessary to clarify the detailed mechanism of retarding action of the impurities.

In this chapter, the influence of impurities on the hydration of tricalcium aluminate and tricalcium silicate is also studied.

The samples used in this study are the eleven varied phosphogypsums produced from the wet process in many places in Japan and some artificial gypsums containing the impurities corresponding to the quantity of that of phosphogypsum. Table 44 obtained by Murakami shows the time of set of pastes containing each kind of eleven varied phosphogypsums. Total SO_3 content of these cements is 2.0%. The chemical compositions of phosphogypsums have been shown in Table 5. When phosphogypsum containing a small amount of the water-soluble impurities is used, such as HDS-1, 2 and 4, a normal set is given as in the case of pure gypsum. When phosphogypsum containing a large amount of the water-soluble impurities is used, such as HDS-3, HD-1, 4 and D-1, the setting of cement is retarded. Especially, when D-1 is used, it is char-

acteristically retarded.

Since the tendency of setting is identical with that predicted by the results of the chemical analysis of the impurities of phosphogypsum, it is possible to conclude that the proposed procedures for the chemical analysis of the impurities of phosphogypsum are very appropriate. Murakami prepared some early strength portland cements containing phosphogypsum and artificial gypsum and measured the one day-strength of mortar. His results shown in Table 45 are closely related to the chemical compositions of the impurities given in Table 5. In other words, the one day-strength is sensitively influenced by the amount of impurities.

Heat Liberation during Hydration of Portland Cement and Clinker Minerals with Phosphogypsum

Since the hydration of portland cement and its clinker minerals is generally an exothermic reaction, the mesurement of the heat liberation process during hydration has helped in understanding the nature of various changes in the normal hydration or the prolonged hydration caused by the impurities in phosphogypsum.

For this purpose, various calorimeters have been developed by many investigators. Calorimeter is generally classified into adiabatic and conduction types (approximately "isothermal"). In the field of cement hydration, one of the former was developed by Carlson and Forblich (72) and the first of the conduction calorimeter was devised by Carlson and Lerch (72). Recently, various modifications of the conduction calorimeter have been devised and used for the studies of the cement hydration by Stein (73), Danielson (74), Portland Cement Association in

U.S.A. (75) and Amaya (76). In the present study, both types of the calorimeter devised in the author's laboratory are used. The cross sections of these two calorimeters are schematically shown in Figures 12 and 15, respectively. The detailed operating procedure of the adiabatic calorimeter has already reported (77).

The valuable characteristic of this device is that the heat liberation developed immediately after cement comes into contact with water can be easily measured. Therefore, it is better than the conduction calorimeter in order to study such rapid reaction as a hydration of tricalcium aluminate. It has been well known that the hydration process of tricalcium aluminate is intricately affected by the temperature of hydration and the co-existing other material in the hydration (77–79). Therefore, for the purpose of studying the role of tricalcium aluminate on the hydration of portland cement, the system required for measuring the hydration process of tricalcium aluminate should be corresponded to the condition of hydration of portland cement.

However, there are some unsolved phenomena which may be caused by the complicated matrix structure of cement clinker or alkali in clinker in the hydration of portland cement. It is still difficult to understand completely the hydration behavior of tricalcium aluminate.

In spite of the features mentioned above, some relatively simple systems are used to study the effects of impurities of phosphogypsum on the hydration of

tricalcium aluminate, namely: C_3A–H_2O system, C_3A–C_3S–$CaSO_4 2H_2O$–H_2O system and C_3A–$CaSO_4 2H_2O$–H_2O system. The curves illustrated in Figure 13 show the heat liberation process of the hydration of tricalcium aluminate in various systems at 20°C. Curve I shows that the hydration of tricalcium aluminate alone in water consists, first, of the rapid rising on heat liberation indicating the first formation of hexagonal plate-like crystals (C_4AH_x and C_2AH_8) on the surface of tricalcium aluminate grains immediately after they come into contact with water and, second, of the subsequently slow rising on the heat liberation indicating probably the termination of the initial rapid hydration by the formation of protective coating on the surface of tricalcium aluminate grains. Also, it has been suggested that the conversion from C_4AH_x and C_2AH_8 to cubic C_3AH_6 as well as the direct formation of C_3AH_6 in the hydration of tricalcium aluminate occures in the latter half of curve I. Curve II shows that the combination of calcium hydroxide produced from the hydration of tricalcium silicate and gyspum is very effective on retarding the hydration of tricalcium aluminate. Some investigators have emphasized that the tight protective coatings of trisulfate formed on the surface of tricalcium aluminate grains suppress the subsequent hydration of tricalcium aluminate (78, 79). Curve III shows that the addition of only gypsum accelerates the rapid formation of trisulfate, and does not give an available suppression on the hydration of tricalcium aluminate. Curves IV, V, VI and VII show that, when tricalcium aluminate is mixed with phosphogypsum and aritficial gypsum containing impurities, the suppressing action

to the heat liberation is a little more strengthened than when it is mixed with pure gypsum. This tendency is also observed on the heat liberation process immediately after portland cement comes into contact with water. The early stage of hydration of tricalcium aluminate and portland cement is considerably different from that of tricalcium silicate, moreover, their hydration processes are not markedly affected by the impurities of phosphogypsum, even when a large amount of phosphogypsum is used.

Especially, it has frequently been said that "immediate heat" in early stage of the hydration of portland cement is not mainly caused by the hydration of tricalcium aluminate and calcium aluminoferrite, but that it may be partly caused by such complex exothermic reaction as the hydration of clinker minerals containing alkali or the hydration of defect in all the clinker minerals. Therefore, it is consequently considered that the influence of tricalcium aluminate on a initial heat liberation of the hydration of portland cement may be relatively small. The results illustrated in Fig. 14 show that the initial heat liberation of portland cement is only slightly lowered by phosphogypsum D-1 and aritficial gypsum with the large amounts of impurities.

Temperature 25°C ± 0.01°C.

Since the calorimeter, as illustrated in Fig. 15, is not capable of determining the rate of the hydration reaction immediately after cement comes into contact with water, it is not suitable for measuring the rapid hydration of tricalcium aluminate. On the other hand, such device is very appropriate for the slow and long continued hydration of tricalcium silicate and portland cement, because the rate of their hydration can be determined by using the paste and mortar prepared with a practical water-cement ratio and a definite agitation. The conduction calorimeter used in this experiment consists of three parts, namely: sample holder (4, 5, 7), heat flow meter (6) aluminum base and block (2, 1). The heat flow meter is made of a polyvinylchloride round plate (thickness 3 mm, diameter 50 mm), on each of both surfaces of which thirty-eight thermocouples [chromel (diameter 0.1mm)—constantan (diameter 0.1mm)] are arranged in series. The sample holder is a double layered container, consisting of the inner tray being made of 18-8 stainless steel and the outer tray being made of copper. They directly contact together for good thermal conduction and the inner tray can be easily removed from the outers. The former directly holds the cement paste and mortar owing to its resistance to the strong alkali solution in cement paste. The outer tray does not directly holds the paste for fear that it may be ruined by the strong alkali solution in the cement paste.

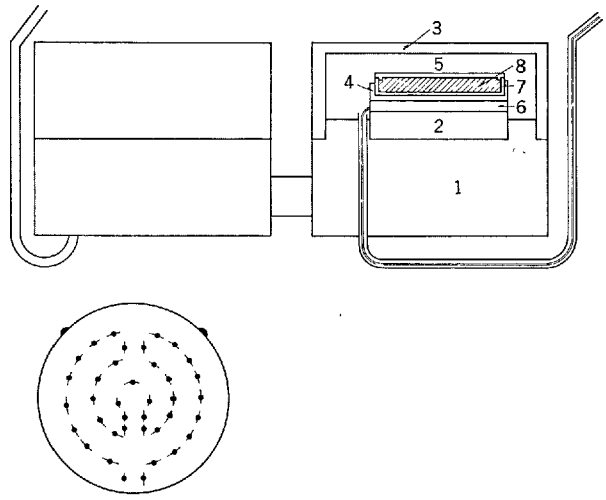

Fig. 15. *Construction of devised conduction calorimeter.*
1. Aluminum block
2. Aluminum base
3. Aluminum cap
4. Copper vessel (Outer tray)
5. Steel cap
6. Polyvinylchloride heat flow meter
7. Sample holder (Inner tray)
8. Cement paste

The bottom surface of the outer tray is tightly bound to the upper surface of the heat flow meter with a thin layer of epoxy resin in order to provide for a good electric insulation and a thermal conduction between the both surfaces. Similarly, the under surface of the heat flow meter is tightly bound to the upper surface of aluminum base. Moreover, the lower half of aluminum base is tightly set in a cavity made on the surface of aluminum block. Aluminum has a good thermal conductivity and the outer surface of the block always comes into contact with water in the both which is kept at constant temperature (20 ± 0.005°C) during the runs. Though the construction of the present device is approximately analogous to that of Stein's calorimeter, it is dum-bell type and is capable of measuring the heat liberation of two paste simultaneously.

In the case of this device, the rate of heat liberation of paste (cal/g.hr.) is shown by the following equation:

$$q = A\Delta E + B \cdot d(\Delta E)/dt$$

where ΔE is the temperature difference or voltage difference between the two surfaces of heat flow meter (mV), t is the time (hr.), A is the thermal conductivity (cal./g.hr.mV) of the heat flow meter and B is the total heat capacity (cal./g.mV) of sample holder, cap and paste.

A_I 9.83×10^{-1} B_I 15.83×10^{-1}

A_{II} 10.73×10^{-1} B_{II} 15.97×10^{-1}

Murakami measured the rate of heat liberation on the hydration of pastes made from portland cement containing phosphogypsum given in Table 5. Tables 46-1 and 46-2 show the chemical compositions of portland cement clinker, tricalcium aluminate and tricalcium silicate. The curves shown in Figs. 16-24 indicate that the time when the apex on the second cycle corresponding to a period of the most rapid hydration of tricalcium siliate phase in cement clinker appears is delayed as the amount of impurities of phosphogyspum increases. In other words, "dormant period" from the end of the first cycle to the beginning of the second cycle is markedly lengthened with increasing the amount of impurities. The development of the second cycle with phosphogypsum with less impurities, such as HDS-1, 2, 4 and 5 and HD-2, is approximately similar to that with pure gypsum (Figs. 16 and 17). This tendency closely relates to the results When the artificial gypsums containing such water-soluble phosphates as phosphoric acid, monocalcium phosphate and dicalcium phosphate which adhered to the surface of gypsum crystals with the substituted P_2O_5 are used, their retarding actions increase as the acidity of phosphates which adhered to the surface increases, namely; its degree is strengthened in the order of phosphoric acid > monocalcium phosphate > dicalcuim phosphate. In this case, the retarding action of the setting time of cement paste and the strength development of early strength cement mortar in reference to the quantity of impurities. The retarding action of artificial gypsum with only P_2O_5 substituted in the crystal lattice is relatively weak (Fig. 18).

also increases in proportion to the quantity of the substituted P_2O_5 in the crystal lattice (Figs. 19-22). Figure 23 shows the effect of artificial gypsum with the water-soluble F which adhered to the surface of the pure gypsum crystals and the gypsum crystals substituting P_2O_5. From these results, it is apparent that the retarding action of the water-soluble F is stronger than that of the water-soluble P_2O_5. Also, the retarding action is progressively strengthened as the quantity of the water-soluble F and of the substituted P_2O_5 in gypsum increase (Figs. 23 and 24).

The curves illustrated above on the rate of the heat liberation process show that there is no appreciable difference between the tangent of the ascending curve of the second peak that is normally developed and that of the ascending curve of the second peak that is considerably retarded. Therefore, the mechanism of retardation is likely that the impurities of phosphogypsum do not directly relate to the hydration reaction of tricalcium silicate, but that the hydration products connected with the impurities are formed as the protective coatings on the surface of cement particle, thus, those suppress temporarily the hydration reaction of tricalcium silicate.

In order to confirm whether the hydration of tricalcium silicate is mainly retarded by the impurities in phosphogypsum or not, the rate of the heat liberation is measured on the hydration of pastes made from the mixture of tricalcium silicate and tricalcium aluminate

with phosphogypsum and artificial gypsum as illustrated in Fig. 25. These results show that the change caused by the impurities in the development of the second peak is more apparently observed in experiments using the mixture of the both clinker minerals than those using portland cement. Consequently, it may be concluded that only the hydration reaction of tricalcium silicate is predominantly delayed by the impurities of phosphogypsum.

Another interesting phenomenon concerned with the retarding action is also observed in Fig. 25. It has been well known that the third peak in the heat liberation curve is caused by the rapid hydration of tricalcium aluminate occurring immediately after the protective coatings of trisulfate produced on the surface of tricalcium aluminate grains at early stage of the hydration were broken. The development of the third peak on the hydration of the mixture of

tricalcium aluminate and tricalcium silicate is observed after approximate thirty hours, when pure gypsum is used. However, when phosphogypsum with a large amount of impurities such as D-1 and some artificial gypsums is used, the development of the third peak is markedly accelerated and is characteristically found on the apex of the second peak in the heat liberation curve.

A resonable explanation for the accelerated third peak is probably that the protective coatings suppressing the first rapid hydration of tricalcium aluminate are not only made of trisulfate, but also structurally strengthened by calcium silicate hydrates produced from the hydration of tricalcium silicate. Because, when the hydration of tricalcium silicate is extremely delayed by the impurities, the development of third peak is more markedly accelerated than that without impurities.

Measurement of Specific Surface Area by Water Vapor Adsorption

It is suggested that the thermal measurement alone on the hydration process of portland cement or clinker minerals is still insufficient for understanding the mechanism of the retardation of set and the development of the strength at early stage by the impurities. In addition to this, the quality and morphology of the hydration products formed in the presence of impurities should be studied. For this purpose, the measurement of the specific surface area of hydration products is considered to be meaningful. On the measurement of specific surface area, it has been frequently discussed about the kinds of adsorbed gas. Powers (81), using water vapor, has reported the details of the structure of cement paste hardened under various conditions. Recently, Hunt and Mikhail (82, 83) studied the structure of the hardening psate by using water vapor, nitrogen, methanol vapor, isopropanol vapor and cyclohexan vapor. They reported that the fine structure of the hardening paste is so sensitive to the polarity and the molecular cross area of adsorbed gas that the change of fine structure of paste with varying the water-cement ratio could be evidently detected.

Since the molecular cross area of water vapor is

smaller than any one of the aforementioned gases, it is favorable to measure total surface area of the hydration products of cement independent of the water-cement ratio. Table 47 obtained by Murakami shows the specific surface area of pastes made from portland cement and the mixture of tricalcium aluminate and tricalcium silicate with various gypsums listed in the first column of Table 47. Since there is no difference caused by the kinds of gypsum in the specific surface area of plastic paste after thirty minutes, it can be also said that the hydration of tricalcium aluminate or the early stage of hydraion of portland cement is not relatively affected by the impurities of phosphogypsum. The increase of specific surface area of the paste of portland cement during the period from three hours to twenty-four hours or that of the mixture from six hours to twenty-four hours, namely, corresponding to the setting period, is markedly lowered as the amount of impurities increases. Accordingly, it is natural that the development of one day-strength of mortar becomes insufficient when the increase in specific surface area is delayed into what is normally the hardening period. A similar results has also been obtained in the case of one day-strength of mortar of the early strength portland cement.

Since the lag caused by the impurities in specific surface area of the hydration products in setting period, as shown in Table 47, is gradually restored from twenty-four hours to fourty-eight hours, even when the retarding action is relatively strong, it is true that development of three day-strength is scarcely affected.

Consequently, it is again confirmed that the impurities of phosphogypsum effectively retard the hydration of tricalcium silicate. However, phosphogypsum containing less impurities, such as HDS-1, 2, and 4 as well as pure gypsum, does not seriously affect the hydration of portland cement and the cement clinker minerals.

Retarding Mechanism of Water-Soluble F and Water-Soluble P_2O_5

The author has already suggested that the mechanism of the retarding action may be that the impurities of phosphogypsum probably form the protective coatings on the grains of the cement and tricalcium silicate to suppress temporarily the hydration of cement. The study for ascertaining the proposed explanation has been undertaken by Murakami (65), Suzukawa and Kobayashi (71). The former reported that only little amount of P_2O_5 is detected in the liquid phase extracted from the paste from one minute to eight hours after the preparation of paste. Since the liquid phase in paste of portland cement has generally the high pH value due to the high concentration of lime and alkali, it is naturally suggested that the insoluble calcium salts are produced near the cement particles immediately after P_2O_5 enters into the liquid phase and subsequently they cover the surface of the cement grains. Suzukawa and Kobayashi, quoting the explanation proposed by Jones and Forsen, said that the P_2O_5 in gypsum may be settled consequently near cement particle in the paste as the compounds of C_3A–$CaSO_4$–P_2O_5 system.

Furthermore, Murakami, considering such phenomenon that sodium silicofluoride usually produces silica gel or alkali silicates by the reaction with strong alkali, proposed the following equations on the

retarding action of the water-soluble F originated from sodium silicofluoride;

$$Na_2SiF_6 + CaO + H_2O \text{ (or } Ca(OH)_2) \rightarrow CaF_2 + SiO_2 + NaOH \quad \ldots\ldots(1)$$

$$\text{or} \rightarrow CaF_2 + \text{Calcium Silicate Hydrates} + NaOH \quad \ldots\ldots(2)$$

$$\text{or} \rightarrow CaF_2 + \text{Calcium Silicate Hydrates} + \text{Sodium Silicates} \quad \ldots\ldots(3)$$

In spite of the incomplete reaction, the reaction products corresponded to the right side of the above equations have a larger specific surface area (115 $m^2/g.$) than the algebraical sum of those of each component, namely; CaO–H_2O (16.2 $m^2/g.$) and Na_2SiF_6 (1.3 $m^2/g.$). Additionally, X-ray diffraction pattern of the reaction products showed the formation of calcium silicate hydrates. These results indicate that the reaction between the water-soluble F and the lime in high alkaline solution of the cement paste is available.

It may be confirmed by explanation that the high-lime surface of the cement particle is attacked by the water-soluble F and that the protective coatings consisted of silica gel or calcium silicate hydrates are produced on the surface of cement grains. However, the chemical compositions of these coatings have essentially the isomeric relations to the hydration products of portland cement. Therefore, the author suggested that they do not injuriously act on the hydration of portland cement, but may cause only the temporary retardation.

The water-soluble F of fluorogypsum does not so markedly retard the hydration of cement as the water-soluble F of phosphogypsum, because most of them originate from fluoric acid.

Electronmicroscopic Observation on the Surface of Hydrating Tricalcium Silicate Grains

Murakami, using electron microscope, observed directly the influence of impurities on the hydration of tricalcium silicate. He prepared some pastes from tricalcium silicate and the mixture of tricalcium silicate and tricalcium aluminate with artificial gypsum containing the watersoluble F 1.0% and the water-solbule P_2O_5 1.0% and phosphogypsum D-1. Then, the carbon replica of the hydration products at 15 minutes, 30 minutes, 120 minutes and 300 minutes were made by the dispersion method.

Electronmicrophotographs illustrated in Photo 2 show that the formation of CSH-like products is increasingly developed with time on the hydration of tricalcium silicate containing pure gypsum. In the three cases using gypsums with impurities, it is apparent that a small amount of the CSH-like products is produced only at the latter stage of the hydration and that the hydration is markedly retarded.

Closure

The present investigations have been undertaken at the time when various gypsums in Japan are being utilized progressively in cement industry. It has been recognized that phosphogypsum among chemical gypsums is valuable as a main source of gypsum for cement industry. However, there have been many problems to be solved on the impurities included in phosphogypsum. The results obtained in the present study show significantly that a prediction that the impurities of phosphogypsum injuriously affect the hydration of portland cement should be converted to a view that the impurities of phosphogypsum can be useful as the suitable retarder for portland cement.

If, however, the presence of impurities is still undesirable, they can be removed or inactivated by applying the chemical treatment shown in this paper.

Considering the great advantages which are brought by the utilization of waste products such as chemical gypsum, the present success in Japan will certainly become a valuable example.

Written Discussion

Richard A. Kuntze and Peter Hawkins

The false set of portland cement is attributed to the dehydration of gypsum to hemihydrate during the grinding of the cement clinker and the subsequent reprecipitation of gypsum in the cement paste. The relationship between the stiffening of the cement paste and the crystallization of gypsum has been studied mainly by determining the changes in the SO_3 concentration of the liquid phase of the cement. These studies have shown that the false set is affected by nuclei present in the cement which accelerate the crystallization of gypsum. The effect of impurities and additives which delay the crystallization of gypsum have been examined to a lesser extent.

However, it is well known that various types of hemihydrate, particularly those prepared from phosphogypsum, have different hydration properties and form gypsum at different rates. For this reason the effects of some of these properties on the false set of portland cement have been studied and the results are discussed in the present paper. In this study, various types and amounts of retarders for the hydration of hemihydrate have been added to the cement to delay the crystallization of gypsum. The quantities of gypsum and ettringite formed during the first 30 minutes after mixing cement and water have been determined by differential thermal analyses and compared with the rate of stiffening of the cement paste.

The relationship between different retarders and the quantity of unconverted gypsum, which provides nuclei and accelerates the recrystallization of hemihydrate to gypsum, has been studied also. Mixtures of gypsum and hemihydrate in various proportions have been added to the cement and the time and magnitude of a small temperature rise indicative of gypsum precipitation has been measured by a method developed for this purpose. Retarders have been added in conjunction with the gypsum-hemihydrate mixtures to demonstrate the effect of both retardation and acceleration on the crystallization of gypsum. This procedure provides information about the quantity of gypsum which must crystallize under certain conditions before false set is obtained.

The severity or degree of the stiffening of cement paste cannot be determined adequately with standard penetration methods. Therefore, a cone penetrometer has been developed with which it is possible to study the normal setting process and deviations from it, such as false set.

The results of these studies indicate that the occurrence of false set in portland cement depends not only on the quantity of gypsum crystallizing but also on the time and the rate of crystallization. These factors are influenced by additives and impurities such as phosphates that may be present in dehydrated phosphogypsum. Ettringite appears to contribute to the false set, probably because it forms crystals with a needle-like habit and has a tendency to form crystal clusters similar to gypsum.

Introduction

K. Murakami reported data by Suzukawa and Kobayashi (1) which indicate that dehydrated phosphogypsum behaves differently from natural gypsum with respect to the formation of false set in portland cement. These data show that the development of false set is affected not only by the quantity and the grade of dehydrated gypsum, but also by the type and amount of impurities present. He concluded that the anomalous setting behaviour of cement containing chemically untreated phosphogypsum may be caused by the large amounts of phosphate impurities.

Considering our own data, we would like to suggest that the differences observed may be due to the effect of phosphate impurities on the hydration or setting characteristics of dehydrated phosphogypsum. It is well known that some hemihydrates prepared from phosphogypsum hydrate at a different rate and respond to accelerators to a lesser extent than hemihydrates obtained from natural gypsum. Also, the setting behaviour of natural hemihydrates can be mod-

ified to resemble that of dehydrated phosphogypsum by the addition of polyphosphates or polycarboxylic acids which are known to retard the crystallization of gypsum. Using various types of retarders, we have found that the time and the rate at which the gypsum crystallizes in the cement paste substantially affects the false set phenomenon.

At the Fourth International Symposium on the Chemistry of Cement in Washington in 1960, it was the consensus of opinion that false set is the result of the dehydration of gypsum to hemihydrate during grinding or storage, and the subsequent reprecipitation of gypsum in the cement paste. Hansen (2) states that the crystallization of gypsum is demonstrated by the reduction of the SO_3 concentration in the liquid phase of the cement paste at the time when false set is determined by penetration measurements. It is also generally agreed that the crystallization of gypsum is accelerated by the cement particles and undehydrated gypsum present in the cement. Consequently, false set is not observed when the crystallization of gypsum is accelerated sufficiently to take place during the mixing period. In contrast, false set may be observed after aeration of the cement, which apparently delays crystallization until the mixing is completed.

The above statements are based to a large extent on the correlation between the changes in SO_3 concentration and penetration measurement during the early stages of the setting process. Direct determination of gypsum in the cement paste has not been carried out except by X-ray diffraction which is capable of detecting only changes on the surface of the paste. Also no attempt has been made to examine the role of calcium sulphoaluminates, particularly ettringite. For this reason we have studied the relationship between the stiffening of the cement paste and the concentration of gypsum and ettringite as determined by a direct analytical method (DTA) and a method by which small temperature changes during the setting process can be detected.

Differential Thermal Analysis of Hydrates Formed in Cement Paste

A sample of false setting cement was obtained by the addition of 4 percent hemihydrate to a commercial portland cement. Another sample was prepared by adding, in addition to the hemihydrate, 0.25 percent of an aminopolycarboxylic acid, which was known to delay the crystallization of gypsum without directly affecting the setting behaviour of the cement.

The rate of stiffening of mortars prepared from

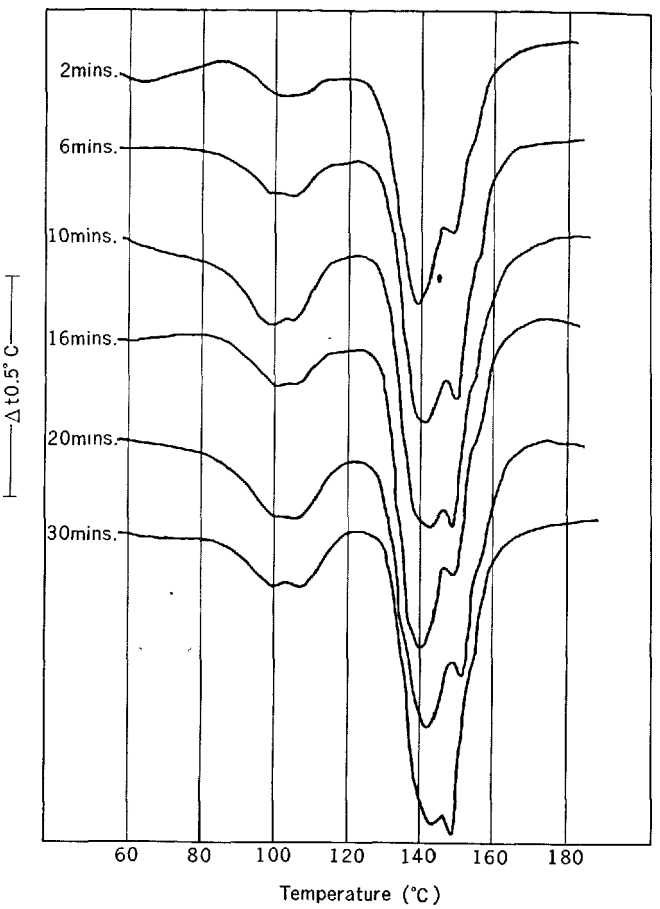

Fig. 1. *Differential thermograms for cements hydrated in the absence of retarder heating rate 4°C/min.*

both samples was determined by penetration measurements (3) over a period of 30 minutes. During this period samples were taken at regular intervals and dispersed in ethanol to prevent further hydration. Differential thermal analyses were carried out on these samples using a procedure and an apparatus described in detail elsewhere (4, 5). The areas under the peaks in the thermograms (Fig. 1 and 2) were used to determine the amounts of ettringite (first endotherm) and gypsum (second endotherm).

As shown in Fig. 3, the cement containing hemihydrate only exhibited false set approximately 6 minutes after addition of water. The false set of the cement containing both hemihydrate and the retarder was delayed to about 10 minutes and was more severe.

The rates of formation of gypsum and ettringite are shown in Fig. 4. These results indicate that the crystallization of gypsum is delayed in the presence of retarder and less gypsum is precipitated even after 30 minutes hydration time. However, ettringite is formed at a considerably faster rate when retarder is present,

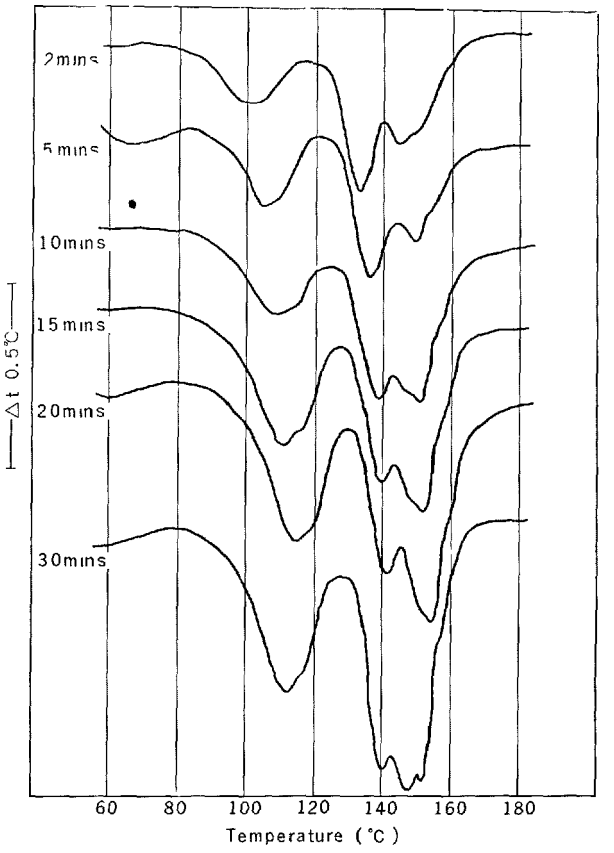

Fig. 2. *Differential thermograms for cements hydrated in the presence of retarder heating rate 4°C/min.*

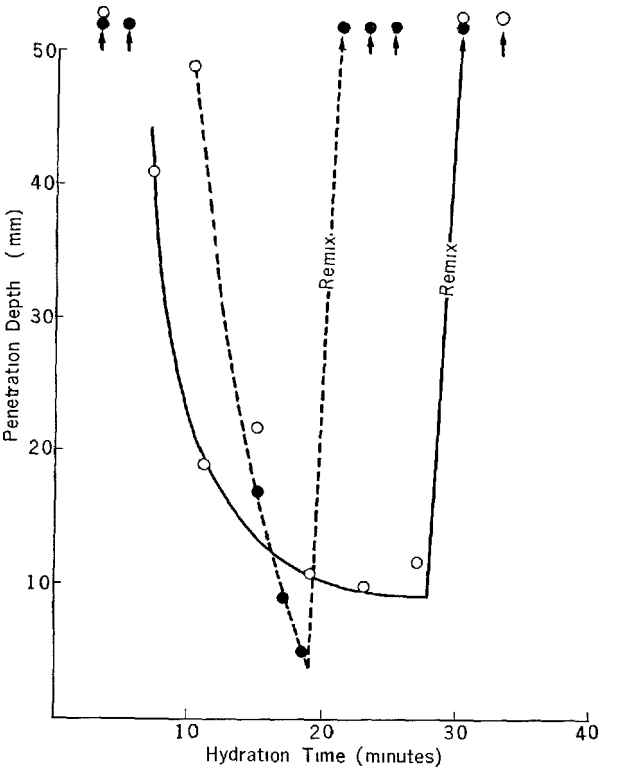

Fig. 3. *Stiffening of cements hydrated in the presence or absence of retarder*

probably due to a longer period of supersaturation with respect to gypsum (high concentration of SO_3) in the cement paste during the initial stages of the hydration.

The crystallization of gypsum coincides with the beginning of the rapid stiffening when only hemihydrate is present. In the presence of retarder the stiffening takes place before the maximum amount of gypsum has crystallized. The difference in the behaviour between the two samples may be due to the contribution of ettringite to the stiffening of the cement, since both ettringite and gypsum have a similar needle-like crystal habit and a tendency to form crystal stellates. Therefore, less gypsum is required to produce a false set when the ettringite content is high.

The Effect of the Hemihydrate-Gypsum Ratio on the False Set

It has been suggested that the gypsum added to the cement is often incompletely converted to hemihydrate during grinding. The remaining gypsum particles act as nuclei and therefore accelerate the recrystallization of hemihydrate to gypsum. If the crystallization of gypsum is accelerated sufficiently to fall within the mixing time false set is not obtained because stiffening is destroyed by the mixing.

However, some impurities or additives which delay the crystallization are particularly effective in reducing the accelerating capacity of the gypsum. To study this effect, several samples of cement were prepared by adding mixtures of gypsum and hemihydrate in various ratios maintaining a constant concentration of 2.5 percent SO_3. The temperature variations occurring in mortars prepared from these cements were measured continuously by a differential thermocouple in conjunction with a preamplified recording potentiometer. The data obtained were compared with the rates of stiffening of the mortars as determined by standard penetration methods (3).

As shown in Table 1, a hemihydrate concentration of less than 60 per cent does not produce a stiffening of the cement mortar because the quantity of crystal-

lizing gypsum is insufficient and the crystallization takes place during mixing. At a concentration of 60 to 80 percent of hemihydrate some stiffening is obtained, particularly at the initial penetration. This indicates that part of the crystallization takes place after the mixing is completed. However, the stiffness is relatively weak since most of it is destroyed by slight vibration on handling during the initial test. At a concentration of 90 and 100 percent hemihydrate sufficient gypsum crystallizes after mixing to produce a more severe stiffening which can only be destroyed by remixing.

Fig. 5 shows the corresponding temperature rise curves of the same cement samples, beginning immediately after mixing. All curves show a single peak which increases in size with increasing hemihydrate content. These peaks are due to the exothermic effect of gypsum crystallization superimposed on another but unidentified exothermic effect. This can be demon-

strated by adding retarder (amino polycarboxylic acid) to cements containing hemihydrate and gypsum in various proportions. As shwon in Fig. 6 the exothermic effect due to the crystallization of gypsum is progressively delayed by the retarder. This indicates that the stiffening of the cement mortar will be postponed also. The extent to which gypsum crystallization is delayed depends on the type of retarder and the concentration of the unconverted gypsum available for nucleation. With some retarders the effect is considerable (Fig. 7) and with others which behave similarly to phosphates, the effect is relatively small (Fig. 8).

The Effect of Phosphates on the False Set of Portland Cement

The standard penetration methods are often not sufficiently sensitive to distinguish between false sets with various degrees of stiffening. However, the determination of the severity of the false set is important, since it is indicative of a variety of factors which influence false set, particularly the hydration behaviour of the dehydrated gypsum. For this reason a more sensitive penetration method has been developed using a blunted cone with an apex angle of 20° and a weight of 250 grams.

The effect of polyphosphate on the false set of cement is demonstrated in Fig. 9. A mild false set was

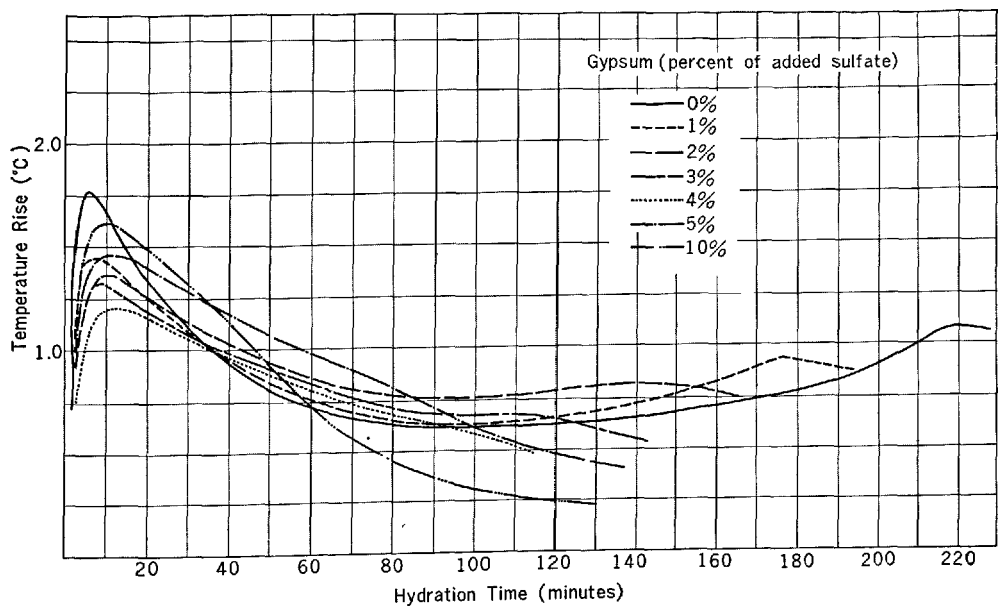

Fig. 7. *Acceleration of the precipitation of gypsum in cement hydrated with 0.2% amino polycarboxylic acid retarder*

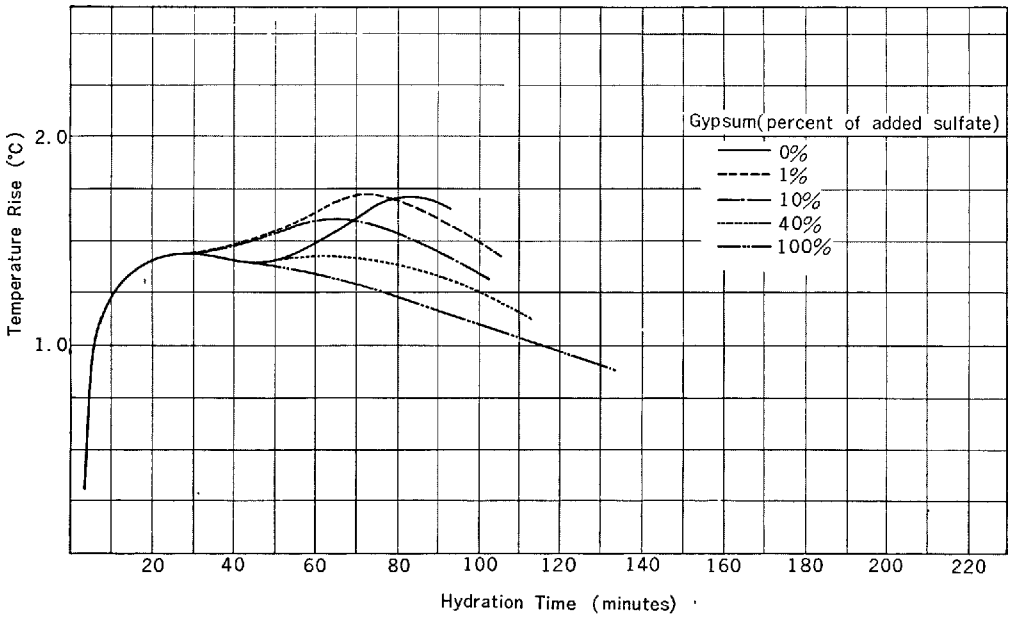

Fig. 8. *Acceleration of the precipitation of gypsum in cement hydrated with 0.2% polycarboxylic acid retarder*

-◆-- Cement containing 4% hemihydrate and 0.5% polyphosphate.

obtained by adding hemihydrate to portland cement to a total of 4 percent. The relatively small deviation from the setting pattern of normal portland cement is considered to be due to the fact that part of the gypsum crystallizes during the mixing period. This is a borderline case which may not be detected by the usual false set method. The addition of polyphosphate delays the crystallization sufficiently to take place largely after the mixing is completed. Consequently, the false set is somewhat more severe. This type of set will be detected by standard methods to determine false set.

These results indicate that impurities which interfere with the precipitation of gypsum have a considerable effect on the false set of cement. It is felt that the properties of dehydrated phosphogypsum should be examined from that point of view.

Conclusions

The false set behaviour of portland cement may be affected by the type of impurities present in the gypsum which is added to the cement clinker and forms hemihydrate during grinding. If these impurities are capable of retarding the hydration of hemihydrate, e.g. phosphates in phosphogypsum, the reprecipitation of gypsum in the cement paste is delayed until the mixing is completed. Therefore, false set is observed since the gypsum crystals are no longer broken up during the mixing.

Impurities that retard the hydration of hemihydrate also increase the rate of ettringite formation becuse

they maintain a high SO_3 concentration (supersaturation with respect to gypsum) for a longer time, Ettringite appears to contribute to the false set possibly because of a needle-like crystal habit similar to that of gypsum and a greater tendency to form crystal stellates. Consequently, less gypsum is necessary to produce false set at a high ettringite content and the false set tends to be more severe even before all gypsum has crystallized.

Acknowledgement

This work was carried out with a research grant to the Ontario Research Foundation received from the Department of Trade and Development, Province of Ontario. The authors also wish to thank Mr. A. Adami for his contribution to the development of the cone penetrometer.

Author's Closure

Keiichi Murakami

Here, I would like to introduce the written discussion proposed by Dr. Kuntze and Mr. Hawkins to my principal paper and subsequently to tell you a new data by us about the false set which is attributed to the impurities in phosphogypsum.

In my principal paper, I have concluded, by quoting the experimental results obtained by Dr.Suzukawa and Mr. Kobayashi, that the anomalous setting of cement containing untreated phosphogypsum may be caused by the large amounts of impurities.

In respect to the false set caused by the dehydration of gypsum to hemihydrate occured during grinding, Hansen has stated at last symposium that the crystallization of gypsum is demonstrated by the reduction of the SO_3 concentration in the liquid phase of the cement paste at the time when false set is determined by penetration measurement.

And the false set is not observed when the crystalliza tion of gypsum is accelerated sufficiently to take place during the mixing period.

In contrast, false set may be observed after introduction of CO_2 into the cement by areation, which delays the crystallization until the mixing is completed.

However, Dr. Kuntze and Mr. Hawkins has pointed out some of lacks in the Hansen's statement as follow; Hansen's statement are based to a large extent on the correlation between the changes in SO_3 concentration and penetration measurement during the initial stages of the setting process.

But, the direct determination of gypsum in the cement has not been carried out and also no attempt has been made to examine the role of ettringite.

Then Dr. Kuntze and Mr. Hawkins have studied the relationship between the stiffening of the cement paste and the concentration of gypsum and ettringite by using DTA and a standard penetration method and by measuring small temperature changes of the cement mortar during the setting process.

They have prepared the cement samples containing hemihydrate and both of hemihydrate and retarder such as aminopolyoxylic acid.

Initially, the rate of stiffening of mortars prepared from both samples was determined by penetration measurement.

Then it was reconfirmed that the false set of portland cement does not occur if the crystallization of gypsum which converted to hemihydrate during grinding takes place during the mixing.

But, if the crystallization is delayed by retarder until after the mixing, the false set occures.

Fig. 3 shows the above relationship in penetration measurement.

Fig. 6 shows that the exothermic effect due to the crystallization of gypsum is progressively delayed by the retarder, such as aminopolycarboxylic acid.

Secondary, they have suggested that the ettringite which produced in initial stage of hydration of portland cement contributes to the stiffening of the cement because both ettringite and gypsum have a similar needle-like crystal habit and the former will be act as neuclei in the crystallization of gypsum.

Besides, ettringite is formed at considerable faster rate when retarder is present.

Finally, they have developed a new penetration method which is capable of detecting the weak stiffening impossible to determine with the standard penetration method.

Fig.9 shows the results obtained by using the new method.

Paper No. 127

NEW CRYSTALLOGRAPHIC DATA OF SOME CALCIUM SILICATE PHASES

F. K. F. Liebau (West Germany)

This report deals with six papers on the structure and the crystal chemistry of three major mineral constituents of cements: Tricalciumsilicate (C_3S, alite), dicalciumsilicate (C_2S, belite) and ferrite (C_2F, C_4AF). One paper treats in addition some other Ca-silicates. Accordingly, the contributions are treated in three groups:

GROUP I: TRICALCIUMSILICATE AND ALITES

(1) N.A. Toropov, Leningrad, USSR
"Cation and Anion Replacement in the Structure of Tricalciumsilicate"

(2) Th. Hahn, W. Eysel and E. Woermann, Aachen, Germany
"Crystal Chemistry of Tricalciumsilicate Solid Solutions"

GROUP II: DICALCIUMSILICATE (BELITES) AND OTHER Ca-SILICATES

(3) M. Regourd, M. Bigaré, J. Forest and A. Guinier, Paris, France
"Synthesis and Crystallographic Investigations of some Belites"

(4) K. Suzuki and G. Yamaguchi, Tokyo, Japan
"A Structural Study on α'-Ca_2SiO_4"

(5) F.K.F. Liebau, Kiel, Germany
"New Crystallographic data of some Calcium Silicate Phases"

GROUP III: FERRITES

(6) E. Woermann, W. Eysel and Th. Hahn, Aachen, Germany
"Polymorphism and Solid Solution of the Ferrite Phase"

GROUP I: TRICALCIUMSILICATE AND ALITES

In both contributions solid solutions of Ca_3SiO_5 are discussed with respect to types and limits of substitution as well as effects of polymorphism.

Two problems have been investigated independently by both authors (Toropov; Hahn, Eysel & Woermann): Polymorphism and solid solution in the system Ca_3SiO_5-Ca_3GeO_5 and the stoichiometry of pure Ca_3SiO_5.

System Ca_3SiO_5-Ca_3GeO_5: The two investigations are in good accord and confirm each other. This is the only case known in which Ca_3SiO_5 forms a complete solid solution series, in contrast to the very limited solution ranges observed for other oxides.

[Table I] [Figure 1]

This solid solution corresponds to the substitution formula

$$Ca_3(Si_{1-x}Ge_x)O_5 \quad \text{with} \quad 0 \leq x \leq 1 \quad (Ca/Ge = 3.0)$$

The polymorphism of Ca_3GeO_5, as obtained by both authors, is demonstrated in Table I and compared with that of Ca_3SiO_5. The DTA results of the system Ca_3SiO_5-Ca_3GeO_5 are shown in Figure 1. Throughout the series, modification T_I occurs at room temperature.

The similarity of the silicate and the germanate extends even further: Hahn et al. report, that foreign atoms (Al, Zn, Mg etc.) can be incorporated into Ca_3GeO_5 with similar stabilization effects as in Ca_3SiO_5. Thus, there exist germanate alites analogous to the silicate alites. Ca_3GeO_5 also is metastable at low temperatures (below 1335°C), the decomposition rate being much higher than that of Ca_3SiO_5.

Stoichiometry of Ca_3SiO_5: Here the two authors disagree: Toropov has found an excess of CaO (between 0.5 and 1.0 wt.% CaO, error of the analysis $\pm$ 0.3% CaO) in the strucuture, corresponding to $CaO:SiO_2$ ratios between 3.02 and 3.04. He reports a similar excess for Ca_3GeO_5 (up to 1.5 wt.% CaO). This effect is interpreted as additional incorporation of CaO into vacancies of the structure.

Hahn, Woermann and Eysel, on the other hand, could find neither a composition range for C_3S nor a significant deviation from the stoichiometric composition $3CaO \cdot SiO_2$. They attribute a small excess of CaO which lies within their limit of error ($\pm$ 0.2 wt.% CaO) to the effect of introducing additional SiO_2 by fining the samples in an agate mortar.

Solid Solution Ca_3SiO_5-Y_2SiO_5: Toropov discusses this solid solution series, which involves the substitution $3Ca \rightarrow 2Y$, producing vacancies in the Ca lattice of Ca_3SiO_5. Analogous results have been obtained for La_2SiO_5.

[Figure 2]

The phase diagram Ca_3SiO_5-Y_2SiO_5 (Figure 2) shows a temperature-dependent solubility of Y_2SiO_5 in Ca_3SiO_5, e.g. 8 wt.% at 900°C. Beyond the solubility limit Y_2SiO_5 occurs as a second phase. Throughout the range modification T_I appears at room temperature.

All samples within the solid solution range contained ß- and

γ-Ca_2SiO_4. The amount of C_2S (up to 10-15% Ca_2SiO_4) increased with the Y_2SiO_5-concentration. As second surprising effect is that the excess of CaO increases with the Y-content, ranging from 0.5 wt.% CaO in pure C_3S to 2.5 - 3.0% CaO at the solubility limit for Y_2SiO_5 (corresponding to an increase in the $CaO:SiO_2$ ratio from 3.02 to 3.13). According to Toropov this additional incorporation of CaO is caused by the vacancies produced by the 3Ca → 2Y replacement. Thus, the solid solution must have a ratio Ca/Y smaller than 1.5, the value for pure 3Ca → 2Y substitution.

Combined substitution of MgO, Al_2O_3 and Fe_2O_3 in Ca_3SiO_5

Hahn, Eysel and Woermann have investigated the substution of the most important minor components of clinker - MgO, Al_2O_3 and Fe_2O_3 - in Ca_3SiO_5, i.e. the alite phase in the three quaternary systems $CaO-MgO-Al_2O_3-SiO_2$, $CaO-MgO-Fe_2O_3-SiO_2$ and $CaO-Al_2O_3-Fe_2O_3-SiO_2$ and in the quinary system $CaO-MgO-Al_2O_3-Fe_2O_3-SiO_2$.

For the three quaternary systems it was found, that the C_3S-phase must be represented by three-dimensional bodies of solid solution. The shapes and extensions of the bodies are given in Figures 3, 4 and 5.

[Figures 3 to 5]

The fact that bodies occur implies that the C_3S solid solutions in these systems have 3 degrees of freedom: Two are the concentrations of foreign oxides, the third is the concentration of CaO. All bodies, therefore, possess a "CaO-width", i.e. solid solutions with constant concentrations of foreign oxides may still vary in CaO-content. This result is of interest for the preparation of cement mixtures and for the evaluation of "lime-standard" formulae. The shapes of the bodies indicate that MgO and Al_2O_3 as well as MgO and Fe_2O_3 do not influence each other upon substitution in C_3S, while there exists an

interaction between the trivalent atoms Al and Fe (curved face in Figure 5).

In the solid solution characteristic composition regions occur in which the modifications T_I, T_{II} and M_I are stabilized at room temperature. These regions are indicated in Figures 3, 4 and 5.

The combined substitution of the various atoms essentially is a superposition of the individual substitution types:

Mg replaces Ca
Fe replaces Ca and Si
Al replaces Ca and Si and occupies 6-coordinated voids in the structure.

From this viewpoint the "CaO-width" of the solid solutions appears as a variation of the distribution scheme of Al in the three structural sites. Therefore, it is predominantly Al, which is responsible for the "CaO-width".

The results in the quaternary systems permit conclusions to be drawn about the alite phase in the quinary system $CaO-MgO-Al_2O_3-Fe_2O_3-SiO_2$ and in cement clinker.

GROUP II: DICALCIUMSILICATE AND OTHER Ca-SILICATES

Ca_2SiO_4 occurs in four principal forms: γ, β, α' and α. Two of the papers to be reported here are concerned with the forms α' and β, both of which occur as belites in cement clinker. The third paper by Liebau treats some other newly discovered Ca-silicates.

β-Ca_2SiO_4

Regourd, Bigaré, Forester and Guinier have determined accurate lattice constants of pure β-Ca_2SiO_4:

$a = 5.506$ Å
$b = 6.749$ Å (Space group $P2_1/n$)
$c = 9.304$ Å
$\beta = 94.62^{\circ}$

Different belites have been prepared by incorporation of various foreign atoms. According to the authors, these substances correspond to the formula

$$Ca_2[Me_x^{3+}Si_{1-x}]O_{4-\frac{x}{2}} .$$

with $Me = B^{3+}$: $0 \leq x \leq 0.10$
$Me = Fe^{3+}$: $0 \leq x \leq 0.02$
$Me = Al^{3+}$: $0 \leq x \leq 0.06$

(The solubility limits, i.e. the maximal values of x, have been obtained by DTA investigations of the α'- α - C_2S transformation.)

This formula involves the exchange

$$2Si^{4+} + O^{2-} \rightarrow 2Me^{3+}$$

which is particularly interesting because it implies vacancies in the oxygen framework of β-C_2S.

The authors distinguish two forms of β-Ca_2SiO_4: β_1 is the variety in which the lattice of pure β-C_2S is not significantly modified and which also occurs in technical clinkers; β_2 is a belite (e.g. $Ca_2Fe_{0.05}Al_{0.05}Si_{0.90}O_{3.95}$) in which the powder lines are very broad and where larger variations in the cell parameters c and β are observed.

Two forms of α'-Ca_2SiO_4

In the extant literature, two different cells and several space

groups have been reported for the α'-modification of Ca_2SiO_4 (Table II).

[Table II]

Recently it has been shown, that two different α'-Ca_2SiO_4 forms exist: a "high" form (α'_H) and a "low" form (α'_L). The transformation $\alpha'_L \longleftrightarrow \alpha'_H$ occurs at 1170°C and is reversible. The first indications for these forms were given by Smith, Majumdar and Ordway and by Niesel and Thormann.

Regourd et al. have confirmed these two forms by careful high-temperature powder investigations and by indexing the patterns (Figure 6).

[Figure 6]

The transition $\alpha'_L \rightarrow \alpha'_H$ is characteristed by the disappearance, by discontinuities and by merging of some lines in the powder patterns.

For the α'_H form the simple orthorhombic cell, first suggested by Bredig, was established. The structure is very similar to low-K_2SO_4. The extinctions in the powder pattern clearly establish Pmcn as space group (the non-centrosymmetric space group $P2_1cn$ being excluded due to the analogy with the centrosymmetric low-K_2SO_4 structure).

The α'_L-form, on the other hand, is characterized by a doubling of the a- and b-axes caused by some additional weak lines in the powder pattern. It corresponds to a superstructure of α'_H-Ca_2SiO_4. Regourd et al. have chosen the same space group for this larger cell as for α'_H-Ca_2SiO_4, Pmcn. It should be noted, however, that the extinctions in the powder pattern are equally compatable with Pmnn (obtained by Douglas for bredigite) and even better with Pbcn (the okl reflections with k = 2n are absent in the pattern). Excluded, however, is a

C-centered cell (obtained by Suzuki and Yamaguchi, see below).

The "weak" superstructure of α_L' and the fact that the transition $\alpha_L' \longleftrightarrow \alpha_H'$ is accompanied by a very small reversible DTA signal at 1170°C indicate that both structures are closely related and that α_L' represents a small displacive deformation of the low-K_2SO_4 structure (see structure determination below). It should be noted that all stabilized crystals in Table II are of the α_L'-type.

Suzuki and Yamaguchi have grown single crystals of α'-Ca_2SiO_4, which are stabilized by BaO (11.2 wt.%), SrO (8.6 wt.%) and B_2O_3 (0.9 wt.%). The authors make the reasonable assumption that Ba and Sr substitute for Ca while B replaces Si. The lattice constants are contained in Table II. They fit well into the system of the α_L'-forms. The space group of all 3 crystals is given as $Cmc2_1$. [This is not unique since C2cm and Cmcm have the same extinctions; in view of the successful structure determination (see below), however, this non-centrosymmetric space group must be accepted.] It should be noted that this space group differs from the two space groups reported above for α_L': Pmcn (Regourd et al.) and Pmnn (Douglas, obtained from single crystals of bredigite).

Suzuki and Yamaguchi stress the fact that a high-temperature X-ray diagram (152 lines) of pure α'-Ca_2SiO_4 at 1000°C is completely compatible with the large cell, derived from the single crystals. Since 1000°C lies within the temperature range of α_L', the stabilized α'-forms are α_L' too. It is noteworthy that the Ca_2SiO_4-powder patterns of Regourd et al. and of Suzuki et al. - both obtained at 1000°C - indicate different space groups.

Suzuki and Yamaguchi have determined the crystal structure of α_L'-Ca_2SiO_4, using the BaO-stabilized crystals. This is the first structure determination of α'-Ca_2SiO_4. The intensities were measured by the multiple film technique. The structure was

refined by two- and three-dimensional Fourier series to an R-factor of 0.11. (Figure 7).

[Figure 7]

The structure shows that the doubling of the a- and b-axes is caused by small shifts of the atoms with respect to the low-K_2SO_4 structure.

The authors list only some of the bond lengths (Table III).

[Table III]

There appear to be large deviations in the Si-O distances from the accepted value (1.60 Å) as well as rather different O-O distances within the tetrahedra. No errors of atomic positions are given, however. The authors state that three of the six different Ca-atoms show 8-fold, the other three Ca 6-fold coordination.

Further Ca-silicates

Liebau has obtained single crystals of several new Ca-silicate phases. These materials were obtained during experiments to grow Ca_3SiO_5 and Ca_2SiO_4 single crystals under various conditions.

(1) A new stacking modification of high-Ca_3SiO_3 (pseudowollastonite, Si_3O_9-ring structure) was obtained by heating Ca_3SiO_5 + small amounts of $Ca(OH)_2$ and CaF_2 at 1300°C. The crystals are disordered and represent analogues to the disordered forms of $SrSiO_3$ and $BaSiO_3$. The various forms of pseudowollastonite, known so far, are characteristed in Table IV.

[Table IV]

(2) In mixtures of Ca_2SiO_4 + CaO with excess of $CaCl_2$ needle-like single crystals of two related forms were found. The composition of these crystals is still unknown and their cell dimensions (Table V) show no simple relations to any known Ca-silicate.

[Table V]

(3) In mixtures of Ca_3SiO_5 + Ca_2SiO_4 with large excess of $CaCl_2$, heated to 1500°C, plate-like single crystals were obtained, most of which were twinned. First it was thought, that they were α'-Ca_2SiO_4. Untwinned crystals gave the following cell dimensions:

a = 9.89 Å
b = 6.77 Å
c = 10.91 Å
ß = 106.0°

Space group $P2_1/c$

The chemical composition of this phase probably is $Ca_2SiO_4 \cdot CaCl_2$.

GROUP III: FERRITES

The last paper by Woermann, Eysel and Hahn deals with the ferrite solid solution series $Ca_2(Fe_{1-p}Al_p)_2O_5$.

Substitution of Mg in ferrite

The types and limits of incorporation of Mg atoms in the ferrite structure were analyzed by the lime deviation method.

Two types of substitution have been found, none of them representing the simple replacement Ca/Mg (Table VI).

[Table VI]

The first type implies that two of three Mg atoms substitute for R(Fe+Al), while the third Mg occupies interstitial sites. The second type involves replacement of Ca and R atoms by Mg in addition to occupation of interstitial positions by Mg.

The change in the mode of Mg-incorporation near p = 0.50 indicates that at this composition a discontinuity in the ferrite series occurs.

Discontinuities and polymorphism of the ferrite solid solution series

Smith has described a small structural change at $p \approx 0.30$, involving a gradual transition from space group Pnma to Imma and explained by a change in the distribution of Al over the tetrahedral and octahedral sites.

The cell dimensions of the ferrite series as a function of p, both for MgO-free and MgO-saturated samples, exhibit weak but distinct changes of slope at $p = 0.30$ and $p = 0.50$ (Figure 8), thus confirming the two discontinuities.

[Figure 8]

$Ca_2Fe_2O_5$ shows two weak reversible DTA signals at 430°C and 690°C resp. High-temperature X-ray patterns reveal no change of symmetry, especially no transition from space group Pnma to Imma, in either of these transitions.

The variation of the DTA signals as a function of temperature in the ferrite series, again both for MgO-free and MgO-saturated samples offers further evidence for the discontinuities at $p = 0.30$ and at $p = 0.50$ (Figure 9).

[Figure 9]

At $p = 0.30$ the two signals, mentioned above, disappear, but a new weak signal occurs in the region 780-800°C. At $p = 0.50$ this signal disappears also and for $p > 0.50$ there is no indication of any phase change.

The investigation has revealed several small discontinuities and phase changes in the ferrite series, the structural nature of which still remains to be elucidated.

TABLE I: PHASE TRANSFORMATION IN Ca_3GeO_5 AND Ca_3SiO_5

(Toropov; Hahn, Eysel, Woermann)

Transformation	Ca_3SiO_5 (Bigaré et al.)	Ca_3GeO_5 (Toropov)	Ca_3GeO_5 (Hahn, Eysel, Woermann)
T_I - T_{II}	~600°C	750°C	745°C

GENERAL REPORT
OF
SESSION I-2: PHASE EQUILIBRIA AND FORMATION OF PORTLAND CEMENT MINERALS

Y. Suzukawa (Japan)

The following Supplementary Papers are summarized in this report.

Paper No. I-9

MANUFACTURE OF PORTLAND CEMENT FROM PHOSPHATIC RAW MATERIALS

W. Gutt (United Kingdom)

Paper No. I-18

BURNABILITY OF RAW MIXES

J. P. Sulikowski (Poland)

Paper No. I-38

ON KINETICS OF FORMATION OF PORTLAND CEMENT CLINKER

P. F. Rumyantsev (U.S.S.R.)

Paper No. I-49

CLINKER BURNING IN FLUIDIZED BED

Y. Suzukawa, H. Kono, H. Miyazaki & S. Nakai (Japan)

Paper No. I-75

NEW COMPOUND $Ca_{12}Si_4O_{19}F_2$ IN THE SYSTEM CaO-SiO_2-CaF_2 AND THE ROLE OF CaF_2 IN THE BURNING OF CEMENT CLINKER

M. Tanaka, G. Sudoh & S. Akaiwa (Japan)

Paper No. I-82

FORMATION OF DOUBLE SALTS IN CEMENT BURNING

M. Amafuji & A. Tsumagari (Japan)

Paper No. I-94

PROBLEM OF ADMIXTURES

M. M. Sichov (U.S.S.R.)

Paper No. I-98

MECHANISMS AND KINETICS OF PORTLAND CEMENT CLINKER FORMATION FOR AN EXAMPLE OF THE SOLID-STATE REACTION IN THE PRESENCE OF A LIQUID PHASE

R. Kondo & S. Choi (Japan)

Paper No. I-133

A REFINEMENT OF THE LIME STANDARD FORMULA

E. Spohn, E. Woermann & D. Knoefel (West Germany)

Among nine Supplementary Papers of this Session, Nos. 9, 75, 82, and 94 presented by Gutt, Tanaka, et al., Amafuji and Tsumagari, and Sichov, respectively, are on the minor components or admixtures in portland cement clinker.

In No. 133 SP, an improved new lime standard formula of cement raw mix is presented by Spohn, et al.

Nos. 18, 38, and 98 SP presented by Sulikowski, Rumyantsev, and Kondo and Choi, respectively, are on the burnability of cement raw mix or on the kinetics of cement clinker formation.

The last one No. 49 presented by Suzukawa, et al. is on the clinker burning in fluidized bed which has already been known as the Pyzel process.

SP No. 9 by W. Gutt

To utilize phosphatic limestone for cement manufacture in Uganda, Africa, studies have been made by Nurse, et al. at the Building Research Station since 1950. This work was further extended by the author to detailed studies in the ternary system $2CaO \cdot SiO_2$-$3CaO \cdot P_2O_5$-CaO as shown in Fig. 1. Tricalcium silicate has a primary crystallization field extending to 13 per cent P_2O_5, and there are two reaction points R_1 and R_2. Compatibility relations were established that apply at 1500°C, and the existing solid solutions defined in the phase diagram were identified. The practical significance of the phase data for this ternary system to the cement making process is discussed.

Since fluorides are sometimes added to the raw mix to improve the

quality of phosphatic cement, the role of fluorine has been explored by investigations of the ternary system $CaO-SiO_2-CaF_2$. Two new calcium silicofluorides were found; $(C_2S)_2 \cdot CaF_2$ and a compound of the approximate composition $(C_3S)_3 \cdot CaF_2$ which correspond to Phase B and A reported by Breczky, respectively. A calcium silicofluoride which differs slightly in composition from the latter compound was reported by Tanaka, et al. as described in SP No. 75, but their X-ray diffraction pattern is identical with each other. Based on the results, the following reaction sequences have been identified as shown in Tab. 1. Further, existing knowledge of the quaternary system containing P_2O_5 is discussed.

As the amount of SO_3 in the clinker influences the quality of phosphatic cement, the ternary system $CaO-SiO_2-SO_3$ and to a limited degree the quaternary system containing fluorine are being studied. A new calcium silicosulfate $(C_2S)_2 \cdot CaSO_4$ was found. Moreover, compositions on the join C_3S-SO_3 with and without 0.5 per cent fluorine have been tested for strength.

Finally, the properties of the phosphatic cements made in Uganda are described, especially, on the low early strength of "Spot" samples of clinkers taken from the plant.

This paper is very valuable not only to the manufacture of portland cement from phosphatic limestone but also to the possible utilization of industrial by-products containing phosphates and fluorides.

SP No. 75 by M. Tanaka, G. Sudoh, and S. Akaiwa

The authors studied the role of CaF_2 in the burning of cement clinker by investigations of the ternary system $CaO-SiO_2-CaF_2$. They found a new ternary compound $11CaO \cdot 4SiO_2 \cdot CaF_2$ and further an unknown phase designated tentatively as Phase II. Optical, crystallographic, and thermal properties

of this ternary compound are given in detail. The results obtained by Breczky, Gutt and Osborne, and the authors, respectively, are comparatively shown in Tab. 2. This ternary compound melts incongruently at 1185°C into trigonal C_3S and α'-C_2S, together with a liquid phase. Further, primary crystallization field in the ternary system $2CaO \cdot SiO_2$-SiO_2-CaF_2 was determined.

When cement raw mix containing CaF_2 was heated, the formation of this compound was conspicuous at about 1050°C, and at 1100 to 1150°C it melted incongruently. Accordingly, the addition of CaF_2 decreases the temperature of formation of alite at 150 to 200°C in comparison with that in a raw mix containing no CaF_2. During cooling, this compound is again formed by peritectic reaction with covering alite. This peritectic structure is considered to be a cause of decrease in the strength of cement. Further, the addition of CaF_2 increases the amount of ferrite phase, and its composition becomes rich in Al_2O_3. On the other hand, the the amount of aluminate phase is decreased.

SP No. 82 by M. Amafuji and A. Tsumagari

The ring formation in cement rotary kiln is related not only to the operating condition of the kiln but also to the mineral composition and texture of the ring. In this paper the authors studied the mineral composition of the ring and found that $CaCO_3$, $CaSO_4$, and $(K \cdot Na)_2SO_4$ and double salts, such as $2C_2S \cdot CaCO_3$, $3C_2S \cdot 2CaSO_4$, and $2CaSO_4 \cdot K_2SO_4$, are formed. The composition of this calcium silicosulfate is assigned tentatively. However, its X-ray diffraction pattern is identical with that of $(C_2S)_2 \cdot CaSO_4$ reported by Gutt and Smith.

Laboratory experiments in an electric furnace showed that the above compounds are formed by gas-solid reaction between CO_2 or SO_2 and cement

raw mix or clinker. Further, when mixed gas having a composition similar to that of the exit gas in rotary kiln was used, the reaction of clinker and SO_2 preferred to that of clinker and CO_2.

The coagulation force of the double salts at high temperatures was also measured with an improved Vicker's apparatus and expressed by penetration degree.

This paper is valuable for elucidating the ring formation and also for evaluation of the temperature of the kiln lining.

SP No. 94 by M. M. Sichov

The author studied the effects of minor components or a small amount of admixtures on sintering and properties of cement. At first the presence of P_2O_5 or B_2O_3 on the synthesis of C_3S is described. When their amount is larger than their solubility limit in C_3S, respectively, the dissociation of C_3S and simultaneously the passivity of CaO and SiO_2 occur. The addition of TiO_2, Mn_2O_3, and Cr_2O_3 decreases the mechanical strength of sintered C_3S, thus the grindability being improved. Hydraulic activity of C_3S increases by the addition of P_2O_5, Cr_2O_3, and TiO_2, etc. The upper allowable amount of these additions has been studied.

Further, it is shown that the increase in hydraulic activity of cement by the addition of admixtures is due not only to the formation of solid solution but also to the modification of microstructure of clinker. Typical modifiers of microstructure are Cr_2O_3 and P_2O_5 because their addition decreases the surface tension of clinker liquid phase. Finally, the effects of MgO and alkali oxides are described on the viscosity of the eutectic melt in the quaternary system and also on the crystallization and microstructure of clinker minerals.

Based on the results, it is concluded that when the amount of admixtures is within a certain limit, their addition is desirable but when the amount exceeds this limit, it has a harmful effect on the sintering and properties of the resulting cement.

SP No. 133 by E. Spohn, E. Woermann, and D. Knoefel

Lime standard formulas suggested by Kuehl and later modified by Lea and Parker are well known. Both formulas, however, are functions of four major components, and minor components, such as MgO, alkali oxide, and SO_3, are not being considered. In this paper the authors modified the formula by including a factor for MgO.

To a series of laboratory-prepared clinkers having a different chemical composition, various amounts of MgO were added, and after reheating at 1500°C, free CaO was determined by the Franke method. An example of the results is shown in Fig. 2. Temperature dependence of the amount of MgO combined was also determined. This value can be assumed as 0.6 per cent MgO per 100°C.

In order to apply successfully to commercial clinker manufacture, the results obtained may be simplified as follows: a maximum 2.0 per cent MgO can be combined in clinker at a CaO/MgO ratio of 0.75. Accordingly, the new formula by the authors will be as follows (Tab. 3):

$$\frac{100(CaO + 0.75\ MgO)}{2.80\ SiO_2 + 1.18\ Al_2O_3 + 0.65\ Fe_2O_3}, \text{ where } MgO \leq 2.0\% \text{ and}$$

$$\frac{100(CaO + 1.50)}{2.80\ SiO_2 + 1.18\ Al_2O_3 + 0.65\ Fe_2O_3}, \text{ where } MgO > 2.0\%.$$

To check the validity of this formula, commercial clinkers from nine different plants were tested, and for the greater part of the tested clinkers, the results were satisfactory.

SP No. 18 by J. P. Sulikowski

The author suggests a laboratory method which makes it possible to estimate comparatively the burnability of cement raw mix in rotary kiln. This method consists of two series tests: the first is the determination of free lime after heating at 800-1400°C and the second is the measurement of the deformation of cylindrical specimens during heating under a constant load of 0.02 kg/cm^2.

From the test results, the following three values characterizing the burnability are obtained:

"K" is the ratio of the lime content of ignited cement raw mix to the maximum free lime content which occurs during heating;

"L" is the temperature range at which the content of free lime is over 10 per cent as shown in Fig. 3; and

"M" is the temperature at which the height of cylindrical specimens contracts by 5 per cent.

Long time observations were made on the behavior of cement raw mix in the burning zone of rotary kiln at four cement plants from which the tested cement raw mixes were sampled. It was found that the above three values "K", "L", and "M" are effective to estimate comparatively the behavior of cement raw mix during burning. The actual meaning of each value as regards the behavior during burning in rotary kiln is also shown.

SP No. 38 by P. F. Rumyantsev

Investigation of portland cement clinker burning as a single process and derivation of a general kinetic equation are inconceivably difficult. Therefore, the author considered the sintering of clinker as a complex of the following three interdependent processes:

(1) dissolution of the minerals in raw mix and the solid-state reaction products in the liquid phase of clinker;

(2) diffusion of Ca^{2+} and SiO_4^{4-} ; and

(3) crystallization of new phases.

As these processes are connected with each other and have a chain character, the process which proceeds with a minimum rate has a determining role in the sintering of clinker. From the analysis of previous reports, it is assumed that the dissolution process has a minimum rate. Observations under high-temperature microscope showed that the crystallyzation of clinker liquid phase at above 800°C occurs very quickly.

Therefore, the formula which describes the dependence of the dissolution time on temperature and diameter of the dissolving particles may be used in reciprocal expression as the kinetic equation for clinker formation.

SP No. 98 by R. Kondo and S. Choi

The authors assumed that in the presence of the melt the reaction of CaO with C_2S to form C_3S is controlled mainly by the diffusion of each component in the liquid phase. Specimens made with two compact disks consisting of CaO and β-C_2S, respectively, were used, the two disks being sandwiched with powdered glassy phase. After heating the specimens, the boundary surface of the formation of C_3S and the concentration distribution of four major elements, i.e., Ca, Si, Al, and Fe were determined. The viscosity of the liquid phase containing various amounts of CaO, γ-C_2S, and C_3S was measured by the ball pulling-up method.

Time does not permit to explain the mathematical derivation of the kinetic equation in detail, and so let me just show you the final result as shown in Tab. 4. From Equation (3), a curve is obtained on α versus

$t/t_{0.5}$. This curve showed a good agreement with experimental results.

Further, the activation energy calculated by the Arrhenius equation increased with increasing the amount of the melt. Finally, the diffusion coefficient calculated from Equation (1) in Tab. 4 and from the viscosity measurement, respectively, was compared with that obtained by the tracer diffusion results reported by Towers and Chipman. All these results show that the assumption on the kinetics described in this paper seems to be reasonable.

SP No. 49 by Y. Suzukawa, H. Kono, H. Miyazaki and S. Nakai

The authors established the basic chemical process designs of the burning of clinker in fluidized bed through the operation of the pilot plant, especially on the combustion of fuel oil in the bed, control of the size distribution of solid particles in the bed, and heat-recovery devices of the exit gas and of the red hot clinker from the bed.

Fig. 4 shows the schematic diagram of the pilot plant. Fuel oil was injected into the bed through injection nozzle (6), and by means of the hot-air jet stream which does not pass through gas distributor, complete combustion of the fuel oil was attained, thus the bed being held at a high temperature required for sintering of clinker. The size distribution of solid particles in the bed was controlled by the following two parameters: (I) the gas velocity for use to discharge selectively coarse clinker particles through discharge pipe opening (12); (II) the size and feed amount of seed pellets made with cement raw mix. The enthalpy of high-temperature exit gas from the bed was recovered by using cyclones in which calcareous and argillaceous components are preheated separately and also the former component is calcined partially, thus the inside wall of cyclone being prevented from the adhesion of cement raw mix.

The resulting clinker showed a low value in free lime and alkalis and also superior quality. However, it is indispensable to obtain superior clinker that cement raw mix fed into the bed is partially calcined.

GENERAL REPORT
OF
SESSION I-5: ANALYSIS OF PORTLAND CEMENT CLINKER

A. E. Moore (United Kingdom)

The following Supplementary Papers are summarized in this report.

Paper No. I-12

THE MINOR ELEMENTS IN ALITE (TRICALCIUM SILICATE) AND BELITE (DICALCIUM SILICATE) FROM SOME PORTLAND CEMENT CLINKERS AS DETERMINED BY ELECTRON PROBE X-RAY MICRO-ANALYSIS

H. G. Midgley (United Kingdom)

Paper No. I-57

THE EFFECT OF CHROMIUM OXIDE ON THE STRUCTURAL TRANSFORMATIONS IN TRICALCIUM SILICATE

A. I. Boikova (U.S.S.R.)

Paper No. I-42

THE USE OF THERMOGRAVIMETRIC MEASUREMENTS IN CEMENT CHEMISTRY

P. Longuet (France)

Paper No. I-64

ON THE COLOR OF PORTLAND CEMENT

K. Miyazawa & K. Tomita (Japan)

Paper No. I-76

MISCIBILITIES OF SPECIAL ELEMENTS IN TRICALCIUM SILICATE AND ALITE AND THE HYDRATION PROPERTIES OF RESULTED SOLID SOLUTIONS

R. Kondo & K. Yoshida (Japan)

Paper No. I-79

MICROSCOPIC OBSERVATIONS OF ALITE AND BELITE AND HYDRAULIC STRENGTH OF CEMENT

Y. Ono, S. Kawamura & Y. Soda (Japan)

Paper No. I-95

THERMAL STABILIZATION OF β-$2CaO.SiO_2$

V. I. Korneev & E. B. Bygalina (U.S.S.R.)

Paper No. I-101

PROPERTIES OF SUBSTITUTED DICALCIUM SILICATE AND ALUMINO-FERRITE

M. K. Gharpurey & V. N. Pai (India)

Paper No. I-105

THE EFFECT OF MINOR COMPONENTS ON THE EARLY HYDRAULIC ACTIVITY OF THE MAJOR PHASES OF PORTLAND CEMENT CLINKER

T. Sakurai, T. Sato & A. Yoshinaga (Japan)

Paper No. I-126

THE DISTRIBUTION OF ALKALIS IN PORTLAND CEMENT CLINKER

H. W. W. Pollitt & A. W. Brown (United Kingdom)

Paper No. I-131

CEMENT SURFACE AREA DETERMINATION BY GAS ADSORPTION NEAR ROOM TEMPERATURE

A. A. Tabikh (U.S.A.)

Paper No. I-136

THE CRYSTALLIZATION OF COMPOUNDS IN THE PRESENCE OF Cr_2O_3, P_2O_5 OR SO_3 AND THE PROPERTIES OF THE CEMENT RESULTED

Yu. M. Butt, V. V. Timashev & L. I. Malozhon (U.S.S.R.)

Of the twelve papers presented to this session only two deal mainly with a single analytical technique; the remainder all report work using a number of different techniques, on aspects of the problem of the role of minor elements in modifying the major phases. This problem has already been discussed in Session I, but I think the majority of the papers in this session deal not only with crystallographic modification but also with effects on reactivity. This leads to a question on which I hope we shall hear discussion; to what extent is the reactivity affected by crystallographic modification, and to what extent is the effect purely chemical, or due to the presence of the modifying oxide in solution.

I will deal first with the two purely analytical papers; first "Cement surface area determination by gas adsorption near room temperature" by TABIKH describes a method of specific surface measurement which is applicable both to anhydrous and to hydrated cements. The method is based upon the adsorption of nitrogen or organic vapours at known partial pressure from a gas stream, followed by desorption of the adsorbate into an inert carrier gas stream whose thermal conductivity may be compared with that of the pure carrier gas by means of a thermistor bridge. This gives a d.c. voltage output which is integrated to give a calibration for each adsorbate in terms of samples of known specific surface.

Alternatively, measurements can be made at several partial vapour pressures and the BET equation used to calculate the specific surface.

Dr Tabikh's Table 1 shows results for 5 anhydrous cements and three different organic liquids, as well as measurements of specific surface from adsorption of nitrogen or benzene using the BET calculation determinations. These show that a single point determination can give sufficiently satisfactory agreement with nitrogen/BET to be a useful laboratory method, although the specific surface is about 10 times that measured by the Blaine method.

The technique when used for hydrated cements may be open to some criticism: the sample is oven dried, then heated to 200°C in a helium stream with presumably a very low water content. This must surely change the nature of some of the hydration products (e.g. ettringite, if no other). However, this is a reflexion of the need to choose a sample condition which can be accurately reproduced, before and after the adsorption-desorption cycle. The curves shown for two hydrated cements suggest that the technique at least offers a useful method for comparison of hydration rates.

The next paper - "The use of thermogravimetric measurements in cement chemistry" by LONGUET - presents an exhaustive review of the technique and literature of thermogravimetry.

He draws attention to a number of experimental details which require particular care such as heating rate, sample size, buoyancy correction, thermocouple materials, and control of atmosphere, especially water vapour pressure. Techniques employed in conjunction with thermogravimetry such as DTA or evolved gas analysis are discussed.

Two reactions of interest to the Portland cement field are dealt with in detail; decarbonation, of both $CaCO_3$ and $MgCO_3$, and de-hydration of $Ca(OH)_2$ and $CaSO_4.2H_2O$. Other processes dealt with include oxidation-reduction and adsorption-desorption. Also in the cement field, the use of TGA for a study of reactivity is described, where additions of calcium fluoride are shown to promote the early loss of CO_2 from $CaCO_3$. A point of particular interest is the use of thermogravimetry in a CO_2 atmosphere to determine the C_3S content of clinker. C_3S reacts with CO_2 at between 600 and 800°C to form a mixture of spurrite and $CaCO_3$ in variable proportions; yet in the presence of fluoride, the reaction proceeds more rapidly and quantitatively:

$$2\ C_3S + 2\ CO_2 \longrightarrow CaCO_3 + (C_2S)_2\ CaCO_3$$

and the two different forms of combined CO_2 are released at two distinct temperatures in equal steps (Fig. 8). It is not quite clear to me how the fluoride is combined during this reaction, one would expect the formation of $(C_2S)_2\ CaF_2$.

The next group of four papers deals with studies of single compounds in the anhydrous cement field, modified by the addition of usually only one or two other oxides. These studies make use of a number of techniques, some well-known such as optical and electron microscopy, XRD and DTA, some less well-known such as conductivity and colour measurement.

Starting with the simplest system, we have "Thermal stabilization of β $2CaO.SiO_2$" by KORNEEV and BYGALINA. These authors show that use of a carefully controlled annealing treatment, 30 mins at 1000°C, will permit 85% stabilization of pure β C_2S. This material has the habit of γ C_2S but the birefringence and reactivity of β, as well as X-ray and DTA properties characteristic of β.

The authors further show that the presence of 10% excess CaO over that required to form C_2S will permit the stabilization of β C_2S over a wide range of temperature, as is well known, but in addition gives a material having apparently much improved hydraulic properties in terms of strength at 91 days or later. The authors suggest that the improved reactivity is due to irregular Ca co-ordination in the β C_2S, but it is unfortunately not clear how much of the excess lime is disposed in the β C_2S lattice and how much remains as free CaO, or even possibly forms C_3S.

Another comparatively simple system is described by BOIKOVA in "The effect of chromium oxide on the structural transformations in tricalcium silicate". Mixtures of C_3S and chromium oxide were fired at 1500°C in air and using optical and X-ray methods, DTA and free CaO determination, it was found that the limit of solid solution was 1.5% Cr_2O_3; this solid solution was light green with higher refractive indices than C_3S. The system is unusual in that above 2% Cr_2O_3, the solid solutions decompose to C_2S and free lime, and above 5% Cr_2O_3, no solid solution occurs.

Mixtures of C_3S with MgO as well as Cr_2O_3 show that MgO prevents this decomposition. This presumably indicates stabilization of one of the higher symmetry polymorphs of C_3S.

The colour of chromium-substituted C_3S can be changed by the conditions of heat treatment. Annealing at 600°C in air gives yellow; at 1500°C in air green; and 16-1800°C in argon gives blue coloration.

Chemical analysis shows the valence state of the Cr in these preparations to be mainly Cr^{6+}, mixed Cr^{6+} and Cr^{3+} and mainly Cr^{3+}, respectively.

Boikova suggests that Cr^{6+} replaces Si^{4+} with production of holes:

$$3\ Si^{4+} \rightleftharpoons 2\ Cr^{6+} + \square$$

but that Cr^{3+} replaces Ca:

$$3\ Ca^{2+} \rightleftharpoons 2\ Cr^{3+} + \square$$

also with production of a vacancy.

The next paper - "The effect of minor components on the early hydraulic activity of the major phases of Portland cement clinker" by SAKURAI, SATO and YOSHINAGA also deals with the effect of chromium oxide additions to C_3S.

These authors consider that, at 1550°C in air, the limit of Cr_2O_3 solubility in C_3S is 1.7% wt. (This should be compared with 1.4% at 1550°C found by Woermann, Hahn and Eysel (1) and 1.5% at 1500°C by Boikova (paper in this session).) They find that up to 1.4% the modification remains triclinic (T_I), with decreasing lattice parameters, but between 1.4 and 1.7% Cr_2O_3; T_{II} is formed. The discontinuity $T_I - T_{II}$ is both larger and in the opposite sense from that produced by Al_2O_3. The average valency of the chromium is 4.6 throughout this series, suggesting that there is no change in the replacement at the transition. The average valency for Boikova's three green mixes, which are comparable, is 5.15, 4.71, 5.14; this is perhaps due to the slightly lower firing temperature of Boikova's mixes, 1500°C against 1550°C.

For their next series of mixes, the authors made a series of high-lime C-S-A-F-Cr_2O_3 mixes with graduated Cr_2O_3 content, designed to give C_3S, C_3A and Fss but no C_2S. They then dissolved the C_3S to analyse its A, F and Cr content, and re-synthesized these C_3S compositions, which are saturated with A and F, for a given Cr_2O_3 content. The limit of Cr_2O_3 content was again found to be 1.7%, the modification T_{II} and average chromium valency 4.6 as before. The authors suggest that both Cr and Al

are substituting for Si, but that even so, it is impossible to balance the charges on the basis of this simple replacement. Using conduction calorimetry, they also show that (Fig. 3) increased Cr content both increases the maximum rate of heat production on hydration and shortens the time for this maximum rate to be attained, although it does not affect the total heat production. They go on therefore to a study of the dc conductivity of these compositions, which show (Fig.4) a considerable increase in conductivity for increasing Cr content. The activation energy of the conductivity calculated from these measurements is slightly greater than that for Cr^{3+} - Cr^{4+} and the authors suggest that the conduction mechanism is due to a combination of Cr^{3+} - Cr^{4+}, Cr^{4+} - Cr^{5+} and Cr^{3+} - Cr^{5+}.

Electron microscopy of fractured and etched surfaces in these samples confirms that etch-pit density increases with Cr content, both screw dislocations and grain boundary dislocations being observed. A series of electron micrographs illustrates the way in which reaction is initiated at these dislocations and at the surfaces of contact with interstitial phases.

The authors describe a further series of C_3S compositions in which chromium is replaced by fluorine and phosphorus while maintaining saturation with respect to Al and Fe. The compositions found are tabulated in Fig. 23.

The effects in this system are by no means as clear-cut as in the C-S-A-F-Cr_2O_3 system.

A further study is reported by the same authors on the effects of chromium oxide additions to the ferrite phases. The limits of Cr_2O_3 stability in both C_2F and C_4AF are found to be about 5% (wt.) but the authors feel that the changes in lattice parameters are anomalous. I would suggest that these changes are most interesting and merit further study as they must reflect a preference of chromium atoms for either the tetrahedral or the octahedral sites, which overrides the normal preference for the aluminium to occupy the tetrahedral sites first. The valence state of the chromium is obviously of great importance here.

The authors feel that the XRD intensities are also anomalous but I suggest that this is simply a preferred orientation effect, which occurs also with ferrites containing SO_3. The crystal growth along the b axis is inhibited and thin platelets are formed with faces parallel to h0l; the tendency to preferred orientation can be removed by fine grinding as is seen in Fig. 34. The analogy with sulphur may indicate that the chromium atoms have a preference for the tetrahedral sites.

Because it also deals with the effects of chrome oxide additions, I think that "The crystallization of compounds in the presence of Cr_2O_3, P_2O_5 or SO_3 and the properties of the cement resulted" by BUTT, TIMASHEV and MALOZHON should be considered next.

These authors prepared clinkers designed to contain either C_3S or C_2S and an interstitial phase calculated as 6% of C_3A and 14% of C_4AF with Cr_2O_3, P_2O_5 and SO_3 added singly at levels of 0.5, 1.0, 1.5, 2.0 and 3% by weight as the oxide. Table 1 shows the amount of each oxide retained after firing but for chrome oxide only Cr_2O_3 is reported; in the light of the previous papers, it would be interesting to know if CrO_3 was present. The clinkers were examined by both reflected and transmitted light microscopy and the refractive indices and crystal development are tabulated. It is interesting that although no SO_3 was retained in the belite series, the refractive indices were still lower than those of β C_2S in the zero SO_3 mix. Possibly the fluxing action of the SO_3 introduces additional Al_2O_3 and Fe_2O_3 into the lattice.

These clinkers were than ground with 5% $CaSO_4$ to a specific surface of 3000 cm^2/g and made into paste cubes 1.41 cm side. These were tested in compression at ages from 0.5 days to 6 months and examined by XRD to determine the rate of reaction of the compounds, at 0.5, 3 and 28 days. The results are shown in Table 3 (XRD) and Figures 3, 4 and 5.

The X-ray measurements suggest that both SO_3 and Cr_2O_3 give increased reactivity in C_3S at one day and this is partially borne out by the strength measurements; but at later ages, there is no marked increase in strength and the X-ray measurements show that at 28 days the cements with Cr_2O_3 and SO_3 are very comparable to the cement with no additions; only the P_2O_5 cement is still less reactive and weaker at 28 days. In this case, there is a tendency to show increased strength at 6 months, presumably due to the slow reaction of the C_2S-C_3P solid solution.

The last paper in the group dealing with single compounds and a single added oxide is "Miscibilities of special elements in tricalcium silicate and the hydraulic properties of the resulted solid solutions" by KONDO and YOSHIDA, which studies the effect of titanium or manganese oxide additions to C_3S or Alite. These authors made four series of compositions: C_3S - "$3CaO.TiO_2$", C_3S - "$3CaO.MnO_2$", Alite - "$3CaO.TiO_2$" and Alite - "$3CaO.MnO_2$". By both free lime determination and lattice parameter measurement, they found the limits of titania solid solution to be 13 mol % at 1500°C and 14% at 1600°C, with the transformation to T_{II} occurring at 5 mol % TiO_2. With Alite, the limit of titania solid solution is the same as with C_3S, 13 mol %, even though the alite is already saturated with respect to Al^{3+} and Mg^{2+}; the monoclinic II form transforms to rhombohedral (R) at about 6 mol %. The authors feel that in both cases this is a true solid solution with Ti^{4+} replacing only Si^{4+}.

In the case of manganese, the picture is rather different; for both C_3S and alite, free-lime is detected at 1% replacement and free-lime curve (see Figures 1 and 2) shows an inflection at 6% replacement. For C_3S, the symmetry transformations are $T_I \rightarrow T_{II}$ and 1% and $T_{II} \rightarrow T_{III}$

at 6% replacement. For alite however, there is a decrease in symmetry from M_{II} to M_I at 6%. I feel some reserve about the authors interpretation of this system; surely the valency of manganese is likely to be reduced to 2 at 1600°C, and possibly at 1500°C; and replacement of CaO by MnO is most likely together with formation of a (CaMn)O solid solution.

For the hydration studies the author used one composition from each series, C_3S and alite with 7 mol % Ti, or 5 mol % Mn. These samples were ground to 3220 cm^2/g (C_3S) and 3420 cm^2/g (alite) and formed into both neat-paste samples and mortar bars. The progress of hydration was followed by free $Ca(OH)_2$ determination, XRD of anhydrous phases, conduction calorimetry and strength development. These studies present a consistent picture, typified by Fig. 11. Both Mn and Ti retard reaction between 0 and 24 hours but at this point there is a rapid acceleration in Ti-containing pastes and by 3 days they have overtaken the unmodified C_3S or alite. By 28 days the Mn-containing materials have also caught up or overtaken the unmodified materials. The mortar strength measurements show a very similar picture.

The authors use the measurements of initial particle size and degree of hydration to calculate the thickness of the hydrated layer, assuming all particles spherical, and show that this can be represented by two straight lines on log thickness/log time scales (Fig. 15). They suggest that this indicates a three-stage reaction process, first an induction period, then an accelerating period in which hydration is auto-catalytic, and finally, a third stage where the rate is diffusion controlled and therefore proportional to the density of the hydration product. This part of the paper is due for discussion in the session on kinetics, but I hope that the question of the relative effect of the

chemical composition and the crystallographic modification will be ventilated, either in this session or later.

We come now to papers dealing with systems closer to commercial cements, containing both several phases and several modifying oxides.

"Properties of substituted dicalcium silicate and alumino-ferrite", by GHARPUREY and PAI deals first with an attempt to prepare a C_2S in which $\frac{1}{16}$, $\frac{1}{8}$ or $\frac{1}{4}$ of the Si^{4+} are replaced by Al^{3+}, using felspars (bytownite or microcline) as the source of tetrahedrally co-ordinated alumina. Unfortunately, no chemical analyses are given for the compositions so it is not clear if they were designed as C_2S -"C_2A", C_2S-C_3A or even C_2S - A series. It seems probable that the first was the case and the formation of C_3A from excess alumina has resulted in a shortage of lime for complete reaction of the silica to C_2S and hence the formation of γC_2S which is notoriously favoured by excess silica. The X-ray diffraction diagrams given for the bytownite series certainly suggest that C_3A has formed to an extent which makes it difficult to separate the effects of this during hydration from those due to alumina substitution in C_2S.

The second part of the paper deals with the hydration reactions of some compositions in the system C-A-F-M-M' (M' = Mn_2O_3).

A number of authors[2, 3] have indicated that in the "C_2A"-C_2F series, greater reactivity in solution is correlated with higher aluminium content. The figures which the present authors gave for combined water indicate that the C_6AF_2 in this series was unduly reactive; the unit cell dimensions found for this compound are much closer to those of C_2F than those usually reported for C_6AF_2 and it seems probable that equilibrium was not reached during firing and the sample therefore contained CA, $C_{12}A_7$, or C_3A, any of which would have

shown increased ractivity. (The unit cell dimensions quoted for C_6A_2F are qrong, possibly due to incorrect indexing in the original publication; they should read a = 5.32, b = 14.48, c = 5.53.)

The compositions C_4AF, $C_4AF_{0.85}M'_{0.15}$, $C_4AF_{.5}M'_{.5}$, C_4AM' were also prepared; since these have constant aluminium content, any differences in reactivity should be due to the effect of manganese-iron replacement only, and would be expected to be comparatively small. The combined water measurements for $C_4AF_{0.85}M'_{0.15}$ indicate such a marked increase in reactivity compared with those for C_4AF, while higher manganese contents show much less reactivity, that it seems almost certain that equilibrium was not reached in the preparation of this series.

The next paper in this group, which also deals with the ferrite phase is by MIYAZAWA and TOMITA "On the color change of Portland cement". These authors prepared synthetic cements of three compositions, normal, high C_3S and high C_2S, with graduated additions of MgO, 0, 0.5, 1.0, 1.5, 2.0, 2.5 and 3% (wt.). The colours of these cements were measured photoelectrically for L (luminance), a (+ = red, - = green) and b (+ = yellow, - = blue) component. In all three types there was a marked darkening with increasing MgO content to a minimum L at about 1.5%, b also decreased (i.e. the colour became less yellow) and a was approximately constant.

A series of ferrite phases was prepared in which MgO replaced CaO in C_4AF at levels 0, 1.5, 3.0, 4.5, 6.0 and 9.0 molar %. These compositions were examined both for colour and resistivity and Fig. 5 shows that luminance and specific resistance show very similar relations with MgO content. Because they find very little change in the XRD patterns of this series, the authors suggest that the resistivity

change is not related to structure but to replacement of Fe^{3+} by Mg^{2+} with consequent production of positive holes.

A further series of experiments was made to study the effect of cooling conditions on colour and reactivity of industrial clinkers. Two industrial clinkers were re-heated and cooled in five different ways. All ten samples were then made into cement with added gypsum (1.6% as SO_3) and examined for colour, heat of hydration and strength of mortar bars (in compression and bending). Early strength does appear to be inversely correlated with luminance but at later ages the slowly cooled clinker which is not the lightest shows least strength development.

From the XRD patterns in Fig. 6 I would suggest that it is the effect of cooling on the C_3A which has had the marked effect on early strength. The sample quenched in water shows a micro-crystalline ferrite phase (broad diffraction lines) with a cubic C_3A; all the other patterns show a well-crystallized ferrite and an orthorhombic C_3A. Forrester and Skalny[5] have shown that orthorhombic C_3A is more reactive than cubic at early ages; so apparently, even though a glassy ferrite is considered to be more reactive than a crystalline one, it is not enough to counteract the effect of the cubic C_3A.

The next paper "Microscopic observations of alite and belite and hydraulic strength of cement" by ONO, KAWAMURA and SODA, correlates microscopic and crystallographic properties of clinker minerals in commercial cements and laboratory preparations; it shows how these properties are affected by burning and cooling conditions and hence how they may be used to predict strength of cements.

The authors point out that the presence of impurities in alite (especially alkalis and sulphate) raises the birefringence, that

slow cooling may allow exsolution of these impurities and that an alite slowly cooling in the range 1250 - 1300°C may show low birefringence and mosaic structure; XRD shows it to be monoclinic alite, not C_2S + CaO, but it is possibly disordered.

In belite, impurities are absorbed by the α form but not by α' and are exsolved according to the cooling rate; if they are fully exsolved, the colour of the belite goes to muddy yellow.

The α and α' polymorphs of C_2S have been reported to be weakly- or non-hydraulic but these authors show that this is not always so; three synthetic belites stabilised in the α, α' and β forms are described, with strengths as follows:-

	7 days	28 days	91 days	
α	47	80	169	(kg/cm^2)
α'	11	41	86	
β	11	38	51	

Furthermore, using only one composition but varying the proportions of the C_2S polymorphs (excluding γ) by the burning and cooling conditions, strength (of 1 x 1 x 7 cm mortar bars) at 91 days is shown to be correlated with α content (as determined by XRD).

Similar experiments on plant raw mixes show that conditions which favour high α content, and therefore high later-age strength, need not be incompatible with high alite strength. Finally, a survey of 45 Japanese commercial cements shows that high strength correlates with (1) high α C_2S content, (2) colourless belite, and (3) high birefringence alite. The authors therefore suggest that a fairly long high temperature burn, followed by quick cooling from a moderately high temperature, is desirable.

The remaining two papers deal mainly with analyses of commercial cements in order to estimate true chemical compositions of the clinker phases.

The paper by POLLITT and BROWN on "The distribution of alkalis in Portland cement clinker" is based mainly on chemical analyses of commercial cements separated into fractions by selective solvent extraction and hydrolysis.

These authors show that the alkali sulphates may occur as members of the range of K_2/Na_2SO_4 solid solutions or as the double sulphate, calcium langbeinite, $2CaSO_4.K_2SO_4$ (see Fig. 2). I think that this is the first time this compound has been reported in Portland cement, although it is known to occur in kiln rings. It seems likely that it occurs only in high K_2O/Na_2O ratio cements.

Most interesting also are Table 2 and Fig. 3 which show clearly what I take to be a partition coefficient for potassium and sodium, between sulphate and clinker minerals of two to one. The authors deduce that this reflects the greater affinity of potash for sulphate but I would like to suggest that the similar ionic radii of Na and Ca favours retention of Na in the clinker minerals.

The authors tabulate the distribution of K and Na in sulphates, silicates, aluminate and ferrite phases in Table 4, and show that several correlations can be extracted.

The K/K + N ratio seems to be the same for the ferrite and the C_3A, and the silicates, but there is also a correlation between the potassium/alumina ratio of the C_3A and that of the ferrite phase. There is not much evidence to support Newkirk's suggestion that potash goes preferentially into belite. The authors show also that both potassium and sodium are capable of inducing the cubic-to-orthorhombic transformation of C_3A, at 2.8% equivalent potash or 1.8% equivalent soda.

The last paper, by MIDGLEY, reports "The minor elements in alite and belite from some Portland cement clinkers as determined by electron probe X-ray micro-analysis". It contains analyses for N, K, M, A, F, Ti and Mn. The main problem in obtaining quantitative estimates from the electron-probe lies in the inter-element absorption effect. Midgley has surmounted this by using as standards synthetic materials made to compositions very close to those being analysed. He reports partition coefficients for these elements between the silicate phases, which have not appeared in print before, to my knowledge.

In Table 9 (the last column) values >1 indicate enrichment in belite with respect to alite; thus only MgO is higher in alite than in belite; even Al_2O_3, usually considered to be the essential stabilising oxide in alite, is in fact enriched 3:2 in belite. It seems possible that the alite was not saturated with respect to MgO, as none of these cements contained more than 1.34%; this possibility seems to be borne out by Yamaguchi's EPMA figures for MgO (page 67 of the Principal paper) which indicate that in two cements with MgO contents of about 1.4%, the belite has the higher MgO content. Belite is also shown to be very considerably enriched in potash (in contradiction of Pollitt and Brown's findings) with a higher partition coefficient than any of the other oxides measured. The figures Midgley gives for average molar composition of belite (p.7) correspond to 3.3% replacement of the cations (and only 3% of the oxygen, i.e. an 0.3% oxygen defect).

One of the uses which we hope to make of this kind of measurement is to predict the composition of the phases in a given clinker and hence possibly to arrive at a better calculated composition. A number of the previous papers have made it clear that burning and cooling conditions may have as much effect on reactivity as does composition but it is still tempting to see what correlations exist between total chemical analysis and concentrations in the phases. For Fe_2O_3 and Al_2O_3, using measurements

by Peterson[6], Midgley[7], Fletcher[8], Terrier and Hornain[9] one obtains the relation shown in Slide no. 1 for alite and belite. This seems to indicate a fairly promising correlation for Fe_2O_3, but considerable scatter for Al_2O_3.

P. P. Williams (New Zealand)

Paper No. I-90

THE SOLID-SOLUTION IN THE SYSTEM C_2AS (GEHLENITE)-CA_2 AND A NEW TERNARY PHASE

K. Sugiura & T. Yoshioka (Japan)

Paper: "The Crystal structure of $11CaO.7Al_2O_3.CaF_2$" by P.P. WILLIAMS

This paper is of particular interest in that it provides a convincing explanation of the peculiar zeolitic behaviour of $C_{12}A_7$ first reported by Roy and Roy, and Nurse, in 1960 and subsequently investigated in more detail by Majumdar and reported this year[1].

Briefly, at temperatures up to 1100°C '$C_{12}A_7$' can retain water, even in an environment of low partial water vapour-pressure and indeed as normally prepared '$C_{12}A_7$' must be regarded as a ternary compound in the system $CaO-Al_2O_3-H_2O$ and not a binary compound. In equilibrium conditions $C_{12}A_7H$ appears to be the composition of this substance. Dr Williams has obtained a specimen of a compound apparently isomorphous with $C_{12}A_7H$ in which the water, as $Ca(OH)_2$ has been substituted by CaF_2. This compound is not only more stable than $C_{12}A_7H$ but also lends itself more readily to crystal structure analysis and Dr Williams has presented in convincing detail a structure which agrees well with observed x-ray diffraction data.

A further merit of the proposed structure is that it offers an acceptable explanation of the reactivity of '$C_{12}A_7$' toward water and for the close similarity of the structure of anhydrous $C_{12}A_7$, $C_{12}A_7H$ and the halogen substituted analogues.

The proposed structure of $C_{11}A_7.CaF_2$ is a three dimensional network of linked AlO_4 tetrahedra in which the Ca-O and Ca-F coordination is

very iregular. To quote Dr Williams: "the anions which cannot be accommodated in a fully ordered structure are randomly distributed on a 12-fold equipoint of point symmetry $\bar{4}$. These anions contribute to a modified octahedral coordination of up to one-third of the calcium atoms. Large holes occur in the structure where sites in this equipoint remain unfilled, and adjacent calcium atoms have an unbalanced coordination shell".

The compound $C_{12}A_7$ contains one more oxygen atom per formula unit than can easily be accommodated in a simple fashion in its unit cell and no doubt the presence of this excess atom is associated with the reactivity of the anhydrous compound towards water and equally with the close similarity of the X-ray diffraction pattern of the anhydrous compound and $C_{12}A_7H$.

The majority of the paper is devoted to a lucid exposition of the reasoning which has led to the definition of the proposed structure of $C_{11}A_7CaF_2$ and of compounds generally of the composition $C_{11}A_7CaX_2$ where X can be OH^-, F^- or Cl^- and calls for no further comment from me.

What, however, is of some interest is the stability of the compound $C_{12}A_7H$. There are very few substances which are capable of retaining water at temperatures above 1000°C and one might justifiably speculate upon the reasons for the greater stability of the O-H bonds in $C_{12}A_7H$ compound with, say $Ca(OH)_2$ or the hydrates which are formed when portland or aluminous cements react with water. Dr Williams has given an expalanation of the manner in which the $\overline{OH}$ (or F^- or Cl^-) is incorporated in the structure of these compounds. Perhaps the thermodynamicists would come to offer an explanation for their stability?

Paper: "The Solid Solution in the System C_2AS (Gehlenite) - CA_2 and a new Ternary Phase by K. SUGIURA and T. YOSHIDA

This interesting paper describes a detailed investigation of a small region of the ternary system $CaO-Al_2O_3-SiO_2$ bounded by CAS_2 (anorthite), CA_2 and C_2AS (gehlenite).

The authors show clear evidence that a metastable ternary phase can be formed in melts having compositions represented by a zone in the $CAS_2-CA_2-C_2AS$ triangle and that this phase can have the compositions C_3A_3S and $C_3A_3S_2$ as well as other compositions. It appears that this ternary solid solution phase can exist as a monophase without much change in optical properties or cell dimensions in compositions represented by a considerable area of the phase diagram and if my interpretation of the authors' explanation for this is correct, this implies that:-

(i) A continuous series of solid solutions exists of composition represented by a portion of the line C_3A_3S - CAS_2 (anorthite) starting at C_3A_3S.

(ii) A continuous series of solid solutions exists of composition represented by a portion of the line CA_2- CAS_2 (anorthite).

(iii) Solid solutions can apparently be formed between any member of the solid solutions mentioned above as (i) and (ii), thus giving a wide range of compositions in which monophase production is possible.

(iv) The area of the phase diagram which represents this wide range of compositions cannot be regarded as homogeneous because when the properties of solid solutions represented by lines running from CAS_2 (anorthite) towards the $CaO - Al_2O_3$ boundary are studied, there are inflexions in the refractive index v composition graph as one passes the compositions represented approximately by the line $C_3A_3S_2$ - $C_5A_6S_4$ - $C_2A_3S_2$. There are thus perhaps two zones of

composition which represent similar but not identical kinds of solid solution.

The composition of the compound C_3A_3S lies on the edge of one of the zones mentioned above and is also on the line C_2AS (gehlenite) - CA_2.

It is shown that C_3A_3S clearly exists as a monophase when equimolar proportions of C_2AS and CA_2 are heated to 1000-1100°C, and the authors have passed on from this to study the phase composition of mixtures with compositions represented by other points along the C_2AS - CA_2 line to discover whether solid solutions can be formed between C_2AS and CA_2 over a limited range of proportions.

The authors show that when such mixtures are heated to temperatures in the range 950 - 1530°, the sole identifiable phases are a melilite, a glass, CA_2 and phase "X", a ternary phase. They argue that phase "X" is C_3A_3S but do not appear to support this contention by experimental evidence.

As the ratio CA_2/C_2AS in the mixtures is increased at temperatures of 1000-1100 and with compositions having a CA_2 content up to 15 per cent, there is a corresponding increase in a_o cell dimension of the melilite as the CA_2 content increases. This the authors take to indicate that there is a small range of compositions which form solid solutions of CA_2 in C_2AS giving a melilite in which aluminium atoms substitute equally for calcium atoms in the "A" sites of the melilite structure and aluminium atoms substitute for silicon atoms in "C" sites. The latter substitution was foreshadowed by Christie[1] as possible but the former substitution seems unlikely because of the great difference in size of aluminium and calcium atoms. If such substitution does take place, it ought to give rise to a considerable decrease in the c_o cell dimension from that found in gehlenite but the authors do not say whether this change was observed.

If, as the authors claim, phase "X" has truly the composition C_3A_3S, then the claim that CA_2 is entering into solid solution with C_2AS is well founded. If, on the other hand, phase "X" is not C_3A_3S but has some other composition, for example, one represented by the large area mentioned earlier in (iv) or lying along the line C_3A_3S-$C_3A_3S_2$, then the melilite composition must, in the case of the preparations which contained only melilite and phase "X", be silica deficient and lie off the C_2AS - CA_2 line towards the CaO - Al_2O_3 boundary.

To summarise, the authors have clearly demonstrated the existence of a new metastable phase in the CAS_2 - CA_2 - C_2AS region and have offered strong but not completely convincing evidence that C_2AS can absorb up to 15 per cent CA_2 to form a continuous solid solution series.

THE ALTERATION OF SILICATE ANIONS IN TOBERMORITE GELS

H. Funk (West Germany)

SYNOPSIS

The degree of condensation of silicate anions in tobermorite gel has been investigated by H. Funk. A criterion for the degree of condensation is the rate of formation of molybdato silicic acid, which occurs after addition of paramolybdate to the sample dissolved in methanolic hydrochloric acid. The results show that the hydration products of tricalcium silicate and dicalcium silicate contain as well monosilicate as higher condensed silicates. The degree of condensation increases with decreasing CaO/SiO_2 ratio in the tobermorite gel and with aging. H. Funk assumes that the coexistence of various silicate anions is the cause for the low degree of crystallisation of tobermorite gel.

The crystal structure of tricalcium aluminate hexahydrate $3CaO.Al_2O_3.6H_2O$, especially the positions of the hydrogen ions, was determined by R. Kiriyama, H. Kiriyama and M. Takagawa with proton magnetic resonance studies. Accordingly the structure consists of $[Al(OH)_6]^{3-}$ anions, which form a ionic lattice of the garnet type together with the Ca^{2+} cations. Inside the oxygen tetrahedrons there are no discrete H_4 clusters.

According to recent investigations of M. H. Roberts the tetracalcium aluminate hydrate $4CaO.Al_2O_3.aq$ occurs in 4 stages of hydration with 19, 13, 11 and 7 H_2O depending on the drying conditions.

The hydrates with 13, 11 and 7 H_2O can dehydrate and rehydrate reversibly. X-ray investigations of S. J. Ahmed, L. S. Dent Glasser and H. F. W. Taylor have shown that the crystal structure of tetracalcium aluminate hydrate consists of principal layers of the composition $[Ca_2Al(OH)_6]^+$, each combined with an interlayer containing one OH ion per unit cell and the water molecules. The principal layer is composed of $Al(OH)_6$ and $Ca(OH)_6$ octahedrons connected with one another by common edges.

The composition of the complex compounds of tetracalcium aluminate hydrate corresponds to the general formula $3CaO.R_2O_3.Ca(X,Y_2).aq$ with R representing Al^{3+}, Cr^{3+}, Ga^{3+} und Fe^{3+}, with X representing a divalent anion such as CO_3^{2-}, SO_4^{2-}, CrO_4^{2-}, and Y representing a monovalent anion such as Cl^-, Br^-, J^-, NO_3^- or BrO_3^- respectively. X-ray investigations of H.-J. Kuzel and of F. Le Bel and G. Grasland confirm that the complex compounds have the same crystal structure as tetracalcium aluminate hydrate and that the anions replace the OH^- ions in the interlayers. Furthermore H.-J. Kuzel describes double salts of the composition $3CaO.Al_2O_3.1/2CaSO_4.1/2CaCl_2.12H_2O$ and $3CaO.Al_2O_3.1/2Ca(NO_3)_2.1/2CaCl_2.10H_2O$, in which sulfate and chloride containing interlayers alternate in the unit cell.

There is a continuous series of solid solution between the monosulfate $3CaO.Al_2O_3.CaSO_4.12H_2O$ and the compound $3CaO.Al_2O_3.1/2Ca(OH)_2.1/2CaSO_4.12H_2O$, which probably belongs to the double salts described by H.-J. Kuzel. The investigations of M. H. Roberts indicate that in the adequate systems hydroxide-carbonate and hydroxide-chloride exist similar series of solid solution.

A complete solid solution series also occurs between the compounds $3CaO.Al_2O_3.CaCO_3.11H_2O$ and $3MgO.Al_2O_3.MgCO_3.11H_2O$. According to G. Sadran and B. Cottin the phases of this series can be prepared by addition of hydromagnesite $3MgCO_3.Mg(OH)_2.3H_2O$ to a metastable calcium aluminate solution with a molar ratio $CaO/Al_2O_3 = 3$. They also occur when high alumina cement hydrates in presence of hydromagnesite and when various calcium aluminate hydrates react with hydromagnesite in a paste.

1. INTRODUCTION

This general report is concerned with the structural composition of tobermorite gel, with the crystal structure of tricalcium aluminate hexahydrate and with equilibrium relations and crystal structure of tetracalcium aluminate hydrate and the related complex compounds. It is based on the following supplementary papers:

Tobermorite gel

Arrival Nr. 14

G. Sadran, B. Cottin: Contributions to the study of complex aluminates: Hydrated calcium and magnesium monocarbo-aluminates.
Arrival No. 15

2. TOBERMORITE GEL

The paper of H. Funk is concerned with the degree of condensation of silicate anions in calcium silicate hydrate formed by hydration of tricalcium silicate and β-dicalcium silicate at 25 °C. To determine the degree of condensation, a weighed sample is dissolved in methanolic HCl and then a paramolybdate solution is added, which forms a complex compound together with the silicic acid. Under standardized conditions the rate of reaction only depends on the degree of condensation of the silicic acid in the solution which corresponds to the condensation of the silicate anions in the tobermorite gel.

The increase in content of molybdato silicic acid $H_4SiMo_{12}O_{40}$ plotted against reaction time on a logarithmic scale yields a straight line, the slope of which is a criterion for the rate of reaction and consequently for the degree of condensation, too (1)(2)(3)(4). Using this method the monosilicic acid of β-Ca_2SiO_4, the disilicic acid of $Na_6Si_2O_7$, the tricyclosilicic acid of α-$CaSiO_3$,

the tetracyclosilicic acid of $K_4H_4Si_4O_{12}$, and hexacyclosilicic acid of $Cu_6Si_6O_{18}.6H_2O$ can be significantly distinguished (fig. 1a). Mixtures of silicic acids with different degrees of condensation yield a curve instead of a straight line. From the profile of the curve the type and the amount of silicate components in the mixture can be estimated.

The results of adequate investigations on hydration products of tricalcium silicate and β-dicalcium silicate show that both substances contain monosilicate and higher condensed silicates, too. Compounds with more that 6 SiO_4 tetrahedrons are produced by tricalcium silicate to less than 4o %, by β-dicalcium silicate to about 5o %. The degree of condensation of silicate anions in tobermorite gel does not depend on the kind of the basic material only, but on the conditions of hydration, too. Tricalcium silicate hydrated for 9o days at 25 °C in a saturated calcium hydroxide solution yields a calcium silicate hydrate with a molar ratio CaO/SiO_2 of 1.76, consisting of mono-, di-, tri-, and tetrasilicates.

Hydrating tricalcium silicate under same conditions but in water calcium silicate hydrates with a CaO/SiO_2 ratio of 1.54 are formed, 4o % of which have a degree of condensation of 6 or more. Still higher condensed calcium silicate hydrates with about the same CaO/SiO_2 ratio of 1.51 arise from paste hydration of tricalcium silicate after 5 years.

Furthermore the influence of CaO/SiO_2 ratio on the degree of condensation was investigated on calcium silicate hydrates produced by reaction of a o.1 molar solution of $Na_2H_2SiO_4$ with a solution of $Ca(ClO_4)_2$. The CaO/SiO_2 ratio was gradually raised

from o.89 to 1.41 by addition of increasing amounts of NaOH. The degree of condensation in the calcium silicate hydrates increases intensely with decreasing CaO/SiO_2 ratio. There is an increase of condensation, too, when the calcium silicate hydrates remain in contact with the mother liquor for a longer period or when they were dried after filtration (fig. 1b).

The investigations show that the SiOH groups in the tobermorite gel can react to larger units. The degree of condensation mainly depends on the content of CaO in the tobermorite gel and on the method of preparation, especially on aging. Consequently in tobermorite gel silicate anions of various degrees of condensation are present. H. Funk assumes, that the occurence of different silicate anions in the tobermorite gel is the cause for the low degree of crystallization of the calcium silicate hydrates.

3. CRYSTAL STRUCTURE OF TRICALCIUM ALUMINATE HEXAHYDRATE

The crystal structure of tricalcium aluminate hexahydrate with the formula $3CaO.Al_2O_3.6H_2O$ or $Ca_3Al_2(OH)_{12}$ was investigated by R. Weiss and D. Grandjean (5) using X-ray diffraction. Accordingly the space group is Ia3d and the lattice constant at room temperature is 12.573 Å.

The positions of the heavy atoms are:

16 al in (a) (o, o, o)

24 Ca in (c) (1/8, o, 1/4)

96 O in (h) (x_o, y_o, z_o)

where $x_o = o.o3o$

$y_o = o.o52$ and

$z_o = o.64o$

The positions of the hydrogen atoms are not yet known. They are

of special interest with regard to the isomorphism with grossularite $Ca_3Al_2(SiO_4)_3$, which requires a substitution of 1 Si^{4+} by 4 H^+. Therefore R. Kiriyama, H. Kiriyama and M. Takagawa used the proton magnetic resonance method to determine the position of hydrogen atoms.

Tricalcium aluminate hexahydrate was prepared by slow addition of aluminium powder to a saturated solution of calcium hydroxide. The exact X-ray investigations showed a lattice constant of 12.566 Å at 24 °C and 12.536 Å at -170 °C respectively.

The infrared absorption indicated that the sample contained no adsorbed water and that the hydroxyl group was free from any hydrogen bond. The measurements by proton magnetic resonance were carried out in a temperature range between -186 ° and +25 °C. From 20 measurements at low temperature and 15 measurements at room temperature for the second moment ΔH_2^2 mean values resulted of

$$22.7 \pm 0.3 \text{ gauss}^2 \text{ at } -186\,^{\circ}\text{C and}$$

$$19.6 \pm 0.5 \text{ gauss}^2 \text{ at } +25\,^{\circ}\text{C}$$

respectively.

From considerations of symmetry the hydrogen atoms must occupy the 96 (h) positions with the parameters x_H, y_H, and z_H. Since only one value of the second moment is available from the proton magnetic resonance, the three parameters cannot be determined independently. So for the various model structures theoretically possible the second moments were calculated by the method of J. H. van Vleck (6) and compared with the measured moments. For the positions of the hydrogen atoms following parameters resulted:

$$x_H = 0.093;\ y_H = 0.074;\ z_H = 0.681$$

These values differ from those of C. Cohen-Addad, P. Ducros and G. F. Bartaut (7), who found the following positions for the

hydrogen atoms, resulting from neutron diffraction at 4 °K:

$$x_H = 0.101; \; y_H = 0.049; \; z_H = 0.662$$

For this static model the calculated second moment is 26.9 gauss^2 compared with the experimental value of 22.7 gauss^2 at -186 °C. However both investigations showed that there are no discrete H_4 clusters inside the oxygen tetrahedrons.

The distances between two hydrogen atoms of the same $(OH)_4$ tetrahedron are 1.96 Å and 2.56 Å, the shortest H-H distance between adjacent tetrahedrons is 2.02 Å. This arrangement of the hydrogen atoms confirms that the structure is composed of $[Al(OH)_6]^{3-}$ anions, which together with the Ca^{2+} cations form a ionic lattice of the garnet type. The Al-O-H bond is not linear as in a free $[Al(OH)_6]^{3-}$ complex owing to electrostatic interactions but forms an angle of 138 ° caused by the approach of the other ions.

4. TETRACALCIUM ALUMINATE HYDRATE

4.1 Composition, Water Content

The composition of the tetracalcium aluminate hydrates, especially their water content was studied again by M. H. Roberts. As all phases of tetracalcium aluminate hydrate react with CO_2 very quickly, any contact with atmospheric CO_2 during preparation and investigation had to be avoided strictly. The tetracalcium aluminate hydrate with the composition $4CaO.Al_2O_3.19H_2O$ is only formed as a metastable phase in an aluminate solution with a high content of lime under atmospheric pressure at temperatures in the range from 1 ° to 50 °C. There are two polymorphs α_1 and α_2 which have the same longest basal spacing d_B = 10.7 Å but slight differences in the position of the non-basal reflections.

At relative humidities in the range from 81 to 11 % the $4CaO.Al_2O_3.19H_2O$ dehydrates to $4CaO.Al_2O_3.13H_2O$ with a longest basal spacing of 7.9 Å. Rehydration of the 13 H_2O hydrate to 19 H_2O hydrate is not possible. In earlier publications M. H. Roberts (8) and F. E. Jones and M. H. Roberts (9) assumed that $4CaO.Al_2O_3.13H_2O$ exists in two polymorphs α and β with d_B = 8.2 Å und 7.9 Å respectively. But recent X-ray investigations showed that the α-modification with d_B = 8.2 Å is a CO_2 containing phase of the composition $3CaO.Al_2O_3.1/2Ca(OH)_2.1/2CaCO_3.12H_2O$ (chapter 6.2). So $4CaO.Al_2O_3.13H_2O$ only exists in one modification with d_B = 7.9 Å, the water content of which - 13 H_2O - was confirmed by exact chemical determinations.

The investigations of P. Seligmann and N. R. Greening (10)(11) gave the same results. In contrast to this view R. Alègre (12), F. Lavanant (13) and W. Dosch and H. zur Strassen (14) suggested that there exist a $4CaO.Al_2O_3.12H_2O$ with d_B = 7.9 Å and a $4CaO.Al_2O_3.13H_2O$ with d_B = 8.2 Å. According to W. Dosch and H. zur Strassen this 8.2 Å spacing likewise is derived from a compound of composition $3CaO.Al_2O_3.3/4Ca(OH)_2.1/4CaCO_3.aq$. These differences M. H. Roberts attributes to an inadvertent carbonation which can hardly be avoided during preparation and X-ray investigations.

$4CaO.Al_2O_3.11H_2O$ with d_B = 7.4 Å is formed by drying $4CaO.Al_2O_3.13H_2O$ over anhydrous $CaCl_2$ or solid NaOH. When exposed to a moist atmosphere, $4CaO.Al_2O_3.11H_2O$ rehydrates very easily giving the 13 H_2O hydrate. When dried over P_2O_5, $4CaO.Al_2O_3.7H_2O$ with a weak basal reflection with d_B = 5.5 Å is formed. Higher

values for the longest basal spacing found by other authors (12)(13)(14), M. H. Roberts attributes to rehydration which occurs very readily, or to carbonation.

4.2 Crystal Structure

The crystal structure of various stages of hydration of tetracalcium aluminate hydrate is described in the supplementary paper of S. J. Ahmed, L. S. Dent Glasser and H. F. W. Taylor based on recently published results (15)(16). The X-ray investigations were carried out on single crystals of the approximate composition $4CaO.Al_2O_3.12\text{-}13H_2O$, containing some structural carbonate. The crystals are trigonal, space group R $\bar{3}$ c, the unit cell with a = 5.73 Å, c = 47.16 Å (referred to trigonal axes), contains 6 formula units of mean composition $Ca_2Al(OH)_{6\ 3/4}(CO_3)_{1/8}.2\ 1/2H_2O$ or in the carbonate-free compound $Ca_2Al(OH)_7.2\ 1/2H_2O$.

The structure (fig. 2) consists of 6 "principal layers" of the composition $[Ca_2Al(OH)_6]^+$ perpendicular to c with a distance of 7.86 Å in c-direction. The layers are formed by $Al(OH)_6$ and $Ca(OH)_6$ octahedrons which are connected with one another by common edges. The Ca^{2+} ions, however, are shifted along the c-axes for $\pm$ o.5 to o.6 Å out of the plane of the Al^{3+} ions at z = o. Accordingly the $Ca(OH)_6$ octahedrons are distorted. Each principal layer is combined with an interlayer containing one further $(OH)^-$ ion and the water molecules. Two of the water molecules occupy sites marked P in fig. 2, raising the Ca-coordination to 7. The OH ion and eventually one further H_2O molecule occupy the cavities designated by X. The layer complexes, each of them composed of principal and interlayer, are displaced to each other by 2/3 a and 2/3 b.

Including the results of M. H. Roberts the principal layers and interlayers of tetracalcium aluminate hydrates have the following composition and c distances:

$4CaO.Al_2O_3.19H_2O$	$[Ca_2Al(OH)_6.2H_2O]OH.4H_2O$	1o.7 Å
$4CaO.Al_2O_3.13H_2O$	$[Ca_2Al(OH)_6.2H_2O]OH.H_2O$	7.9 Å
$4CaO.Al_2O_3.11H_2O$	$[Ca_2Al(OH)_6.2H_2O]OH$	7.4 Å
$4CaO.Al_2O_3.7H_2O$	$[Ca_2Al(OH)_6]OH$	5.5 Å

According to S. J. Ahmed, L. S. Dent Glasser and H. F. W. Taylor the great diminuation of the layer distance of $4CaO.Al_2O_3.7H_2O$ is caused by a small changing of the arrangement of the $Al(OH)_6^{3-}$ octahedrons and the Ca^{2+} ions. The $4CaO.Al_2O_3.19H_2O$ contains one additional layer of water molecules between the principal layers.

5. COMPLEX COMPOUNDS OF TETRACALCIUM ALUMINATE HYDRATE

5.1 Composition

The composition of the complex tetracalcium aluminate hydrates corresponds to the formulas $3CaO.Al_2O_3.CaX.nH_2O$ or $3CaO.Al_2O_3.CaY_2.nH_2O$ with X representing a divalent and Y representing a monovalent anion respectively. At relative humidities of about 35 % the compounds contain 1o-12 water molecules per formula unit.

The supplementary paper of H.-J. Kuzel describes the crystal structure of compounds containing Cl^-, Br^-, J^-, NO_3^-, and BrO_3^- as monovalent and SO_4^{2-} and CrO_4^{2-} as divalent anions. The compounds with Cl^-, Br^-, and NO_3^- were investigated by S. J. Ahmed, L. S. Dent Glasser and H. F. W. Taylor, too, the compound with Br^- by F. Le Bel and G. Grasland.

From these complex salts series of similar compounds can be derived replacing Al^{3+} by other trivalent cations. G. Malquori and V. Cirilli (17) already reported about the corresponding ferrite hydrates. New results about the substitution of Al^{3+} by Ga^{3+} or Cr^{3+} are communicated here by H.-J. Kuzel.

According to the supplementary paper of G. Sadran and B. Cottin it is moreover possible to replace the Ca^{2+} in the monocarbonate $3CaO.Al_2O_3.CaCO_3.11H_2O$ by Mg^{2+} gradually. These results will be reported in the last chapter about the formation of solid solutions between tetracalcium aluminate hydrate and the related complex compounds.

5.2 Preparation

Bulk preparations of complex compounds can be made by mixing adequate solutions of calcium and aluminium salts with addition of calcium hydroxide solution. Instead of aluminium salt solution often a metastable solution of calcium aluminate is used. Complex salts are also formed when a suspension of $4CaO.Al_2O_3.19H_2O$ in mother liquor is treated with a sufficient addition of corresponding calcium salt.

F. Le Bel and G. Grasland prepared single crystals of monobromide, $3CaO.Al_2O_3.CaBr_2.10H_2O$ with a diameter up to 0.4 mm involving the slow diffusion of a basic alkali aluminate solution or of a calcium bromide solution into water or into a bromide containing solution. H.-J. Kuzel obtained single crystals of monosulfate, $3CaO.Al_2O_3.CaSO_4.12H_2O$ and monochromate, $3CaO.Al_2O_3.CaCrO_4.12H_2O$ with diameters up to 1 cm by reaction of $3CaO.Al_2O_3.6H_2O$ with calcium sulfate or

calcium chromate solutions respectively. Smaller single crystals of compounds which are stable at temperatures above 100 °C can be prepared by heating CaO and $Al(OH)_3$ with adequate solutions of calcium salts at about 150 °C in autoclaves for several weeks. X-ray inspections showed that crystals prepared under hydrothermal conditions were ordered completely, but crystals precipitated from metastable aluminate solutions often showed considerable disorder.

5.3 Crystal Structure

The results of H.-J. Kuzel's X-ray investigations are listed in tables 1 and 2. For the unit cell of the monobromide, $3CaO.Al_2O_3.CaBr_2.10H_2O$, F. Le Bel and G. Grasland found the same value as H.-J. Kuzel for a_o (5.76 Å), but half the value for c_o (24.45 Å) and the space group R 3 or R $\bar{3}$ instead of R 3 c or R $\bar{3}$ c.

According to a former investigation of H.-J. Kuzel (18) the monochloride, $3CaO.Al_2O_3.CaCl_2.10H_2O$ occurs in two polymorphic modifications with the transition point at about 28 °C. The crystals of both polymorphs are small pseudohexagonal plates, but the α-phase stable at lower temperature is monoclinic with d_B = 7.89 Å, the β-modification is trigonal with d_B = 7.81 Å.

The new compound, $3CaO.Al_2O_3.1/2Ca(NO_3)_2.1/2CaCl_2.10H_2O$ is very similar to the compound $3CaO.Al_2O_3.1/2CaSO_4.1/2CaCl_2.12H_2O$ already described earlier (19). Single crystals were prepared under hydrothermal conditions.

H.-J. Kuzel assumes that in the crystal structures of these compounds interlayers containing Cl^- alternate with interlayers containing SO_4^{2-} or NO_3^- respectively. Thus double layers result with composition $[Ca_4Al_2(OH)_{12}]^{2+}.Cl^-.1/2SO_4^{2-}.6H_2O$ or

$[Ca_4Al_2(OH)_{12}]^{2+}.Cl^-.NO_3^-.6H_2O$. The unit cell of these complex salts contains six double layers. According to H.-J. Kuzel compounds of this type are to be expected in similar systems with anions of considerably different sizes. Probably the compounds $3CaO.Al_2O_3.1/2Ca(OH)_2.1/2CaSO_4.12H_2O$ and $3CaO.Al_2O_3.1/2Ca(OH)_2.1/2CaCO_3.12H_2O$ described by M. H. Roberts (chapter 6.1 and 6.2) belong to this type, too.

The values in table 1 show that with increasing size of the anions the lattice constant c_o grows, but a_o remains nearly constant. But when Al^{3+} is replaced by the larger cations Cr^{3+}, Fe^{3+} or Ga^{3+} a_o increases and c_o decreases.

Further information about the crystal structures of these complex compounds give the dehydration reactions of monochloride, monobromide and mononitrate observed with thermal analysis, X-ray investigations and infrared absorption measurements by S. J. Ahmed, L. S. Dent Glasser and H. F. W. Taylor. After longer heating at 100 °C the reaction products showed the composition $3CaO.Al_2O_3.CaY_2.6H_2O$ with a basal spacing of 6.8 Å for monochloride, 7.1 Å for monobromide and 7.9 Å for mononitrate respectively. These infrared absorption spectra compared with those of the initial materials are nearly unchanged. On further heating the residual water is expelled and the crystal lattice is destroyed.

All present results agree with the crystal structure proposed by S. J. Ahmed and H. F. W. Taylor (16), which is especially confirmed by the preliminary Fourier synthesis of monojodide by H.-J. Kuzel. Accordingly the complex compounds of the type $3CaO.R_2O_3.Ca(X,Y_2).aq$ have unit cells similar to those of the various phases of tetracalcium aluminate hydrate (fig. 2). Each

principal layer with the composition $[Ca_2R(OH)_6]^+$ consisting of $R(OH)_6$ and $Ca(OH)_6$ octahedrons is combined with one interlayer containing the anions ($1/2X^{2-}$ or Y^-) and 2 or 3 H_2O molecules. Two of these H_2O molecules occupy regular sites marked P (fig. 2), the monovalent all and the divalent anions half of the cavities of the type marked X, which eventually can take up further H_2O molecules.

6. SOLID SOLUTION BETWEEN TETRACALCIUM ALUMINATE HYDRATE AND THE VARIOUS COMPLEX COMPOUNDS

6.1 Tetracalcium Aluminate Hydrate - Monosulfate

The formation of solid solution between $4CaO.Al_2O_3.mH_2O$ and $3CaO.Al_2O_3.CaSO_4.nH_2O$ was investigated by M. H. Roberts. The various solid solution phases were prepared by treating a suspension of $4CaO.Al_2O_3.19H_2O$ in mother liquor with increasing additions of gypsum.

The results of the X-ray investigations are shown in fig. 3. The indexing of these particular reflections was based on the hexagonal pseudocell with a_o = 5.76 Å and c_o = 26.79 Å determined by H.-J. Kuzel (19). Fig. 3 shows that for $CaSO_4/Al_2O_3$ molar ratios from o.5 to 1 the values for 1/3 c, corresponding to the longest basal spacing (oo3), increase continuously from 8.77 Å to 8.96 Å with increasing $CaSO_4$ content, but a_o with 5.75 Å remains constant. These results indicated that there is a solid-solution series between the compounds $3CaO.Al_2O_3.1/2Ca(OH)_2.1/2CaSO_4.12H_2O$ and $3CaO.Al_2O_3.CaSO_4.12H_2O$. Solids of $CaSO_4/Al_2O_3$ ratios below o.5 consist of mixtures of $4CaO.Al_2O_3.19H_2O$ and the limiting solid-

solution compound with the lowest sulfate content, for ratios over 1 the mixtures consist of monosulfate and $3CaO.Al_2O_3.3CaSO_4.32H_2O$.

The compound $3CaO.Al_2O_3.1/2Ca(OH)_2.1/2CaSO_4.12H_2O$ probably belongs to the type of double salts described by H.-J. Kuzel (chapter 5.3) just as the corresponding carbonate compound, mentioned in the next chapter. It may be assumed that interlayers with hydroxyl ions alternate with interlayers containing sulfate ions in the unit cell and that in the hydroxyl interlayer the OH^- ions can be replaced by sulfate ions continuously.

6.2 Tetracalcium Aluminate Hydrate - Monocarbonate

To prepare carbonate containing tetracalcium aluminate hydrates M. H. Roberts treated suspensions of $4CaO.Al_2O_3.19H_2O$ in mother liquor with different amounts of carbon dioxide. With increasing content of carbonate increasing amounts of a carbonate containing phase with d_B = 8.2 Å occured. When the molar ratio CO_2/Al_2O_3 of 0.5 was reached only this compound was present. Hence it follows that the composition of the 8.2 Å compound corresponds to the formula $3CaO.Al_2O_3.1/2Ca(OH)_2.1/2CaCO_3.12H_2O$. With still larger amounts of CO_2 the monocarbonate, $3CaO.Al_2O_3.CaCO_3.11H_2O$ with d_B = 7.6 Å was also formed while the 8.2 Å compound diminished.

So in this way it was not possible to detect any solid solutions between $3CaO.Al_2O_3.1/2Ca(OH)_2.1/2CaCO_3.12H_2O$ and $3CaO.Al_2O_3.CaCO_3.11H_2O$. But when samples of $3CaO.Al_2O_3.1/2Ca(OH)_2.1/2CaCO_3.12H_2O$ were treated with dilute solution of calcium hydroxide, part of the Al_2O_3 is dissolved from the solid phase and thus the CaO/Al_2O_3 ratio increased. X-ray investigations showed that the basal spacings decrease continuously from 8.15 Å to 7.8 Å.

Already on drying at 33 % relative humidity the compound $3CaO.Al_2O_3.1/2Ca(OH)_2.1/2CaCO_3.12H_2O$ loses two water molecules. The new lo H_2O hydrate with a longest basal spacing of 7.7 Å is even stable over waterfree calcium chloride. When dried over phosphorus pentoxide it loses two more H_2O molecules and the basal spacing decreases to 7.3 Å. On the other hand the monocarbonate $3CaO.Al_2O_3.CaCO_3.11H_2O$ is essentially more stable. Even when dried over waterfree calcium chloride it loses no water.

6.3 Tetracalcium Aluminate Hydrate - Monochloride

Some preliminary investigations of M. H. Roberts obtained on suspensions of $4CaO.Al_2O_3.19H_2O$ with increasing additions of calcium chloride, suggest that there exists a limited solid solution series between $4CaO.Al_2O_3.13H_2O$ and $4CaO.Al_2O_3.CaCl_2.1oH_2O$, similar to the series between $4CaO.Al_2O_3.1/2Ca(OH)_2.1/2CaSO_4.12H_2O$ and $4CaO.Al_2O_3.CaSO_4.12H_2O$. The basal spacing of the solid solution phases decreases from about 8.o Å to 7.8 Å, when the $CaCl_2/Al_2O_3$ molar ratio increases from o.5 to 1.o. A solid solution series between monosulfate and monochloride was not yet observed. The phase $3CaO.Al_2O_3.1/2CaSO_4.1/2CaCl_2.12H_2O$ found by H.-J. Kuzel (18) is a stoichiometric compound.

6.4 Substitution of Calcium by Magnesium in Monocarbonate

Possibilities for the replacement of calcium in monocarbonate, $3CaO.Al_2O_3.CaCO_3.11H_2O$ by magnesium were examined by G. Sadran and B. Cottin. At first they treated a calcium aluminate solution with a CaO/Al_2O_3 ratio of 3 with increasing amounts of hydromagnesite $3MgCO_3.Mg(OH)_2.3H_2O$.

The X-ray investigations showed that without addition of hydromagnesite only dicalcium aluminate hydrate $2CaO.Al_2O_3.8H_2O$ with a longest basal spacing of d_B = 1o.8 Å was formed. With low additions of hydromagnesite also monocarbonate with d_B = 7.6 Å and (according to M. H. Roberts) $3CaO.Al_2O_3.1/2Ca(OH)_2.1/2CaCO_3.12H_2O$ with d_B = 8.2 Å occured. At hydromagnesite contents just required for the formation of $3CaO.Al_2O_3.MgCO_3.aq$ the solid consisted of monocarbonate only. For still higher hydromagnesite additions corresponding to CO_2/Al_2O_3 ratios above 1, monocarbonate coexisted with calcite and aragonite.

Differential thermal analysis showed that the magnesium hydroxide present in hydromagnesite, did not react and occured unchanged in the precipitates. From the chemical composition of the solid including the results of the thermal and X-ray analysis the phase composition of the solid and the chemical composition of the monocarbonate were calculated with the assumption that the molar ratio CO_2/Al_2O_3 of the monocarbonate is 1 and that the magnesium hydroxide of the hydromagnesite did not react. The results indicate that a substitution of Ca^{2+} by Mg^{2+} in monocarbonate is possible. With increasing addition of hydromagnesite the CaO/Al_2O_3 ratio in monocarbonate decreases from 4.5 to o.2 and the MgO/Al_2O_3 ratio increases from o.6 to 4.1. Thus the composition of the monocarbonates corresponds to the general formula $[Ca_{2-x}Mg_xAl(OH)_6]CO_3.5\text{-}6H_2O$, where x can vary from o to 2. The solid solution phases show the same X-ray patterns as $3CaO.Al_2O_3.CaCO_3.11H_2O$, but if more than half the Ca^{2+} ions are replaced by Mg^{2+} ions only the considerably broadened main reflections of monocarbonate occur.

When mixtures of high alumina cement and hydromagnesite hydrated in suspensions with a water/solid ratio of lo or in pastes with a

water/solid ratio of o.5 at first monocalcium aluminate hydrate $CaO.Al_2O_3.10H_2O$ was formed, at higher temperatures dicalcium aluminate hydrate $2CaO.Al_2O_3.8H_2O$ and the cubic tricalcium aluminate hydrate $3CaO.Al_2O_3.6H_2O$. But afterwards all aluminate hydrates reacted with the hydromagnesite forming monocarbonate solid solutions. Pastes prepared from the pure aluminate hydrates with addition of hydromagnesite showed a similar behaviour. In any case the monocarbonate solid solutions were formed very quickly, especially from the cubic tricalcium aluminate hydrate.

GENERAL REPORT

OF

SESSION II-2: CRYSTAL STRUCTURES AND PROPERTIES OF CEMENT HYDRATION PRODUCTS (HYDRATED CALCIUM ALUMINATES AND FERRITES)

(b) Papers regarding Properties

M. H. Roberts (United Kingdom)

The following Supplementary Papers are summarized in this report.

Paper No. II-6

STABILITY OF HYDROGARNET SERIES TERMS TO SULPHATE ATTACK

B. Marchese & R. Sersale (Italy)

Paper No. II-40

FORMATION OF HYDRATED GEHLENITE THROUGH THE REACTION OF CLAY MINERALS AND LIME

A. Ariizumi (Japan)

Paper No. II-67

SUCCESSFUL PREVENTION OF LOSS OF STRENGTH IN CONCRETE MADE WITH HIGH-ALUMINA CEMENT

P. K. Mehta (India)

Paper No. II-68

AMORPHOUS PHASE IN THE $CaO-Al_2O_3-CaCl_2-H_2O$ SYSTEM

F. Tamás (Hungary)

Paper No. II-81

BARIUM ALUMINATE AND BARIUM SILICATE AND THEIR HYDRAULIC PROPERTIES

H. Uchikawa & K. Tsukiyama (Japan)

SUMMARY

The contents of five Supplementary Papers to be presented at the Fifth International Symposium on the Chemistry of Cement, Tokyo, October 1968 are summarised and discussed. Two of the papers deal with particular aspects of specific hydrated compounds, and are respectively concerned with the precipitation of different calcium chloroaluminate hydrates by mixing calcium chloride and monocalcium aluminate solutions, and with the reaction of silica-containing hydrogarnets related to $3CaO.Al_2O_3.6H_2O$ with lime-calcium sulphate solutions. Of the remaining papers, one is devoted to an attempt to prevent the loss in strength of high-alumina cement concrete under warm and wet conditions, another paper discusses the reaction of certain clay minerals with lime solutions to form the so-called 'hydrated gehlenite' ($2CaO.Al_2O_3.SiO_2.8\ H_2O$), and the final paper describes the properties and crystal structures of barium hydroxide monohydrate and particular anhydrous and hydrated barium aluminates and silicates.

Building Research Station, Ministry of Public Building and Works

Five Supplementary Papers have been assigned to a theme devoted to the properties of hydrated calcium aluminates and ferrites and related more complex hydrates. Two of the papers deal with particular aspects of specific hydrated compounds, and are respectively concerned with the precipitation of different calcium chloroaluminate hydrates by mixing calcium chloride and monocalcium aluminate solutions, and with the reaction of silica-containing hydrogarnets related to C_3AH_6 with lime-calcium sulphate solutions. Of the remaining papers, one is devoted to an attempt to prevent the loss in strength of high-alumina cement concrete under warm and wet conditions, another paper discusses the reaction of certain clay minerals with lime solutions to form the so-called 'hydrated gehlenite' (C_2ASH_8), and the final paper describes the properties and crystal structures of particular anhydrous and hydrated barium aluminates and silicates. In view of the widely varying nature of the topics covered in these Supplementary Papers, it is therefore proposed in this General Report to separately summarise and discuss the more essential details of each paper.

1. F. Tamas, "Amorphous Phase in the $CaO-Al_2O_3-CaCl_2-H_2O$ System"

A study is made of the solids precipitated when supersaturated monocalcium aluminate solutions are mixed with calcium chloride solutions at temperatures in the range 0°-70°C, but mainly at 22°-25°C. The concentration of the $CaCl_2$ solution varied from 0.125 molar to 2.0 molar, but that of the calcium aluminate solution is not given. The precipitates were separated from the reaction mixtures after 1 hour, and investigated by chemical and X-ray analysis, infra-red spectroscopy and electron microscopy.

It is concluded that the concentration of the $CaCl_2$ solution has a marked effect on the nature of the precipitated solid. While crystalline precipitates are obtained at $CaCl_2$ concentrations of 0.4 molar and below, higher concentrations of 0.5 molar and above resulted in the formation of amorphous solids giving X-ray patterns with only a broad band in the region 3.6-4.4Å. The crystalline solids gave X-ray patterns very similar to that reported for the calcium monochloroaluminate decahydrate ($C_3A.CaCl_2.10H_2O$), but their chemical compositions varied considerably, the alumina content always being higher than that of this formula while the calcium content is lower, and it is inferred that they are members of a $C_4AH_{13}-C_3A.CaCl_2.10H_2O$ solid-solution series. The reported transition from a crystalline to an amorphous solid appeared to be a gradual change, and it is not markedly affected by temperature in the range 0°-70°C. The crystalline and amorphous phases are also said to differ under the electron microscope and in their infra-red spectra, but few details are given.

It is of interest to compare these results with those obtained in previous studies on the system $CaO-Al_2O_3-CaCl_2-H_2O$ by other investigators[1-4]. On the

one hand, provided that sufficient free $Ca(OH)_2$ is present in solution, it has been established that pure crystalline $C_3A.CaCl_2.10H_2O$ is obtained when the $CaCl_2$ concentration in the equilibrium solution is about 3per cent (or 0.27 molar), but lower $CaCl_2$ concentrations in solution resulted in the formation of a solid-solution series between C_4AH_{13} and $C_3A.CaCl_2.10H_2O$, probably only over a restricted range of compositions. On the other hand, when insufficient $Ca(OH)_2$ is present in the reaction mixture, it has been shown[1] that hydrated alumina is also precipitated. The composition of the product obtained by mixing $CaCl_2$ solutions and calcium aluminate solutions will therefore depend not only on the $CaCl_2$ concentration but also on the composition of the calcium aluminate solution and on the amount, if any, of added lime.

Since a monocalcium aluminate solution was used in the experiments by Tamas, it seems probable that the results were influenced by the lack of free $Ca(OH)_2$, together with the progressive reduction in pH caused by increasing $CaCl_2$ concentrations, and the consequent precipitation of alumina gel. It could be suggested that the broad band in the X-ray patterns of 'amorphous' solids may really arise from alumina gel. Similarly, the weak spacings at about 4.8Å and 4.35Å which are included in the X-ray patterns of 'crystalline' solids may also be attributed to hydrated alumina. It is noteworthy that the latter spacings are more intense in the preparation made at 70°C (Table 1, column 5), and this could be explained by better recrystallisation of the hydrated alumina to bayerite and/or gibbsite at the higher temperature. Furthermore, the reported partial solubility of the precipitates in nitric acid may also be an indication of the presence of more difficultly soluble hydrated alumina. The 'crystalline' precipitates may therefore really consist of mixtures of hydrated alumina and $C_3A.CaCl_2.10H_2O$, at any rate at the higher $CaCl_2$

concentrations. The presence of varying amounts of hydrated alumina, probably with some occluded and/or adsorbed Ca and Cl ions, could well account for the widely varying chemical compositions which are indicated. It is clear therefore that further work is needed before the conclusions made by Tamas with regard to the reaction products from $CaCl_2$ and monocalcium aluminate solutions can be accepted.

2. B. Marchese and R. Sersale, 'Stability of Hydrogarnet Series Terms to Sulphate Attack'

An investigation is made of the reactivity at ordinary temperatures of particular hydrogarnet compositions in contact with calcium sulphate solutions saturated with respect to $Ca(OH)_2$ for periods up to 4 months. The four hydrogarnets studied were members of the solid-solution series C_3AH_6-$C_3A.3SiO_2$ (grossularite). These compounds were prepared hydrothermally at 150°C from glasses of appropriate compositions to give respective molar ratios of SiO_2/Al_2O_3 of 0.22, 0.28, 0.35 and 0.43, and a corresponding increasing shrinkage of the crystal lattice relative to that of C_3AH_6.

After treatment with calcium sulphate solution, X-ray analysis and optical and electron microscopy showed the formation of $C_3A.3CaSO_4.31H_2O$ in each case. The extent and rate of this reaction was followed by chemical and X-ray analysis and by differential calorimetry. Similar results were obtained with each method, and these showed that both the rate and the extent of reaction with sulphate progressively decreased with increasing SiO_2 content of the original hydrogarnet.

The diminished reactivity of silica-containing hydrogarnets with calcium sulphate solution indicated by these results may therefore partly account

for the improvement in sulphate resistance obtained by high-pressure steam curing of cements. In this connection, it may be noted that it has also been established[5] that in the case of the hydrogarnet solid solutions formed at room temperature in which Fe_2O_3 replaces Al_2O_3 the relative reactivity towards calcium sulphate solution decreased with increasing Fe_2O_3 content, and the behaviour is thus very similar to that of the silica-containing hydrogarnets.

3. P.K. Mehta, 'Successful Prevention of Loss of Strength in Concrete Made with High-Alumina Cement'

This paper describes an attempt to develop a suitable additive for high-alumina cement to prevent the loss in strength which occurs especially in concretes exposed to warm and wet conditions, and is accompanied by the conversion of the initial main hydration product CAH_{10} into C_3AH_6 and γ-$Al_2O_3\ 3H_2O$ (gibbsite). Recent investigations[6,7] have established that the diminution in strength is associated with an increase in internal porosity in high-alumina cement samples of normal or high water/cement ratio, arising from the conversion of the constituent hydrates, and high strengths and low porosities can be obtained at low water/cement ratios even when C_3AH_6 and gibbsite are formed.

In the described investigation, 2 in. x 4 in. (50 mm x 100 mm) concrete cylinders were prepared at 4°-10°C, using a water/cement ratio of 0.60, standard sand and crushed quartz aggregate, and a laboratory-prepared high-alumina cement composed essentially of monocalcium aluminate, both without and with 5 per cent (by weight of total cementitious material) of an additive consisting of a synthetic anhydrous calcium sulphoaluminate

of composition $C_3A_3.CaSO_4$. The concrete cylinders were cured in cold water (4°-10°C) up to an age of 28 days, and tests were then made on some of the cylinders, while the remaining cylinders were stored in water at 38°C and similarly tested periodically up to an age of 24 weeks. The tests included determinations of the compressive strength and modulus of elasticity of the various concretes, and X-ray analysis of the separated hydrated cement fractions to establish the proportions of the hydrated compounds present.

The compressive strength data showed that comparable strengths of about 8000 lb/in.^{2} (55.2 N/mm^2) are obtained from concretes with and without the sulphoaluminate additive after 28 days at low temperature. On storage at 38°C, the strength of both concretes initially increased during the first 28 days to about 11,000 lb/in.^{2} (75.8 N/mm^2), probably caused by further hydration of the cement, but subsequently the strength of the plain concrete progressively diminished to about 2,000 lb/in.^{2} (13.8 N/mm^2) at an age of 24 weeks, whereas only a slight decrease in strength to about 10,000 lb/in.^{2} (68.9 N/mm^2) occurred over the same period in the concrete with the sulphoaluminate additive. Similar trends are also observed in the values of the modulus of elasticity of the different concretes.

The X-ray diffraction analysis of the hydrated cement fractions from the different concretes confirmed the findings of many previous studies, and established that while CAH_{10} is the main hydration product in the concretes cured at low temperatures, changes in the mineralogical composition occurred in the concrete without any additive and the loss in compressive strength at 38°C is accompanied by the formation of increasing amounts of C_3AH_6 relative to CAH_{10}. Only a small amount of C_3AH_6 appeared

to be formed at 38°C in the concrete containing the sulphoaluminate additive. It is therefore concluded that the $C_3A_3 \cdot CaSO_4$ additive is capable of stabilising the CAH_{10} hydrate, thereby maintaining a high compressive strength and preventing the usual loss in strength of high-alumina cement concretes when these are exposed to warm and wet conditions.

The mechanism of the action of the sulphoaluminate additive in preventing the conversion of CAH_{10} into C_3AH_6 and gibbsite seems to be rather obscure. This $C_3A_3 \cdot CaSO_4$ compound would be expected to react with water to produce alumina gel and calcium monosulphoaluminate hydrate, and it is possible that these hydrates precipitate as protective coatings on the CAH_{10} produced during the hydration of high-alumina cement and prevent its subsequent dissolution to form C_3AH_6. Alternatively, the solution composition may be changed in the presence of the monosulphoaluminate hydrate so that the formation and growth of C_3AH_6 nuclei from the aqueous phase is decreased. Further work is needed to investigate these possibilities, and it also appears to be desirable to carry out additional experiments with commercial high-alumina cements, and at longer duration, in order to confirm the effectiveness of the $C_3A_3 \cdot CaSO_4$ additive in preventing the conversion reaction and the associated loss in strength in high-alumina cement concretes.

4. A. Ariizumi, 'Formation of Hydrated Gehlenite through the Reaction of Clay Minerals with Lime

A review is made of studies on the reaction of saturated lime solution with co-precipitated alumina-silica gels and with hydrated aluminium silicate clay minerals, such as allophane, halloysite and kaolinite, and on the so-called 'hydrated gehlenite' C_2ASH_8 that is thereby formed. The extent

of the reaction was followed by determining the amount of lime removed from solution, and the reaction products were characterised by X-ray diffraction, differential thermal analysis and other methods.

Treatment of allophane with saturated lime solution produced C_2ASH_8, C_3AH_6 (or eventually a silica-containing hydrogarnet), 'C_4AH_{13}' and $C_3A.CaCO_3.11H_2O$, depending upon the lime concentration and the temperature. The C_2ASH_8 hydrate is obtained at temperatures below 50°C, and also at low lime concentrations at 60°C, but C_3AH_6 is formed with high lime concentrations at 60°C and at all concentrations at 80°C. A certain minimum lime concentration is necessary to form C_2ASH_8, while it is unstable in the presence of excess lime. Preliminary heat treatment of the allophane resulted in higher reactivity with lime solutions. In addition, allophane reacted with lime-calcium sulphate solutions to form calcium sulphoaluminate hydrates, either the monosulphate or the trisulphate depending upon the temperature and the amount of calcium sulphate present. On the basis of this type of reaction, it has been established that treatment with lime and gypsum is effective and economical for soil-stabilisation purposes.

Hydrated halloysite showed a similar reaction course to allophane in lime solutions, and absorption of lime from solution is followed by the formation of 'C_4AH_{13}' and $C_3A.CaCO_3.11H_2O$, and eventually C_2ASH_8 is obtained at longer reaction times. The better-crystallised halloysite samples absorbed larger amounts of lime and showed increased reactivity, but dehydration of the halloysite by heating at 150°C decreased its reactivity. Finely-ground kaolinite also reacted easily with lime solutions to form C_2ASH_8.

The reaction of co-precipitated alumina-silica gels of varying Al_2O_3/SiO_2 ratios with saturated lime solution showed a similar behaviour to that observed with natural allophane. In particular, the treatment of a gel with an Al_2O_3/SiO_2 ratio of 1.0 with saturated lime solution at 20°C for 1 year resulted in a product of composition $2.50\ CaO.1Al_2O_3\ 1.08SiO_2.0.18CO_2.8.69H_2O$, after drying over $CaCl_2$. This preparation consisted predominantly of C_2ASH_8, together with small amounts of calcite and hydrogarnet, and possibly also traces of a calcium silicate hydrate. Apart from calcite, the latter compounds are not observable in the DTA curve, which showed an endotherm at 210°C owing to the loss of hydrate water and an exotherm at 940°C arising from the formation of C_2AS. The thermal dehydration curve showed no definite steps, but loss of water started at 50°C, became intensified at about 150°C and all water is practically completely removed at 350-400°C. The X-ray powder diffraction data and the electron microscopical observations showed broad agreement with previously published data for hexagonal C_2ASH_8.

It may be noted that the C_2ASH_8 preparation described above contained 1.7 per cent CO_2, and while this is attributed to the presence of calcite it is possible that some $C_3A.CaCO_3.11H_2O$ is also present. Indeed, the formation of this monocarboaluminate hydrate with a basal spacing of 7.6Å was also observed during the reaction of the various clay minerals with lime solution. Furthermore, the 'C_4AH_{13}' which was frequently present was apparently identified by a 8.2Å basal spacing in the X-ray powder patterns, and this hydrate probably really corresponds to the quaternary carbonate hydrate $C_4A.\frac{1}{2}CO_2.12H_2O$. Unintentional carbonation may therefore have had some influence on the reactions studied by Ariizumi, as also seems to be

the case in previous work[8] on the reaction of montmorillonite with lime solution, where $C_3A.CaCO_3.11H_2O$ was evidently formed.

5. H. Uchikawa and K. Tsukiyama, 'Barium Aluminate and Barium Silicate and their Hydraulic Properties'

The final paper gives an account of investigations on the properties and crystal structures of barium hydroxide monohydrate and particular anhydrous and hydrated barium aluminates and silicates.

Anhydrous monobarium aluminate and dibarium silicate were synthesised by heating stoichiometric mixtures of $BaCO_3$ and α-Al_2O_3 or silica powder at 1500°C. The crystal lattice constants and atomic co-ordinates of the respective hexagonal and orthorhombic compounds were determined from X-ray powder diffraction data. It is also shown that Fe_2O_3 can replace Al_2O_3 in $BaO.Al_2O_3$ with expansion of the crystal lattice to form a solid-solution series.

Hydration of the dibarium silicate at room temperature resulted in the initial precipitation of a fibrous dibarium silicate hydrate ($2BaO.SiO_2.n\ H_2O$), but this hydrate later converted into thin plates of a monobarium hydrate, $BaO.SiO_2.6H_2O$, together with hydrated barium hydroxide. The latter hydrate is referred to as the monohydrate $Ba(OH)_2.H_2O$, but it evidently should occur as the octahydrate $Ba(OH)_2.8H_2O$ in contact with solution. X-ray studies on the $BaO.SiO_2.6H_2O$ hydrate showed it to be orthorhombic, and its X-ray pattern remained essentially unchanged in dry and wet nitrogen, but an orthorhombic basic barium carbonate hydrate ($BaCO_3.m\ Ba(OH)_2.n\ H_2O$) is readily formed on exposure to moist CO_2.

Both barium hydroxide and hydrated alumina are liberated when $BaO.Al_2O_3$ is treated with water at room temperature, and initial precipitation of alumina gel and rectangular plates of a monobarium aluminate hydrate of composition $BaO.Al_2O_3.6.5H_2O$ is followed by the additional formation of polyhedral plates of a hexagonal dibarium aluminate hydrate, $2BaO.Al_2O_3.9H_2O$. The rate of hydration, as measured by quantitative X-ray analysis, increased as the water/solid ratio is raised from 0.4 to 0.6 and then to 1.0. Measurements of heat liberation with a conduction calorimeter showed the presence of a second peak after 3-4 hours, and this is considered to arise from the later formation of the dibarium aluminate hydrate. However, the hydration product obtained after a long period of hydration at a water/solid ratio of 0.6 apparently consisted essentially of $BaO.Al_2O_3.6.5H_2O$, while it appears that a different compound of composition $BaO.Al_2O_3.4H_2O$ is produced at a water/solid ratio of 0.4. The difference in properties and relationship between the different barium aluminate hydrates is not clearly established, and the drying conditions used to obtain the stated water contents are not given.

From a study of the X-ray and electron diffraction patterns, it is concluded that the crystal structure of the monoclinic $BaO.Al_2O_3.6.5H_2O$ compound contains the structural framework of that established for orthorhombic $Ba(OH)_2.H_2O$, with a linkage of two AlO_4 tetrahedra extending along the c-axis and water molecules also stacked along this axis. The latter water molecules can be removed without destruction of the crystal structure, since a reversible transformation is observed under different drying conditions, the longest spacing in the X-ray powder patterns changing from about 7.4Å in dry nitrogen to about 8.2Å in wet nitrogen. Exposure to moist CO_2 resulted in the gradual appearance of the X-ray pattern of a basic barium carbonate hydrate.

The behaviour of hydrated barium aluminate samples at elevated temperatures varied somewhat, depending upon the initial water/solid ratio, and hence upon the particular hydrates present. X-ray, DTA and thermal dehydration studies showed in some cases the formation of an apparently amorphous phase at temperatures up to about 200°C, though the external form of the original crystals is retained, and at higher temperatures a cubic monohydrate, $BaO \cdot Al_2O_3 \cdot H_2O$ is first obtained, followed by the formation of anhydrous $BaO \cdot Al_2O_3$. Associated with these changes, the compressive strength of 1:2 $BaO.Al_2O_3$: sand mortars first increased by drying of the specimens at temperatures up to about 250°C, then decreased slightly with increasing temperature up to about 700°C, followed by a marked increase in strength up to 1300°C accompanied by the formation of anhydrous $BaO \cdot Al_2O_3$. Except at the highest temperature, higher strengths are obtained with mortars of initial water/solid ratio of 0.4 as compared with 0.6. A similar relation between water/solid ratio and compressive and bending strengths of 1:2 mortars is also obtained at ordinary temperatures. The strength values decreased with age from 3 to 28 days, and this is attributed to carbonation and the consequent formation of the basic barium carbonate hydrate $BaCO_3 . m\ Ba(OH)_2 . n\ H_2O$ which can be identified in the X-ray powder patterns of moist-cured mortar specimens at 28 days.

It is evident from these results that the hydration reactions and products of these barium compounds bear some analogies to those of the corresponding calcium silicate and aluminate. However, in contrast to the hydration products of the latter, the barium-containing hydrates are highly water soluble, and they appear to harden mainly by processes of drying and possibly carbonation. The behaviour of $BaO.Al_2O_3.6.5H_2O$ on dehydration in

dry nitrogen, resulting in changes in the X-ray powder pattern, resembles that of the hexagonal-plate dicalcium and tetracalcium aluminate hydrates, though CAH_{10} behaves differently in that loss of water from this compound occurs without marked changes in the X-ray pattern apart from its deterioration. The possibility of the existence of different states of hydration in other barium aluminate hydrates seems to warrant further investigation, as well as the possibility of the formation of complex quaternary carbonate hydrates similar to the calcium carboaluminate hydrates.

However, despite the apparent similarities in composition between some calcium and barium aluminate hydrates, the view has been expressed[9,10] that the various barium aluminate hydrates are in no way analogous to the calcium aluminate hydrates, since they show distinct differences in crystal habit, refractive indices, binefringence and X-ray powder patterns. On the other hand, it has been established[11,12] that the two strontium aluminate hydrates, $3SrO.Al_2O_3.6H_2O$ and $SrO.Al_2O_3.10H_2O$, show properties very similar to those of C_3AH_6 and CAH_{10}, and the corresponding hydrates are isomorphous.

Paper No. II-122

ELECTRON MICROPROBE STUDIES OF CEMENT PHASES

D. M. Roy & M. W. Grutzeck (U.S.A.)

Among the Supplementary Papers presented to topic II-4, Nos. 122, 43, 62, 26, 41 and 96 deal with the mechanism of hydration of cements.

The first two show that the electron microprobe is a useful instrument for the study of portland cement hydration. The third one is concerned with the behavior of aluminate-ferrite phase during hydration. The fourth one deals with the influence of sugars on the hydration of C_3A, and the fifth one presents some principles in cement hydration. The last one deals with the development of new binding materials in the solid-liquid system.

This report summarizes these papers.

I. ELECTRON MICROPROBE STUDIES OF CEMENT PHASES (SP No. 122)

by D.M. Roy and M.W. Grutzeck

This study was undertaken in order to explore the possibility of obtaining direct analytical information on hydration products of C_3S, C_2S, C_3A, and their mixtures at various stages by using an electron microprobe.

After the allocated reaction time the hydrated sample was mounted in polyester resin, polished, and examined by the electron microprobe. Visual cathode-ray tube displays of characteristic elemental emission, and electron back scatter displays were used to follow the progress of hydration. Further, counting techniques of characteristic elemental emission were employed to obtain quantitative analytical data. In order to eliminate the effect of many non-random sources of error in quantitative measurements, empirical correction was made by use of calibration standards.

X-ray intensities of the sample were measured at 1 μ intervals taken from the central portion of the crystal through the rim into the plastic. Figure 1 shows an example of the actual data obtained

on a C_3A sample hydrated for one day. This figure gives measured X-ray intensities and shows the electron back scatter photograph. The latter shows the sharp boundaries of the crystal and the distinct hydration rims. The vertical lines seen in the curves of the X-ray intensities also show these boundaries. The points of first break in the slope of these curves represent a CaO/Al_2O_3 molar ratio of approximately 2.8. Although X-ray diffraction data identify the hydration product as C_4AH_{13}, it is postulated on the basis of the microprobe and other microscopic data, to further consist of a crystalline solution of C_4AH_{13} with C_2AH_8 or a 1:1 mixture of them.

Furthermore, such data were obtained on the hydration products of C_3S and of a mixture of C_3S, βC_2S, and C_3A. It appears that the relatively slow rate of hydration of C_3S prevents sufficient buildup of the hydration rim for the accurate analysis.

The authors conclude that existing electron microprobe techniques have been successfully modified to cope with the specialized problems inherent in portland cement hydration studies. They also conclude that the use of electron back scatter display data and elemental display data offer a physical description of the grain-hydrate relationships during the progress of hydration and the use of the elemental analysis data make it possible to follow the progress of hydration in a quantitative manner.

II. CONTRIBUTION OF ANALYSIS BY MEANS OF AN ELECTRON MICROPROBE TO THE CEMENT CHEMISTRY (SP No. 43)

by P. Terrier

In this study an electron microprobe analysis was also applied to the study of the composition of the minerals of cement clinker, the composition of fly ashes, the hydration of portland cement, and

the pozzolanicity of the fly ash. The quantitative analysis is carried out by comparing the intensities of the radiation emitted by the sample with those emitted by standard samples.

Compositions of alite and belite of portland cement clinker as determined by the electron microprobe are shown in Table 1. It appears that alite contains about 3 % minor oxides and belite as much as 5 % minor oxides. On the other hand, the C_3A phase contains about 3 % SiO_2, 5 % Fe_2O_3, 0.6 % MgO, 0.9 % K_2O, etc., and the C_4AF phase about 2 % SiO_2, 2 % MgO, and 1.8 % TiO_2.

The chemical composition of fly ashes is relatively constant. However some heterogeneity is observed between the grains in the same fly ash as the result of the rapid passage of the coal leavings through the flame.

In portland cement pastes the hydration of aluminates takes place with fixation of the sulfate ion and produces acicular crystals which are grouped in discrete sites in the intergranular interstices. The hydration of tricalcium silicate occurs with the penetration of water which transforms the anhydrous silicate into hydrated silicate, while a part of the lime diffuses outside the grain and crystallizes in the hydroxide form: portlandite. The measurements obtained by electron microprobe analysis have shown that the hydrated silicate had a mean ratio CaO/SiO_2 of 1.65 for a duration up to 90 days.

Furthermore, the portlandite crystals have the following composition at the end of three years: 74.2 % CaO, 2.5 % SiO_2, 1.7 % Al_2O_3, 0.7 % K_2O.

The reaction of the ash grains in cement or lime pastes takes place with formation of a hydrated envelope with a low silica content.

The author points out that the electron microprobe is a basic research instrument which is unique for the punctual analysis by comparison with standards placed in the same geometry and detected by the same radiation.

III. THE BEHAVIOR OF ALUMINATE-FERRITE PHASE DURING HYDRATION (SP No.62

by H.E. Schwiete, U. Ludwing and P. Jäger

In this paper, the mechanism of hydration of C_3A, C_6A_2F, C_4AF and C_2F in the presence of $Ca(OH)_2$ and gypsum or anhydrite has been investigated by chemical means, infrared spectroscopy, X-ray diffraction, and electron microscopy.

In the system C_3A-$CaSO_4$-CaO-H_2O, ettringite was formed immediately after the addition of water and the formation of monosulfate hydrate was retarded by gypsum: that is, the amount and the stability of ettringite increases with the rising content of gypsum. When all the sulfate ions have been used to form ettringite or the concentration of sulfate ion becomes insufficient to allow this mineral to crystallize, ettringite reacts with the remaining C_3A to form monosulfate hydrate and mixed crystals of monosulfate hydrate and tetracalcium aluminate hydrate.

In the system calcium aluminoferrite-$CaSO_4$-CaO-H_2O, similar reactions take place. With increasing alumina content of calcium aluminoferrite, the trisulfate hydrate ($C_3(A,F)3CaSO_4.H_{32}$) is altered faster into monosulfate hydrate and mixed crystals of monosulfate hydrate and tetracalcium aluminate hydrate by using up the remaining aluminoferrite. Weight increase of the solid substance in the hydration of aluminate and aluminoferrite is shown in Figure 2. Furthermore, the kind of calcium sulfate used has a great influence

on the hydration of aluminoferrite. The reaction is much faster in the presence of anhydrite than in the presence of gypsum.

Principal hydration products of calcium aluminate and aluminoferrite in portland cement clinker are trisulfate hydrate, monosulfate hydrate and mixed crystals of monosulfate hydrate and tetracalcium aluminate hydrate.

The trisulfate hydrate first formed is more or less completely altered to monosulfate hydrate after a few hours depending upon the amount of sulfate present.

These results lead to the authors to conclude that the amount and the kind of calcium sulfate used is of prime importance for the rate and course of initial hydration of C_3A and calcium aluminoferrite. Particularly, the accelerative effect of anhydrite as compared to gypsum is of great importance in the production of portland cement low in, or free of C_3A.

IV. THE INFLUENCE OF SUGARS ON HYDRATION OF TRICALCIUM ALUMINATE

(SP No. 26)

by J. F. Young

This paper presents results of studies on the influences of monosaccharides and polysaccharides on the paste hydration of C_3A with or without gypsum for periods up to 90 days by means of X-ray diffraction, thermal analysis, and electron microscopy.

Each of nine kinds of the sugars used was found to retard the hydration of tricalcium aluminate paste. According to the results of quantitative X-ray diffraction analyses of the C_3A remaining in pastes after different times of hydration, sucrose and raffinose strongly retarded the hydration of C_3A at all ages. Xylose, ribose, and trehalose were the weakest retarders. The other sugars studied gave

intermediate results.

In pastes without additives the main hydration product is C_3AH_6, and in pastes containing sugars C_4AH_{13} is the predominant phase while C_2AH_8 is often present.

In C_3A-gypsum pastes with a C_3A: gypsum ratio of 2, ettringite is the only product detected up to 14 days. By 28 days monosulfate hydrate is forming in pastes without sugars. However, its appearance is delayed to after 60 days in pastes containing lactose, trehalose, and raffinose, and beyond 90 days with other sugars.

The amount of ettringite formed in C_3A-gypsum pastes which was calculated from TGA is shown in Table 2. Sucrose also retarded strongly at all ages, and lactose, trehalose, and raffinose were initially strong retarders. On the other hand, xylose, glucose, and fructose accelerated the hydration of C_3A-gypsum pastes at early ages, but retarded strongly later. As described above, sugars retarded the formation of ettringite and its subsequent conversion to low-sulfate. Furthermore, morphology of ettringite was modified by sugars.

From the results of these experiments, no definite correlation between the effects of different sugars and their structural differences was observed, as sugars are structurally labile and can exist in several different forms.

Mechanism of retarding by sugars may be explained by complexing, adsorption, and solubility change. The author suggests that complexing of sugars with metals, especially calcium, aluminum, and iron, may be the main factor underlying their behavior as retarders.

V. SOME PRINCIPLES IN CEMENT HYDRATION (SP No. 41)

by A. Joisel

The paper presents some principles extracted inductively in the hydration of calcium silicate and aluminate and the reaction mechanism of retarders and accelerators.

The hydraulic components of the cement grains go into solution in water, and this dissolution is accompanied by a hydrolysis, that is to say that the acids (particularly silica and alumina) and the bases (mainly lime), which constitute cement, regain a certain individuality at the time of dissolution.

Calcium silicates have an incongruent dissolution, i.e. lime passes into solution much faster than silica, and their hydration occurs as shown in schematizing in Figure 3a. The initial surface of each silicate grain keeps a solution of continuity in the hydrated paste during hydration, and the bonds which are formed in the interstices of the grains are growing in number. When recovering a certain individuality during hydration, the lime has a tendency to make its concentration roughly uniform in the whole paste. Therefore, the hydrated silicate has a total composition roughly situated between CSH and $C_{1.5}SH_{1.5}$.

Calcium aluminates pass into solution in their stoichiometric ratio, the faster the richer they are in lime. The hydration of C_3A takes place as indicated in Figure 3b. The surface of the grains in contact with the solution is progressively dissolved by water. It results that the hardening occurs immediately after the moment in which the first bonds are established. Thus this hardening is always rapid and the most stable hydrated aluminate is C_3AH_6.

The products which accelerate or retard the dissolution of the hydraulic components of cement are accelerators or retarders. The acid anions which accelerate the dissolution of the lime are Cl^-, NO_3^-, and SO_4^{--}. On the other hand, the basic cations which accelerate the dissolution of alumina and silica are Na^+, K^+, and NH_4^+, etc.

Retarders are classified into two groups. One is reducers of solubility and the other is coaters. Representative of the reducers is $Ca(OH)_2$, and those of the coaters are alkaline tetraborates and fluorides, etc.

Calcium sulfate is amphoteric and it behave as an accelerator for silicates and aluminates low in calcium and as a retarder for highly calcic aluminates.

The author emphasizes that future researches will formulate more precise knowledge concerning hydration, particularly from the point of view of the development of more quantitative data.

VI. SYNTHESIS OF THE ANALOGUES OF PORTLAND CEMENT AND OTHER MATERIALS ON THE BASIS OF ACIDIC-BASIC REACTIONS (SP No. 96)

by N. F. Fedorov

This study was undertaken to search for new binding materials in the solid-liquid systems where the acid-base reactions take place, because the hardening of portland cement, alumina cement and other most widely distributed binding materials is the result of the chemical reactions in which acid radicals and metal cations interact.

Four groups of materials including less distributed and even rare elements have been investigated in this paper. A great number of combinations in each group have been examined mainly from the

aspect of compressive strength.

First: in the mineral-water system, plumbates, stannates, titanates, and zirconates of the alkali earths have been synthesized and examples of those binding properties are shown in Table 3. These minerals show pronounced binding properties, and autoclaving intensifies the process of hardening of these minerals.

To determine the character of the hydration process of the analogous minerals of calcium silicate, the hydration of calcium stannate has been investigated by means of X-ray, infrared and chemical analyses. As a result, it is shown that calcium orthostannate is hydrolyzed giving off calcium hydroxide and forming hydrostannates, while metastannate is hydrated.

Second: in the metal oxide-acid system, HNO_3, H_2SO_4, HCl, $H_2C_2O_4$, etc., have been used as acid and combined with oxides of different groups of the periodic table. It is shown that on the basis of metal oxide-acid system many kinds of cements may be synthesized, their strength characteristics being similar to those of portland cement and sometimes even much greater.

Third: in the base oxide-acid oxide-water system, oxide of elements of group II are used as base oxides and ones of group IV are used as acid oxides. Prepared mixtures of these materials are ground, molded under pressure, and autoclaved. In this system high strength artificial stones have also been produced.

Fourth: in the metal oxide-polyatomic alcohol system, calcium, strontium, barium and lead oxides when mixed with glycerine or glycol form high strength materials.

The author concludes that it is theoretically possible to obtain new binding materials having much greater strength or having more specific properties than existing cements. He also concludes that the combination of solid inorganic powders and organic liquids will lead to the development of many new binding materials.

GENERAL REPORT
OF
SESSION II-4: KINETICS OF HYDRATION OF CEMENTS

(b) Paper regarding Kinetics

Paper No. II-120

THE HYDRATION OF THE FERRITE PHASE OF CEMENTS

W. L. de Keyser & N. Tenoutasse (Belgium)

Kinetic data on the very early stages of the paste hydration of C_3S (liquid/solid ratio 0.7 to 1.0) are reported by K. Fujii and W. Kondo. By isothermal calorimetry, in the main the same heat evolution rate vs. time curve is found as that reported earlier [1)2)], showing an increasing heat evolution rate in the beginning. Fujii and Kondo, however, are able to discern various stages before the heat evolution rises: During the first five minutes, some heat evolution is observed (stage 1) followed by a dormant period (about 30 minutes). After that, the reaction proceeds sluggishly for about three hours (stage 2), and then the heat evolution rate rises rapidly (stage 3).

During stage 1 C_3S starts to dissolve congruently; soon, however, the molar CaO/SiO_2 ratio in solution becomes higher than 3. The amount of combined water at the end of stage 1 corresponds to a layer of 3 to 4 moles on the surface; the authors conclude that stage 1 corresponds to the dissolution of one mole of C_3S throughout the surface. They have to assume, however, that the hydrate formed during stage 1 has the composition CSH_2, (which means that it is the equilibrium product formed in the solution concerned), and that "adsorbed water" is a principal constituent of combined water (which means that it cannot be removed by organic solvents; it is regarded as a "compensation" for the C_3S dissolved). Assuming further that per mole of C_3S reacting during stage 2 as much Ca^{2+} ions are given off to the water phase as during stage 1, it is remarked that about 4 mole layers of C_3S react during stage 2. During stage 2, heat of hydration per mole of combined water is high; this is ascribed to a rearrangement of "adsorbed water" to the formation of hydrates.
The onset of stage 3 is thought to be connected with incipient precipitation

of $Ca(OH)_2$, but no other argument is adduced for that apart from the simultaneity of the phenomena.

No explanation is offered by Fujii and Kondo for the retardation of the hydration reaction near the end of stage 1, and for the sluggish character of the subsequent reaction during stage 2. For this dormant stage of the hydration of C_3S, de Jong, Stein and Stevels[2)3)], basing themselves partly on results obtained by Kantro et alii [4)], had postulated earlier the formation of a metastable hydrate called "First Hydrate" by these authors. They report now data on the interaction of C_3A and C_3S during their hydration, obtained in pastes of water/solid ratio 1:1, and varying C_3A/C_3S ratio. The heat evolution peak due to C_3S hydration is shifted towards later hydration times by small amounts of C_3A, but not by greater amounts of C_3A. This is explained as follows: In suspensions of C_3A in water, small amounts of C_3S accelerate C_3AH_6 precipitation, presumably because silicate ions are built into C_3AH_6 crystals and accelerate therefore C_3AH_6 nucleation; the concentrations in the water phase adjust themselves ultimately to the C_3AH_6 solubility line. However, at high C_3S/C_3A ratio the crystallization of C_3AH_6 is suppressed, and the concentrations, after leaving the point of metastable coexistence of C_2AH_8 and C_4AH_{19} with solution, follow the C_4AH_{19} solubility line; the solution continues to contain considerable amounts of aluminate ions. Heat evolution rate and X ray analyses of the hydration products indicate that the same phenomena occur in pastes, though the time scale may be different: small amounts of C_3S accelerate C_3AH_6 formation, large amounts retard it. The strong retardation, exerted on C_3S hydration by small amounts of C_3A, may then be understood by the retarding action of aluminate ions, such as found also in pastes $C_3S + Al(OH)_3 + H_2O$[5)]. This has been ascribed to aluminate ions being built into "First hydrate" stabilizing the latter toward conversion, as reported by Kalousek[6)] for the case of tobermorite. The absence of this strong retarding action in pastes of high C_3A/C_3S ratio can then be understood by the formation of C_3AH_6, lowering the aluminate ion concentration in the water phase. It might be objected that C_3AH_6 formation is expected at later times only, such as to make this mechanism operative only after some hours'hydration; however, X ray data indicate in mixed $C_3A + C_3S$ + water pastes of high C_3A/C_3S ratio

the presence of C_3AH_6 and the absence of hexagonal calcium aluminate hydrates at very early stages. A confirmation of these ideas will be found in the results of Tenoutasse on pastes $C_3S + C_3A + CaSO_4.2H_2O$ + water, to be discussed later.

A mathematical simulation of processes during the hydration of C_3S by Frohnsdorff, Fryer and Jonhson indicates that an induction period alone cannot be regarded as a proof for the existence of the First Hydrate as postulated by Stein and Stevels. The authors postulate equations describing the rate of dissolution of C_3S as a function of ion concentrations in solution, and the rate of precipitation of hydrates to be governed in addition by the surface area of nuclei. By suitable choice of parameters in these equations, Frohnsdorff et alii are able to obtain a heat liberation vs. time curve resembling experimental data (fig. 2). The course of events suggested is:

a. solution of the anhydrous C_3S untill the aqueous phase is close to saturation with respect to C_3S.
b. nucleation of the products of hydration,
c. growth of the nuclei to form larger particles,
d. as the surface area of particles increases, the rate of product formation increases and the concentrations of the ions in solution fall. This can be considered as an autocatalytic reaction in which the rate-determining step is the deposition of the products of hydration on the growing particles.
e. At a still later stage, as the surface area of the anhydrous C_3S falls, its rate of solution appears to become rate controlling.

The authors emphasize that they regard these calculations as crude first approximations, intended to illustrate how simulation can be used. Such considerations cannot prove or disprove any mechanism proposed on independent evidence. The model is not yet able to take into account different retarding effects of hydrates on the hydration, but such effects could easily be included.

The kinetics of hydration reaction of cement compounds in a more restricted sense are the subject of an investigation by Taplin. This author distinguishes "linear kinetics" (reaction rate proportional to the surface area of cores of unreacted cement) and "quadratic kinetics" (reaction rate inversely proportional to the resistance to diffusion provided by a coherent coating of

reaction products, with special attention to the case where the resistance of the outer products is negligible compared to that of the inner products). It is easily seen that for a reaction characterized by quadratic kinetics the rate decays more rapidly than for a reaction characterized by linear kinetics. Taplin compares the kinetics of various hydration reactions (MgO in $MgCl_2$ or $MgSO_4$ solution; $CaSO_4$ in potassium alum solution; β-C_2S, alite and C_3S in water) with those calculated on the basis of either "linear" or quadratic kinetics, giving due regard to particle size distributions.

In stirred suspensions or slurries, linear or quadratic kinetics are found except for β-C_2S, where the rate decays too slowly for even linear kinetics. This is explained by assuming a process accelerating the reaction (as evidenced by an induction period) counteracting the retarding effects of hydrates. In hardening pastes, the rate tends to decay more rapidly than in stirred suspensions or slurries, for C_3S especially in the later stages.

The data are consistent with a model where the reactions start linear but may become diffusion controlled if the resistance of the diffusion process exceeds that of the surface decomposition. At least the outer products are thought to form a coherent network [7]) and to minimise the generation of disruptive stress; it is assumed that these products must be precipitated from material which has diffused away from the cement grains. Nucleation and precipitation of hydrates near the grain surface is thought to be inhibited by the narrow pore size at those places.

However, then the outward diffusion process must always keep pace with the rate of mineral decomposition; and if we suppose that the hydration rate is controlled by the inward diffusion of water, then the outward diffusion of hydrated material should occur more readily than the inward diffusion of water. But this seems difficult to accept, in view of the higher concentration and greater mobility of water compared to say divalent cations.

In the case where the solubility difference between cement mineral and hydration product is small (e.g., $CaSO_4$ - $CaSO_4.2H_2O$) a mechanism is possible

where the dissolution rate of the anhydrous material is retarded because the concentrations rise towards the solubility of $CaSO_4$. For thermodynamically unstable materials such as C_3S, it is assumed that a stable surface is produced by the adsorption of an outward diffusing chemical species which in this way poisons the reaction if its concentration rises. Joint control by the surface decomposition and by the outward diffusion of the poisoning species is possible too. The experiments indicate that such joint kinetics can exist only in those regions where the kinetics are affected by merging outer products.

Turning to C_3A hydration, we direct our attention first to an investigation by H. Mori and K. Minegishi on the effect of temperature on the early hydration of the system $C_3A + CaSO_4.2H_2O + Ca(OH)_2 + H_2O$.

Again, isothermal calorimetry is used to classify the reaction into stages; two heat evolution peaks are observed. The interpretation follows in the main that given by Stein [8]: gypsum retards C_3A hydration by formation of an ettringite layer, the second heat evolution peak occurs when the gypsum content in the system is insufficient for ettringite formation. However, an important difference with earlier interpretations is that the ettringite layer, previously considered to be removed by scaling off [9][10] is now thought to be removed by a chemical reaction: the amount of ettringite decreases during the rising branch of heat peak II, in marked contrast to the situation in pastes $C_4AF + CaSO_4.2H_2O$ to be discussed later. By direct experiment it is shown that ettringite is converted by C_3A in $Ca(OH)_2$ solution. Similar ideas have been put forward previously [11] for the reaction of C_3A with $CaSO_4.2H_2O$ in water.

Temperature differences in the range 5 - 70°C do not greatly influence the reaction during the first heat evolution peak, but in the "dormant" period between the two peaks the reaction rate is considerably increased by an increase in temperature [12]. This is ascribed to differences in properties of the ettringite layer: at lower hydration temperatures finer ettringite crystals are formed and the ettringite coating of the C_3A is more compact. This interpretation is supported by microscopical observations. At 70°C, no protective layer is formed. Addition of $Ca(OH)_2$ acts similarly as lowering of the temperature.

Kinetically the reaction is discussed on the basis of the equation

$$(1 - \sqrt[3]{1 - \alpha})^N = KT$$

with α = degree of hydration, t = time, N and K = constants. During the dormant period between the two heat evolution peaks, N is rather high (=4) at 5°C, indicating that the coating becomes more compact as the reaction proceeds. With increasing temperature, N decreases, it is equal to 2 at 40°C : at this temperature an increase in the amount of ettringite during the progress of the reaction increases the thickness of the surface layer but brings no change in its structure.

After the second heat evolution peak, N is higher than 2, at all temperatures investigated, indicating that the hydrates form a new barrier around the C_3A grains in this stage.

Similar phenomena are described by Tenoutasse for pastes $C_3A + CaSO_4 . 2H_2O + H_2O$: two heat evolution peaks are found. This stands in contrast with results published previously by Stein [11]) showing a more complicated heat evolution ascribed to successive formation of ettringite, amorphous $Al(OH)_3$, monosulphate and C_4AH_{19}. The difference between the results obtained by Tenoutasse and those reported by Stein may be due to differences in particle size (the sample employed by Tenoutasse contained smaller particles than that used by Stein) in water/C_3A ratio, and to the presence of quartz employed as a filler by Stein. The interpretation is in the main along the same lines as that discussed already for pastes $C_3A + CaSO_4 . 2H_2O + Ca(OH)_2$ solution, but gypsum is considered to be consumed at the top of the second peak. Kinetically, the reaction is described by the same equation as that used by Mori and Minegishi, but N is now found to be = 2. From the temperature dependence of the reaction, an activation energy of 12 Kcal.mole^{-1} is calculated.

Pastes $C_3A + CaCl_2$ + water show a similar behaviour, but in combined pastes $C_3A + CaSO_4 . 2H_2O + CaCl_2$ + water more complicated phenomena are observed: At the beginning a small amount of $CaCl_2$ reacts to give chloroaluminate, but sulphate ions react more extensively to give ettringite. Consumption of Cl^- ions starts again after the sulphate ions have been used up.

Tenoutasse reports also some results on the hydration of C_3S (agreeing with previously published data [2)3)]) and finds that it is accelerated by $CaCl_2$. No hydrate containing Cl^- is formed except at very high $CaCl_2$ contents.

Results on combined pastes C_3S + C_3A + water agree with the results of de Jong, Stein and Stevels mentioned earlier: C_3A slows down the hydration of C_3S (C_3A/C_3S ratio = 0.25). The additional presence of $CaSO_4.2H_2O$ modifies the results as follows: when the second heat peak attributed to the hydration of C_3A + $CaSO_4.2H_2O$ + water lies before the peak due to the hydration of C_3S, the latter peak is greatly retarded. If, however, the second heat peak attributed to C_3A hydration lies after the peak due to the hydration of C_3S, the latter peak is practically unchanged. Tenoutasse does not offer an explanation for these observations; it should be remarked however that they can be explained by the mechanism proposed by de Jong, Stein and Stevels: aluminate ions retard the start of the C_3S heat evolution peak, but in order to do so their concentration must be reasonably high, i.e. sulphate ion concentrations should not be such as to precipitate ettringite.

Analogous phenomena are reported on hydrating calcium aluminoferrites by de Keyser and Tenoutasse. C_2F hydrates very slowly, but the hydration velocity increases with replacement of iron by aluminium. Hexagonal hydrates are found first, and are ultimately converted into cubic $C_3(A,F)H_6$. $Ca(OH)_2$ accelerates the hydration of C_2F, and retards the conversion of hexagonal hydrates in the case of C_6A_2F and C_4AF.

Addition of $CaSO_4.2H_2O$ exerts an influence similar to that observed in the case of C_3A. $CaCl_2$ however reacts so fast with calcium aluminoferrites that it is very difficult to analyse the reaction; the hydrate $C_3(AF).3CaCl_2.30H_2O$ is formed under certain conditions but easily converted into $C_3(AF).CaCl_2.12H_2O$. Replacement of H_2O by D_2O greatly reduces the rate of hydration.

In mixed pastes C_4AF + $CaSO_4.2H_2O$ + $CaCl_2$ + water, three heat peaks are seen. Between the first and second peaks, gypsum reacts forming calcium-trisulphoaluminoferrite; all gypsum is consumed when the top of the second peak has been reached. During the rising branch of the second peak, the

trisulphoaluminoferrite X ray diffraction lines still increase in intensity; this is an interesting difference with the observations of Mori and Minegishi in pastes $C_3A + CaSO_4.2H_2O + Ca(OH)_2 + H_2O$. When the gypsum has been consumed, the hydrates rich in sulphate are converted into hydrates poor in sulphate, but this transformation does not occur as long as Cl^- ions are present. Instead, monochloroaluminoferrite is formed. This is explained by assuming that trisulphoaluminoferrite reacts above all with the hydrated aluminoferrites, $C_4(AF)H_{13}$ and $C_2(AF)H_{17}$.

S. Koide and K. Okada studied the hydration of alumina cement by ultrasonics. Much attention is paid to the development of apparatus that can be used to investigate muddy samples or slurries by ultrasonics. The ultimate apparatus works well at W/C ratios 0.28-0.30, but when W/C ratio drops below 0.28 it becomes difficult to obtain sharp modes of the sonic wave on the oxilloscope by lack of homogeneity of the sample.

Use of the apparatus is exemplified by sound velocity vs. time curves at different hydration temperatures. Sound velocity is found to rise sharply, simultaneously with a drop in electrical conductivity. An increase of the temperature from 20 to 30°C retards this effect, but still higher temperatures accelerate it.

From the sound velocity of the hardened specimen, Young's modulus is calculated and Mechanical strength is predicted, on the basis of a relationship previously established [13].

GENERAL REPORT
OF
SESSION II-5: HYDRATION OF PORTLAND CEMENT

H. zur Strassen (West Germany)

The following Supplementary Papers are summarized in this report.

Paper No. II-2

CONTRIBUTION OF CALCIUM THIOSULFATE TO THE ACCELERATION OF THE HYDRATION OF PORTLAND CEMENT AND COMPARISON WITH OTHER SOLUBLE INORGANIC SALTS

H. Tanaka & K. Murakami (Japan)

Paper No. II-4

SIGNIFICANCE OF TOTAL AND WATER SOLUBLE ALKALI CONTENTS OF CEMENT

W. J. McCoy & O. L. Eshenour (U.S.A.)

Paper No. II-22

THE INFLUENCE OF LEAD AND ZINC COMPOUNDS ON THE HYDRATION OF PORTLAND CEMENT

W. Lieber (West Germany)

Paper No. II-47

SOME OBSERVATIONS UPON THE DETERMINATION OF HEAT OF HYDRATION OF SLAG AND PORTLAND CEMENTS BY THE METHOD OF DIFFERENTIAL HEAT OF SOLUTION

G. A. Toubeau (Belgium)

Paper No. II-117

THE INFLUENCE OF ALKALI-CARBONATE ON THE HYDRATION OF CEMENT

E.M.M.G. Niël (Netherlands)

Paper No. II-129

AQUEOUS PHASE IN PORTLAND CEMENT PASTES CONTAINING SOLUBLE CHLORIDE ION

K. T. Greene & K. E. Palmer (U.S.A.)

Paper No. II-134

THE EFFECT OF TRICALCIUM ALUMINATE ON THE HYDRATION OF TRICALCIUM SILICATE AND PORTLAND CEMENT

A. Celani, P. A. Moggi & A. Rio (Italy)

This General Report deals with the following Supplementary Papers:

1. G.A. Toubeau: Some observations upon the determination of heat of hydration of slag and Portland cements by the method of differential heat of solution.

2. K.T. Greene, K.E. Palmer: Aqueous phase in Portland cement pastes containing soluble chloride ion.

3. A. Celani, P.A. Moggi, A. Rio: The effect of tricalcium aluminate on the hydration of tricalcium silicate and Portland cement.

4. W.J. McCoy, O.L. Eshenour: Significance of total and water soluble alkali contents of Portland cement.

5. E.M.M.G. Niël: The influence of alkali-carbonate on the hydration of cement.

6. H. Tanaka, K. Murakami: Contribution of calcium thiosulfate to the acceleration of the hydration of Portland cement and comparison with other soluble inorganic salts.

7. W. Lieber: The influence of lead and zinc compounds on the hydration of Portland cement.

The Papers are ordered in such a manner, that the first two deal with measuring of properties of the cement paste - heat of hydration (No.1) and supersaturation of the aqueous phase (No.2) - the other ones with the influence of variation of cement composition on the setting and hardening and other properties - variations of C_3A content (No.3) and alkali content (No.4) in the clinker, addition of potash (No.5), calcium thiosulfate (No.6), lead and zinc (No.7) to the paste.

HEAT OF HYDRATION

For the purpose of winter concreting, the Belgian cement industry intended to classify the cements according to heat development after curing for 3 days at + 5°C. In a first series of comparative determinations, the original ASTM heat of solution method was used, but the results were not satisfactory (Table 1, first column). When using the modified solution method by Santarelli and Goggi, however, the results of the participating laboratories agreed well (second column).and allowed a classification of Belgian cements into 6 classes (third column).

Table 1

Later on, however, a repetition of these comparisons showed marked differences up to 15 calories between the results of the various laboratories; it appeared that some laboratories had modified the mode of procedure. The present work, therefore, was undertaken to clarify and eliminate the possible causes of error.

Among other factors, the most important sources of error were found the determination of the loss on ignition and the grinding of the hydrated sample. The loss on ignition requires a calcination temperature of 1050 ± 50°C. For blast-furnace cements, too, the direct determination - instead of analyzing the CaO-content - is the best method and must be carried out in a nitrogen or argon atmosphere.

The best conditions for grinding the hydrated sample, however, are still a problem. After curing for three days at + 5°C, the hardened paste is still relatively humid; it is not possible, therefore, to grind the paste in the dry state, but only in an organic liquid, alcohol - according to Goggi - or acetone being used. The resulting heats of hydration are dependent both on the nature of the liquid used and on the conditions of washing and drying the sample.

The Author prefers the use of alcohol because it is easier to eliminate this liquid without alterating the paste structure. He questions if it would be advisable to use a liquid for grinding of samples which are cured for longer periods at + 20°C.

The work done by Dr. Toubeau is of high value for the heat of solution method. But it should be considered if this method may yield exact values when the sample is grond in an organic liquid because the hydration stage after drying is not the same as in the original paste.

AQUEOUS PHASE CONTAINING CHLORIDE ION

The results of the equilibrium study by Greene and Palmer on the aqueous system containing the ions K^++ Na^+, Ca^{++}, SO_4^{--}, OH^-, Cl^- are reproduced in 3 diagrams in the Abstract. These diagrams show the equilibrium values of Ca^{++}, SO_4^{--}, and OH^- when the solutions are saturated with $CaSO_4 \cdot 2H_2O$ and $Ca(OH)_2$ at different levels of K^+- and Cl^-- content. The Ca^{++}- content increases with increasing Cl^- and decreasing K^+, SO_4^{--} and OH^- increase with decreasing Cl^- and increasing K^+.

Table 2 shows the compositions of some extracts of cement pastes. With the aid of the solubility diagrams, the ion products in these extracts are calculated and compared with the analytical values (Table 3). From this comparison is shown that some supersaturation with gypsum exists in cement pastes

containing calcium chloride up to 15 minutes after mixing, and that supersaturation with calcium hydroxide is sometimes very high.

Table 2

Table 3

THE EFFECT OF C_3A ON THE HYDRAULIC PROPERTIES

In a comprehensive work Celani, Moggi and Rio studied the influence of various contents of C_3A in the clinker, upon strength development, rate of hydration and development of specific surface, combined with the additional influence of gypsum and calcium chloride. The C_3S and C_2S content of the clinkers were kept constant at about 50 and 25 %, respectively. the C_3A content varied from 3 to 15 %, the rest being the ferrite phase. The correlations between C_3A content, compressive strength and specific surface are represented in Figures 1 and 2.

Figure 1

In Figure 1 a slightly different connection is chosen than given by the Authors, the compressive strength being represented as function of the C_3A content. This figure shows clearly, that the compressive strength - determined on ISO mortar 1 : 3, w/c ratio 0.5 - has in each series at every age - except the 1 day values of cement without added

gypsum - an optimum value shifting from the third cement (- 10 % C_3A) at the early ages to the second one (5.5 % C_3A) at the later ages. At the age of 28 days, the strengths fall off considerably if the C_3A content is raised markedly over the optimum value.

In the series containing gypsum, the gypsum content was adapted to the C_3A content so that the ratio $C_3A/CaSO_4$ was ~1,75. The addition of calcium chloride was constant 2 % by weight of cement, dissolved in the mixing water. The addition of gypsum + calcium chloride results in the highest strengths in any case.

Similar representations are possible for the other parameters studied, but it seemed more informative to show in Figure 2 the strong correlation between strength and specific surface, the only exception being two points at the age of 28 days. If the revealed correlation is not accidental, the deviations of these two points would result with high probability from a false determination of the specific surface.

Figure 2

A close relation, too, exists between strength and the extent of hydrolisis, but the dependence is not linear as in the case of specific surface.

The Authors propose the theory that the presence of C_3A promotes the penetration of water into the clinker grain, so that more water becomes available for the hydration of tricalcium silicate. Successively the aluminate would crystallize without contribution to the specific surface and to the strengths.

TOTAL AND WATER SOLUBLE ALKALI OF PORTLAND CEMENT

The study of McCoy and Eshenour was carried out to clarify the effects of total and water soluble alkali. The solubility was found to vary between 10 and 60 % of total alkali. Potassium and sodium sulfate are the most soluble compounds. Then follows sodium as contained in the NC_8A_3 phase. The most insoluble is potassium as contained in the $KC_{23}S_{12}$ phase.

To obtain information about the influence of alkalis on strength development from a commercial clinker three lots of cement were prepared: the one by reburning the clinker in a laboratory kiln (0,57 % alkali as Na_2O), the second by reburning the clinker with addition of NH_4Cl to eliminate the alkalis (0 % alkali), the third with addition of KOH to the alkali free cement. Table 4 shows the compressive strength of these 3 cements. The strength of the

Table 4

alkali free cement is abnormally low, but can be raised by the addition of KOH.

The effect of total and water soluble alkali on alkali - reactive aggregates was studied with 3 cements with equal total but different soluble alkali content. Table 5 shows that the expansion of the mortar bars is dependent on the content of soluble alkali.

Table 5

INFLUENCE OF ALKALI CARBONATE

The work of Niël had the aim to clarify the irregularities on setting and hardening by addition of potash.

Potash is known as a rapid accelerator of setting. But Figure 3 which shows the setting properties of a Portland cement in function of the K_2CO_3 content reveals that at very little amounts potash acts as retarder. There are three extreme points at approximately 0.25 %, 2.5 %, and 20 % K_2CO_3. The properties of these distinguished compositions are studied in detail.

Figure 3

In Figure 4 are represented the temperature curves during setting which reflect the changes in setting properties. Also the hardening in the first hours shows characteristic differences (Figure 5).

Figure 4

Figure 5

The most detailed research is done in analyzing the rate of hydration by X-ray and infrared measurements. The results of the X-ray study are represented in Figures 6 and 7. For better comparing, the curves are somewhat otherwise ordered than it was done by the Author.

Figure 6

Figure 7

In Figure 6 the decrease of C_3S, C_3A and gypsum and the formation of $Ca(OH)_2$ as caused by different amounts of admixture are compared. Neglecting the - possibly accidental - differences in the first hour, by the addition of 0.25 % K_2CO_3 the decompositions of C_3S and C_3A are markedly delayed during the first day, whereas the reaction of gypsum is accelerated.

At higher amounts of K_2CO_3, the gypsum seems to be decomposed instantly. The reactions of C_3S and C_3A are accelerated during the first hours, but at the end of 28 days the decomposition of C_3S is very incomplete. In the case of 2.5 % addition, the decomposition of C_3A is incomplete, too, the X-ray intensities not being changed from 16 hours to 28 days.

From Figure 7 it is seen that by addition of 0.25 % K_2CO_3 the formation of ettringite, $C_6A\bar{S}H_{31}$, is accelerated and its amount augmented. At higher amounts of K_2CO_3, the sulphate exists as K_2CO_3, only at the 2.5 % level there remains a rest of ettringite for two hours.

The CO_2 content of the pastes is found as monocarbonate $C_4A\bar{C}H_{11}$ at 0, 2.5 and 20 % K_2CO_3 in increasing amounts, at the highest level as $3K_2CO_3 \cdot 2CaCO_3 \cdot 6H_2O$ and $CaCO_3$, too. At 0.25 % addition no carbonate containing phase is recorded, but one can assume that the so - called C_4AH_{13} phase - as well as the same in the paste without admixture - is in reality the quater - or semi - carbonate phase. The "ups and downs" of several curves are not easy to be explained; in the case of the monocarbonate $C_4A\bar{C}H_{11}$, the decrease in X-ray intensity during the first hour at 20 % K_2CO_3 cannot be ascribed to decomposition of this phase at higher temperatures because such a decomposition is only described at the tricarbonate phase $C_6A\bar{C}_3H_{31}$.

In general, the phases as observed by X-rays are in accordance with the changing chemical composition of the pastes and with their setting behaviour. Especially the observed retardation of setting by addition of 0.25 % K_2CO_3 is well to be explained: by conversion of some $CaSO_4$ to $CaCO_3$ and K_2SO_4, the SO_3 content of the aqueous phase is increased and the formation of ettringite augmented; the larger coat of ettringite causes a delayed setting.

CALCIUM THIOSULPHATE AS ACCELERATOR

Tanaka and Murakami have detected that calcium thiosulphate $CaS_2O_3 \cdot 6H_2O$ can be used as accelerator for setting and hardening of cement pastes. In Figure 8 heat liberation curves

of Portland cement containing admixtures of calcium chloride and of various amounts of thiosulphate are represented. It is shown that both salts cause at about the same acceleration of setting time but that the intensity is higher in the case of chloride. By larger additions of thiosulphate, the effect can be improved.

Figure 8

In accordance with this, the gain of early strength is slightly poorer than caused by calcium chloride. In blast furnace slag cement, calcium thiosulphate is used very advantageously because it acts only on the Portland clinker part of the cement. The early strength is improved, therefore, according to the ratio admixture / clinker, whereas the development of strength in the later ages is caused by hydration of the slag part and is not affected by the admixture.

The specific advantage of the thiosulphate admixture compared with calcium chloride is that it is not corrosive on steel. Test pieces of mild steel embedded in mortar with 3 and 6 % admixture of thiosulphate were scarcely corroded after 6 months, whereas the same steel embedded in mortar containing 2 % of chloride showed considerable corrosion after one month.

INFLUENCE OF LEAD AND ZINC

Lead and zinc were known as strong retarders of the setting time, even in very small quantities. The rules of retardation as revealed by Lieber are illustrated by the following figures.

Figure 9

Figure 9 shows the influence of various amounts of PbO on the setting time of two Portland cements, as measured by the rise of temperature in the paste. The influence differs considerably for different cements. The heat evolution is about the same or larger then in the unretarded cement. After the retardation period has finished the cements harden quite normally and attain even better final strength.

When ground to different finenesses the retardation changes in inverse sense as the specific surface (Figure 10).

Figure 10

By experiments on pure cement minerals, it was shown that lead oxide has only an influence on tricalcium silicate, the other phases being not retarded. During the retardation period of a C_3S paste, no water is bound and no lime split off, but with the setting a very rapid hydration takes place.

The technological behaviour of zinc oxide is identically the same as that of lead oxide, but with regard to chemical reactions a deviation was found. During the retardation period, the formation of an intermediate phase was detected which proved to be calcium hydroxo zincate, according to the equation

$$2\ ZnO + Ca(OH)_2 + 4\ H_2O \longrightarrow Ca[Zn(OH)_3H_2O]_2$$

This compound begins to disappear at about the same time when the hydration of tricalcium silicate starts. Consequently, the behaviour of cement pastes was studied in which the admixture of zinc oxide was replaced by the equivalent amount of zincate. From Figure 11 it is seen that the retardation caused by calcium hydroxo zincate is very short as compared with the effect of zinc oxide.

Figure 11

In a last diagram (Figure 12) the influence of the various admixtures on the reactions of added gypsum is represented. In the presence of calcium zincate, gypsum reacts with the aluminates and ferrites in approximately the same way as if no admixture were present. Lead and zinc oxide, however, retard the combination of about half of the SO_3 for several days.

Figure 12

By admixture of calcium zincate, in spite of a slight retardation of setting, the initial and final strengths are markedly increased.

A satisfactory explanation for the mechanism of retardation by lead and zinc is not yet to be given. The retardation is caused obviously by a blocking up of the C_3S surface. With the beginning of the hydration period, the retarding elements probably enter the crystal lattice of the calcium silicate hydrates. But it is still obscure which factor causes the hydration to start.

W. Richartz (West Germany)

"CHANGING OF THE SPECIFIC SURFACE OF CEMENT-STONE IN DIFFERENT CONDITIONS OF HARDENING" O. P. Mchedlov-Petrosian & D. A. Uginčius.

These investigators studied the development of the specific surface of cement-stone under different temperatures of curing and in the presence of chemical additives. The surface was calculated in accordance with the BET theory. Fig. 3 of the paper shows the influence of water-cement ratio on the surface obtained with a Type II cement. Curves 1, 2, 3 and 4 represent respectively the surfaces at 1, 3, 7 and 28 days at 20°C.

Fig. 4 shows the influence of heating on a Type I cement. Specimens were heated in closed molds at the rate of 40°C per hour. Curves 1, 2, and 3 respectively represent the data for temperatures of 40, 60 and 90°C. After the temperature reached the prescribed value, the specimens were maintained at that temperature for from 1 to 9 hours and then at 20°C for 28 days. These data show that the surfaces of the specimens cured at 40 were much greater than were those of the specimens cured at 60 and 90. Also that the surfaces generally decreased with time after the initial heating for 1 hour and became constant at 3 hours of heating at 40, at 5 hours at 60 and at 6 hours at 90. The authors point out that heating accelerates the rate of hydrolysis and solution but causes the formation of dense hydrate films on the cement grains which retard the diffusion of water and formation of new nuclei. All of these result in a gel with a coarser texture and less specific volume.

Fig. V represents data for a Type III cement. Curve 1 represents

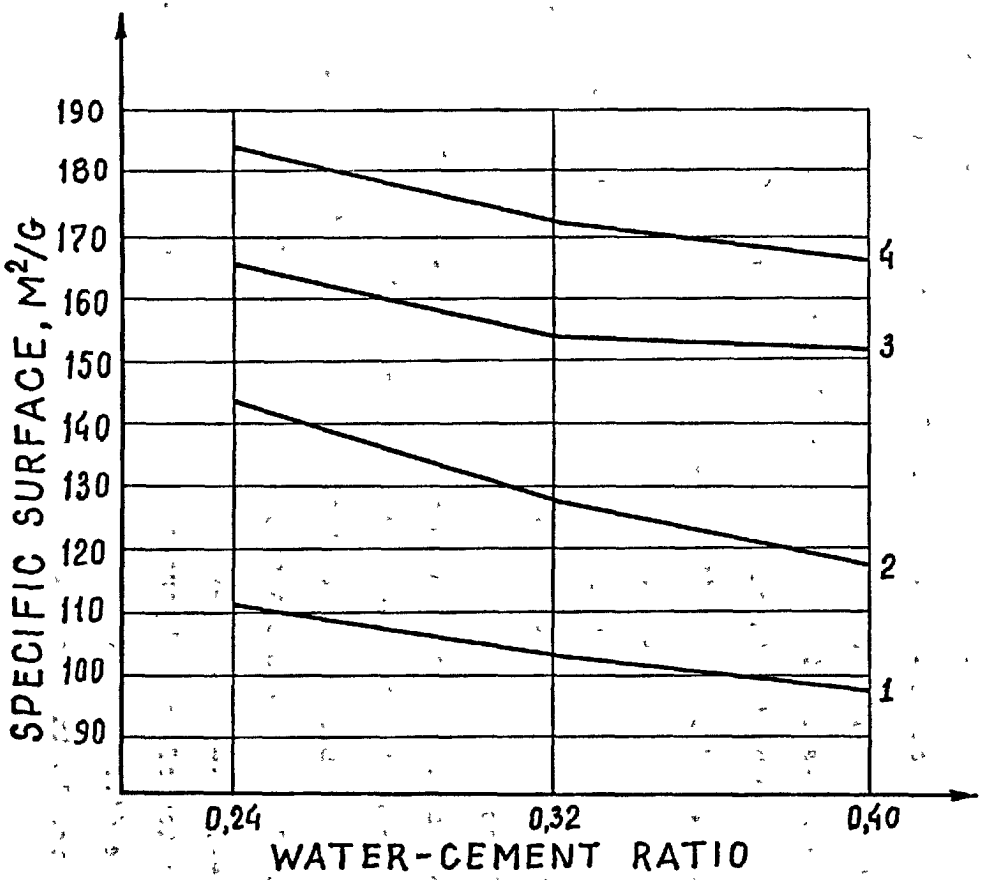

FIGURE 3 (by Otar P. Mechedlov-Petrosyan and Dmitrijs A. Uginčius)

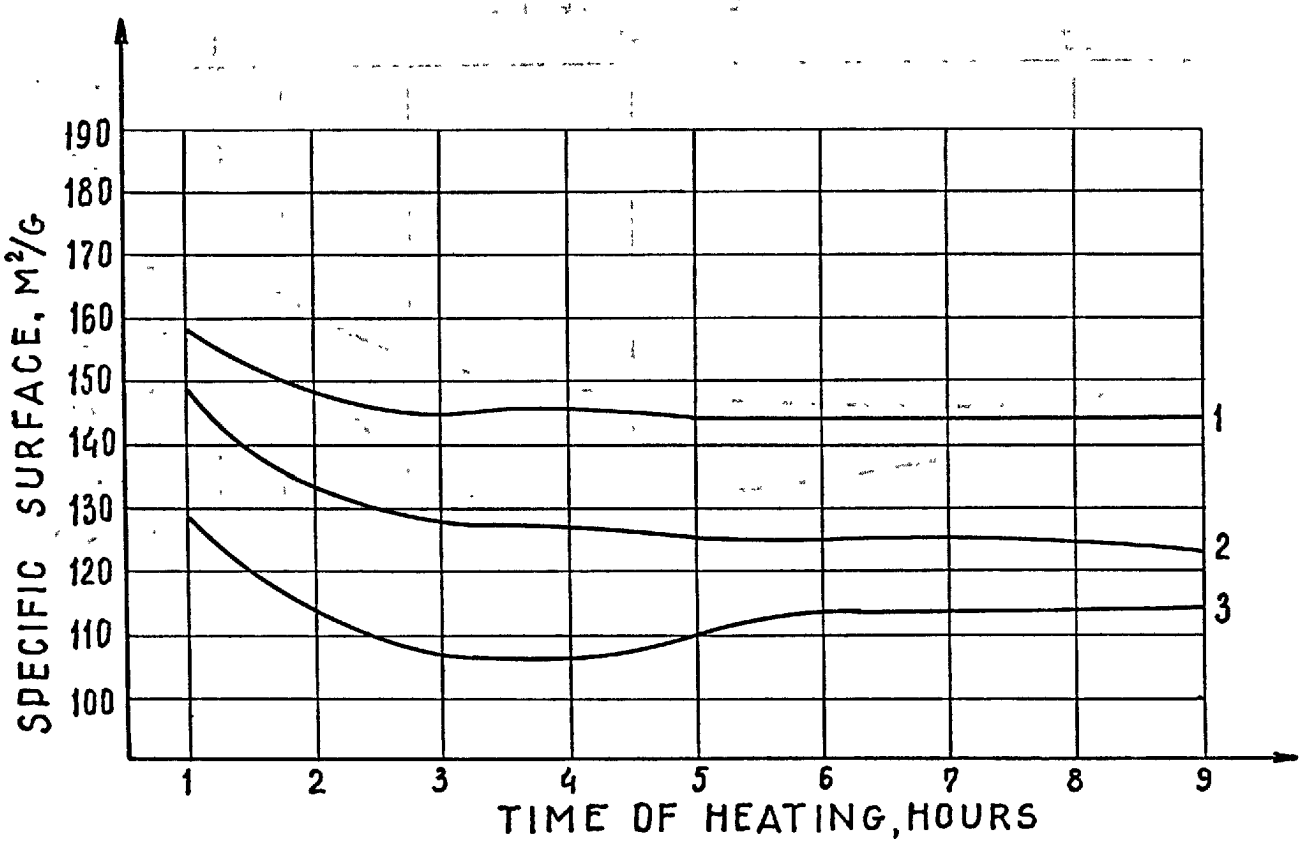

FIGURE 4 (by Otar P. Mechedlov-Petrosyan and Dmitrijs A. Uginčius)

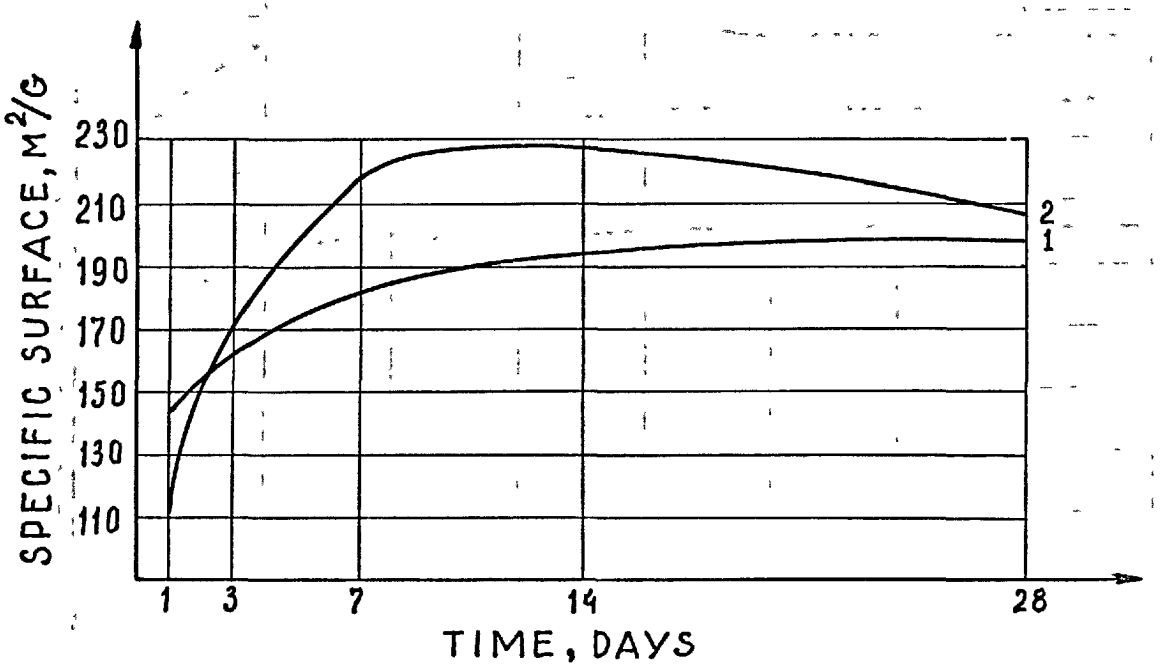

FIGURE 5 (by Otar P. Mechedlov-Petrosyan and Dmitrijs A. Uginčius)

the control sample cured at 20°C. Curve 2 a specimen which immediately after molding was placed in a freezer at minus 20° for 1 day and which after demolding was cured at 20°. Surface measurements were begun after 1 day at 20°.

The author points out that the solubility of the silicate minerals decreases with decreasing temperature but that the probability of the appearance of more basic hydrosilicates increase because the solubility of calciumhydroxide increases. These favorable conditions created in the primary cooling period greatly influences the hardening of the paste at normal temperatures.

"SORPTION AND LENGTH-CHANGE SCANNING ISOTHERMS OF METHANOL AND WATER ON HYDRATED PORTLAND CEMENT" R. F. Feldman

Detailed studies of sorption and desorption isotherms led to the conclusion that the surface area of hydrated portland cement was considerably less than the value of approximately 200m^2/g obtained from determinations by the BET equation for adsorbed water. This is based on the fact that the BET equation, which is valid for the low pressure region of the adsorption isotherm, implicitly assumes reversibility and a constant surface area and the fact that detailed studies of the adsorption and desorption isotherms at low pressures show that irreversible changes occur when hydrated portland cement is dried at low vapor pressures.

The author made detailed studies, by means of scanning loops, of hydrated cement and compacts of bottle-hydrated cement. His Fig. 1 shows weight changes vs vapor pressure for I. compact degassed in a vacuum at 80°C and II. compact degassed in a vacuum at 96°C. The scanning loops show that the isotherm is irreversible even at as

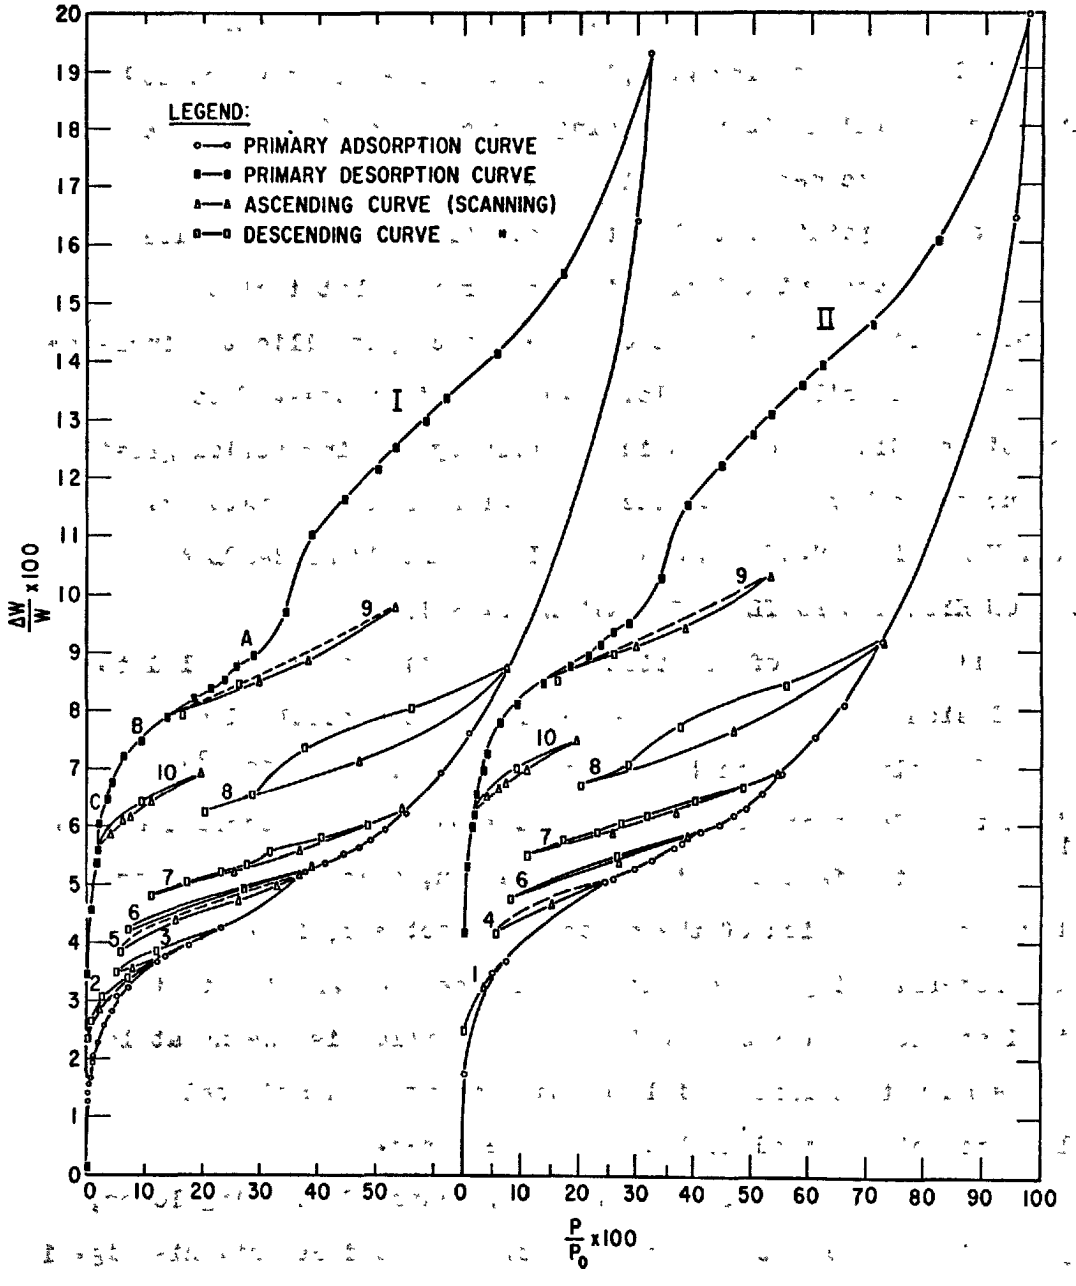

FIGURE 1 (by Rolf F. Feldman)

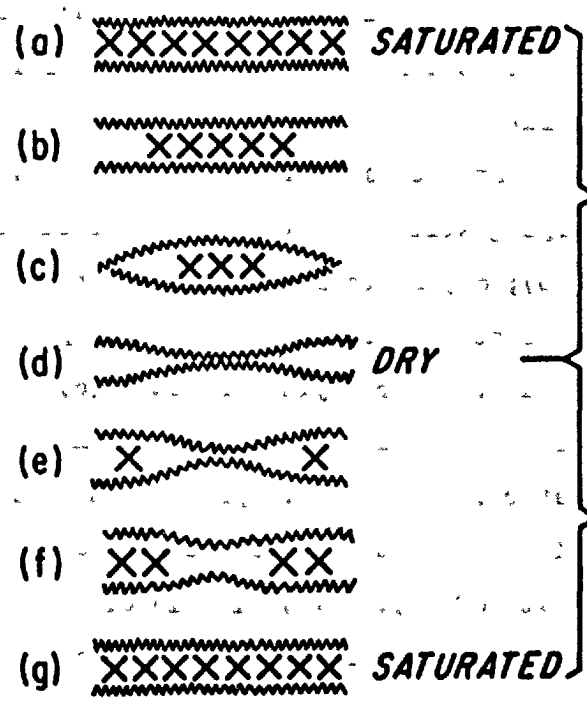

FIGURE 7 (by Rolf F. Feldman)

low a p/p_o of 0.05 and that much of the irreversibly sorbed water is sorbed below p/p_o of 0.35. Calculations based on the scanning loops lead to the conclusion that irreversibly sorbed water is interlayer water in tobermorite.

The process of exit and entry of interlayer water is illustrated in his Fig. 7. Initially drying will take place from the edges with little contraction (a) to (b); drying to state (c) will provide some collpase and large contraction; drying at the edges probably occurs below p/p_o of 0.30 and stronger drying of state (c) below p/p_o of 0.07. Final removal of water in the middle will not occur above p/p_o of 0.09. This water is believed to provide the main bracing for a higher rigidity and removal decreases the modulus as his results show. The state of drying (d) also involves possible reorientation of the plates to produce irreversible contraction. Resorption occurs at the edges, states (c) and (f) being initiated by physical adsorption and resultant surface free energy change on the external surfaces.

The author believes that the surface areas based on nitrogen adsorption probably are nearer correct than those based on water adsorption.

"ON SOME ASPECTS OF THEORY OF SOLIDIFICATION AND STRENGTH FORMATION OF CEMENT-STONE AND CONCRETE" I. P. Vyrodov.

The author divides his paper into three chapters as follows:

I. On the possibility of applying the main principles of molecular physics and thermodynamics for the study of the character of change of mineral binders.

II. Role of diffusion kinetics of reactions in the process of hardening of mineral binders.

III. On some principal aspects of the theory of solidification and strength formation of cement-stone and concrete.

Time does not permit any meaningful review of the highly mathematical material covered in chapters I and II. In chapter III the author points out that (a) some foreign workers consider the modern point of view of Soviet workers to be that of Rebinder and coworkers and (b) that some foreign and Soviet scientitists also share the false impression that Rebinder and coworkers continue the main hypothesis of Baikov in their through-solution theory of the solidification of mineral binders. The theory of Baikov was based on a topochemical mechanism and was divided into three periods.

1. Dissolving of the original mineral binder with the formation of a supersaturated solution.

2. Colloidation, that is the formation by chemical reaction on the surfaces of the binder the small particles of the final product sponsoring the formation of high supersaturation.

3. Crystallization of amorphous gels.

According to the author these concepts seem to be accepted by many Soviet and foreign scientists except for the main point of Baikov's theory regarding the solidification of mineral binders. According to Baikov solidification occurred primarily because of the topochemical reactions of step 2 and not from the crystallization which occurs in step 3. The author restates the three steps of the Baikov theory as follows:

1. Dissolving of hydrates formed by the interaction of cement grains with water.

2. Formation of solid crystalline products or semicrystalline products

on the surfaces of the cement grains after the liquid becomes saturated.

3. Crystallization of the semicrystalline products.

These processes may occur simultaneously. The author has found from X-ray studies that crystalline products are formed at the very beginning of the reaction with water. However the topochemical reactions of step 2 are responsible for the solidification and development of strength.

"CEMENT PASTE SHRINKAGE-RELATIONSHIPS TO HYDRATION, YOUNG'S MODULUS AND CONCRETE SHRINKAGE" Harold Roper.

The paper presents paste shrinkage, hydration and Youngs's modulus data for sixteen cements. It also presents shrinkage data for concrete specimens

Linear regression analyses relating paste shrinkage at constant w/c to cement composition were calculated using an equation of the form

$$dl = a(C_3S) + b(C_2S) + c(C_3A) + d(C_4AF) + e(SO_3)$$

where dl = paste shrinkage.

The only regression coefficient which was consistently significant was that for C_3A. The most significant equation for predicting shrinkage is of the form,

$$1/dl = f - g(C_3A)$$

The constant f remains the same for all w/c ratios, whereas the coefficient g changes systematically. Up to 80 per cent of the variations of paste shrinkage is explicable by the variation in C_3A. It was concluded from the results of all these analyses that the role of C_3A was dominant in explaining the variance in shrinkage.

It was considered that the effects of differences in hydration rates were influencing the shrinkage results significantly hence the non-evaporable water contents of the various pastes were determined. By means of an emperical approach the following equation was found to apply for each individual cement.

$$1/dl = a - b(W_n)$$

dl is the paste shrinkage expressed as a percentage, W_n is the non-evaporable water and a and b are constants. "a" in physical terms is interpreted as representing the reciprocal of the percentage shrinkage which an unhydrated cement compact undergoes from a saturated state to the experimental drying condition. Treating the results as a series of endependent variables gives the following equation.

$$1/dl = 10.844 - 37.035W_n$$

Including Young's modulus gives the following equation.

$$1/dl = 7.620 - 27.301W_n + 0.485E$$

Regression analyses were conducted on data for paste shrinkage and concrete shrinkage for fifteen cements. Paste shrinkage at 28 days was used. The correlation coefficients for 13 degrees of freedom were 0.962; 0.966; 0.886 and 0.841 for shrinkages of concrete at 7, 28, 90 and 365 days. A value of "r" greater than 0.760 indicates a significant relationship at the 0.001 level. It is concluded that highly significant correlation exists between the paste and concrete shrinkage even for drying periods up to one year.

"THE STRUCTURE OF CEMENT-STONE AND THE USE OF COMPACTS AS STRUCTURAL MODELS", I. Soroka and P. J. Serada.

This study was undertaken to obtain data on the structure of

cement-stone, particularly with regards the nature of the interparticle bonds. The specimens were discs of the following.

I. Cement pastes porosity 73 to 98 per cent.

II. Compacted cement paste porosity 25 to 60 per cent.

III. Compacts of bottle-hydrated pastes porosity 20 to 55 per cent.

Some believe that the limited swelling of cement-stone in water is evidence for the existence of some chemical (primary) bonds between the gel particles although they believe that secondary bonds account for most of the strength. The authors interpret primary and secondary bonds as follows: Chemical bonds between particles are solid to solid contacts similiar to that of a grain boundary in a polycrystalline material where some atoms approach the spacing arrangement in the crystal. Secondary bonds assume that adsorbed water is a constituent part of the interparticle bond; hence the general term of van der Waals forces is considered appropriate.

The authors' Fig. 2 is a plot of modulus of elasticity vs porosity together with the regression lines calculated to fit the data. It is seen that the modulus vs porosity relation is the same for the cement paste as for cement paste compacted from a porosity range of 40 to 70 per cent to a porosity range of 25 to 60 per cent. This is taken as strong evidence for the absence of chemical bonds because it is likely that these bonds would be broken (if they were present) when the pore volume is reduced by half during compaction. Also the fact that the values for the modulus of the compacts of bottle-hydrated cement fit so closely to those of the paste and compacted paste lends further support to the idea that the system has none or very few chemical bonds. The results of their Fig. 3 in which hardness is plotted against porosity lead to the same conclusion.

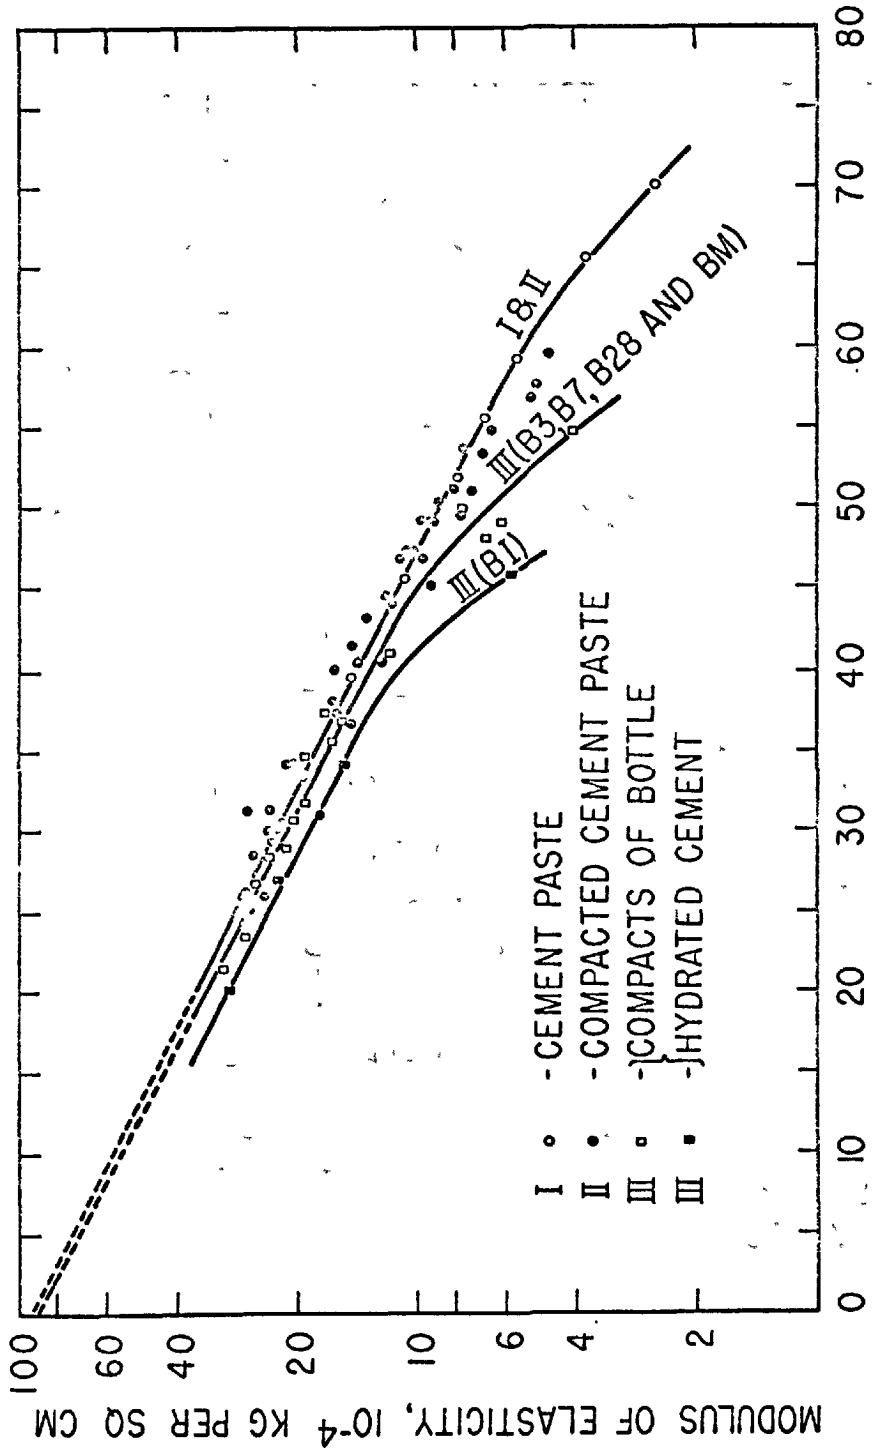

FIGURE 2 (by I. Soroka and P. J. Sereda)
MODULUS OF ELASTICITY VS POROSITY FOR THE CEMENT SYSTEMS

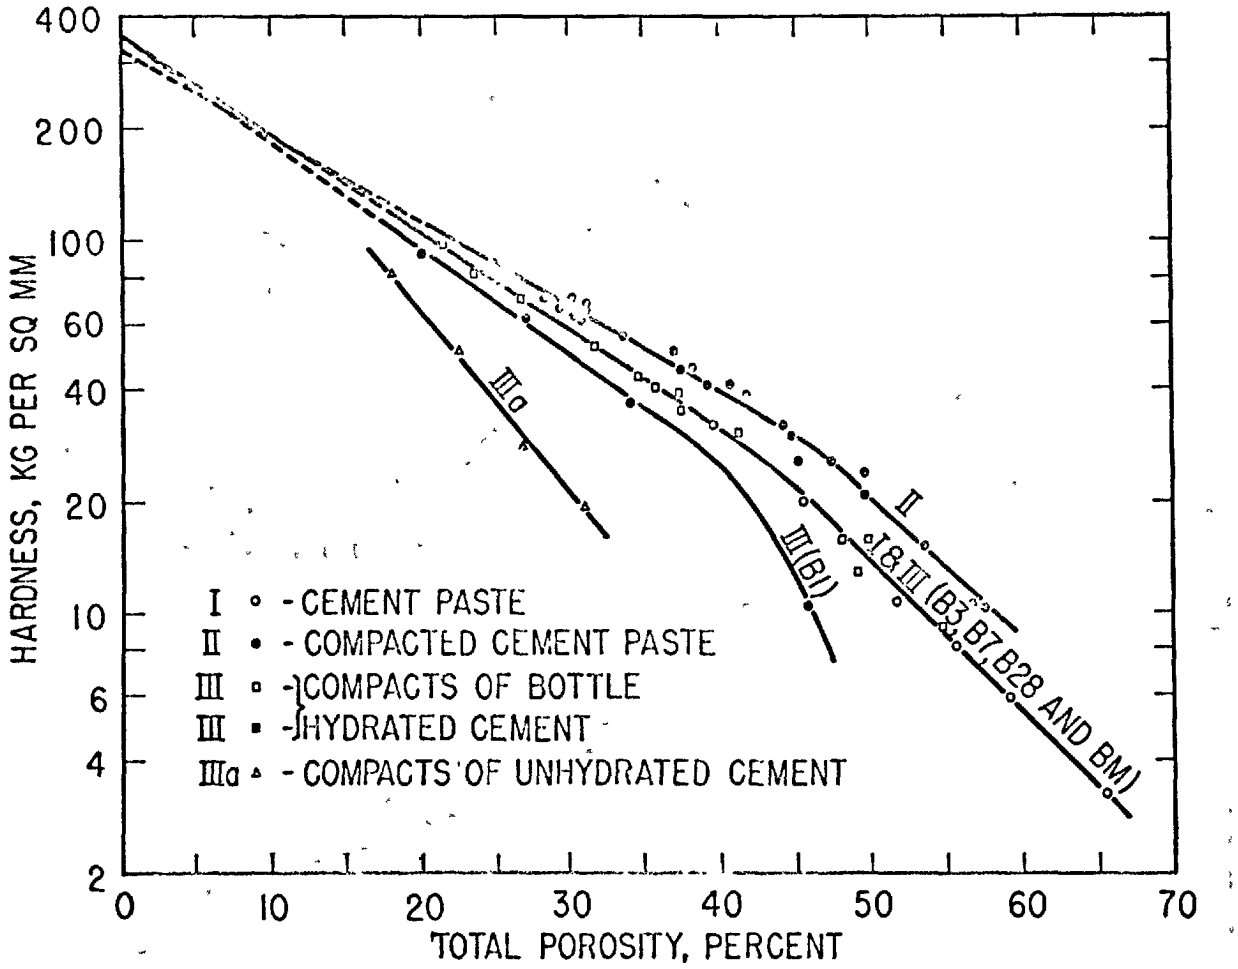

FIGURE 3 (by I. Soroka and P. J. Sereda)
HARDNESS VS POROSITY FOR THE CEMENT SYSTEMS

These results lead the authors to the conclusion that the strength of cement-stone is mainly derived from a particular type of interparticle bond. It is further concluded that this bond is a solid to solid contact resulting from the bringing together of surfaces and that it is essentially the same in compacts as in cement pastes.

"MOLECULAR SIEVE EFFECT IN CONCRETE." R. H. Mills

Investigators have shown that hardened cement pastes act as molecular sieves in that the quantity of fluid adsorbed is a function of the size of the molecules of the fluid. Water is capable of greater penetration than other fluids but it is not capable of complete penetration of the finer pores.

Oven dried specimens were vacuum saturated with an organic fluid, such as kerosene, and then resaturated with water. A "k" factor was calculated by the equation $k = (V_w - V_f)/V_w$ in which V_w and V_f represent respectively the volumes of water and organic fluid at saturation. This ratio represents the fraction of water which has access to space which excludes the organic fluid. To a first approximation, kV_w is a measure of the pore water strongly adsorbed in the micro-cellular structure of the cement hydrate. It is that portion of the pore water which is active in the sense of applying swelling or drying pressure tending to separate primary particles of the paste.

The author's model for the structure of the paste is based on electron microphotographs which show hydrated calcium silicate flowers growing on a grain of cement. The author concludes that the space separating primary particles is unlikely to have parallel

sides and judging from the microphotographs may be described as wedge shaped with the sharp end of the edge pointing in random directions. In terms of this model, water is excluded from the apex of the wedge where interparticle cohesion is provided by primary bonds.

Strength is a linear function of k. Volume changes due to creep and shrinkage appeared to increase with increase in k but values of kV_w after shrinkage and creep had taken place were less than at the start of the test. This suggests a collapse of structure in the cement hydrate. The volume kV_w was found to represent between 1 and 3 monolayers of water and corresponds to the water held at relative humidities between 0 and 28 per cent. Shrinkage varies linearly with weight of water gained or lost within this range of relative humidities.

The author concludes that the parameter $k = (V_w - V_f)/V_w$ is related to the degree of hydration, surface area and strength. And that further research may show a close dependence of creep and shrinkage characteristics on this parameter.

"ELECTRON MICROSCOPIC INVESTIGATION ABOUT THE RELATION BETWEEN STRUCTURE AND STRENGTH OF HARDENED CEMENT." Werner Richartz.

According to the author, electron microscopy shows that the hardening of cement may be divided into three stages. In stage I ettringite crystals form as a thin layer on the cement grains and calcium hydroxide forms as thin plates in the liquid phase. These phases are visible within minutes after the paste is prepared. After about an hour a thin layer of hydrated calcium silicates can be observed on the cement grains. As hydration continues, ettringite and hydrated calcium silicate crystals grow as interlocking fibers

and extend across the large pores and divide them into smaller pores. After hydration is completed these fibers act as a micro-reinforcement of the structure and will increase the ultimate strength. Following this stage II, which requires about twenty four hours, the remaining pores are filled with new hydration products. During this stage hydrated tetracalcium aluminoferrite is formed instead of ettringite and the latter is converted to the monosulfate. Hence the contribution of ettringite to the total strength is doubtful, but it influences the setting of the cement and the early strength.

Low temperatures retard hardening but generally result in higher ultimate strengths. Extension of stage II results in increased formation of long fibrous calcium silicate hydrate crystals and increases strength. Retardation of hardening also results in the formation of long fibers of the calcium silicate crystals and in higher strengths.

When hardening is accelerated either by finer grinding, higher temperatures or accelerators, the surfaces of the cement grains are activated so that the solution in the pores is always supersaturated. This favors spontaneous nuclei formation and increased crystal growth. Accordingly only a few crystals can grow as long fibers in stage II. During about the first 28 days the strength of the accelerated cement exceeds that of the unaccelerated cement but after that the strengths are reversed. These results show that a strict relationship exists between the development of structure and strength. The author gives sixteen electron photomicrographs in support of the conclusions given in the paper.

"A STATISTICAL STUDY OF THE EFFECTS OF TRACE ELEMENTS ON THE PROPERTIES OF PORTLAND CEMENTS." RAYMOND L. BLAINE

A digital computer was used to evaluate significant relationships between the properties of 199 commercial cements. The tests were hydration, autoclave expansion, potential sulfate resistance, compressive strengths of mortars and concretes, and nonrestrained and restrained shrinkage. The computer was used to find and evaluate significant relationships between the results of tests (dependent variables) and variuous independent variables which included chemical composition, minor constituents and trace elements. Multivariable regression equations were calculated by a least-squares method using only commonly determined variables, including sodium and potassium oxides, and these variables together with trace elements. Numerous trial equations were required to determine independent variables which were significantly related to the dependent variable, and the combination of variables which resulted in the lowest estiamted deviation for the equation.

Up to 13 dependent variables could be accomodated in an equation with the computer program used. The output of the computer included the estimated coefficient of each of the endependent variables as well as the estimated standard deviation of each of the coefficients. An independent variable was retained in an equation if the ratio of the estimated coefficient to the estimated standard deviation (coef./s.d.) was greater than 1.0. Although this represents a very low probability of significance, such independent variables were retained primarily because these studies were exploratory. Values between 1.0 and 2.0 may also be considered of doubtful significance.

Values of 2.0 or greater would occur by chance with a probability of 0.05 and therefore independent variables having values of coef/s. d between 2 and 3 are referred to as probably having a significant relationship to thedependent variable. When used as independent variables in multivariable equations, the coefficients of sodium and potassium oxides, in some tests, were highly significant and in other tests variations in one or both of these alkalies had no apparent effect on the property measured. Trace elements that were found to have coef./s. d. greater than 1.0 were Sr., Ba, Cu, and Rb most often, second were Zn, V, P, and Cr and third were Co, Ni, Mn, Li, Pb and Ti. Mo detected in a few cements did not appear in any of the equations.

GENERAL REPORT

OF

SESSION III-1: STRUCTURES AND PHYSICAL PROPERTIES OF CEMENT PASTE

(b) Papers regarding Application

W. L. Dolch (U.S.A.)

The following Supplementary Papers are summarized in this report.

Paper No. III-1

COMPARISON OF VARIOUS MEASUREMENTS CONCERNING THE KINETICS OF HYDRATION OF PORTLAND CEMENTS

S. Popovics (U.S.A.)

Paper No. III-5

MECHANICAL PROPERTIES OF PRECOMPRESSED MORTAR SPECIMENS

O. Ishai (U.S.A.)

Paper No. III-33

DEFORMATIONS OF PLAIN CONCRETE

F. O. Slate & B. L. Meyers (U.S.A.)

Paper No. III-72

CORRELATION OF STRENGTH AND HYDRATION WITH THE COMPOSITION OF PORTLAND CEMENT

K. M. Alexander, H. Taplin & J. Wardlaw (Australia)

Paper No. III-119

SOME RECENT ADVANCES IN THE STUDY OF CEMENT AND CONCRETE

H. E. Vivian (Australia)

This is a condensation and summary of seven supplementary papers on the general relationships between the nature and structure of cement pastes and the engineering properties of concretes and mortars made therewith.

The seven papers can be divided logically into three groups: 1) a general review of deformation processes (Slate and Meyers), 2) the influence of composition and other properties of the cement on engineering properties of concrete (Alexander et al, Popovics, Vivian) and 3) the influence of chemical and physical properties of the paste on these same engineering properties (Ishai, Mishima, Seki et al). Categories 2 and 3 are, of course, a separation based on emphasis rather than on the fundamental difference.

The present author has, in his reportorial function, deliberately not taken the part of critic, but has tried merely to summarize the main aspects of the papers assigned to him.

Slate and Meyers discuss in turn the various components of a concrete that are subject to deformation, called deformees, and the various influences that bring about deformation, called deformers. The former comprise all the phases of the concrete: the aggregate pieces, the larger crystals and small crytallites of the paste, the free, capillary, adsorbed, and chemically-combined water, and any air-filled spaces such as bubbles, voids and cracks in the paste or at the paste-aggregate interface.

The deformers considered are the forces attributable to chemical reaction, such as hydration and carbonation, stress and pressure, and changes in moisture content.

The processes that are brought about by interactions of these forces and objects are elastic strain, fracture, flow, diffusion, solution, and reprecipitation.

The authors evaluate these processes in terms of the magnitude of the resulting deformations. Important distinctions are made between deformations from short term loads that result in elastic strain and fracture and those from long term loads that result in creep.

Particular emphasis is placed on the aggregate-paste interface and on the effects that result from cracks at this place. In general, important distinctions are drawn between generalized and localized deformations, and the conclusion is made that the engineering behavior of concrete is determined by and limited by the localized changes that take place at crack tips, water filled voids, and aggregate-paste interfaces.

The paper of Popovics is an attempt to describe the changes in important engineering parameters of concrete by a model that has simple properties. The most important ones are that the cement is composed of only two active components, the C_3S and everthing else, and that the decelerations in the values of any properties associated with the hydration are, at any time, proportional to the magnitude of the property yet to be developed. For example, at any time the deceleration of the strength change would be proportional to the difference between the strength at that time and the ultimate strength to be obtained. This proposition has previously been tested with respect to strength development. In this paper, in

addition to a review of the strength results, the model is tested against two other indexes of cement hydration, the non-evaporable water content and the specific surface of the gel formed. A further assumption was made that the C_3S component is responsible for the generation of three times the non-evaporable water of "other" component.

The test was made by a comparison of the experimental values of others with the values predicted by the model. In addition, effects of curing temperatures are included by combining the model with the Arrhenius equation.

The results are that the model provides a reasonable prediction of the parameters in question, with the agreement for strength being the best and that for specific surface the poorest. The coefficients of deceleration were found to be linear functions of the C_3A content of the cement in the cases of strength and non-evaporable water development.

The considerations of temperature gave a result similar to the well-known maturity rule.

One of the interesting empirical aspects of Popovic's model is that it seems to include the consequence, often observed, that any condition that increases the early strength of concrete will result in a decreased final strength and vice versa. Such conditions as temperature, the presence of accelerators or retarders, and cement fineness seem to follow this generality.

Alexander, Taplin and Wardlaw present data showing the relationships between composition and certain other properties of thirty

cements and the strength and degree of hydration of pastes made therewith. The conditions of hydration include a wide range of water-cement ratios, 0.35-0.80, and temperatures from 5 to 75 C. The duration of hydration of the pastes was from a few hours to six months. The compound compositions of the cements varied from about 40-62 percent for C_3S and from practically nil to 11 percent for C_3A.

The resulting data were analyzed by means of mutiple regression analysis. The most significant general result is the very great dependence of the strength differences on the C_3A contents of the cements. This influence was predominant at ages from 7 days to three months and most important at intermediate ages and water-cement ratios, i.e. at just those conditions under which the strength of concrete is most often determined as an index of its quality, water cement ratios of about one-half and an age of 28 days. This influence of the C_3A seems to be in accord with the findings of Popovics, mentioned earlier. The relatively large differences in C_3S content proved to be comparatively unimportant.

Since the influence of C_3A left a relatively small but significant residual variation unaccounted for, the influence of other compositional and physical property variables was examined. Particle size, free lime, and potassium were the only ones that correlated significantly with strength. The influence of the reciprocal of the mean particle size on strength was positive and appreciable in magnitude at intermediate ages. The influence of free lime was negative and greatest at later ages and lower water-cement ratios. It was also found that the influence of the

manganese content on strength variation was significant at very early ages.

The data seem to show that the silicates are hydrating faster in cements with higher C_3A contents. Speculation is advanced for the possible reasons for this effect.

The data on hydration and on the influence of temperature showed the influence of C_3A content on hydration to be even greater then for strength and to be most important at intermediate temperatures.

Vivian examines certain properties of cement that may be of considerable importance to the workability, strength, and durability of concrete and that are not adequately controlled or measured in current cement production practice.

It is pointed out that the particle size distribution of the finished cement is influenced by the particle size distribution of the raw meal as well as by the final grinding. Inadequate control of these features of the meal can result in variability of the cement that is significant in its performance in concrete. An important aspect is the difference in grindability between the clinker and the gypsum, which results in the presence of the gypsum in predominantly the finer fractions of the cement. Further differences in the cement can be introduced during grinding if the mills are air-swept and the cement is subject to variable amounts of aeration.

Vivian advocates a reduction in the amount and temperature of the air stream, closed circuitry of the air system and increased

separator efficiency to minimize the time the finer particles stay in the circuit.

The paper describes the problems the author states arise when gypsum particles are occluded by the hydration products of the cement and thereby become prevented from going into solution for perhaps long periods of time. This condition can result in insufficient gypsum for normal retardation and a consequent lack of workability of the concrete. At much later times a further problem can exist when some influence, perhaps the volume changes associated with wetting and drying, disrupts the encapsulation of the still-unreacted gypsum and liberates it to undergo possibly expansive reaction with aluminate components of the paste. It is stated that this may be the cause of surface crazing of concrete subjected to temperature and moisture-content cycles.

The author discusses also the influence of particle size and particle size distribution of the cement on the strength and shrinkage of concrete. The main differences seem to be in the distances hydration products may travel during their deposition as well as in the more obvious matters of degree of hydration at any given time.

The paper by Seki, Kasahara, Kuriyama, and Kawasumi examines the relationships between the degree of hydration of cement and several mechanical properties of concrete.

Experiments were conducted with a moderate heat cement in a concrete designed to be typical of mass concrete construction, although the largest size aggregate was screened out prior to the casting of samples. The concrete was then cured under water.

Bound water was determined on pastes by vacuum drying at 5mm Hg over silica gel for three days. The resulting value of 0.37 of the cement weight for complete hydration means the "bound" water in this study includes more than the non-evaporable water of other studies. Values of bound water were used to determine the degree of hydration of the concrete at any given time.

The compressive strengths showed a linear relationship to the ratio of hydrated cement to original water content ratio, both for the laboratory concretes and for samples taken from various dams in Japan. This relation is similar to the well-known gel-space ratio relationship, which is discussed in the principal paper of this session.

Elastic moduli were determined by measurement of the longitudinal wave velocity in the concrete samples. The wave velocity was found to be a linear inverse function of the volume of water in the sample that was not "bound", i.e. the greater the extent of hydration, the higher the velocity and therefore, the elastic modulus, which is normal.

Comparisons were also made between the static and dynamic Young's moduli of elasticity, and the empirical relationship obtained was that the dynamic modulus was about 37 percent greater than the static.

The creep studies resulted in a linear relationship between the creep factor, which is proportional to the creep strain, and the volume of "uncombined" water present. Such results are an additional

confirmation of the seepage theory of creep behavior of concrete.

In general, these studies show, once again, the commanding importance of the amount of hydrated cement in determining the mechanical properties of concrete.

Ishai investigated the strength, elastic modulus, shrinkage, and creep of mortars that had either been cured in the usual fashion or had been subjected to preconsolidation by an applied pressure of about 2400 psi at various times early in their lives.

The preconsolidation always brought about changes in the measured properties. Since the compaction squeezed out a considerable portion of the mixing water and resulted in a lower water-cement ratio, it is understandable that such changes in mechanical properties should occur. It is possible, of course, that the compaction also resulted in a changed structure including more bonding points of contact between the solid phases than are present in normally-cured materials.

When the mortar was preconsolidated about 3 hours after casting the strength was over twice that of normally-cured specimens. The elastic modulus difference was smaller and not nearly proportional to the strength change, which probably in itself is an indication of microstructural change. Precompressed specimens exhibited smaller volume changes on wetting and drying and somewhat less creep strain than their counterparts. Further, specimens that were oven-dried showed no creep strain at all, a result that confirms earlier work.

All the foregoing papers were concerned with problems of portland cements. The paper by Mishima turns to problems of high-alumina cement.

He examines the relationships between the compound composition of the hydration products of high-alumina cement and the strengths of their mortars. The conditions included water-cement ratios of 0.4-0.7, curing temperatures of 10-40 C, and curing times up to 7 days.

The compound compositions were determined by semi-quantitative x-ray diffraction methods. The predominant hydrates formed at 10 and 20 C were CAH_{10} and C_2AH_8, there being relatively more of the former at the lower temperature. At 40 C no CAH_{10} was found and the larger amount of C_2AH_8 initally formed progressively converted to the stable cubic C_3AH_6 and gibbsite, AH_3, in the well-known reaction that brings about important engineering problems in the use of these cements.

At 30 C the formation of significant amounts of any hydrate was delayed until about 12 hours and the conversion to C_3AH_6 began only after several days.

Strengths roughly followed the amounts of hydrates produced except that the conversion to C_3AH_6 resulted in the usual strength decrease. Strengths attributable to the presence of CAH_{10} seemed to be greater than those attributable to the presence of C_2AH_8. The influence of the water-cement ratio was about the same as with portland cements.

At 30 C, which temperature seems to represent the onset of the conversion reaction, the lesser reactivity was reflected in longer setting times and lower strengths.

GENERAL REPORT
OF
SESSION III-2: DURABILITY OF CONCRETE

I. Biczok (Hungary)

The following Supplementary Papers are summarized in this report.

Paper No. III-24

BEHAVIOUR OF MORTARS AND CONCRETES IN THE TEMPERATURE RANGE FROM +20° TO -196°C

G. Tognon (Italy)

Paper No. III-25

THE INFLUENCE OF TEMPERATURE ON SULPHATE ATTACK ON PORTLAND CEMENT MORTARS

J. H. P. van Aardt (South Africa)

Paper No. III-30

THE FROST RESISTANCE OF CEMENT GROUTS FOR PRESTRESSED CONCRETE APPLICATIONS

C. MacInnis (Canada)

Paper No. III-31

CHEMICAL REACTIONS OF STRONG CHLORIDE-SOLUTIONS WITH CONCRETE

H.-G. Smolczyk (West Germany)

Paper No. III-39

A DURABILITY STUDY OF CONCRETE USING MONTE CARLO SIMULATION

K. R. Lauer & C. W. Gray (U.S.A.)

Paper No. III-59

MEASURING OF GAS DIFFUSION FOR THE VALUATION OF OPEN POROSITY ON MORTARS AND CONCRETES

H. J. Böhme, U. Ludwig & H. E. Schwiete (West Germany)

Paper No. III-99

THE BEHAVIOR OF CONCRETE SUBJECTED TO FREEZING AND THAWING AS A REFERENCE FOR FROST RESISTIVITY OF CONCRETE

Y. Koh & E. Kamada (Japan)

Paper No. III-123

EFFECT OF CONVERSION ON PROPERTIES OF CONCRETE USING HIGH-ALUMINOUS CEMENT

R. Tsukayama (Japan)

Paper No. III-124

THE INFLUENCE OF CHLORIDE AND HYDROCARBONATE ON THE SULFATE ATTACK

F. W. Locher (West Germany)

Paper No. III-138

MECHANISMS OF SULPHATE EXPANSION OF HARDENED CEMENT PASTES

S. Chatterji (United Kingdom)

The resistance of the concrete respectively of the cement stone against external aggression is a constant subject of international conferences. On the occasion of the III. International Symposium on the Chemistry of Cement, Washington, 1960, the VI. Section /Destructive Process in Concrete/ dealt with questions of corrosion, but during the deliberations of other sections questions related to the corrosion of concrete were breached as well. Since then, in 1961 the RILEM had a Colloquium in Prague on the durability of concrete. - In 1966 an international conference on silicates was held in Weimar; its III. Section discussed problems of the corrosion of concrete. In 1967 a conference in the same field of interest was organized in Leipzig. Representatives of 37 states participated in the three last mentioned gatherings and more than 90 papers were read, concerned directly or indirectly with problems of concrete corrosion.

It must be mentioned here that among several states, in Japan the Cement Association of Japan organizes General Meetings, where papers are read in this subject matter, and are published in the yearly Reviews.

After such antecedents it may be appropriate to consider, what

kind of phenomena should be included in the scope of concrete corrosion problems. In first concept we mean by the term 'corrosion processes of concrete' damages of concrete caused by the penetration of liquid or gaseous substances into the solidified concrete.

Thus we may speak about corrosion by carbonic acid, by nitrogen oxide, hydrogen sulphide, by gases or by sulphatic, chloridic or other salt solutions of natural origin or occurring as industrial by-products. I would term these as external corrosive effects. Nevertheless the internal transformations of the cement stone, and the recrystallization of the hydrated compounds, produced during the binding of the cement, can cause also structural changes which may initiate or accelerate the start of corrosive processes.

In my German book - Betonkorrosion - Betonschutz, i.e. Concrete corrosion - Concrete Protection; 1968 - I termed these processes as processes of internal origin, shortly as internal corrosive processes. Properly speaking, the destruction of the cement stone caused by the free lime and magnesia and accompanied by expansion, comes also under this heading, although it is not usual to discuss these occurrences within the scope of corrosive effects.

Nevertheless the expansion induced by an excessive quantity of gypsum interground to the clinker, or the destruction effected by the recrystallization of the hydrate compounds of aluminate cements, had appeared in the discussions also as a corrosion phenomenon since a longer time. These latter typical phenomena of internal corrosion were considered always as belonging to this subject matter.

The occurrences of external corrosion are effected by solutions diffunding into the cement stone. Any occurrences promoting diffu-

sion, i.e. increasing the porosity of the concrete, accelerate the proceeding of corrosion. Therefore phenomena having a bearing on the porosity of the cement respectively cement stone can not be separated from the investigation of concrete corrosion. Many observations and theoretical considerations lead to the assumption, that the increasing of the pore volume is brought about by the transformation of the unstable hydrate compounds, developed primarily during the hydratation, or of hydrate compounds getting unstable due to the changes of the surrounding to stable compounds. If the filling of the space by this stable formation is diminishing, fine cracks appear which facilitate the penetration of aggressive solutions and gases.

The study of the corrosive phenomena within the concrete necessitates therefore the examination of the internal corrosive phenomena as well as the exploration of the pertaining research results. It follows from this statement that I deem it necessary to take into consideration the thermodynamical investigations concerning the stability of the products appearing during the setting of cement. On the occasion of the Washington Symposium Brunauer and Greenberg rendered account of such investigations. /Monography, Vol.I. p.155: Free Energies and Entropies of Hydratation/ as well as Mchedlov-Petrosyan and Babushkine /Monography, Vol.I. p.533: Thermodynamics of the hardening processes of cement/. In 1962 a book edited by Mchedlov-Petrosyan appeared in Russian, later in 1965 in German, discussing the thermodynamics of silicates /Thermodynamik der Silikate/. – The same authors have read a very important paper in the next year at the Weimar conference

with the heading: "Die Thermodynamik der Korrosionsreaktionen des Zementsteins" /The Thermodynamics of the Corrosion reactions of the Cement Stone/.

According to these theoretical investigations and estimations, during the hydratation of the tricalcium silicate /C_3S/ and of the beta-dicalcium silicate /C_2S/, any of the known calcium hydrosilicates may be produced. The values of free reaction enthalpies of the development of hillebrandite, phosphagite, tobermorite, riversideite and xonotlite are so near to each other that from a thermodynamical point of view the production of any named hydrate compounds is possible. However only the hillebrandite possesses a stable material structure up to 200 centigrades. In its elementar cell films of xenotlite /$Ca_6[Si_6O_{17}](OH)_2$/ and portlandite occur stratified alternately, yet its $Ca(OH)_2$-content may be more or less. – Thus the proportion CaO/SiO_2 can vary without a change of the basic structure /see e.g. Kantro, Brunauer and Weise, Portland Cement Ass. Bulletin 1961 and 1962, – further Locher: Zement-Kalk-Gips, 1964/.

Although several research workers term this product tobermorite, instead of hillebrandite, in accordance with thermodynamical investigations the stable product constitutes hillebrandite. /I do not consider it as my task to discuss this contradiction./ Due to the variable proportion of Ca/Si, deformations occur, wherefore the hydrate changes its original uniform structure and appears sometimes in a lamellar structure, or in a coiled habit, similar to halloysite. This stable phase is represented in the technical literature by the formula C_2SH and the different morpho-

logies are differentiated by the three capital letters A, B, C. Influenced by various outer factors the hydrosilicates may transform or recrystallize, however this process is accompanied on the one hand by more or less swelling, mostly by volume decrease and the generation of structural discontinuities, which contribute to the shrinkage consequent upon the removal of the gel-water, – on the other hand hair cracks develop easing the diffusion as a consequence of the transformed structure.

From X-ray photographs one must conclude that neither of the mentioned appearances possesses a good stable lattice structure, which fact renders their identification difficult.

These symptoms, the kinetics of the transformations, are influenced by the rate of hydratation, the water-cement ratio and the temperature, – thus the rate of stabilization depends on the mineral composition of the clinker, the grinding fineness of the cement, moreover on the technology of concreting. As the shrinkage of the mortar is somewhat slowed down due to mechanical and physical facts – by the sand blended to the cement paste, and this is veryfied by the fact that the mortar shrinkage estimated on the base of the shrinkage of the cement paste, measured in laboratories, surpasses essentially the actually measured value, – it is apparent that the occurrence of cracks promoting the corrosion is dependent also on the ratio of the cement/fine sand. /Under the term "fine sand" an aggregate finer as a grain size of 0,2 mm is meant./

Here already I want to indicate that, contrarily to the above mentioned proceedings, the self-sealing processes – in most

cases occurrences of calcite /which is a result of carbonization caused by the carbonic dioxyde content of the air/ or of its modifications – may occlude in the case of a Portland-cement binding agent the capillaries carrying water, still with concretes in which the formation of calcium carbonate is not probable or is lacking a possibility, this process – increasing greatly the durability of concrete – does not develop. – It is to be noted that in a moist air the hillebrandite reacts with the carbonic-dioxide content of the air, and some modification of calcium carbonate comes to being, accompanied by a segregation of a silica-gel contributing also to the self-sealing.

It is a known fact that during long-time studies of concrete, fluctuations can be observed, with investigations of strength as well as with measurements of dilatations. It is deplorable that these observations were not cross checked until now by mineralogical investigations and by tests of stability.

The thermodynamical studying of the aluminate hydrates needs yet completions. According to the present computations in the temperature range of 20 to 120° C, the C_4AH_{19} is the stable hydrate compound /which is mentioned mostly as C_4AH_{13} in the technical literature/, whereas at a higher temperature the hydrate compound C_3AH_6 – appearing in the cubic system of crystallization – is stable. Hence it follows that tetracalcium aluminate hydrate ought to originate equally from C_3A, from $C_{11}A_7$, C_2A and CA.

However the experimental results contradict this statement in some respects. The tesseral modification arises already at a lower temperature than 120° C, while below 25° C if C_4AH_{19} or CA

is hydrating the monocalcium aluminate hydrate is the dominating product. As for the calcium aluminate hydrates, I will deal with them in connexion with the dissertation of van Aardt.

Two types of sulphatic aluminate hydrates are known; their formation is equally possible according thermodynamical computations, yet the stable crystallizing compound up to 70° C is the trisulphate, the so called ettringite; above this temperature the formation of a monosulphate is more probable.

Although the classic opinion – evolved already at the end of the past century – was accepted generally for a long while, and was in accordance with the practical experiences, – recently different misgivings arose, as our knowledge was deepened by the development of new instrumental investigations and new theories have been published. For a long time the begin of crystallization of the ettringite could not be observed by microscopic examination, by means of the latest instrumental analytics it could have been proved that the ettringite crystallizes in the cement stone after a delay of some minutes following its getting mixed with water. /Schwiete, H.E.; Ludwig, U.; Jaeger, P. – Zement-Kalk-Gips. 17, 1964. p. 103/. – Nevertheless this statement is contradicted by the observation that at a temperature of about 20° C also a monosulphate may come into being, further that ettringite can be found in a concrete strengthened by steam curing and autoclave treatment.

Some research workers furnished data referring to the possibility that ettringite may decompose at a temperature of about 20° C. Thus Koyanagi showed on the occasion of the 1952 London

Symposium a microphotograph which enabled readily the observation of disintegrated crystalline ettringite needles. /Report ... 1952. p. 252./ Schwiete and Niel /see Zement-Kalk-Gips, 18, 1965. p. 157./ established by means of infra-red absorption photographs that the aluminate-sulphate hydrates issuing from the first minutes of the binding process, disintegrate partly and that gypsum separates out. It has been verified that this disintegration is due to the change of concentration of the cement water.

The calcium-sulpho-aluminate formed on occasion of the binding of cement may be characterized by two features. Investigations conducted up to now show that within a pH-value margin of 11,5 - 11,8, minute rods precipitate from the solution into the dispersed pores, yet their formation does not endanger by any means the stability of the cement stone, on the contrary, their intergrowth increases its strength. /It is an established fact that the hardening of the sulphatic blast-furnace slag cement is due in the first place to the ettringite./

However with a pH-value of the cement water between 12,5 - 12,9, spherically protruding crystal agglomerations arise from the tricalcium-aluminate grains – probably by some topochemical effect – which produce a swelling by their crystallization pressure. Therefore if the CaO-concentration of the cement water is high, /in this case it is usual but perhaps not justified to speak of supersaturation/ a swelling may issue. Not many electron-microphotographs are available, showing a cement structure which has produced in the practice a swelling by gypsum, nevertheless from the few photographs we obtained, the same structure can be

identified which was verified in the case of the ettringite produced by a topochemical process. A difference may be established perhaps by the fact that the ettringite needles do not radiate from a single point, but they appear also in bundles. /See e.g. Dreizler, Zement-Kalk-Gips, 19, 1966. p. 221./ This harmful crystallization of the ettringite can be diminished by the same measure by which we are able to decrease the Ca-ion-content of the cement water, respectively its pH-value. – No ulterior recrystallization is to be feared, as this process can not take place except through a solution, but in this case only an ettringite can be produced which is harmless from a morphological view. While the swelling phenomena caused by the ettringite are proven by microscopic, and in exceptional cases also by macroscopic observations, in recent times – as I mentioned it already – other explanations became known too, which will be discussed in my report referring to the individual papers.

We consider it a necessity to pay further great attention to the elucidation of the formerly outlined phenomena. Before fifty years a dosage of more than 3% of gypsum was not permitted; today there exist cement norms which do not object to a dosage of 9% gypsum stone, if during the grinding of cement a specified fineness or a specific surface area expressed in "Blaine" value can be attained. As a result of an intensive mechanical exploration it is expected that the transformation of calcium aluminates accompanied by a volume increase takes place already prior to the solidification of the cement stone. By this way on the one hand the initial strengthening effect of the ettringite crystal-inter-

growth is fully exploited, on the other hand – and this is of importance from the viewpoint of resistance against corrosion – there remains hardly any tricalcium aluminate as anhydrite in the cement stone, therefore no ulterior sulphate-effect can appear.

Following our opinion the development of the processes can not be clarified so readily, as the change of concentration of the solution must be taken also in consideration, as well as the chemical potemtial of different clinker-minerals and the accessory processes, which increase or decrease the Ca-ion content of the solution. There await many uncleared questions their elucidation till the introducement of increased gypsum quantities ensuring the enhancement of the initial strength could be recommended with responsibility. This remark refers to the formulas also, which were proposed by some research workers for the permissible gypsum dosage.

The sulphatic corrosion and the products appearing at the hydratation of the calcium-aluminates in presence of gypsum, are dealt with by the dissertations of J.H.P. Aardt and S. Chatterji. These two papers represent the continuation of the discussion arisen by the publication in 1963 of the "New Hypothesis of Sulphate Expansion" – a theory of S. Chatterji and J.W. Jefferey.

In his present treatise Chatterji introduces this hypothesis; he starts from the fact that on occasion of the hydratation of calcium aluminates the primary product is the C_4AH_{13}, which reacts with the $CaSO_4$ being in solution, and forms the complex salt termed monosulphate. This formation of crystals is one cause of the sulphatic corrosion, vulgarly of the gypsum swelling. In the

last years several research workers /M.H. Robert, P.K. Mechta, A. Klein/ expressed their opinions on this theory.

Van Aardt does not agree completely with this theory. In the first part of his paper presented on "The Influence of Temperature on Sulphate Attack on Portland Cement Mortars" he furnishes new data, completing the knowledge of the hydrate compounds originating from the hydratation of the tricalcium aluminate. These compounds are characterized by the basal spacing of the lattice in the crystal phases, thus the cubic C_3AH_6 by 5,14 Å; the hexagonal tricalcium-aluminate hydrate by 7 Å; the C_4AH_{19} by 10,6 and 5,3 Å; the C_2AH_8 by 10,7 Å. Those are all known hydrates, but he has found an other, which he terms by 8,2 and 4,1 Å. As there exist some differences between the literary publications, it is to be noted that the C_4AH_{13} is identic with a C_4AH_{19} dehydrated in a small degree.

Among the sulphatic complexes Aardt has detected beside of the known ettringite /9,7 and 5,6 Å/ and the monosulphate compounds /8,9 and 4,4 Å/ 3 intermediary products, which he characterizes by the d-spacing data 10,3 Å, /9,6 and 4,77 Å/ and last by /8,5 and 4,23 Å/.

Though the limited space of such a summarizing report does not permit digressions and the approach of special details, I feel it justified to stress the observation of the intermediary products, because the instrumental analytical methods at our disposal make it already possible to control the views and opinions accepted up to now and considered almost as classic. It turns out in nearly every case that the endproducts develop through instable

intermediary products, nevertheless those intermediary products get in many times stabilized.

Van Aardt published his observations of reactions at 5° respectively 25° C.

At 5° C the aluminate-hydrate substance 10,6 Å forms from the tricalcium aluminate, which produces with 1 mole $CaSO_4$ the intermediary product 9,6 Å; in the course of time the monosulphate develops from this substance.

Similarly at 5° C with 3 moles $CaSO_4$ ettringite forms, which disintegrates after 10 days producing an instable product characterized by 10,3 Å.

At 25° C different transitions lead ultimately to ettringite, but a transitory product 9,6 Å comes into being too. Thus the temperature of hardening influences the set up of the hydrates forming during the hydratation, as well as the composition of the complex compounds forming under the influence of the gypsum.

The author deals with the favourable influence of autoclaving. The autoclaved concretes – as established by other research stations also – are in a great measure sulphate resistent. Without intending to predict the results of future research works, I may remark that any heat treatment, in consequence the autoclaving too, increases the rate of recrystallization; the solubility of the rough-grained calcium hydroxyde lessens, the pH-value of the cement water decreases, what all has a bearing on the composition of the complex sulphate compounds.

By those means we obtain about the same effect as when we diminish the quantity of the Ca-ions dissolved in the cement

water by acidic additions or by intergrinding of blast-furnace slag.

S. Chatterji proposes in his thesis on "Mechanisms of sulphate expansion of hardened cement pastes" to add fineground calcite to the cement and transform this way the C_4AH_{13} into a well known product containing $CaCO_3$, which is unable to transform into a sulpho-compound causing swelling. The author deals further with the specific effect of cations which he classifies into three groups.

The treatise of Dr.Ing. Heinz G. Smolczyk "Einige Beobachtungen und neue Gesichtspunkte zur Einwirkung von Meerwasser auf Beton in der Wasserwechselzone" /Some observations and new viewpoints on the effect of sea-water on concrete in the zone of tidal fluctuations/ /RILEM Bulletin, Nr. 32. 1966./ can be considered as an introduction to his paper presented here on the Chemical Reactions of Strong Salt-Solutions with Concrete. The author surveys the present state of the Helgoland experiments carried out since fifty years concerning the action of sea-water on concrete.

He states that the sea-water having a relatively high chloride content causes on a compact concrete but a slow sulphatic corrosion. /This statement will yet come up in this report later./ However the salt solutions get concentrated in the tidal zone by evaporation. This necessitates the study of the corroding effects of concentrated salt solutions. In his later paper, before our Symposium, he describes the preparation of the test specimens with a water-cement ratio of 0,4, which were stored in a salt solution containing 1,3 mol/liter, further in concentrated salt

solutions. His research results which were not concluded till the spring of 1968, can be harmonized in general with other research results.

The most intensive corrosion was brought about by the solution of magnesium chloride. /We know that this type of corrosion is due not only to the chlorine-ion, effecting chemical decomposition, but also to the ability of the magnesium-ion to replace the chlorine-ion. – To a lesser degree the calcium chloride causes corrosion too, and the sodium chloride was proved harmful to a least extent. It is surprising that the Portland cement possessing but a small saturation by lime, supported the attack of saturated solutions better than expected. For the sake of completeness we may remark that the American Concrete Institue Committee Report 515 declares all chlorides as aggressive, strongly aggressive the calcium-, magnesium-, sodium- and potassium-chlorides, and infers with the ferrous-, copper- and zincum-chlorides a slow concrete destructing effect.

During the last eight years many treatises appeared on aggressive effect of de-iceing solutions. As no paper concerning this theme was submitted to our symposium, I do not want to discuss this most important question in detail. Nevertheless it is evident that against the influence of these solutions containing magnesium-, sodium-, calcium- and often potassium-chlorides, the floorplates of pavements and road surfaces must be protected. One method of protection is the maintaining of the fines-content of the dry concrete mix above a minimum value /of 500 kg/m^3/, further the production of an air-entraining concrete.

It must be stated that the question of sulphate-resisting concrete was discussed by very many authors in the last eight years. The participation of the individual clinker minerals in the sulphate-resistance of the concretes was cleared, except the specific behaviour against sulphatic solutions of the products proceeding from the hydratation of the brownmillerite; this latter problem awaits yet its full elucidation. It has been established what quantity of blast-furnace slag ensures the sulphate resistance of cement, further a light was thrown on the fact that not every metallurgical slag behaves the same way.

The adopting of the rapid testing method by Koch and Steinegger /Zement-Kalk-Gips, 13, 1960, p. 317./ facilitated largely the performing of these examinations, further other investigation methods were employed, which had not been at disposal in the earlier years, e.g. the infra-red spectroscopy, the frequency distribution of the resonance and the electron microscopy. It is but natural that routine tests of strength, of the relative bending-strength value, and measurements of dilatation are used further on, and even the old needle-test of Le Chatelier is employed again.

F.W. Locher /"Influence of Chloride and Hydrogen carbonate on the sulfate attack"/ carried out experiments with small prismatic specimens to study the influence of chloride and hydrocarbonate on sulphatic attack. His dissertation submitted to our Symposium has the purpose to clear the problem, why a concrete shows a greater resistance in sea-water than in solutions of identical concentration prepared in various laboratories. It was supposed till now that this differential behaviour is due to the presence

of sodium chloride. – The work of Professor Locher does not verify this assumption, as he found out that the hydrocarbonate content of the sea-water attenuates the aggressivity of the salt solution. – The formation of a calcite stratum protects the interior of the concrete from the diffusion of the aggressive solution. He proved further that the sodium chloride alone does not diminish the amount of ettringite and that the occurring monochloride originates from the C_3A unconsumed up to then. The determination of these facts will enforce the revision of our present knowledge. The remaining conclusions of the dissertation verify prior research results.

This work proves once more how important a water-insoluble finegrained coating, precipitated on the surface of the concrete is. The fine precipitates seal the microchannels promoting the inflow of the salt solution, as well as the fine cracks originating from the water loss of concretes containing excess water for easier workability, or cracks due to the stabilization of hydrate compounds. The different physical processes and phenomena overlap each other and it is often most difficult to analyse the sometimes uncommunicative descriptions of the research symptoms and to harmonize them with the practical experience.

From among the pores of the cement stone those are important from the view-point of resistivity, which enable the throughflow of gases and solutions in particular. This "apparent porosity", its determination and interdependence with corrosion phenomena, were the objects of several investigators. Thus Schwiete and Ludwig published methods for the measurement of pore sizes /Tonindu-

strie-Zeitung, 90, 1966. p. 562./ Žagar introduced the unit of measurement for the specific permeability, the "perm". – Schwiete and Ludwig show most valuable diagrams demonstrating the frequency distribution of the different pore radii and the variation of this distribution during the hardening of the concrete resp. the cement stone.

It would have been most interesting to compare these research results with our knowledge concerning the stabilization of the hydrate compounds in dependance of time and the pertinent role of different hydraulic additives. /This has been done partly, though in the form of a short reference, in the case of changes taking place in the structure of aluminous cements./

Schwiete, Ludwig and Böhme submitted to this Symposium a dissertation on this subject matter. Their paper on "Measuring of gas diffusion for the valuation of open porosity on mortars and concretes" discloses the determination theory of specific permeability and comes from experimental results to the conclusion that beside the volume diffusion into the cement stone, surface diffusion must also be taken into account. The authors deduce an interdependence between the specific permeability, the carbonization, the compressive strength and the freeze proofness.

I have to mention here that Schwiete and Ludwig presented also a second and very important study with the heading "Influence of open porosity on the stability of concrete and mortar against aggressive solutions" which can be considered as a continuation of the former and contributes by a most valuable item to the clarifying of this very important problem. – The authors performed

their experiments in solutions of sodium-, magnesium- and calcium-sulphates, and of sodium-phormiate and acetic acid. They layed down the fact that a low permeability renders the cement stone corrosion resistant to a greater extent, than could be expected on the basis of the mineral composition of the cement, and of its hydraulite- or blast-furnace-slag-content. In order to ensure the sulphate resistance of the concrete by chemical means, the corrosivity-limit value mut be below 0,8. /Under corrosivity-limit value the following fraction of mol-values is meant: $\frac{CaO}{SiO_2 + Al_2O_3}$ ./

It is an interesting statement that the composition of the cement stone undergoes after a time a change by the influence of a sulphatic corrosive attack. Not only SO_4^{-2} diffuses into the cement stone, but there takes place a migration of material also in the opposite direction. – If the Ca-content of the system is reduced to a certain extent, the further sulphatic corrosion slows down or may cease completely.

This dissertation contains extremely many interesting and important observations. Nevertheless one could want an answer to the question: if ettringite is produced subsequently, what conditions make possible the development of the harmless type of ettringite, – taking into consideration that the sulphatic slag cements contain even after a delay of several months some anhydrite. Moreover in the brownmillerite cements the rate of hydratation of this ferrite phase is so small that a hydratation of aluminates can occur even in the cement stone hardened already. – I consider the the compilation reporting on the results of the more important

seventeen corrosion tests as a particularly valuable item of the treatise.

Concerning the high-aluminous cement, this time a self-contained dissertation comes before the Symposium: Ryuichi Tsukayama's "Effect of Conversion on Properties of Concrete Using High-Aluminous Cement".

Questions in connection with aluminate cements were handled at the Washington Symposium by L'Hopitalier /Paper VIII.-4/, who summarized the research results since 1938, particularly stressing the hydratation of the different calcium aluminates. – He introduces in his report the table of Wells and Carlson, according to which under 24° C the monocalcium aluminate hydrate is the dominating product, whereas at a higher temperature the C_3AH_6, crystallizing in the cubic system, dominates. This result compares fairly with the statements of other researchers, yet there exists a research result, according to which hexahydrate can be found already at 10 centigrades in case of a higher water-cement ratio.

All these results verify in general the thermodynamical computations, and as the differences of free enthalpy are in the case of different hydratation phases not significant, at least temporarily unstable hydrate compounds may arise, which transform at a higher temperature, or after a longer period, or influenced by both, to a stable hydrate. This transformation is accompanied by a 40% diminution of the solid matter volume.

This stabilization process increases greatly the porosity, which fact implies – according to the formerly discussed papers – a lessening of strength and the deterioration of the corrosion

resistance. Research Eng. Talabér reported on the experiments concerning the loss of strength, conducted for 25 years approx., at the RILEM colloquium /Report II. 1962. p. 109/. – This diminishing of strength starts in general after a delay of six months, and no settling of this process at some lower strength level can be determined. With the parallel series of Portland cement fabricates, the increase of strength continues in average for a year, and from this time on the strength remains stable. – It could be recommended to perform on occasion of such well defined experiments complete crystal-chemical investigations.

Now the treatise of Tsukayama brings new data pertaining to this question. The curing of the samples was done at 50 centigrades, at which temperature the hexahydrate should be already the dominating product. As at the time of setting also the formation of unstable mono- and dicalcium-hydrate is possible, the researcher could state a loss of strength. However the apparition of the stable product in a greater quantity could have slackened the extent of transformation and the attendant structural decomposition. It would be of interest to compare these research results with the formerly treated items. – One must agree fully with the author stating that the transformation and the accompanying growth of the pores is interdependent with the loss of strength.

The author raises the idea too, whether the destruction of the high-aluminous cement could be avoided by enforcing initially the formation of stable products. However this technological approach would imply the loss of the great initial strengths.

The durability problem of high-aluminous cements is not only

a scientific question but one of great economic consequence. Biczók summarized at the Leipzig conference in 1967 the damages of conretes made with aluminous cements, come out in the last decade in several countries, which necessitated e.g. in Hungary and Bavaria costly reconstruction works.

In this connexion I show a diagram /see the figure in the Annex/, which is the result of many years of research and practical data collection, and appeared in the Hungarian Cement Handbook, published in 1967.

This diagram enables the designer to predict the development of the strength of an aluminous cement mortar under the influence of the temperature in function of time.

I can't omit to mention here that the cement stone made of a high-aluminous cement shows various changes of colour due to its intrinsic transformations. An oxydizing firing produces a brownish-rosy shade, a reducing one a dark grey or light gray shade; whereas cements produced from iron-free raw materials — by burning in a metallurgical/blast furnace — show a discolouration of white into gray. These discolourations enable the technicians in a certain measure to draw conclusions concerning a qualitative change. In the course of the reconstruction works mentioned formerly, the grade of the decomposition of concretes is established by means of diffraction radiograms, and recently also by the thermographic determination of the $Al/OH/_3$ proceeding from the CAH.

The frost resistance of the concretes is the subject of three papers; one of them investigates the behaviour of the concrete at an extremely low temperature of -180° C. Yoshiro Koh and Eiji

Kamada judge /in their paper on "The Behaviour of Concrete Subjected to Freezing and Thawing as a Reference for Frost Resistivity of Concrete"/ the freeze proofness of concrete on the basis of its freezing and thawing characteristics. The researchers controlled the length change of the 25 cm high test cylinders with recording dilatometers. Part of the test specimens were first dried cautiously and then exposed to alternate thermal effects, part of them were saturated at the start of the experiments by storage in water. There have been prepared test specimens also with differently absorptive aggregates.

The specimens water saturated in a different measure behaved – as expected – in a different manner during, respectively after, the 13 freezing and thawing cycles. The specimens marked by the author with an "s" showed in the course of experiments no greater volume change than corresponding to the temperature change. On the other hand the saturated specimens expanded at freezing and following the experimental cycles a residual volume increase up to 0,3% was observed.

In connection with this treatise some former experimental and theoretical research results deserve mentioning. – In the cement stone – as a result of the occurring chemical proceedings – an internal dewatering ensues, because the fill by the substances of hydrate compounds requires less volume than the volume of the reacting clinker minerals and the necessary hydrating water together. At hardening uniformly distributed pores develop in the cement stone, possessing enough volume to take up the volume increase caused by the freezing of the residual water in the air-dry concrete.

I may refer here to the computations of Czernin /Zement-Kalk-Gips, 9, 1956. p. 525/.

This extraction of water proceeds in parallel with the hydratation, therefore a period exists when the necessary porosity is already developed; from this point the concrete attains the grade of curing where it can be considered as freeze resistant. /RILEM recommendation, see BETON, 14, 1964. p. 411./ The desirable pore volume estimated on this train of ideas obtains only 1%, whereas we aim with air-entraining cements at a pore content of 3-5%. This is explained by the fact that it is impossible to ensure such an uniformity of pore distribution in the air-entraining concretes which comes about automatically in the cement stone as a result of the processes taking place automatically. This question was handled in theory by Powers in 1956 on occasion of a Symposium dealing with the concreting in winter.

G. Tognon controls by his treatise on "Behaviour of mortars and concretes in the temperature range from +20 to -180° C" the effect of freezing on the three strength characteristics and on the modulus of elasticity. – It is somewhat surprising that by the decrease of the treating temperature the strength of the specimens increased, yet this increase halted in the temperature range of -35° and -60° C.

For being able to value such experiments, the structure of the specimens, their pore distribution and their grade of saturation ought to be known. One can not disregard that the cement stone contains a certain quantity of water which – absorbed by the surface of the hydrated products – does not freeze, respective-

ly remains in such a state that it may be nearly considered as a solid, even at +20 centigrades. Consequently the experimental determination of the water distribution should belong to the valuation of the experimental results.

Professor C. MacInnis is occupied by the "Frost Resistance of Cement Grouts for Prestressed Concrete Applications". – He reports on three experimental programs and comes to the conclusion that even with prestressed concrete in a restrained condition /under pressure/ the curing period is the most important factor determining the frost resistance. – His statement that the utilization of air-entrained concrete has also good results, coincides with the results of other workers and with the practice.

K.R. Lauer and C.W. Gray deal in their paper "A Durability Study of Concrete Using Monte Carlo Simulation" with an investigation of the durability of a hypothetical bridge deck. They accomplish their study by employing a calculus of probability known as Monte Carlo simulation method. This work can be considered also as a comparative study of the ordinary dense concrete and of the air-entrained concrete.

This mathematical method, employed formerly on other fields of scientific research, studies by the consideration of the stochastic variables the probability of material qualities. The method termed formerly "model sampling" would be impractical without a high-speed /digital/ computer.

In order to judge the durability of a concrete bridge deck the following influencing factors concerning the material were considered:

the probability of occurrence for compressive strength,

the probability of occurrence for air content, if air-entrained concrete is employed,

the probability of compressive strength loss, due to air-entrainment,

the time and temperature effects /that is the effects of curing/ on the gain in strength, studies by a half-year experiment conducted between −8 and +38 centigrades,

dynamic modulus of elasticity and freeze-thaw cycles, and

de-icing salt scale rating and the number of scale cycles.

The experiments were conducted in a climatic environment comparable to that of South Bend, Indiana /near Lake Michigan/. The results were summarized in 10 diagrams, the computations in 7 tables.

According to the computations the air-entrained deck will be in service for about five times as long /16 years/ as the non air-entrained concrete /3,1 years/. It would be of interest to compare the results of these computations with the experiences obtained with the practical concrete decks in the chosen climatic environment.

- o -

The aforesaid summarizing remarks accentuate the fact that in the last years a very considerable development of the research on concrete corrosion can be recorded. Several phenomena of corrosion were put in a new light.

MECHANISMS AND KINETICS ON CARBONATION OF HARDENED CEMENT

R. Kondo, M. Daimon & T. Akiba (Japan)

Contents:

G E N E R A L R E P O R T

1. Introduction

It is a great honour for me to give a summarizing report of the three very interesting papers by Professor K.H. Wesche and Mr. W. Manns, by Professor A. Meyer and by Professor R. Kondo, Mr. M. Daimon and Mr. T. Akiba.

These very extensive works reveal an abundance of experimental results concerning the carbonation of concrete under quite different test conditions.

It gives me great pleasure, indeed, to be able to indicate that the experimental results without exception show a surprisingly good conformity. Furthermore there is additional proof given by the test results of other authors and also by our own comprehensive studies.

On the other hand I am afraid that I cannot extend this statement as far as the theoretical evaluations and conclusions are concerned. In few cases, moreover, I could not see the relation between experimental results and final conclusions.

Therefore - to overcome this difficulty - it proved useful to differentiate strictly between the measured test results and the conclusions of the authors.

The following abbreviations have been chosen:

x = depth of carbonation
t = time of carbonation

PZ = Portland cement (Portland Zement)
HOZ = blastfurnace slag cement in general (Hochofenzement allgemein)
EPZ = blastfurnace slag cement with less than 30 % of slag (Eisenportlandzement)

All the other abbreviations are explained in text, figures and tables.

2. The Work of R. Kondo, M. Daimon and T. Akiba

"MECHANISMS AND KINETICS ON CARBONATION OF HARDENED CEMENT"

a) Experimental results

Mortar prisms 2 x 2 x 8 cm with 1 PZ (65 % CaO) and 1 HOZ (55 % CaO) are carbonated in CO_2-gas of 44 % RH. After 7 days' respective 28 days' curing in saturated $Ca(OH)_2$ solution and before carbonation the prisms are stored at 44 % RH to approach equilibrium. Their surfaces are sealed with epoxi-resin in such a manner that only one surface 2 x 2 cm remains free for CO_2-penetration. Part of the mortars are made with an additive (0,3 cm^3 vinsol resin / 1 kg cement).

The pore size distribution of 7 specimens (75 to 75000 Å) is measured. A surview on the total pore volume of the 6 best comparable specimens is shown in Table 1.

The chemical analysis of fixed CO_2 after complete carbonation does not correspond with the content of free $Ca(OH)_2$ before carbonation. On the contrary the amount of fixed CO_2 is equivalent to the total content of CaO in the specimen. The amount of produced calcite - as tested by X-ray analysis - is lower because the certainly also produced vaterite has not been taken into account in the calculation.

The carbonation strongly depends on the curing conditions before carbonation and on the w/c ratio, and the HOZ carbonates at a faster rate than the PZ. The carbonation curves - expressed as $x = f(\sqrt{t})$ - do not start from the origin. After a short period of induction they increase at a markedly faster rate than a function

$$x \sim \sqrt{t}$$

would permit.

b) Evaluations and conclusions

The authors evaluate a carbonation formula for concretes and mortars on the supposition that the approximation

$$x^2 = k_e \cdot t$$

is applicable to further calculation, and taking into consideration the diffusion of CO_2 and of H_2O.

The calculation itself is to be seen in Table 2. The connection between the experimental constant k_e and the calculated theoretical constant k_t is given by introducing the "tortuosity" f. By taking into consideration the order of magnitude of "f" it is possible to decide when the rate of neutralization was controlled by diffusion of CO_2 into the specimen and when by diffusion of H_2O out of the specimen.

The comparison of the rate of neutralization measured by M. Hamada and the new formula of the authors results in the empirically expected value $f = 10$.

3. The Work of W. Manns and K. Wesche

"VARIATION IN STRENGTH OF MORTARS MADE OF DIFFERENT CEMENTS DUE TO CARBONATION"

a) Experimental results

Cores taken from concrete structures with supersulfated slag cement had shown a lower compressive strength in the carbonated layer near the surface than in the deeper located alkaline parts.

For further investigation of this phenomena mortar prisms 4 x 4 x 16 cm, w/c 0,6 with 6 very different cements after 28 days' watercuring are completely dried at 40 °C and then completely carbonated with 9 % CO_2 at 25 °C. During the whole carbonation period a great number of strength tests are performed.

The final result is clearly recognizable on one diagram of the authors which is copied in Figure 1.

First of all it proves clearly that the supersulfated slag cement shows a behaviour quite different from all the other cements. With this cement the drying has resulted only in a very little increase in strength of 16 % and the carbonation effects a genuine loss in strength.

The five other cements - on the contrary - have gained strength increases between 27 % (PC) and 48 % (TBFC I) as a result of the drying process.

(Remark: These strength increases are comparable with the normal afterhardening of concretes during the very slow longtime process of carbonation in practice.)

Furtheron there is to be seen that under these practice-like conditions (afterhardening and carbonation = full marks) all the tested cements show an increase in strength which is largest with the PZ and small with the two cements with 25 % clinker and 18 % clinker.

Taking the strength after the drying procedure as starting point (carbonation without afterhardening = open marks) all the strengths are lower in exact equivalence to the missing afterhardening, naturally.

It is remarkable that in both the forms of representation the PZ and the two trass-blastfurnace cements form a straight line corresponding to the clinker content, whereas the two HOZ show 10 - 20 % higher strengths with respect to their clinker contents. Under the chosen experimental conditions the strengths obviously increase most with regard to the clinker content and least with respect to the trass content of the five cements.

The tensile strengths (F) change in a similar way as the compressive strengths (B). On the other hand the fact has to be emphasized that the well-known relation [1] for mortar prisms 4 x 4 x 16 cm

$$F \simeq B^{0,7}$$

which has proved valid for all cements, so far, (also for supersulfated cements and high alumina cements, and also for completely carbonated mortars) does not prove to be valid any more after the applied drying procedure and also after the carbonation.

Furthermore, the change in weight of the prisms are measured during carbonation. An increase in strength is accompanied by an increase in weight and with decreasing strength also a decrease in weight is measured.

The carbonation is slowest with the HOZ with 60 % clinker and fastest with the trass-blastfurnace cement with 25 % clinker. The HOZ with 60 % clinker carbonates approximately according to the function

$$x \sim \sqrt{t}$$

The carbonation curves of the other cements increase at a faster rate after a short period of induction.

b) Evaluations and conclusions

The authors come to the conclusion, that not only with supersulfated cements but also with all other cements containing less than 40 % clinker the strengths of concretes would decrease with progressing carbonation.

Further they state: "... it cannot be expected, in general, that a building may loose its stability. This statement can, however, be considered as secured only by profound investigations in all questions, ...".

4. The Work of A. Meyer

"INVESTIGATIONS ON THE CARBONATION OF CONCRETE"

a) Experimental results

Numerous tests on old constructions and on test specimens in the laboratory are carried out because the carbonation is suspected to have a very negative effect upon the corrosion of reinforcement.

In a forty-year-old dairy the carbonation of the concrete had reached a depth of 26 mm. In places where the concrete cover of the reinforcement was only 15 mm, the steel was severely corroded, where, however, the cover increased to about 60 mm, the steel showed no sign of corrosion.

The change in compressive strength is tested with tiny mortar cylinders of 11,3 mm in diameter which - after 28 days' water curing - are carbonated in 10 % CO_2 within 21 days. Three PZ, two EPZ, two HOZ, and one high alumina cement show increases in strength, two HOZ with 75 % slag come up to the same average strength after the carbonation as they have after 56 days' water curing, and one supersulfated cement shows a loss in strength of more than 40 %.

On cores from old constructions the permeability and the moisture movement is measured. The permeability is about the same in the carbonated part and in the noncarbonated part. The drying rate at the beginning, however, is much higher in the carbonated part than in the noncarbonated part.

The majority of the tests deal with the parameters of carbonation. The experimental conditions of the five test series carried out in the laboratory are shown in Table 3. As the test conditions listed in the supplementary paper differ slightly from the ones given in the corresponding German publication, I took the test values in the identical diagrams for granted and made use of the already published information (2).

Four parameters are investigated:

Type of cement
Water/cement ratio
Storage conditions during carbonation
Effect of age.

Not investigated are the influences of

Hydraulic capacity of the cement
Chemical composition of the cement and its hydration products
Curing condition before carbonation.

In all the test series all the PZ carbonate less than all the HOZ and all the pozzolanic cements. In the upper part of Figure 2 the results of the test series 4 are shown as a typical sample.

The carbonation increases gradually with growing w/c ratio (Test series 2, 3, 4 and 5). The carbonation ratio of HOZ to PZ on the average decreases with increasing w/c. This gets particularly evident in the test series 3 with concrete.

The moister the storage conditions are, the slower gets

the carbonation. (Test series 2 and 5)

In any case (Test series 1, 2, 3, and 5) the carbonation increases faster than is corresponding to the function

$$x \sim \sqrt{t} \quad .$$

In general this deviation is worse with the PZ than with the HOZ.

In addition a so-called "test series 6" with 60 concretes is mentioned. This, however, brings nothing new, because it includes 12 chosen specimens of test series 3, furthermore, 15 of the remaining 48 specimens are not older than two years. As these specimens are not defined by far as well as those of the test series 2 - 5, an only very indistinct connection of the carbonation with the w/c is to be seen. The main result of this test series, I presume, consists of the reference that here again the average carbonation of the PZ is about half as strong as the average carbonation of all the other cements.

The also mentioned numerous tests on old and very old concrete structures are far more informative. Here the exact conditions of the three types of storage "indoors", "outdoors" and "outdoors protected from rain" can also not be defined accurately, but at least the older concretes with the storage of the type "outdoors protected from rain" should be rather comparable. Furthermore this study includes a great number of tests, and the mean age of the specimens is 5 times greater than the one of the "test series 6".

The carbonation depths and the compressive strengths were measured. To calculate the w/c ratios of these old concretes it was necessary, however, first to estimate the mixing water content of the fresh concrete mix and its porosity. Therefore these values are not given here as measured test results. The curing conditions before carbonation are unknown. Assuming that the general usability "indoors" and "outdoors" is the same for PZ as well as for HOZ and that the specimens are fairly comparable, I calculated the average values of all test results in Table 4.

The difference in compressive strength between the concretes with PZ and the concretes with HOZ after about 23 years amounts to 49 kp/cm^2. The measured difference in carbonation depth of 4 mm to 5 mm corresponds exactly to the theoretical value which is to be expected with this difference in compressive strength.

Taking into consideration that all storage conditions and many other unknown influences have been included, this result proves an excellent experimental technic.

b) Evaluations and conclusions

Mr. Meyer draws the conclusion that the carbonation of concrete can be characterized satisfactorily and also be predicted up to 50 years by using the following parameters:

Age

The carbonation at all events obeys the equation

$$x = \text{const} \cdot \sqrt{t}$$

which is evaluated with the application of Fick's first diffusion law.

Water/cement ratio

The carbonation of all concretes increases linear with increasing w/c ratios, and with w/c 0.80 it will be twice as deep as with w/c 0.50 (see Fig. 2).

Type of cement

The resistance against carbonation is largely due to the content of free $Ca(OH)_2$ in the paste. Therefore the carbonation depths in concretes with slag cements and with pozzolanic cements are always expected to be deeper than those in concretes with Portland cement, all other conditions being identical. The relative ratio of the carbonation depths remains constant in all storage conditions, all carbonation periods, all w/c ratios, and all curing conditions of the young concretes.

S t o r a g e c o n d i t i o n

Concrete with PZ and w/c 0.50 will have a carbonation depth of 10 - 15 mm after 50 years if it is stored outdoors protected from rain. In case it is unsheltered from rain, less carbonation will occur. Stored in a closed dry room, the carbonation will be deepest.

Mr. Meyer's final statement is: "The carbonation resistance of a fully compacted and normally cured concrete is essentially determined by its water/cement ratio and by the type of cement used."

5. Comparison of Results being in Complete Accordance

Comparing all the carbonation tests known to me - the published as well as the unpublished ones - I discovered two empirical relations which have been proved by all tests results very nearly without exception, so far. Therefore, I think, they have the significance of universal rules. They are once again demonstrated by these three reported papers in a surprisingly distinct way.

T h e c a r b o n a t i o n i n c r e a s e s n e a r l y a l w a y s a t a f a s t e r r a t e t h a n a f u n c t i o n $x \sim \sqrt{t}$ w o u l d p e r m i t .

This can distinctly be observed if - drawing carbonation depth x and carbonation time t to double logarithmic scale - the gradient 1/v of the curves is greater than 1/2.

Figure 3 shows the carbonation of the specimens A_{1-4} of R. Kondo, M. Daimon and T. Akiba and also the carbonation curves published by W. Manns and K. Wesche. In both cases the function appears to be

$$X \simeq \text{const.} \cdot \sqrt[v]{t - t_o}$$

The values of v are calculated without taking into account the induction period t_o. Therefore they are even a little bit too high.

Figure 4 shows the mean results of the test series 3 of A. Meyer. The slope of the curves is extremely strong in this case - especially with the PZ - though the concretes carbonated in normal room atmosphere only. The test series 1 likewise resulted in an average v-value $\bar{v} \tilde{=} 1{,}7$, and the test series 2 in $\bar{v} \tilde{=} 1{,}6$. Both the test series 1 and 2 show short induction periods. The test values are taken from the original German paper[2].

Many authors calculate with the approximation $x \sim \sqrt{t}$. This can lead to bad mistakes as far as extrapolations over long-time periods are concerned, as is to be seen in Figure 5. The thick curves represent the genuine experimental carbonation functions of the two cements Z 1 and Z 9 of our own mortar carbonation studies:

$$x_1 \sim \sqrt[2{,}15]{t}$$

$$x_9 \sim \sqrt[1{,}74]{t} \quad \text{(typical for PZ)}$$

Among the three possibilities of a linear $\sqrt{t}$ -approximation, the simple linear extrapolation of the one-year-old carbonation curves (thin lines) leads to unbearable deviations after 10 years.

The second general conformity of test results has even more consequences for practice:

The carbonation of concretes and mortars with increasing time becomes closely proportional to the factor $1/\sqrt{\text{compressive strength}}$.

This fact is proved by all experimental carbonation studies which include strength tests. Probably the permeability - as reported by R. Kondo and several other authors - is the essential factor, which is only represented by the far better measurable strength.

This relation includes the influences of w/c ratio, type of cement, and precuring condition, and has been proved to be valid for cements of most different compositions. The only exceptions are the supersulfated cements and the high alumina cements, so far.

This relation, moreover, is apt to interpret the fact that the slow-hardening PZs (e. g. C_3A-free PZs) carbonate at a markedly faster rate than quick-hardening cements, and that HOZs with higher strengths, if sufficiently cured, often carbonate less than normal PZs.

Therefore, in the results of W. Manns and K. Wesche - see Figure 6 - it is not the PZ that shows the least carbonation depth but the mortar which had the highest strength at the beginning carbonation. Consequently it is not the cement with the lowest clinker content that shows strongest carbonation but the mortar with the lowest compressive strength. The test values are taken from the original German paper [3].

This relation is also valid for very different w/c ratios, as is to be seen in Figure 7, in which the results of the test series 4 of A. Meyer are evaluated. Because of the still very steep strength increase at the beginning of the carbonation (7 days), in this case the 14 days' strengths had to be taken into account. The test values are taken from the original German paper [2].

The studies on old and very old concrete structures by A. Meyer and by two other authors reveal the same tendency [2], [4] and [5]. The concretes being best comparable must be those which had been stored outdoors sheltered from rain and which are old enough for a statistical surview without inaccurate extrapolation of carbonation depths. In Figure 8 all the specimens (without exception) are shown which firstly met this storage condition, secondly were older than 20 years, and thirdly were published with strength datas. (The dotted line is calculated according to results of another very comprehensive German longtime study including more than 15 cements and 3 w/c ratios.) In the case of the old structures, only the final strengths are known. A calculation with the initial strengths and with the certainly very different afterhardenings would surely have brought about a more accurate diagram.

6. Final Conclusions for Practice

The empirical relation $x \sim 1/\sqrt{B}$ is proved by so many test results - also by our own laboratory studies - that a rule can be taken for granted. Before estimating the carbonation behaviour of a concrete with given strength, its afterhardening must be taken into consideration, which possibly can result in remarkable strength increases, especially if slow-hardening cements are concerned. Naturally, this process takes much more time in air than it would take in water, but the carbonation is a longtime process, too.

Provided that also the slow afterhardening in air corresponds to Sadran's formula [6]

$$\frac{1}{B} \sim \frac{1}{t}$$

- which must be slightly altered for this purpose - I calculated the diagram of Figure 9, which takes into consideration all the carbonation studies known to me so far. It is valid for concretes with dense aggregates, which are carbonated outdoors sheltered from rain in average German air conditions. It does neither require the knowledge of the w/c ratio nor the type of cement, with exception of supersulfated cements and high alumina cements.

This diagram contains quite a number of statements and evaluating possibilities. Only two of them shall be pointed out here:

Figure 9 gives an explanation for the fact that a strength difference from 335 to 384 kp/cm^2 after ~ 23 years must result in a carbonation difference of about 5 mm. (See Table 4)

Then Figure 9 shows that in short time tests, i. e. without the effect of afterhardening, a greater carbonation difference must be taken into account, comparing slow-hardening and quick-hardening cements, especially in case of small specimens and short precuring periods [7]. In longtime studies, however, these differences will be compensated or diminished, at least, by the higher afterhardening of the slower cements. This explains the fact that by a statistical evaluation of numerous tests on old and very old concrete structures only very little if any differences in the carbonation behaviour of different cements could be observed [8] and [9].

SUMMARIZING SURVIEW

The three reported papers reveal a number of corresponding test results and observations which enable us to enlarge our present knowledge and to recognize new aspects of carbonation. At this not the type of cement or the amount of free $Ca(OH)_2$, but the permeability and the quality of the concrete and the special storage condition proved to be the decisive factors.

Unfortunately there have been reported no experimental studies on steel corrosion itself, which does not depend on carbonation only, but also on the durability of the concrete in other aggressive media. To complete this surview I just want to mention the comprehensive longtime studies on seawater action on reinforced concretes, carried out in England, Belgium, France, and Norway [10], [11], [12] and [13]. In these studies especially those cements which are often reported of as carbonating faster than Portland cements, provided the better protection of reinforcement against steel corrosion.

GENERAL REPORT
OF

SESSION III-4-a: HYDRATION OF PORTLAND CEMENT PASTE AT HIGH-TEMPERATURE UNDER ATMOSPHERIC PRESSURE

and

SESSION III-4-b: HIGH-TEMPERATURE CURING OF CONCRETE UNDER ATMOSPHERIC PRESSURE

P. J. Sereda (Canada)

The following Supplementary Papers are summarized in this report.

Paper No. III-65

INFLUENCE OF CEMENT CHARACTERISTICS ON MIX PROPORTION FOR STEAM-CURED PRESTRESSED CONCRETE

R. K. Lewis & F. A. Blakey (Australia)

Paper No. III-91

HEAT OF HYDRATION OF PORTLAND CEMENT DURING STEAM CURING UNDER ATMOSPHERIC PRESSURE

H. Teramoto & N. Kawada (Japan)

Paper No. III-108

PHYSICAL AND CHEMICAL PROPERTIES OF CEMENT MORTAR CURED AT ELEVATED TEMPERATURES

P. Freiesleben Hansen, J. Jessing, K. Mønsted & E. Trudsø (Denmark)

These papers present results of a number of the physical and chemical changes that occur during curing of cements and their constituents at elevated temperatures. These studies were carried out for the purpose of explaining the complex processes involved in hydration of cement with the hope that such understanding will enable the prediction of the useful properties, such as strength.

Paper No. 65 - INFLUENCE OF CEMENT CHARACTERISTICS ON MIX PROPORTIONS FOR STEAM CURED PRESTRESSED CONCRETE by F. A. Blakey and R. K. Lewis

The Australian Code for Prestressed Concrete requires that a compressive strength of 4000 p. s. i. on cylinders be obtained before transfer of prestress is permitted.

The authors set themselves the goal of establishing relations to enable the prediction of the strength of concrete at any age, given the chemical composition of the cement, the cement factor, and water/cement ratio, after fog curing and following the steam-curing cycle.

Six cements were used with the phase composition shown in Table I.

TABLE I

PHASE COMPOSITION OF THE CEMENTS TESTED, %

Cement No.	Phase Composition			
	C_4AF	C_3A	C_2S	C_3S
1	10	12	12	59
2	13	9	19	53
3	16	4	36	39
4	13	5	14	48
5	11.2	4.4	18.6	58
6	13.1	2.2	27.7	50.6

The slump of all mixes was maintained at approximately 2 in. Samples were compacted for 10 sec. on a vibrator table. When steam curing was used, a delay time of 4 hr was followed by a temperature-time gradient of 10 deg. C/hr and an isothermal period of 6 hr at 80° C.

Typical curves for strength development for fog-cured concrete and steam-cured concrete followed by fog curing is shown in Fig. (2).

The plot for fog-cured samples can be represented by two straight lines on a semi-log plot. The authors made use of the slopes of these two curves naming them as the Initial Gradient Constant (L) and Second Gradient Constant (M) and succeeded in obtaining empirical relations where:

$$L = 50(C_3S + (X)\,C_3A + 0.75C_2S)\sqrt{\frac{S}{3500}}$$

where (X) is a function of the ratio of SO_3 to C_3A and

S is the specific surface area.

$$M = 50(0.64C_3S + 4.23C_2S - 2.36\,(X)\,C_3A\,\sqrt{\frac{S}{3500}}$$

The authors also obtained an equation relating the Initial Gradient Constant and the cement factor.

The success attained by the authors in predicting concrete properties is shown in Table V, part of which is included in this report.

TABLE V

CALCULATED VALUES OF COMPRESSIVE STRENGTH OF CONCRETE

Cement No.	Compressive Strength (Fog Cured), lb/sq. in.			
	1 day		91 day	
	Theoretical	Error, %	Theoretical	Error, %
1	1700	+ 1.8	9020	+ 0.1
2	1690	- 6.1	9610	- 1.2
3	1770	0	13100	- 0.6
4	1680	+11.2	9140	+ 7.1
5	1720	+ 4.2	9460	0
6	1690	- 4.6	9650	- 4.8

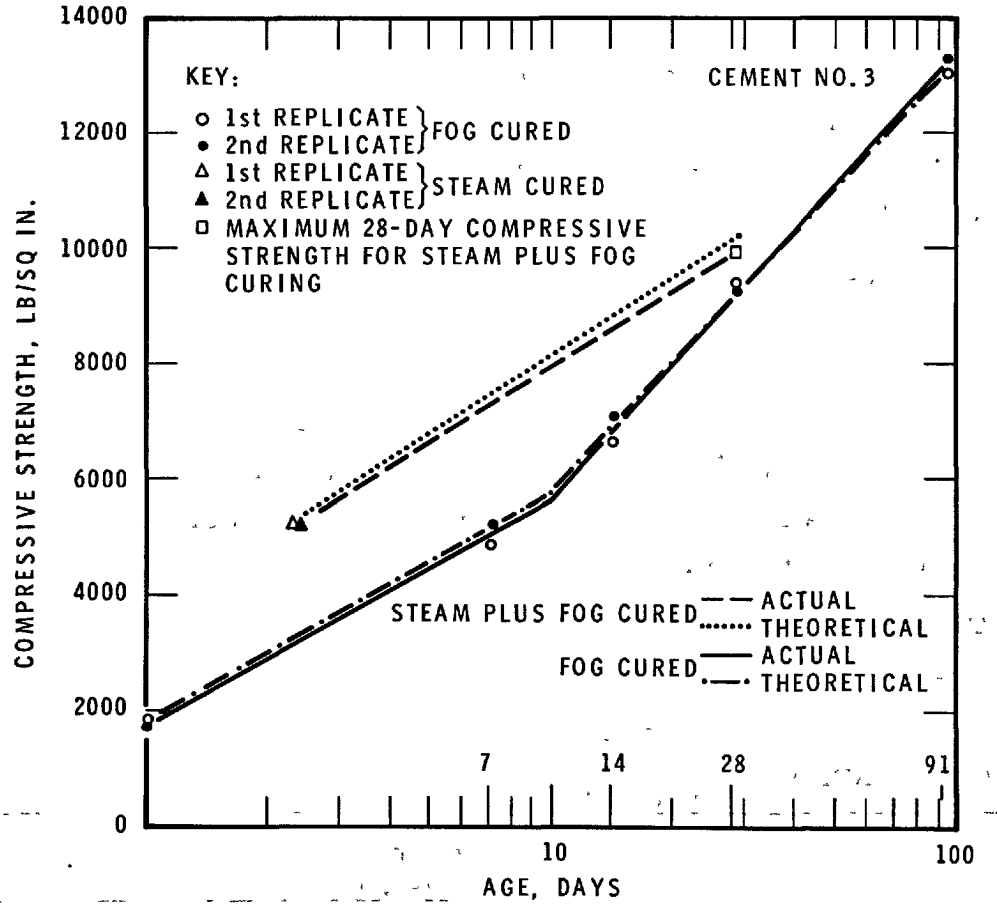

Figure 2 Relationship Between Compressive Strength and Age (from Blakey and Lewis)

The cement factor was predicted to within ±5 per cent, the 1-day compressive strength to within +11.2, -6.1 per cent and the 91-day compressive strength to within +7.1, -4.8 per cent.

The authors state that the results apply only to concrete mixes having the same type of ingredients. Variations in the grading of the sand aggregate, the maximum particle size of the stone, the strength level after steam curing and the workability desired will all affect the relationship. They suspect that a cement which produces rapid early strength in the first 24 hr followed by a lower rate of strength growth thereafter, will give different relationship from the one found in this investigation.

Conclusions

Thus the authors claim to have found a relationship that enables the prediction of strength-age characteristics of fog-cured concrete, proportioned to give a compressive strength of 5100 p.s.i. after a steam cycle giving a maturity of about 1200 deg. C. hr. Such concrete need not necessarily have a strength less than the normal 28-day fog-cured strength. Prediction can also be made of the development of strength of steam-cured concrete with subsequent fog curing to 28 days. The cement factor necessary to produce this strength can be predicted from the chemical characteristics of the cement. The important characteristics of the cement, from the standpoint of these predictions, were found to be the proportions of C_3S, C_3A, C_2S, the specific surface area, and the SO_3/C_3A ratio.

Paper No. 91 - HEAT OF HYDRATION OF PORTLAND CEMENT DURING STEAM CURING UNDER ATMOSPHERIC PRESSURE by Hideo Teramoto and Naoya Kawada

To understand the hydration process of cement during steam curing under atmospheric pressure the authors measured a number of parameters.

These included the rate of heat liberation, volume change, non-evaporable water and uncombined SO_3 as sulfoaluminate in the paste of samples of pure constituents of cement as well as normal portland cement.

By measuring the rate of heat liberation with a twin-type conduction calorimeter the authors were able to follow the progress of the hydration reactions especially, as these were compared for the different conditions of presteaming and different temperatures of isothermal heating.

The authors describe the principal features of several twin-conduction calorimeters and show comparable results obtained with several different types. Using two conduction calorimeters, one having a dummy sample, enables the measurement of rate of heat evolution during a heating period.

Volume change measurements were made by placing the sample in a rubber container and weighing it in water during the progress of the reaction. Volume change was obtained by multiplying the density of water by the change in weight of sample in water.

In Figure 7 the authors show the effect of gypsum on the hydration of normal portland cement for 5 hr at 25°C then heated at the rate of 20°C/hr up to 75°C at which temperature it was cured for 16 hr. The maximum rate of heat liberation at 75°C was 5 to 6 times higher than at 20°C. The two peaks observed are considered to be due, first, to aluminate hydration and second, to the hydration of alite. At SO_3 content of 2.8 per cent, the two occurred together.

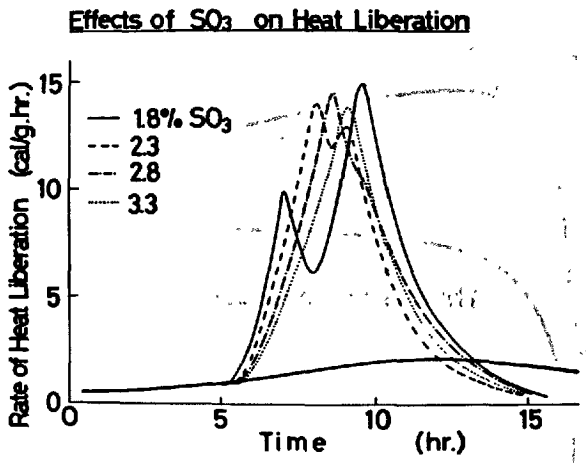

Figure 7 (from Teramoto and Kawada)

In Figure 8 the authors show the strength that developed in cement mortar when different times of presteaming were used. All samples were cured for 5 hr at 85°C and followed the same cycle of rate of heating and cooling. Figure 9 shows the rate of heat liberation for the same series of samples. The fact that maximum strength when measured 1 hr after cooling is obtained at a different presteaming time than that for 28-day cured specimens leads to the conclusion that presteaming time must be determined according to conditions necessary for practical performance and not from heat liberation curves.

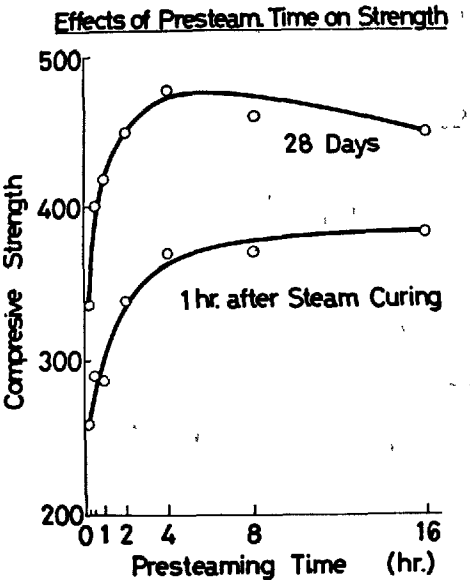

Figure 8 (from Teramoto and Kawada)

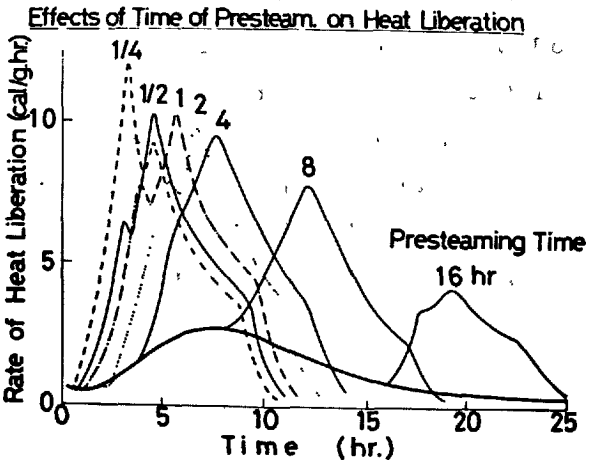

Figure 9 (from Teramoto and Kawada)

Figure 26 shows, for normal portland cement, typical results of rate of volume change, rate of heat liberation, increase of combined water and the SO_3 content obtained during the curing cycle of presteaming time of 2 hr, and curing temperature of 60°C. A large number of similar results are presented by the authors for normal portland cement and pure constituents of cement at different temperatures and different presteaming times.

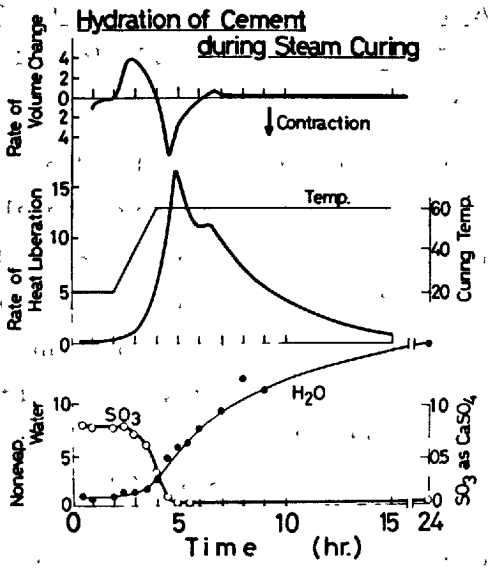

Figure 26 (from Teramoto and Kawada)

A large number of D. T. A. curves are included to indicate the changes in composition that occur during hydration reactions.

Conclusions

The results of physical and chemical changes occurring during accelerated curing of cement and its constituents seem to give a fairly informative picture of the hydration processes. Especially significant are the simultaneous measurements of the various parameters so that interrelations of different effects such as heat liberation and volume change could be assessed.

Paper No.108-PHYSICAL AND CHEMICAL PROPERTIES OF CEMENT MORTAR CURED AT ELEVATED TEMPERATURE by P. F. Hansen, J. Jessing, K. Mønsted and E. Trudsø.

The purpose of the investigation was to explain the effect of the curing temperature by the changes it produces in the chemical and physical processes during hydration. The basic variable was the curing temperatures of 25, 45, 60, and 80°C. A standard cement mortar, made from a rapid-hardening portland-type cement having a fineness of 3930 cm^2/g. (Blaine) was used. The ratio of water to cement was 0.5 and the ratio of paste to sand was also 0.5 (by weight). Two types of specimens were used: cylinders 4 by 8 cm. and a rectangular prism 5 by 10 by 20 cm.

Measurements of compressive strength, dynamic modulus, volume contraction, sound velocity, internal damping, electrical resistance, alkalinity, and content of non-evaporable water were determined intermittently or continuously at the four levels of temperature at ages from 1/2 to 24 hr.

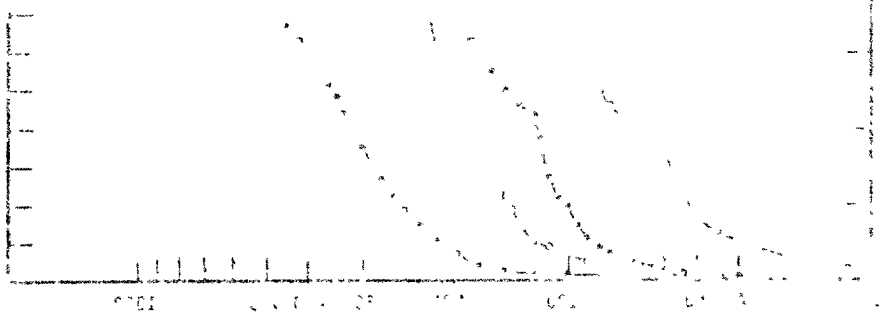
The results for the various physical and chemical changes obtained by the authors are too voluminous to include in this short summary. Some of the more common properties were selected to illustrate the nature of the results and indicate the behaviour of the mortar at the different levels of temperature.

Mechanical Properties

The authors show in Figure 7 that the compressive strength in the early stages of the hardening process may be represented by exponential growth curves which are parallel until a certain level of strength is reached. When this level is reached, specimens at 60 and 80°C begin to develop strength at a lower rate than those at 25 and 45°C. Similar results were obtained for dynamic modulus of elasticity as shown in Figure 8 and obtained by the pulse velocity method. The same apparatus and method were used to measure the internal friction which was expressed as $\log \frac{1}{V}$ where the assumption was made that V (the voltage) was proportional to the amplitude of the pulsed wave. The correspondence of the changes in E (dynamic) and the internal friction parameter were made apparent in plots of the type shown in Figure 11b.

Chemical Reactions and Mechanical Properties

To indicate regions of different reactions or changes in rates of reactions the authors plotted the parameters of dynamic modulus of elasticity, electrical resistivity, temperature, pH and volume contraction



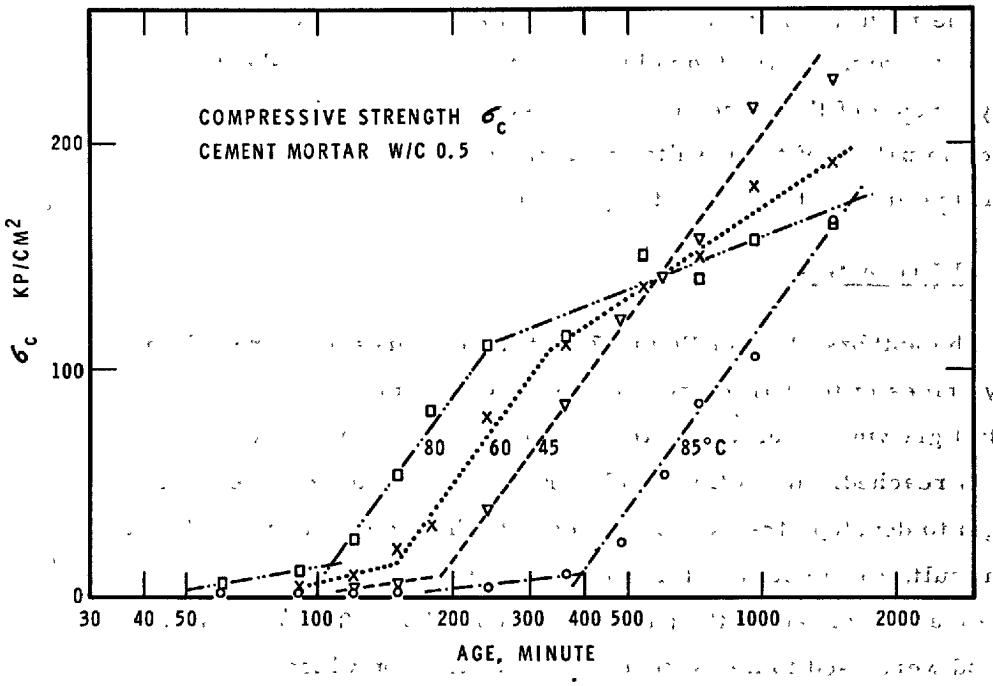


Figure 7 (from Hansen, Jessing, Mønsted and Trudsø)

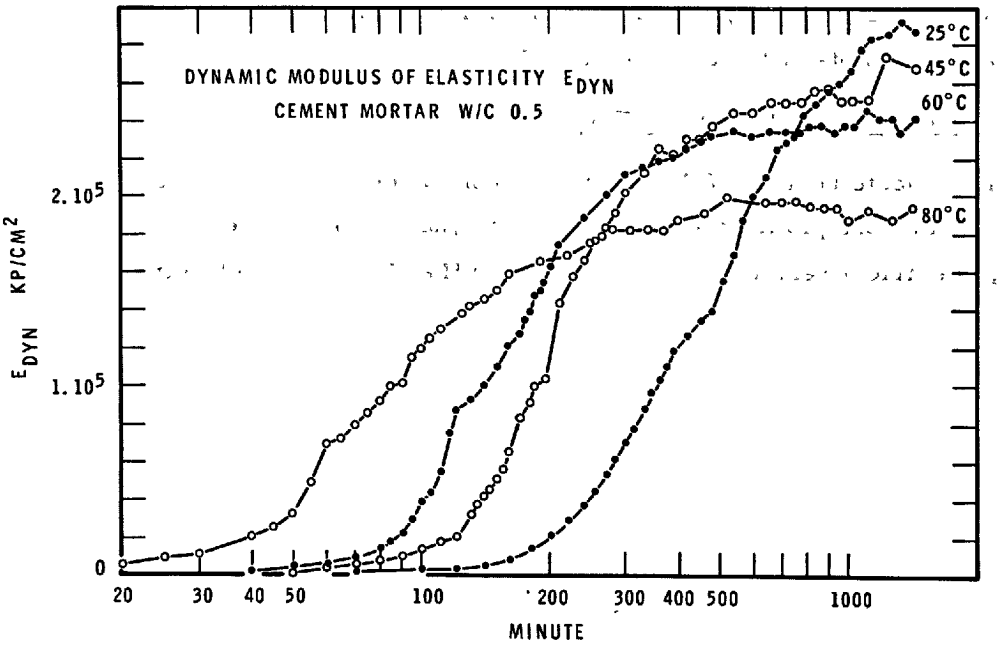

Figure 8 (from Hansen, Jessing, Mønsted and Trudsø)

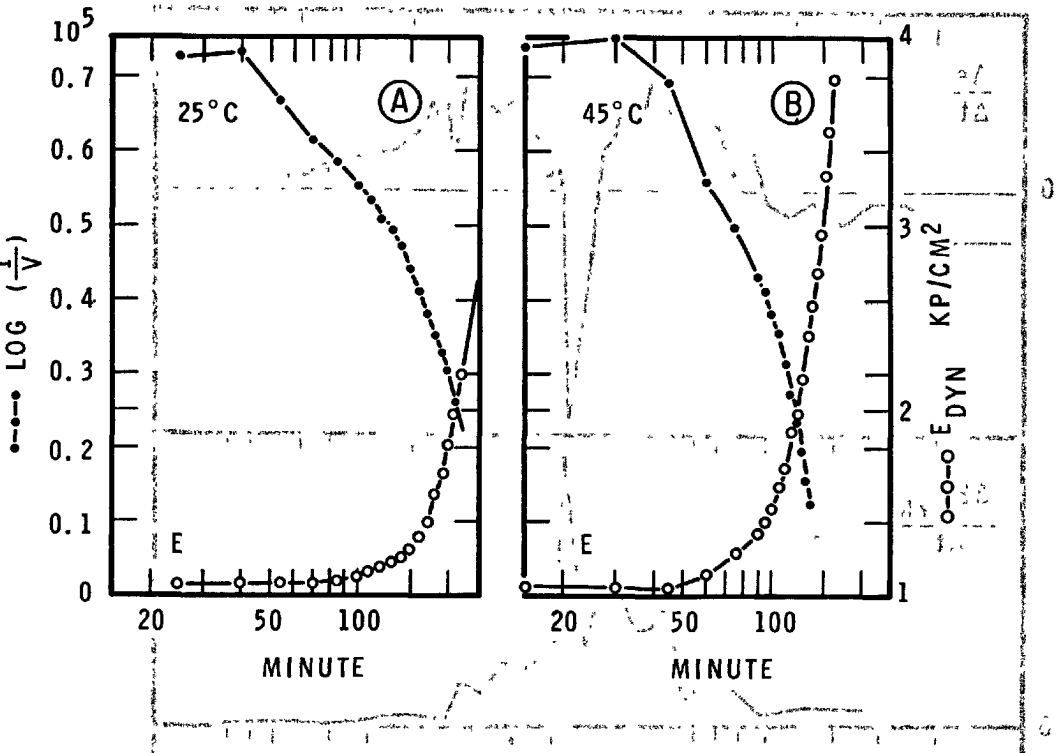

Figure 11 (a and b) (From Hansen, Jessing, Mønsted and Trudsø)

as differentials with respect to time. Thus maxima and minima on the differentiated curves correspond to inflection points on the basic curves. These appeared quite reproducible as shown in Figure 17 for changes in resistance, E_{dyn}, ΔV, temperature, and pH with time. The various maxima and minima are explained as representing different reactions and different stages of hydration beginning with hydration of C_3A then followed by hydration of C_3S.

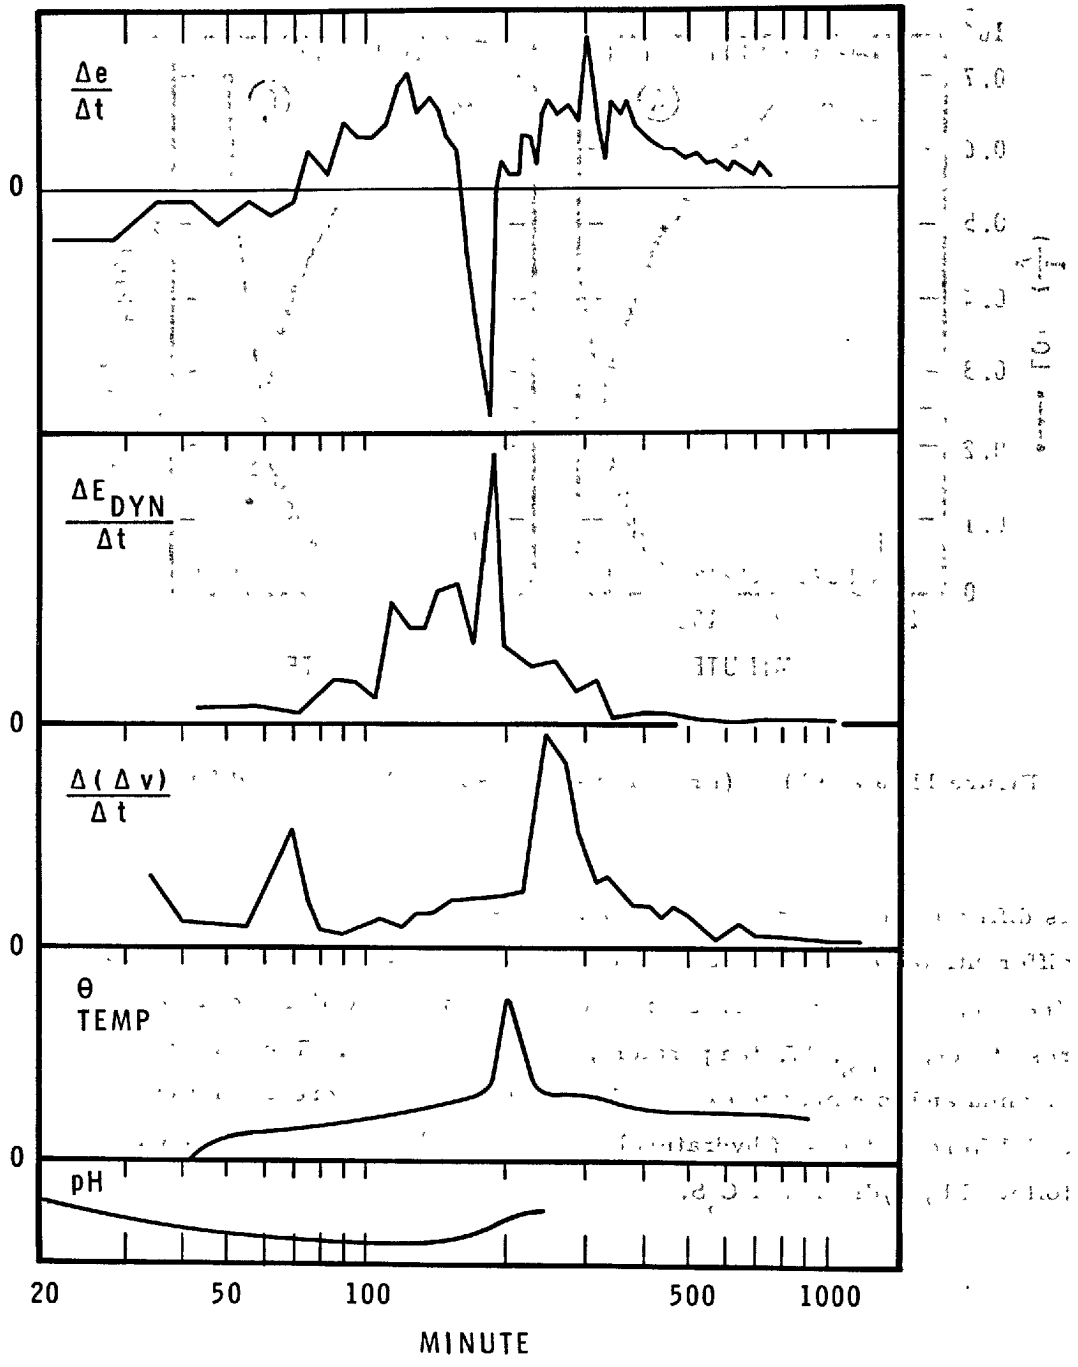

Figure 17 (from Hansen, Jessing, Mønsted and Trudsø)

The authors show that the plot of the log of the rate of the reactions, as indicated by various measured parameters, versus the inverse of the absolute temperature give fairly straight lines thus indicating a fairly good agreement with the Arrhenius equation. Activation energy corresponds to the reaction energy of C_3S.

Conclusions

The authors conclude the following:

1. Curing at elevated temperatures below 100°C accelerates the development of mechanical properties. The acceleration can be accounted for by the concrete maturity, but at ages above 24 hr the quality obtained by curing above 45°C may be impaired due to other influences.

2. By curing at temperatures above 45°C it seems that the hydration of C_3S is accelerated in particular; in cases where this process starts before the hydration of C_3A, the mechanical properties may be impaired.

GENERAL CONCLUSIONS

These papers have indeed advanced the understanding of cement curing at elevated temperature and have given some possibility of predicting the useful properties and the optimum conditions for curing. Perhaps the most useful results of these investigations are the techniques that were developed for the measurement of a number of physical properties during the progress of the curing. These can be used for evaluation of different cements.

GENERAL REPORT
OF
SESSION III-5: HIGH-TEMPERATURE CURING OF CONCRETE UNDER HIGH PRESSURE

H. E. Vivian (Australia)

The following Supplementary Papers are summarized in this report.

Paper No. III-80

HYDROXYL ELLESTADITE PRODUCED BY HYDROTHERMAL REACTION CONTAINING CALCIUM SULFATE

K. Takemoto & H. Kato (Japan)

Paper No. III-87

SOME PHYSICAL PROPERTIES OF AERATED CONCRETE UNDER AUTOCLAVE PROCESS

K. Ono & K. Ojiri (Japan)

Paper No. III-111

INFLUENCE OF MINOR COMPONENTS ON THE STRENGTH OF CALCIUM SILICATE HYDRATE SYNTHESIZED BY HYDROTHERMAL REACTION

G. Shikami (Japan)

These three papers, which are concerned with rather different aspects of hydrothermal reactions of clinker compounds and raw materials, are not closely interconnected. Consequently this summary may appear to be somewhat disjointed. All these papers discuss reactions that occur at elevated temperatures and steam pressures, the compounds formed under these conditions and the effects of various admixture compounds on the chemical reactions and the mechanical properties of the reaction products. Some conclusions drawn from these studies may be usefully applied in the manufacture of concrete products and could have some significance in other fields.

Paper No. 111 by G. Shikami is concerned with the effects on the hydrothermal reaction rates of calcium hydroxide and silica of small additions of beryllium, zinc and alkali metal oxides and with the strength of the resultant calcium silicate hydrate. The results obtained indicate that additions of beryllium and zinc oxides in quantities up to 0.4 per cent retard, but do not inhibit, the rate of hydrothermal reaction. The chemical composition of the reaction products formed in the presence of beryllium and zinc oxides is comparable with that of products formed in the absence of these compounds even though their degree of crystallization is generally poorer. Higher temperatures and longer reaction times tend to correct these defects.

In contrast to the depressing effects of beryllium and zinc oxides, small additions of alkali metal oxides promote the calcium hydroxide-silica reaction and improve the strength

developed by the reaction product. Additions in excess of 0.3 per cent appear to retard the calcium hydroxide-silica reaction and reduce the mechanical strength of the reaction product. It is considered that the progressive lowering in the calcium hydroxide solubility, as the alkali concentration is increased, accounts for the reduced reaction product strength. The physical properties of the hydrothermal reaction products suggest that for autoclaved products the bulk density should increase and the water absorbency and permeability should decrease.

It can be indicated briefly that small alkali additions improve the reaction characteristics and physical properties of lime-pozzoloma mixtures even when cured at atmospheric temperature. It would appear that the presence of the more common alkali metal hydroxides (e.g. sodium and potassium) can increase the rate of lime-silica reaction by acting as a catalyst. Other work has indicated that lithium hydroxide behaves very differently from sodium and potassium hydroxides and under some circumstances may inhibit silica reaction.

Paper No. 80 by K. Takemoto and H. Kato is concerned with the effect of calcium sulphate on the strength of hydrothermally-formed calcium silicate hydrate. The formation of hydroxyl ellestadite, $Ca_{10}(SiO_4)_3(SO_4)_3(OH)_2$, has been demonstrated in mixtures with CaO/SiO_2 molar ratios exceeding 1 while in mixtures of lower CaO/SiO_2 molar ratios anhydrite was the only observed sulphate-bearing phase.

Various properties of synthetically prepared hydroxyl ellestadite were measured and the strength of hydrothermally

produced paste specimens determined. It was observed that, as the SO_3 content of the raw material increased to 2 per cent, the measured specimen strengths increased. At greater SO_3 contents however the measured strengths decreased. It is suggested that the formation of hydroxyl ellestadite could reduce the strength of these pastes.

The actual mechanism of strength improvement in pastes made from materials containing up to 2% SO_3 followed by strength decline when the raw material SO_3 content exceeds 2 per cent has not yet been studied. Such a study would have very wide implications for specifications for cement used in autoclaved products and may help to account for some of the anomalous behaviour observed in such products. The authors also suggest that hydroxyl ellestadite or some of its thermal decomposition products can be observed in sulphate ring deposits in rotary kilns. The effect of these ring deposits on burning and kiln performance is economically significant especially in oil fired kilns and consequently further studies of the formation, composition changes and properties of these products would be desirable.

Paper No. 87 by K. Ono and K. Ojiri is concerned with the physical properties of autoclaved aerated or light-weight concrete specimens. These authors have recognized the difficulty in obtaining suitable test measurements and consequently have discussed equipment and experimental techniques as well as product properties and changes.

Although this paper contains a considerable amount of discussion on the dimensions of specimens, heating and cooling

treatments and heat and moisture distributions in specimens, the most interesting part of this paper is concerned with the linear measurements of specimens during the autoclaving process. An apparatus using an "optical differential lever method" has been described and its use discussed.

It was concluded that the observed expansion-temperature relationship was mainly dependent on the thermal expansion of the solid phase of the specimen and that moisture movements and changes in the amount of hydrated material could also affect the overall measured movements. It is of interest to note that the thermal expansion of specimens is virtually independent of density.

Additions of increasing amounts of hard burnt magnesia to specimens caused expansion, severe cracking and ultimately disintegration. The expansion-contraction performance of specimens indicates that two separate and distinct mechanisms can operate simultaneously in a specimen and affect the observed movements. Even though a specimen is expanded by the hydration of magnesia, shrinkage can occur under appropriate conditions due to the shrinkage characteristics of the hydrated cement and the magnitude of the shrinkage is largely unaffected by the magnitude of the expansion.

This paper points out the significance of thermal stressing and cracking in specimens and emphasises the need to determine specimen requirements and autoclaving procedures in relation to the physical performance of concrete specimens.

As a group these papers, while acknowledging the importance of chemical composition of cements raw materials and hydrothermally-prepared specimens, place a somewhat greater than usual emphasis on physical characteristics and changes in specimens. The reviewer commends these authors for taking up this view since it is considered that the performance of cement and concrete is very largely dependent on the physical properties of the materials and the physical changes that occur in specimens as a result of changes in the environmental conditions.

GENERAL REPORT
OF
SESSION IV-1: USE OF SURFACE ACTIVE AGENTS IN CONCRETE

K. Okada (Japan)

The following Supplementary Papers are summarized in this report.

Paper No. IV-5

INFLUENCE OF SOME ADMIXTURES ON CREEP OF CONCRETE

E. L. Jessop, M. A. Ward & A. M. Neville (Canada)

Paper No. IV-45

EFFECTS OF ORGANIC COMPOUNDS ON THE HYDRATION REACTIONS OF TRICALCIUM ALUMINATE

K. E. Daugherty & M. J. Kowalewski, Jr. (U.S.A.)

Paper No. IV-51

ABNORMALLY DELAYED SETTING OF A LOW-HEAT PORTLAND CEMENT WITH CALCIUM LIGNOSULPHONATE ADMIXTURES

R. Bauset (Canada)

Paper No. IV-89

INVESTIGATIONS ON THE METHOD OF TEST FOR SETTING TIME OF CONCRETE ESPECIALLY FOR CONCRETE CONTAINING WATER REDUCING ADMIXTURE

J. Okabe, K. Nakajima & T. Yoshihara (Japan)

Paper No. IV-107

STUDY ON THE ADMIXTURE FOR AERATED CONCRETES INCLUDING ANHYDRIDE MODIFIED RESIN

K. Akutsu (Japan)

Five papers concerned with the theme of Section IV-1 have been studied for this reports, and the following account is the reporter's summary of their contents.

Four of the papers are essensially related to the water-reducing admixtures, two papers (IV-45, 51) dealing with the effects of additives on the phase composition of hardening cement water paste, one (IV-5) on the creep of concrete and one (IV-89) discussing the testing method of setting time of concrete when additive has been used. Remaining one paper (IV-107) is devoted to the research on using an organic resin as foam-forming agent in foamed cellular concrete.

Two kinds of admixtures as dealt with in the papers - water reducing admixtures and foaming admixtures - are to be classified to different groups, although both being the surface active agents.

IV-45 Effects of Organic Compounds on the Hydration Reaction of Tricalcium Aluminate

Kenneth E. Daugherty

Milton J. Kowalewski

This paper describes the investigation on reaction of organic compounds containing various types and number of hydroxyl groups and carbonyl groups with C_3A. Reviewing literatures reveals that the α-hydroxyl carbonyl group HO - C - C = O adsorbed on C_3A is thought to play a major role in

retarding hydration of portland cement, and this investigation aimed at determining the relationships of carbonyl and hydroxyl groups relative to the set-retardation of C_3A hydration in the absence of sulfate and calcium ions.

Possible mechanism for hydration of tricalcium aluminate in the presence of organic compound is believed to pass through the metastable hexagonal hydroaluminates (C_2AH_8, and C_4AH_n, n = 13 or 19) and transformed to the more stable C_3AH_6 under normal conditions.

Some organic compounds delay the conversion of C_2AH_8 and C_4AH_n to C_3AH_6 while others permit the C_3AH_6 to be formed readily.

Thirteen well-characterized, interrelated, water-soluble organic compounds including acetic acid, glycolic acid, glyceric acid, sucrose, fructose, manitol, sorbibol etc. were selected and used in this study.

The method of investigation is to observe the disappearance of tricalcium aluminate and the appearance of new hydrated phases in the course of the hydration of C_3A in the presence and absense of organic compound by x-ray diffraction using a C_3A-C_3AH_6 calibration curve.

Mixtures having a H_2O/C_3A ratio of 0.6 and containing 1 % by weight of organic compound to C_3A were stored at 20°C for 22 minutes to 64 days. These samples were ground and analysed by x-ray diffraction. Special emphasis was placed on sucrose and the effect of varying concentration of sucrose on the hydration of C_3A was examined. Effects of the blocking action of organic compounds preventing the hexagonal hydroaluminates from forming C_3AH_6 are also discussed.

Principal conclusions derived from the investigation are

(1) Organic compounds containing hydroxyl, carboxyl or carbonyl groups act as either accelerators or retarders for the hydration of C_3A depending upon their concentration levels and composition.

(2) The α-hydroxyl carbonyl group does not appear to be especially important in the hydration of C_3A.

(3) A simple organic compound containing a carboxylic acid group and zero or one hydroxyl group accelerates C_3A hydration and a simple organic compound containing two or more hydroxyl groups retards C_3A hydration. In this test mandelic acid is a strong accelerator and sorbitol a strong retarder.

IV-51 Abnormally Delayed Setting of a Low-heat Portland Cement with Calcium Lignosulfonate Admixture

R. Bauset

This paper reports abnormally long setting time which occurred in the dam concrete at one of the sites of hydro-electric power project in Canada.

Low heat cements were used in the concrete combined with lignosulfonate type of water-reducing agent, and cements from one supplyer showed excessive delay in setting time.

Chemical composition and compressive strength development of the cement compared with other normally-set cements show that the slow setting of the particular cement with calcium lignosulfonate additive was probably due to low C_3A and low SO_3 content in cement.

A similar case of slow-hardening concrete were reported in tunnel lining construction in California[1] and Milenz[2] pointed out that it might be caused due to the low-alkali cement of high C_4AF and low C_3A content in that case.

Table 4 in the paper shows that the cements designated as "A" and causing the slow setting have higher C_3S content (44, 40 %), lower C_3A content (4.4, 5.3 %) and lower SO_3 content (1.27, 1.31 %) than the other low-heat

cements, and appear to belong rather to type II (ASTM) cement, actually corresponding to the moderate heat cement of Japan when judged from only the chemical compounds.

The retarding effect of the admixture on the concrete containing cements supplied by the particular manufacturer "A" was very pronounced when cement contained 1.1 % SO_3. Therefore it appeared that addition of normal dosage of the lignin-base water reducing agent to cement "A" might cause excessive retardation of setting when higher percentage of SO_3 than the value described above was present. Thus, "Having discounted possibility of a high sugar content lignosulfonate being used and the possibility of overdosage of the mixture and delayed addition of the admixture", the dosage of the admixture was regulated to dependending upon the SO_3 content of the cement as follows.

for < 1.6 % SO_3 ..... dosage < 0.2 %

for ~ 2 % SO_3 ..... dosage ~ 0.3 % (normal)

Author also suggests that lower alkali content of $0.5 \sim 0.6$ % for cements "A" may be a contributory factor in this case.

IV-5 Influence of Some Admixtures on Creep of Concrete

E. L. Jessop, M. A. Ward

A. M. Neville

Authors reported before that larger creep was observed in concrete containing water-reducing and set-retarding admixtures than in the corresponding plain mixes having the same workability and the same compressive strength at the time of application of sustained loading.

This paper describes the experimental study done to find the mode of influence of admixtures on creep, on the less of water from hydrated paste

at higher temperatures, density of hydrated paste, surface tension of the solution of admixture in water, and morphology of the hydrated paste and therefore the shape of stress-strain curve.

Tests were done using neat cement pastes of w/c = 0.5 with and without admixture. Type III high early strength portland cement and two admixtures (one belonging to hydroxylated carboxylic acid and one to lignosulfonic acid) were used.

Results of test show that no possible correlations between the surface tension of water or density of hydrated paste and creep exist, and that some relation between the ease with which water can move within and out of the paste and creep is shown to exist.

Several workers observed change of crystal size and shape of hydration products of tricalcium aluminate and of calcium aluminoferrite and changes in the morphology of hydration products of C_3S and C_2S when the admixture is added.

Although the electromicrographs, of which the magnification is 15,000 times, was inadequate in this test to show significant morphological difference between the mixes with and without an admixture, it may be imaginable that the modifications described above as well as the possible modification of boundary relationship among the hydration products undoubtedly affect the creep of hydrated cement.

More important effects of admixtures on physical properties of cement paste are change of pore size distribution and porosity.

Stupachenko's observation[3] using absorption method of benzol and the mercury porosimeter revealed that use of a lignosulfonate admixture at the rate of 0.25 % did not significantly change the total porosity but the volume portion of pores with smaller radius of 500 to 1000 Å was decreased 3 % in mortar and 30 % in paste with admixture.

Hence theoretically the cement paste with the admixture should be more permeable, and therefore more easily loss water from the gel than that without the admixture.

This conclusion, however, would not necessarily relate to the practical concrete as a whole which involves various other factors.

In this investigation moist loss of cement paste was measured in an over at 105°C on specimens cured in fog at RH 100 % for 28 days. Considering this result and the measured value of surface tension in parallel, the authors concluded that some relationship between the ease with which water in paste can move and creep may exist.

IV-89 Investigations on the Method of Test for Setting Time of Concrete Especially for Concrete Containing Water Reducing Admixtures

Jiro Okabe, Koji Nakajima
Takuji Yoshihara

The term "setting of concrete" is used to describe the comparative hardening of concrete with and without set-controlling agents, although the definition is somewhat arbitrary. Easily available methods for measuring the time of setting of concrete are

(1) determination of resistance to the penetration of a needle according to ASTM Standard C 403, and

(2) determination at various intervals of time of the resistance to pulling out of a series of pins[4].

And the penetration resistance method (ASTM C 403) is being used more widely. This method requires wet-screened concrete mortar in order to obtain information more closely related to the hardening characteristics of

concrete to be used in site.

However, in the penetration test, which is essentially more suitable for mortar than for concrete, additional handling and compaction of wet-screened mortar are needed. Hence, use of mortar instead of wet-screened mortar from concrete is sometimes tried in the laboratory.

Authors investigate the effects of mix-proportion, kind of lignosulfonate water-reducing admixtures, mixing sequence and time and temperature on the time of setting by using the mortar method as well as ASTM method, and clarified that the mortar method can give satisfactory information on setting time of practical concrete and obtain more accurate and more reproducible results than ASTM C 403 method.

In the mortar method, test should be performed as follows.

(1) The proportion of mortar shall be theoretically indentical that of the screened mortar from concrete, that is, shall have the same water cement ratio and sand-cement ratio.

(2) The same materials as in the concrete shall be used.

(3) Similar mixing sequence as in the concrete shall be adopted.

Mixing sequence has remarkable effect on the setting time as already pointed out by V. H. Dodson and E. Farkas[5] who discussed on the effect of delayed addition of set-retarding admixture to concrete.

When cement and surface dry saturated aggregates are premixed before the admixture solution is added, the setting time of concrete delays by two to five hours depending upon the kind of admixtures compared with when the mixing starts after the whole materials are introduced into the mixer.

The above delayed setting due to change of mixing sequence was caused probably by quick reaction of cement with a small amount of water absorbed in aggregates prior to addition of admixtures as illustrates by Bruer[6].

The retarding or accelerating effect of the water-reducing and set-retarding or set-accelerating admixture on the setting time of concrete also varies with the change in proportion, mixing sequence, mixing period and temperature.

It seems that the accelerating affect of the water-reducing and set-accelerating admixture decreases with increase in consistency of the concrete and that the prolonged mixing alleviates the retarding effect of the water-reducing and set-retarding admixture.

The above findings indicate that due considerations should be taken of the various factors described above in establishing the standard testing method for setting time of concrete.

IV-107 Study on the Admixture for Aerated Concrete Including Anhydride Modified Resin

Kenji Akutsu

Some surface-active agents used in structural sand-gravel air-entrained concrete may be used as foaming agent for foamed cellular concrete.

Foaming agent is required to introduce stable, and uniformly distributed minute foams into the slurry concrete and consequently to reduce bleeding.

Author tested the basic properties, to be required as foaming agent, of a maleic anhydride modified resin and compared with those of surface active agents such as salt of resin, salt of sulfonated lignin, alkylbenzene sulfonate, and non-ionic compounds.

Maleic anhydride modified resin which is processed by adding maleic anhydride to abietic acid, has totally three carboxyl groups, and so the negative charge may be increased much. The admixture was finaly produced

by saponifying the said maleic acid copolymer and emulsifying it with synthetic foam stabilizers, thus the superior stability of quality and storability being obtained.

Addition of 0 to 0.2 % concentration of the maleic resin admixture decreases surface tension so much in the saturated lime solution with increasing concentration successively to nonionic agent and alkylbenzene sulfonate.

The least bleeding was obtained by using the maleic resin foaming agent in cement paste of w/c = 0.65. It is inferred that the carboxyl groups introduced into the molecule of the maleic anhydride modified resin, may be combined with calcium ions to form an insoluble salts.

All foaming agents except lignosulfonate had little effect on the setting time of cement paste, so far the dosages of admixtures ranged from 0.05 to 1.0 % by cement weight. When adding accelerating or retarding agents to the maleic resin foaming agent, the normal acceleration or delay of setting time was obtained.

In the tests of mortars having mix proportion of 1 : 2 (w/c = 0.60) to 1 : 4 (w/c = 1.00) and containing the maleic resin foaming agent, maximum air content (10 to 20 %) as well as maximum flow was obtained when the dosage of the foaming agent was 0.1 to 0.2 %, almost corresponding to the critical micells concentration.

Strength of mortar decreased with increasing air content, and the compressive strength at 28 days being 90 to 250 kg/cm^2 for around 15 % air content depending upon the mix-proportions.

Drying shrinkage also varied with mix proportions and was 0.09 to 0.17 % at 28 days. Another test revealed that mortar of 1 : 3 mix proportion containing the foaming agent of not less than 0.5 % by weight and so containing about 10 % air showed good waterproofness comparable to the non-foamed

plain mortar.

Author concluded that the maleic anhydride modified resin used in this study may be approved as an effective foaming agent.

GENERAL REPORT
OF
SESSION IV-2: FLY ASH AND FLY ASH CEMENT

A. Joisel (France)

The following Supplementary Papers are summarized in this report.

Paper No. IV-7

HYDRATED PHASES AFTER REACTION OF LIME WITH "POZZOLANIC" MATERIALS OR WITH BLAST FURNACE SLAGS

R. Sersale & P. G. Orsini (Italy)

Paper No. IV-17

STUDY OF REACTIONS BETWEEN CaO OR $3CaO.SiO_2$ AND β-$2CaO.SiO_2$ AND POWER STATION FLY ASHES UNDER HYDROTHERMAL CONDITIONS

Z. Šauman (Czechoslovakia)

Paper No. IV-63

INVESTIGATIONS ON THE BEHAVIOUR OF NATURAL AND ARTIFICIAL PUZZOLANAS

H. E. Schwiete, P. Kastanja, U. Ludwig & P. Otto (West Germany)

Paper No. IV-135

THE DIFFERENT ACTION MECHANISM OF POZZOLANIC MATERIALS AND SLAGS IN THE HYDRAULIC BINDERS

A. Celani, P. A. Moggi & A. Rio (Italy)

INTRODUCTION

Among the supplementary papers on Topic IV - 2, Sauman's paper relates to fly ash and those by Celani - Moggo - Rio , Schwiete - Kastanja - Ludwig - Otto , and Sersale - Orsini relate to puzzolanas. Fly ash is a special artificial puzzolana which can be distinguished from other puzzolanas (natural or artificial) by the form of the grains or by a given carbon content, for example. This topic could therefore be entitled "Puzzolanas and Puzzolanic Cements".

I am going to endeavour to compile a survey of these papers which is not a repetition of the synopses prepared by the Authors and which takes account of all the principal papers read at the Symposium which I have received and in particular the paper by Masatane Kokubu on the same topic.

RAW MATERIALS

The substances studied by the Authors are varied. Their chemical compositions by weight are plotted on figure 1 in which the apices of the triangle correspond respectively to SiO_2, to the sum $Al_2O_3 + Fe_2O_3 + TiO_2 + SO_3$, and to the sum $CaO + MgO + Na_2O + K_2O$. (Figures 1 and 3 have been drawn under these conditions for simplification. It is known that many constituents are only interchangeable molecularly , and not without some reservations which are mentioned in the study by Sersale - Orsini in particular).

These raw materials comprise:

- natural "puzzolanas": Italian puzzolanas, trass, tufa, molererde, zeolites: zone (a) of fig.1
- fly ashes (b)
- one acid slag (c)
- basic slags (d)
- artificial glasses (e)

- one clinker (in the triangle C_3S - C_2S - C_3A) (f).
- one silica sand (g)

The overall chemical composition is not enough to characterise the substance for a variety of reasons. For example, a given composition may correspond to a complex mass of grains of very different chemical and mineralogical compositions, and in particular the vitreous nature has a most important influence. A vitreous substance, at the molecular scale, always involves local arrangements analogous to those of glass, and in addition a crystalline substance may be amorphous in part, particularly at the surface since the atoms are not regularly surrounded by their neighbours at the surface like they are within the body of the substance. This may explain, at least partially, why a siliceous sand, which is habitually considered to be inert,"fixes" a small quantity of lime as has been shown by Celani - Moggi - Rio.
However, a substance is not truly puzzolanic unless it is vitreous, in part at least. This is why these Authors indicate a considerable difference between the behaviour of sand and that of "puzzolana 2" in spite of the close similarity of their chemical compositions, (fig. 1).

"Puzzolana", by definition, combines with lime at ordinary temperatures in the presence of water to give bonding products. Sauman reports reactions at 175°C. The other papers relate to the reactions at ordinary temperatures or at 40°C.

The combination with lime has been studied in several ways:

- the development of the concentration of a solution of lime,
- X rays,
- differential thermal analysis,
- electron microscope,
- B.E.T. surface adsorption,
- leaching of the lime,
- mechanical strength.

FIXING OF LIME

The development of the concentration of a solution of lime in the presence of puzzolana has been traced by all the Authors by means of acidimetry, complexometry, and weighing methods. Maintaining a temperature of 40°C as practised by Celani - Moggi - Rio, accelerates the fixation of lime without modifying the process qualitatively. Naturally increasing the fineness of the substance is favourable to combination. But this substance has also an intrinsic puzzolanity in this respect.

Celani - Moggi - Rio, classified the puzzolanity of the substances they studied in the following descending order:-

- "puzzolana 2", "puzzolana 1", "slag 1", "slag 2", sand.

Their fineness is classified by the residue on a 40 micron sieve:-

25 % for the puzzolanas, 14 % for the slags, 21 % for the sand.

Schwiete - Kastanja - Ludwig - Otto, classified their substances in the following order:-

- molererde, Austrian trass, Rheinland trass, Italian puzzolanas and acid slags, Bavarian trass.

But their fineness may be considerably different; the Blaine specific area in particular, which is so important in all the hydration reactions (as pointed out by the Authors) above all at the early stages (as found by Sauman). The fineness of the molererde, for example, is three times greater than that of the trasses and the Italian puzzolanas. These are overall classifications therefore and they do not necessarily affect the intrinsic puzzolanity of these subatances.

Bersale - Orsini, have used substances "powdered to 230 mesh" and they obtained the values reproduced in figure 2.

It will be seen from figure 1 therefore, in accordance with the several papers, that in general the fixing of lime increases as the ratio $A + F + T + SO_3 / C + M + N + K$ of the substance increases.

The basic slags (which almost conform in figure 1 to the simplified potential formula $C_{4.5} AS_{2.5}$) fix little lime. The same applies to glass $C_{3.5} AS_{0.6}$. Furthermore it is known that clinker (which in figure 1 conforms to the simplified formula $C_{16} AS_5$) does not fix lime but liberates it instead during hydration.

The substances which are capable of fixing lime, and which are volcanic substances (puzzolanas, trasses, tufas, molererde) or artificial substances of similar chemical composition (calcined clays, fly ashes, acid slags, artificial glasses) are more "acid" than the slags known as "basic slag". A limiting composition between substances which liberate lime and those which fix it, is given approximately by compositions situated on the $CS - C_3A$ line, (for example those corresponding to the simplified formula $C_6 AS_3$). That may thus be made out: hydrated substances, the most stable, may be considered as formed of silicate which is designated C - S - H (I) (the molecular ratio C/S of which is more often about 1) and of tricalcium aluminate in the hydrated condition $C_3 AH_6$.

Thus Celani - Moggi - Rio, have found that in a mix consisting of 75 % puzzolana and 25 % calcium hydroxide at 40°C all the hydroxide disappeared. Šauman found the same thing at 175°C for 75 % of fly ash and 25 % of CaO or C_3S.

HYDRATED SUBSTANCES

All the papers gave data regarding the X-ray analysis of hydrated substances.

During the hydration of puzzolanas in the presence of lime at 40°C, Celani - Moggi - Rio, found C - S - H (I). They did not find C - S - H (II) (with a high C/S ratio), $C_4 AH_n$ and $C_2 ASH_n$, which they obtained during the hydration of basic slags.

Schwiete - Kastanja - Ludwig - Otto, only found "CSH",(which may contain small amounts of aluminate) as a hydration product of molererde at ordinary temperatures. With all other puzzolanas which they hydrated in the presence of lime they found in addition hydrogarnets C_3 (A,F) H_6 - C_3 (A,F) S_3 which we will write C_3 (A,F) S_pH_n. With volcanic puzzolanas they found C_4AH_n. C_2 ASH_n only appeared occasionally. With Austrian trass containing 2 % of SO_3 , or by adding calcium sulphate during the hydration, they obtained mono-sulphoaluminate, and also tri-sulphoaluminate in the case of adding sulphate.

Sersale - Orsini found by the hydration of puzzolanic and zeolite substances of the (a) zone in figure 1 and of slags in the (d) zone, in the presence of lime: "CSH", C_2ASH_n, C_3AH_n, or C_4AH_n or $C_3ACaCO_3H_n$ and hydrogarnets $C_3AS_pH_n$. At times some hydrates were missing: C_2ASH_n or C_4AH_n or $C_3AS_pH_n$.

With the artificial glasses viz. CAS, $C_2AS_{0.4}$ and $C_{3.5}AS_{0.6}$ they obtained $C_3AS_pH_n$, and with CAS glass they found "CSH" and C_2ASH_n. $C_{3.5}AS_{0.6}$ glass may give $C_3AS_pH_n$ even without the addition of lime. The C/A ratio of the hydrate therefore follows the ratio of the anhydrous substance.

Sauman working on fly ash at 175°C obtained "CSH" and $C_3(A,F)S_pH_n$ as hydrated substances in the presence of lime or of C_3S (the hydration of which releases a high proportion of lime). On the other hand there is scarcely any reaction with the ash in the presence of βC_2S and even the hydration of βC_2S is retarded unless from 1 to 3 % of lime is added. The Author attributes the cause to a coating of the grains of βC_2S by a silica gel from the ash, even when the ash is only present in small amounts (8 to 10 %). The hydrogarnet is also formed from mullite, S_2A_3 and from $Ca(OH)_2$ principally when the two compounds are present in equal proportions, and from mullite and C_3S principally when the ratio between the two compounds is 2/1 by weight.
The composition of these hydrogarnets is approximately, with CaO : C_3ASH_n and with C_3S or βC_2S : $C_3AS_{1.5}H_n$.

The studies carried out by differential thermal analysis, by electron microscope and by surface adsorption have only confirmed the results obtained by R-ray diffractometry.

Thus a summary of the principles which can be derived from the four papers can be seen in figure 3:

- The "basic" slags have compositions which are intermediate between the clinkers and the puzzolanic substances. (The areas of the puzzolanas, basic slags and clinkers shown on figure 3 are the most usual ones. They correspond to molecular ratios $S/A + F + T + SO_3$ of the order of 3 and weight ratios of the order of 2).

- Substances the hydration of which tends to fix lime are situated to the right of the CS - C_3A line. The further they are from this line the more "puzzolanic" they are providing they are vitreous.

- The hydration of clinkers situated to the left of the CS - C_3A line is accompanied by the liberation of lime (portlandite).

- Hydrated substances defined as the most stable are mainly (CS, C_3AS_3, C_2AS, $C_3A)H_n$.

- Some of these hydrates since they are situated to the right of the CS - C_3A line may be thought to be capable of "fixing" (in a manner which has not been explained perfectly) a certain amount of hydrated lime.

This may explain why Celani - Moggi - Rio found an essential difference, during leaching experiments, between puzzolanas and basic slags which are situated on either side of the broken line CS - C_3AS_3 - C_2AS - C_3A . They hydrated both substances at 40°C in the presence of saturated lime water. They then found on subjecting the hydrated substances to leaching with diluted lime water that the slags gave up lime while the puzzolanas continued to fix it.

MECHANICAL STRENGTH

Combination with lime is an essential condition of puzzolanity, but it is not a sufficient condition: it is also essential that bonds should result from this combination from which mechanical strength results ipso facto. Mullite which, according to Sauman, combines with lime but does not give practically any strength, even at 175°C is not a puzzolana therefore.

Sauman considers that there is a certain proportion between the vitreous silica content of puzzolana and the mechanical strength it can develope.

Schwiete - Kastanja - Ludwig - Otto have observed that the mechanical strength confered by puzzolanic substances depends not only on their intrinsic puzzonality but on the fineness and then on the amount of water required for mixing.

CONCLUSIONS

The papers given at the symposium relating to puzzolanas and fly ashes constitute a coherent whole. The results presented in them are not at variance with those which had been obtained previously and they provide very useful information on puzzolanic substances and their hydration products.

Substances richer in lime than the compositions corresponding to line CS - C_3A (figure 3) liberate lime during hydration. Substances which are capable of fixing lime are vitreous substances less rich in lime. They then give the hydrated products, C - S - H, $C_3AS_3(H_n)$, C_2ASH_n, C_3AH_6, some of which fix a small quantity of lime themselves which can be said to be adsorbed. This lime is not revealed by X-rays but it can be leached out more easily than the lime from well defined hydrates.

GENERAL REPORT
OF
SESSION IV-3: SLAGS AND SLAG CEMENTS
(a) Papers regarding Slag

R. Sersale (Italy)

The following Supplementary Papers are summarized in this report.

Paper No. IV-11

A METHOD OF UTILIZING BLAST-FURNACE SLAG AS A STRENGTH-IMPROVING AGENT FOR CONCRETE

T. Iwai, T. Mori, A Yoda & M. Oshima (Japan)

Paper No. IV-28

INVESTIGATION OF THE PHYSICOCHEMICAL PROCESSES OF HARDENING OF SLAG PORTLAND CEMENT

V. I. Satarin & Y. M. Syrkin (U.S.S.R.)

Paper No. IV-48

CO-ORDINATION STATE OF ALUMINIUM, MAGNESIUM AND MANGANESE IONS IN SYNTHETIC SLAG GLASSES

S. K. Chopra & C. A. Taneja (India)

Paper No. IV-100

A CONTRIBUTION TO THE STUDY OF THE PHYSICAL PROPERTIES OF HARDENED PASTES OF PORTLAND CEMENTS CONTAINING GRANULATED BLAST-FURNACE SLAG

C. Cesareni & G. Frigione (Italy)

Paper No. IV-102

REACTIVE SLAG-LIKE GLASSES OF THE S-A-F-C-M SYSTEM

V. N. Pai & R. R. Hattiangadi (India)

Paper No. IV-106

STUDIES ON A METHOD TO DETERMINE THE AMOUNT OF GRANULATED BLAST-FURNACE SLAG AND THE RATE OF HYDRATION OF SLAG IN CEMENTS

R. Kondo & S. Ohsawa (Japan)

Paper No. IV-110

MINERAL COMPOSITION OF BLAST-FURNACE SLAG

H. Minato (Japan)

Paper No. IV-113

PORTLAND BLAST-FURNACE CEMENTS--A CASE FOR SEPARATE GRINDING OF SLAG

N. Stutterheim (South Africa)

Paper No. IV-121

THE ROLE OF MAGNESIA AND ALUMINA IN THE HYDRAULIC PROPERTIES OF GRANULATED BLAST-FURNACE SLAGS

M. Cheron & C. Lardinois (Belgium)

In the session "Slag and Slag Cements" nine valuable papers have been devoted to investigate the different aspects of the effects of the composition, the constitution, the way of activation, the nature of the hydration products, on the properties of blastfurnace slags and blastfurnace cements.

Three papers have in fact investigated the influence of different slag treatments on the hydration process and on the properties of the slag cements.

Two papers have investigated the rate of slag hydration and the related physico-chemical phenomena in the slag cements.

Three papers have investigated the composition or the structure of natural or synthetic slags in relation to the pratical behaviour.

One paper has shown the possibility of employing melted and granulated raw materials (unsuitable for portland cement) for cementious products manufacture.

Hydration and hardening processes of rapid-hardening slag portland cement, in comparison to portland cement and ordinary slag portland cement, have been studied by Satarin and Syrkin (1), by means of diffe-

rent experimental facilities.

Rapid-hardening slag portland cement, widely produced in U.R.S.S., is manufactured by mixing clinker, at a Blaine fineness of 5000 cm^2/gr, with slag, at a fineness of 3000 cm^2/gr, in the ratio 60:40 and 50:50, with 4-5% gypsum addition. Such a binder is characterized by mechanical strenght values very similar, at early stages, to those of portland cement.

The Authors have systematically followed the course of hydration and hardening processes by means of chemical, as well as electron microscopy and diffraction, X-ray and thermal investigations.

Samples were prepared by mixing cement with water (water:cement ratio = 0,5) and the composition of the liquid phase, isolated at different time intervals by means of a special pressform under very high pressure, determined. Composition changes in $Ca(OH)_2$, $CaSO_4$ and alkalies content were examined.

It has been ascertained that after 4 minutes hydration, calcium hydroxide content of liquid phase, isolated from ordinary slag portland cement samples (prepared both with basic and with acid granulated respectively slag), is much lower than for portland cement and for rapid hardening slag portland cement. Calcium hydroxide concentration in portland cement and in rapid-hardening slag portland cement liquid phases overpasses, on the other hand, saturation. Lime saturation of liquid phase, reached after 4 hours and maintained during 24 hours, falls down after three days for all cement types. Gypsum content of the liquid phase after 4 minutes hydration does not reach saturation value for all type of cements. The disappearence of gypsum from the liquid phase, which indicate the completeness of the reaction leading to hydrated calcium sulphoaluminate

of ettringite type, has been observed after 24 hours in the liquid phase isolated from portland cement and from rapid-hardening slag portland cement, but only after 3 days for ordinary slag portland cement.

Hydration and hardening processes seem therefore to be somewhat inhibited in slag portland cement in comparison to portland cement and rapid-hardening slag portland cement. Moreover liquid phase isolated from all samples show an alkalies concentration increasing with the time and lower for ordinary slag portland cement.

The kinetic of the hydration process has been evaluated by determining the chemically bound water, too. It has been ascertained that chemical water content, which increase with the age of the sample, is higher for portland cement and for rapid-hardening slag portland cement than for ordinary slag cement, manufactured with the same slag, according with the higher hardening rate of the rapid hardening slag portland cement.

Electronographic examinations have definitely confirmed the results of chemical investigations and showed that at early stages the newly formed hydration products are similar for portland cement and for rapid hardening slag portland cement. Mechanical strenght which caracterizes rapid hardening slag portland cements depend therefore from a more intensive production of high sulphate form of hydrated calcium sulphoaluminate, together with low basic hydrated calcium silicates.

The formation of hydrated compounds goes on in the same way for portland cement as well for rapid hardening slag portland cement, but at early stages the high sulphate form of hydrated calcium sulphoaluminate plays a role of great importance. In the rapid-hardening slag portland

cement samples, cured for one year, hydrated calcium silicates have the main role, while ettringite crystals are quite rare. Thus, particularly at early stages, when it is necessary to stimulate the output from the slag of newly formed compounds, the fineness of the clinker positively affects the properties of slag cements.

Rapid-hardening slag portland cement is to be considered a binding material which share alike the rapid hardening of portland cement with the tendency of slag cements to form hydrated calcium silicates.

The results of electronographic investigations have been confirmed by X-ray and thermal examination.

The first stage of slag cement hydration seems therefore to be the hydrolysis of the clinker. In consequence of this fact, calcium hydroxide and alkalies pass into the liquid phase, thus exciting the hydraulic activity of the slag. The newly formed products are hydrated calcium sulphoaluminate and hydrated calcium silicates similar to tobermorite.

Mori, Iwai, Yoda and Oshima (2) have investigated the possibilities of increasing one-day strenght of portland cement, by employing high-alumina latent hydraulic admixtures.

The rapid strenght development of alumina cement depends upon the prompt monocalcium aluminate hydration, while tricalcium aluminate is the (secondary) component responsible of initial strenght in the portland cement.

It's well known that the alumina content of the slags and fly ashes is higher than that of portland cement. Such admixtures increase therefore the alumina content of portland cement but hydrate slowly and the strenght development is likewise slow.

The study of Mori and Coll. deals with a method of activating the slags by employing a mechanical and chemical treatment.

Unprocessed slag with 50 microns maximum particle size and processed one (namely 25 minutes wet ground slag in a vibrating ball mill) with ten to fifteen microns maximum particle size, were respectively added to rapid hardening portland cement. Strenght development was found to be grater after a week when mortars made with processed slag were used, and smaller for portland cement mortars. This result was notyet satisfactory for having high strenght development in 1-3 days.

Slag was then activated by a mechanical chemical treatment. Samples were prepared by wet grinding slag, calcium sulphate (and sometimes sodium sulphate) and successively addition of such a slurry to portland cement clinker.

Strenght of mortars with milled admixtures varies with slag:sulphate ratio. One-day strenght of mortars made with 80 parts cement and 20 parts admixtures attained in fact maximum point (140 Kg/cm^2) when slag:sulphate ratio was about 15:5.

Partial replacing calcium sulphate by sodium sulphate increases one-day strenght (196 Kg/cm^2) when clinker:slag:calcium sulphate:sodium sulphate ratio equals 80:16:1:3. Sodium sulphate does not however exceed 2% in order to prevent efflorescences.

With reference to grinding time of slurry, a milling time longer than 25 minutes gave a negligible improvement of mortar strenght.

With reference to the slag and anhydrite (or sodium sulphate) mortar content (for a constant amount of sulphates), the optimum slag amount was found to be about 15%, when 4% sulphates is present.

Water:cement ratio higher than 0.5 decreases strenght for samples prepared with clinker:slag:anhydrite:sodium sulphate ratio 81:15:2:2, while strenght ratio for mortar specimens with and without admixtures increases with water:cement ratio.

The opportunity of a separate grinding of blast furnace slags and of portland cement has been emphasized by Stutterheim too, (3) in comparison to the integral one.

It's known that slag tends to vary considerably in grindability, depending upon composition and granulation conditions. Moreover slag is generally much harder to grind than portland cement clinker, so that slag component of an integrally ground cement tends to be coarser than the clinker component. Slag is besides much easier storable than portand cement.

In order to improve quality, reduce costs and produce more uniform materials, the use of separately ground slag, successfully adopted in South Africa, appears to be profitable.

Separate grinding in fact gives control over fineness and uniformity of quality. Slags and clinker can be ground in geographically separated plants in the environs of the production sites and the mixtures prepared on the construction site with different slag:clinker ratio, and with slags of different specific surface. Concretes with properties variable in a pretty large range are therefore obtainable at the discretion of the consulting engineer. The resultant product compares favourably with portland cements for civil engineering works.

With finely-ground slag available at the construction site, concrete workability can be significantly improved. It's therefore possible

to reduce water content compared to the case for portland cement and gain higher strenghts at long stages and lower shrinkage.

The ex-factory cost of ground granulated slag is finally appreciable lower than that of portland cements.

The problem of evaluating slag hydration rate in slag cements has been tackled by Kondo and Ohsawa (4). The possibilities of determining the amount of unreacted slag on the hydration process of slag and slag portland cement pastes, prepared by mixing granulated slag (Blaine 4000 cm^2/g) and portland cement (Blaine 3100 cm^2/g) in the ratio 40:60 and 70:30, respectively, hydrated at 20°C with water:cement ratio 0.4 for different time intervals, have been thoroughly investigated.

Super sulphate slag cement pastes, composed of granulated slag, calcium sulphate and tricalcium silicate in the weight ratio:80:15:5 and tricalcium silicate-slag pastes, prepared in the weight ratio:50:50, with water:cement ratio 0.5, were also examined.

Conditions in which unhydrated slag of slag portland cement hydrated pastes is pratically undissolved, while most of the hydrated slag, clinker minerals and their hydrates are dissolved, have been determined, by adopting a method established by Takashima and improved by the authors.

This method bases itself on the following principle: in a salicylic acid and aceton-methanol solution, slag is pratically insoluble, while most of the hydrated slag, some clinker components and their hydration products dissolve. The method accuracy can be exalted by making some corrections concerning the insoluble or less soluble constituents of the examined cements (aluminate, ferrites, etc.) in the above mentioned solution.

Is therefore possible to determine both the slag content of a cement and the hydration rate of the slag.

The Authors have moreover investigated the chemical composition of the hydration products and the reaction rate of each component: slag, tricalcium silicate etc., as well as the thickness of the reacted layer on the slag and on C_3S particles.

The graphics obtained from experimental data show the unreacted slag percentage in the different type of cement examined, versus hydration time, as well as the reacted slag percentage (in respect of the amount of total slag contenened in the samples) versus hydration time.

Those graphics showed that hydration rate of the slag contained in every type of slag cement is unexpectedly slow.

For all type of cement the experimental results showed that the proposed method is satisfactory and reproducible, particularly by making corrections owing to the fact that a fraction of unreacted slag dissolves into solution (0.7%); a fraction of C_3S is insoluble as well C_3A, C_4AF and the high sulphate form of calcium sulphoaluminate.

Referring to a cement manufactured with slag and clinker, it is necessary to make the following corrections concerning the slag soluble fraction and the clinker components, according to the relation:

Unreacted slag = Insoluble part - clinker x 0,211.

It's to be noticed that the treatment of portland cement with the solvent solution leaves off an insoluble part equal to 21.1%.

Considering that the treatment of ettringite with the solvent solution leaves off an insoluble fraction equal to 61.5%, the unreacted slag amount in the supersulphate cement can be obtained from the follo-

wing relation:

Unreacted slag = Insoluble part - formed ettringite x 0.615.

The formed ettringite amount can be in turn obtained by determining the free calcium sulphate in the cement by the Forsen method and subtracting the reacted calcium sulphate amount (assuming that calcium sulphate forms ettringite only).

The determinations of non evaporable water, free lime, $Ca(OH)_2$ crystals size, free $CaSO_4$ in the above mentioned cements and the x-ray patterns of the newly formed products in the pastes have been also reported by the Authors, together with the connections between the thickness of the layer formed around C_3S (and unreacted slag particles, and the hydration rate of cement pastes. The slowing down of hydration reactions has been after all ascribed to the formation of a sheat around the unhydrated particles.

Cesareni and Frigione (5) have thrown light at the physico-chemical phenomena which occur during hydration of slag portland cement. Hydration process of slag portland cement, in comparison to portland cement, has been investigated by means of experimental methods proposed by Powers and collaborators, namely:
fresch pastes sedimentation; non evaporable water content, surface area and porosity of hardened pastes. Slag cements were prepared by mixing different amount of three types of slags with three types of industrial clinkers, rich in tricalcium silicate and containing different amounts of tricalcium aluminate, with 4% gypsum addition. Wagner specific surface values were about 1850 cm^2/g.

It has been pointed out that a small amount of non-evaporable water

caracterizes hydrated pastes containing slag, though they give place to a gel production similar to that of portland cement pastes. For mixtures containing up to 50% slag, this fact can be interpretated both on the basis of a lower content of $Ca(OH)_2$ and $3CaO.SiO_2$, and with reference to pozzolanic activity of the slag. For mixtures richer in slag, the lower content of non evaporable water attributable to gel, is rather difficult to explane.

It is Author's opinion that the lower content of lime gives place to a more impermeable gel which retard the hydration process and interfere with pozzolanic activity, owing to the a topochemical absence of lime.

Lower basicity of the newly formed products also must be taken into consideration, because of the lower water demand.

Chemical composition of the clinker, particularly tricalcium aluminate content, affects hydration phenomena of the slag, rather indipendently of the type of the slag. The higher content of C_3A seems to influence positively slag hydration. Bleeding capacity and velocity of fresch pastes increase with slag content. The porosity of there pastes is moreover lower in comparison to portland cement.

Physico-chemical phenomena which caracterize hardening process of slag portland cement pastes appear therefore very similar to those concerning portland cement pastes, at least up to 50% slag content.

Portland cement containing more than 50% slag seems to be somewhat different both for the amount of fixed lime and for physico-chemical caracteristic of the pastes.

With reference to the connections between slag chemical composi-

tion and the properties of the corresponding cements, Cheron and Lardinois (6) have studied the influence of magnesium oxide and alumina on the hydraulic properties of granulated industrial slags.

Industrial slags as well as synthetic slag samples obtained by melting and granulating industrial slags and pure oxide mixtures were examined. Slags hydraulic activity was evaluated by determining mechanical strengths (according to the Rilem Cembureau method) of cements obtained by mixing 20;50 or 70% slags separately ground, with 3% gypsum to a 3500 or 4500 Blaine finesses, with standard portland cement containing 3% gypsum to a 3300 Blaine finesses.

Slags and clinker have been separately ground in order to prevent differences in the specific surface due to different chemical composition of the slags. Considering that a partial crystalline state affects hydraulic values, slags vitrosity was checked by X-ray diffraction.

Mechanical tests data obtained after 3 and 7 days were tabulated and plotted in ternary diagrams which showed the beneficial influence of the Al_2O_3 and MgO on the compressive strengths. Such an influence has been also confirmed by 28-days strengths.

Ternary diagrams result from quaternary $CaO-MgO-Al_2O_3-SiO_2$ diagram, by maintaining constant at the levels 9;12 or 15% the Al_2O_3 content.

A linear relation between slags chemical composition and the mechanical strenght of the corresponding cements has been also experimentally deduced, and expressed by the formula:

$$I_h = \frac{CaO + 1,4\ MgO + 0,56\ Al_2O_3}{SiO_2} ,$$

which is in good agreement with the one proposed by Tetmayer. For I_h

values lower than 1,4 a better correlation is obtained when the coefficient 0,56 for Al_2O_3 is replaced by the 0,70 value.

The states of coordination of Al, Mg and Mn ions in synthetic slag glasses corresponding to compositions of the Indian slags which are characterized by comparative lower $CaO:SiO_2$ and higher $Al_2O_3:SiO_2$ ratios, have been determined by Chopra and Taneja (7).

It's known that hydraulicity of granulated blast furnace slags, used for the manufacture of slag cements, is influenced primarly by $CaO:SiO_2$ ratio and by the content of each of the oxides of aluminium, magnesium, manganese etc. Since the stability and the rate of solution of slag glasses, which are foundamental for hydraulic hardening, are dependent upon glass constitution, it is important to know how aluminium, magnesium and manganese oxides are present in the glassy structure.

Six different series of glasses with molecular formulae given below were prepared

Series	Glass composition	n (in moles)
A	$10CaO.8SiO_2.nAl_2O_3$	1 to 7
B	$10CaO.nSiO_2.3Al_2O_3$	7 to 10
C	$10CaO.(10-n)SiO_2.nAl_2O_3$	1 to 4
D	$10CaO.8SiO_2.4Al_2O_3.nMgO$	1 to 4
E	$(12-n)CaO.8SiO_2.4Al_2O_3.nMgO$	
F	$9CaO.8SiO_2.3,5Al_2O_3.nMnO$	0,5 to 1,5

The coordination state was determined by a combination of techniques such as specific volume, molar refractivity, fluorescence in U.V. light, differential thermal analysis. Density determinations were performed by the displacement method (samples weighed in air and in xilene at 27°C,

referred to water at 4°C). Refractive index of powdered glass (passing at No 100 B.S. sieve) was measured by the immersion method, employing liquids of known refractivity indices and examining the Becke line under a microscope.

The total molecular refractivity of a glass was calculated with Lorentz-Lorenz equation. Differential thermal analysis were performed on glass powdered samples diluted with an equal amount of periclase of the same fineness, with heating rate of 10°C per minute up to 1100°C. For magnetic susceptibility measurement a semi-micro aperiodic balance was used; change of weight of the sample (powdered glass) before and after exciting the electromagnet with a 3 amp. current was observed, ferrous ammonium sulphate being used for calibration purposes.

The state of coordination of Al ions was studied by determining the effect of varying Al_2O_3 content on the density and refractive indices of series A, B glasses. The partial molar refractivity of Al_2O_3 indicated that Al ions are always present in four-fold co-ordination. This was also supported by the value of partial specific volume of Al_2O_3 and the rise in temperature of the exothermic peak due to devetrification on substituting increasing amounts of alumina in place of silica in series C glasses. Similarly, partial molar refractivity of magnesia in series D, E indicated a four-fold state of coordination of Mg ions. This was also confirmed by the purple fluorescence of Ni ions in glasses where part of MgO was substituted by NiO. The average value of partial molar refractivity of manganese oxide in series F glasses showed that manganese ions were present in six-fold co-ordination. This was also indicated by the red fluorescence of manganese glasses. The partial molar

refractivity data however indicated further that a part of manganese was present in a higher state of valence and the magnetic susceptibility measurement confirmed that about 18 ÷ 24% of Mn was present in trivalent state.

The connections between cooling rate and mineral composition of blast furnace slags have been investigated by Hideo Minato (8), by means of chemical analysis, X-ray diffraction, optical and electron microscopy. Composition of slags examined ranges as follows:

SiO_2 30 ÷ 35; Al_2O_3 13 ÷ 20; MgO 2 ÷ 6; CaO 40 ÷ 50%.

Six different water quenched slags, examined by X-ray powder method, showed essentially glassy structure with presence of small amounts of melilite (faint 2.8 Å peak). This result is confirmed by the observation of thin sections under polarizing microscope.

Three different slow cooled slags were examined. A stalactitic body spontaneously grown in a cavity inside one of them, and two melilite single crystals isolated in two different slags, have been also studied.

The former shows enrichment of manganese, alkalies and sulphur in comparison with the corresponding slag. Melilite single crystals showed a characteristic zonal structure under the polarizing microscope; its nucleus appeared to be highest in gehlenite while the rim lower.

General constituents of slow cooled slag are melilite, dicalcium silicate and pseudowollastonite.

As it concerns raw materials, Pai and Hattiangadi (9) have investigated the possibility of manufacturing a cementitious product from low grade limestone (unsuitable for portland cement manufacture because the high silica and magnesia content) and from alumina rich materials (such

as bauxite and laterite). These raw materials, after being activated by portland cement, hydrate to give a strenght producing compound.

The process consist in grinding the low $CaCO_3$ stone with bauxite to the same fineness as cement raw materials, melting it and quenching the melt in a manner analogous to the granulation of blast furnace slag. Using the results of previous investigation in the $CaO.Al_2O_3.SiO_2$ and $CaO.MgO.Al_2O_3.SiO_2$ systems as a basis, composition were chosen to have "liquidus" temperature below 1350°C; the melts were fired to 1450 ÷ 1500°C in order to preserve the vitreous state during the quenching with water.

It is now generally agreed that a Ca:Si ratio between 1,5 ad 2,0 in the tobermorite gel obtained by hydration of C_3S and C_2S, is desiderable from the point of view of the mechanical strenght of the hardened paste. Considering this, C_3S alone must be regarded as a too basic component of anhydrous cement, even if reacts with acceptable speed at earlv stages of hydration and if the excess of lime, not combined in tobermorite, forms plates of $Ca(OH)_2$ which give a high pH environment for protecting the reinforcing steel. In the same time this lime is a source of weakness when sulphates are present. The use of a less basic anhydrous material could be, therefore, an advantage; since it is not possible with cristalline solids, the use of materials in the vitreous state offers a possible solution.

A furnace employing butane gas as fuel and developing 1550°C in three hours was used. Nodules of precalcined raw mix were molten in the furnace and quenched in water. The glass content was estimated with the optical microscope and was generally well above 90%. The quenched melt

was ground with portland cement clinker and 5% gypsum. The clinker had a potential C_3S content of about 35%.

The compressive strenghts were tested on 2" mortar cubes prepared according ASTM method of test n° C 109-64 when small quantities of glass were available. When larger quantities of glass were prepared, 4" concrete cubes made according to the British Standard 12-1958 were tested in addition to the mortar cubes above.

The products of hydration were identified by D.T.A. and X-ray diffraction. Cement low in Al_2O_3 and high in Fe_2O_3 showed ettringite up to 7 days in addition to tobermorite. They gave poor strenght, larger exothermic effect due to unreacted glass as well as a fair amount of $Ca(OH)_2$ which has not been taken up by the melt due to its slow hydration.

Those higher in Al_2O_3 gave monosulphates at same ages, and showed traces of lime indicating that lime released by portland clinker has been immediately fixed up by the reactive melt.

Suitable compositions with "liquidus" temperature and compressive strenght have been thoroughly investigated.

Paper No. IV-130

A COMPARATIVE ASSESSMENT OF THE RESISTANCE OF SUPERSULPHATED, SULPHATE RESISTANT PORTLAND, AND ORDINARY PORTLAND CEMENTS TO SOLUTIONS OF VARIOUS SULPHATES AND DILUE MINERAL ACIDS

G. H. Thomas (United Kingdom)

Of the three papers in the subgroup of Session IV-3, the first paper entitled 'Anhydritecement' by Prof. Hute reports in main the findings of an investigation on the development of a synthetic cement composed of mainly blast furnace slag and the anhydrite obtained by calcining waste gypsum from the phosphoric industry. The basic approach in this investigation is the search for an optimum composition of the anhydritecement which will result not only in highest possible mechanical strengths but also possess other physical properties comparable to those of portland cement.

The anhydrite cement reported to have been used sucessfully in Asiatic Russia and Germany consists of ground gypsum anhydrite ($CaSO_4$) and a catalyser (1,2). The anhydrite cements under report additionally contain ground blast furnace slag as the third component and are akin to anhydrite-slag binders of Grimme (1). In this investigation anhydrite was prepared by calcining waste gypsum (76% $CaSO_4$, 1.15% total P_2O_5 and 1% Fe etc.) at 850-900°C. "Quenched" blast furnace slag having CaO from 35 to 45 per cent, SiO_2 preferably 30 to 33 per cent but not more than 35 per cent, Al_2O_3 not less than 15 per cent, and S not more than 1.5 - 1.8 per cent is recommended for use. The third component is a new catalyst and consists of a mixture of K_2SO_4, $Ca(OH)_2$ and the Lafarge

*Central Building Research Institute, Roorkee (U.P.) INDIA.

aluminous cement. Each of the components of the anhydritecement was ground to a fineness of less than 63 microns.

The physical and mechanical properties of the experimental anhydritecement were tested as per the Belgian Specifications and compositional limits of the catalyst for anhydrite/slag ratio between 45/45 and 50/40 were established as 1.0 to 1.5% per cent $Ca(OH)_2$, 0.9 to 1.2 per cent K_2SO_4 and 5 to 9 per cent aluminous cement. In order to determine more precise limits for the optimum composition, the author carried out a systematic investigation on the influence of the relative quantities of the dirrerent components on the flexural and compressive strengths of the experimental cements at 3, 7 and 28 days. The author reports on more than 100 cement blends and concludes that the strongest anhydrite cement is obtained with a 50/40 anhydrite/slag ratio and the optimum composition of the catalyst for the anhydrite-cement to be strong at 3 days are aluminous cement 6-7%, $Ca(OH)_2$ 1.5% and K_2SO_4-1.2%. For anhydritecement to be strong at 28 days a higher proportionof aluminous cement (8 per cent) and lower proportion of lime (1.1%) are to be used. Such cements show compressive strengths in the range of 400 to 550 Kg/cm^2 at 28 days and satisfy the requirements specified for ordinary portland cement except that initial set takes longer time. Although full information on long-term performance and scope of application of this class of cement under different environments is lacking, this piece of work is of great interest as byproduct gypsum or anhydrite is available in many countries for disposal and utilization, and production of a cement from it is an attractive and profitable proposition.

In the second paper entitled "Chemistry of Slag-rich Cements" Dr. Yang reports and discusses the setting and hardening characteristics of slag-rich cements and evaluates their scope of application. The slag-rich cements are defined as those consisting mainly of 65 to 95 per cent of slag and the balance of portland cement or anhydrite or both. This study pertains to five different American slags and one high magnesia slag from South Africa. Hydration of slag cement under normal curing conditions was studied on pastes at a water/solid ratio of 0.60. A water suspension of of 2 grams of slag cement in 40 distilled water was used for studying hydration under hydrothermal conditions.

Ettringite and tobermorite like CSH-I are reported as the main binders in a supersulphated cement composed of 83% slag, 12% gypsum anhydrite and 5% portland cement and hydrated at atmospheric pressure and temperatures below 75°C. Hydration at 95°C was found to result in the formation of tobermorite and a poorly defined hydrogarnet. Under hydrothermal conditions, i.e. at 100 psi. and higher, ettringite decomposed to fine crystalline $CaSO_4$ which recrystallized during hydration process and grew to crystals upto 20 microns. In view of this and likelihood of delayed expansions due to the action of free CaSO4 with slag constituents in a set product supersulphated cement is recommended for use only for air cured products requiring good sulphate resistance and not for autoclave cured products.

The main hydration products identified in a slag cement containing 25 per cent of portland cement are CSH-1 and $C_4A\ H_{13}$ or its solid solution with $3\ CaO.\ Al_2O_3.\ CaCO_3.\ 12H_2O$. These findings are in general agreement with the main conclusions

of the hydration studies reviewed in the principal paper by Schroder (3). However, it is noteworthy that the slag cement prepared from a slag containing about 15% magnesia does not show upon hydration any detectable free MgO or $Mg(OH)_2$. It will be interesting to know how magnesia is consumed and how it affects the properties of the set cement products.

Under hydrothermal conditions of curing, blast furnace slag cement yielded tobermorite and hydrogarnets, the latter bestowing sulfate resistance and high resistance to carbonation. As autoclaving temperatures approached 225°C the reaction rims around slag grains were found to thicken and a hydrogarnet resembling plazolite was formed. At still higher autoclaving temperature of 300°C, the hydrogarnet formed resembled hibschite.

Addition of silica flour to the slag rich cements in amounts more than 30 per cent was found to check the formation of hydrogarnets and produce greater quantities of CSH compounds and consequently higher strengths. Another advantage mentioned by the author is the lowering of production costs.

The scope of application of slag cement in producing autoclaved asbestos-cement building products was also investigated upon by the author. Flexural strengths of autoclaved specimens consisting of 20 per cent chrysotile fibre blend, 40 per cent silica flour and 40 per cent slag-rich cements are reported and compared with the strengths of a blend of 20 per cent asbestos fibre, 30 per cent silica and 50 per cent Type I portland cement. The data show that optimum strength is achieved with a cement consisting of 75 per cent slag and 25 per cent portland cement at autoclaving pressure of 100 to 125 psi. The slag-rich cements

were further evaluated in a pilot plant and the setting properties and mechanical strengths of asbestos cement pipe products show that satisfactory autoclaved formulation can also be achieved when portland cement is replaced by a blast furnace slag cement. The results of corrosion tests for soft water and dilute sulfuric acid also point out to the soundness of using blast furnace slag cement in producing asbestos cement products.

The last paper in this group by Mr. George H. Thomas reports the results of a specific investigation on the relative merits of a supersulphated cement for use under aggressive environments. The comparative assessment has been based on the results of three different groups of tests carried out on the commercial brands of a supersulphated cement, a sulphate-resisting protland and ordinary portland cement.

In the first group of tests 28 days old specimens of a rich concrete mix were immersed separately in six solutions of sulphates of sodium, magnesium and ammonium, each having two levels of SO_3 concentration as 0.35 and 3.5 per cent, and also in 0.25 and 2.0% W/V of H_2SO_4 solutions. The sulphate resistance was assessed mainly by determining compressive strengths of the specimens after 8 to 10 years storage in aggressive waters versus storage in ordinary water, and statistical methods were employed for analysing the data. The temperatures of storage of specimens in different solutions are not mentioned, it is presumed that tests were done under controlled temperature in view of storage temperature being one of the variables (4).

In the second group of tests the comparative assessment of the acidic resistance of the supersulphated cement was made by

subjecting three different batches of the supersulphated cement concrete to attack in an experimental section of the sewer at Burton-on-Trent. The basis of evaluation were the same as for the tests in the first group.

The third group of tests aims to assess aggressive solution resistance of cement rapidly by immersing ½ inch micro-concrete cubes, prepared from a mix consisting of graded washed silica sand, cement and water adjusted to a constant workability, in sulphate solutions. The curing and testing procedures of the specimens were the same as for tests in the first group.

The results and conclusions of each group of tests are reported in the paper. The statistical techniques have helped undoubtedly in differentiating between the real effects of the different aggressive solutions and the experimental variations. But the author has rightly cautioned that statistical superiority or inferiority should not be taken to imply satisfactory or unsatisfactory performance or life. His other recommendation is that, apart from the general trends of attack of aggressive solution, the rate of deterioration and the residual strength of a cement must also be taken into account. Finally, the important conclusions of this investigation are as follows:

(1) In sodium sulphate solutions supersulphated cement gives by far the best performance. No significant attack was registered in 3.5% SO_3 solution even after eight years. As against this even sulphate-resisting portland cement did not show satisfactory performance. However, in the 0.35% SO_3 sodium sulphate solution the advantage for supersulphated cement is less marked.

(2) Although the sulphate-resisting portland cement gave a statistically better performance in 3.5% SO_3 solution of magnesium

sulphate, in real terms neither this nor supersulphated cement appear to be suitable for use in such high concentrations of this salt. But both of these cements resist the attach of weaker solution of 0.35% SO_3 concentration and the supersulphated cement shows somewhat better resistance.

(3) All the three cements e.g. sulphate-resisting portland, ordinary portland and supersulphated are attacked by ammonium sulphate solutions with 0.35 and 3.5% SO_3 concentration, but again supersulphated cement shows better performance.

(4) The results of both the first and second group of tests in this study confirm the earlier reports about the superiority of supersulphated cement in weak sulphuric acid concentrations.

General Report on Supplementary Papers

Part IV - 4 - "Expansive Cements"

by George Verbeck*

The authors of each of the seven Supplementary Papers on Expansive Cement are to be complimented for their contributions to the subject. In addition, and most fortunately, the papers encompass a broad range of areas of interest concerning such cements and their uses.

These papers total 152 pages of text, 92 tables, and 145 figures. Needless to say, it will not be possible to present more than a few of the significant contributions contained in these papers.

Broadly speaking, and for convenience of discussion, the papers may be separated into three general categories:

(1) Four papers primarily concerning clinker phase formations in the C-A-$\overline{S}$ system and the influence of phase composition on the hydration process, and the study of the nature of the hydration products using a variety of techniques,

(2) Two papers primarily on laboratory studies of concretes including those made with all three types of expansive cements; the factors affecting expansivity and cracking tendency and the various engineering properties of such concretes, and

(3) A paper describing practical field experience with an expansive cement in wall plastering, floor topping, pipe lining, reinforced concrete beams, roof slabs, and a pavement.

Regarding the papers on clinker phase compositions in the C-A-$\overline{S}$ system and the nature of the hydration products, Klein and Mehta prepared

*Director of Materials Research Department, Research and Development Division, Portland Cement Association, Skokie, Illinois

mixtures of high-purity $C_4A_3\overline{S}$, calcium sulfate, and calcium oxide at A to $\overline{S}$ molar ratios from 0.25 to 1.25 and C to $\overline{S}$ molar ratios from 2.0 to 8.0. The products of hydration of 45 such mixtures were determined by X-ray diffraction techniques. The formation of ettringite, considered to be required for expansivity was observed in varying amounts except for mixes having A to $\overline{S}$ ratios greater than 1 along with C to $\overline{S}$ ratios greater than 4. A phase diagram was presented to show the nature of the final hydration products in the over-all system. Monosulfate hydrates with 18 and 12 moles of water were also observed and a third monosulfate hydrate, perhaps having 15 moles of water was postulated.

Fukada prepared a wide range of clinker compositions in the C-A-$\overline{S}$ system and identified $C_4A_3\overline{S}$ as the only ternary compound formed. With the addition of silica the clinker may contain C_2AS. When the raw mixture contains sufficient calcium and sulfate the silica appears to have no effect on the formation of $C_4A_3\overline{S}$. When $C_4A_3\overline{S}$ is mixed with normal portland cement and hydrated, ettringite will not be formed and expansivity not observed unless sufficient additional sulfate is present to compensate for the alumina in the portland cement fraction. Quick setting was attributed to the formation of C_2AH_8 the formation of which can be controlled by the addition of gypsum.

Nakamura, Sudoh, and Akaiwa studied the clinkering of mixes of a kaolin clay (containing about 40% S and 30% A), limestone, and gypsum and showed that the mole ratio of C to (A + 2S + 3F) must be greater than 1 to form $C_4A_3\overline{S}$ which was, under such circumstances, the only alumina-containing compound except for $C_{10}A_2F_3$. By means of X-ray diffraction they also showed that below 1285°C a ternary silicate compound $C_5S_2\overline{S}$; forms and above 1285°C this is decomposed

into β-C_2S and $C\bar{S}$. The heat of hydration of $C_6S_2\bar{S}$ was shown to be very similar to that of β-C_2S. Differential thermal analysis, electron probe, electron microscopic, and calorimetric techniques were used to study the clinkers produced and the hydration products. X-ray diffraction and microscopic studies revealed that ettringite formation is necessary for expansion and that only the ettringite formed in the presence of a high lime concentration is effective. Quick setting with this experimental cement could be controlled by adding gypsum, and the resultant increase in expansion was controlled by the addition of blast-furnace slag.

Okushima, Kondo, Muguruma, and Ono also showed a high lime concentration to be necessary for expansion and studied the hydration reactions of pure materials using X-ray diffraction, light microscopy, differential thermal analysis and thermogravimetric analysis. They concluded on the basis of a special experimental technique that the hydration product forms directly on the surface of the $C_4A_3\bar{S}$ or C_3A grains and proceeds from the initial formation of the monosulfate to ettringite at that location. Clinkering studies indicated that relatively large crystallite size and particle size of the $C_4A_3\bar{S}$ produced the best expansivity. The relationships between pore size and expansion and shrinkage characteristics were studied. The authors described the manufacture of expansive cements of the $C_4A_3\bar{S}$ type and discussed those general characteristics of a sulfoaluminate-containing cement necessary to reduce shrinkage cracking in concrete and the need for residual compressive stress in the concrete after shrinkage. They also discussed the role of creep in restrained concretes and the factors of importance to the use of this cement for chemical prestressing. They showed that high expansions tend to give low compressive strengths. Data showing the effect of restraint (up to 1.6% steel) on expansion and strength were

included.

As previously mentioned, two of the papers primarily concerned laboratory studies of mortars and concretes made with expansive cements and the engineering properties of such concretes. These two papers generally confirm and supplement each other.

The paper by Nishi, Harada, and Koh, as with the other previously discussed papers, dealt only with expansive cement made with the calcium sulfoaluminate type clinkers, sometimes referred to as Lossier or Klein type expansive cement. In reality this paper is an extensive collection of the works of 15 different investigators representing 12 different universities, institutes, or organizations and the many important results cannot be adequately summarized briefly.

The study of factors influencing the expansion and shrinkage of mortars and concretes included the effect of

- the composition and amount of the calcium sulfoaluminate clinker used
- the paste content and water-cement ratio of the concrete
- the use of normal weight or lightweight aggregate
- the moisture condition, temperature, and duration of curing, and the use of different steam curing cycles, and
- the use of admixtures (an air-entraining agent, a water-reducing agent and a set-retarder).

In addition to these broad studies regarding expansivity under various conditions, many test results were reported on the engineering properties of mortars and concretes produced under various conditions. These studies included the determination and the comparison with normal portland cement concretes of

- the compressive, flexural and tensile strength properties of such concretes
- the elastic modulus and creep properties
- pull out bond tests of reinforcement
- the rate of carbonation and rusting of embedded steel
- the chemical resistance (to acid, to alkali, and to seawater)
- the resistance to freezing and thawing, and
- the fire resistance and thermal conductivity of such concretes.

Broadly speaking, if the expansion of the concrete was not excessive, the engineering properties would be considered essentially normal for the quality of concrete evaluated in comparison with non-expansive concretes. It should be noted that most of these studies involved the use of non-restrained concretes.

I have enumerated these various factors to demonstrate the breadth of the paper and the wealth of information the paper contains.

The paper by Klieger and Greening also concerned factors influencing expansivity and the properties of shrinkage-compensating and self-stressing concretes. However, the paper differed from the other supplemental papers in that it compared results obtained with all three types of expansive cements as currently recognized and defined by the American Concrete Institute as follows:

(1) Type K, the Klein or Lossier type, the essential ingredient of which is an anhydrous aluminosulfate such as has been discussed in the previous papers. (Currently this general type of cement is being produced in the U.S.A. in three different ways, as an enriched clinker subsequently

blended with portland cement, in a single integral clinkering operation, and as an enriched clinker having, unlike the aforementioned clinkers, a low free lime content).

(2) Type M, the Mikhailov type, which is a mixture of portland cement, calcium aluminate cement, and calcium sulfate, and

(3) Type S, sulfated cement, which is made from a high C_3A clinker (about 20% calculated C_3A content for shrinkage-compensated cement) and calcium sulfate in a quantity above the usual optimum for portland cement.

It is shown that each of these types of cements, adjusted to the same level of expansive potential, will perform in an approximately similar manner and produce concretes having essentially similar engineering properties.

As in the previous paper, many of the factors influencing expansivity and the physical properties of the resulting concretes were studied, but for concretes made with all three basic types of expansive cement, and in addition, comparisons were made with similar concretes made with ASTM Types I, II and V cements.

The effect of degree of restraint was studied in some detail and for many of the concretes evaluated the expansion had been partially restrained. Additional factors studied include the effects of duration of mixing and the evaluation of the long-time volume stability of concretes subjected to alternate wetting and drying, and resistance to de-icer scaling and surface abrasion.

The last paper by Ohno, Nakamura, and Saji summarizes the work of 14 individuals and 5 different universities or organizations. It is largely devoted to description of practical field experiences in the use of the calcium sulfoaluminate type of expansive cement.

The usefulness of expansive mortars was evaluated in wall plastering, floor topping and pipe lining. If the expansive level was sufficiently high, the cracking of wall plaster was avoided. This may be attributable to the modest degree of restraint offered by the concrete subbase wall and perhaps to the expansive tendency of the mortar during the early period during which the mortar was subjected to drying and drying shrinkage. These two effects could offset each other during the early and most critical stages of drying when the mortar has not developed sufficient tensile strength to resist the shrinkage stresses that would otherwise normally occur. As a floor topping, excessive expansion was observed -- this is attributed to the extended period of water curing used and an excessively high level of expansive component. Satisfactory performances as a pipe lining was observed. This is presumed related to the high degree of restraint afforded by the confining pipe.

The authors report encouraging results with the use of shrinkage-compensating cements in large-scale reinforced concrete specimens, slabs and beams, the results depending upon the inherent expansivity of the cement and the amount and type of reinforcement. The authors used this shrinkage-compensating cement in construction of an instrumented, reinforced concrete building and reported distinct benefits in decreasing shrinkages and cracks. In addition they reported lack of cracking (to date) in instrumented experimental concrete pavements made with shrinkage-compensating and normal portland cement concrete.

In summary, these papers demonstrate that the chemistry of the expansive sulfoaluminate type of cements and their hydration products is well advanced. Many factors that influence the expansivity have been elucidated and many of the practical engineering properties of such concretes

determined. There appears to be further need for suitable engineering design criteria for the use of such cements in various types of applications. With proper design criteria the construction of suitably engineered structures will permit proper evaluation of the technologic and economic aspects related to the use of expansive cements.
