Investigations of cement paste have shown that on hardening of calcium sulfoaluminate calcium hexagonal hydroaluminates and ettringite revealed on the radiograms of hydrated samples even after an hour from the moment of preparation of samples are formed. A size of crystals increases by the period

of 28 days. To this moment the sample is characterized by a high density. The distinctly formed crystals of new formations are in a close interweaving with each other. The interspaces consisted of the net of acicular crystals are filled with dense mass probably formed from  $Al(OH)_3$ .

#### DISCUSSING OF RESULTS

It has been found that regardless of w/c ratio accepted for the investigation of samples hydration products have a similar habit. Morphology of crystals, hydrate compounds typical of an early stage of hydration does not practically change during more prolonged hardening. Increase in the crystal size is only observed. Nature of crystallization of hydration products together with a chemical composition of a liquid phase make possible to say that hydration of  $C_3A_3CS$  proceeds through solution of a starting grain and crystal growing of hydrate compounds in solution as well as by water diffusion inside the  $C_3A_3CS$  grain and crystallization and growth of tubular ettringite on the surface of an anhydrous starting particle with formation of gel of aluminum hydroxide.

**CONCLUSION.** On hydration of  $C_3A_3CS$  at an early stage two types of hydrate compounds have been discovered: a gel-like phase and tubular crystals which formation was found on the surface of a starting cement particle, on aluminum hydroxide as a substrate and through crystal growing in solution. The data obtained can be used as an explanation of the mechanism of hydration and expansion of cement stone.

# Utilisation des réactions de formation de l'ettringite pour l'action orientée sur les processus de formation de structure du ciment durci

## *Use of ettringite formation reaction for directed influence on the structure formation processes of the cement stone*

I.V. KRAVTCHENKO, Professeur, Docteur ès Sciences Techniques,  
V.L. BERNSTEIN, Collaborateur Scientifique, Candidat ès Sciences Techniques, Niitsement,  
Youguiprotsement, U.R.S.S.

Sur la base des calculs thermodynamiques et des études physico-chimiques complexes on a montré qu'il est possible de commander la réaction de formation de l'ettringite dans le système contenant les aluminates de calcium de diverse basicité -  $C_3A$  et  $CA_2(CA)$ .

On a établi que l'addition contenant les aluminates de calcium faiblement basiques exerce une influence positive sur le processus d'hydratation du ciment, ses indices de résistances et propriétés techniques.

On a déduit les dépendances fonctionnelles des propriétés des ciments vis-à-vis le rapport de  $C_3A$ ,  $CA_2$  et  $CaSO_4 \cdot 2H_2O$  qui participent à la formation de l'ettringite.

Based on thermodynamic calculations and complex physical-chemical investigations, the possibility of ettringite formation reaction in the system containing calcium aluminates of different basicity -  $C_3A$  and  $CA_2(CA)$  - has been revealed.

Positive influence of the low-basic calcium aluminates containing addition on the cement hydration process, its strength characteristics and construction-technical properties have been found out.

Functional relationships between cement properties and  $C_3A$ ,  $CA_2$  and  $CaSO_4 \cdot 2H_2O$  ratio in the process of ettringite formation have been deduced.

Le processus de formation de la forme fortement sulfatée du sulfoaluminate hydraté de calcium, l'ettringite, qui a lieu lors de l'interaction du constituant d'aluminate du clinker de ciment portland avec le gypse, exerce une grande influence sur la formation de structure du ciment durci et ses propriétés. Toutefois les possibilités de cette réaction sont loin d'être utilisées complètement, ce qui est lié avant tout à la formation des pellicules de sulfoaluminate hydraté sur la surface des grains d'aluminate tricalcique.

L'objectif visé par nos études est de mettre au point le procédé de commande du processus de formation de l'ettringite par introduction dans la composition du ciment des additions contenant les aluminates. Pour choisir les additions les plus efficaces on a procédé aux calculs thermodynamiques des réactions d'hydratation dans le système aluminates de calcium - gypse - eau -  $\text{Ca}(\text{OH})_2$ . On a établi de cette façon qu'il est rationnel d'introduire dans la composition du ciment des additions contenant les aluminates de calcium faiblement basiques -  $\text{CaO} \cdot 2\text{Al}_2\text{O}_3$  et  $\text{CaO} \cdot \text{Al}_2\text{O}_3$ .

Selon les calculs thermodynamiques, dans le système contenant simultanément les aluminates de calcium de diverse basicité:  $3\text{CaO} \cdot \text{Al}_2\text{O}_3$  et  $\text{CaO} \cdot 2\text{Al}_2\text{O}_3$  la formation de l'ettringite aura lieu avant tout grâce à l'interaction du gypse avec  $\text{C}_3\text{A}$ , ce qui est dû à une plus grande valeur absolue de la variation du potentiel isobare-isotherme de cette réaction (-45 kcal/mole). Après que toute la quantité possible de  $\text{C}_3\text{A}$  fut liée, ce qui est limité aux stades d'hydratation précoces par la composition du milieu et les facteurs cinétiques, la fixation du gypse continue grâce à son interaction avec le dialuminate de calcium qui se caractérise par la valeur du potentiel  $Z$  égale à -7 kcal/mole. Ceci nous permet de supposer qu'en présence dans le milieu du ciment durcissant des aluminates de basicité différente le processus de fixation du gypse a un caractère continu, ce qui nous permet de commander le processus par variation du rapport des aluminates de calcium et du gypse qui prennent part à la réaction.

Les études physico-chimiques effectuées sur des mélanges différents de matériaux

synthétisés avec utilisation de l'analyse aux rayons X, de la spectroscopie infrarouge et de la microscopie électronique ont permis d'établir les faits suivants. Lors de l'interaction du dialuminate de calcium avec le gypse il se forme l'ettringite, produit final de cette réaction, qui reste stable durant un temps prolongé indépendamment du rapport des constituants de départ. Une faible vitesse de cette réaction conditionne la cristallisation de l'ettringite sous forme de gros cristaux de forme prismatique avec un rapport d'axes peu élevé (jusqu'à 3-5). La structure dense du ciment durci est imprégnée du gel  $\text{Al}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$  qui se dégage

lors de la réaction étudiée dont l'équation stoechiométrique peut être représentée sous la forme suivante:

La vitesse de liage du gypse augmente avec l'accroissement du rapport de  $\text{CA}_2$  à  $\text{CSH}_2$ .

Le trait distinctif de ce processus est l'absence de pellicules de sulfoaluminates hydratés sur la surface des grains d'aluminate. La cristallisation de l'ettringite a lieu à travers la solution.

Les méthodes physico-chimiques étaient utilisées pour l'étude de la formation de l'ettringite dans le système où sont présents simultanément deux aluminates de calcium:  $\text{C}_3\text{A}$  et  $\text{CA}_2$ . Le traitement des données de l'analyse aux rayons X et de la spectroscopie infrarouge, donné sur la figure 1, a permis de confirmer les conclusions des calculs thermodynamiques sur l'ordre d'interaction avec le gypse des aluminates de basicité différente. Le dialuminate de calcium identifié sur les spectrogrammes des rayons infrarouges d'après la bande d'absorption de  $820 \text{ cm}^{-1}$  et sur les radiogrammes d'après les maximums de diffraction avec  $d=4,44$ ;  $2,59 \text{ \AA}$ , entre en réaction avec le gypse après la fixation de la quantité principale (jusqu'à 50-60%) de l'aluminate tricalcique (bande d'absorption de  $750 \text{ cm}^{-1}$ ,  $d=2,69 \text{ \AA}$ ).

L'introduction de  $\text{Ca}(\text{OH})_2$  ne modifie pas le mécanisme et l'ordre de succession dans lequel les aluminates  $\text{C}_3\text{A}$  et  $\text{CA}_2$  entrent en réaction avec le gypse. Cependant,

sa présence dans le milieu du ciment durcissant diminue brusquement le degré de participation de l'aluminate tricalcique à la formation du sulfoaluminate hydraté de calcium aux stades d'hydratation les plus pré-

Fig. 1. Cinétique de l'interaction des aluminates de calcium  $C_3A$  et  $CA_2$  avec le gypse

----- d'après les données de la spectroscopie infrarouge;

----- d'après les données de la radio-

graphie;

1- dans le système  $C_3A-CA_2-CaSO_4 \cdot 2H_2O$ ;

2-  $CA_2$  dans le système  $C_3A-CA_2 - Ca(OH)_2-CaSO_4 \cdot 2H_2O-H_2O$ ; 2'-  $C_3A$  dans le système

$C_3A-CA_2-Ca(OH)_2-CaSO_4 \cdot CaSO_4 \cdot 2H_2O-H_2O$

coces (courbe 2 sur la figure 1). L'excès de  $C_3A$  aux stades plus tardifs conduit à la décomposition de l'ettringite et à sa transformation en forme de monosulfate (le potentiel  $Z$  de cette réaction est égal à  $-77$  kcal/mole). Donc pour augmenter l'efficacité de l'action d'une addition il est rationnel d'introduire dans la composition du ciment une addition minérale active, par exemple le laitier granulé de haut fourneau.

Le caractère continu du processus de formation de l'ettringite à partir des aluminates de basicité différente ( $CA_2$  et  $CA_2$ )

rend possible l'intensification du processus de fixation du gypse aux stades précoces d'hydratation du ciment. Ceci conduit, d'une part, à l'élimination de phénomènes de destruction indésirables accompagnant la cristallisation de l'ettringite aux stades plus tardifs et, d'autre part, la formation d'une quantité supplémentaire de l'ettringite aux stades précoces crée les conditions pour l'expansion du ciment. La formation de l'ettringite à partir de  $CA_2$  sous forme de cristaux de forme prismatique capables de développer des pressions de cristallisation

élevées, a permis de prédire que les ciments avec une addition contenant le dialuminate se caractériseront par une valeur d'expansion

Fig. 2. Domaine optimal des compositions des ciments:

----- isolignes de résistance à la compression, kgf/cm<sup>2</sup>;

----- isolignes de dilatation linéaire, %;

----- isolignes de prise initiale, mn

sion élevée.

Par suite des recherches effectuées on a trouvé des additions efficaces ayant dans sa composition de 60 à 80% du dialuminate calcique.

Vu l'absence de données à priori sur les propriétés des ciment avec addition indiquée, les études des compositions de ciment et la détermination de leur constitution optimale était effectuées avec utilisation de la planification mathématique à deux stades de l'expérience. Sur la figure 2 est représenté le domaine optimal des compositions des ciments additionnés sur le diagramme "simplex" à 3 constituants "composition (clinker-gypse-addition) - propriété". Les compositions dans le domaine optimal se caractérisent par la résistance à la compression de 30 MPa au minimum, la valeur de la dilatation linéaire de 0,5 à 2,0%, le début de prise pas plus tôt qu'après 1 heure. Le modèle mathématique de la variation de résistance du ciment à l'âge de 28 jours en fon-

ction de la composition minéralogique a la forme suivante:

$$R_{\text{comp}}^{28} = 396,5 - 11,1x_1 + 42,7x_2 + 22,9x_3 + 0,23x_1 \cdot x_2 + 0,078x_1 \cdot x_3 - 2,32x_2 \cdot x_3 + 1,195x_1^2 - 2,58x_2^2 - 2,12x_3^2;$$

où  $x_1, x_2$  et  $x_3$  représentent la quantité du laitier de haut fourneau, du 1<sup>er</sup> addition contenant  $CA_2$  et du gypse (%).

Le traitement des équations de la régression et les études sur les clinkers de composition minéralogique différente ont permis d'établir les rapports optimaux de  $CA_2/C_3A$  et de  $CA_2/SO_3$  pour résoudre les problèmes d'accroissement des indices de résistance du ciment (respectivement de 0,8 à 1,5 et de 2 à 4) et pour obtenir une grande expansion au cours du durcissement (0,5 à 1,0 et 0,8 à 1,2).

On a étudié l'influence de l'addition contenant  $CA_2$  sur les processus de formation de structure du ciment durci. L'introduction de l'addition indiquée dans la composition du ciment diminue le temps total de fixation du gypse, cette diminution étant proportionnelle à la quantité de l'addition introduite, ce qui ressort clairement de la figure 3. L'allure de la courbe de fixation de  $SO_3$  varie également: sur la courbe cinétique disparaît la partie horizontale caractérisant la période inductive de fixation du gypse et due à la formation sur la surface des grains d'aluminate tricalcique des pellicules de sulfoaluminate hydraté. Les données de la figure 3 correspondent aux conclusions faites sur la base des calculs thermodynamiques et des études physico-chimiques des monominéraux, sur le caractère continu du processus de fixation du gypse dans le système contenant en même temps les aluminates de calcium  $C_3A$  et  $CA_2$ ; A l'aide de la microscopie électronique on a démontré l'intensification de la formation de l'ettringite aux stades précoces: pendant la période entre la fin de prise et 1 jour d'hydratation. A notre avis, ceci explique justement la manifestation par les ciments de l'effet d'expansion. La structure du ciment durci se caractérise, lors de l'introduction d'une addition, par une densité élevée. On peut dire que de gros cristaux d'ettringite renforcent la structure dense du ciment en lui conférant une résistance élevée.

L'influence de l'addition contenant  $CA_2$  sur les propriétés techniques des ciments fut étudiée en comparaison du ciment ordinaire. On a établi que le ciment avec addition indiquée se caractérise par l'accroissement accéléré de la résistance tant lors du durcissement normal que lors du traitement à la vapeur humide, et les bétons à base de ce ciment se caractérisent par l'imperméabilité et la résistance au gel élevées. L'étude des déformations du ciment avec addition contenant le dialuminate de calcium a montré que dans toute la gamme d'utilisation de l'addition (de 3 à 10%) la stabilisation

de l'expansion a lieu durant le premier jour du durcissement. L'effet d'expansion se manifeste lors du durcissement dans l'eau et à l'air.

Le trait distinctif des compositions avec addition contenant le dialuminate est la durée de prise ralentie en comparaison des autres compositions connues des ciments expansifs: prise initiale de 1,5 à 2,0 h, prise finale de 3,0 à 4,0 h.

En même temps la possibilité d'obtenir des ciments expansifs à prise rapide n'est pas exclue.

Fig.3. Influence de l'addition contenant  $CA_2$  sur la cinétique de fixation de  $SO_3$ : A-ciment sans addition; B-ciment contenant 5% d'addition; C-ciment contenant 10% d'addition.

#### CONCLUSIONS

L'introduction dans la composition du ciment des additions contenant les aluminates de calcium faiblement basiques modifie le mécanisme de formation de l'ettringite, rend possible la commande du processus de formation de structure du ciment durci dans la direction de la résolution des problèmes visant à accroître les indices de qualité du ciment et à conférer à ce dernier les propriétés spéciales.

# Portland cement strength depending on technological factors

## Micromechanism of destruction

### *Résistance du ciment portland en fonction des facteurs technologiques et micromécanisme de destruction*

B. YUODOVITCH,

B.D. KLICHANIS, Niitsement, Moscou,

OU. I. PAPIACHVILI, Institut des ingénieurs du Bâtiment par correspondance de l'U.R.S.S., Moscou,

V.G. ABRAMOVA, Institut Polytechnique - Novorossiisk, U.R.S.S.

L'accroissement de la teneur en  $C_2S$  et de la dispersion du clinker conduit lors de l'hydratation à la diminution des dimensions moyennes des agrégats cristallins de l'ettringite et de  $C-S-H(II)$ , des zones de la portlandite et accélère le cheminement des microfissures sous charge. L'amélioration de la morphologie de  $C_2S$  ne conduit pas à ces changements, car elle est liée à une moindre tortuosité des frontières entre les blocs de la mosaïque-canaux pour la pénétration accélérée de l'eau lors de l'hydratation, ce qui est montré par la méthode de la microscopie électronique à contraste de phase. L'introduction dans le ciment des constituants de cristallisation (krents) simplifie la topographie de la surface de cassure de  $C-S-H(II)$ , ce qui peut être dû seulement à l'abaissement du niveau des microcontraintes.

During hydration,  $C_2S$  content growth and clinker degree of dispersion increase lead to:

- a) ettringite and  $C-S-H(II)$  crystalline concretions average size decrease;
- b) portlandite zones decrease;
- c) microcracks development increase under load.

Morphology improvement of  $C_2S$  does not lead to such transformations since it is connected with lesser tortuousness of the boundaries between mosaic units (channels for accelerated penetration of water during hydration) - it has been demonstrated by the method of phase-contrast electron microscopy. Incorporation of the crystallizing components (krents) in the cement simplifies fracture surface  $C-S-H(II)$  topography, what can be motivated only by microtension level reduction.

**RESUME:** The growth of the  $C_3S$  content and specific surface of clinker at hydration decreases the average size of the crystalline concretions of ettringite, C-S-H (II), portlandite zones and accelerates formation of microcracks under load. Improvement of the  $C_3S$  crystals morphology does not lead to such changes since it involves more straight boundaries between the mosaic blocks, i.e. channels for accelerated diffusion of water during hydration which is shown by the phase-contrast electron microscopy method. Addition of crystallizing components ("crests") into cement simplifies the topography of the fracture surface of C-S-H (II) that may follow only after the decrease of microstress level.

The present paper deals with the results of the investigations of hardened cement paste submicrostructure (W/C-0.25 and 0.35) of a regular (1) and high-strength (2) portland cements (composition,  $C_3S$  - 61,  $C_2S$  - 16,  $C_3A$  - 6,  $C_4AF$  - 15) produced by the Zdobunovsk plant (see Table 1) performed with the use of the UEMB-100 and 100 K transmission and "Stereoscan-2A" scanning electron microscopes. Samples for TEM were vacuum dried at  $10^{-4}$  torr during 0.5 h at a temperature of 25°C and aiming self-shaded coal replicas were prepared. A layer of Au was vacuum deposited on the fracture surface before observation of the relief by SEM.

Investigations in the cement pastes of different age show that the submicrostructure is based on a two-component mutually penetrating three-dimensional netting of fibres I (ettringite, AFT; phase) and II (fibrous calcium hydrosilicates), which heals the high-strength cement paste pores after 8-10 h and the pores of a regular cement, after 14-16h. The netting pores starting from the boundaries of the cement initial particles accommodate phase III (portlandite) and phase V (gel-like calcium hydrosilicate zones) which appears 10-12 h later. By the end of the first day phase IV (AFM, in particular  $C_4AH_{13}$ ) is distributed in the form of loose nodes in the netting cells I+II. By the seventh day phase V fills almost the entire fracture surface of a high-strength cement paste by the 28th day, of a

Characteristics of Cements

Table 1.

No.	SO <sub>3</sub> , %	cm <sup>2</sup> /g S	Fraction contents				Compression strength, kgf/cm <sup>2</sup>			
			5	5-30 microns	30-60	60	1	3	28	
1	2.2	2840	12	44	28	16	112	231	560	
2	2.5	4080	23	56	15	6	225	394	673	

regular cement paste phase II of the skeleton and phase V are more dispersed in the first case. Domination of angles of 60 (120)-90° in certain knots of netting I+II, pointed out also by D.M.Roy, M.W.Grutzeck and T.Ciach, allows regarding a part of its cells as having a local rhombohedral symmetry. This determines a rhombohedral symmetry of the submicrostructure metric tensor as a whole that includes in the decisive conditions of isotropy of the cement paste non-porous part.

Investigations of the differential porosity by the mercury porometry method indicate reduction of the capillary pores volume (effective radius over 0.5 microns) in a high-strength cement (Fig.1). By the 28 day the latter becomes free from open pores larger than 3-5 microns, as compared with 10 microns at lower specific surface.

Similar investigations were performed to compare hydration structures of cement with different  $C_3S$  contents (58 and 65%) and different characteristics of clinker microstructure (average size of alite crystals 20 microns - fine-crystal clinker prepared from a mergel raw mixture, and 50 microns - large-crystal clinker). It was found out that with increase of the alite content the column-shape zones around the cement grains become somewhat thinner, whereas the size and number of portlandite zones increase, the ettringite fibre length shortens and the size of the netting cells of fibres I+II decreases. If alite crystal size is changed, in addition to decrease of the cell I and II size and general acceleration of hydration, the tightness of the hydration submicrostructure increases more intensively. This is seen from changes of the constant of water diffusion rate through the

Fig. 1. The differential porosity of hardened cement paste

hydrate membranes (at stage II of the hydration process, Fig.2). A similar phenomenon is observed also when merely increasing the specific surface of cement. Thus, the hydrate membranes of fine-crystal clinkers have higher density, strength and screening ability to water and to obtain the same strength level the specific surface of cement may be smaller.

Fig. 2. The kinetics of cements hydration: G - degree of hydration,  $\tau$  - time, hours and days, 1 - cement No 1, 2 - cement No 2, both of clinker with 50 microns alite crystals; 3 - cement from clinker with 20 microns alite crystals, S = 3000 cm<sup>2</sup>/g

N.V.Belov, G.G.Kuznetsova and some authors of this paper had studied the reason of this facts by the method of impregnation of hydrating cement with methylmetacrylate and benzoyl peroxide after vacuum drying and thermal treatment. Black zones is polymethylmetacrylate in places of cement paste pores and channels between the blocks along the external monolayer in the alite crystal. We can conclude that on passing between the blocks, water then separates them from each other and from the remaining part of the crystal which leads to the formation of known globular internal product. Investigations of 20 industrial clinkers have proved that dimensions of alite crystals visible through the optical microscope are directly proportional to the average size of the blocks. The growth of block boundaries density on cement particle surface leads to said increased tightness of hydrate membranes. This situation changes when introducing crystallizing components; for instance the limit of alite content in clinker (70%) dictated by the increase in the structure portlandite zone dimensions is

Fig. 3. The submicrostructure of metilmetacrylate impregnated cement paste. x 7500: 1 - metilmetacrylate (parabolic microcrack), 2 - the monolayer of mosaic alite blocks with channels between them

eliminated. Addition of the crystallizing components, alongside with increasing the amount of ettringite, decreases the number of bends of hydrosilicate flakes on the fracture surface of the C-S-H (II) gel and makes the topography of said fracture more uniform and more similar to the actual gel.

Microcracks under load in hardened cement paste of up to 3 days old concentrate at pores. After 7 days, the interphase cracks around the submicrostructure zones with lower categories of symmetry (parallel concretions III, nodes IV, column shaped zones II) dominate. The parallel crystal bundles near the pores loose stability after shearing and their fracture is indicative of relaxation of stresses owing to instantaneous microstrain.

The nature of formation V fracture is very important. We have managed to find out in said formation cylindrical pores with microcracks in the bottoms thereof (Fig. 4, 28 days, cement I, SEM). Their location, similar to that occurring in a round plate on a resilient base with peripheral attachment and central loading, shows that phase V is destroyed owing to the lateral rupture in the tensitive zone with the cracks width of 0.1-0.5 microns.

In a number of studies of the concrete fracture mechanism, this phenomenon was attributed to either the influence of the "inter-molecular bonds", which cannot be manifested at such distances, or to plastic "hinges".

The present paper confirms that hardened cement paste and concrete work as a composite material comprising statistically distributed fibres.

## Characteristics of the compositions with low water-demand based on gypsumless portland cement

### *Propriétés des compositions nécessitant une petite quantité d'eau sur la base du ciment portland sans gypse*

S.M. ROYAK,  
T.Y. GALPERINA,  
Y.N. PERMINOVA,  
M.G. DOROGUINA, Vzisi, Sibniiproekttsement, U.R.S.S.

Les compositions nécessitant une petite quantité d'eau furent obtenues sur la base du ciment portland sans gypse, du surfactif (vinasse de sulfite et de levures), du silicate ou du carbonate d'un métal alcalin. La quantité d'eau nécessaire pour ces compositions est de 30 à 40% plus petite que pour le ciment portland ordinaire. Leur résistance est élevée surtout après l'étuvage.

Une petite quantité d'eau exigée par ces compositions est due à la capacité des additions de diminuer la vitesse d'adsorption des surfactifs par les produits d'hydratation  $C_3A$  et d'assurer une haute concentration des surfactifs dans la phase liquide de la pâte de ciment. Les produits d'hydratation des compositions ont une dispersité élevée et la composition des phases stable dans le temps, ce qui assure une grande résistance et la durabilité de la pierre de ciment. On a étudié l'influence sur les propriétés des compositions de la minéralogie du clinker, du mode d'introduction des additions et de la composition granulométrique de la poudre de ciment.

Compositions with low water-demand have been got on the base of gypsumless portland cement, surface-active agents (sulfid-yeast malt grains), silicate or carbonate of an alkali metal. They have water-demand 30-40% lower than ordinary portland cement, as well as high strength, especially after steaming.

Low water-demand of the compositions, is caused by the ability of additions to reduce the adsorption rate of SAA by the products of  $C_3A$  hydration and to provide high concentration of SAA in liquid phase of cement paste. Products of compositions hydration have high degree of dispersion and phase structure stable in time, what results in cement stone high strength and durability.

The influence of clinker mineralogy, additions introduction method, and cement powder grain formation on the characteristics of the compositions has been studied.

It was established in [1] that addition of lignosulphonate and alkali metal carbonate in optimal amounts to finely ground clinker gives a composite binder of high strength and density and with water consumption by 30-40% less than of usual Portland cement.

We have established that compositions with similar properties may be also obtained on the basis of sulphite-yeast waste (SYW) (a waste of pulp and paper industry) and alkali metal silicate [2]. On addition of up to 1.0-1.5% of SYW and 0.25-1.0% of  $\text{Na}_2\text{SiO}_3$  to gypsum-free Portland cement with specific surface of about  $5000 \text{ cm}^2/\text{g}$  (according to Tovarov's method) reduces water consumption by 30-40% and gives setting period close to those of compositions with  $\text{K}_2\text{CO}_3$ . The strength of mortar specimens formed according to standard GOST 310.4-76 at  $\text{W/C} = 0.24-0.27$  directly after steaming is 60-65 MPa, 28 days after steaming 70-80 MPa. Under normal conditions at early stages (1-3 days) compositions with  $\text{Na}_2\text{SiO}_3$  harden less intensively than with  $\text{K}_2\text{CO}_3$ , however at the age of 28 days the strength of both reaches 60-70 MPa.

The positive effect of steaming on properties of compositions with high dosages of SYW is due to low  $\text{W/O}$  ratio and the nature of the forming pore structure of the cement stone. Study of porosity of mortar specimens by the method of threestep water saturation [3] showed that porosity of steamed specimens is lower than porosity of normal-hardening specimens. Total porosity and pore volume and the volume of pores capable of being saturated with water at atmospheric pressure is by 1.5-2 times lower than in specimens of usual Portland cement.

The mineralogical composition of the clinkers, the method of introducing the additives and the mix temperature significantly affect the setting periods and strength of gypsum-free Portland cement compositions. Data presented in the Table indicate that in order to obtain compositions with high strength and practicable setting periods it is advisable to use clinker with not less 55% of  $\text{C}_3\text{S}$ , not more than 8% of  $\text{C}_3\text{A}$  and not more than 1.0% of unbound lime. At high contents of  $\text{C}_3\text{A}$  (9-12%) and of

unbound lime in the clinker the setting periods are sharply reduced.

Acceleration of setting is also caused by increase of the amount of SYW added during grinding of the cement. The best strength and setting values are obtained when the clinker is ground with small additions of SYW (0.1-0.2%) and remaining SYW and  $\text{K}_2\text{CO}_3$  or  $\text{Na}_2\text{SiO}_3$  is added with the hydration water.

Setting is also accelerated by reduction of the temperature of concrete mixture or mortar from 20-22 °C to 0-5 °C, which is connected with enhanced solubility of  $\text{Ca}(\text{OH})_2$ .

The water consumption of gypsum-free Portland cement with additives ( $\text{SYW} + \text{K}_2\text{CO}_3$ ) or ( $\text{SYW} + \text{Na}_2\text{SiO}_3$ ) is practically independent of mineralogical composition of the clinker and method of introducing the additives. Of paramount importance is the granular composition of the cement powder. Compositions based on polydispersed cements obtained from open-cycle mills have lower water consumption than compositions based on cements of separator grinding.

In order to elucidate the nature of low water consumption and hydration and hardening features of gypsum-free compositions the processes of SYW adsorption by clinker minerals in the presence of  $\text{K}_2\text{CO}_3$  and  $\text{Na}_2\text{SiO}_3$  and products of their hydration with these additives were studied. Investigation showed that of the clinker minerals the determining a effect on the properties of compositions with low water consumption is exerted by  $\text{C}_3\text{A}$  mineral. The dosage of additives and the rates of hydration and hardening of gypsum-free Portland cement depend on its content.

Low water consumption of the compositions is due to the capacity of  $\text{K}_2\text{CO}_3$  and  $\text{Na}_2\text{SiO}_3$  to slow down the rate of  $\text{C}_3\text{A}$  hydration and to reduce its adsorption capacity in relation to the plastifying additive. A high concentration of SYW is ensured in the liquid phase of cement paste that facilitates mobility of the paste at low  $\text{W/C}$  ratios. At high dosages of SYW gypsum becomes ineffective as a decelerator of  $\text{C}_3\text{A}$  hydration and regulator of cement paste setting.

Hydration products of Portland cement in the presence of SYW + K<sub>2</sub>CO<sub>3</sub> or SYW + Na<sub>2</sub>SiO<sub>3</sub> are characterized by very high dispersion. They are represented by X-ray amorphous calcium hydroaluminates C<sub>4</sub>AH<sub>13</sub> and C<sub>2</sub>AH<sub>8</sub> and calcium hydrosilicates of the type C<sub>2</sub>SH<sub>2</sub>.

The content of calcium hydroxide in the hydration products is by 1.5-2 times less than in common Portland cement which is connected with the higher basicity of hydrates forming at low W/C ratios.

Recrystallization of hexagonal C<sub>4</sub>AH<sub>13</sub> into cubical C<sub>3</sub>AH<sub>6</sub> is not observed during hardening of the compositions. This is in agreement with the accepted notion about the stability of hexagonal calcium hydroaluminates in the presence of SYW [4]. High dispersion and stable phase composition of hydration products allows to obtain cement stone with minimal internal stresses, with high density and strength.

Direct testing of concretes showed that on the basis of compositions with low water consumption easily placable concrete mixtures with very low W/C ratio (0.23-0.27) may be obtained as well as high-strength steamed concretes of grades 700-800 with cement consumption 500-600 kg/m<sup>3</sup>. Concretes from these compositions display low porosity and high sulphate and frost resistance.

It may be considered that composition with low water consumption containing gypsum-free Portland cement, SYW and alkali metal carbonate or silicate will be effective binders for the production of high-strength steamed concretes with low W/C ratio.

#### Laitier phosphorique activé - Matière première pour la production de ciment Portland de laitier

#### *Activated phosphorus slag raw material for slag Portland cement production*

A. T. SOULEIMENOV

T. B. PARCHIKOVA Institut Chimico Technologique de Kazakhstan, Tchimkent, U.R.S.S.

On a élaboré la technique de transformation complexe du laitier phosphorique par la méthode d'introduction de la poussière secondaire de la cimenterie de Tchimkent lors de la granulation du laitier phosphorique.

On a établi que l'activité hydraulique des laitiers électrothermophosphoriques modifiés augmente lors de l'introduction dans le laitier des oxydes de métaux alcalins.

On a tracé les voies d'utilisation de la poussière capturée en fonction de ses propriétés chimiques et physiques.

Dans les conditions industrielles on a obtenu le liant à base des laitiers phosphoriques activés par la poussière des électrofiltres.

Les laitiers phosphoriques activés de composition proposée se caractérisent par une grande activité hydraulique et peuvent être utilisés dans l'industrie du ciment en tant qu'addition (jusqu'à 40%) dans la fabrication du ciment portland de laitier.

The technology of phosphorus slag complex workingover with incorporation into it during granulation the secondary dust of Chimkent cement plant has been developed.

The hydraulic activity of modified electrothermophosphorus slags was found to increase with incorporation of alkali metals oxides into the slag.

Means of collected dust using depending on its chemical and physical properties were planned.

Binder based on phosphorus slags activated by the dust from electro-static precipitators was received in industrial conditions.

Activated phosphorus slags of the composition proposed features significant hydraulic activity and can be used in cement industry as an addition up to 40% in the manufacture of slag portland cement.

Much consideration is being given to the use of wastes in the cement production. Of particular interest is the use of electrothermal phosphorus-bearing slags formed in electrothermal production of phosphorus.

Phosphite ores are employed as a main raw material in the electrothermal phosphorus production. The phosphites (23-25%  $P_2O_5$ )

with a higher content of impurities compared to that allowed in acid phosphorus production are suitable for electrothermal processing consisting of reduction of phosphate ore into phosphorus in special electric furnaces, burning of phosphorus and hydration of phosphorus anhydride so as to obtain a pure concentrated "thermal" sulphuric acid. Such phosphorus ores usually comprise a loose sand-claying material with fragments of phosphites. Thus, in addition to a final product electrothermal slag is formed during thermal sublimation of phosphorus.

In the Soviet Union the use of electrothermal slags in the cement production was started on a commercial scale in 1977. In the recent decade the slags have been used as a component of a raw mix at two and as an active mineral additive at nine cement plants. According to the Yuzhgiprotsement developments the cement industry is now producing not only ordinary portland-slag cement with the granulated phosphorus-bearing slags additives but also sulphate-resistance portland-slag cement.

Phosphorus is employed in production of sulphate-resistance portland-slag cement containing 60% of slag due to a specific mineralogical composition (low content of aluminium compounds). The resistance of this cement to an aggressive media is higher than that of a standard sulphate-resistant portland cement.

The technology has been developed to produce oil-well cement with the addition of up to 20% of the granulated phosphorus slag.

Among current methods of slag processing the best is granulation having a number of advantages over other methods. It enhances a hydration activity as well as improves labour conditions and reduces operational costs.

The output of the electrothermal slags will be considerably increased owing to the

development of phosphorus and mineral fertilizer production in the Central Asiatic Soviet republics and Kazakh SSR of the basis of the local raw material.

In electrothermal production of yellow phosphorus there are produced 10 tons of flame-liquid phosphorus slags per a ton of phosphorus, annual output of the slags being more than 1 million tons at present. In the phosphorus production in electric furnaces using sublimation of the charge consisting of natural phosphites, silica and coke reducer the following reaction takes place:

The basic components of the slag are calcium oxide and silica which total quantity equals 95%. Electrothermal phosphorus slags differ from blast-furnace slags by a low content of  $Al_2O_3$  (up to 3%) and  $MgO$  (3-4%),  $CaO/Si$  ratio of 0.8-1.2 as well as by the presence of  $P_2O_5$  (1-3.3%) and  $F$  (2-2.4%). The

chemical composition of the slags depends on a composition of phosphorus ore and technology of phosphorus production (1,2).

A high stability of the electrothermal slags chemical composition allows their use in cement production. It has been proved by the investigations of Yuzhgiprotsement. The scientists of the institute have carried out statistical processing of the data on the chemical composition of electrothermal slags (1040 samples). In the plant probes taken at an hour interval and in the averaged slag batches shipped to the enterprises mean value of  $P_2O_5$  did not exceed 2% and its maximum content in the samples taken at half an hour interval was 2.65%.

Slag hydration is to a greater extent determined by a composition and structure of a glassy phase. Petrographic investigations have shown that a basic phase of electrothermal phosphorus-bearing slags is glass of a wollastonite composition (90-92%). However, the glass of electrothermal phosphorus-bearing slags differs from a pure pseudowollastonite glass by the presence of  $P_2O_5$  and  $F$ ,  $Al_2O_3$  and  $MgO$  which cause structural reconstruction in it.

According to (4),  $P_2O_5$  and  $F$  contained in the slags in minor quantities do not have independent phases and enter into the com-

position of pseudowollastonite. These data are proved by the Yuzhgiprotsement investigations (5,6) which using petrographic and X-ray diffraction analysis have revealed the absence of phosphorus-bearing slags in these granulated slags.

Since the glass of a pseudowollastonite composition is a predominant in quantity phase its properties and structure should decisively effect the slag properties. At the same time chemical, petrographic, and X-ray diffraction analysis have shown that slag calcium silicate is basically represented by wollastonite glass of various degree of crystallization. Lower basicity of electrothermal phosphorus-bearing slags results in increase of silicon-oxygen effect, reducing their hydration activity.

However, according to (7), universally adopted conceptions of a glass structure also cover slag glasses. The slag consists of complex anions of  $(\text{SiO}_4)^{4-}$ ,  $(\text{AlO}_4)^{5-}$  and others connected with each other by oxygen bonds into polytetrahedral radicals of a different composition and kind. Cation-modifiers are also connected to these anions according to the scheme  $-\text{Si}-\text{O} \dots \text{Me}$ . During water adsorption by glass an exchange takes place between fairly loosely bound ions-modifiers of alkali and alkali-earth metals from glasses and hydrogen anions of water to water to form on the surface of glass particles films of hydrated-silica containing the groups of  $-\text{SiO} \dots \text{H}$ . These films hinder a further interaction of slag with water. However, the formation of stable silicates (and aluminates) at the limit concentrations of metal oxide hydrates is accompanied by destruction of the hydrated silica films. As a result, deeper glass sites lie bare and become accessible for water. This in turn is attended by its further hydrolysis and hydration. In these conditions considerable solubility of alumina and calcium aluminates in water favours their dissolution and formation of pores and capillary tubes securing a further intensive access for water hydrolyzing glass.

Thus, the introduction of minor quantities of alkali activators creates a specific impact disturbing a thermodynamically unstable balance of slag glass which then during interaction with water spontaneously reorganize itself to form more stable hydrosilicates, calcium hydroaluminates at the expense of the component of glass itself and these compounds cause setting and hardening of all the system.

This served as a basis for conducting investigations on enhancing hydration activity of electrothermal phosphorus-bearing slags through a crystallochemical activation method, i.e. the introduction of alkali metal cations into a melt. The dust retained by precipitators of rotary kilns of one of the cement plants containing a considerable quantity of Na and K oxides was used as an activator.

The aim of the preliminary investigations was to obtain clinker with a given mechanical strength. During the investigations there were used Mark 40Q clinker (70%) and

finely ground electrothermal phosphorus-bearing phosphorus-bearing slag (30%) activated in the laboratory conditions in a melted state with precipitator dust taken from different fields of precipitators. As a result it has been found that activity of experimental portland-slag cement is considerably increased when the slag activated with a high alkali content slag is used (Table 1).

The subsequent investigations have revealed that the introduction of dust from the precipitator third field in the quantity of 3% in a greater extent activates thermal phosphorus-bearing slags.

In the course of the further investigations the pilot batch of portland-slag cement has been obtained in commercial conditions. Electrothermal phosphorus-bearing slags were activated by the precipitators dust and, to do this, 5% of the dust from 2 and 3 fields of precipitators were introduced into melted slag before granulation at the temperature of 1450-1600°C. The chemical composition of starting materials (in mass %) is given in Table 2.

The use of activated phosphorus-bearing slag (Table 3) results in increase of portland-slag cement activity especially by 28 days. The activation of the slag by the method described permits the use of 40% of electrothermal phosphorus-bearing activated slags in the portland-slag cement production against 30% used at present.

As it is shown in Table 3 an activated phosphorus-bearing slag is characterized by a considerable hydration activity and can be used in the cement industry instead of shipped blast-furnace slag. It has been found that the slag can be used as an hydraulically active additive during clinker grinding in the quantity of 40%, with possible obtaining of the Mark 500 cement.

Thus, the use of activated phosphorus-bearing slag and dust of the precipitators of the cement plant rotary kilns in the portland-slag cement production will enable one markedly to increase technical and economical efficiency of production as a whole and utilize the accumulated byproducts and this in turn creates conditions for a complex employment of natural resources and possibility for the development of a low- and waste-free technology.

The use of the activated phosphorus-bearing slags is expected to stimulate not only the expansion of the cement industry raw material base, further economization of production by the change of transported blast-furnace slags for local chemically produced but also improvement of portland-slag cement quality.

The further investigations are directed to optimization of the process of phosphorus-bearing slags activation with alkali-content wastes of the cement production, i.e. dust retained by precipitators on clinker burning in rotary kilns.

# Hydratation des ciments portland de laitier à différentes températures

## *Hydration of blastfurnace cement under different temperatures*

S.A. MIRONOV, Prof., Dr. Tech. Sc.,

I.I. KURBATOVA, Cand. Chem. Sc.,

S.A. VYSOTSKY, Cand. Tech. Sc., NIIZhB, Moscow, U.R.S.S.

Par une série des méthodes d'analyse physico-chimique, y compris, l'examen de la composition de la phase liquide et la méthode d'extraction, sont étudiées les caractéristiques de durcissement de hydratation des ciments avec la différente teneur en laitier granulé de haut fourneau (0-80%) dans les conditions normales et sous le traitement thermique à la vapeur.

On a étudié le rapport des facteurs constructifs pendant l'étuvage qui sont conditionnés par l'accélération de la hydratation du liant en comparaison avec le processus de hydratation pendant le durcissement normal, et des facteurs destructifs provoqués par la différence de la dilatation thermique des composants de la pâte ou du béton.

Est éclairci le rôle déterminant de l'activité d'hydratation du liant et de ses composants pour l'obtention des caractéristiques physico-chimiques prescrites des compositions de ciments-laitiers.

Est mentionné une considérable accélération de la dissolution du ciment portland de laitier et une accélération de la vitesse de cristallisation des nouvelles phases sous l'étuvage. Sont étudiés les caractéristiques de la composition de phase des produits de la hydratation des ciments avec une différente teneur en laitier et est mis en évidence l'influence de ces caractéristiques sur les propriétés physico-mécaniques des ciments.

Particularities of hydrated hardening of cements with different content of granulated blast furnace slag (from 0 to 80%) during normal condition and steam curing have been studied by complex methods of physico-chemical analyses including the composition of liquid phase investigation and using the extraction method.

Correlation during steam curing of constructive factors connected with acceleration of cement hydration in compare with normal hardening and destructive factors stipulated by different thermal expansion of paste or concrete ingredients has been examined.

The main role, of hydrated activity of cement and its components (slag and clinker) in formation of physico-mechanical properties of cement-slag compositions has been discovered.

Significant acceleration of blast furnace cement solution and increasing of crystallization velocity of new phases during steam curing has been noted.

Particularities of phase composition of hydration products of cement with different content of slag have been examined and their influence on physico-mechanical properties has been shown.

Sont étudiées les particularités de durcissement d'hydratation des ciments avec la différente teneur en laitiers granulés de haut fourneau (0; 20; 40; 60 et 80%) dans les conditions normales et sous le traitement thermique à la vapeur. En réalisant ces essais on a utilisé une série des méthodes (chimique, radiographique, thermodynamique, méthode de microscopie électronique, essai de la phase liquide et méthode spéciale d'extraction [1] permettant de déterminer le degré d'hydratation du laitier :

$$E = \left(1 - \frac{H_0 - n \cdot H^k}{H - n \cdot H^k}\right) 100 (\%),$$
 où H et  $H_0$  sont les résidus insolubles du ciment non-hydraté et du ciment hydraté additionnés par laitier dans une solution d'extraction,  $H^k$  et  $H_0^k$  - la même chose pour le ciment de clinker, "n" - la fraction de clinker dans le ciment).

Les études se fondaient sur le fait que le caractère de durcissement des compositions des ciments-laitiers se détermine par l'interaction de deux groupes des facteurs: des facteurs destructifs liés avec la différence de la dilatation thermique des constituants du béton, et des facteurs constructifs conditionnés par accélération d'hydratation du liant en comparaison avec le durcissement normal. Les essais ont montré que la modification des caractéristiques physico-mécaniques du béton en fonction de la teneur en laitier dans le ciment, de son activité, des conditions et du régime de durcissement se détermine, à priori, par l'activité d'hydratation du liant (1).

L'activité d'hydratation du laitier se diffère nettement de celle du clinker. Le degré d'hydratation du laitier, le durcissement étant normal, est extraordinairement médiocre (6 - 8,5% à l'âge de 28 jours) c'est-à-dire ce est 8-9 fois plus petit que celui d'hydratation d'alite. L'analyse des courbes cinétiques de  $C_{Ca} 2+(\tau)$  et de  $C_{R+}(\tau)$  obtenues pendant l'essai de la phase liquide montre (Fig.1) que les processus de la dissolution du liant de base ainsi que celui de la cristallisation des phases nouvelles et d'hydratation en entier sont considérablement ralentis dans le ci-

ment contenant 80% du laitier. Une haute  $C_{Ca} 2+(60 \text{ mg/équiv./l})$  s'établissant instantanément dans la phase liquide au contact de l'eau de gâchage avec le liant s'abaisse très lentement durant 24 heures et atteint seulement dans 48 heures la valeur égale à 6,3 mg/équiv./l, ordinaire pour les ciments portlands à l'âge de 24 heures (3). Sur la courbe cinétique de  $C_{Ca} 2+(\tau)$  il n'y a pas de baisse brusque dans la période de 6-8 heures témoignant l'élimination intensive des phases contenant le calcium. La formation d'ettringite est ralentie. L'allure en pente douce de la courbe  $C_{R+}(\tau)$  con-

firme la dissolution lente du ciment portland de laitier. Il est nécessaire de mentionner que malgré la basse énergie de liaison des ions des métaux alcalins dans les unités de structure du verre de laitier

(par exemple:  $\text{Na-O-Si-}$ ) leur concentration dans la phase liquide caractérise indirectement la participation de tout le laitier dans le processus d'hydratation puisque pendant ce processus ont lieu le rompement d'équilibre dans la structure du verre et l'augmentation de sa capacité réactionnelle. L'enrichissement de la phase liquide par les ions des métaux alcalins pendant 24 heures se passe pratiquement pour le compte de la dissolution de composante de clinker de ciment portland de laitier. Le clinker essayé contient 0,54% de  $R_2O$ ; les  $R_2O$  qui

sont facilement dissolubles et qui passent instantanément dans la phase liquide et assurent dans 10 minutes  $/C_{R+}=60,07 \text{ mg/équiv./l}$  font 24% de quantité totale de  $R_2O$ . Dans

le ciment portland de laitier il y a 0,77% de  $R_2O$  y compris 0,66% du laitier, et avec cela il n'y a pratiquement pas d'alcalis facilement dissolubles. La concentration non-élevée  $/R+/$  dans la phase liquide du ciment portland de laitier pendant le processus d'hydratation (9,29 mg/équiv./l dans 10 min.) présentant environ 0,2 de la concentration  $/R+/$  dans la phase liquide de clinker est conditionnée par le passage dans cette phase seulement des alcalis facilement dissolubles de clinker. Par la suite, les ions des métaux alcalins passent aussi dans la phase liquide venant principalement de clinker et ce n'est que vers 24 heures que l'on peut observer la participation de lai-

Fig.1. La variation de composition de la phase liquide pendant l'hydratation des ciments dans différentes conditions: — durcissement normal; ---- traitement à la vapeur sous 95°C; 1.3-ciment portland de laitier contenant 80% de laitier; 2.4 - ciment de clinker

tier ( $C_{R^+}$  dans la phase liquide du ciment portland de laitier dans cette période est plus que 0,2  $C_{R^+}$  clinker).

L'hydratation ralentie des ciments avec la teneur élevée en laitier (40-80%) dans les conditions normales conditionne le formage de la structure poreuse et non-résistante du ciment durci, et explique aussi une effectivité non-importante de leur conservation avant le traitement thermique (2). Dans le ciment durci contenant 80% de laitier à l'âge de 28 jours de durcissement normal prédominent les grains non-hydratés

du laitier couverts d'une couche mince des hydrosilicates geuleux de calcium avec un espace capillaire rempli par des cristaux d'ettringite.

Le traitement thermique accélère considérablement l'hydratation et le durcissement des ciments portlands de laitier (2,4). Le degré d'hydratation du laitier sous le traitement à la vapeur pendant 8 heures et sous 80°C augmente jusqu'aux 6-16% en fonction de la basicité, et sous 95°C - jusqu'aux 22% pour des laitiers basiques les plus actifs. Sur la courbe cinétique de  $C_{Ca^{2+}}(t)$  pour le ciment portland de laitier, le maximum se déplace à gauche et ce fait témoigne l'accroissement de la dissolubilité de la verre de laitier, et une brusque chute postérieure de la courbe témoigne la cristallisation intensive des nouvelles formations. L'hydratation active de laitier sous le traitement thermique est aussi confirmée par le changement de la concentration de  $R^+$  dans la phase liquide qui non seulement augmente intensivement en fonction de temps mais surpasse dans les périodes du temps correspondants 0,2 de la concentration de ces ions du ciment de clinker.

Les études ont montré que le traitement à la vapeur accélère plus l'hydratation du liant que l'accroissement de son résistance. A mesure d'élévation de la teneur en laitier dans le ciment les déformations de la dilatation du béton (comme la mesure des dérèglements structuraux obtenus au stade d'élévation de la température) s'accroissent; ce fait est lié au ralentissement d'hydratation pendant la période de la conservation préalable et pendant l'élévation de la température, ainsi qu'à la basse résistance de la structure incapable de percevoir sans dérèglements les contraintes qui y surgissent. (Fig.2). En rapport avec ce

Fig.2. La dilatation thermique du béton avec le E/C = 0,5 sous le traitement à la vapeur: 1 - 0% de laitier; 2 - 40% de laitier; 3 - 80% de laitier

fait, pour les ciments de ce type est efficace le traitement à la vapeur sous recharge et dans le milieu avec la pression excédente.

Il est possible de subdiviser conventionnellement les ciments essayés en 2 groupes: - avec la teneur en laitier modéré (jusqu'aux 40%) qui sont pratiquement équivalents aux ciments portlands dans les conditions du traitement thermique, - et avec la teneur en laitier élevée - plus de 40%. Après le traitement à la vapeur sous 95°C pendant 6-8 heures la quantité de l'eau chimiquement liée et la résistance des ciments du deuxième groupe peuvent dépasser jusqu'aux 20% celles des échantillons à l'âge de 28 jours et durcies dans les conditions normales. Avec cela se forme une structure compacte et homogène des nouvelles formations représentée, essentiellement par les hydrosilicates de calcium de basse basicité appartenant au groupe de CSH (B) et assurant les hautes caractéristiques mécaniques du ciment durci, surtout par rapport à l'action des contraintes de traction. Le traitement à la vapeur des compositions du premier groupe provoque les changements défavorables dans le composé de phase des produits d'hydratation surtout sous 90-95 °C. Dans les conditions données dans ces produits se forme la phase hydro-grénatique avec la teneur en SiO<sub>2</sub> médiocre dont la composition est pareille à celle de C<sub>2</sub>AH<sub>6</sub> ( $d = 5,05; 4,38; 3,31; 2,53; 2,26; 2,00$  et  $1,71 \text{ \AA}$ ) conformément aux données du (5); cette phase range l'agrégat cristallin avec le volume élevé des vides et contribue à l'abaissement de la résistance du ciment durci. La quantité de la phase donnée ainsi que la quantité de Ca(OH)<sub>2</sub> divisant les nouvelles formations hydrosiliceuses diminue considérablement dans les compositions contenant plus de 60% de laitier, et dans le ciment durci contenant 80% de laitier elle ne peut pas être captée par la radiographie. Au total les produits d'hydratation des ciments avec la teneur en laitier élevée se caractérisent par un plus grand pouvoir liant confirmé par une grande sorption de vapeur d'eau par le ciment durci calculée par rapport à l'unité de la masse conventionnelle des nouvelles formations.

L'intensification de l'activité des laitiers sous le traitement à la vapeur et les différences mentionnées dans la composition de phase des produits d'hydratation amènent au rapprochement des propriétés mécaniques des compositions avec la teneur en laitier différente; Pourtant, pendant le durcissement postérieur après le traitement thermique l'hydratation des ciments du premier groupe est plus intensive et ceci amène à une "guérison" partiel des défauts de la structure et à l'obtention d'une résistance plus grande.

# Nouvelles compositions à base de laitiers

## *New binding compositions based on slags*

V.A. BELETSKAJA, Aspirante,

I.G. LOUGININA, Docteur ès Sciences Techniques, Professeur, Belgorod, U.R.S.S.

La diversité des combinaisons alcalines manifestant les propriétés liantes ouvre de grandes perspectives pour la création de nouvelles espèces des composés polyminéraux au spectre étendu d'utilisation.

On a effectué le contrôle expérimental pour établir la présence des propriétés liantes des produits de calcination des compositions existant au système  $R_2O-RO-R_2O_3$ , où  $R_2O$ ,  $RO$ ,  $R_2O_3$  - sont les oxydes du 1<sup>e</sup>, du 2<sup>e</sup>, du 3<sup>e</sup> groupe dans le tableau de Mendelév.

On a obtenu les liantes d'une grande activité.

Le milieu alcalin créé par des oxydes alcalins et les oxydes alcalino-terreux est la condition déterminée pour une synthèse de nouveaux ciments alcalino-métallurgiques mixtes.

On a obtenu les liants alcalino-métallurgiques hydrauliques portant du laitier granulé, métallurgique et électrothermophosphorique.

On a à présent trouvé que les compositions liantes existant au système  $R_2O-RO-R_2O_3$

sont les composants actifs des ciments alcalino-métallurgiques. On a déterminé les proportions optimales, les conditions de la synthèse et les caractéristiques physico-mécaniques des ciments alcalino-métallurgiques.

On a étudié alcalino-métallurgique le composé des produits de l'hydratation du liant.

L'hydratation de nouveaux ciments alcalino-métallurgiques est déterminée par l'alcalinité d'une phase liquide

The variety of alkaline combinations demonstrating binding properties gives great possibilities for the creation of new types of polymineral binding substances having a wide range of application.

An experimental examination of the present binding properties of the products of burning composition existing in the system of  $R_2O-RO-R_2O_3$ , where  $R_2O$ ,  $RO$ ,  $R_2O_3$  are oxides of the 1<sup>st</sup>, 2<sup>nd</sup>, 3<sup>rd</sup> groups of Mendeleev's Periodic System. The binding materials of high activity have been got.

The alkaline medium created by the alkaline and alkaline-earth oxides is a determining condition of the synthesis of new combined slag-alkaline cements. Slag-alkaline hydraulic binding materials based on the granulated metallic and electric thermo-phosphoric slags have been created.

The binding compositions existing in the system of are established to be an active component of the slag-alkaline cements. The optimal correlations of components, the conditions of synthesis and physical-mechanical characteristics of slag-alkaline cements have been determined.

The composition of the products of hydration of slag-alkaline binding materials have been investigated. The hydration of new slag-alkaline cements is determined by the alkaline character of the liquid phase.

Une série de ciments de laitier alcalins à la base des laitiers des compositions différentes est proposée en Union Soviétique. Il est établi que les laitiers basiques aussi bien que les laitiers acides peuvent être utilisés pour leur fabrication à condition que le choix du composant alcalin soit correct (1). L'alcali caustique, les sels non-siliceux de faibles acides, les sels siliceux, les aluminates alcalins sont utilisés le plus souvent pour une fabrication des ciments de laitier alcalins.

Les ciments alcalins et alcalino-terreux, mono- et polyminéraux hydrauliques à la base des compositions des métaux alcalins sont obtenus à l'Institut technologique de Lénin-grad (2,3). Ces données précédaient une vérification expérimentale de la présence des propriétés visqueuses dans le produit de grillage des compositions existant dans le système  $R_2O-RO-R_2O_3$  ou  $R_2O$ ,  $RO$ ,  $R_2O_3$  sont des oxydes du premier, du deuxième et du troisième groupe du système périodique des éléments de Mendéléev.

On avait pour but d'obtenir des ciments de laitier alcalins hydrauliques à la base des compositions des laitiers granulés, métallurgiques, électrothermophosphoriques et visqueux synthétisés au système  $R_2O-RO-R_2O_3$ .

Les visqueux sont obtenus au moyen du moulin à moudre fine des produits du grillage avant l'agglomération des oxydes indiqués pris en proportions différentes. Les compositions obtenues à la base des composants du potassium sont capables de durcir effectivement dans les conditions aqueuse, aériennes et d'autoclave. Une résistance des visqueux de sodium au durcissement en air atteint 80 MPa. Les visqueux synthétisés ont une grande réflectivité et ne durcissent pas sous l'action de hautes températures.

Pour l'obtention des ciments de laitier alcalins on a utilisé les laitiers des cinq unies dont les compositions chimiques sont citées au tableau 1. Les visqueux synthétisés ont été utilisés en qualité du composant alcalin. Les laitiers étaient préalablement broyés jusqu'à la surface spécifique égale à  $2900-3100 \text{ cm}^2/\text{g}$  selon le mesureur de surface -2. Le ciment de laitier alcalin était obtenu sans grillage par le mélange du laitier et du visqueux-excitateur pendant 45-60 min.

Les propriétés physico-chimiques du vis-

queux était étudiées sur les échantillons ( $1 \times 1 \times 3 \text{ cm}$ ) préparés de la pâte au durcissement aqueux et aérien. Un traitement d'autoclave des échantillons ( $175^\circ\text{C}$  4 heures) a été fait dans 24 heures après le formage avec le séchage postérieur jusqu'au poids constant à la température  $90^\circ\text{C}$ . La durée de la prise des visqueux de laitier alcalins a été déterminée par l'appareil de Vic.

Une microstructure des laitiers a été examinée en lumière passante et polarisée dans les appareils à immersion. Un analyse radiologique de phase des laitiers et des visqueux de laitier alcalins a été fait à l'aide de la méthode de poudre avec l'enregistrement ionisé des maximums de diffraction à la température ambiante. Les courbes de l'intensité étaient faites par l'appareil ionisant YPO-50HM à l'utilisation de la radiation cuivrée au filtre de nickel.

Il est établi que la masse importante des laitiers est composée du verre (70-80%). Les indices de son réfraction de lumière sont - de 1,662 à 1,646. Une phase cristalline est présentée par une gélenite et une mélelite. Selon les données de l'analyse radiologique de phase, une phase cristalline du laitier N1 est composée d'un quartz, du ceux N2-N5 est composée de la mélelite surtout.

On peut observer l'influence de la nature des composés des métaux alcalins suivant les propriétés visqueuses du laitier granulé au tableau II, où il y a des indices de résistance de la pâte de laitier de l'épaisseur normale, contenant des composants alcalins égaux à 3% de  $R_2O$ .

En se basant sur les données citées ci-dessus, il convient, que la résistance des visqueux autoclavés dépasse celle des visqueux durcissant pendant les 28 jours dans de l'eau. Une appréciation comparative de la résistance mécanique du pierre de laitier alcalin a permis de tirer une conclusion que l'activité des visqueux de laitier s'accroît dans une série:

$ROH$   $RO-R_2O_3$   $R_2CO_3$   $R_2O-RO$   $R_2O-RO-R_2O_3$   
Les durées du durcissement du ciment de laitier alcalin dépendent de la composition d'un composé alcalin: les hydroxydes et les carbonates des métaux alcalins les diminuent, les visqueux synthétisés les augmen-

tent.

Ainsi, les mélanges des visqueux synthétisés dans le système R<sub>2</sub>O-RO-R<sub>2</sub>O<sub>3</sub> et des laitiers présentent de nouveaux visqueux hydrolitiques possédant une haute activité.

On essayait d'obtenir un visqueux des laitiers granulés dont la composition chimique est indiquée au tabl. I et du visqueux synthétisé.

Les compositions visqueuses obtenues à cette base (dessin 1) ont une grande durabilité et une résistance à l'eau. Il convient de noter que la substance en état de pierre se formant dans le système durcis-

sant visqueux - laitier conserve sa résistance à l'eau à l'augmentation dans le visqueux de la teneur en R<sub>2</sub>O<sub>3</sub> jusqu'au 40

mol % malgré la diminution importante de sa résistance au cas des laitiers basiques aussi bien qu'au cas des ceux alcalins.

Une activité des visqueux de laitier alcalins durcissant dans les autoclaves est citée au tableau III.

Une activité des compositions étudiées augmente en cas du vaporisage dans l'autoclave. Donc dans les conditions naturelles du durcissement une interaction des compositions examinées passe relativement lentement. Ap-

Tableau IV

Dépendance de l'activité du ciment de laitier alcalin de la teneur en visqueux

Numéro du laitier	Quantité du visqueux %	eau/dureté	Résistance au durcissement MPa	
			en air	dans de l'eau
1	5	0,25	6	15
	10	0,25	3	14
	20	0,27	12	26
	30	0,32	22	38
2	5	0,25	7	40
	10	0,25	13	43
	20	0,27	26	56
	30	0,30	51	57

rès le durcissement aqueux de longue durée et le vaporisation dans l'autoclave la résistance du pierre à la base du laitier acide avec l'addition du visqueux syntétisé est beaucoup plus grande de celle du pierre de laitier alcalin à la base du laitier basique.

Les indices fixés de la résistance de la pâte de laitier alcalin ne présente qu'une idée générale des possibilités de l'obtention du visqueux à la base des laitiers de différentes usines, car on ne peut pas considérer la proportion choisie parmi les visqueux syntétisé comme optimale.

Une dépendance de l'activité du ciment du débit du composant alcalin a été étudiée pour les compositions "laitier 1,2 - visqueux 1". Les échantillons, préparés dans la pâte durcissaient dans de l'eau et en air pendant les 28 jours. Les résultats sont cités au tableau IV.

Les données du tableau IV montrent que l'activité du ciment s'accroît à l'augmentation du visqueux alcalin débité.

Un analyse différentiel thermique des produits de l'hydratation des visqueux de laitier se fait à l'aide du dérivatographe du système des F.Paulik, I.Paulik, A.Erdei à l'intervalle des températures jusqu'à 1000 °C dans un creuset à corindon à l'utilisation du  $Al_2O_3$  comme étalon à la vitesse 20°/min. Selon les données de l'analyse thermographique à l'interaction des visqueux syntétisés et des laitiers se font les mêmes formations nouvelles qui se pro-

Fig. 1. Dépendance de l'activité du ciment de l'espèce de l'excitateur alcalin: 1, 2, 3, 4, 5 - numéro du laitier

sent à l'hydratation du ciment de laitier alcalin synthétisé auparavant (1).

cendres volantes et hydratation des ciments  
aux pouzzolanes et aux cendres volantes

*Structure of pozzolana and fly-ash and the  
hydration of pozzolanic and fly-ash cements*

---

The use of  $\text{SiO}_2$ -residues  
as admixtures for pozzolanic portland cements

*Utilisation de résidus siliceux comme pouzzolane des ciments*

R. HERR, W. WIEKER and G. PRIEM, Zentralinstitut für Anorganische Chemie der Akademie der Wissenschaften der DDR - Berlin, RDA.

### Summary

The residues remaining in a mineral acid extraction process of thermal activated Al-Silicates with layer structure (clay minerals) are rich in  $\text{SiO}_2$  and poor in  $\text{Al}_2\text{O}_3$ . These "residues of clay extraction" (RCE) show extraordinary pozzolanic properties. The use of these pozzolanic residues RCE as admixture to portland cement results in a special type of quickly hardening pozzolanic portland cement. In this report the most important chemical and physical properties of the RCE as well as of the pozzolanic portland cements are discussed.

RESUME : Certains procédés d'extraction à chaud de minéraux dans les argiles, au moyen d'acides, laissent des résidus riches en  $\text{SiO}_2$  et pauvres en  $\text{Al}_2\text{O}_3$ . Ces résidus ont des propriétés pouzzolaniques extraordinaires. Leur addition à des clinkers Portland permet d'obtenir des ciments pouzzolaniques à forte résistance initiale. On a étudié les propriétés physiques et chimiques les plus importantes de ces résidus, ainsi que la qualité des ciments pouzzolaniques obtenus.

The residues remaining in a mineral acid extraction process of thermal activated Al-silicates with layer structure (clay minerals) are rich in  $\text{SiO}_2$  and poor in  $\text{Al}_2\text{O}_3$  and show pozzolanic activity.

The use of these pozzolanic "residues of clay extraction" (RCE) as admixtures to portland cement clinker and gypsum results in a special type of quickly hardening pozzolanic portland cement with improved chemical resistance.

Table 1 shows the chemical composition of the investigated RCE.

Table 1: Chemical composition of "residues of clay extraction", resulting from a HCl-extraction process

oxid	concentration (mass-%)
$\text{SiO}_2$	72....84
$\text{Al}_2\text{O}_3$	0,4....15
$\text{Fe}_2\text{O}_3$	1 ....3
$\text{CaO} + \text{MgO}$	0,01...0,5
$\text{K}_2\text{O} + \text{Na}_2\text{O}$	0,2....1,5
$\text{TiO}_2$	1 .... 3
$\text{Cl}^-$	0,01...0,25
L.O.I.	5 .... 15

According to their chemical composition the RCE are to compare with some types of natural siliceous earths, for instance diatomite earth /1/, Gliezh-earth /2/ or Sacro-fano-earth /3/.

The mineralogical composition of RCE was investigated by the X-ray diffractometric method. In table 2 the qualitative and the quantitative results of the X-ray analysis are placed together.

For the use of the  $\text{SiO}_2$ -residues as admixtures for pozzolanic portland cements especially the not crystalline, X-ray amorphous parts and the semicrystalline parts of the RCE are of interest. The high chemical activity of RCE in the reaction with  $\text{Ca}(\text{OH})_2$  can be correlated to these components. The crystalline parts of RCE operate in PC-RCE-pastes as inert microfillers only. Dried RCE contain about 80 to 90 mass-% reactive sili-

cid acid and metakaolinite.

Some physical properties of the RCE are shown in table 3.

The pozzolanic activity of the RCE in the reaction with  $\text{Ca}(\text{OH})_2$  and portland cement was measured by chemical, physical and mechanical test methods.

Figure 1 shows the results of experiments in which the RCE is treated with  $\text{Ca}(\text{OH})_2$  in suspensions. The amount of  $\text{Ca}(\text{OH})_2$  which has reacted with RCE has been estimated by a titrimetric procedure in dependence of the reaction time.

Fig. 1 Time dependence of the reaction of RCE with saturated  $\text{Ca}(\text{OH})_2$ -solution, measured by shaking tests. For comparison the reaction of a lignite fly ash from the power station Hagenwerder (GDR) is also shown.

Test conditions: saturated  $\text{Ca}(\text{OH})_2$ -solution 1,20 g  $\text{CaO}/\text{l}$ ; molar ratio  $\text{CaO}/\text{SiO}_2 + \text{Al}_2\text{O}_3 = 1:1$ ; temperature  $20^\circ\text{C}$ .

After a reaction time of 1,3 and 28 days the following amounts of  $\text{Ca}(\text{OH})_2$ , calculated in mg of  $\text{CaO}$ , have reacted with 1 g of RCE.

1 day	140....190 mg $\text{CaO}/1\text{ g RCE}$
3 days	250....350 mg $\text{CaO}/1\text{ g RCE}$
28 days	520....560 mg $\text{CaO}/1\text{ g RCE}$

This shows, that the reactivity of RCE with respect to  $\text{Ca}(\text{OH})_2$  is much higher than other types of pozzolanas, i.e. ground lignite coal fly ash or pozzolanic tuffs /4/ or trass /5/.

The pozzolanic portland cements, we have investigated here, were produced by mixing of commercial portland cement (standard type PC 1), milled RCE and small amounts of gypsum to adjust the aluminate-sulfate-ratio of these mixed cements. The pozzolanic portland cements contained up to 30 mass-% RCE.

In figure 2 the results of the compressive strength tests of PC/RCE cement pastes are demonstrated in comparison with the strength development by PC-quartzpowder-pastes.

At constant water-solid-ratios the compressive strength of PC-RCE-pastes increases up to an admixture of about 10 mass-% of RCE to the PC. Above a RCE-content of 10 mass-% the compressive strength decrease slowly, especially in the early stage of hydration. After 28-days-hydration pure PC-pastes and PC-RCE-pastes 75/25 have the same compressive strength. At higher amounts of RCE in the cements the compressive strength de-

creases rapidly.

In order to get a better insight in the differences of the strength development of RCE and quartzpowder blended portland cements we have analysed the contents of the "free lime" and of acid soluble  $\text{SiO}_2$  in the hydrated PC-RCE-pastes.

The free lime content of the samples was determined by the Franke method. The results (Fig. 3) show, that the content of free calciumhydroxide decreases very rapidly with increasing amounts of RCE and the hydration time due to the reaction with the amorphous  $\text{SiO}_2$  of the RCE.

This result is underlined by the change in the amount of soluble  $\text{SiO}_2$  during the hydration reaction, measured by the Molybdatmethod of Thilo, Wieker and Stade /6/. In table 4 it is shown, that the amount of soluble  $\text{SiO}_2$  increases from 16,65 % (resulting from the alite and belite content of the

Fig. 2: Compressive strength of PC-RCE-pastes and of PC-quartz-powderpastes after 1, 3, 7 and 28 days

Test conditions: ratio water/PC+RCE = 0,40 = const.; ratio water/PC + quartz = 0,40 = const.; specific surface of the quartzpowder  $O_s = 8000 \text{ cm}^2/\text{g}$  (Blaine method); sample storage under water; temperature  $20^\circ\text{C}$ .

Fig. 3: Lowering of the "free lime content" in hydrated PC/RCE-pastes by increasing amounts of RCE

Test conditions: Alcohol-ether-dried samples, determination of the free CaO by the extraction method of B. Franke

portland cement) up to 30,97 % after 28 days as a result of the conversion of the very high molecular amorphous  $\text{SiO}_2$  to low molecular silicate species by the reaction with  $\text{Ca}(\text{OH})_2$  which is formed by the hydration of the portland cement.

Table 4: Increase of the amount of acid soluble  $\text{SiO}_2$  during the hydration reaction of PC/RCE 80/20-pastes (Ratio water/solid 0,50; temperature of storage  $20^\circ\text{C}$ )

time of hydration days	$\text{H}_2\text{SO}_4$ -soluble $\text{SiO}_2$ %
0	16,65
1	19,22
3	21,16
7	23,41
14	27,05
28	30,97
extrapolation time	33,50

On the basis of these results one must conclude, that during the hydration in the cement pastes additional amounts of CSH-phases and CAH-phases are formed.

The investigation of the PC/RCE-pastes by the Molybdatmethod also shows that the degree of polymerisation of the silicate anions in the CSH-phases increase with increasing amounts of RCE in the cement paste.

Fig. 4: Effect of RCE-admixture on the degree of polymerisation of the silicates in hydrated PC/RCE-pastes, measured by the Molybdatmethod of Thilo, Wieker and Stade.

Storage conditions of the samples: Hydration under water, 28 days, temperature  $20^\circ\text{C}$ .

An important property of the PC/RCE-mix cements is their relatively high resistance against aggressive solutions, i.e. Mg-salt-solutions. The chemical resistance of the mix cements was evaluated by compressive strength tests of the samples (paste cubes  $1 \times 1 \times 1$  cm) versus the storage time in the solutions. Some results of the corrosion test show figure 5.

Fig. 5: Compressive strength of 28 days hydrated PC/RCE-pastes in dependence of the time treated by  $\text{MgSO}_4$ - and  $\text{MgCl}_2$ -solutions

Test conditions:  
 $\text{MgSO}_4$ -solution 7,6 % = 1,53 %  $\text{Mg}^{2+}$ ;  
 $\text{MgCl}_2$ -solution 6,0 % = 1,53 %  $\text{Mg}^{2+}$ ;  
 storage temperature 20 °C.

According to our attitude the reasons for the enlarged resistance of PC/RCE-mix cements against chemical attack are due to the deminishing of free lime content, the additional formation of CSH-phases and the increase of the degree of polymerisation of the calciumsilicatehydrates.

# Fly ash from Kakanj Power Plant in Cement Production

## *Production du ciment aux cendres volantes de la centrale thermique de Kakanj*

V. KORAC et V. UKRAINCIK, Institut de Génie Civil, Zagreb, YUGOSLAVIE.

RESUME : Des recherches de laboratoire ont permis de déterminer la composition optimale d'un ciment à faible chaleur d'hydratation, constitué d'un clinker à teneur relativement élevée en  $C_3A$  et  $C_3S$ , et de cendre volante de la centrale thermique de "Kakanj".

C'est un ciment unique en Yougoslavie avec l'adjuvant de la cendre volante, qui s'utilise pour bétons hydro-techniques de masse.

Dans la centrale thermique "Kakanj", la poussière de charbon brun est brûlée exceptionnellement à la température d'environ  $1600^{\circ}C$ , tandis que dans les autres centrales thermiques yougoslaves cette température est d'environ  $1000-1100^{\circ}C$ .

La cendre volante est composée des constituants principaux suivants : environ 42 %  $SiO_2$ , 19 %  $Al_2O_3$ , 9 %  $Fe_2O_3$  et 23 %  $CaO$ . La propriété caractéristique de ce ciment est qu'il diminue le besoin de l'eau et qu'il démontre les propriétés de plastification. Ce qui est particulièrement évident dans le béton frais. Avec un grain de maximum 63 mm du granulat et avec seulement 225 kg ciment/m<sup>3</sup> de béton et 108 litres d'eau, on peut produire un béton très ouvrable de la résistance à la compression de 30 N/mm<sup>2</sup> après 28 jours.

SUMMARY: On the basis of laboratory research of blended cement having as ingredients portland cement, with relatively high  $C_3A$  and  $C_3S$  content and fly ash, the optimum composition of low heat cement was chosen. Now, after several industrial trial grindings, fly ash from Kakanj power plant is the only one in Yugoslavia used as addition in production of cement for hydraulic mass concrete.

Extraordinary, in Kakanj power plant, brown coal dust burns at the temperature of about  $1600^{\circ}C$ , while in the others at  $1000-1100^{\circ}C$ . Fly ash under consideration contains 42%  $SiO_2$ , 19%  $Al_2O_3$ , 9%  $Fe_2O_3$  and 23%  $CaO$ . The substantial property is that it unusually decreases the water requirement and its plasticizing effect is expressive. This came strikingly out in fresh concrete mix design. With maximum aggregate grain size 63 mm, with 225 kg/m<sup>3</sup> of blended cement containing 50% fly ash, 108 l of water, well-workable concrete with characteristic 28-days strength of 30 N/mm<sup>2</sup> is obtained.

Several Yugoslav thermo-electric power plants are fired with coal dust obtained from brown coal of more recent geological age.

Because Yugoslav fly ashes have not been adequately and thoroughly studied in terms of their application in the cement industry, practically no use at all has been made of this waste material as an addition to clinker.

However, our systematic studies of a series of cement and concrete batches has shown fly ash obtained from the Kakanj (near Sarajevo) power plant to possess extraordinary good properties as an addition to clinker in cement production in terms of both pozzolanic and physical features. Whereas in other Yugoslav power plants fly ash develops by burning coal dust at the temperature of 1000-1200°C, Kakanj fly ash is produced by burning at 1600-1650°C, which substantially affects its structure and physico-chemical features.

Coal dust is obtained from separated brown coal with a calorific value of about 3200 kcal/kg. Our project entailed the determination - for a new cement plant in the area of the Kakanj power plant - the optimum composition of cement with a low hydration heat for hydraulic engineering applications; accordingly, a series of laboratory cement batches was produced by homogenizing pure Portland cement with 30, 40, 50, 60, 70 and 80 percent of fly ash.

#### BASIC CHARACTERISTICS OF PRIME MATERIALS

##### CLINKER

Phase composition

	Bogue	X-ray
C <sub>3</sub> S	62.63 %	68.00 %
C <sub>2</sub> S	8.54 %	10.00 %
C <sub>3</sub> A	11.65 %	6.00 %
C <sub>4</sub> AF	12.41 %	11.00 %
Hydraulic modulus:	2.14	
Silicate modulus:	1.75	
Aluminate modulus:	1.71	
Degree of saturation:	99.9	
Free CaO:	1.04 %	
Specific area (Blaine):	3200 cm <sup>2</sup> /g	
Density:	3.08 g/cm <sup>3</sup>	

##### FLY ASH

Average Chemical Composition in %

Loss on ignition	1.63
Insoluble	0.30
SiO <sub>2</sub>	41.95
Al <sub>2</sub> O <sub>3</sub>	19.13
Fe <sub>2</sub> O <sub>3</sub>	0.04
CaO	22.93
MgO	2.02
SO <sub>3</sub>	2.01
Na <sub>2</sub> O	0.39
K <sub>2</sub> O	1.10
free CaO	1.41

The aforementioned chemical composition represents the one-year average of thirty analyses.

The range of standard deviation for the basic components (SiO<sub>2</sub>, Al<sub>2</sub>O<sub>3</sub>, Fe<sub>2</sub>O<sub>3</sub> and CaO) was 0.74-1.49, and for the other components 0.09-0.52.

In terms of its chemical composition, according to A.Jarrige (1) this fly ash can be considered atypical because its SiO<sub>2</sub> and Al<sub>2</sub>O<sub>3</sub> content brings it close to silicate-aluminum type ashes, while on the other hand it contains much CaO but few sulfates. It is also distinguished by a very low loss on ignition.

##### X-RAY - DIFFRACTION AND THERMAL ANALYSIS OF FLY ASH

These tests showed fly ash to be of an almost exclusively amorphous glassy structure, without thermal effects, which is indicative of possible pozzolanic properties.

(1)

A.Jarrige: Les cendres volantes, Editions Eyrolles, 61, Boulevard Saint-Germain, Paris V<sup>C</sup>, 1971, p. 63

Fig. 1

Fig. 2

Fig. 3

Fig. 4

Figures 1 and 2 show the Kakanj power plant fly ash. It consists of very fine glassy, closed, dense and regular spherical particles, with very few unburnt coal particles of an irregular form.

For the sake of comparison we are also enclosing figures 3 and 4, showing fly ash from another Yugoslav power plant, of a very similar chemical composition in terms of the basic component, i.e.,  $\text{SiO}_2$ ,  $\text{Al}_2\text{O}_3$ ,  $\text{Fe}_2\text{O}_3$  and  $\text{CaO}$  content. However, this ash was produced by burning at the temperature of  $1000 - 1050^\circ\text{C}$ , and did not melt (apart from the smallest particles) during burning, but was only synerized. Hence its porous and alveolate structure, resulting in a higher water requirement.

# Fly ash sieve analysis

Specific area (Blaine):  $4042 \text{ cm}^2/\text{g}$   
 Density:  $2.62 \text{ g/cm}^3$

Particles smaller than 40 microns were determined by a Sartorius automatic balance. As shown in the diagram, Kakanj fly ash is distinguished by extremely great particle fineness. Particles larger than 45 microns accounted for only 9,7 %.

Pozzolanic activity according to Fratini (after 8 days)

Pozzolanic activity was tested on a variety of cement types containing 30 to 80 % of fly ash. All the cement types showed a positive pozzolanic activity at the temperature of +40°C as early as after 8 days.

\*\* The foregoing compressive strength testing results are mean values of 6 individual results. The values for bending strength are means for 3 individual results.

## COMMENTS

The results of these tests have shown that the addition of 50% of Kakanj fly ash can produce cement having very good characteristics for hydraulic engineering applications:

- standard consistency is low (about 20.7%)
- setting begins after 4 hours
- the cement is sound
- hydration heat values are below the prescribed maximum values for the heat by solution method
- the strength growth rate is very high till 90 days.

## CONCRETE APPLICATIONS

Mixed cement with 50% of fly ash has already been used for six months in the production of concrete for the Salakovac dam and Bočac dam hydro-electric power plant. The anticipated advantages of such cement, as determined by laboratory testing, were confirmed again by on-site concrete checks:

- marked plastifying effect
- good workability with only 108 l of water and 225kg of cement per  $m^3$  of concrete, and maximum aggregate size of 63 mm
- maximum temperature within the mass concrete of  $49^{\circ}C$  with initial temperature of fresh concrete  $23^{\circ}C$
- with a w/c ratio of 0.48, concrete compressive strength in  $N/mm^2$  was as follows:

	$\bar{x}$	$\bar{s}$
28 days	44.0	3.5
90 days	52.0	3.5

# A Study on the mechanism of the reaction of Santorin earth during its hydration with Portland Cements

## *Etude sur le mécanisme de la réaction de la terre de Santorin pendant son hydratation avec des ciments Portland*

Dr. CH. FTIKOS, Dr. G. PARISSAKIS,

HERACLES General Cement Co. - National Technical University of Athens, Lab. of Inorg. and Anal. Chemistry, Greece

**SUMMARY :** The subject of the present work is the study of the phenomena which take place during the hydration of portland cements containing different proportions of pozzolan and the explanation of the way of their interaction.

The activity of pozzolan constituents depends on their lattice defects or even on the deficiency in their structure, attributed to various physical or technical treatments that the material has undergone. Under these conditions the interaction between  $\text{OH}^-$  and pozzolanic constituents is facilitated.

This interaction results the dissolution of  $\text{Al}_2\text{O}_3$  and  $\text{SiO}_2$  in the alkali solution, their transition into the solution by the form of hydroxycomplex ions, and their reaction with  $\text{Ca}^{2+}$  to form CAH and CSH compounds.

**RESUME :** Le sujet du présent travail est l'étude des phénomènes qui se passent pendant l'hydratation des ciments Portland contenant différentes proportions de pouzzolane et l'explication du mode de leur interaction.

L'activité des constituants pouzzolaniques dépend des défauts de leur réseau ou même de leur structure déficiente attribuée à divers traitements physiques ou techniques que le matériel a subis. Sous ces conditions l'interaction entre  $\text{OH}^-$  et les constituants pouzzolaniques est facilitée.

Cette interaction résulte la dissolution de  $\text{Al}_2\text{O}_3$  et  $\text{SiO}_2$  dans la solution alcaline, leur transition dans la solution par la forme d'ions hydroxycomplexes et leur réaction avec  $\text{Ca}^{2+}$  pour former des composés de CAH et CSH.

## 1. Introduction

It is well known (1,2) that the grinding of clinker with Santorin earth or with a pozzolan in general, leads to the production of cements which present some advantages regarding their physical and chemical properties, as compared to those of pure portland cements.

Though the phenomena which take place during the hydration of cement with pozzolan have been studied by many researchers (3,4,5), some of them have not yet been clarified.

The aim of the present work is the study of these phenomena in cements containing different proportions of Santorin earth and the explanation of the way of its interaction.

The hydration phenomena are studied by XRD, EPMA and SEM, as well as by determining the active part of Santorin earth in cement pastes. These pastes have been prepared from two portland cements of different composition in mixtures containing 0, 10, 20, 30 and 40% of Santorin earth respectively, cured in water at  $18 \pm 2^\circ\text{C}$  for 7, 28, 90 and 365 days. Strength development of these blended cements has also been studied.

The results of this study provide useful information about the way in which pozzolans interact during their hydration with portland cement.

## 2. Experimental

The materials which have been used are two Portland cements ( $P_1, P_2$ ) of different composition regarding their  $C_3S, C_2S, CaO_f$  content and Santorin earth (S.e.) which is a well known natural pozzolan.

Both the chemical and the mineralogical composition (according to Bogue) of the two Portland cements and the chemical composition of the Santorin earth, as well as their fineness are shown in Table I.

TABLE I: Composition of materials used										
	L.O.I.	SiO <sub>2</sub>	Al <sub>2</sub> O <sub>3</sub>	Fe <sub>2</sub> O <sub>3</sub>	CaO	MgO	Na <sub>2</sub> O	K <sub>2</sub> O	SO <sub>3</sub>	
P <sub>1</sub>	1,60	20,48	5,94	2,82	63,10	3,54	0,85	0,65	2,48	
P <sub>2</sub>	1,74	21,71	5,44	2,64	60,16	2,20	0,35	0,65	2,42	
S.e.	2,40	63,50	15,65	6,10	3,95	1,83	2,87	2,73	Traces	
	C <sub>3</sub> S	C <sub>2</sub> S	C <sub>3</sub> A	C <sub>4</sub> AF	CaO <sub>f</sub>	Sp. surface cm <sup>2</sup> /g (Blaine)				
P <sub>1</sub>	50	21	11	9	2	3500				
P <sub>2</sub>	33	38	10	8	1	3500				
S.e.	—	—	—	—	—	6000				

Specimens have been prepared, according to ISO-RILEM-CEMBUREAU-CEN, by mixing the cements  $P_1$  and  $P_2$  with 0, 10, 20, 30 and 40% of Santorin earth respectively, for the study of strength development. These specimens were cured in water at  $18 \pm 2^\circ\text{C}$  for 7, 28, 90 and 365 days.

The results derived from cement mixtures  $P_1$  and  $P_2$ , are presented in Fig. 1 and Fig. 2 respectively.

Fig. 1.: Compressive strength development.

Fig. 2.: Compressive strength development.

Pastes prepared from the above mixtures were also cured under the same conditions. The ratio W/C used for the preparation of the pastes is shown in Table II.

TABLE II: W/C ratio used.			
Mixtures	W/C	Mixtures	W/C
P <sub>1</sub>	0,27	P <sub>2</sub>	0,26
P <sub>1</sub> + 10% S.e.	0,28	P <sub>2</sub> + 10% S.e.	0,27
P <sub>1</sub> + 20% S.e.	0,32	P <sub>2</sub> + 20% S.e.	0,30
P <sub>1</sub> + 30% S.e.	0,34	P <sub>2</sub> + 30% S.e.	0,31
P <sub>1</sub> + 40% S.e.	0,35	P <sub>2</sub> + 40% S.e.	0,32

The hydration phenomena in these pastes have been studied, according to the following methods:

- Determination of the active part of S.e. by chemical treatment.
- Study by X-Ray Diffraction (XRD)
- Study by Electron Probe MicroAnalysis (EPMA)
- Study by Scanning Electron Microscopy (SEM)

#### a. Determination of the active part of S.e.

For the determination of the active part of S.e., the cement pastes were ground and treated with hydrochloric acid (HCl) 1:1, at -3°C for 10 min. The residue was treated with hot Na<sub>2</sub>CO<sub>3</sub> solution 5% for 5 min. The residue defived after ignition gives the active part of S.e., during its hydration with Portland cement.

It should be mentioned that in anhydrous samples all the contained S.e. appears to be insoluble.

The results after the above mentioned treatment of the mixtures derived from cements P<sub>1</sub> and P<sub>2</sub>, appear in Figures 3 and 4 respectively.

Fig. 3.: Determination of the active part of S.e. % of the added.

Fig. 4.: Determination of the active part of S.e. % of the added.

#### b. Study by XRD.

Some of the patterns of the cement pastes examined by XRD are presented in Figures 5 and 6.

Fig. 5.: XRD patterns of hydrated cement pastes, (A) P<sub>1</sub> (B) P<sub>1</sub>+10% S.e. (C) P<sub>1</sub>+20% S.e. (D) P<sub>1</sub>+30% S.e. (E) P<sub>1</sub>+40% S.e. cured in water at 18+2°C for 1 year.

Fig. 6.: XRD Patterns of hydrated cement pastes  
(A) P<sub>2</sub> (B) P<sub>2</sub>+10% S.e. (C) P<sub>2</sub>+20% S.e.  
(D) P<sub>2</sub>+30% S.e. (E) P<sub>2</sub>+40% S.e.

cured in water at  $18 \pm 2^\circ\text{C}$  for 1 year.

What may be noticed here is the reduced intensity of the peaks of  $\text{Ca(OH)}_2$  (4.92, 2.63, 1.80 Å), as the S.e. content is increased.

In the patterns of Fig. 5 the increased intensity of the peaks of CSH (3.02, 2.75, 1.83 Å) in the pastes by increased content of S.e. is also noticeable.

#### c. Study by EPMA

A series of photos are presented in Fig. 7 concerning the examined cement paste prepared from cement P<sub>1</sub>, with 40% of S.e. after 1 year time of hydration.

Fig. 7.: Hydrated cement paste (P<sub>1</sub>+40% S.e.)  
cured in water at  $18 \pm 2^\circ\text{C}$  for 1 year.  
Ph<sub>1</sub>: Absorbed electrons, 100 μ

Ph<sub>2</sub>: Al x-rays Ph<sub>4</sub>: Si x-rays

Ph<sub>3</sub>: Fe x-rays Ph<sub>5</sub>: Ca x-rays

In photo No. 1 a grain of pozzolan (point P) appears reacted with  $\text{Ca(OH)}_2$ . Around this grain the reaction products are observed.

As these photos reveal there is a remarkable heterogeneity even in a small grain of pozzolan. Furthermore, the way of interaction between the pozzolan and  $\text{Ca(OH)}_2$  may be traced in these pictures,

#### d. Study by SEM

Two photos are provided concerning the examined cement paste prepared from pure cement P<sub>1</sub> (Fig. 8).

Fig. 8.: Ph<sub>1</sub> M x 2.000 Ph<sub>2</sub> M x 10.000  
Hydrated pure portland cement (P<sub>1</sub>)  
paste cured in water at  $18 \pm 2^\circ\text{C}$  for  
1 year.

In photo No. 1 crystals of portlandite grown from CSH. A grain of  $C_3S$  with its hydration products may be seen as well. By higher magnification, the same grain of  $C_3S$  may be seen in photo No. 2.

A point of special interest in this photo is the zone of reaction around the  $C_3S$  grain.

In Fig. 9, the four photos presented concern the examined paste prepared from cement  $P_1$  with 40% S.e. cured for 1 year.

Fig. 9.:  $Ph_1$  M x 10000,  $Ph_2$  M x 10000  
 $Ph_3$  M x 10000  $Ph_4$  M x 10000  
 Hydrated cement paste ( $P_1$ +40% S.e)  
 cured in water at  $18 \pm 2^\circ C$  for 1  
 year.

In these photos grains of pozzolan are shown after their interaction with  $Ca(OH)_2$ . The hydration products appear around these grains.

The remarkable points in these photos are the zone of reaction as well as the cohesion and adhesion of the hydration products.

### 3. Discussion

The research concerning the mechanism of the action of Santorin earth or of a pozzolan in general, during its hydration with portland cements consists in the study of the behavior of the active constituents of pozzolan in the alkali solution derived during the hydration of clinker constituents.

In the present work the study of the hydration phenomena by the above mentioned methods has been conducted in four periods of time, as follows:

- 1st period 0 - 7 days
- 2nd period 7 - 28 days
- 3rd period 28 - 90 days
- 4th period 90 - 365 days

1st period: During this period of hydration they have not yet been observed any remarkable reactions between the constituents of S.e. and  $Ca(OH)_2$ , which can effect the strength development.

A selective dissolution takes place on the vitreous phase as well as on the low crystallinity constituents of S.E. This selective dissolution is caused by the  $OH^-$  released during the hydration of clinker.

2nd period: The formation of calcium aluminate hydrates (CAH) is now clearly observed, the formation of CSH and the decrease in  $Ca(OH)_2$  are beginning.

3rd period: The reaction between the Santorin earth active constituents, especially the  $SiO_2$  and  $Ca(OH)_2$ , are still taking place. Thus, CSH gel and some crystals of tobermorites begin to form.

4th period: The reaction between the  $Al_2O_3$  and  $SiO_2$  of S.e. with  $Ca(OH)_2$  is continued to form CSH and CAH compounds at low rate due to the reduced alkalinity because of the binding of  $Ca(OH)_2$ . The transformation of the CSH gel in tobermorites of small lattice parameters (d) is remarkable too. Regarding the pastes prepared from the cement  $P_2$  and S.e, it is concluded that the released amount of  $Ca(OH)_2$  is insufficient to react with Santorin earth.

#### 4. Conclusion

The study of the results and remarks provided in the present work, in combination with the mechanism of hydration of portland cement (6,7) gives useful informations of the way of interaction of Santorin earth or of a pozzolan in general, during its hydration with Portland cement.

The activity of the clinker constituents is attributed to the increased ionization of the Ca-O bond with formation of double oxides during clinkerization.

The activity of pozzolanic constituents depends on their lattice defects or even on the deficiency in their crystal structure, attributed to various physical or technical treatments that the material has undergone. Under these conditions, the interaction between OH<sup>-</sup> and pozzolanic constituents is facilitated.

This interaction results the dissolution of  $Al_2O_3$  and  $SiO_2$  in the alkali solution, their transition into the solution by the form of hydroxycomplex ions, and their reaction with  $Ca^{2+}$  to form CAH and CSH compounds.

The most probable form of aluminium transition into the solution is that of  $Al(OH)_3^-$ . This is concluded from the study of the hydration products and the PH(8,9) values, during hydration.

Taking into consideration the above mentioned alkalinity and the C/S low ratio of the hydration products, it is concluded that the most probable form of silica transition into the solution is that of  $SiO_2OH^-$ .

As soon as the concentration of  $Al(OH)_3^-$ ,  $SiO_2OH^-$ ,  $Ca^{2+}$  and  $CaOH^+$  in the solution becomes saturated, crystallisation nuclei are created on which the formed hydrated compounds are built. The most probable position of the crystallization nuclei is on the surface of other particles present in the solution.

The above explains the cause of inactivity of some oxides e.g. MgO, which during the hydration of pure Portland cement produce harmful compounds.

# Influence of alkali sulphates on setting and hardening of pozzolanic cements

## *Influence des sulfates alcalins sur la prise et le durcissement des ciments pouzzolaniques*

V. SABATELLI, Assistant Professor and G.L. VALENTI, Assistant Professor  
Institute for Applied Chemistry, Faculty Engineering, University of Naples, Italy.

**SUMMARY:** The hydraulic behaviour of a pozzolanic cement (clinker 58.5%, pozzolana 39.0%, gypsum 2.5%) in presence of accelerators and hardeners, such as lithium, sodium and potassium sulphates has been investigated. The additives were separately added to the mixing water in concentrations ranging from 0.5 to 3.0 weight percent of cement. Reference terms have been the same pozzolanic cement without accelerators and a Portland cement prepared with the same clinker and the same percentage of gypsum, hydrated under the same experimental conditions.

Setting times, water contents for normal consistency, compressive and flexural strengths at 16h, 24h, 3 days, 7 days and 28 days were evaluated.

It has been pointed out that pozzolanic cement in the presence of additives shows considerable increases in mechanical strength, especially at 16 and 24 hours, while the 28 days strengths are practically coincident with those of the same cement without additive. Specimens of Portland cement, containing the same additives, show increases at early ages considerably lower, while at long ages significant reductions in strength often occur. It has been emphasized that alkali sulphates generally accelerate the setting and reduce the water of normal consistency with an effectiveness which depends on the amount of additive and is of the same order for both the cements. Lithium sulphate is generally the most effective additive, while potassium sulphate appears to be the least effective.

The course of hydration process and the characterization of the neo-formed products have been followed by thermal and X-ray diffraction analyses, achieving useful informations on the influence of alkali sulphates on the pozzolanic cement behaviour.

**RESUME:** On a étudié le comportement hydraulique d'un ciment pouzzolanique (clinker 58.5%, pouzzolane 39.0%, gypse 2.5%) en présence d'accélérateurs tels que sulfates de lithium, sodium et potassium. Les adjuvants ont été dissous séparément dans l'eau de mélange en concentrations comprises entre 0.5 et 3.0 pour-cent du poids de ciment. Deux termes de référence ont été choisis: le même ciment pouzzolanique sans adjuvants et un ciment Portland préparé avec le même clinker et le même pour-cent de gypse, hydraté sous les mêmes conditions expérimentales.

On a évalué le temps de prise, l'eau de consistance normale, la résistance à compression et à flexion après 16 heures, 24 heures, 3 jours, 7 jours et 28 jours.

On a souligné que le ciment pouzzolanique en présence des adjuvants manifeste considérables augmentations de résistance, surtout à 16 et 24 heures, tandis que la résistance à 28 jours coïncide pratiquement avec celle-là que le même ciment montre sans adjuvants. Echantillons de ciment Portland qui contiennent les mêmes adjuvants montrent aux échéances brèves augmentations remarquablement inférieures, tandis que à celles-là plus longues il y a beaucoup de réductions significatives de résistance. Les sulfates alcalins en général accélèrent la prise et diminuent l'eau de consistance normale avec un'efficacité qui dépend de la quantité d'adjuvant et est du même ordre de grandeur pour les deux ciments. Le sulfate de lithium est en général l'adjuvant le plus efficace, tandis que le sulfate de potassium est le moins efficace.

Le cours du processus d'hydratation et la caractérisation des produits de néo-formation ont été suivis par analyses thermiques et par diffraction aux rayons X, en obtenant informations utiles au sujet de l'influence des sulfates alcalins sur le comportement du ciment pouzzolanique.

## 1. INTRODUCTION

About 40% of the total cement production in Italy is covered by pozzolanic cements. The interest for these cements derives not only from their high chemical resistance and low heat of hydration which represent useful characteristics in particular applications, but also from the saving of thermal energy involved in their production, due to the substitution of a considerable amount of Portland cement clinker with pozzolana. On the other hand such replacement causes in pozzolanic cements reductions in strength at early ages in comparison with Portland cements. It may be therefore interesting to evaluate the influence of accelerators and hardeners on the hydraulic behaviour of pozzolanic cements.

It is known that alkali substances present in clinkers or added to cements can considerably influence the hydration process and consequently modify the technical behaviour: significant changes in setting time, shrinkage and expansion under water, as well in mechanical strength are observed.

Literature data on the influence of alkali sulphates on the hardening almost exclusively concern Portland cement and are generally based on the use of a single additive in a single concentration. Alkali sulphates in Portland cement generally cause shortening in setting time, increase in mechanical strength at early ages and decrease at longer ages.

Aim of this work is the evaluation of the hydraulic behaviour of a pozzolanic cement (clinker 58.5%, pozzolana 39%, gypsum 2.5%) in presence of different alkali sulphates, added separately in different concentrations. Two reference terms have been employed: the same pozzolanic cement without additions and a Portland cement prepared with the same clinker and the same percentage of gypsum, hydrated under the same experimental conditions.

## 2. EXPERIMENTAL

In preparing Portland and pozzolanic cements, an industrial clinker, natural pozzolana and gypsum were employed. Gypsum was added to both the cements in a measure of 2.5% by weight. Fineness of cements was about 4000 cm<sup>2</sup>/g (Blaine). The chemical composition of clinker and pozzolana is shown in Tab. I. Clinker/pozzolana ratio in the pozzolanic cement was 1.5.

Sodium, potassium and lithium sulphates were employed as additives. These were dissolved in the mixing water, so as to obtain preselected concentrations in respect to the cement, namely: 0.5%; 1.5%; 3.0%.

The mixing water content required for normal consistency, the initial and final setting times, and the flexural and compressive strengths (at 16 hours, 24 hours, 3 days, 7 days, 28 days of aging) were measured. Tests were performed in accordance with Italian specifications.

TABLE I - Chemical composition of clinker and pozzolana.

%	clinker	pozzolana
SiO <sub>2</sub>	22.07	44.47
Al <sub>2</sub> O <sub>3</sub>	5.87	18.52
Fe <sub>2</sub> O <sub>3</sub>	3.10	9.99
CaO	66.08	11.96
MgO	1.21	5.49
K <sub>2</sub> O	0.98	3.28
Na <sub>2</sub> O	0.38	2.02
H <sub>2</sub> O <sup>+</sup>	-	3.50

Specimens to be submitted to thermal and X-ray analyses were prepared under paste form: water/cement ratio was 0.5. At preselected times of reaction, ranging from 10 minutes to 28 days, the hydration was stopped by acetone and the samples were washed with acetone and dried with diethyl ether. For determining the rate of hydration of the alite fraction X-ray quantitative analysis was employed: the alite peak at 51.8 °2θ CuKα was used.

## 3. RESULTS AND DISCUSSION

The water content for normal consistency is generally reduced by alkali sulphates for both the cements: the lowest reductions have the same order of magnitude (-9%) but are more frequent in pozzolanic cement.

As regards the setting, potassium sulphate promotes for pozzolanic cement (Fig. 1) at the lowest concentration a delay, but at higher concentrations induces an accelerating effect, as the other two sulphates, generally increasing with the amount of additive. In Portland cement (fig. 2) no delay occurs and the accelerating effects have the same order of magnitude as in pozzolanic cement; the maximum shortening of setting time is about 75' for pozzolanic cement and 90' for Portland cement. Obviously the shortenings are proportionally more significant for Portland cement whose setting time is lower in comparison with pozzolanic cement.

At all ages, exception made for 28 days, increases in flexural and compressive strengths are found, more considerable at shorter than at longer times. Such increases are growing with the amount of additive: lithium sulphate is generally the most effective additive, while potassium sulphate appears to be the least effective.

At 16 hours (fig. 3) lithium and sodium sulphates, for all the employed concentrations, induce mechanical strengths different from zero, generally greater than those shown by the cement without additives after 24 hours of aging. Such circumstance is presented by po-

Fig.1 - Setting time of pozzolanic cement.

Fig.2 - Setting time of Portland cement.

assium sulphate only at concentrations larger than 0.5%.

Fig.3 - Pozzolanic cement strength after 16 hours..

At 1 day (fig.4) the greatest increases in strength are ranging, depending on the kind of additive from 100% to 200% for the bending, from 400% to 600% for the compression. The values obtained with lithium sulphate at 3% overcome those shown by the cement without additives after 3 days of aging.

At 3 days (fig.5) the largest increases are 55% for the bending and 85% for the compression; at 7 days (fig.6) are about 30% and 40% respectively.

At 28 days (fig.7) flexural and compressive strengths show different trends: flexural strengths display in every case increases ranging from 5% to about 20%; compressive strengths often show reductions which do not overcome 3% and are increasing with the amount of additive for Na<sub>2</sub>SO<sub>4</sub> and K<sub>2</sub>SO<sub>4</sub>, decreasing for Li<sub>2</sub>SO<sub>4</sub>. This, on the contrary, at 3% of concentration promotes a rise in strength of 5%.

Like pozzolanic cement, Portland cement shows increases in strength at 16 hours, 1 day, 3 days and reductions in compressive strengths after 28 days of aging (fig.8). Such changes however have for Portland cement a very different order of magnitude: increases in strength up to four times lower and reductions ten times higher may be found. Other important differences conce

Fig.4 - Pozzolanic cement strength after 1 day.

Fig.5 - Pozzolanic cement strength after 3 days.

Fig.6 - Pozzolanic cement strength after 7 days.

rn the reduction in strength shown by Portland cement after 7 days and the negative influence of additives on the flexural strengths of Portland cement after 28 days of aging.

During the first 24 hours of reaction the hydration degree of the alite fraction is considerably higher (fig.9) for cement in presence of additive, especially until 11 hours of aging; this effect, common to Portland cement too, is generally more marked in the case of lithium sulphate addition. It is also to be pointed out the positive influence of pozzolana on the hydration rate of the alite fraction present in the cement.

The roentgenografic and thermal analyses, at least in the range of the examined concentrations and preselected times of aging, have not shown significant differences as regards the nature of hydration products, which were basically calcium silicates hydrate, calcium hydroxide and ettringite.

Much more informations are however needed in order to elucidate the relationships between the physical properties already described and the characteristics of the hydration process; further investigations are therefore carrying out.

The writers gratefully thank prof. R. Sersale for his useful discussions and Mr. A. Annetta for his technical assistance.

# Aspects chimiques et technologiques de l'utilisation des mâchefers granulés lors de la fabrication du ciment

## *Physicochemical and technological aspects of application of furnace granulate slags in cement production*

L.Y. GOLDSTEIN, Candidat ès Sciences Techniques, Institut « Guiprotsément », U.R.S.S.

Les travaux entrepris par l'institut "Guiprotsément" au cours d'une série d'années sont liés à l'élaboration des bases physico-chimiques et technologiques de l'utilisation dans la fabrication du ciment des mâchefers granulés obtenus lors de la combustion des différents combustibles solides de l'URSS dans les foyers énergétiques avec évacuation des mâchefers à l'état liquide.

On a étudié l'activité des mâchefers en fonction de leur composition chimique et minéralogique ainsi que des particularités structurales du laitier vitreux. Lors de la combustion de certains charbons bruns, dans les mâchefers obtenus peut se cristalliser, outre  $C_2S$ , la phase alitique. On a montré la possibilité de fabriquer le ciment portland et les ciments portlands de mâchefer avec utilisation des mâchefers en tant qu'additions actives. On a relevé certaines propriétés physiques des mâchefers granulés, qui ont une grande importance dans la pratique. On a envisagé également les possibilités d'utiliser les mâchefers en qualité du constituant du mélange cru du ciment.

On a mis au point les schémas types d'utilisation des mâchefers dans la fabrication du ciment.

Over a number of years the Giprocement Institute is engaged in research works aimed on development of physicochemical and technological fundamentals for application in cement production of furnace granulated slags as a product of burning various solid fuels of the USSR in energy furnaces with wet slag disposal.

The subjects studied in the process of the research were activity and other properties of furnace slags depending on their chemical and mineralogical composition as well as structural peculiarities of slag glass.

Experimental and commercial scale works carried out have proved it practicable to produce portland cement and portland blast-furnace slag cement for various purposes using furnace slags as active additives.

Some physical properties and characteristic features of furnace slags have been revealed which have practical significance as regards technological peculiarities of applying them;

A typical diagram of a plant for taking from the steam electric station and dispatching for consumers of furnace granulated slag of low water content without forced dewatering (drying) has been evolved. Besides typical diagrams have been elaborated for utilizing furnace slags with due account for the ability of these slags to a higher evaporation when stored.

Potentialities of furnace slag application as a component of cement raw mix were also under consideration.

Involving these furnace slags into the rank of the traditional cement materials will contribute to the expansion of the raw material base of the cement industry.

Il est connu (1,2) que les mâchefers granulés sont les produits d'un brusque refroidissement dans l'eau de la partie minérale fondue des combustibles solides, qui se forme lors de la combustion de ces derniers dans les foyers énergétiques avec évacuation des mâchefers à l'état liquide. Une série de centrales thermiques équipées de puissants générateurs de vapeur fonctionnent actuellement en U.R.S.S. avec évacuation des mâchefers à l'état liquide. Les mâchefers à l'état liquide. Les mâchefers se présentent en général sous forme de granules sombres et denses dont les dimensions varient de 0,15 à 15-20 mm; parfois ils ont une forme de plaques et de fils de dimensions de 30 à 35 mm.

La composition chimique de mâchefers granulés est déterminée par les particularités de la composition de la partie minérale des combustibles solides et varie donc (en fonction du type de combustible) dans de très larges limites (1).

Il faut noter que les compositions chimiques des mâchefers se distinguent quelque peu de la composition de la partie minérale des combustibles solides correspondants. Cette distinction s'explique par une certaine redistribution des constituants de la partie minérale du combustible entre le laitier liquide et les cendres volantes. A la différence des cendres volantes, les

laitiers ayant les compositions basiques ne contiennent pas de CaO libre et en général n'ont pas de perte de calcination (i.e. ne contiennent pas de particules non brûlées du combustible). La particularité caractéristique de la composition chimique des mâchefers est une teneur élevée (jusqu'à 20 % et même plus) en oxydes de fer, principalement sous forme bivalente (FeO).

L'absence de conditions de cristallisation équilibrée et un brusque refroidissement des laitiers fondus conduisent à ce que les mâchefers ont en général une structure vitreuse. Dans la phase vitreuse peuvent prédominer les domaines polymérocristallitiques de compositions soit mullitique (teneur en CaO jusqu'à 10%), soit méllitique ainsi que wollastonitique (teneur en CaO de 10 à 40 %), parfois gehlénitique (teneur en CaO de 40 à 50%). Les phases cristallines peuvent être représentées par la mullite, la gehlénite, la pseudowollastonite, la monticellite ferreuse,

le silicate  $\beta$ -dicalcique. La teneur en ce dernier des laitiers schistocendreaux peut atteindre 60 à 70 % (fig.1). Lors de la combustion dans les foyers à décrassage en phase liquide de certains charbons dont la partie minérale contient une quantité élevée de CaO, la phase alitique inhabituelle pour les mâchefers peut se cristalliser dans ces derniers (fig.2).

Fig.1. Microstructure des mâchefers granulés schistocendreaux (B-bélite, lumière réfléchie, X200)

Compte tenu d'une ressemblance déterminée des caractéristiques chimico-minéralogiques des mâchefers et des laitiers de haut fourneau granulés (en présence de différences tout à fait évidentes avant tout dans la teneur des oxydes de fer) on ne peut pas s'attendre aux différences de principe brusques dans le déroulement des processus de durcissement et les produits basiques d'hydratation des ciments contenant les laitiers de haut fourneau et les mâchefers. Ce point de vue est confirmé par les résultats du travail (3).

Fig.2. Microstructure des mâchefer granu-  
lés à alite (A-alite, B-bélite, lumière  
réflectie, X200)

Il est naturel que l'activité et d'autres propriétés des mâchefer soient le mieux caractérisées par leur composition chimico-minéralogique. Toutefois pour plus de commodité on se sert également de caractéristiques modulaires bien connues malgré le caractère conventionnel de ce procédé.

À l'Institut Guiprotsement on a procédé à l'étude de l'activité des mâchefer en fonction de leur composition chimique et minéralogique ainsi que des particularités structurales du verre de laitier.

On a montré en particulier que

1. Avec l'accroissement des valeurs du module de basicité des laitiers (rapport  $\% \text{CaO} + \% \text{MgO}$  à  $\% \text{SiO}_2 + \% \text{Al}_2\text{O}_3$ ) jusqu'à 1,0 pour les valeurs constantes du module d'activité (rapport  $\% \text{Al}_2\text{O}_3$  à  $\% \text{SiO}_2$ ) on observe

un accroissement de la résistance des ciments à leur base. Un accroissement ultérieur des valeurs du module de basicité s'accompagne d'une certaine diminution de l'activité des laitiers.

2. Avec l'augmentation de la teneur en  $\text{Al}_2\text{O}_3$  (l'accroissement des valeurs du module d'activité jusqu'à 0,6) l'activité des laitiers augmente. Un accroissement ultérieur des valeurs du module d'activité entraîne une diminution de l'activité.

3. Les études physico-chimiques ont montré que la diminution de l'activité des mâchefer vitreux qui se distinguent par la teneur élevée en  $\text{Al}_2\text{O}_3$  (dans les limites de 21 à 28%) était liée à la modification structurale interne du verre de laitier.

Avec l'augmentation de la teneur en  $\text{CaO}$  (et respectivement avec la diminution de la

teneur en  $\text{Al}_2\text{O}_3$  et  $\text{SiO}_2$ ) a lieu une modification structurale essentielle des laitiers liée à la dépolymérisation de la carcasse alumo-oxygénée du verre de laitier. On observe en même temps le passage d'une partie d'ions aluminium de la coordination tétraédrique à la coordination octaédrique avec la diminution de l'énergie de liaison  $\text{Al-O}$ . Ceci conduit à une diminution de la stabilité chimique et par conséquent à un accroissement de l'activité hydraulique des laitiers (et respectivement des ciments à leur base) (4).

4. L'augmentation de la teneur en fer divalent des laitiers basiques jusqu'à 4% influence peu sur leur activité. Un accroissement ultérieur de la teneur des laitiers en  $\text{FeO}$  diminue leur activité. À la différence des laitiers basiques une diminution de l'activité des laitiers acides est moins intense (fig.3).

Fig.3. Variation de l'activité des ciments à base des mâchefer avec l'augmentation de la teneur de ces derniers en oxyde ferreux:  
1-Ière série ( $\text{CaO}=48,5$  à  $48,7\%$ ;  $\text{Ma}=0,5$ );  
2-IIème série ( $\text{CaO}=36,3$  à  $36,5\%$ ;  $\text{Ma}=0,5$ )

En se fondant sur les résultats des travaux expérimentaux et industriels et des travaux d'étude aux cimenteries de Krasnoïarsk et Timoulsk on a démontré qu'il est possible d'utiliser les mâchefer granulés basiques et acides pour la production tant du ciment portland avec additions minérales actives que du ciment portland de laitier (ordinaires et hydrotechniques, à exothermie abaissée).

Le Tableau 1 donne les caractéristiques comparatives de résistance des ciments portlands de laitier hydrotechniques de la cimenterie de Krasnoïarsk avec addition du mâchefer (centrale électrique régionale d'Etat Nazarovskaïa) et du laitier de haut fourneau (combinat métallurgique de Magnitogorsk). Les ciments avec addition du mâchefer ont un dé-

TABLEAU 1

Laitier	Teneur, %		
	Laitier	SO <sub>3</sub>	R <sub>008</sub>
Mâchefer	35,3	1,24	10,8
Laitier de haut fourneau	35,8	1,57	10,7
Mâchefer	37,9	1,75	7,2
Laitier de haut fourneau	37,8	2,23	11,2

Noté: La teneur du clinker en C<sub>2</sub>S est de 49 à 50%.  
La teneur en CaO du mâchefer est de 34,5 à 36,5 % et du laitier de haut fourneau de 40 à 42 %.

gagement de chaleur beaucoup plus petit que celui des ciments au laitier de haut fourneau (3).

Le tableau 2 donne les caractéristiques de résistance du ciment portland de laitier de la cimenterie de Timluisik avec addition de mâchefers acides de la centrale électrique Goussinozorskaja.

Au cours des travaux expérimentaux et industriels on a montré que les mâchefers provenant des crassiers des centrales électriques thermiques et amenés aux cimenteries possédaient une constance tout à fait suffisante de la composition chimique et de phase. On a relevé certaines propriétés physiques spécifiques des mâchefers granulés ayant une grande importance pratique du point de vue des particularités technologiques de leur utilisation. Par exemple, on a montré que les mâchefers absorbent l'eau au moindre degré (par rapport au laitier de haut fourneau) et la cède beaucoup plus facilement non seulement lors du séchage mais au cours du stockage ordinaire (Tableau 3).

La comparaison directe de ces laitiers à l'aide de la méthode de porosimétrie à mercure a montré que la porosité intégrale du mâchefer était beaucoup plus petite que celle du laitier de haut fourneau (fig.4). Il importe de noter que la différence de porosité des laitiers comparés se conserve lors du broyage jusqu'à R<sub>008</sub>=15%. Le mâchefer peut donc être considéré comme addition pour le ciment, qui exige une petite quantité d'eau.

Sur la base de ces données on a mis au point le schéma type de l'installation pour le prélèvement sur les centrales thermiques et l'expédition aux consommateurs des mâchefers granulés à basse humidité sans leur déshydratation forcée (séchage). On a également élaboré les schémas types de l'utilisation des mâchefers aux cimenteries, qui tiennent compte des particularités physiques indiquées des mâchefers.

Avec le passage à la combustion, pour

l'évacuation des laitiers à l'état liquide, d'une série de charbons perspectifs de la Sibérie, en particulier des charbons du gisement Bérézovskojé avec une teneur élevée de la partie minérale en CaO, dans les mâchefers, comme il est indiqué ci-dessus, peut apparaître une nouvelle phase cristalline fortement basique (C<sub>2</sub>S) qui assure à ces mâchefers une activité hydraulique élevée (Tableau 4).

En ce qui concerne l'utilisation des mâchefers en tant que constituant du mélange cru, ces problèmes doivent être résolus de

façon concrète et avant tout du point de vue de l'efficacité technologique et économique de cette utilisation. On doit alors tenir compte du fait que dans une série de cas pour obtenir le clinker de composition de ciment portland normale il faut introduire dans le mélange cru de grandes quantités d'additions de correction. Les études montrent qu'il est plus rationnel d'utiliser à cette fin les mêchefers à teneur très élevée en CaO ou simultanément à teneur élevée en CaO et en Al<sub>2</sub>O<sub>3</sub> (1).

L'utilisation des mêchefers granulés comme matériaux de ciment traditionnels permettra dans certains cas d'obtenir un effet technico-économique important et contribuera à l'élargissement des ressources de matières premières de l'industrie du ciment.

# Alite composition and structure state of ferrum in high-basic furnace slags

## *Composition de l'alite et état structural du fer dans les mafechers à haute basicité*

M.B. SVATOVSKAYA,  
M.M. SYTCHEV,  
L.Y. GOLDSTEIN, Guiprotsement, Ilt Lensovet, U.R.S.S.

Lors de la combustion à haute température des charbons du Bassin de Kansk-Achinsk on obtient des mafechers qui se distinguent par l'activité hydraulique élevée. La composition des phases des mafechers: alite (jusqu'à 35%) et bélite (jusqu'à 53%). Les études instrumentales montrent que d'après sa caractéristique cristallochimique l'alite se rapporte à la modification hautement symétrique et contient les quantités élevées des ions aluminium et magnésium.

Le rapport stoechiométrique de  $\text{CaO}$  à  $\text{SiO}_2$  dans sa composition était de 3,15 à 3,20. L'état structural du fer bivalent et trivalent dans ces mafechers fut étudié sur une série de compositions synthétiques avec le rapport de  $\text{Fe}^{+3}$  à  $\text{Fe}^{+2}$  de 1,66 à 0,26. On a étudié les mafechers de composition méilitique: vitreux et cristallins. On a montré que l'amorphisation du système s'accompagne d'une diminution de symétrie de l'entourage local des ions  $\text{Fe}^{+2}$  et d'une augmentation de symétrie de  $\text{Fe}^{+3}$ . On a révélé que  $\text{Fe}^{+3}$  et  $\text{Fe}^{+2}$  entrent dans la structure de la gélénite lors de la substitution partielle aux ions  $\text{Al}^{+3}$  des ions  $\text{Fe}^{+3}$ . Les résultats obtenus ont permis, dans une certaine mesure, d'élucider le mécanisme de la décomposition hydrolytique des mafechers lors de leur interaction avec de l'eau.

When burning at high temperatures coals of certain deposits of the Kansk-Achinsk basin one obtains slags of high hydraulic activity. The phase composition of such slags includes high-basic calcium silicates - alite (up to 35%) and belite (up to 53%). It has been ascertained through instrument examinations of the alite phase extracted from the furnace slag in a monomineral form by means of a heavy fluid centrifuge process that in its crystallochemical characteristics alite can be related to the high-symmetrical modification.

It has been found out as well that furnace slag alite includes a higher amount of aluminum and magnesium ions.

The stoichiometric ratio between  $\text{CaO}$  and  $\text{SiO}_2$  in the furnace slag alite was in the order of 3.15-3.20. The structure state of bivalent and trivalent ferrum in the furnace slags of the Kansk-Achinsk basin was studied on a series of synthetic compositions with a  $\text{Fe}^{+3}$  to  $\text{Fe}^{+2}$  ratio varying from 1.66 to 0.26. The investigations were conducted applying NGR spectroscopy. Slags of melilite composition, both glass-like and crystalline, were also under examination. The study showed that the amorphous-prone state of the system is characterized by reduction of the symmetry of the local surrounding of  $\text{Fe}^{+2}$  ions and by increase of the  $\text{Fe}^{+3}$  symmetry. It was revealed that  $\text{Fe}^{+3}$  and  $\text{Fe}^{+2}$  are a part of the gellenite structure with partial replacement of  $\text{Al}^{+3}$  ions by  $\text{Fe}^{+3}$  ions. The results obtained made it possible, to a certain degree, to clear up the mechanism of the hydrolytic decomposition of furnace slags when reacting with water.

High-temperature combustion of coals of the Kansk-Achinskii deposit with removal of liquid slags and subsequent grinding of the silicate melt yields a product which is characterized by the following features:

1. Formation of high-basic calcium silicates, alite and belite.
2. The presence of considerable amounts (3-16%) of ferrous oxide.

The appearance of high-basic calcium silicate (alite) in the composition of a fuel slag, is observed for the first time, and it was interesting to examine the composition and structure of this slag. The alite phase was isolated in mineral form by separation in heavy liquids [1]. For comparison the alite phase was also separated from clinker obtained in the traditional way by sintering and from melted clinker synthesized from calcium carbonate and mineral fraction of Estonian fuel shales. The chemical compositions of the specimens are presented in Table 1.

The composition of alite phase was determined from the difference in content of the main components in fractions enriched with alite and ferrite components.

Separation of the silicate component from the ferrite one was carried out in several stages (extraction in absolute alcohol selective treatment with solvents separation in high-density liquid ( $\rho=3.32$ ). Due to the specific morphological characteristic of the fuel slag special attention was devoted to selection of solvents. Further enrichment of the phases was carried out by repeated centrifugation of specimens in liquids of various density from  $\rho=2.49$  to  $\rho=3.32$ . The degree of enrichment was monitored by microscopic examination. Phases were obtained with the degree of monomineralization in the range of 94-96%.

Chemical compositions of the isolated alite phases are presented in Table 2. The obtained data indicate that the presence of admixture elements in the alites correlates with their presence in the starting material (Table 1).

The content of  $Mg^{2+}$  and  $Al^{+3}$  in the alite obtained from the fuel slag is higher than in similar phases extracted from the sintered and melted clinkers. The amount of  $Fe^{+3}$  cations corresponds to the values determined by instrumental methods [2]. The stoichiometry of the alite phases corres-

ponds to values of 3.04-3.20. Enhanced concentration of  $Al^{+3}$  and  $Mg^{+2}$  ions in the alite of fuel slag may be connected with high temperature level during combustion of high-calcium coals and also with increase of the degree of inequilibrium of silicate phases due to rapid cooling of the melt.

Crystallochemical study of the fuel slag alite by X-ray diffractometry and optical microscopy in transparent glass cells (Fedorov's table) showed that the phase under study belongs to the highly symmetrical modification [3]. According to several researchers [4] crystallization of alite in the highly symmetrical modification is one of the causes of enhanced hydraulic activity.

Fig.1. Microphotograph of fracture surface of alite-containing fuel slag, electron microscope, carbon replace X10000. The block submicrostructure of alite is distinctly revealed

Estimation of the crystalline microstructure of the fuel slag alite by electron microscopy showed (Fig.1) prevalence of fine and medium-block structure that, as established previously [5], facilitates forma-

tion of a more dispersed product during mechanical grinding.

The valent state of iron was studied by nuclear gamma-resonance spectrometry. A series of synthetic slag compositions with calcium oxide content of 38-50% was studied. The Fe<sup>3+</sup>/Fe<sup>2+</sup> ratio varied from 1.86 to 0.26. Phase composition changed from glass to crystalline. Measurements were carried out at room temperature in combination with a pulse analyzer AI 40-96. <sup>57</sup>Co in palladium was used as a radiation source, activity 10 mC. Variation of Fe<sup>3+</sup>/Fe<sup>2+</sup> ratio was accompanied by change of the shape of the Mossbauer spectrum (Fig.2). The Mossbauer spectrum of high-basic fuel slag with Fe<sup>3+</sup>/Fe<sup>2+</sup> = 1.86 (Fig.2a) represented by crystalline silicates displayed two quadrupole doublets correspondings to Fe<sup>3+</sup> in octaand tetrahedral environment. The latter points to inclusion of Fe<sup>3+</sup> into the aluminoferrite phase with substitution of Al<sup>3+</sup>, which is in agreement with (6).

$\delta_1 = 0.51 \pm 0.02$  mm/s;  $\Delta_1 = 1.56 \pm 0.03$  mm/s [FeO<sub>6</sub>];  
 $\delta_2 = 0.33 \pm 0.02$  mm/s;  $\Delta_2 = 1.48 \pm 0.03$  mm/s [FeO<sub>4</sub>].

Amorphization of the system is accompanied by change of the shape of Mossbauer spectrum (Fig.2b) and indicates increase of local Fe<sup>3+</sup> symmetry and lowering of local Fe<sup>2+</sup> symmetry.

The spectrum of glass-like fuel slag of melilite composition with Fe<sup>3+</sup>/Fe<sup>2+</sup> = 0.35 is

Fig.2. Mossbauer spectra of High-Basic fuel slags: a-crystalline, Fe<sup>3+</sup>/Fe<sup>2+</sup> = 1.86; b - glass-like, Fe<sup>3+</sup>/Fe<sup>2+</sup> = 0.35

represented by superposition of three quadrupole doublets: two doublets of trivalent iron

$\delta_1 = 0.22 \pm 0.02$  mm/s;  $\Delta_1 = 1.53 \pm 0.03$  mm/s

$\delta_2 = 0.52 \pm 0.02$  mm/s;  $\Delta_2 = 0.60 \pm 0.03$  mm/s;

and one doublet of  $\text{Fe}^{+2}$

$\delta = 1.15 \pm 0.04$  mm/s  $\Delta = 2.03 \pm 0.03$  mm/s.

Analysis of this spectrum allows to assume that  $\text{Fe}^{+3}$  replaces  $\text{Ca}^{+2}$  in tetrahedral sites of gehlenite glass. Possessing a strong field, it exerts a considerable polarizing effect on the Si-O-Me bond. The latter hinders processes of hydraulic decomposition of high-basic slags containing bivalent iron with water.

#### CONCLUSIONS

1. The composition, crystal-optical characteristics and microstructure of alite phase isolated from high-basic fuel slag were studied by chemical methods, optical and electron microscopy.
2. NGR spectroscopy was employed to elucidate the structural state of bi and trivalent iron in glass-like and crystalline fuel slags.
3. An explanation of the reduced hydraulic activity of glass-like fuel slags containing iron in +2 oxidation state is given.

# Influence des matériaux analogues aux pouzzolanes sur la formation de la structure du ciment durci

## *Influence effects of pozzolana-like materials on structure formation of cement stone*

L. KOURASSOVA, Collab. Sc. Super. (NIIZhB, Moscou)

Z. LARIONOVA, Chef de Laboratoire, U.R.S.S.

Les fractions finement dispersées de la plupart des agrégats poreux sont les analogues des pouzzolanes dont les propriétés hydrauliques dépendent du degré de leur dispersité, de leur composition de phase et de leur structure.

Ayant pris comme un échantillon d'exemple le kéramsite dont la composition de phase et la structure sont différentes dans les parties de granule différemment éloignées de son centre, on a étudié l'influence de ses fractions finement dispersées sur la formation de la structure du ciment durci. Est étudié la structure des grains de kéramsite disposés dans des parties différentes de granule. Est mise en évidence la microdureté du ciment durci contenant les particules du kéramsite (ainsi que la microdureté de ces particules, proprement dit) et la phase essentielle de formation de sa structure favorisant l'accroissement de la résistance du ciment durci et son imperméabilité à l'eau.

Est mis à jour le mécanisme de l'interaction des particules du kéramsite finement dispersées avec le ciment durci. Ce mécanisme consiste en formation de la couche de contact du ciment durci, compactée et chimiquement modifiée.

Fine-dispersed fractions of most of porous aggregates are similar to those of pozzolanas the hydraulic properties of which depend on the degree of their dispersity, phase composition and structure. Ceramsite being taken as a specimen of a mineral with granules noted for their phase composition and structure, the effects of its various fine-dispersed fractions on the structure formation of the cement stone has been studied. The structure of ceramsite particles from various parts of its granule.

Microhardness of cement stone with ceramsite particles in it has been revealed, as well as the basic structure forming phase that increases its strength and water impermeability.

The mechanism of physico-chemical interaction between the fine-dispersed ceramsite particles and cement stone has been brought to light.

This mechanism consists in formation of compacted, chemically transformed contact layer of cement stone.

Les fractions finement dispersées de la plupart des agrégats poreux sont les analogues des pouzzolanes dont les propriétés hydrauliques dépendent du degré de leur dispersité, de leur composition de phase et de leur structure. Ayant pris comme un échantillon d'exemple le kéramsite dont la composition de phase et la structure sont différentes dans les parties de granule différemment éloignées de son centre, on a étudié l'influence de ses fractions finement dispersées sur la formation de la structure du ciment durci.

L'étude complexe physico-chimique des composants finement dispersés des zones extérieure et intérieure de granule de kéramsite a été réalisée pour la première fois. Une telle étude différentielle est conditionnée par le fait qu'en fonction de la technologie de la préparation du béton, les uns ou les autres y peuvent prédominer.

Il a été constaté que la composition de phase, la microstructure, la porosité, la masse spécifique et volumique des fractions finement dispersées de zone intérieures et de zone extérieure du kéramsite sont différentes.

La composition de phase de la zone extérieure se diffère principalement de celle de la zone intérieure par la présence de la forme oxyde de fer, ce qui amène à la formation dans cette zone des minéraux de hématite -  $\text{Fe}_2\text{O}_3$ , magnétite -  $\text{Fe}_3\text{O}_4$ .

L'activité hydraulique (déterminée d'après l'absorption de  $\text{CaO}$  de la solution) des particules de la zone extérieure, d'habitude, est plus grande que celle des particules de la zone intérieure, simultanément leurs masses volumique et spécifique est moins à 4%,  $S_{sp}$  étant  $3000 \text{ cm}^3/\text{g}$ , et à 7%,  $S_{sp}$  étant  $= 7000 \text{ cm}^3/\text{g}$ .

Les particules de la zone extérieure se caractérisent par une surface incohérente et avec une grande quantité des pores 2  $\mu\text{m}$ . Les particules de la zone intérieure de kéramsite se distinguent par une surface régulière et dans ces particules les pores rares, mais ayant les dimensions plus grandes, égales à 10-12  $\mu\text{m}$ , prédominent.

La microdureté des cloisons des deux sortes des particules du kéramsite est à peu près égale et est comprise entre 10000 et 14000 MPa en fonction de la composition de phase de la phase de verre du kéramsite.

Les valeurs citées correspondent à la microdureté de minéraux tels, que quartz; ces valeurs sont 2,5 fois plus grandes que les valeurs de microdureté de minéraux de clincker et 10-20 fois plus grandes que la masse hydratée du ciment durci.

Cette différence des particules conditionne la différence de leur action sur le ciment durci, et ce fait, ensuite, amène à une évolution bien différente du processus de la formation de structure.

Par les expériences réalisés spécialement est mis en évidence que la présence des particules finement dispersées du kéramsite (également de la zone extérieure et de la zone intérieure) provoque les changements considérables dans la composition de phase du ciment durci: se forme le hydro-grenat bas-siliceux  $\text{C}_3\text{A}(\text{F})\text{S} 0,5\text{H}_x$ , abaisse la quantité de  $\text{Ca}(\text{OH})_2$ ; avec cela la phase essentielle de hydrates est CSH(I). L'application d'un complexe des méthodes physico-chimiques a permis de mettre en évidence la différence de microstructure du ciment durci additionnée et non du kéramsite. Dans le dernier cas la masse hydratée faiblement cristallisée a une structure incohérente et des fissures de largeur égale à 0,5  $\mu\text{m}$ . Le ciment durci contenant les particules des zones intérieure et extérieure du kéramsite se distingue par une compacité plus grande, par l'homogénéité de la microstructure il n'y a presque pas de fissures; la quantité des pores est diminuée. Les particules corrodées du kéramsite sont liées avec la phase essentielle des hydrates par des différentes formes cristallines (Fig.1).

Il a été établi que les particules finement dispersées du kéramsite font diminuer la porosité intégrale du ciment durci et autant plus considérablement que leurs dispersité s'accroît; avec cela la quantité des macropores diminue, particulièrement quant aux macropores ayant un rayon  $R > 5000 \text{ \AA}$ , ce fait doit amener à l'accroissement de l'imperméabilité à l'eau. Dans les compositions contenant les particules avec  $S_{sp} = 2700 \text{ cm}^3/\text{g}$  (et également sans particules) le maximum est dans les pores ayant un rayon  $R = 100 \text{ \AA}$  et 1250  $\text{ \AA}$ . Avec  $S_{sp} = 7000 \text{ cm}^3/\text{g}$  dans la composition contenant les particules de la zone extérieure  $R$  étant, égal à 1250  $\text{ \AA}$  le maximum, diminue et la formation d'un nouveau ma-

Fig. 1. La variation de microdureté  $H_M$  (en MPa) lorsque la distance  $l$  (en mm) entre la ligne de contact et les grains ayant les dimensions égales 0,15 mm (1), 0,25 mm (2), 0,5 mm (3), 1,2 mm (4), 2,5 mm (5), 5 mm (6), s'accroît

ximum avec le  $R=750$  Å en résulte; dans la composition contenant les particules de la zone intérieure il y a un maximum dans les pores ayant  $R=200-250$  Å (Fig. 2). Par l'étude donnée a été déterminé le mécanisme de l'interaction physico-chimique des grains hydrauliquement actifs du kéramsite et du ciment durci. Il consiste en formation de la couche de conde contact du ciment durci qui a des modifications chimiques et dont le largeur est égal à 10-30 mkm. Son microdureté autour les particules 10 mkm, qui est 4-7 fois plus grand que le microdureté de la masse hydratée en volume, est conditionné par la présence de nouvelles formations et des particules plus petites du kéramsite, joints epitaxialement avec le ciment durci. Le volume des zones consolidées (particulièrement au contact avec les particules de la zone

Fig. 2. Programmes des mortiers de cimentables sans particules (1) et avec les particules de la zone extérieure (a) et de la zone intérieure (b) du Kéramsite, leur surface spécifique  $S_{sp}$  étant égale à 2700  $\text{cm}^2/\text{g}$  (2) et 7000  $\text{cm}^2/\text{g}$  (3):  $v$  - volume des pores;  $r$  - rayon des pores

extérieure) est 10-100 fois plus grand que le volume des particules et accroît la résistance du ciment durci. C'est pourquoi l'influence positive des particules de la zone extérieures 10 mkm se manifeste même si la teneur en ces particules est égale à 1-2% de la masse du ciment. Avec l'augmen-

tation des dimensions des grains la largeur des zones ne change pas, et le volume relatif diminue. Donc, les particules de la zone extérieure du këramsite avec les dimensions 50 mkm et se caractérisant par leur activité hydraulique et la microstructure spécifique représentent une composante qui est la plus active dans le processus de la formation de structure. Les particules de la zone intérieure du këramsite sont d'une moindre activité hydraulique; une action positive sont seulement les particules de 10-15 mkm, pratiquement privées de la porosité; ces particules représentent une sorte de centre de la cristallisation des unités des hydrates et sont des éléments consolidants la structure (en remplissant des espaces vides).

Donc, les résultats obtenus ont permis de mettre en évidence le rôle positif des particules finement dispersées du këramsite dans le processus de la formation de la structure du ciment durci et d'expliquer du point de vue de physique et de chimie l'influence qu'elle exercent sur certaines propriétés techniques du ciment durci, ainsi que sur celles du béton léger.

#### Centres basiques sur la surface des solutions solides du silicate bicalcique

#### *Basic centers on the surface of dicalcium silicate*

KAZANSKAIA A.N.,

SYTCHEV M.M., Docteur ès Sciences Techniques, Professeur, SPIROV I.S., Institut Technologique Lensovet de Leningrad, U.R.S.S.

Par la méthode de l'adsorption du phénol suivie d'une détermination différentielle thermique de la quantité d'une substance chimisorbée on a évalué la force et la concentration des centres basiques (propriétés électrodonatrices) sur la surface du silicate bicalcique et de ses solutions solides de type  $\beta\text{-Ca}_{2,56}\text{Si}_{0,047}\text{Cr}_{0,09}\text{O}_3$  et  $\beta\text{-Ca}_{2,48}\text{Si}_{0,11}\text{Cr}_{0,09}\text{O}_3$ .

On a décelé deux types de centres basiques correspondant de toute évidence aux groupes OH et O<sup>-</sup> sur la surface.

La concentration des centres basiques sur la surface de  $\beta\text{-Ca}_2\text{SiO}_3$  dépend du traitement préalable de la surface, de la concentration et du type des constituants d'impureté. On peut se représenter que le processus d'hydratation se développe d'après le mécanisme dissociatif généralisé et acido-basique.

Intensity and concentration of basic (electron-donor properties) centers on the surface of dicalcium silicate and its solid solutions - type  $\beta\text{-Ca}_{2,56}\text{Si}_{0,047}\text{Cr}_{0,09}\text{O}_3$  and  $\beta\text{-Ca}_{2,48}\text{Si}_{0,11}\text{Cr}_{0,09}\text{O}_3$  has been estimated by the method of phenol adsorption with subsequent differential-thermal definition of the chemisorbed substance quantity. Two types of basic centers have been discovered, having on the surface, probably, OH and O<sup>-</sup> groups.

Concentration of the basic centers on the surface  $\beta\text{-Ca}_2\text{SiO}_3$  depends on previous surface processing, concentration and type of additions. One can imagine, that the hydration process develops according to the generalized dissociation and acid-basic mechanism.

La nature et la concentration des centres actifs apparaissant sur la surface des constituants de clinker au cours de la synthèse à haute température sont dues aux défauts de leur structure cristalline et à la présence de corps étrangers (1), au régime de traitement thermique et au degré de vieillissement de l'échantillon en contact avec les gaz atmosphériques ( $O_2$ ,  $H_2O$ ,  $CO_2$ ) (2 à 4).

Pour le silicate tricalcique contenant sous forme d'impureté les ions  $Al^{3+}$ , on a révélé trois types de défauts ponctuels (5): 1) centres électroniques sur les vacances d'oxygène dans les complexes de calcium-oxygène, 2) centres électroniques sur les atomes d'oxygène des tétraèdres en fragments, 3) centres lacunaires sur les atomes d'oxygène en fragments.

Dans le cadre de la théorie (6) l'apparition de centres lacunaires sur la surface des oxydes (en particulier sur le silicagel) en présence de cations étrangers, peut conduire à deux types de structure de ces centres:

1) "en pont" dans le cas des cations de valence minimale (silicagel contenant  $Al^{3+}$ )

2) dans le cas des cations de valence maximale, les structures des anions-radicaux superficiels finals ayant formellement dans leur sphère de coordination une vacance cationique:

Selon la théorie d'acide base (7, 8) les centres accepteurs d'électrons sont interprétés comme centres acides de Lewis (centres  $\alpha$ ,  $OH^-$  sur la surface des aluminosilicates). En présence d'eau ces centres se transforment en centres acides de Bronsted (centres  $\beta$ ,  $OH^-$  sur la surface) ayant une capacité caractéristique de transfert du proton. Les centres donneurs d'électrons qui transmettent un doublet électronique à l'acide adsorbé (proton) sont définis comme centres basiques. Les atomes d'oxygène chargés négativement, les groupes  $OH^-$  peuvent

constituer les centres basiques. D'après la fréquence de la vibration principale les groupes hydroxyles acides et basiques se distinguent peu dans les spectres infrarouges. Toutefois, lorsque ce groupe hydroxyle entre en réaction, les différences dans son acidité commencent à se manifester de façon sensible (9).

Selon la théorie des clusters on peut simuler le centre actif avec une force différente de l'acidité de Bronsted en faisant varier dans de larges limites le potentiel d'ionisation des atomes du voisinage immédiat du centre à l'intérieur du cluster (dopage par les cations polyvalents, adsorption des molécules accepteurs et des molécules-donneurs d'électrons, etc.) (10).

La nature du centre actif définit sa réactivité dans les processus d'adsorption, d'hydratation, de polycondensation, etc. Ainsi on observe une corrélation qualitative entre la réactivité des centres lacunaires "en pont" (propriétés d'accepteur d'électrons) et la profondeur à laquelle se trouvent les niveaux accepteurs correspondants dans la zone "interdite" de l'oxyde. Les centres lacunaires finals ont les propriétés du radical libre (6). Pour les groupes  $OH^-$  en pont (groupes  $OH^-$  sur la surface des aluminosilicates) on peut observer, lors de l'absorption de l'eau, l'adsorption à deux points conduisant à la formation des particules semblables aux ions hydroxonium adsorbés et influant sur la réaction d'échange de protons entre l'adsorbant et l'adsorbat (10):

Lors de l'adsorption sur la surface du semi-conducteur (11) le complexe donneur-accepteur formé défaut-molécule adsorbée peut cesser de jouer le rôle du centre de capture de porteurs libres. S'il s'agit de l'adsorption des molécules-donneurs ( $H_2O$ ) le complexe commence à jouer le rôle du centre de capture des trous. Si le trou est localisé au voisinage de ce complexe d'adsorption la déformation de la molécule d'eau adsorbée devient plus grande. La capture d'un trou aux niveaux donneurs de la molécule d'eau

conduit à la dissociation  $H_2O \rightarrow H^+ + OH^-$ . Le développement d'un tel processus de dissociations de l'eau aux centres actifs d'un constituant de clinker peut contribuer de façon efficace, selon M.M. Sytchev (12), à la protonisation des liaisons dans ce constituant.

Par la méthode d'adsorption du phénol (13) suivie de la détermination thermique différentielle de la quantité d'une substance chimisorbée (7) on a évalué la force des centres basiques (propriétés de donneur d'électrons) et on a mesuré leur concentration. Au cours de l'étude de  $\beta-C_2S$  ( $B_2O_3$  stab.) les solutions solides de type  $\beta-C_{2,56}^{SA}O_{0,47}Cr_{0,09}$ ,  $\beta-C_{2,48}^{SA}O_{0,11}Cr_{0,03}$  et CaO (étalon de haute basicité) avec les particules de dimension inférieure à  $60 \mu$  sous forme de comprimés de poids de 0,5 g étaient traitées dans le vide (dépression de  $10^{-4}$  mm Hg) aux diverses températures (300 et 500 °C) pendant un temps différent (2 à 3 h), ensuite elles étaient refroidies dans le vide jusqu'à 100 °C et soumises à l'adsorption par les vapeurs du phénol (48 h à 50 °C).

La désorption du phénol était réalisée dans les conditions quasi statiques (4 h à 60 °C jusqu'au poids constant de l'échantillon et 5 h à 500 °C) et dans les conditions dynamiques (levé dérivatographique à l'aide du dérivatographe de Paulik et Erday pour la vitesse de chauffage de l'échantillon de 5 degrés/mn jusqu'à 600 °C; la valeur de la charge TG=0,5g et de la sensibilité de l'appareil d'après TG= 20 à 200, d'après ATD =  $\pm 1/2$  à  $\pm 1/5$ ). L'évacuation d'une plus grande partie du phénol physiquement adsorbé dans les conditions quasi statiques a permis d'augmenter la sensibilité du dérivatographe en TG et de diminuer ainsi l'erreur de mesure de la valeur de la chimisorption.

Les résultats d'étude des propriétés d'adsorption de la surface pour toutes les solutions solides à base de  $\beta-C_2S$  et de CaO sont donnés dans le tableau. Il résulte de ce tableau que pour tous les objets étudiés on a décelé la présence de centres basiques (désorption du phénol chimiquement lié dans le domaine de températures de 275 à 550 °C). Dans plusieurs cas (CaO,  $C_2S$  ( $B_2O_3$  stab.) et  $C_2S_{Al_nCr_m}$  traités à 500 °C dans le vide de  $10^{-4}$  mm Hg pendant 3h) on a révélé deux types de centres basiques (résolution des effets endothermiques sur les courbes ATD).

Les centres basiques faibles correspondant au pic de désorption sur la courbe ATD à plus basse température sont évidemment formés par les groupes  $OH^-$  de la surface. Des centres basiques plus forts correspondent à une température plus élevée de l'effet endothermique et il se forme  $O^-$  sur la surface. Ainsi pour l'échantillon de  $\beta-C_2S$  ( $B_2O_3$  stab.) les centres basiques faibles se caractérisent par la température de désorption du phénol de 275 °C et les centres basiques forts par la température

de 425 °C. Les centres les plus forts sont décelés sur la surface de CaO (température du pic de désorption de 550 °C) et pour les solutions solides, sur la surface de  $\beta-C_{2,48}^{SA}O_{0,11}Cr_{0,03}$  (température du pic de désorption de 470 °C).

La concentration des centres basiques sur la surface du silicate bicalcique  $\beta$  et de ses solutions solides est beaucoup plus petite (0,025 à 0,066 mmol/g) que la concentration des centres basiques sur la surface de CaO (0,55 mmol/g), est en accord avec les données de référence (7, 11), et dépend du traitement préalable de la surface, de la concentration et du type de constituants étrangers. La concentration des centres basiques sur la surface des solutions solides de  $C_{2,56}^{SA}O_{0,47}Cr_{0,09}$  et de  $C_{2,48}^{SA}O_{0,11}Cr_{0,03}$  (0,063 et 0,066 mmol/g respectivement) dépasse la même valeur pour  $\beta-C_2S$  ( $B_2O_3$  stab.) (0,060 mmol/g).

L'analyse simultanée des courbes ATD et TG du dérivatogramme a permis d'évaluer le rapport quantitatif des centres basiques de force différente d'après la quantité de chaleur nécessaire pour la désorption du phénol (7). Ainsi, la quantité relative des centres basiques les plus forts pour l'échantillon de  $\beta-C_2S$  ( $B_2O_3$  stab.; 500 °C, 3 h) est de 0,0125 mmol/g pour la concentration totale des centres basiques de 0,060 mmol/g ou 21 % de la quantité totale des centres actifs de type basique.

Ainsi le silicate bicalcique et les solutions solides à base de ce dernier de type  $\beta-C_{2,48}^{SA}O_{0,11}Cr_{0,03}$  et  $\beta-C_{2,56}^{SA}O_{0,47}Cr_{0,09}$  possèdent une basicité sommaire très basse qui est cependant en corrélation avec leur activité dans la réaction d'hydratation (diminution fixée de la concentration et de la force des centres basiques, de l'activité hydraulique et accroissement des temps de prise dans la série) :

$$\beta-C_{2,48}^{SA}O_{0,11}Cr_{0,03} > \beta-C_{2,56}^{SA}O_{0,47}Cr_{0,09} > \beta-C_2S (B_2O_3 \text{ stab.})$$

Compte tenu des données de Fiereus (2) qui a établi, dans le système silicate de calcium-eau, le fait de participation à la formation des liaisons de chimisorption des électrons dont le donneur est le cros solide, on peut se représenter que le processus d'hydratation se développe selon le mécanisme généralisé dissociatif et acido-basique (11). Dans ce cas les centres actifs (parties de surface autour de l'atome actif) sont responsables de la formation des complexes donneurs-accepteurs défaut-molécule adsorbée d'eau et de la dissociation des molécules adsorbées d'après le schéma  $H_2O \rightarrow H^+ + OH^-$ . Par la suite le mécanisme de la réaction d'hydratation devient analogue au mécanisme acido-basique avec le transfert d'un doublet électronique au proton sur les centres basiques de la surface ( $Si-O-Ca-O(H^+)$ ). La protonisation initiale des groupes basiques dif-

# Mechanical-chemical activation of mixed portland cement with increased content of technogen belite product of alumina industry

## *Activation mécano-chimique du ciment portland mixte à teneur élevée en produit bélique technogène de la production de l'alumine*

S.D. MAKACHEV,  
V.I. AKOUNOV,  
T.A. ARBEKOVA,  
T.V. KOUZNETSOVA,  
B.E. YUODOVITCH, Niitsement, Moscou, U.R.S.S.

Dans la technologie ordinaire du ciment portland la teneur en produit belitique technogène de la production de l'alumine est limitée à 10-15%.

On a mis au point une nouvelle technologie du broyage et de l'activation mécano-chimique simultanés du ciment portland permettant d'augmenter la teneur en produit bélique technogène jusqu'à 30%.

Ce ciment a une activité à l'âge de 3 jours: 257 kgf/cm<sup>2</sup> à la compression et 47 kgf/cm<sup>2</sup> à la flexion, à l'âge de 28 jours respectivement 487 kgf/cm<sup>2</sup> et 71 kgf/cm<sup>2</sup>, ce qui correspond aux exigences sur le ciment portland à durcissement rapide de marque 500 d'après GOST-10178-76 (URSS).

L'activation du ciment est atteinte grâce à la combinaison optimale de deux mécanismes de broyage: de fragmentation et d'écaillage permettant d'obtenir le système dispersé ayant une composition granulométrique et une morphologie déterminées, réunissant l'état spécifique de la surface avec la destruction suffisante des particules.

It is common in portland cement technology that the content of belite technogen product is limited to 10-15%.

A new technology of combined grinding and mechanical-chemical activation of portland cement has been developed permitting for increase the content of technogen belite product up to 30%.

Such a cement has the 3-day activity: 257 kg/sm<sup>2</sup> compression strength and 47 kg/sm<sup>2</sup> bend strength; and the 28-day activity: 487 kg/sm<sup>2</sup> and 71 kg/sm<sup>2</sup> respectively, meeting the requirements for quick-hardening portland cement (brand 500, according to the USSR GOST-10178-76).

The cement activation is achieved due to optimum combination of two grinding mechanisms: cracking and shelling. This makes it possible to get the dispersed system of a particular granulometric content and morphology, thus combining the specific surface condition and satisfactory particles destruction.

**RESUME:** Decrease of clinker formation and hydration activation energy at jet pulverization considerably increases the degree of utilization of potential physical and chemical energy of such clinker components as technogenic  $\text{CO}_2\text{S}$  and provides for organizing an economic production of various-activity cement on its basis. The jet pulverization process differs from milling process with free milling bodies by the rate of crack formation in the particles approaching the sonic one and two orders as high and substantially zero mutual abrasion of the particles.

The works by M. Wilson, T. Suzuki (theory) and A. Shand (experiments) show the diagram of increase of winding of the crack path (Fig. 1) when its opening speed approaches the

Fig. 1. Crack Trajectory in Half-Plane Depending on Opening Rate: 1-0.01s; 2-0.1 s; 3-0.3 s; 4-0.5 s; 5-0.7 s; 6-0.9 s; — average sound velocity in material

sound velocity in the solid body up to beginning of branching. Therefore, the jet pulverization products should feature a more angular shape of particles and, in particular, particles with inward angles. Investi-

gations of the jet pulverization products with the use of a scanning electron microscope after application of an Au film show (Fig. 2) that such inward angles are actually formed on the particles of clinker crushed to a specific surface of  $3000 \text{ cm}^2/\text{g}$ . The microphotos show general view of the particles left on a screen with a mesh size of 80 microns.

Formation of sharp edges and inward angles increases accessibility of the particle internal regions for chemical reaction, hydration in this case, and determines increased strength of the jet pulverization cements over the ball mill cements, mentioned by some of us in the report at the Vth Congress on Chemistry of Cement in 1974 which discussed production of high-strength and rapid-hardening cements.

The electron microscopy investigations reveal another characteristic feature of the jet pulverization products stemming from high energy stress in the air-pressure mills which is about one order as high (per unit volume) as that of the ball mills. We mean the mechanochemical aggregation of particles (Fig. 3) which forms bridges between grains containing mainly intermediate substance in case of clinker. A similar phenomenon is observed in case of jet pulverization of a cement raw mix where the soft carbonate component (chalk) particles are main subject of aggregation.

Fig. 3. General View of Portland Cement Clinker Jet Pulverization Product Fraction  $> 80$  Microns. Bridges (Jumpers) between Particles are Seen: Scale - 1 micron

The technological importance of this phenomenon as applied to cements resides in the increase of water requirements of the jet pulverization cements. The amount of

Fig. 2 b

and leads to considerable variations of the mixture dispersion at the mill outlet; therefore the reaction ability of the raw mixture rises at separate jet pulverization of components followed by intermixing or at jet pulverization of one and milling of other components (Table 1).

The theoretical analysis of the stream mill pulverization process the results of which are published in the "Cement" periodical in 1979, Leningrad, reveals that the periodical fluctuations in the dispersion of charges consisting of two components with different crushing ability are more vividly manifested in the stream mills than in the ball ones. Therefore, the stream mills are less suitable for pulverization of multi-component charges. Further the theory witnesses that owing to only impact crushing and higher level of energy stress the grain composition of the stream mill products should be narrower, whereas the uniformity coefficient in the Rosin-Rammler-Shperling equation for the granulometric composition of said products should approach 1.

These postulates are supported by the experiment (Fig. 4). In view of the conclusion on the correlation between the high strength of cement and the degree of uniformity of its granulometric composition drawn by S. Sprung in his general report at the Vth Congress on Chemistry of Cement, it is clear that a narrower grain composition is one of the factors increasing the strength of jet pulverization cements. The fact that is somewhat above 1 (1.17-1.22 in the data of the experiment, Fig. 4) may be explained by multi-phase structure of the material being crushed and stimulated formation of cracks in the inter-phase boundary region. A number of factors mentioned above and decreasing of the jet pulverization products both in the clinker formation and cement hydration pro-

Fig. 2 c

water for the normal thickness grout increases at jet pulverization for 1.5-2 abs. % as compared with the ball mill cements at the same specific surface. As regards the raw materials, aggregation impedes the process of homogenization of the raw mixture

cesses may be regarded as providing for the reduction of the activation energy of said processes and make it possible to believe in activation at jet pulverization of some materials passive as compared with the portland clinker which was pointed out by some of us at this Congress in a written report dealing with technogenic belite products. In addition to the above data it will suffice to report on the test results of the jet pulverization product of the mixture consisting of 70% of the industrial portland cement clinker and 30% of belite slime of

the Volkhov combine. The technological advantages of this process reside in that when using overheated steam or hot furnace gases as an energy carrier for the stream mills, there is no need for pre-drying of the belite slime which is necessary in case of crushing of charge with such a high content of technogenic belite in a ball mill. A 150-kgf/cm<sup>2</sup> higher strength at the age of 28 days - 3 months as compared with a check mix of the ball mill cement proves that the activating effect of the jet pulverization, irrespective of its physical essence of those mentioned above, makes it more technologically preferable for mixed cements than the ball mill method. Thus, in this case the theoretical limitation linked with fluctuations of the multi-component charge jet pulverization product dispersion is eliminated. The analysis of the composition of separate fractions of the jet pulverization mixed cements reveals that the reason for activation is dictated in this case by the conversion of a more considerable part of the belite material into a fine fraction of the cement than ever registered at ball milling even with preliminary complete drying of the belite products.

A detailed analysis of belite grain resistance to crushing which is being carried out at present provides for drawing a preliminary conclusion that the technogenic belite offers higher resistance to abrasion than clinker minerals but fails to withstand impact loads. Substantial domination of the latter in the jet pulverization process leads to concentration of said material in the fine fractions of the product and its activation in the mixed cements. The corresponding technological process is to be organized at the cement plants of the USSR using or intending to use the technogenic belite products.

# Synthèses à basse température de silicates bicalciques actifs

## *Syntheses at low temperature of active dicalcium silicates*

B. MORTUREUX, E. REVERTEGAT, B. THURET, CERILH, Paris, France.

Un intérêt essentiel de la synthèse de  $C_2S$  hydrauliquement actif est d'ouvrir une voie de recherche en matière d'économie d'énergie. Plusieurs chercheurs ont obtenu du  $C_2S$  actif, même à relativement basse température, comme D.M. ROY qui a mis au point plusieurs techniques de synthèses entre 750°C et 900°C.

ARNOULT et STRUILLON (1), ont synthétisé un  $C_2S$  sulfaté (5% de  $SO_3$ ) à partir de spongolithe et de nitrate de calcium. Ce  $C_2S$  hydrauliquement très actif a des performances voisines de celles d'un CPA. Le nitrate, qui fond vers 680°C permet d'obtenir une réaction rapide et pratiquement totale dès 750°C avec une silice réactive comme la spongolithe.

La méthode nitrate ne constitue pas une voie industrielle en raison de la difficulté de recyclage des vapeurs nitreuses et de la valeur élevée de la chaleur de dissociation du nitrate de calcium qui pèse très lourdement sur le bilan thermique de la synthèse de  $C_2S$ . Elle a eu le grand mérite de montrer l'existence d'un  $C_2S$  très actif.

L'objet des travaux effectués au C.E.R.I.L.H. était d'examiner si un tel silicate pouvait être obtenu par d'autres moyens, et particulièrement sans faire intervenir le nitrate dont le rôle n'est pas parfaitement élucidé.

On a examiné en premier lieu le domaine de stabilité thermique du produit synthétisé par la méthode nitrate, tout en cherchant à préciser quelques-unes de ses caractéristiques afin de mieux identifier par la suite les solides obtenus par d'autres voies. L'examen par diffraction des rayons X des préparations par voie nitrate, avant et après traitement thermique et trempe a été utilisé à cette intention. Selon la température de traitement on aboutit aux constatations suivantes:

1°) Préparation sans traitement ultérieur (température d'obtention: 750°C).

Les pics de diffraction très larges suggèrent la présence simultanée de  $\alpha'$   $C_2S$  et  $\beta$   $C_2S$  mal organisés. La proportion  $\alpha'/\beta$  étant assez variable pour les diverses préparations. On note la présence en faible quantité de quartz et de chaux libre, ainsi que de sulfospurrite  $2 C_2S, Ca SO_4$  ce dernier caractère n'étant nullement systématique.

2°) Préparation examinée après traitement thermique :

(a) de 800 à 950°C

Les pics correspondant aux phases  $C_2S$ , observés dans les préparations initiales, se précisent et se développent, de sorte que les variétés  $\alpha'$  et  $\beta$   $C_2S$  deviennent identifiables sans ambiguïté: les formes cristallines de  $C_2S$  initialement présentes ont un degré d'organisation croissant avec la température de retraitement. Cette observation est également valable pour la sulfospurrite.

(b) à 1000°C. la phase  $\alpha'$   $C_2S$  disparaît.

(c) de 1000 à 1200°C la sulfospurrite se forme dans tous les cas.

(d) après 1250°C la sulfospurrite disparaît et l'anhydrite apparaît comme produit de décomposition.

Ces observations sont en accord avec les travaux de PLIEGO CUERVO et GLASSER (2) sur la stabilité de la sulfospurrite.

Les traitements thermiques altèrent progressivement les propriétés hydrauliques. A 1000°C le phénomène s'accroît, les résistances mécaniques en compression sur pâtes pures étant alors réduites au dixième de leur valeur initiale.

Le domaine de stabilité du produit actif apparaît donc limité aux basses températures. La technique de synthèse a donc été orientée vers la recherche de matières premières très réactives physiquement, en évitant d'introduire des ions étrangers.

La matière crue est obtenue par hydrolyse d'un mélange de silicate d'éthyle et de sulfate diéthyle par une suspension aqueuse de chaux maintenue pendant 16 heures à 90°C. On obtient une sorte de gel de silicate de calcium hydraté. Ce "gel" a été soumis à diverses conditions de cuisson. Un traitement de 24 heures à 750°C conduit à un produit dont les caractéristiques cristallographiques sont identiques à celles du  $C_2S$  synthétisé par la méthode nitrate. La teneur en  $SO_3$  du produit ainsi préparé est de 5 %, le rapport C/S étant ajusté à 2.

Une seconde propriété commune aux produits des deux synthèses réside dans la perte de poids caracté-

ristique entre 900° et 1000°C observée en Analyse Thermique Ponderale. Il est intéressant de noter que cette perte ne s'observe pas si le gel cru est directement soumis à l'examen A.T.P. On en conclut que le silicate sulfaté n'a pas le temps de se former dans les conditions de montée en température de l'essai (300°C/H).

Il faut enfin signaler que les produits des synthèses par cuisson du gel donnent des pâtes de résistances très variables suivant les préparations et cette variabilité est vraisemblablement liée à la très grande altérabilité au gaz carbonique du cru; mais les résistances peuvent dans certains cas approcher celles qui sont atteintes par la méthode nitrate spöngolithe et sont en tous cas bien supérieures aux résistances de pâtes de  $\beta$   $C_2S$ .

En conclusion, bien que les auteurs de la méthode, nitrate ne mentionnent que la forme  $\beta$   $C_2S$ , il est clair que les points de vue sont convergents pour attribuer en première approche les propriétés hydrauliques observées à une forme de  $C_2S$  mal organisée, modifiée par insertion de  $SO_3$  dans le réseau. En ce qui concerne les possibilités de synthèses:

- l'insertion du  $SO_3$  se fait à basse température.
- le silicate sulfaté actif devient instable dès 800°C.
- le nitrate, utile, n'est pas indispensable et ne conditionne pas l'activité du produit formé.
- la phase  $\alpha'$  peut jouer un rôle important dans l'insertion et le maintien de  $SO_3$  dans la structure.

Les travaux de REVERTEGAT (3) et REVERTEGAT et CHOISNET (4) donnent un autre exemple de la réactivité d'une phase  $\alpha'$   $C_2S$  stabilisée par un ion étranger. En effet, ces auteurs ont pu attribuer à cette phase l'effet bénéfique sur les propriétés mécaniques du clinker de l'introduction de baryum.

C'est pourquoi l'on a tenté d'appliquer les méthodes de préparation décrites précédemment pour synthétiser un éventuel  $C_2S$  activé par cet ion. Bien que les travaux ne soient pas suffisamment avancés pour conclure, on peut signaler que l'on a obtenu - par la technique du gel d'hydrolyse du silicate d'éthyle par une solution de chaux + baryte cuit à 800°C - un produit actif à durcissement assez rapide. L'analyse par diffraction des rayons X montre qu'il s'agit d'un mélange de  $\alpha'$   $C_2S$  et de  $\beta$   $C_2S$  mal organisés auxquels s'ajoute une phase X: correspondant à un silicate de baryum-calcium  $Ba_x Ca_y SiO_4$  avec  $x + y = 2$ .

On obtient par la méthode nitrate un produit de caractéristique cristallographique comparable.

Le traitement thermique ultérieur jusqu'à 900°C provoque une organisation des trois phases. Au-dessus de 900°C on observe une dilatation de la maille de  $\alpha'$   $C_2S$  et une diminution de la phase X qui disparaît complètement lorsque la température de retraitement atteint 1300°C.

## *Mineral formation processes and phase composition of alinite clinker*

M. BIKBAOU, Candidat ès sciences techniques, Chef de laboratoire de l'Institut des Recherches scientifiques et des projets des matériaux de construction, Tachkent, U.R.S.S.

RESUME : L'étude de la formation des minéraux du clinker d'alynite obtenu par la cuisson des matières premières en présence de chlorure de calcium a démontré que ces processus sont assez compliqués; nous avons découvert la formation de nouvelles phases minérales : du chlorure de calcium carbonaté, de la spourrite, de l'orthosilicate et de l'aluminoferrite de chlorure de calcium. A l'étape initiale de la cuisson, les phases minérales contiennent une quantité considérable d'atomes de Cl; à l'étape finale, par contre, on n'observe que des minéraux avec un faible Cl (3-4 % de la masse) - l'alite et l'aluminate de chlorure de calcium. Dans ces derniers minéraux, le chlore est solidement lié dans les positions structurales.

A part les minéraux indiqués, le clinker d'alynite contient également de la bélite et du ferrite de calcium, qui peuvent contenir un peu de chlore (1 % de la masse environ) dans leur structure. La contenance quantitative des phases minérales dans le clinker d'alynite varie dans les limites suivantes (% de la masse) :

l'alynite	60 - 80
la bélite	10 - 30
l'aluminate de chlorure de calcium	5 - 10
la ferrite de calcium	2 - 10

Des recherches effectuées ont permis de décrire le caractère de la cristallisation des phases siliciques du clinker, qui ont généralement une structure distincte à grains fins. Nous avons établi que les conditions de la cuisson et de la déchloration exercent une influence sensible sur le caractère de la cristallisation du clinker d'alynite.

Cette influence s'explique par la genèse des phases intermédiaires de la spourrite, de l'aluminoferrite et de l'orthosilicate de chlorure de calcium.

SUMMARY : The investigation of mineral formation processes of alinite-clinker produced by kilning the raw material together with calcium chloride has shown their considerable complication which leads to the formation of new phases - calcium chloride carbonate, spurrite, orthosilicate and aluminoferrite of calcium chloride.

At the initial stage of kilning new phases with considerable content of the chlorine atoms (about 15% of the mass) - orthosilicate and aluminoferrite of calcium chloride - are formed only the minerals containing small quantity of chlorine (3-4% of the mass) - alinite and aluminate of calcium chloride are kept at the final stage. In the above mentioned minerals the chlorine is tightly cohered in structure positions.

Besides the minerals mentioned above, the alinite clinker comprises also belite and calcium ferrite, which could comprise small quantity of chlorine (about 1.0% of the mass).

The quantitative content of mineral phases in alinite clinker varies within the following limits (% of the mass):

alinite	60 - 80
belite	10 - 30
aluminate of calcium chloride	5 - 10
calcium ferrite	2 - 10

The research data have allowed to describe crystallization of silicate phases of the clinker, which are normally characterized by clear but fine-grained structure.

Important dependence of the character of cristallization of alinite clinker upon the conditions of kilning and dechlorination has been established.

This dependence is closely connected with the genesis of intermediate phases of the clinker.

La cuisson du clinker de ciment en présence de la fusion des sels de chlorure de calcium provoque des changements radicaux dans la cinétique des processus de la formation du clinker, ainsi que dans sa composition de phase (I). Le présent travail montre les résultats d'une étude sur la suite des processus de la formation du clinker en présence de  $\text{CaCl}_2$ , ainsi que les données sur la composition plus précise des produits intermédiaires et finales de la cuisson du clinker d'alynite; ces données n'ont pas été décrites dans les publications spéciales.

Des mélanges suivants ont été préparés:

1. Un mélange des réactifs:

$\text{CaCO}_3$	$\text{SiO}_2$	$\text{Al}_2\text{O}_3$	$\text{Fe}_2\text{O}_3$	$\text{MgO}$	$\text{CaCl}_2$
69.2	16.1	2.5	1.9	1.3	9.0

2. Un mélange de limon de loess, de cendres et des calcaires de l'usine de ciment d'Akhan-garan avec 9% de chlorure de calcium, à raison de  $\text{CS} = 0,92$ ;  $n = 2,6$ ;  $p = 3,1^*$ .

Des mélanges ont été préparés sous forme de granules de dimension de 7-8 mm et cuits dans un four électrique de laboratoire. La vitesse de la montée de la température était égale à  $5^\circ\text{C}$  ce qui correspond à peu près aux conditions de production industrielle. À partir de  $400^\circ\text{C}$ , un échantillon des matériaux a été pris toutes les  $50^\circ$  et refroidi en l'air. À part cela, un essai isothermique aux températures données était employé afin de déterminer la composition de phase des produits de la cuisson.

Le produit cuit a été analysé sur le contenu de l'oxyde de calcium  $\text{CO}_2$  libre et du chlore.

La composition de phase des produits de la cuisson a été déterminée par les méthodes quantitative et qualitative de l'analyse optique et celle aux rayons X. La méthode de l'analyse thermique différentielle a aussi été utilisée.

La suite et le contenu des processus de la formation du clinker à basse température se diffère carrément des processus analogiques de cuisson du clinker de ciment portland. La présence de la chlorure de calcium, composante supplémentaire dans le mélange brut servant à produire le clinker à basse température provoque une complication considérable des processus de la formation des minéraux. La présence de la chlorure de calcium abaisse la température du processus final de la cuisson des minéraux de sortie du clinker du ciment d'alynite aussi que tous les processus intermédiaires. Ces processus sont illustrés par les courbes de l'analyse thermique différentielle (courbe ATD) (fig.1). À partir de  $500^\circ\text{C}$ , la courbe ATD du mélange brut du ciment change à cause de l'évaporation de l'eau des hydrates.

Nous avons utilisé une méthode d'étude de la composition de phase dans une couche mince qui a permis de découvrir le commencement de l'interaction chimique entre les composantes du mélange brut pour la formation du clinker d'alynite au niveau de  $450 - 500^\circ\text{C}$ .

Le processus de la formation des composés complexes commence déjà aux températures de  $530 - 600^\circ\text{C}$  grâce à l'interaction de  $\text{CaCl}_2$  et de  $\text{CaCO}_3$ , le carbonate de la chlorure de calcium<sup>2</sup> ( $\text{CaCO}_3 \cdot \text{CaCl}_2$ ).

À  $620 - 640^\circ\text{C}$  ce composé se transforme en phase X qui est, peut-être, sa modification de haute température qui existe dans l'intervalle de  $630 - 800^\circ\text{C}$ ; leurs propriétés chimiques et les paramètres des cellules sont assez proches (voir le tableau).

Dans l'intervalle de  $650 - 750^\circ\text{C}$  une décarbonisation plus intense fait apparaître l'oxyde de calcium libre. À ces températures, les composantes acides entrent en action mutuelle ce qui mène à la formation du spurrite dans les produits de la cuisson  $2\text{Ca}_2\text{SiO}_4 \cdot \text{CaCO}_3$ .

\*CS - coefficient de saturation, n - module silicique, p - module alumineux

Fig. 1. La courbe de la ATD de la formation du clinker d'alynite (1) et du clinker portland (2).

Aux températures de 750 - 800°C les produits de la cuisson contiennent, à part le spourrite prédominant, l'alumoferrite et l'aluminate de la chlorure de calcium.

Les diffractogrammes des phases synthétisées intermédiaires du clinker sont représentés sur la fig. 2.

Fig. 2 - Les diffractogrammes des phases intermédiaires du clinker d'alynite:

- 1 - du spourrite;
- 2 - de l'orthosilicate de la chlorure de calcium;
- 3 - de l'aluminate de la chlorure de calcium

C'est dans l'intervalle de 650-850°C que les exoeffets correspondent aux processus exothermiques de la formation de ces minéraux sur la courbe ATD.

Le changement quantitatif de la teneur des phases à chaque étape de la cuisson caractérise le mécanisme de la formation du clinker. Ainsi, la courbe du changement de la

teneur d'oxyde de calcium libre dans les produits de la cuisson a deux valeurs extrêmes (fig. 3). La teneur plus élevée de CaO libre due à une température plus haute est en corrélation avec la courbe du changement de la teneur de CO<sub>2</sub> - l'oxyde de calcium libre apparaît au cours de la décarbonisation de la calcite.

Pourtant, les températures de 700-750°C provoquent une formation intense du spourrite dont la quantité atteint le maximum à 800°C (fig. 3).

Fig. 3. Changement du contenu de CaO libre (1) et du spourrite (2) dans les produits de la cuisson du clinker d'alynite en fonction de la température

La formation du spourrite s'effectue grâce à la liaison intense entre la silice et l'oxyde de se libérant à la décomposition de CaCO<sub>3</sub>:

En même temps une partie de molécules de la calcite participe à la formation du minéral nouveau, spourrite. Il convient de souligner le rôle très important de CaCl<sub>2</sub>, agent de dispersion qui intensifie considérablement le processus de la décarbonisation et joue le rôle du milieu catalytique de cristallisation.

Aux températures de 750-800°C, il est intéressant à noter la formation de l'orthosilicate de la chlorure de calcium en présence de la chlorure de calcium. La fig. 4 montre les données expérimentales sur le changement de la teneur en orthosilicate de la chlorure de calcium 2 Ca<sub>2</sub>SiO<sub>4</sub> · CaCl<sub>2</sub> dans le processus de la cuisson.

On peut supposer la possibilité de l'isomorphisme des anions au cours de la formation du spourrite et de l'orthosilicate de la chlorure de calcium quand une partie des d'atomes de l'oxygène dans la molécule de la calcite du spourrite - 2 Ca<sub>2</sub>SiO<sub>4</sub> · CaCO<sub>3</sub> est remplacée par les atomes du chlore. Les résultats des expériences sur la séparation du chlore du spourrite synthétique synthétisé en présence de CaCl confirment que le remplacement de O par Cl dans le spourrite est possible. Ces expériences ont montré la conservation de 2% de Cl dans le minéral, probablement grâce à l'élévation du Cl dans la structure. Il n'est pas exclu que 2 Ca<sub>2</sub>SiO<sub>4</sub> · CaCO<sub>3</sub> et 2 Ca<sub>2</sub>SiO<sub>4</sub>CaCl<sub>2</sub> forment des solutions

solides grâce à l'isostructure de ces composés contenant à la base une molécule de  $\text{Ca}_2\text{SiO}_4$ . Ces phases intermédiaires sont stables dans un intervalle déterminé, car à 800-850°C le spourrite commence à se décomposer et aux températures supérieures à 950°C disparaît tout à fait.

Fig. 4. Changement du contenu de l'orthosilicate de la chlorure de calcium (1), de l'aluminate de la chlorure de calcium (2) et de l'alumoferrite de calcium (3) des les produits de la cuisson du clinker d'alynite en fonction de la température.

Les fig.3-5 montrent des résultats des mesures sur le changement de la teneur quantitatives des phases minérales du clinker d'alynite dans le processus de la cuisson.

Elles sont effectuées à l'aide d'une analyse quantitative aux rayons X. La formation du spourrite et de l'orthosilicate de la chlorure de calcium lie l'oxyde de calcium libre se libérant au cours de la décarbonisation. Sa quantité dans l'intervalle de 700-900°C ne dépasse pas quelques pourcents. Ceci est juste pour la vitesse normale de l'élévation; 5-20% par min. Grâce au nivellement des facteurs cinétiques, le traitement isothermique prolongé aux températures 700-900°C libère tout l'oxyde de calcium du mélange brut, sauf sa quantité liée par le spourrite, l'orthosilicate, l'aluminate et l'alumoferrite de la chlorure de calcium (fig.4); même dans ce cas la quantité de l'oxyde de calcium libre ne dépasse pas 10-12% ce qui est égal à un cinquième de sa quantité totale. Ces données sont en accord avec les résultats de la détermination de la teneur en  $\text{CO}_2$  des produits de la cuisson. L'aluminate de la chlorure de calcium commence à se former à 700-750°C; il est stable sur toutes les étapes ultérieures de la formation du clinker. Par contre, l'alumoferrite de la chlorure de calcium n'existe que dans un intervalle limité de températures. Il commence à se former à 750-800°C, mais à 950°C il se décompose en ferrite de calcium, un composé stable et en même temps il fournit l'aluminium pour la formation de l'alynite. Il est probable que ce fait explique le commencement de la cristallisation de l'alynite aux tempéra-

tures de l'alumoferrite de la chlorure de calcium, c'est-à-dire à 900-950°C (fig.5).

Fig.5. Changement du contenu de l'alynite (1) et du bélite (2) et le ferrite de calcium (3) en fonction de la température.

L'hypothèse citée explique l'effet de forte minéralisation en présence de  $\text{Fe}_2\text{O}_3$  dans le mélange brut au cours de la cuisson du clinker d'alynite. Grâce à la formation et à la décomposition de l'alumoferrite de la chlorure de calcium, l'aluminium, un des éléments principaux du réseau cristallin de l'alynite, est fourni au moment de la cristallisation de l'alynite. Cela se trouve en accord avec le fait de l'absence de l'alumoferrite de calcium dans le clinker d'alynite.

L'hypothèse proposée explique la nécessité d'une augmentation sensible de la concentration de l'aluminium dans le mélange brut utilisé au cours de la cuisson du clinker d'alynite blanc. Le bélite se forme à 850-900°C, car la quantité de Cl ne suffit pas à lier toute la substance en orthosilicate de chlore (15% de chlore dans la structure), aluminate de chlore (4% de chlore dans la structure) et alumoferrite de chlore (15% de chlore dans la structure).

De cette façon, à 900°C tout le chlore est déjà pratiquement lié en composés, l'alynite se forme à partir de l'orthosilicate de la chlorure grâce à une nouvelle répartition du chlore entre lui et le bélite, pendant que les  $\text{CaO}$  et  $\text{Al}_2\text{O}_3$  superflus libérés à la décomposition de l'alumoferrite, sont liés. Ainsi, la cristallisation de l'alynite est suivie du dégagement de  $\text{HCl}$  grâce à la décomposition thermique de l'alumoferrite et de l'orthosilicate de la chlorure de calcium. Une partie de  $\text{HCl}$  fournit les particules voisines et participe au processus ultérieur de la formation du minéral en homogénéisant la composition de phase du clinker; une autre partie s'en va avec les gaz grâce à la sublimation. De cette façon, une étude de la suite de la formation du clinker à basses température a démontré une grande importance des phases intermédiaires du clinker dont la formation et la genèse, par notre opinion, exerce une influence décisive

\*La composition du minéral est, probablement, la suivante:  $\text{Ca}_4\text{Al}_2\text{Fe}_2\text{Cl}_2\text{O}_9$ .

sur le caractère de la cristallisation du clinker d'alynite.

Le mécanisme des processus de la formation du clinker à basses températures que nous venons d'examiner nous permet de comprendre les particularités de la composition de phase du clinker d'alynite.

Le clinker d'alynite est représenté par quatre minéraux (% de la masse).

1. L'alynite -  $\text{Ca}_{11}(\text{Si}, \text{Al})_4\text{O}_{18}\text{Cl}$  - 60 ÷ 80
2. Le bélite -  $\text{C}_2\text{S}$  - 10 ÷ 30
3. L'aluminate de la chlorure de calcium -  $\text{Ca}_6\text{AlO}_7\text{Cl}$  - 5 ÷ 10
4. Le ferrite de calcium -  $\text{Ca}_2\text{Fe}_2\text{O}_5$  - 2 ÷ 10

La formation du clinker d'alynite s'effectue dans la lutte concurrentielle des atomes et de leurs configurations pour les atomes du chlore qui sont les plus actives aux hautes températures de cristallisation du clinker; ces atomes passent facilement de la phase solide en liquide (fusion), en phase gazeuse et de nouveau solide (chloration).

Cette lutte aboutit à ce que le chlore ne reste que dans l'alynite, ou il est solidement lié dans un motif structural original et entoure étroitement par huit atomes de calcium (2), ainsi que dans l'aluminate de chlorure de calcium, ou il est aussi lié dans les motifs structuraux solides (3).

Le bélite et le ferrite de calcium sont identiques sur tous les indices aux minéraux portlands.

Certaines particularités de la morphologie et de la composition des cristaux sont liées à une faible solubilité du chlore (1,0-1,5% de la masse) dans le bélite et le ferrite de calcium.

Dans les clinkers obtenues à la base des matières premières aux différentes usines de ciment de l'URSS d'après la technologie de basse température avec l'utilisation de la fusion catalytique de la chlorure de calcium, l'alynite se cristallise sous forme des plaques hexagonales, des petits prismes allongés dans le même sens et des formations des rayons aiguisés. On peut y observer des grains de forme des rhomboédrique et des tablettes. Les clinkers ont une structure à grains fins irréguliers, la cristallisation de l'alynite est distincte. Les dimensions des grains varient de plusieurs  $\mu\text{m}$  à 30-35  $\mu\text{m}$ . Les particules de dimension de 15-20  $\mu\text{m}$  prédominent.

On y observe des agrégats de l'alynite, quelquefois des macles des grains à l'extinction zonale caractéristique. La birefringence est basse, l'extinction est directe. Les index de réfraction varient dans les limites: 1.710 - 1.714.

Une autre phase silicique du clinker d'alynite observée dans les matériaux étudiés est représentée par le bélite (silicate basique bas), qui se diffère de l'alynite par

sa forme arrondie, ovale ou celle de lentille; les débris des grains sont le plus souvent incolores, à l'extinction directe. Les index de réfraction sont  $N = 1.724 - 1.730$ . La birefringence et les index de réfraction sont les seuls indices distinctifs des études microscopiques des phases du clinker d'alynite.

Les études minéralogiques des clinkers synthétisés à basse température sont très difficiles à accomplir à cause de la structure microcristallin des phases minérales. Les études au microscope électronique nous ont permis d'étudier le faciès et la morphologie des cristaux dans le clinker.

Le bélite est représentée dans le clinker sous forme des grains arrondis et des débris irréguliers; souvent, on l'observe sous forme des incorporations dans les cristaux de l'alynite (fig.6).

Fig. 6. Stéréomicrophotographies\* d'un cristal de l'alynite avec des incorporations du bélite (stéréoskan - 4). Agrandissement - 5000.

Dans le clinker, l'alynite est représentée par les polyèdres bien cristallisés aux facettes distinctes reproduisant de différentes variations du faciès tétragono-pyramidal (fig.7).

Une étude des microcristaux de l'alynite dans le clinker par la méthode de l'analyse microscopique du spectre aux rayons X à l'aide de l'appareil "Komeka" nous a permis de préciser la composition des éle-

\*L'auteur remercie vivement m-me N. Sirotkine d'avoir exécuté une analyse.

ments des cristaux de l'alynite, dont le contenu qualitatif est représenté par Ca, Si, O, Cl, Al, Fe et Mg (fig.8) et le contenu quantitatif par: Ca = 46-47 Si = 10-11 Al = 1,5-3,0 Mg = 1,0-1,5 Fe = 1,2-1,3 Cl = 2,5-3,0 O = 35-36.

Fig. 8. Spectrogramme d'un grain d'alynite dans le clinker.

#### CONCLUSIONS:

Le présent travail montre la suite de la formation et des transformations des phases intermédiaires et finales du clinker d'alynite.

A l'étape initiale du processus, les auteurs ont établi la formation du carbonate de la chlorure de calcium et de la phase X dont la composition est à peu près la même ils ont déterminé les paramètres de leurs cellules élémentaires. Le spourrite, l'alumoferrite et l'orthosilicate de la chlorure de calcium se forment également en tant que les phases intermédiaires du clinker d'alynite.

La contenance quantitative des phases minérales dans le clinker d'alynite varie dans les limites suivantes (% de la masse):

l'alynite	60 - 80
le bélite	10 - 30
l'aluminate de la	
chlorure de calcium	5 - 10
le ferrite de calcium	2 - 10

Le changement la proportion quantitative des phases minérales intermédiaires et stables dans le processus de la formation du clinker d'alynite est démontré.

Les auteurs donnent la description du caractère de la cristallisation des phases minérales du clinker - alynite; ils soulignent sa dépendance des conditions de la cuisson des matières premières liée à la genèse des phases intermédiaires du clinker.

# Calculation of strength parameter for hydrated portland cements from hydration heats measured by differential calorimetric analysis (DCA)

## *Prévision des résistances des ciments portland au moyen de leur chaleur d'hydratation*

G. OLIEW, W. WIEKER, Zentralinstitut für anorganische chemie der Akademie der Wissenschaften der DDR, Berlin, R.D.A.

### Summary:

Precalculation of compressive strength for hydrated portlandcement is an important question for scientist as well as for practical men.

Setting and hardening of cement is influenced by those factors which also influence the heat liberation, measured by differentialcalorimetric analyses (DCA) too. Small differences in chemical and mineralogical compositions and in burning-and cooling conditions of the clinker lead to different DCA-curves (fig. 1).

Increasing  $\text{SO}_3$ -content and surface area (BLAINE) determines the position of the 3 rd DCA-Peak (fig. 2). Hydration of PC under steam curring conditions influence considerably DCA-curves (fig. 3).

Hydration heat  $Q_I$  (first reaction of cement with water - first DCA-Peak area) and  $Q_t$  ( $t = 24...672$  h) clearly depend on surface area and  $\text{SO}_3$ -content (fig. 4 and 5). Compressive strength depends on surface areas and  $\text{SO}_3$ -content too (fig. 6).

A set of correlation equations allow to precalculate the strength of hardened cement for 1 up till to 28 days and after hardening under steamcuring conditions already after 1 hour ( $Q_I$ ) (tab. 1). More reliable results can be calculated from heat developed after reaction times more than 72 hours ( $Q_t$ ) (tab. 2).

Results of the calculations are to be seen in fig. 7. The factors and constants of these equations must be changed if a cement of another cement is to be investigated.

RESUME : La prévision des résistances des ciments pose un important problème aux chercheurs et aux praticiens. Elle peut se faire grâce à leur courbe d'analyse calorimétrique différentielle. Ces courbes (A.C.D.) sont fortement influencées par la composition minéralogique et le mode de cuisson du clinker, ainsi que par la teneur en  $\text{SO}_3$  et la granulométrie du ciment broyé, et même par le procédé de conservation des éprouvettes.

Des formules de corrélation entre les pics et la forme de ces courbes, et la résistance du ciment à 28 jours de conservation normale, ou à 1 heure de conservation dans la vapeur chaude, ont été établies. Elles nécessitent le relevé de ces courbes jusqu'à 72 heures.

Des résultats expérimentaux sont exposés. Les paramètres des formules varient avec les ciments.

The precalculation of strengthparameter for hydrated portlandcements is an important question for scientist as well for practical men. Starting from the fact, that setting and hardening of cement is influenced by those factors which also influence the heat liberation, we tried to precalculate strengthparameter from hydration heats, measured by differentialcalorimetric analysis (DCA).

As it known from literature, small differences in chemical and mineralogical compositions of the clinker lead to different DCA-Curves (fig. 1).

Fig. 1 Heat liberation (DCA)-Curves from PC's of different PC-Plants (W/C = 0,5; temp. = 20 °C)

The differentialcalorimeters which had been used are described in [1,2,7.

To get correlation functions between the strength developed by portlandcement pastes and the heat of hydration, a set of cements with different  $SO_3$  contents and surface areas are prepared from clinkermaterial of the cement plants A and B. Fig. 2 shows the results of DCA measurements of portlandcement samples with different  $SO_3$ -contents and surface areas of the plant B.

From this figure it is to be seen, that with increasing  $SO_3$ -content the III. DCA-maximum is shifted to longer reaction times and that with increasing surface of the cement this peak is shifted to shorter hydration times for cements with a constant  $SO_3$  content of 3.8 %.

Fig. 2 Hydration of PC-Type B with various contents of  $SO_3$  and various surface area (W/C = 0,5; temp. = 20 °C)

Under commercial aspects there is very often an interest in strength-development at higher temperatures too. Therefore we have measured the heat liberation of the mentioned cement samples during a programmed temperature treatment with a maximum at 85 °C [27. The results of these experiments in fig. 3 show, that only at a  $SO_3$ -content of 4,4 % there is a shift of the hydration peak to longer hydration times. With increasing surface at a constant  $SO_3$  content of 3,8 % we found at medium surface areas (4050 cm²/gr) a shift to higher reaction times and at high surface values (5600 cm²/gr) to shorter reaction times.

Fig. 3 Hydration of PC-Type B with various contents of  $SO_3$  and various surface area (W/C = 0,5; max. temp. = 85 °C; curing conditions according to TGL 28 103/08).

The reaction heats ( $Q_t$ ) developed up till 1, 24, 72 hours were calculated from the DCA-curves by direct integration. For the calculation of reaction heats at longer reaction times we used the formula

$$\frac{1}{Q} = a \cdot \frac{1}{t} + b$$

published by SCHWIETE u. ROTH [23\_7.

The results in fig. 4 show, that there is

Fig. 4 Dependence of  $Q_t$  on  $SO_3$ -content and surface area measured by BLAINE method.

already for the heat developed after 1 hour ( $Q_I$  = area of the first DCA-peak) a clear dependence from the  $SO_3$ -content and the surface area of the tested cement. The same results we got for hydration times up till 28 days (fig. 5).

Fig. 5 Heat of hydration  $Q_t$  vs  $SO_3$ -content and surface area measured by BLAINE method

Beacause there are good correlations between compressive strength measurments and  $SO_3$ -content and surface area (fig. 6) too,

Fig. 6 Compressive strength vs  $SO_3$ -content and surface area

it should be possible to get mathematical regression equations between the developed reaction heat ( $Q$ ) and the compressive strength ( $D$ ). In table 1 there are given some equations we got for calculation of compressive strength after 24, 72 and 672 hours of hydration at 20 °C using  $Q_I$ -values.

Tab. 1 Equations for calculation of compressive strength parameters ( $D_{24} \dots D_{672}$ ,  $D_w$ ,  $D_{w672}$ ) from hydration heat  $Q_I$  ( $D_t$  [MPa];  $Q_t$  [J/g])

Nr.	PC - PLANT A		$\bar{\Delta D} \pm s$	
1.	$D_{24}$	$= 0,83 Q_I - 2,64$	5,5	4,3
2.	$D_{72}$	$= 0,67 Q_I + 12,88$	3,7	2,3

Tab. 2 Equations for calculation of compressive strength parameters ( $D_{24} \dots D_{672}$ ,  $D_w$ ,  $D_{w672}$  [MPa]) from hydration heat  $Q_t$  ( $t = 1 \dots \infty$  [J/g])

Nr.	PC - PLANT A	$\Delta D$ [%]	$\pm s$
1	$D_{24} = 0,08 Q_{24} + 0,1 Q_{72} - 17,49$	4,2	4,4
2	$D_{24} = 0,008 \text{ BLAINE} - 8,91$	4,2	4,1
3	$D_{72} = -0,21 Q_{12} + 0,18 Q_{24} + 0,1 Q_{672} - 21$	1,3	0,9
4	$D_{72} = 0,07 Q_{168} + 0,004 \text{ BLAINE} - 4,40$	2,0	1,3
5	$D_{672} = 0,03 Q_{168} + 0,004 \text{ BLAINE} + 20,65$	0,8	0,5
6	$D_{672} = 0,38 Q_I + 0,05 Q_{168} + 20,72$	1,0	0,8
7	$D_w = 0,10 Q_{24} + 9,77$	4,8	3,9
8	$D_{w672} = 0,11 Q_{\infty} - 3,38$	3,0	2,4
9	$D_{w672} = 0,09 Q_{672} + 6,45$	3,2	2,9

In addition there are in table 1 two equations to calculate compressive strength of steam cured samples directly after steam-curing ( $D_w$ ) and 672 hours later ( $D_{w672}$ ). From the medium error  $\Delta D$  [%] and standard deviation it is to be seen, that the results are relatively good, for cements of plant A as well as for those from plant B.

More reliable results can be received from calculations in which reaction heats developed after longer reaction times than one hour are used. Some of these equations we got are listed in table 2. The noted values for the medium error and standard deviation shows, that these equations really give better results than those using  $Q_I$  values only.

In fig. 7 measured compressive strength is plotted against the corresponding calculated

values. This gives the proof, that there is really a very good correlation between compressive strength and heat development during hydration of a portland cement. Therefore we think that DCA measurements are very convenient for production controll measurements in cement plants and that it will be possible to reduce the extensive number compressive strength measurements in cement plants. But we have to remark, that the factors and constants given in the equations of table 2 are only valid for cement plant A. If one wants to use these equations on other cement plants one had to estimate these factors and constants by an investigation of a set of cement samples of that special plant.

### Summary

The effect of the addition of three water soluble polymers. Versicol W13, Dextran and hydroxyethyl cellulose to the mixing water of a bottle hydrated Portland cement was studied. Surface areas obtained from nitrogen adsorption isotherms are presented along with pore size distributions calculated using the method of Dollimore and Heal.

RESUME : On a étudié l'effet de l'addition de trois polymères solubles dans l'eau : le Versicol W 13, le dextrane et la cellulose hydroxyle-éthylrique, à l'eau de prise du ciment Portland hydraté en flacon. On présente les valeurs des surfaces spécifiques obtenues, en utilisant les isothermes d'adsorption d'azote, aussi bien que les valeurs de la distribution de la structure poreuse calculées à l'aide de la méthode proposée par DOLLIMORE et HEAL.

## INTRODUCTION

The surface area of cement pastes obtained from water vapour adsorption are usually larger than those obtained from nitrogen adsorption (1,2). Mikhail et al conclude that either the pores are too small to allow nitrogen in or that 'ink-bottle' pores exist (3,4). Feldman and Sereda believe that the water must, at least in part, be chemically adsorbed, and nitrogen adsorption reflects the true surface (5,6). To remove free water from the hydrate, D-drying is commonly used (7,8) although Lawrence recommends treatment with methanol (9). The adsorption of an organic polymer is thought to occur with the ionic group away from the solid surface (10), but recent work has provided alternative explanations (11).

## EXPERIMENTAL

### 1) Materials

The cement used was ordinary Portland cement (OPC), obtained commercially (phase composition,  $C_3S$ , 47.6%;  $C_2S$ , 22.55%;  $C_3A$ , 11.06%;  $C_4AF$ , 7.66%;  $C\bar{S}H_4$ , 4.65%). The surface area (Blaine) was  $3,200 \pm 200 \text{ cm}^2 \text{ g}^{-1}$ . The polymers investigated were Versicol W13, a nonionic polyacrylamide, (pH 8-9 at 20%). Dextran, a carboxymethyl starch (pH 6.0 at 1%) and hydroxyethyl cellulose (HEC), a nonionic cellulose ether (pH 6.5-8.0 at 1%). The nitrogen used in the adsorption experiment was dry and oxygen free.

### 2) Preparation of Samples

A sample without the polymers present was first used as a control. In this, 100g of OPC was mixed with one litre of distilled water in a sealed

airtight polythene bottle. It was rotated on a ball mill at 87 r.p.m. at  $22 \pm 2^\circ\text{C}$  for up to 28 days. In experiments involving polymers enough of a 1% solution of each polymer was added to give an initial ratio of 0.08% dry polymer/dry cement. At various times up to 28 days after mixing, about 100 ml of suspension was removed and filtered in a  $\text{CO}_2$  free nitrogen atmosphere. After one hour's vacuum pumping the sample was placed in a small polythene bottle and dry excess methanol added. It was further rotated for two weeks, followed by vacuum filtration from the methanol in a nitrogen atmosphere and a 15 minute evaporation of the methanol at  $30-35^\circ\text{C}$ . Any calcium hydroxide crystals were removed from the sample by sieving through a BS 200 mesh sieve ( $75 \mu\text{m}$ ). These crystals were ground in an agate mortar until they also passed through the sieve. They were then remixed thoroughly with the rest of the sample, and it was these samples that were used in the adsorption experiments.

### 3) Adsorption

Nitrogen adsorption-desorption isotherms (at 77.4 K) were carried out on a volumetric adsorption apparatus (12). The pore size distributions were calculated using the method of Dollimore and Heal (13).

## RESULTS AND DISCUSSION

Samples exhibiting definite hysteresis loops in the adsorption-desorption isotherms were subjected to the pore size distribution calculation. These were samples beyond seven days hydration. The general observation is that as hydration time increases, then the size of the hysteresis loop also increases, along with the volume of nitrogen

adsorbed. The isotherms would be best designated as Type II by the classification of Brunauer et al (14), but the adsorption approaches the value of  $P/P_0 = 1$  with a large increase in adsorption and a hysteresis loop on desorption. The loop closes between  $P/P_0$  values of 0.3 to 0.5 depending upon the sample. A comparison of the 28 day old samples shows that the effect of the addition of the polymers appears to reduce the volume of nitrogen adsorbed, compared to the control. Surface areas were calculated on the basis of the evacuated weight of the sample taken after the experiment was over. Representative surface areas, total pore volumes and cumulative areas for the control are shown in Table 1. Tables 2, 3 and 4 show surface areas and porosity properties for samples modified with Versicol W13, Dextran and HEC respectively. The results are tabulated as a ratio of the sample result to the corresponding result for the control. In general, it can be seen that the ratio  $S_{BET}/S_{BET\ CONTROL}$  is highest for the Dextran modified cement between one day and 14 days hydration. This shows that these samples have the highest surface area of all modified samples. All series show a sharp increase in surface area between ten hours and one day's hydration.

The addition of all polymers reduce the total pore volume compared to the control. This can be seen by the fact that the ratio  $V/V_{CONTROL}$  in Tables 2, 3 and 4 are all lower than unity. In the case of samples modified with polymers at ages of 7 and 14 days, the  $V/V_{CONTROL}$  ratio increases whilst the  $S_{BET}/S_{BET\ CONTROL}$  ratio decreases. It would appear therefore that the addition of water soluble polymers tend to favour the formation of

smaller pores that would not ordinarily be present.

The model used for the pore size distribution is that of a cylindrical non-intersecting pore. An alternative analysis, based on a slit shaped model will be the subject of a further publication.

# Hydration and hardening processes modeling

## *Simulation des processus d'hydratation et de durcissement des ciments*

V.B. TCHERNIAVSKI,

V.Y. DOUBNITSKI, Promstroiniiproekt, Kharkov, U.R.S.S.

On décrit la construction et les résultats de fonctionnement du modèle de la structure du ciment durci et les transformations physico-chimiques qui s'y déroulent par rapport aux stades d'hydratation tardifs. Le principe de construction consiste en ce que les constituants de structure du ciment durci sont groupés en éléments conventionnels réunis compte tenu de l'unité de leur rôle fonctionnel dans le processus de formation des propriétés du ciment durci.

L'objectif visé par le travail est d'optimiser les propriétés de construction du ciment durci en fonction des conditions du milieu ambiant en choisissant les paramètres initiaux de la constitution des compositions ciment-eau. La source d'information principale sur la dynamique réelle du modèle est un ensemble d'études physico-chimiques. Par suite du traitement statistique des données on a effectué l'identification des paramètres des équations du modèle.

Sur la base de la méthode de Monte-Carlo on a étudié le fonctionnement du modèle et résolu une série de problèmes d'optimisation de la structure initiale du ciment durci, permettant de prévoir les propriétés du ciment durci en fonction de la composition de base et de l'intensité de l'interaction avec le milieu ambiant.

Structure and results of functioning of cement stone texture model and transformations in the late hydration stages of the cement stone has been described. The principle of model structure is that the structural components of cement stone are grouped together in arbitrary units with regard to their functional part in the process of cement stone characteristics formation.

The purpose of the work is to optimize cement stone constructional characteristics depending on the environmental conditions by choosing initial parameters of cement-water compositions.

The main source of information of the model real dynamics is the complex of physico-chemical investigations. The identification of model equations has been developed as a result of data statistical interpretation.

On the base of Monte-Carlo method, functioning of the model has been studied and some problems on the optimization of cement stone initial structure have been solved, and hence there is a possibility of forecasting cement stone characteristics as a function of initial composition and intensity of interaction with environment.

Later stages of cement hydration taking place on the background of intense interaction between cement rock and its environment include complicated processes which are hard to be described analytically. A number of circumstances (multicomponent macro- and microstructure, substantial role of destructive phenomena, deformation and strength characteristics, permeability changing with time) define non-monotonous pattern of change of cement rock properties even though the environment parameters being constant. This makes the change of the material properties fixed at the end phase of early hydration period impossible to be formally extrapolated to later period.

The development of engineering cybernetics caused a specific method of complex system investigation - simulation [1]. Simulation model is an analog of a complex real phenomenon realized in a computer which permits to discuss consequences of changes in process proceeding conditions and of making decisions concerning the control of properties of the system under study. Such a model is peculiar in the process being described step by step which permits making changes in due time (for control purposes) in the model equations caused by a long-term existence of the real object.

In simulating the process of non-hydrated binder grains hydration in cement rock notions of its structure are used based on grouping multiple structural elements according to their functional properties [2]. Percentage of non-hydrated clinker, slag, pozzolan, ash, etc. grains is designated as  $V_1$ , percentage of hydrate, formations as  $V_2$ , relative amount of empty "pores" (excluding "gel" pores), capillaries ( $r > 10^{-7}$  cm) as  $V_3$ , percentage of corrosion products and other inclusions with sharply reduced strength and deformation characteristics as  $V_4$ .

Liquid phase in cement rock represented by chemically fixed, crystallization, adsorption, capillary and gravity forms is taken into account while constructing and evaluating each of the model elements.

The processes taking place at later stages of the cement rock existence in the form of element interaction are summed up in Table I and reflect a creative process (pos.

I) and destructive processes (pos. 2, 3). The latter may be subdivided into those including removal of elementary volumes  $V_1, V_2, V_4$ , and those including formation (introduction) of an elementary volume  $V_4$ .

Statistical evaluation of quantitative X-ray definitions ascertained that  $\alpha_{12}$  is independent upon the kind of clinker mineral ( $C_3S, C_2S, C_4AF$ , seldom  $C_A$ ) at later stages (up to 10 years) of cement hydration in water, sulfate-containing solution in water under their continuous and batch influence.

Assume all the elements of  $V_1$  are uniformly distributed along each coordinate axis, i.e. in each elementary volume all the elements are present in ratio corresponding to the complete volume; connections of any element with other elements are continuous and mutually independent. Change of element  $V_3$  is ascribed both to the transformations of  $V_{31}$  and  $V_{13}$  as noted in Table I and to the compensation of volume expansion during transformations of other elements. The intensity of interactions is invariant relative to the coordinates of an elementary unit volume and the macrovolume. The process is viewed upon as determined and monotonous on a segment.

The efficacy of the model proposed has been verified on real objects (cement rock, concrete). Close connection between change of cement rock strength in time and change of the model components percentage has been established [2]. To evaluate prognostic properties of the model of cement rock as the main component of concrete vectors are formed which include  $R, V_1, V_3, V_4$  [3]. The degree of destruction of the material is proposed to be defined as  $\tilde{V}_3 = V_3 + V_4$  [4]. It has been shown that at the stage of destruction (irrespective of the type of binder) the vectors  $\tilde{V}_1 = (V_1, \tilde{V}_3)$  and  $\tilde{V}_2 = (R, V_1, \tilde{V}_3)$  are statistically undiscernable [5].

In practice cement rock in concrete is never isolated from the environment which influence upon the intensity of transformation of cement minerals at later stages of existence of cement rock by accelerating hydrate formation process as well as by partial

Table I

Position	Description of a process of structural elements interaction	Process formalization, rates of transformations	
		Elementary mutually independent transformations for time $\Delta t$	Intensity of transformation $\alpha_{ij}^{xx} = \frac{\Delta V_i}{\Delta t \rightarrow 0}$
1	Transformation of $V_I$ into $V_2 - V_{12}$ , volume increased	$\Delta V_1 \rightarrow K_{12}^{xx} \Delta V_2$	$-\alpha_{12} = \alpha_{21}$
2	Transformation of $V_I$ , $V_2, V_4$ into $V_3 - V_{13}$ , $V_{23}, V_{43}$	$\Delta V_1 \rightarrow \Delta V_3$ $\Delta V_2 \rightarrow \Delta V_3$ $\Delta V_4 \rightarrow \Delta V_3$	$-\alpha_{13} = \alpha_{31}$ $-\alpha_{23} = \alpha_{32}$ $-\alpha_{43} = \alpha_{34}$
3	Transformation of $V_I$ , $V_2, V_3$ into $V_4 - V_{14}$ , $V_{24}, V_{34}$ , volume preserved and/or increased	$\Delta V_1 \rightarrow K_{14} \Delta V_4$ $\Delta V_2 \rightarrow K_{24} \Delta V_4$ $\Delta V_3 \rightarrow K_{34} \Delta V_4$	$-\alpha_{14} = \alpha_{41}$ $-\alpha_{24} = \alpha_{42}$ $-\alpha_{34} = \alpha_{43}$

<sup>x)</sup>  $K_{ij}$  - factor of volume change during transformation of structural elements ( $0 < k < 1$ )

<sup>xx)</sup> positive values of  $\alpha_{ij}$  are ascribed to increase of the component designated with the first index

transformation of anhydrous combination into corrosion products. Naturally a period comes when the store of non-hydrated cements becomes insufficient to restore the properties of cement rock. From that time on being in contact with corrosive environment the cement rock begins to destroy irreversibly. To simulate this process differential equations of transformations of  $V_i$  into  $V_j$  are drawn taking into account  $\alpha_{ij}$  - the value proportional to the intensity of the corresponding transformation.

$$V_2^{(m)} - V_2^{(m-1)} = \alpha_{12} V_1^{(m-1)} - \alpha_{23} V_2^{(m-1)}$$

$$\tilde{V}_3^{(m)} - \tilde{V}_3^{(m-1)} = \alpha_{13} V_1^{(m-1)} + \alpha_{23} V_2^{(m-1)}$$

Equation (I) is a stepped approximation of a system of equations (I) in [2]. Assume that step of division  $m$  corresponds to the time interval between two subsequent measurements made by petrographic method and method of isothermal desorption.

Physically the values  $\alpha_{12}, \alpha_{13}, \alpha_{23}$ , are not mutually independent because transformations  $V_i \rightarrow V_j$  are simultaneous and non-simple. This fact is formally reflected in indeterminate form of the system (I) whose solution is a function of any one of three values  $\alpha_{ij}$ . A simultaneous estimation of these values experimentally without additional computing operations is impossible. Therefore, the values of  $\alpha_{ij}$  are defined by least square method with a limitation. The value of  $V_i$  on each sample was defined ex-

perimentally by planimetric method using transparent flat-parallel samples [7] made of cement rock. Mineralogical composition of cement is given in Table 2.

$$\text{Let } \Delta V_2^{(m)} = V_2^{(m)} - V_2^{(m-1)}$$

$$\text{and } \Delta \tilde{V}_3^{(m)} = \tilde{V}_3^{(m)} - \tilde{V}_3^{(m-1)}$$

Then the criterion of least square method for each line of system (I) takes form:

$$U_1 = \sum_{p=1}^{20} (\Delta_{2p}^{(m)} - (\alpha_{12} V_{1p}^{(m-1)} - \alpha_{23} V_{2p}^{(m-1)}))^2 \rightarrow \min, \quad (2)$$

$$U_2 = \sum_{p=1}^{20} (\Delta_{3p}^{(m)} - (\alpha_{13} V_{1p}^{(m-1)} + \alpha_{23} V_{2p}^{(m-1)}))^2 \rightarrow \min \quad (3)$$

The solution comes to the problem of definition on a conditional extremum with a limitation represented by equality

$$U_1 + U_2 \rightarrow \min \quad (4)$$

$$\text{at } \hat{\alpha}(1) = \hat{\alpha}(2) \quad (5)$$

The symbol  $\hat{\alpha}$  designates an estimate of factor  $\alpha_{23}$  obtained separately for each equation (2) and (3).

The results of computing the values  $\alpha_{ij}$  in fractions of a unit are given in figure 1. It is obvious from this figure that in the course of prolonged contact between cement rock and the active environment three

Table 2

Position	Codes name of cement	Mineralogical composition (weight percent)				
		C <sub>3</sub> S	C <sub>2</sub> S	C <sub>3</sub> A	C <sub>4</sub> A <sub>3</sub> F <sub>2</sub>	Gypszm
1	A	51,6	22,7	6,8	10,8	5,0
2	B	58,6	17,9	2,9	15,5	5,0
3	H	54,5	20,2	9,1	11,1	5,0

stages of the process of structural change for the period corresponding to late stage of hydration can be observed.

Stage 1: mainly creation when

$$\alpha_{12} > \alpha_{13} + \alpha_{23}$$

Stage 2: mainly equilibrium when

$$\alpha_{12} \approx \alpha_{13} + \alpha_{23}$$

Stage 3: mainly destruction when

$$\alpha_{12} < \alpha_{13} + \alpha_{23}$$

The existing methods of experimental definition of the value  $\alpha_{ij}$  permit only to obtain a total estimate of  $V_I$  transformation into  $V_2$  and  $V_3$ . Differentiation between these processes being limited to linear cases became possible to be achieved at only owing to the use of methods of calculation mathematics.

The simulation being performed it has been ascertained that the time of preserving useful properties in cement rock substantially depends upon the values  $\alpha_{ij}$ .

Under such conditions the structure of the material at each stage is in strict compliance with the relation between elements of the model  $V_i$ . In order to define the area of initial structural parameters of cement rock providing the preservation (taking into account the reestablishment caused by the transformation  $V_I > V_2$ ) of its strength properties the problem of optimization of the initial composition of cement rock interacting with the active environment is solved.

Using transformation  $V_3 = V_3 + V_4$  present system of equations (I) in the form

$$V_2(t) + \int_0^t (\alpha_{12}(t) - \alpha_{23}(t)) dt = V_2(t) \quad (6.1)$$

$$\tilde{V}_3(t) + \int_0^t (\alpha_{13}(t) + \alpha_{23}(t)) dt = \tilde{V}_3(t) \quad (6.2)$$

$$V_1(t) = 1 - (V_2(t) + \tilde{V}_3(t)) \quad (6.3)$$

Assume that in any given moment the condition of the system is defined by vector

$\vec{V}(t) = (V_1(t), V_2(t), V_3(t))$  condition

being that

$$V_1(t_0) > 0; \quad i = 1, 2, 3. \quad (7)$$

The main carrier of the strength properties of cement rock is element  $V_2$ . Therefore, it is necessary that by the required moment  $t = \tau$  the percentage of element  $V_2$  in

$$\alpha_{ij}^{(m)}$$

Fig. 1. Values  $\alpha_{ij}$  (m) at the latest period of cements hydration in active medium after  $n$  cycles,  $m$  steps

the material was maximal. Accordingly, the limitations (.3) and (7) being kept to  $t_0$

$t$  in all preceding interval of time.

In this case the purpose function

$$L = V_2(t = \tau) \rightarrow \max. \quad (8)$$

The conditions (6.3), (7), (8) may be satisfied by the linear programming method. As

a result such values of initial composition  $V_i(t_0)$  are obtained which provide the best operating properties by the required moment. Any deviation from the optimum values causes only a decrease in percentage of  $V_2(t=\tau)$ .

We have optimized the initial correlation between elements of  $V_i$  (in fractions of a unit) cement rock in conventional heavy concrete preliminarily hardened under usual conditions of temperature and humidity, made on medium-alumina alitic cement and placed

As we see, the duration of the period of achieving condition  $V_2(\max)$  under present conditions is defined by the non-hydrated stores factor  $R_F = \sqrt[1]{V_2}$  (Figure 2a). The shorter is the period of achieving  $V_2 \max$  the lesser is  $R_F$  which corresponds to a high degree of hydration. On the contrary, the longer is the planned term of service of the material the larger should be the non-hydrated store and  $R_F \rightarrow 1$ .

Therefore, the results given permit to assume that the proposed simulation model reflects reliably (in statistical sense) the diversity of creative and destructive processes in cement rock at every stage of its existence these processes being presented in a generalized form. The transformation of any model element  $V_i$  into  $V_j$  is treated independently of a given mineralogical composition of a property carrier the influence of environment being expressed only in values  $d_{ij}$  irrespective of the mechanism of process similarly to the estimation of a system phase condition as used in phenomenological thermodynamics.

The authors are grateful to Professor O.P. Mchedlov-Petrosyan for continuous attention and support of the work for many years.

# Sur la composition des produits d'hydratation des hydroaluminates et les hydrogrenats de calcium et de magnésium

## *On the quantity of hydroaluminates and hydrogarnets of calcium and magnesium dehydration products*

V.I. KORNEEV,

G.N. KASSIANOVA, Institut Technologique Lensovet de Léningrad, U.R.S.S.

Dans le rapport de stand présenté on a exposé les problèmes de déshydratation des hydroaluminates et des hydrogrenats de calcium et de magnésium; Par les méthodes d'analyse physico-chimique on a démontré l'existence en qualité du composé chimique individuel de la phase de l'hydroaluminate de calcium sesquihydraté, on a étudié ses caractéristiques physico-chimiques on a déterminé la composition des phases intermédiaires qui se forment lors de la déshydratation partielle des hydrogrenats de calcium et de magnésium. On a montré dans le travail que la composition des composés de calcium qui se forment dépend de la teneur de l'hydrogrenat en  $\text{SiO}_2$ : jusqu'à 0,4 moles de  $\text{SiO}_2$  la composition de la phase correspond à la formule  $\text{C}_3\text{AS}_x\text{H}_{1,5-2x}$ ; plus de 0,4 de  $\text{SiO}_2$ , à  $\text{C}_3\text{AS}_x\text{H}_{1,5-x}$ . Dans les hydroaluminates et les hydrogrenats de magnésium l'évacuation de l'eau se fait également en deux stades. La composition de l'hydroaluminate de magnésium partiellement déshydraté correspond à la formule  $3\text{MgO} \cdot \text{Al}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$ . L'interaction des phases partiellement déshydratées avec de l'eau donne les produits de départ.

Questions of hydroaluminates and hydrogarnets of calcium and magnesium dehydration are reported. With the help of physical-chemical analysis the existence of sesquihydrate calcium hydroaluminate phase as a separate chemical compound has been proved, its physical-chemical characteristics have been studied; composition of intermediate phases producing at partial dehydration of hydrogarnets of calcium and magnesium has been determined. Composition of the resulting calcium compounds depends on the  $\text{SiO}_2$  content in hydrogarnet: up to 0,4 mol  $\text{SiO}_2 \rightarrow$  phase composition  $\text{C}_3\text{AS}_x\text{H}_{1,5-2x}$ ; more than 0,4 mol  $\text{SiO}_2 \rightarrow$  phase composition  $\text{C}_3\text{AS}_x\text{H}_{1,5-x}$ . Dehydration of magnesium hydroaluminates and hydrogarnets has two stages too. Composition of partially dehydrated magnesium hydroaluminate is  $3\text{MgO} \cdot \text{Al}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$ . Partially dehydrated phases, on interaction with water, produce initial products.

Les données disponibles sur la composition des produits de dissociation thermique de l'aluminat de calcium hexahydraté ( $C_3AH_6$ ) sont contradictoires: il existe deux points de vue sur ce processus qui se distinguent par l'évaluation de la possibilité de la formation d'un composé intermédiaire de composition  $C_3AH_{1,5}$ , l'aluminat de calcium sesquihydraté. Ainsi, d'après les données (1 à 3) ce composé existe, a un indice de réfraction de la lumière de 1,543 et les caractéristiques radiographiques proches de celles pour  $C_{12}A_7$ ; d'après les données (4 à 6) on propose le schéma de déshydratation suivante:

$Ca(OH)_2$  libre étant fixé par les auteurs par la méthode à l'éthyle-glycérine.

Pour élucider un ensemble de problèmes liés à la composition des produits de dissociation thermique des solutions solides dans le système  $C_3AH_6 - C_3AS_3$  on a étudié (12) les grenats de calcium hydratés avec la teneur variable en  $SiO_2$  (0,0 à 1,13 mole).

La composition chimique des grenats hydratés est donnée dans le Tableau I.

Les grenats hydratés utilisés dans le travail sont monominéraux à 92-97%. Les phases étrangères sont représentées par les hydrocarboaluminates de calcium de composition  $3CaO \cdot Al_2O_3 \cdot CaCO_3 \cdot 11H_2O$ , le carbonate de calcium, plus rarement par  $Ca(OH)_2$ . La caractéristique physico-chimique de  $C_3AH_6$   $\gamma = 2,52 \text{ g/cm}^3$ ,  $N = 1,600$ , les maximums de diffraction pour  $d/n = 5,1; 3,34; 2,79; 2,28 \text{ \AA}$  de la bande d'absorption dans le domaine de 540,800 et 3670  $\text{cm}^{-1}$  correspondent aux données de référence. Dans les grenats de calcium hydratés l'indice de réfraction de la lumière croît avec la teneur en  $SiO_2$  (?),

les maximums de diffraction sur les radiogrammes se déplacent vers les angles  $2\theta$  plus grands, les effets endothermiques sur les thermogrammes se déplacent du côté des hautes températures, ce qui témoigne d'une

plus grande force de liaison de l'eau dans les grenats hydratés par rapport à  $3CaO$ .

L'analyse des produits de déshydratation (8,9) a montré que dans l'intervalle de température de 300 à 450  $^\circ C$  la phase prédominante est représentée par l'aluminat de calcium sesquihydraté. Les preuves de l'individualité du composé obtenu se réduisent au fond à la démonstration de l'absence dans les agglomérés de  $Ca(OH)_2$  libre, car la synthèse directe à partir des oxydes d'aluminat de calcium sesquihydraté est pratiquement impossible. La réaction microchimique de Watt, la détermination de  $Ca(OH)_2$  libre par les méthodes de Franké et d'immersion n'ont pas relevé de présence de  $Ca(OH)_2$ ; il s'est avéré

que le mélange éthyle-glycérine décompose  $3CaO \cdot Al_2O_3 \cdot 1,5H_2O$ : un des produits de décomposition est représenté par  $Ca(OH)_2$  que certains auteurs (5) prenant par erreur pour phase primaire de la dissociation thermique de  $C_3AH_6$ . Sur les radiogrammes il n'y a pas de maximums de diffraction caractéristiques de  $Ca(OH)_2$ . L'hypothèse sur l'identification éventuelle au lieu de  $C_3AH_{1,5}$  des solutions solides de  $C_{12}A_7 - Ca(OH)_2$  ou sur la présence dans la composition des phases en cours de formation des microcristaux d'interpénétration de  $C_3AH_6$  de base n'est pas confirmée en partant des valeurs de l'indice de réfraction de la lumière (il doit être de beaucoup supérieur à 1,543) et de la densité de la phase  $\gamma C_{12}A_7 = 2,40 \text{ g/cm}^3$  (ce qui est

beaucoup plus petit que pour des mélanges hypothétiques probables). La chaleur de dissolution de la phase obtenue (dans le mélange des acides nitrique et fluorhydrique) est de  $548 \pm 2 \text{ C/g}$ , ce qui est inférieur aux chaleurs de dissolution des mélanges mécaniques  $C_{12}A_7$  et  $CaO$  ( $653 \pm 15 \text{ C/g}$ ),  $C_{12}A_7$  et  $Ca(OH)_2$  ( $587 \pm 12 \text{ C/g}$ ), ainsi que de  $C_{12}A_7$  et de  $CaO$  obtenus par cuisson de  $C_3AH_6$  à 700  $^\circ C$  ( $609 \pm 10 \text{ C/g}$ ). Une preuve supplémentaire de l'individualité de la phase  $C_3AH_{1,5}$  est la formation par son hydratation de  $C_3AH_6$  tandis que l'hydratation de  $C_{12}A_7$  don-

TABLEAU I

ne naissance aux aluminates de calcium hydratés hexagonaux. Tout ce qui vient d'être dit sert d'une preuve assez sûre bien qu'il s'agit de l'individualité de la phase d'aluminate de calcium sesquihydraté.

Lors de la déshydratation des grenats de calcium hydratés de composition C<sub>3</sub>AS<sub>x</sub>H<sub>6-2x</sub> pour x jusqu'à 1,13 à la température du premier effet endothermique il se forme des phases du type de l'aluminate sesquihydraté qui se distinguent de ce dernier (12) par la composition et le domaine de stabilité thermique. Dans les grenats de calcium hydratés, surtout avec la teneur élevée en SiO<sub>2</sub>, une partie de silice se dégage par cuisson sous forme d'une phase autonome dont l'indice de réfraction est de 1,480 à 1,490. La teneur en SiO<sub>2</sub> était déterminée quantitativement par les méthodes d'analyse chimique et pétrographique et prise en considération lors du calcul de la composition des phases. Le schéma de décomposition des grenats de calcium hydratés (exemple) peut être représenté de la façon suivante :

$$3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot 0,93 \text{SiO}_2 \cdot 4,24 \text{H}_2\text{O} \xrightarrow{400^\circ\text{C}} 3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot 0,68 \text{SiO}_2 \cdot 0,68 \text{H}_2\text{O} + 0,25 \text{SiO}_2 + 3,56 \text{H}_2\text{O}.$$

Les formules des phases qui se forment après le premier stade de déshydratation sont données dans le Tableau II. On a établi que les grenats de calcium hydratés avec SiO<sub>2</sub> jusqu'à 0,4 mole forment des phases partiellement déshydratées de formule générale C<sub>3</sub>AS<sub>x</sub>H<sub>1,5-2x</sub>; si la teneur en SiO<sub>2</sub> dépasse 0,5 mole la composition des phases formées correspond à la formule C<sub>3</sub>AS<sub>x</sub>H<sub>1,5-x</sub>.

Les aluminates et les grenats de calcium partiellement déshydratés sont stables dans l'intervalle de température assez étroit et lors du chauffage au-dessus de 450 °C il se produit la décomposition de l'aluminate hydraté avec la formation de C<sub>12</sub>A<sub>7</sub> et de CaO, qui est fixé par les méthodes chimique et radiographique. Ces phases sont stables dans l'intervalle de 500 à 1000 °C, lorsque la température s'élève (1000 à 1300 °C) il se forme dans les agglomérés C<sub>3</sub>A qui devient la phase principale à 1200-1300 °C.

Lors du traitement thermique des grenats

de calcium hydratés avec un faible degré de saturation en SiO<sub>2</sub> c'est la phase de composition C<sub>3</sub>AS<sub>x</sub>H<sub>1,5-2x</sub> qui est stable dans l'intervalle de 350 à 450 °C et qui se décompose au-dessus de 450 °C avec la formation de CaO et de C<sub>12</sub>A<sub>7</sub>. Lors du traitement thermique au-dessus de 1000 °C il y a formation dans les agglomérés de C<sub>3</sub>A et de la gehlénite. Dans les grenats de calcium hydratés avec une grande teneur en SiO<sub>2</sub> (>0,5 mole) à 500 °C les phases partiellement déshydratées avec l'indice de réfraction de la lumière de 1,590 à 1,600 se conservent comme phases principales, elles sont également prédominantes à 550-600 °C; la part de C<sub>12</sub>A<sub>7</sub> formé grâce à la décomposition partielle de C<sub>3</sub>AS<sub>x</sub>H<sub>1,5-x</sub> ne dépasse pas 10 à 15 %.

Aux températures plus élevées on observe une décomposition sensible des phases intermédiaires, ce processus étant plus intense dans le grenat hydraté avec une teneur élevée en SiO<sub>2</sub> (1,13 mole). Les produits de décomposition des hydrogrenats partiellement déshydratés aux températures élevées (1000 °C) sont la gehlénite, C<sub>3</sub>A, CaO, C<sub>12</sub>A<sub>7</sub>.

On a procédé à des études analogues avec l'aluminate et le grenat de magnésium hydratés 3MgO·Al<sub>2</sub>O<sub>3</sub>·8H<sub>2</sub>O et 3MgO·Al<sub>2</sub>O<sub>3</sub>·SiO<sub>2</sub>(8-2x)·H<sub>2</sub>O pour x = 0,2 et 0,5. Les composés utilisés sont monominéraux à 85-93 %. Les corps étrangers sont l'hydrocarboaluminate de magnésium, MgO et Mg(OH)<sub>2</sub>. Sur les radiogrammes les maximums de diffraction les plus prononcés pour d/n = 7,42 à 7,75, 3,76 à 3,81, 2,54 à 2,56, 2,26 à 2,28 Å appartiennent aux aluminates-grenats de magnésium hydratés. L'indice de réfraction des aluminates de magnésium hydratés est de 1,505 à 1,515, pour les grenats hydratés il s'élève jusqu'à 1,525-1,530. En comparaison des aluminates de magnésium hydratés les grenats de magnésium hydratés se caractérisent par le déplacement sur les thermogrammes des effets endothermiques liés à la déshumidification vers les grandes températures et par le déplacement des maximums de diffraction principaux dans le domaine des moindres angles 2θ.

En étudiant les processus de déshydratation de l'aluminate et du grenat de magnésium hydratés on a établi que la déshumidi-

TABLEAU II

Composition des grenats de			produits de déshydratation calcium hydratés
Chiffre du grenat hydraté de base	Température du premier effet endothermique sur la courbe ATD	Composition des produits de déshydratation partielle	Indice de réfraction de la lumière
G - 0	360°	$C_3AH_{1,5}$	1,545
G - 1	340°	$C_3AS_{0,07}H_{1,15}$	1,551 à 1,557
G - 2	360°	$C_3AS_{0,37}H_{0,75}$	1,557 à 1,562
G - 3	380°	$C_3AS_{0,44}H_{1,0}$	1,550 à 1,557
G - 4	400°	$C_3AS_{0,68}H_{0,68}$	1,580 à 1,585
G - 5	440°	$C_{2,8}AS_{0,79}H_{0,72}$	1,595 à 1,610

fication avait lieu en deux stades. Notons qu'au premier stade on évacue 5 molécules d'eau et au deuxième les trois molécules restantes, ce qui ne s'accorde pas avec les données disponibles (10, 11) selon lesquelles au premier stade on évacue 7 molécules d'eau et au deuxième, 1 molécule.

D'après nos données, après le premier stade de déshydratation (300 °C) il se forme dans les agglomérés, en tant que phase principale, les aluminates et les grenats de magnésium partiellement déshydratés radioamorphes ayant l'indice de réfraction de la lumière de 1,545 à 1,555. Ces phases sont stables dans l'intervalle de température jusqu'à 450 °C. Aux températures plus élevées (500 à 900 °C) il apparaît dans les produits de traitement thermique, à côté de MgO, la phase intermédiaire radioamorphe dont la composition n'est pas déterminée. L'indice de réfraction de cette phase croît avec l'élévation de la température jusqu'à 900 °C de 1,545 à 1,620 pour l'aluminate de magnésium hydraté et de 1,555 à 1,630 pour le grenat de magnésium hydraté avec 0,5 SiO<sub>2</sub>. Dans l'intervalle de température de 900 à 1300 °C les phases principales sont représentées par le périclase et la spinelle.

Lors du gâchage par l'eau des aluminates et des grenats de magnésium partiellement déshydratés il se produit une formation très rapide des aluminates et des grenats hydratés qui ont la même quantité d'eau chimiquement liée comme ceux de base, dans les grenats de magnésium hydratés l'indice de réfraction étant inférieur à celui de départ, ce qui est lié à la séparation partielle de SiO<sub>2</sub> à partir des grenats de magnésium hydratés par leur traitement thermique.

# Précisions pour la méthode $\alpha$ d'estimation des paramètres de la structure poreuse du ciment durci

## *Method of the cement stone porous structure parameters estimation $\alpha$ improvements*

G.I. GORTCHAKOV,

O.A. MARKOVA,

L.P. ORENTLIKHER,

O.O. PEREBATOVA, Institut des Ingénieurs du Bâtiment Kouibychév de Moscou, U.R.S.S.

Les travaux expérimentaux des dernières années contiennent de nouvelles données obtenues par les mesures directes; Ces données permettent de recalculer les paramètres numériques dans les formules servant au calcul des volumes de pores des différents groupes, utilisés pour l'évaluation de la résistance au gel des produits de ciment. Il s'est avéré possible de préciser également la classification des pores. Il y a une possibilité de calculer séparément les volumes de pores du gel et des intervalles interlaminaires des cristaux de sa phase solide remplis par de l'eau facile à évacuer. Le volume de pores capillaires est calculé comme somme des volumes de l'eau qui n'a pas réagi et du volume libéré par la contraction. Le volume de contraction est considéré en tant que réserve de la résistance au gel; il n'est pas associé comme auparavant à un groupe de pores déterminé mais il est interprété comme déficit de volume de l'eau disponible dans les pores capillaires, de déficit apparaissant par suite de la contraction si l'eau n'arrive pas de l'extérieur.

Les précisions proposées correspondent plus complètement aux concepts actuels de la structure du ciment durci et permettent d'élever la fiabilité du pronostic de la résistance au gel.

Recent works contain new data resulting from direct measurements. These data allow recalculating the numerical parameters in formulae for volume calculation of different groups of pores. The formulae are used for frost-resistance estimation of cement articles. It turned out possible to improve also pore classification. The possibility exists of calculating separately volumes of gel pores and crystalline interlayer gaps of its solid phase, the gaps being filled with readily removable water. The volume of capillary pores is the sum of the unreacted water volume and the volume being released during contraction. Contraction volume is considered as a frost-resistance reserve, but is not ascribed, as earlier, to the definite group of pores, it is looked upon as a volume deficit of water available in capillary pores arising because of contraction in the absence of water coming externally.

The improvements proposed comply in more detail with modern views of cement stone structure, they allow for increasing the frost-resistance forecast reliability.

La technologie d'obtention du ciment durci compact s'appuie sur l'analyse de sa structure poreuse, qui se fonde sur l'utilisation des valeurs expérimentales du degré d'hydratation du ciment  $\alpha$  (proposée par G.I. Gortchakov en 1964 [12]). Cette méthode de détermination de la porosité de groupe doit être développée et précisée vu l'accumulation de nouvelles données scientifiques ayant trait aux concepts et aux grandeurs formant la base de la méthode.

Considérons les nouvelles données obtenues par R.F. Feldman et T.K. Powers. En mettant en jeu les méthodes spécialement élaborées dans une expérience montée de façon soigneuse Feldman établit la densité de: a) la phase solide du gel de ciment saturée au maximum en eau interlaminaire,  $\rho_{(a)} = 2,35 \pm 0,01 \text{ g/cm}^3$ ; b) l'ossature siliceuse de la phase solide du gel qui reste après l'évacuation à partir du gel de l'eau lors du séchage D,  $\rho_{(b)} = 2,51 \pm 0,01 \text{ g/cm}^3$  [3].

Powers construisit un diagramme très important permettant (voir fig. 1) la détermination directe des caractéristiques physico-chimiques nécessaires du gel de ciment. Le point A sur ce diagramme représente la pierre de ciment qui ne se compose que du gel, ce dernier étant caractérisé par la teneur minimale en milieu de dispersion. Le diagramme nous montre qu'au point A correspond  $E/C = 0,38$ ;  $W_t = 0,45$ ;  $W_e = 0,225$ . En prenant

1g du ciment + 0,38 g de l'eau on obtient le ciment durci comprenant le gel A (c'est ainsi qu'on notera le gel dans ce qui suit) de masse de 1,45 g. La quantité d'eau supplémentaire (0,07 g) au-dessus de 0,38 g est prise (aspirée) par le gel du milieu ambiant. La teneur totale en eau est  $W_t = 0,45 \text{ g}$ .

D'après Powers, le volume de 1,45 g du gel obtenu est égal à:

$V_A = 0,315 \text{ cm}^3/\text{g} \cdot 1 \text{ g} + 0,99 \text{ cm}^3/\text{g} \cdot 0,38 \text{ g} = 0,691 \text{ cm}^3$   
(0,315 cm<sup>3</sup>/g est le volume spécifique du clinker de ciment; 0,99 cm<sup>3</sup>/g le volume spécifique de la solution d'aqueuse saturée de  $\text{Ca}(\text{OH})_2$ ).

D'après les données déjà citées de Powers 1g du ciment hydraté fixe  $W_e = 0,225 \text{ g}$  de l'eau évaporée si la saturation est totale. Dans le calcul du volume des pores de gel  $V_3$  divisons l'eau  $W_e$  en eau interstitielle au

Fig. 1. Diagramme de powers

sens propre de ce mot et en eau interlaminaire. Utilisons à cet effet les données de Feldman et écrivons pour la phase solide du gel:

$$2,51(1-x) + 1,25x = 2,35.$$

On en tire:

(1-x), la fraction du volume de la phase solide du gel, associée à l'ossature siliceuse, x, la fraction du volume de la même phase, associée à l'eau interlaminaire

$$(1-x) = 0,873 \text{ et } x = 0,127.$$

Trouvons encore le rapport entre l'ossature siliceuse (OS) et l'eau interlaminaire (EI) d'après la masse:

$OS:EI = 2,51(1-x):1,25x = 0,219:0,016$ ,  
où 0,25 est la densité de l'eau occupant les interstices entre couches dans les cristaux de la phase solide d'après Feldman [3]. Calculons maintenant la quantité de l'eau interlaminaire liée à l'ossature siliceuse du gel  
 $A: \frac{1,225 \cdot 0,016}{0,219} = 0,081 \text{ g}$

Ainsi dans le gel

$1 \cdot 1,225 + 0,081 = 1,306 \text{ g}$  - la phase solide à l'état saturé en eau (i.e. avec l'eau inter-

laminaire),  
 $2,0,225-0,081=0,144\text{g}$  - l'eau dans les pores du gel. Le rapport des volumes est alors

$$\frac{1,306}{2,35 \text{ g/cm}^3} = 0,556 \text{ cm}^3 - \text{le volume de la}$$

phase solide du gel saturée en eau, i.e. comprenant l'eau interlaminaire, et

$0,691-0,556=0,135 \text{ cm}^3$  - le vrai volume des pores du gel; désignons-le par  $V_{3,\text{vrai}}$  à la différence de  $V_3$  comprenant le volume des interstices entre couches de la phase solide. Faisons le bilan. Selon le calcul effectuée, le vrai volume des pores de gel se définit par la formule

$$V_{3,\text{vrai}} = 0,135 \alpha C \text{ cm}^3 \quad (1)$$

sans perturbation de cette valeur par l'introduction dans cette dernière du volume des interstices entre couches de la phase solide du gel. En cas de nécessité on peut calculer  $V_4=0,065 \alpha C$  qui est un volume des interstices entre couches de la phase solide du gel, occupés par l'eau de cristallisation interlaminaire si la saturation en eau de cette phase est totale; on peut calculer également  $V_5=0,556 \alpha C$  qui est un volume de la phase solide saturée en eau du gel.

Passons à la contraction. Le volume de contraction  $V_2$  est déterminée d'après [1,2] à l'aide de la formule

$$V_2 = E - (m-1)v_c \alpha C - (E - W_t \alpha C) = (v_c + W_t - m v_c) \alpha C, \quad (2)$$

où  $m$  est le coefficient montrant l'accroissement du volume lors de l'hydratation et de la transformation en gel d'un gramme du ciment;  $v_c$  - le volume spécifique du ciment.

Trouvons d'après les données de Powers

$$m = \frac{0,691 \text{ cm}^3}{0,315 \text{ cm}^3} = 2,193 \approx 2,2.$$

La même valeur était utilisée également dans [1,2] La formule (2) et ses coefficients n'ont pas besoin d'être précisés. On peut seulement simplifier l'expression (2) en substituant les valeurs numériques  $v_c =$

$=0,315 \text{ cm}^3/\text{g}$ ,  $W_t=0,45\text{g}$  par  $1\text{g}$  du ciment,

$m=2,20$ ; on a dans ce cas

$$V_2 = 0,07 \alpha C.$$

En considérant la valeur  $V_2$  il faut prêter attention sur ce que le gel A aspire du milieu ambiant  $0,45-0,38=0,07 \text{ g}$  de l'eau grâce à la contraction. Comme on l'a vu, le volume des pores du gel A et  $V_{3,\text{vrai}} =$

$=0,135 \alpha C=0,135 \text{ cm}^3$ , par conséquent,  $0,07\text{g}$  de l'eau aspirée de l'extérieur remplissent une partie de ces pores du gel.

Comme interpréter la grandeur  $V_2$ ?

La figure 2a montre le système E+C pris pour l'expérience. Les quantités de E et de C sont arbitraires, mais  $E/C \leq 0,38$ . Le moment où par suite de l'hydratation il s'est formé une certaine quantité du gel est représenté sur la figure 2b. Pour plus de commodité on a choisi le moment où il s'est formé  $1,45\text{g}$  du gel. Ceci donne la

possibilité d'illustrer les schémas de la figure 2 par les données numériques figurant dans le texte. Voyons les changements qui doivent survenir à ce moment dans l'échantillon par rapport à l'état initial représenté sur la figure 2a.

La figure 2c montre la façon dont on divise le volume du gel en volume de sa phase solide et en volume de ses pores. Sur la figure 2d on a dégagé du volume des pores du gel le volume de contraction  $V_2$ . Il est montré ici comme une partie du volume des pores du gel. Les figures 2e,f donnent la redistribution des masses d'eau mobiles dans les échantillons de plusieurs années de Powers. Un espace libéré dans le système E+C grâce à la contraction fut rempli en fin de compte dans les expériences de Powers par l'eau liquide aspirée dans ce système à partir du milieu ambiant.

Procédons maintenant au calcul du volume des pores capillaires  $V_1$ . D'après [1,2] ce volume est calculé à l'aide de la formule

$$V_1 = E - 0,5 \alpha C. \quad (3)$$

Le coefficient 0,5 représente la quantité d'eau  $W_t$  se transformant en gel par hydratation d'un gramme du ciment. La figure 2 montre que la formule (3) est à préciser. Comme on le voit sur le dessin,  
 $V_1 = (E + v_c C) - V_{\text{gel}} - v_c C_{\text{reste}} = E - (m-1) v_c C.$

Substituant  $m = 2,2$  et  $v_c = 0,315$  nous obtenons une formule simple

$$V_1 = E - 0,38 \alpha C. \quad (3')$$

Il est aisé de voir que le volume calculé d'après la formule (3') ne se distingue du volume calculé d'après (3) que par ce que maintenant il comprend, ce qui est de règle d'ailleurs, le volume de contraction.

La figure 3 montre le passage de [1,2] aux grandeurs  $V_1$ ,  $V_2$ ,  $V_3$  calculées d'après les formules précisées.

Pour déterminer le volume de contraction, on peut recommander encore, outre la méthode  $\alpha$ , la méthode [6], ce qui peut être nécessaire pour des objets dont le volume de contraction ne se détermine pas à l'aide de la formule (2) vu l'utilisation de nouvelles additions, l'accroissement de la température de durcissement de la température de durcissement, etc.

Cette détermination nécessite que l'échantillon soit pris sous forme de gros morceaux, que l'air soit pompé de cet échantillon et que ce dernier soit immergé dans l'eau. Après l'extraction de ces échantillons à partir de l'eau il faut évacuer un excès d'eau restant sur la surface de chaque morceau et peser une charge d'environ 7 à 10 grammes de l'échantillon préparé de la façon décrite. Ensuite il faut déterminer pour cet échantillon les pertes de calcination en les calcinant pour  $1\text{g}$  du reste calculé, i.e. pour  $1\text{g}$  du ciment de départ. Ces pertes (nnn') représentent les pertes de calcination d'un échantillon saturé en eau et non pas séché comme d'habitude. La valeur de la contraction est obtenue par soustraction des nnn' de l'eau qui était introduite dans la pierre de ciment étudiée au moment de gâchage. Tout le calcul du résultat de l'analyse peut être

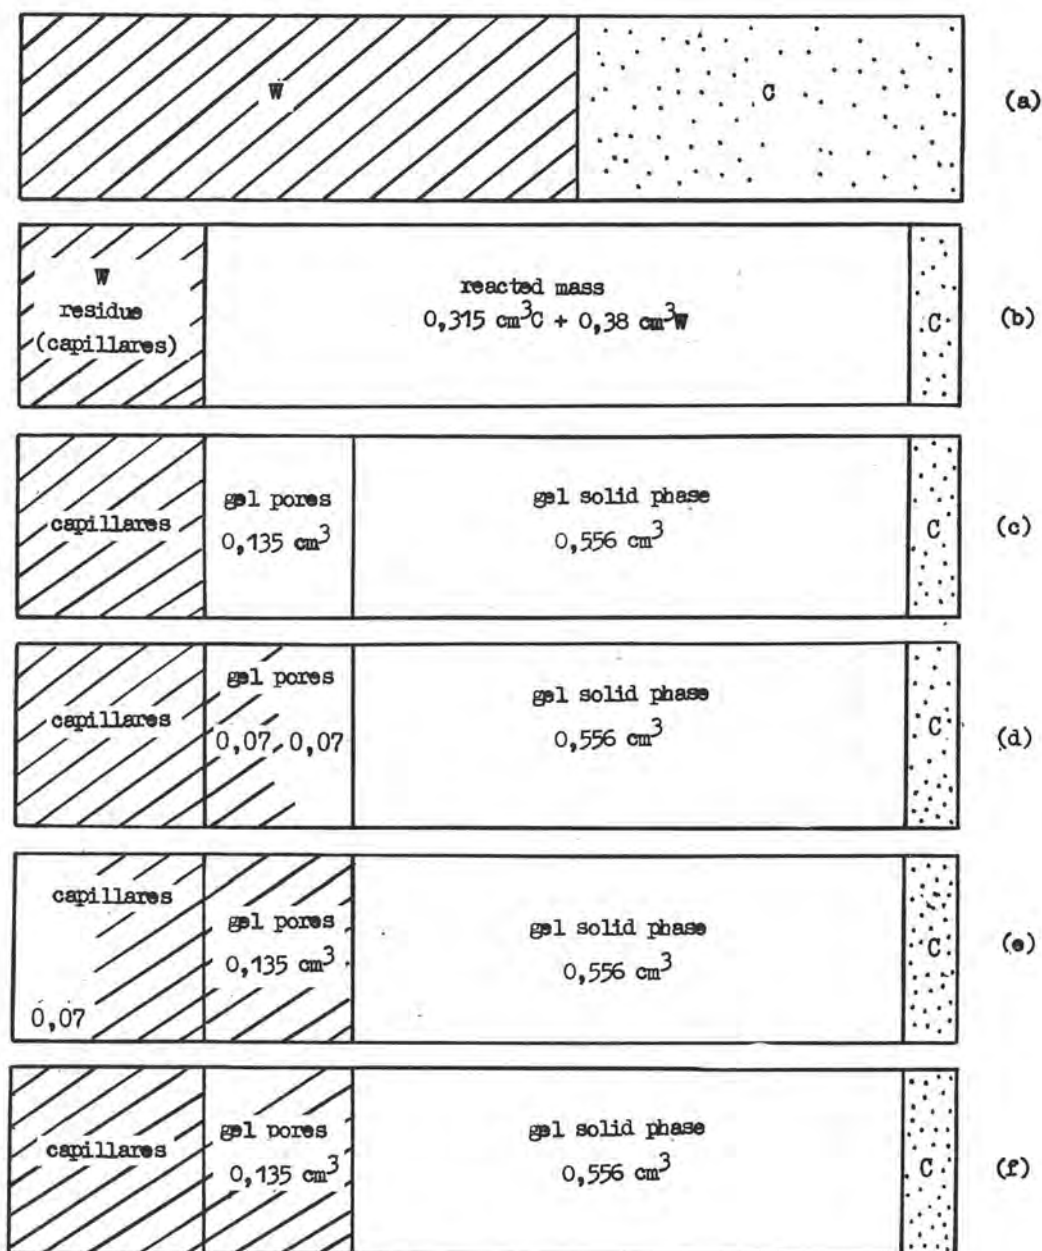

Fig. 2. Contraction et migration de l'eau vers le lieu de la reaction (schema, explications dans le texte)

effectué en pour cent du volume total de l'échantillon d'après la formule suivante simple

$$V_{\text{contr}} = \frac{(nnn' - E/C)}{(E/C + v_c)} 100\% \text{ vol.}$$

Fig. 3. Volumes des parties constitutives du ciment durci (avec changement au cours du durcissement,  $B/C = 0,5$ ): a - d'après 1, 2 et b - selon les précisions effectuées

# Application of physical-chemical and micromechanical formalized models for cement stone pore structure analysis

## *Application des modèles formalisés physico-chimiques et micromécaniques à l'analyse de la structure poreuse de la pierre de ciment*

D.A. UGINCIUS, Vniivodgeo, Kharkov, U.R.S.S.

Le processus de formation et les propriétés mécaniques de la structure poreuse de la pierre de ciment sont envisagés du point de vue des modèles du corps poreux élastique de Laccenzie et du champ réactif d'Onsager. Le processus de consolidation de la structure par diminution de la porosité est décrit par la dépendance exponentielle de Tychkevitch. Les processus de colmatage des pores sont étudiés avec utilisation du modèle microrhéologique de Gut-Simkhi-Gold et du modèle d'adsorption polymoléculaire BET.

On a montré donc que la relation entre la porosité, les propriétés mécaniques et les propriétés de diffusion du ciment durci peut être estimée non seulement statistiquement mais avec utilisation des modèles formalisés fondamentaux connus physico-chimiques et micromécaniques.

The process of formation and mechanical properties of cement stone pore structure have been considered taking into account Laccensey elastic porous body model and Onsager reactive field model. The process of structure hardening with porosity decrease is described by Tychkevich exponent. The processes of pore colmatation have been studied with the use of Gut-Simkhi-Gold microrheological model and BET polymolecular adsorption model.

In this way it is shown that the interconnection of cement stone porosity, mechanical and diffusion properties can be estimated not only statistically, but also with well-known basic physical-chemical and micromechanical formalized models.

When investigation the structure and properties of hydrated Portland cement having polydispersed sponge porous structure a number of general physico-chemical problems (adsorption, diffusion, abovementioned formations, structural sensitivity of properties) is inevitably touched upon. It is reasonable to consider them using theoretical and semiempirical formalized models describing these phenomena.

Sufficiently strict analytical consideration of porosity influence upon the cement stone stress-strain properties is connected with insuperable difficulties relative to high structural sensitivity of properties of defective bodies [1]. To estimate this influence Mackenzie model [2,3] derived from computations based on Frolich "self-consistency" method [4] has been used. The idea [2] implies that a single isolated pore in the center of a sphere of real material with real shear ( $G$ ) and bulk ( $H$ ) moduli is supposed to be surrounded by the spherical "crust of absolutely dense material with hypothetical moduli  $G_0$  and  $H_0$ .

Consideration of such model deformation under the effect of the homogenous stress has given the following dependence.

$$\frac{G_0 - G}{G_0} = \frac{5(3H_0 + 4G_0)}{9H_0 + 8G_0} + AP^2 \quad (1)$$

where,  $A$  - the factor taking into account mutual influence of structural elements (pores).

Kingery [5] using a number of simplifications on the basis of the dependence (1) obtained the simplified formula which adequately describes the experimental dependences  $E/E_0 = f(P)$  for a variety of materials with the Poisson's ratio  $\mu = 0.5$ ; for the cement stone the assumption  $\mu = 0.3$  is insufficiently correct, since in this case the Poisson's ratio varies over rather wide range [6]. On the basis of generalisation made by Verbeck and Helmuth [7], using data on Yong's modulus, the shear and bulk moduli, as well as Mackenzie dependence (1) the following dependence has been derived:

$$E = E_0(1 - 2.18P + 0.5P^2) \quad (2)$$

where,  $E$  - Yong's modulus of the cement stone;  $E_0$  - Yong's modulus of the cement stone with zero porosity.

The formula (2) is a semiempirical case

of the dependence (1) for the idealized cement stone with evenly distributed spherical equidimensional pores. Likewise the general model (1) the formula (2) is valid when  $P < 0.4$ , since with greater  $P$  values interaction of pores becomes essential, i.e. the coefficient values at a quadratic term.

The first Lamet's coefficient of porous  $\lambda_1$  is:

$$\lambda_1 = H - 2/3 E_0 \quad (3)$$

This relationship is valid with the lowest value of the coefficient at a quadratic term of 0.5 [9].

Fig. 1 gives a comparison between the dependence (2) and Helmuth, Turk [10] with the cement stone of 100% hydration; it is obvious that the structure of the cement stone samples is rather close to the modelled one (2) which takes into account real elastic properties of the mineral phase. Relationship between mechanical strength and porosity of the cement stone is of more complex nature; as Griffith and his followers showed that the size and configuration of pores are of essential significance. Additionally, if to consider the kinetics of crack increase process, Laplace's pressure, the coalescence of pores, one may state that the behavior of porous bodies under stress and porous structure formation are exclusively involved complexes which represents and in some cases competitive elemental processes. Therefore, an interesting work [11] treating intermolecular interaction model on the basis of Lennard-Jones potential [12] as applied to the theory of strength can be considered as a basis for model long concepts on dispersed structure strength at the molecular level only.

Due to the complexity of the problem strengthening of porous materials under stress or as a result of various technological effects is considered in most general form, for example, on the analogy of some chemical reaction [13].

Analogous to sintering [9] it is proposed to regard the process of cement materials strengthening as the result of filling its porous spaces with solid phase (hydration hardening, formation new phases when admixtures are added, filling of pores with polymer densifiers etc.) as relaxational process. In this case, using Maxwell equation for

Fig. 1. Dependences  $E/E_0 = f(P)$  FOR cement stones

viscous-elastic body and assuming  $P=f(t)$ , deformation as a constant:

$$dR/dP = -nR \quad (4)$$

and after integration:

$$R = R_0 \exp(-nP) \quad (5)$$

Empirically this dependence is derived (for ceramics) by Ryshkewitch [14] and has been well supported with the examination of dependences  $R=f(P)$  for ceramics and cement.

Modeling concepts on cement stone hardening process on the basis of Ryshkewitch dependence (5) consist in the following:

- $P$  coefficient equivalent to porosity quantitatively reflects the process of cement stone strengthening resulted from filling of pores with solid phase;
- coefficient  $n = f(\varphi_1, \varphi_2, \varphi_3, \varphi_4)$  where  $\varphi_1$  is the function of local densities (pores or ensembles of pores) distribution,  $\varphi_2$  is the function of pore distribution according to size,  $\varphi_3$  is the function of pore distribution according to configuration and  $\varphi_4$  is the function of pore distribution according

to orientation to force action;  
-  $R_0$  - strength of the absolutely dense mineral phase (without pores);

The exponential formula (5) is good for description of the experimental dependences both for ceramics [5, 14] and cement stone [15, 16] including polymer impregnated cement stone [17]. It is necessary to note that dependence (5) can be said adequate porous cement material model only in the case when pores are predominant defects in particular, this dependence is not suitable for properties description of concrete which fails primarily along aggregates or along the contact zone "binder-aggregate". The model postulates the presence of adhesion strength within the contact zone at binder cohesive strength level. Such an assumption might be acceptable only for the cement stone, high-strength fine concrete and polymer impregnated cement materials.

Fig. 2. Generalized dependences  $R/R_0 = f(P)$

When filling a cement stone porous space with organic polymers hydration products of clinker minerals, possessing high specific surface, actively participate in the structure formation processes of the polymer phase. Morphology above molecular structure reorganization under the influence of the mineral phase has been estimated by means of the Guth-Simha-Gold's microrheological equation 18, supplemented (Smoluchowski's method 19) by the quadratic term allowing for the interdependence of dispersed particles:

$$E_k/E_n = 1 + 2.5\varphi + 14.1\varphi^2 \quad (6)$$

where,  $E_k$  - Yong's modulus of composition;

$E_n$  - Yong's modulus of dispersion medium (of polymer)

$\varphi$  - filler volume concentration (of mineral phase).

The equation (6) is invariant to the nature of the filler and matrix surfaces, and therefore it is convenient as a standard for comparison while investigation the polymer

properties in boundary layers. Physico-chemical interaction polymer - mineral backing is expressed in the change of Yong's modulus value calculated according the equation (6), e.i. allowing only for a filling (hydrodynamical) effect. Investigated dependences are approximated by the stright-line equation:

$$K_p = A + B \frac{a}{\varphi_n} \quad (7)$$

where,  $a$  - the adsorption value on a mineral proportional to the specific surface of a mineral phase;

$\varphi_n$  - polymer concentration in the system.

Value  $B$  in the equation (7) is a mesure of the mineral phase physico-chemical activity [20] since it characterizes the rate of polymer reorganization coefficient change  $K_p$  with a mineral phase surface unite being introduced.

It is estimated that the activity of interaction between mineral and polymer phases does not depend upon a degree of a specific chemical interaction: portlandite [21] the most active with regard to the donor-acceptor interaction has  $B$  value which a very close to the similar characteristics of cal-

equation [22] the constant  $C$  is a quantitative measure of the mineral phase adsorption activity (Fig.3). Thus, it can be stated that the polymer structure reorganization in immediate proximity to the cement hydration products surfaces could be accounted for mainly by a physico-chemical interaction (conformal restrictions in adsorption layers), but not by a specific chemical interaction.

A cement stone being impregnated with various polymer compositions, hydrosilicate gel can display properties of a molecular sieve. This phenomenon has been studies experimentally using a series of organic liquids with an increasing size of molecules (methanol, benzol, butanol, methylmethacrylate, hexane, etc.) Having no data on the radii of this molecules averaged out in all possible conformations, we in the calculations made use of Onsager [23] model of intermolecular interaction. This has made it possible to use simple and suitable for experiment dependences in which molecular sizes are determined by the macroscopic properties of liquids [24]. Correlation has been established between the cement stone adsorption volume and Onsager radii of molecules. This correlation quantitatively characterizes the molecular sieve effect which is of great significance from the engineering point view.

Thus, in the investigation of the cement stone structure and properties as a polydispersed porous body, alongside with statistical classical physico-chemical modeling concepts may be successfully made use of.

# Structures et résistances mécaniques sous des traitements hydrothermiques

## *Structures and mechanical resistances under hydrothermal treatments*

G. TEODORU, ancien chercheur en chef INCERC Cologne, République Fédérale d'Allemagne.

RESUME : L'étude des bétons ayant subi un traitement hydrothermique fût commencée en 1957 lorsque l'auteur dirigeait le laboratoire d'essais d'une fabrique de précoilage. Des recherches systématiques sur la structure et sur les résistances mécaniques de ces bétons ont été effectuées à partir de 1967.

Les résultats des essais non-destructifs à l'aide des ultrasons (fig. 1 et 2) permettent de conclure que pour les bétons ayant subi un traitement hydrothermique, existent les relations exponentielles  $V_L-R_C$  et  $A-R_C$ . Les coefficients de corrélation allant de 0,898 à 0,988 sont obtenus.

Les essais laissent entrevoir, d'une manière très évidente surtout dans le cas du traitement à l'autoclave, l'existence des défauts de structure. Les valeurs du module d'élasticité statique des compositions traitées à l'autoclave sont inférieures à celles correspondantes au durcissement normal. Le comportement est sur une grande étendue de la courbe  $\mathcal{E} = f(\bar{\sigma})$  élastique (fig. 3) et on a remarqué une réduction importante de l'aire de la courbe de hystérésis pour les cas du traitement à l'autoclave.

Des recherches à l'aide du microscope optique sur des suspensions de ciment, sections minces et sections polies, et d'autre part, à l'aide du microscope électronique sur des "moulages" contrastés avec du platine ont été effectuées.

La compacité cède le rang d'importance à l'obtention des formations nouvelles caractérisant les traitements hydrothermiques sous pression possédant de meilleures qualités liantes. La capacité liante supérieure résulte de l'augmentation des points de contact créés par la dispersion plus élevée des particules quoique la structure ait plus de défauts.

SUMMARY : The study of concretes subjected to a hydrothermal treatment was started in 1957 when the author directed the testing laboratory of a precasting plant. From 1967, systematic researches onto the structure and their mechanical resistances were carried out.

The results of the non-destructive tests with ultrasonic pulse method (fig. 1 and 2) allow to conclude that for concretes having been subjected to a hydrothermal treatment, the relations  $V_L-R_C$  and  $A-R_C$  are exponential. Correlation coefficients from 0,898 to 0,988 are obtained.

The tests showed very clearly, especially in the case of autoclaving, the existence of structural faults. The values of modulus of elasticity of the autoclaved compositions are inferior to those of cured ones under ordinary conditions. The behaviour of autoclaved mortars had shown the almost linear trend (fig. 3) of the curve  $\mathcal{E} = f(\bar{\sigma})$  and an important reduction of the hysteresis area has been noticed for the cases of autoclaving treatment.

With the help of the optical microscope, researches were carried out on cement-water grouts, thin sections and polished sections and, on the other side, with the help of the scanning electron microscope on platinum-contrasted "moulds".

The compacity cedes the rank of importance to the obtaining of new formations characterising the hydrothermal treatments under pressure which have better cementitious qualities. The superior binding capacity results from the increasing of contact points, created by the higher dispersion of the particles although the structure has more faults.

## I. INTRODUCTION

La constatation faite lors de quelques expertises de la destruction avec une rapidité surprenante des éléments en béton à agrégats ordinaires traités en autoclave, a déterminé les recherches systématiques poursuivies par l'auteur dans le but de préciser la structure de ces bétons. [1].

## II. RECHERCHES EFFECTUEES

### A. Essais non-destructifs à l'aide des ultrasons

A partir de 1967, des recherches ont été effectuées dans le but d'étudier l'effet qu'exercent les principaux types de traitement hydrothermique-étuvage (E), traitement

en moules chauffants (M) et traitement à l'autoclave (A) - sur les relations de transformation des grandeurs mesurées de manière non-destructive en résistance du béton à la compression à des âges différents [2, 3, 4].

Les recherches ont été exécutées dans une usine de précochage sur un béton à agrégats de rivière. Les résultats de l'analyse du ciment et les cycles des traitements hydrothermiques se trouvent dans [2].

Les essais non-destructifs par ultrasons ont été effectués avec l'ausculteur SBR2 des Laboratoires Electroacoustiques de Rueil (France), fonctionnant sur le principe de l'émission d'impulsions ultrasoniques à la fréquence de 100 kHz.

$$A - R_c = 0.07765 e^{1.75 V_L} \quad r = 0.959$$

$$M - R_c = 0.04014 e^{1.62 V_L} \quad r = 0.988$$

$$E - R_c = 0.00483 e^{2.04 V_L} \quad r = 0.959$$

$$S - R_c = 0.00121 e^{2.30 V_L} \quad r = 0.950$$

#### Composition du béton:

Agrégats de rivière 0 - 3 mm 30 %  
3 - 7 mm 20 %  
7 - 15 mm 50 %  
Ciment RIM (HRI) 200 350 kg/m³

Fig. 1 Relation  $V_L - R_c$  pour le béton à l'âge de 28 jours

$$A - R_c = 11.219 e^{-0.109 A} \quad r = 0.924$$

$$M - R_c = 32.181 e^{-0.136 A} \quad r = 0.898$$

$$E - R_c = 87.220 e^{-0.159 A} \quad r = 0.944$$

$$S - R_c = 27.014 e^{-0.13 A} \quad r = 0.970$$

#### Composition du béton: voir fig. 1

Fig. 2 Relation  $A - R_c$  pour le béton à l'âge de 28 jours

La vitesse de propagation longitudinale et l'atténuation des ultrasons donnent des indications qualitatives et quantitatives sur la structure des bétons traités dans l'autoclave (fig. 1 et 2). L'étalon est constitué par le béton standard (S) ayant durci 7 jours dans l'eau et 21 jours à l'air 20°C et 65% humidité relative. On a démontré que la forme des relations  $V_L-R_C$  et  $A-R_C$  est exponentielle. Les relations expérimentales établies montrent de très bons coefficients de corrélation  $r$  allant de 0,898 à 0,988.

Intéressant à citer sont les résultats des essais à ultrasons sur des pâtes de composants minéralogiques purs traités à l'autoclave. Dans tous les cas, le traitement abaisse la vitesse de propagation sauf pour le C<sub>2</sub>S et C<sub>4</sub>AF où on note une croissance de la vitesse de propagation (voir tableau I).

Comp. miner.	TABLEAU I					
	$V_L$ km/s					
	indiv.			Rapp. à C <sub>3</sub> S		
	S	Av	Av/S	S	Av	Av/S
C <sub>2</sub> S	1,9	2,3	1,18	0,48	0,68	5,00
C <sub>3</sub> S	4,0	3,3	0,83	1,00	1,00	0,54
C <sub>3</sub> A	2,6	1,8	0,69	0,65	0,55	0
C <sub>4</sub> AF	3,6	3,9	1,08	0,90	1,18	2,05

### B. Détermination du module d'élasticité de Young

Afin de compléter des indications obtenues par les essais à ultrasons sur la structure formée durant le traitement à l'autoclave, on a déterminé le module d'élasticité statique pour des compositions de mortiers et bétons différant par le rapport E/C et dosage de ciment. Le module d'élasticité a été déterminé sur des prismes 10x10x30 cm. Les déformations ont été enregistrées à l'aide du dispositif Martens et en parallèle à l'aide des tensomètres électrorésistifs. Sur la fig. 3 sont présentés les résultats comparatifs durcissement en autoclave/durcissement dans des conditions normales pour les mortiers (1) (2) et (3).

On remarque une caractéristique importante pour les structures durcies en autoclave: l'allure très linéaire de la courbe  $\epsilon = f(\sigma)$  sur le domaine presque entier avant la rupture. La forme de la courbe montre que la fissuration précédant la rupture se produit, par rapport au béton durci dans des conditions normales, très tard, de façon qu'on peut mieux compter sur un comportement élastique de ce matériel. Cette conclusion est confirmée aussi par la réduction très marquée de l'air de hystérésis suite au traitement à l'autoclave[1]. Les surfaces de rupture des éprouvettes traitées à l'autoclave contiennent un plus grand pourcentage de granulats rompus que les surfaces témoins de béton non autoclavé. Cela indique que les bétons autoclavés, en dehors des résistances supérieures de la

pâte de ciment elle-même, possèdent aussi une meilleure adhérence granulat-pâte de ciment.

Fig. 3 Courbe  $\epsilon = f(\sigma)$  pour les mortiers (1) (2) (3)

### C. Recherches à l'aide de la microscopie optique

Le traitement hydrothermique sans pression a été "simulé" par l'ébullition de la suspension de ciment, parfaitement isolée du milieu extérieur grâce au collage de la lamelle à la lame avec un co-polymère.

Fig. 4 Suspension de ciment RIM (HRI) 200 traitée à 90°C après 72 heures

On observe immédiatement après le traitement des cristaux tabulaires, hexagonaux, sous forme de prismes allongés qui grandissent en permanence (fig. 4). Au moment où ces cristaux atteignent de grandes di-

mensions, on remarque la tendance accentuée de fissuration (fig. 5).

Fig. 5 Suspension de ciment RIM (HRI) 200 traitée à 90°C, après 168 heures

La simulation du traitement à l'autoclave a nécessité des améliorations successives de l'étanchéité des récipients qui, à la fin, ont permis le traitement jusqu'à 220°C.

Les recherches microscopiques - la plupart des résultats se trouve dans [1] - ont démontré (fig. 6) que dans les conditions de traitement à l'autoclave, les formations cristallines possèdent des dimensions beaucoup plus petites que celles obtenues suite aux traitements hydrothermiques sans pression.

Fig. 6 Suspension de ciment PZ 400 traitée à 12 Atm.

Le développement des cristaux après le traitement est réduit, le processus étant presque terminé à ce moment.

A cause des dimensions très petites, il n'a pas été possible de mettre en évidence - à l'aide de la microscopie optique - l'existence des hydrosilicates de calcium.

Afin de mettre en évidence les réactions de surface entre la pâte de ciment et l'agrégat, on a procédé à l'examen mi-

croscopique à la lumière incidente des surfaces polies. Cette méthode est souvent utilisée en pétrographie et métallographie. Les réactions de surface entre la pâte de ciment et l'agrégat sont plus développées dans le cas du traitement hydrothermique (fig. 7 par rapport à fig. 8).

Fig. 7 Interface pâte de ciment/agrégat. Mortier traité hydrothermiquement

Fig. 8 Interface pâte de ciment/agrégat. Mortier (conditions normales)

La liaison entre le  $\text{SiO}_2$  du granulat et les phases CH et CSH de la pâte de ciment a, dans le cas du traitement à l'autoclave, un caractère chimique témoigné par le fait que les hautes résistances mécaniques ne varient pas avec l'humidité comme dans le cas des bétons durcis dans des conditions normales.

A l'aide de Phenolphthaleine, on a mis en évidence l'existence de Portlandit autour des agrégats en plus grandes quantités que dans le cas du mortier durci dans des conditions normales. Cette présence est la prémise de la réaction chimique qui peut mener jusqu'aux formations épitaxiales[5].

Des pâtes de ciment durci, ayant  $E/C = 0,2 \div 0,6$  et des mortiers, ayant  $E/C = 0,45 \div 0,8$ , on a extrait des carottes de  $\varnothing 50$  mm. De ces carottes on a préparé des sections minces (20-25  $\mu\text{m}$ ) qui ont servi à effectuer

des mesurages de la surface des pores à l'aide d'un intégrateur microscopique. Les mesurages comparatifs - traitement hydrothermique/durcissement dans des conditions normales - ont démontré que dans le premier cas, les valeurs sont supérieures de 5% à 12%. Il faut quand-même noter que les mesurages du poids volumique n'ont pas mis en évidence des différences sensibles entre les bétons traités à l'autoclave et ceux durcis dans des conditions normales.

Sur la photo 9 on remarque un cas d'"auto-guérison", c'est-à-dire le remplissage ultérieur d'un pore avec de nouvelles formations, spécialement de Portlandit dont l'existence a été confirmée par ses caractéristiques optiques.

Fig. 9 "Auto-guérison"

#### D. Recherches à l'aide du microscope électronique

On a utilisé la méthode des "moulages" contrastés avec du platine afin de les rendre visibles aux faisceaux d'électrons. Les recherches se sont limitées seulement aux pâtes de ciment et mortiers traités à l'autoclave, ayant comme "témoin" le durcissement dans des conditions normales. Les hydrogrénats, typiques dans le traitement sous pression, peuvent être reconnus sur la photo 10.

Fig. 10 Hydrogrénats. Mortier traité en autoclave

La photo 11 révèle des caractéristiques trouvées très souvent chez les mortiers traités à l'autoclavage.

Il s'agit des surfaces de rupture qu'on peut reconnaître d'après la forme des hydrosilicates de calcium arrachés de la section avec laquelle ils maintiennent encore des "ponts" de liaison. Au vu de ces "ponts", on peut reconnaître la direction de rupture. D'après l'opinion de l'auteur, ces photos témoignent les qualités liantes supérieures des pâtes de ciment durcies à l'autoclave.

Fig. 11 Surface de rupture avec des phases CSH. Mortier traité en autoclave

Sur la photo 12 on voit des phases CSH avec un rapport C/S = 4/5÷5/6 typique pour la Tobermorite qui caractérisent ces traitements hydrothermiques.

Fig. 12 Tobermorite. Mortier traité en autoclave

### III. CONCLUSIONS

Les recherches microscopiques ont mis en évidence le fait que durant les traitements hydrothermiques, se forment des quantités plus grandes de cristaux de  $\text{Ca}(\text{OH})_2$ . Lorsque les cristaux atteignent de grandes dimensions, on remarque la tendance accentuée de fissuration (fig. 5). Les microfissures sont dues aussi bien à la dilatation de l'eau et de l'air durant le processus de chauffage et de refroidissement, qu'à la perte d'eau. La diffusion du Portlandit, favorisée par la haute température, amène une porosité élevée des structures d'hydro-silicates de calcium.

Les recherches faites à l'aide de la microscopie optique et électronique sur des pâtes de ciment et sur des mortiers, traités à l'autoclave, ont mis en évidence que ce traitement donne naissance à de nouvelles formations différentes de celles résultant des autres traitements hydrothermiques et possédant un grand degré de dispersion, ce qui mène à un haut niveau d'énergie potentielle de surface.

En général, on accepte que les résistances finales de la pâte de ciment soient d'autant plus grandes que le contenu en CSH à de longues fibres est plus grand (pour la même compacité de la structure). Cela explique les hautes résistances obtenues par l'hydratation à températures basses, et l'effet favorable des retardeurs de prise. [6]

Dans le cas du traitement à l'autoclave, il paraît que cette hypothèse n'est plus valable.

La grande résistance en compression des bétons traités en autoclave s'explique, d'une part par la quantité plus grande de nouvelles formations qui a son origine dans l'activation du  $\text{SiO}_2$  du granulats quartzueux, et spécialement du sable fin et d'autre part, par les meilleures qualités de ces nouvelles formations.

Par ailleurs, cette structure de la pierre de ciment qui se forme d'une manière presque définitive dans un délai de temps extrêmement court, présente plus de défauts, surtout fissures, de manière qu'il paraît être possible qu'en dépit des grandes résistances en compression, l'action des agents physiques la détruise parfois rapidement. Cet aspect est très bien mis en évidence par les essais à ultrasons.

Mais, sans connaître les conditions de durcissement du béton examiné, une interprétation des essais non-destructifs peut mener à de grandes erreurs.

En dehors de la résistance en compression qui est le plus souvent déterminée, la structure et la distribution des pores, les microfissures dans la pierre de ciment et sa capillarité constituent des éléments très importants pour en juger de la compacité, de la résistance aux agents physiques et chimiques extérieurs, en un mot, de sa durabilité.

### REMERCIEMENTS

L'auteur désire exprimer ses remerciements aux collègues qui lui ont donné la possibilité d'entreprendre et de poursuivre les recherches microscopiques. En particulier, il est reconnaissant à son ancien professeur, plus tard directeur de sa thèse de doctorat, le feu Professeur Dr. Alex. Steopoe auquel tous ceux qui l'ont connu et qui ont bénéficié de son érudition, lui gardent un souvenir inoubliable.

# Rheology of setting Portland cement pastes

## *Rhéologie des pâtes du ciment Portland faisant prise*

P.F.G. BANFILL, Department of Building Engineering, University of Liverpool, U.K.

RESUME : Pendant la prise du ciment les phases solides des minéraux hydratés croissent dans le liquide. On peut étudier la prise par les méthodes chimiques, thermiques, électriques ou mécaniques. Nous avons employé un viscosimètre à rotation pour observer les variations des propriétés rhéologiques des pâtes du ciment pendant la prise.

Les pâtes fraîches montrent la destruction par agitation de la structure, mais la pâte cisailée est un corps de Bingham. A cause des difficultés expérimentales avec les pâtes du ciment dans les cylindres coaxiaux, où une zone immobile peut se produire ou disparaître imprévisiblement, on a employé un nouveau viscosimètre. C'est une pale hélicoïdale qui tourne dans l'axe du cylindre qui contient la pâte.

Les courbes d'écoulement obtenues avec cet appareil indiquent que le seuil de cisaillement décroît au commencement et croît ensuite avec le temps. Si l'on cisaille la pâte continuellement à vitesse fixe, le couple sur la pale décroît jusqu'à un minimum ( $T-T_{min}$ ), au bout du temps  $t$  suivant l'équation :

$$T-T_{min} = A t^b$$

Les accélérateurs et les retardateurs changent la constante  $A$ , mais ne changent pas l'exposant  $b$ .

Ces résultats indiquent qu'on peut employer cette méthode pour étudier la prise des pâtes du ciment.

SUMMARY : Setting of cement is the growth and interlocking of a solid phase of hydrated minerals within a liquid. It can be studied by chemical, thermal, electrical or mechanical methods. We have used rotational viscometry to observe changes in the rheological properties of cement pastes with time.

Fresh cement pastes shows structural breakdown, but the broken down paste conforms closely to the Bingham model. Because of experimental difficulties with cement pastes in coaxial cylinders, where a stationary plug may form or disintegrate unpredictably a new geometry has been used. This is a helical impeller rotating in the paste contained in a cylinder.

Repeated flow curves using this latter geometry show that yield stress decreases at first and then increases uniformly with time according to a power law. When sheared continuously at constant speed the torque on the impeller decreases to a minimum ( $T_{min}$ ) as the structure breaks down and then increases as the hydration structure builds up. The helical impeller shows slower breakdown than coaxial cylinders due to the complex flow pattern. The increase of torque, ( $T-T_{min}$ ), with time,  $t$ , follows a power law relationship of the form:

$$(T-T_{min}) = A t^b$$

The effect of accelerators and retarders is to change the value of  $A$ , while  $b$  remains constant.

These results show that, with suitable development, the technique can be used to monitor setting of pastes.

## INTRODUCTION

Setting is generally agreed to be caused by the interlocking of solid phase hydration products. As these grow through the aqueous phase separating particles the physical manifestation is a change from liquid-like flowing behaviour to solid. This transformation usually coincides with an increase in the rate of hydration. Practically it can be studied by chemical, thermal and electrical methods, or, making use of the change in properties from liquid to solid, a variety of mechanical methods. These latter range from primitive standard penetrometers such as the Vicat needle to the more sophisticated calibrated devices of Bomblod (1) and Forrester (2). We have approached the problem using conventional rotational viscometry.

The rheology of cement pastes has been widely studied at early ages. The main techniques used are flow curves, where the speed of rotation increases to a maximum value and then decreases to zero, and continuous shear, where a constant speed of rotation is maintained. In both cases the torque produced by the rotation is measured. Fig.1 shows a typical flow curve. As shear rate increases the shear stress passes through a maximum as the yield value of the structure is overcome, it then declines as the structure breaks down by shearing. The down-curve follows the Bingham relationship (equation 1).

$$\tau = \tau_0 + \mu_p \dot{\gamma} \quad (1)$$

Fig.1 - Cyclic flow curve for cement paste. Arrows indicate shear stress behaviour as shear rate goes up to a maximum and back to zero.

The existence of a hysteresis loop is often taken to mean that the paste is thixotropic. This term means a reversible breakdown of structure, but there is no evidence that the breakdown in cement paste is reversible and subsequent flow curves show stresses below the original at all corresponding shear rates. Accordingly the term thixotropy should not be used. In continuous shear the torque (shear stress) declines as structure breaks down (Fig.2) and Tattersall found that the breakdown followed first order kinetics (3), equation 2:

Fig.2 - Breakdown of torque in a coaxial cylinder viscometer under continuous shear.

Very little work has been done at later ages of the paste, though it seems reasonable to expect that paste viscosity will increase again as the hydration structure builds up.

## APPARATUS

There are experimental problems with flow of cement pastes in coaxial cylinders (4). A stationary plug of paste forms at the outer cylinder wall with a sheared zone inside. This changes the geometry of the annulus. Additionally the plug may either slide round at some speed below that of the rotating cylinder or disintegrate, in both cases at unpredictable times. To avoid this problem and that of sedimentation during the experiment a helical impeller was designed and constructed (Fig.3.). Direct observation of the flow in this geometry showed that plug flow did not occur, and all stationary zones had been eliminated.

Fig.3 - Dimensions of the helical impeller.

This viscometer geometry was used with a Rotovisco RV2 viscometer with a PG 142 external speed programmer which could produce repeated cycles of shearing. Flow curves, and stress curves in continuous shear were recorded on an X-Y plotter and chart recorder respectively.

## EXPERIMENTAL NOTES

All pastes were mixed by hand as follows: 35g of water were added over a period of 1 minute to 100g of ordinary Portland cement (see Appendix) in a crystallising dish. Lumps were broken up and the whole paste stirred with a spatula for 2 minutes before loading into the viscometer. All experiments took place at  $20 \pm 0.5^\circ\text{C}$ .

## RESULTS

Repeated flow curves show that the yield stress and plastic viscosity decrease initially before increasing with time approximately according to a power law relationship. The data shown in Fig.4. were obtained by flow curves repeated every 10 minutes. The maximum speed of rotation was 200 rev/min (equivalent to mean shear rate =  $35 \text{ sec}^{-1}$ ) and the time taken up for an up-and-down cycle was 2 minutes.

Fig.4 - Variation of yield stress with time, found by repeated flow curves.

In continuous shear the torque on the impeller declines to a minimum value after about 100 minutes when the equilibrium structure has been achieved. Torque then increases as hydration proceeds (Fig.5). The data can be represented by two straight lines on graphs of  $\ln(T-T_{\min})$ , the excess torque above the minimum value, and  $\ln t$ , the time (Fig.6). The hydration section fits an equation:

$$T - T_{\min} = At^b \quad (3)$$

Fig.7 shows the effect of admixtures on the build up curves. The slope of the straight lines of  $\ln(T-T_{\min})$  against  $\ln t$  is unchanged but the whole plot is moved to earlier times by 2%  $\text{CaCl}_2$  and later times by 0.01 and 0.1% citric acid, i.e. these admixtures change the value of  $b$  in equation 3.

Fig.5 - Breakdown of torque with time in the helical geometry, and subsequent build up as hydration proceeds.

Fig.6 - Logarithmic plot of breakdown and build up in the helical geometry.

Fig.7. - Effect of admixtures on the logarithmic build up plot.

## DISCUSSION

In comparison to the results of other workers using coaxial cylinders (3,4) it takes much longer to breakdown the structure present in the cement paste when mixed. This must be due to the complicated flow pattern in the sample. The range of shear rates in the paste is likely to be wide so that some regions are broken down more rapidly than others. Mixing is also taking place so the torque on the impeller at any time is an 'average' of the torque produced by the different elements of paste. At the same mean shear rate in coaxial cylinders and our helical apparatus the speeds of breakdown differ by about ten times, and since

the speed of breakdown varies with shear rate, we can infer that the breakdown rate and shear rate are related non linearly. In the range of shear rates in the helical apparatus those at the lower end are more important in determining the breakdown rate than those at the top end.

The data of Fig.5 may be interpreted in terms of two superimposed processes, the breakdown of structure at short shearing times due to the destruction of weak bonds between cement particles by shearing, and the building up of structure at longer times by hydration.

During hydration water in the paste reacts chemically to give hydrates and is also immobilised physically by the 'onion-shell' and needle shaped gel products. This process surely starts from the initial contact of cement and water, but in the experiments described here was masked by the breakdown. Subsequently a method of preparing fully broken down pastes was developed. The cement and water were placed in a 250 cm<sup>3</sup> beaker and stirred with a propellor turbine mixer at 2500 rev/min for 7 minutes before loading into the viscometer. Pastes made like this gave no further breakdown in the viscometer and build up of structure by hydration was seen right from the start of the experiment. Fig.8 shows this type of curve obtained at 200 rev/min. The slope is different from Fig.7 which indicates that the kinetics are different. This is under investigation.

Fig.8 - Build up of torque for a fully broken down cement paste.

The results of Figs. 7 and 8 show that the build up curve may be used as a guide to the hydration behaviour of cement pastes, but in developing the technique we must consider the process of hydration. According to a recently proposed model initial reactions are surface dissolution and formation of a C-S-H gel layer. This retards hydration which can only restart on rupture. The C-S-H gel is selectively impermeable to silicate ion so that osmotic pressure inside the skin builds up until rupture occurs, whereupon the extruded hydrosilicate combines with Ca<sup>2+</sup> in solution to give secondary C-S-H outgrowths (5). These outgrowths are likely to be damaged by shear-induced

collisions with other particles and this might release more hydro-silicate into solution, i.e. the rate of hydration might strongly depend on the rate of shear, and would be higher at higher shear rates.

Comparison of Figs.4 and 6 supports this suggestion. Taking the work done by shearing to be proportional to the product of time and  $\dot{\gamma}^2$  the paste of Fig.4 was subjected to about 7% of the shear work of the paste of Fig.6. (0-200 rev/min in 2 minutes repeated every 10 as against 200 rev/min). In these cases the exponents of the power-law relationships between excess yield stress or excess torque and time are 2.3 and 3.5 respectively. Clearly factors affecting the rate of hydration also affect the kinetics of the structural build up curve.

Experiments are currently in progress to find the effect of shear rate on the constants in equation 3, and also to study the effect of the shearing process on the rate of hydration of cement by chemical methods. Preliminary results suggest that the trend is not simple and that there may be an optimum value of shear rate at which the hydration rate is scarcely changed compared to an un-sheared paste. If this is confirmed the value of the technique as a monitor of hydration is much enhanced.

Other factors which must be checked are the effects of water/cement ratio, temperature and cement composition. Future work will be to study the effects of admixtures.

## CONCLUSIONS

The technique described here permits us to study the hydration of cement pastes through the effect on rheology. The equilibrium apparent viscosity of a fully broken down paste may be reached either by shearing in the viscometer or externally in a high speed mixer. Subsequently the torque on a continuously rotating impeller increases as hydration takes place. The excess torque above the minimum value is a power law function of time and the exponent of the power law is affected by shear rate, while the presence of retarding and accelerating admixtures changes the constant but not the exponent.

## APPENDIX

The cement used was of the following composition:

Compound	%
C <sub>3</sub> S	65.9
C <sub>2</sub> S	7.3
C <sub>3</sub> A	7.1
C <sub>4</sub> AF	10.1
SO <sub>3</sub>	2.3
Na <sub>2</sub> O	0.36
K <sub>2</sub> O	0.87

# Effects of curing time on the mechanical properties of cement paste

## *Effets du temps d'étuvage sur les propriétés mécaniques de la pâte de ciment*

A. BAJZA, Slovak Technical University, Brastislava, Czechoslovakia.

RESUME: On a étudié les effets du temps d'étuvage et de la température, sous pression de vapeur atmosphérique, sur les propriétés mécaniques de la pâte de ciment. On a suivi en particulier les résistances à la compression, la porosité, et les pourcentages d'eau évaporable.

SUMMARY: The effects of curing time and temperature, under atmospheric steam conditions, on the mechanical properties of cement paste was studied. In particular, compressive strength, porosity and evaporable water contents were monitored.

## INTRODUCTION

Increasing energy cost and volume of concrete used in prefabricated structures, as well as the expanded use of accelerated methods of concrete curing, require a more thorough knowledge of the relationship between curing conditions and mechanical properties of elevated temperature-cured concrete. The following work summarizes preliminary data with portland cement pastes; this is to be followed by optimized mortar and concrete studies.

## EXPERIMENTAL

A cement of the following composition was used in the study: Portland Cement "400" (Bogue: 64.3%  $C_3S$ , 9.5%  $C_2S$ , 9%  $C_3A$ , 9.1%  $Fss$ ; 4%  $CaSO_4$  added as gypsum; Initial set: 3 hours, final set: 4 hours 10 minutes; Blaine surface area: 3000  $cm^2/g$ ). Cement pastes were prepared by mixing cement with water at w/c of 0.3, 0.4 and 0.5 for 3 minutes. Six 2-cm<sup>3</sup> cubes of each mix were molded by vibration for 15 seconds. Samples were subsequently cured at temperatures of 20°, 60°, 70°, 80° and 90°C under atmospheric steam conditions. The control samples (20°C, cured 24 hours in moist room, then in water) were tested after 1, 7 and 28 days. The steam-cured samples were preheated and cured according to the schedule of increasing and isothermal temperatures shown in Fig. 1. The curing temperature was monitored within the cement paste using Cu-constantan thermocouples. The samples were tested at the end of heat treatment, and also after 7 and 28 days of water curing at room temperature. The following properties were measured: density, compressive strength, porosity, and evaporable water at various temperature intervals by simultaneous thermal analysis (DTA/TGA).

Fig. 1 - Temperature profile of curing

## DISCUSSION OF RESULTS

Because of space restrictions, detailed experi-

mental data are not given; they can be found in ref. (1). In brief, the following results were obtained.

**Strength at the end of steam curing.** For up to 6 hours of heat-treatment, the compressive strengths at the time of demolding increased with increased curing temperature. At longer curing times (e.g., 8 and 10 hours), samples cured at 90°C showed a decrease in strength relative to those cured at 70°C and 80°. An example of this, for pastes made at a w/c of 0.4, is shown in Fig. 2. It has been also noted that the strengths obtained at 60°C, for all curing times, were substantially lower than those for the pastes cured at higher temperatures. As expected, the strengths at demolding were strongly influenced by the w/c used.

Fig. 2 - Compressive strength development as a function of curing time and temperature; w/c = 0.4

28-day strength. Irrespective of the initial duration of steam curing, the highest 28-day strengths were obtained for specimens cured at 80°C. However, for all of the temperatures studied, the highest 28-day strengths were obtained from those specimens cured for 5 hours.

For specimens cured for longer times the strengths generally decreased (Fig. 3). As was the case with strengths determined at the end of the heat treatment, the 28-day strengths also decreased with increasing w/c.

Fig. 3 - Relative 28-day compressive strength as a function of steam curing time and temperature; control sample (20°C) = 100%

**Porosity.** In agreement with published literature (2,3), a good correlation between the decrease in porosity and increase in compressive strength was found. This was very obvious for the strength-porosity relationship immediately following steam curing and demolding (Fig. 4); the correlation was not as good for samples tested after 28 days of curing because the total porosities, in contrast to strengths, were all very similar. Differences in the distribution of pores may explain the above finding. Understandably, samples prepared at lower w/c had at all times a lower porosity than those prepared at higher water contents. The higher the original w/c, the more rapid is the decrease in porosity.

**Evaporable water.** The total ignition loss as well as water released in four temperature intervals (20-100°C, 100-450°C, 450-600°C, and 600-1000°C) was measured by simultaneous thermal analysis to give an indication of the relative increase of water content in the main products of hydration. At the end of steam curing and at a given temperature, the amount of water bound in hydrates decomposing below 450°C (e.g., C-S-H, calcium sulfoaluminate hydrates) increased with the temperature of curing. During additional curing in water the amount of bound water

Fig. 4 - Strength at demolding vs. porosity for pastes hydrated at different temperatures

increased. This increase was found to be somewhat higher for samples cured at lower temperatures and for shorter times. It is assumed that evaporable water between 450-600°C represents water present in the form of calcium hydroxide. The amount of water released in this temperature interval was only slightly affected by the curing temperature, especially at longer hydration times.

From the vast amount of data obtained and briefly summarized above, it became obvious that more emphasis has to be given to better understanding of the porosity versus strength relationship; this is because it is the porosity of the paste that correlates better than any other variable to the strength. Better understanding of the changes in porosity and the distribution of pores with changes in rate and mode of hydration and in the type of hydration products will enable a more technically sound rationale for the design of concrete, via a direct application of generated knowledge to the concept of concrete maturity(4,5).

# Early Autogeneous Shrinkage of Cement Pastes

## *Retrait initial des pâtes de ciment*

S. ZIEGELDORF, Dr. rer. nat.

H.K. HILSDORF, Professor, Universität Karlsruhe, West Germany

**SUMMARY:** Results of measurements of early shrinkage of cement paste will be presented. The tests have been conducted in a new dilatometer which has a variety of advantages compared to older systems, the most important being its high accuracy and the possibility to begin recording 8 minutes after mixing.

In the study early shrinkage of cement pastes of different water-cement-ratios with and without admixtures has been studied. During the tests the samples either have been in a sealed condition or open i.e. absorption of additional water was possible during early shrinkage. For open storage the time development of the volume change of cement pastes is independent of the water/cement-ratio when presented as a fraction of the total cement content. Under sealed conditions the volume change as a fraction of cement content is independent of the water/cement-ratio up to the moment at which all the bleeding water has been absorbed by the sample. At this stage some expansion occurs which is followed by further shrinkage however at a slower rate.

It is shown that admixtures as well as the form and dimension of the specimens can have a strong effect on early shrinkage. A hypothesis is presented to explain some of the observed phenomena.

**RESUME :** Les résultats de mesures du retrait initial de pâtes de ciment sont présentés. Les essais ont été faits avec un nouveau dilatomètre, qui présente de multiples avantages sur les appareils existants; les plus importants sont sa grande précision, et la possibilité de commencer les mesures 8 minutes après le malaxage.

Ont été étudiés les retraits initiaux de pâtes de ciment à diverses teneurs en eau, et contenant divers additifs. Pendant ces essais, les éprouvettes sont placées dans des conditions prédéterminées de relations avec l'extérieur; par exemple, l'absorption d'eau complémentaire est possible. Pour une conservation immergée sans protection, la courbe des variations de volume en fonction du temps est indépendante de la teneur en eau initiale. Pour une conservation sous enrobage hermétique, cette courbe est indépendante de la teneur en eau initiale, jusqu'au moment où toute l'eau de ressuage a été absorbée par l'éprouvette. Ensuite, une certaine expansion se produit, suivie par un nouveau retrait, qui s'effectue à vitesse plus lente.

On a observé que les additifs, ainsi que la forme et les dimensions des éprouvettes, avaient une grande influence sur le retrait initial. Une théorie est proposée pour expliquer ces phénomènes.

## 1. Introduction

Most authors consider the chance of concrete cracking as a consequence of autogeneous early shrinkage of the cement paste to be almost negligible. More recently, however, some authors postulate such cracking to be of considerable significance (1). Chatterji (2) even proposed that crack formation due to autogeneous early shrinkage may occur in neat hardened cement paste.

One possibility to get a better insight into the mechanisms of crack formation in young concrete is the determination of the shrinkage behavior of the cement paste. However, though the number of publications dealing with this subject is large, there still remain many unsolved questions. Part of these questions are due to the fact that there are different methods to investigate the shrinkage and particularly the early shrinkage of cement paste, each method giving another aspect of the material behavior. The most widely used methods are described in the following, not considering shrinkage due to drying, carbonation or chemical attack.

## 2. Methods to Determine Shrinkage

Shrinkage experiments on cement paste can be subdivided into two categories: experiments on unsealed specimens, in which case the specimens are able to absorb water or experiments on sealed specimens, in which case the true autogeneous shrinkage is determined.

### a) Unsealed Specimens

In the simplest case a certain amount of fresh cement paste is put into a water-filled vessel with a capillary to indicate the volume changes of the paste (3). The shrinkage thus measured is due to the fact that the hydration products have a higher density than the initial products. The shrinkage thus measured is commonly called chemical shrinkage (in french: shrinkage "Le Chatelier").

### b) Sealed Specimens

A different approach is possible by using sealed instead of unsealed specimens. Experiments can be done in a volumetric as well as in a unidimensional dilatometer. Recently Detriché and Maso (5) and Buil and Baron (6) performed such measurements on cement pastes and mortar in a unidimensional dilatometer and observed a development of shrinkage as shown in Fig. 1. The development of shrinkage can be subdivided into 3 stages:

- I. first shrinkage
- II. expansion
- III. second shrinkage.

I. The first shrinkage develops before and during setting. Detriché and Maso (5) explain this shrinkage by energetic interactions between the solid, the liquid and the gaseous phases, specially referring to capillary forces, which develop when the surface water has evaporated. Buil and Baron (6) furtheron report that the first shrinkage begins between 2 and 3 hours after mixing. However, it is more probable that the first shrinkage is caused by the hydration reactions occurring during the time until setting. These reactions are for once not influenced by evaporation.

Fig. 1: Shrinkage of cement paste in a unidimensional dilatometer

Secondly they begin immediately after mixing, thus causing shrinkage immediately after mixing.

The first shrinkage could be expected to be identical to the so-called plastic shrinkage, i.e. shrinkage before setting. Such plastic shrinkage often had been observed to be the cause for crack formation within the first hours after placing a concrete mix. It must be reminded, however, that plastic shrinkage cracks normally are observed only when the concrete surface is dried by evaporation, thus leading to additional drying shrinkage.

II. The first shrinkage normally is followed by a period of expansion the reasons of which, however, are not yet very clear.

III. The second shrinkage develops in the course of hardening and therefore is often called hardening shrinkage. It may also be referred to as dessiccation shrinkage due to the fact, that this type of shrinkage can be explained by internal dessiccation (1,6). The reasons of this shrinkage predominantly are of physical nature, comparable to the deformations caused by drying shrinkage.

## 3. Comparison of Methods

Fig. 2 summarizes results from the literature

Fig. 2: Comparison of methods

on early shrinkage of cement paste for the three experimental methods described above. When comparing these data large differences can be observed. A close analysis, however, shows that the different methods should yield at least partially identical results.

The first point which has to be mentioned in this connection is shrinkage before setting. It should be identical for all three methods introduced here, at least as long as no internal pore formation occurs. Such pore formation is not to be expected in plastic cement paste or concrete, provided that the w/c-ratio is not extremely low.

Another point which has to be analysed more carefully is the role of the bleeding water in the shrinkage experiments. Buil and Baron (6) overcame the problem by using cement pastes with a very low and thus unrealistic w/c-ratio ( $w/c = 0,27$ ).

Setter and Roy (7) used a different approach: They removed the bleeding water of the sealed specimens 2 hours after mixing. This procedure, too, is problematic since the effective w/c-ratio of the paste is altered, and the removal of all bleeding water is difficult particularly in concretes, where part of the bleeding water is trapped below the aggregates.

When sealed cement paste specimens with bleeding water are examined in a volumetric dilatometer the observed shrinkage should be identical to the chemical shrinkage of unsealed specimens as long as bleeding water does exist. After imbibition of the bleeding water the shrinkage measured thereafter will be a pure bulk shrinkage which thus should be comparable to the bulk shrinkage as measured in the unidimensional dilatometer. Until now, however, experimental evidence does not support this hypothesis.

#### 4. Scope of Investigation

Considering the problems which are unsolved in the area of autogeneous shrinkage of cement paste, mortar and concrete, it was intended to design a dilatometer which should fulfill the following requirements:

- high accuracy, simple and easy to handle;
- volumetric in order to allow comparison of shrinkage of sealed and unsealed specimens;
- permission of the use of specimens with a volume of at least  $1000 \text{ cm}^3$ , such that the shrinkage of real concrete specimens can be determined;
- permission of the use of variable specimens, in order to make possible the evaluation of the influence of specimen size and specimen form on shrinkage;
- suitable for continuous registration of shrinkage and temperature.

In the following a dilatometer designed according to these requirements is described.

#### 5. Dilatometer

The dilatometer vessels used in this investigation consist of a  $3000 \text{ cm}^3$  glass vessel on which a top with openings for a thermometer, for the capillary and for two ventpins is

Fig. 3:  
Dilatometer

fixed by using an adaptor ring (Fig. 3). Six dilatometers are used at a time, such that comparative measurements are easily possible. The dilatometers are filled with deaired water. They operate in a room with a temperature of  $21 \pm 1^\circ\text{C}$ .

Unsealed as well as sealed specimens have been investigated. The unsealed specimens consist of 3 bowls placed on top of each other in order to obtain a sufficiently large total specimen volume of approx.  $600 \text{ cm}^3$  (Fig. 4a). The sealed specimens had various shapes (Fig. 4b). The fresh cement paste is placed in bags made of 0,4 mm-polyethylene sheets which are highly flexible, water-tight and transparent.

Fig. 4: Specimen forms

All materials and apparatus necessary for the experiments are stored in the same constant environment room. Thus the fresh cement paste has the same temperature as the dilatometer water. The latter is mixed with  $1 \text{ cm}^3$  of a detergent which reduces the amount of residual air in the dilatometer water. Remaining air is removed completely by shaking the filled dilatometer. All specimens are vibrated before installation into the dilatometer.

Because of the simple construction of the dilatometer the first results can be obtained about 8 minutes after mixing. Another advantage of the set-up is the possibility of continuous temperature registration which renders the dilatometer a type of calorimeter.

## 6. Accuracy

The temperature registration in the dilatometer is important because small variations of the dilatometer temperature lead to a large amount of fictitious shrinkage. The influence of the variation of the temperature of each dilatometer was taken into account in the calculation of the shrinkage values. Further on fluctuations of the room temperature were considered by comparing the temperature of each dilatometer with the temperature of a reference dilatometer without specimen. Thus the temperature variation due to heat development caused by hydration could be distinguished from temperature variations caused by fluctuations of the room temperature.

The first results in our experiments were obtained in the time interval of 8 to 30 minutes after mixing depending on the time necessary for mixing and vibrating. Naturally, the later recording begins after mixing the larger is the portion of first shrinkage which is not recorded. However it had been observed that all shrinkage curves initially show a linear increase with  $\log t$  with a slope independent of the w/c-ratio, when the shrinkage is related to the cement content of the specimen, i.e. when  $\Delta V/100$  g cement is plotted as a function of  $\log t$ . This relationship was used to correct all shrinkage curves in such a way that shrinkage was considered zero at a time of 10 minutes after mixing. Because of this procedure the scatter of experimental data obtained was small and because of

- identical temperature of all materials and apparatus before mixing;
- no restraint of shrinkage of sealed specimens;
- relatively large specimens;
- no movable parts of the dilatometer.

## 7. Results and Discussion

### 7.1 Unsealed Specimens

In Fig. 5 the development of shrinkage and temperature of unsealed portland cement specimens (German specification PZ 35F) with two different w/c-ratios of 0,4 and 0,6 resp. is shown. This result confirms earlier results e.g. from Czermin (3). It is evident that the shrinkage is independent of the w/c-ratio. This, however, holds true only as long as permeability of the hardened paste allows the imbibition of water at a sufficient high rate. In the diagram three regions of the shrinkage-time relationship can be distinguished:

- Stage I, which is characterized by a small rate of shrinkage (dormant period) and by a linear dependence of shrinkage on  $\log t$ ;
- Stage II, which shows a linear increase with  $\log t$  with a steeper slope;
- Stage III, which is characterized by decreasing rate of shrinkage indicating nearly complete hydration.

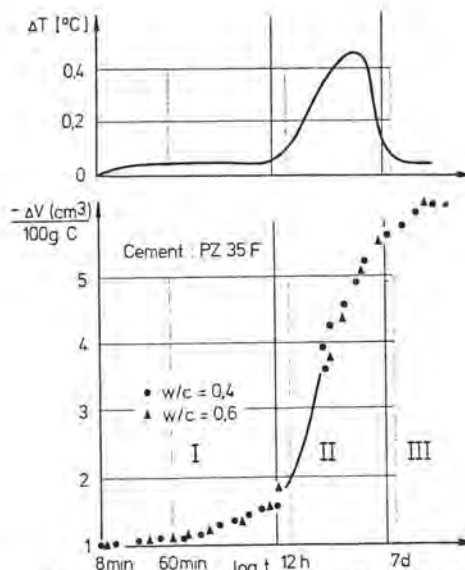

Fig. 5: Shrinkage of unsealed cement paste specimens

The temperature of the dilatometer increases slightly shortly after mixing but remains constant during the dormant period. Following the dormant period the temperature increases rapidly and decreases again after having reached its maximum after about 12 hours.

### 7.2 Sealed Specimens

In Fig. 6 the shrinkage behavior of sealed specimens is demonstrated. The following characteristics are to be observed:

Fig. 6: Shrinkage of sealed cement paste specimens

- plastic shrinkage (shrinkage during the dormant period) of sealed specimens is identical to shrinkage of unsealed specimens and independent of the w/c-ratio;
- the shrinkage curve of sealed specimens coincides with the shrinkage curve of unsealed

- specimens for a period which is the longer the higher the w/c-ratio. By visual observation of the specimens it was verified that during this period bleeding water could be detected on top of the specimens;
- when the bleeding water was absorbed by the specimens, a period of expansion occurred, which was followed by further shrinkage, however at a slower rate;
  - the final value of shrinkage increased with increasing w/c-ratio;
  - the temperature curve shows the same characteristics as in the experiments on unsealed specimens (Fig. 5).

Further on it is to be noted that the time at which the temperature maximum occurs is independent of the w/c-ratio.

Thus these experiments demonstrate the close correlation between bleeding water and shrinkage of sealed specimens. As specimens with a high water-cement-ratio show strong bleeding their final shrinkage value is high. For w/c-ratios  $> 0,55$  no difference in the shrinkage behavior of sealed and unsealed specimens could be detected within the first 28 days. The results of these experiments do not confirm the statement by Buil and Baron (6) that the expansion period normally is not observed in a volumetric experiment.

Another point can be analysed more clearly on the basis of these results. When performing volumetric shrinkage experiments on sealed cement paste specimens Haas et. al. (8) observed higher shrinkage values (shrinkage given in percent of cement paste volume) for lower w/c-ratios up to about 10 hours. After this time an inverse tendency was observed. Haas et. al. as well as Setter and Roy (7) explained this effect by shrinkage caused by ettringite crystals. This explanation seems, however, improbable, as the results of this investigation demonstrate the independence of initial shrinkage on w/c-ratio when shrinkage is related to the cement content of the paste. From this result it follows that shrinkage values which are related to the volume of the cement paste must initially be the higher the lower the w/c-ratio.

### 7.3 Effect of Type of Specimens

In Fig. 7 it is shown that shape and dimensions of the specimens can have a strong influence on the shrinkage of sealed cement paste specimens. In this experiment three different types of specimen made of identical cement pastes have been studied. Type A specimen has a cylindrical form with diameter of 60 mm and a volume of about 600 cm<sup>3</sup>. Type B and C specimens only had a volume of 300 cm<sup>3</sup>. Both specimens consisted of 8 parallel cylinders (see Fig. 6) each with a diameter of 15 mm. As shown in Fig. 7 the cylinders are in a vertical position for the type B specimen and in a horizontal position for the type C specimen.

Obviously the different specimen forms lead to different shrinkage characteristics of the cement paste. The different behavior can be

Fig. 7: Effect of specimen form

explained by differences in the amount of bleeding water. It was observed that bleeding was strongest in the type A specimen and weakest in the type C specimen. The high amount of bleeding water in the type A specimen then led to a high final shrinkage value corresponding to the results of Fig. 6, in which the influence of w/c-ratio on shrinkage of sealed specimens had been demonstrated.

### 7.4 Effect of Admixtures

In a few pilot experiments the effect of admixtures on the shrinkage characteristics of cement paste has been investigated. Three types of admixtures were used:

- UCR 1/10, a mixture of 10 Vol.-% high polymer resin and 90 Vol.-% ligninsulphonate;
- UCR 100, the pure high polymer resin, which is used as a plasticiser;
- polyvinylpropionate.

As shown in Fig. 8 these admixtures had only a slight influence on the shrinkage of the unsealed specimens.

Fig. 8: Effect of admixtures (unsealed sp.)

Fig. 9, on the other hand, shows the result of an experiment on sealed specimens with three different UCR 1/10 concentrations using cement paste with a w/c-ratio of 0,5. In this case, the addition of 0,5% UCR 1/10 slightly

Fig. 9: Effect of admixtures (sealed sp.)

increased the final shrinkage value whereas final shrinkage had been decreased significantly by the addition of larger amounts of admixtures.

The fact that shrinkage of the unsealed specimens with and without admixtures was equal indicates that the admixtures had only a negligible effect (in comparison to the accuracy of the measurement) on the hydration of the different pastes. The shrinkage characteristics of the sealed specimens can be explained - as has been done previously - by different amounts of bleeding water: The addition of 0.5% UCR 1/10 led to a strong reduction of the amount of bleeding water thus decreasing final shrinkage.

#### 8. Outlook

Until now all experiments had been performed by recording each individual data point. Experiments are, however, under way, which will allow continuous reading of shrinkage and temperature. In the final experimental set-up the height of the water in the capillary is recorded by a pressure transducer. Thermocouples determine the temperature in the dilatometer water and in the specimens. The signals of the pressure transducer and thermocouples are processed and recorded by a data recorder. After the experiment the records are connected to a computer which in combination with a plotter will then deliver the final shrinkage plots.

The investigation is being continued. In addition to studies on mechanisms of autogenous shrinkage and of parameters influencing it, the effect of shrinkage on mechanical properties of concrete is being studied.

## THEME VII

### Réaction aux interfaces entre ciment et granulat dans les bétons et mortiers

#### *Interface reactions between cement and aggregate in concrete and mortar*

---

### Etude de l'effet produit sur la déformation des bétons par les alcalis au cours de leur interaction avec la silice dans les agrégats

#### *Investigation of cement alkalis influence on concrete deformations at interaction of the alkalis and silica in aggregates*

G. ROYAK, TsNIIS, Moscou, U.R.S.S.

On a étudié l'influence qu'exercent sur la déformation du béton la teneur du ciment en alcalis, la quantité d'opale dans l'agrégat, la taille de ses grains, le facteur eau-ciment et l'activité de l'addition minérale présent dans la composition du ciment. On a déterminé les déformations qui se produisent dans le béton en fonction du nombre et du type d'adjuvants minéraux actifs d'origine volcanique et sédimentaire additionnés au ciment.

On a examiné le mécanisme d'interaction entre la phase liquide du ciment et la silice.

On a formulé des propositions concernant la composition minéralogique des ciments et leur teneur en alcalis lors queles agrégats contiennent de la silice active.

Influence on concrete deformations of alkalis quantity in cement, opal in aggregate, size of its grains, W/C factor, activity of mineral addition containing in cement composition has been investigated.

Concrete deformations have been determined as a function of quantity and type of sedimentary and volcanic active mineral additions containing in cement.

The mechanism of interaction of cement liquid phase, with active silica has been considered. Suggestions are made about cement substantial composition and relating to the alkalis contents in the cement with active silica in aggregates.

Dans leur rapport détaillé au 4<sup>ième</sup> symposium international sur la chimie du ciment qui s'est tenu à Washington en 1960, P.Bredsdorf, G.M. Idorn et coll. (1) ont exposé les différents aspects des réactions chimiques avec les agrégats. Ils ont noté que le type et la structure des minéraux réactifs et le comportement des grains d'agrégats de grande dimension devaient être considérés comme objets d'importance primordiale dans les études de base ultérieures. Il est connu que la réaction avec la silice dans les agrégats commence sur la surface des grains et embrasse les couches plus profondes grâce à la rupture des liaisons Si-O-Si. S.A.Greenberg et D.Sinclair (2) ont abouti à la conclusion que les liaisons siloxane formées par la polymérisation de l'acide monosilicique sont détruites dans l'eau et cette réaction est réversible. Déjà en 1933 B.N.Dolgov (3) a indiqué la possibilité de formation de la liaison siloxane et du polymère à partir de composés organiques oxygénés de silicium avec le dégagement de l'eau :

$$\equiv\text{Si}-\text{O}-\boxed{\text{H} + \text{OH}}-\text{Si}\equiv \rightarrow \equiv\text{Si}-\text{O}-\text{Si}\equiv + \text{H}_2\text{O}$$

Les échantillons de silice naturelle contenus dans les agrégats surtout sous forme de phases amorphes et microcristallines d'origine sédimentaire possèdent la surface intérieure développée accessible à la pénétration de la phase liquide et à la réalisation rapide des réactions chimiques. La silice formée dans les conditions naturelles sous forme de verre peut aussi contenir des additions d'eau et être caractérisée par la

structure défectueuse et l'activité chimique élevée. Des idées analogues peuvent être généralisées aux pouzzolanes utilisées dans la composition des ciments et absorbant activement l'hydroxyde de calcium formé au cours du durcissement. Pour des grains macroscopiques de silice la part d'ions superficiels est trop petite pour que l'hydratation puisse influencer sur la composition moyenne d'une particule. La surface des particules colloïdales de silice est tellement grande que l'hydratation est mesurable et on peut parler de la silice hydratée. Le fait connu de diminution de l'expansion si les pouzzolanes entrent dans la composition du ciment, ne trouve pas d'explication assez claire bien qu'on liait la diminution de l'expansion avec la propriété traditionnelle des pouzzolanes d'interagir activement avec l'hydroxyde de calcium (1). I.Powers et N.N.Steinour ont supposé quela réaction des alcalis avec la silice se déroule "sans aucun danger", i.e. ne provoque pas d'expansion, lorsque  $\text{Ca}(\text{OH})_2$  arrive dans la zone de réaction assez vite pour pouvoir interagir avec la moitié de la quantité de la silice dissoute dans NaOH. Or ceci n'est possible que lorsque la concentration de  $\text{Ca}(\text{OH})_2$  sur la surface extérieure de la couche des produits de la réaction est assez élevée durant tout le temps. On pouvait supposer que le grain isolé de la silice, par exemple de l'opale, ne deviendrait pas plus grand quant à la dimension ou gonflerait de façon limitée lors de l'interaction avec la solution de NaOH et de  $\text{Ca}(\text{OH})_2$  car les con-

ditions indiquées ci dessus sont observées dans ce cas. La figure 1 montre la variation de la valeur de la solubilité de l'opale dans les solutions de NaOH si ces dernières contiennent un excès de  $\text{Ca}(\text{OH})_2$ . La figure 2 montre l'augmentation de la dimension des

Fig. 1. Variation de la concentration de  $\text{SiO}_2$  soluble en fonction de la concentration de l'alcali et de la teneur en  $\text{Ca}(\text{OH})_2$  de la phase solide: 1 - en solution de NaOH; 2 - en solution de NaOH avec  $\text{Ca}(\text{OH})_2$  solide

grains isolés dans le temps, i.e. leur gonflement, dans différents milieux. Notons le caractère adéquat de l'augmentation de la dimension des grains dans le temps lorsqu'ils se trouvent dans la solution saturée de  $\text{Ca}(\text{OH})_2$ , dans la solution de  $\text{NaOH} + \text{Ca}(\text{OH})_2$  et dans la matrice du ciment durci ou lorsqu'ils se trouvent dans l'eau ou la solution aqueuse de NaOH. Ainsi la diminution de l'expansion lors de l'introduction dans la composition du ciment de la pouzzolane doit évidemment être liée non à la formation du gel "expansif ou non expansif" mais aux conditions telles que l'arrivée des ions  $\text{Ca}^{2+}$  vers les gros grains soit essentiellement détournée. Dans les gros grains il y a une réserve de la silice réactive pour la réalisation d'une réaction chimique prolongée et du gonflement. On détourne l'arrivée des ions  $\text{Ca}^{2+}$  vers ces

grains par introduction dans la composition du ciment d'une quantité déterminée de la pouzzolane active à grains fins (surface spécifique  $\sim 10\,000\text{ cm}^2/\text{g}$ ) dont les particules entreront rapidement en réactions chimiques avec  $\text{Ca}^{2+}$  et la dépolymérisation

Fig. 2. Expansion des grains isolés de l'opale dans les milieux suivants: 1 - solution saturée de  $\text{Ca}(\text{OH})_2$ , avec la teneur de CaO de 1,3 g/l; 2 - matrice du ciment durci; 3 - solution de NaOH, 1 N; 4 - eau; 5 - 1 N solution de NaOH +  $\text{Ca}(\text{OH})_2$

ultérieure de la silice par les ions  $\text{OH}^-$ ,  $\text{Na}^+$  et  $\text{K}^+$  conduira à l'expansion initiale limitée des grains suivie d'une dissolution sans aucun indice d'expansion. Dans le Tableau I on trouve les données sur la diminution des déformations d'expansion des ciments avec les pouzzolanes d'origine sédimentaire et volcanique. On voit sur la figure 3 les isolignes des déformations d'expansion pour les pouzzolanes qui se distinguent par le type et la structure de la silice active caractérisés d'après l'absorption de l'hydroxyde de calcium recalculée pour CaO. La figure 3 montre qu'avec l'augmentation de l'activité de la pouzzolane on peut admettre l'accroissement de la teneur des ciments en alcalis sans aucun risque de voir apparaître dans le béton des déformations critiques. Le traitement statistique des données de l'U.S.A. et de

# La formation de la zone de contact à la limite avec un agrégat poreux

## *Formation of contact zone on the border with porous aggregate*

L. KOURASSOVA, Collab. Sc. Supér., NIIZhB, Moscou  
Z. LARIONOVA, chef de Laboratoire. U.R.S.S.

Les facteurs importants exerçant une influence sur la résistance de la zone de contact dans le béton léger sont: l'activité hydraulique de l'agrégat poreux amenant aux formations nouvelles et l'aspiration par cet agrégat de la phase liquide du ciment durci. En fonction de la grandeur des grains de l'agrégat poreux ces propriétés se manifestent d'une manière différente. Par un complexe des méthodes physico-chimiques est étudiée la zone de contact avec les grains de kéramsite (de 5 mm à 20 mm) dans les échantillons des mortiers. Est constaté l'accroissement de microdureté du ciment durci sur le contact avec les grains (avec d 2 mm) ce qui s'explique par la formation de la couche consolidée résultant de l'interaction chimique intensive entre les grains de grandeur donnée et les composants du ciment durci. A mesure que les grains deviennent de plus en plus grande, la microdureté du ciment durci sur le contact décroît, le rôle de l'interaction chimique abaisse et augmente l'influence de l'aspiration qui abaisse la résistance de la structure. Pourtant l'aspiration de la phase liquide exerce une influence favorable sur la structure de la zone de contact, si elle a lieu avant le début de la vibration du béton frais.

Important factors affecting the strength of the contact zone in lightweight concrete are hydraulic activity of the porous aggregate leading to new formations and extraction by it the liquid phase from the cement stone. Depending on fineness of the porous aggregate particles, these peculiarities reveal themselves in various ways.

Using a several of physico-chemical methods, studies have been made of the contact zone with keramsite particles (d ranging from 5 mm to 20 mm) in mortar specimens.

Microhardness of the cement stone contacting with particles (d 1,2 mm) increases due to intensive chemical interaction between the particles of this size and the cement stone components.

As the particle size grows, the cement stone microhardness in the contact zone is lessened, the role of the chemical interaction being decreased, while the effect of extraction (that reduces the strength of structure) is stepped up. But extraction of the liquid phase has a favourable effect on the contact zone structure if it takes place before the vibration of the concrete mix.

Les propriétés physico-mécaniques du béton sont considérablement influencées par l'état de la zone de contact, c'est-à-dire par sa structure, sa composition de phase et sa résistance. La zone de contact c'est le microvolume du béton, limité conventionnellement par les deux surfaces qui passent dans le ciment durci et dans le grain d'agrégat à une telle distance de la surface de contact qu'il n'y a pas d'influence des phases contigües.

L'état de la zone de contact dépend de propriétés physico-chimiques d'agrégat ainsi que de processus au contact résultant de l'interaction de l'agrégat avec le ciment durci. Les facteurs importants déterminant la résistance de la zone de contact dans le béton léger sont: l'activité hydraulique de l'agrégat poreux amenant aux formations nouvelles et l'aspiration par cet agrégat de la phase liquide du ciment durci. Nous avons mis en évidence que ces propriétés se manifestent différemment en fonction de grandeur des grains de l'agrégat poreux. Par un complexe des méthodes est étudié la zone de contact avec les grains de l'agrégat poreux - kéramsite (d étant égal à 5 mkm - 20 mm). L'étude des couches de contact du ciment durci à la limite avec les grains du kéramsite non-concassé ayant les dimensions différentes a été réalisée sur les trois séries d'éprouvettes qui se distinguaient par les dimensions des fractions étudiées: 0,15 mm; 0,15-5 mm et 5-20 mm. Pour la détermination de la microrésistance de la zone de contact a été utilisée la méthode des mesures de microrésistance à l'aide d'un microscope dans une lumière réfléchie. Cette méthode est basée sur l'enfoncement statique de la charge dans un volume microscopiquement petit du matériau. La microdureté (H) des couches de contact du ciment durci (diagnostiquées visuellement à l'aide d'un microscope lumineux d'après la peinture de rouille brune) immédiatement à la limite avec les grains de 3-7 mkm était égale à 3000-4700 MPa. A mesure de l'éloignement de la limite la microdureté diminuait et à la distance de 10-20 mkm elle était égale à des valeurs correspondant à H de la masse hydratée du ciment durci en volume (600-700 MPa). Donc, autour les particules dont les dimensions sont égales à 3-7 mkm se forment les microvolumes du ciment durci renforcé; les diamètres de ces volumes sont 7-15 fois

plus grands que les dimensions des particules.

L'augmentation de microdureté dans les couches de contact autour les grains de fraction de 0,15-5 mm de sable non-concassé du kéramsite n'était observé qu'à la limite avec les particules de 1,2 mm (Fig.1). A mesure de l'accroissement des dimensions des particules la microdureté diminue à partir de 2200 MPa (pour 0,15 mm) jusqu'aux 900 MPa (pour 1,2 mm), et la largeur de la couche renforcée diminue à partir de 20-25 mkm jusqu'aux 10-15 mkm; c'est-à-dire jusqu'aux 0,01-0,15 du diamètre de la particule. Au contact avec les grains de 2,5-5 mm la microdureté est égal à 650-750 MPa; cette valeur n'excède pratiquement pas de microdureté du ciment durci (400-750 MPa).

Nous considérons que l'aspiration de l'eau du ciment durci par l'agrégat influence favorablement sur la formation de la structure du béton frais seulement jusqu'au moment de son compactage définitif. L'aspiration ultérieure de l'eau porise le mortier et le béton devient d'une résistance moindre. Ce fait a été confirmé par des essais spéciaux, par lesquels on a déterminé l'influence de compactage (vibration) sur la microstructure et la microdureté du ciment durci, contigu à l'agrégat poreux.

Les résultats obtenus correspondent avec nos hypothèses que si la quantité essentielle de l'eau est aspirée par l'agrégat avant le compactage du béton frais (c'est-à-dire la vibration est réalisée 15-20 minutes après la préparation du béton frais) alors l'aspiration de l'eau joue un rôle positif. Dans ce cas-là la formation du béton frais a lieu justement dans la période où sont déjà terminés l'aspiration de l'eau d'agrégat et l'abaissement de E/C et le compactage du ciment durci liés avec l'aspiration de l'eau. L'aspiration ultérieure de l'eau du ciment durci diminue ou n'existe pas de quoi résulte le fait que la porisation de la couche de contact n'a pas lieu. Dans les conditions données, les propriétés de microrésistance du ciment durci au contact sont conditionnées, principalement, par la composition et par la microstructure des nouvelles formations. Si le compactage du béton frais est réalisé immédiatement après sa préparation, alors l'aspiration ultérieure de la quantité essentielle de l'eau, qui dure encore 15-25 minute, amène à la porisation de la

Fig.1. La surface de clivage du ciment durci sans particules (a) et avec les particules des la zone extérieure du kéramsite (b) SEM

couche de contact du ciment durci et à diminution de sa résistance.

Par ces mêmes processus s'explique aussi un tel phénomène que dans les éprouvettes essayés, au contact avec les grains finement dispersés du kéramsite dont l'aspiration de l'eau se réalise pratiquement instantanément, est observé le dépassement de microdureté du ciment durci en fois et plus. Avec l'augmentation des dimensions de la fraction du sable quand l'aspiration de l'eau se réalise pendant une période plus longue l'augmentation de microdureté de la couche de contact en comparaison avec le ciment durci en volume ne constitue que 20-25%. Donc, l'augmentation de microrésistance du ciment durci au contact avec un agrégat poreux (particulièrement avec les grains de 1,2 mm) est conditionné par la formation résultant de l'interaction chimique de la zone transitoire renforcée dont la largeur est égale à 10-20 mkm et qui est constituée des nouvelles formations et des particules submicroscopiques d'agrégat, ainsi que de micro-couches ointes d'une résistance élevée qui se forment autour de ces particules. L'abaissement de microdureté, observée au contact, n'est déterminé que par l'accroissement de la porosité du ciment durci qui résulte de

l'aspiration de l'eau par l'agrégat continuée après le compactage du béton frais.

En se basant sur les résultats obtenus nous sommes amené à la conclusion suivante: à la limite du ciment durci et du kéramsite ont parallèlement lieu les deux processus qui influencent sur la formation de la zone de contact. Ce sont les processus suivants:

1. L'apparition d'un nombre considérable des phases nouvelles (qui résulte de l'interaction chimique du kéramsite avec le ciment durci) amenant à la formation de la structure cristalline plus compacte et à l'accroissement de microrésistance de la couche de contact.
2. L'augmentation de la porosité du ciment durci résultant de l'aspiration de l'eau par l'agrégat continue après le compactage du béton frais; cette aspiration de l'eau contribue à l'abaissement de microrésistance de la couche de contact. La résistance finale de la couche de contact est conditionnée par des processus qui ont lieu à cette étape de la formation de la structure du béton léger frais.

# Investigation of contact zone in cement stone hydrate phases single-crystal concretions and their concretions with aggregates

## *Etude de la zone de contact dans les agrégats de monocristaux des phases hydratées du ciment durci et dans leurs agrégats avec les matériaux de remplissage*

V.V. TIMACHEV,  
Y.I. BENSTEIN,  
L.V. BALKEVITCH,  
N.S. NIKONOVA, MkhTI Mendeleev, Niitsement, U.R.S.S.

On a étudié les agrégats de cristaux des phases hydratées du ciment durci entre eux et les processus de leur cristallisation sur la surface du quartz et de la calcite.

Les agrégats furent étudiés à l'aide de l'analyse structurale aux rayons X d'après la méthode de Laue, de la microscopie optique et électronique.

On a étudié les régularités et déterminé les faces et les angles préférentiels d'agrégation des cristaux de quartz et de calcite. On a découvert l'agrégation épitaxiale des cristaux indiqués d'après le schéma de Royé.

On a étudié la zone de contact dans les systèmes réels durcissants où sur la surface des agrégats on a découvert les couches orientées des cristaux de la calcite. On a dégagé trois secteurs principaux de la zone de contact. On a montré que par les méthodes de l'action chimique, mécanique et combinée sur les constituants du mortier composé de ciment et de sable on peut commander les processus de formation de structure des cristaux ayant lieu lors du durcissement des liants.

Concretions of cement stone hydrate phases crystals one with another and process of their crystallization on the surface of quartz and calcite have been investigated. The concretions have been studied through the use of X-ray diffraction analysis by Laue method, and optical and electronic microscopy.

Mechanism of concretion has been studied and preferred facets and angles of concretion of hydrate phases crystals one with another and with crystals of quartz and calcite have been determined. Epitaxial concretion of mentioned crystals according to Roier have been revealed;

Contact zone in real solidifying systems has been studied. Oriented layers of calcite crystals have been found on the aggregates surface in the contact zone. Three main regions of contact zone have been distinguished. It was demonstrated that one can control the processes of binder crystallization by the methods of chemical, mechanical and combined influence on the components of cement sand solution.

A comprehensive study of concretion of calcium hydrosilicate and portlandite crystals with each other was carried out together with investigation of GHS crystallization from saturated solutions of various stoichiometric composition on quartz and calcite surfaces.

Various methods of crystal growth from aqueous solution and methods of hydrothermal crystallization were used. Concretions of quartz and calcite with large (1-5 mm)  $\text{Ca}(\text{OH})_2$  crystals were obtained by the method of diffusion of saturated  $\text{CaCl}_2$  and  $\text{KOH}$

solutions in water, placing in the reaction zone plates cut out of quartz and calcite single crystals along different crystallographic directions. Accretion of hydrate phase crystals on substrates was carried out by Belyustin's method. Specific features of concretion and of the contact zone structure were studied by Laue X-ray structure analysis, local X-ray spectral analysis, electron microdiffraction and electron microscopy.

#### Contact Zone in Concretions of Hydrate Phase Crystals

Crystals of  $\text{Ca}(\text{OH})_2$  most frequently intergrow along faces of hexagonal and dihexagonal prisms and basis, and twinning planes are faces of ditrigonal scalenohedron and hexagonal dipyrmaid. Angles between triad axes in concretions change abruptly and are multiple of  $15-16^\circ$ . Most of the Laue patterns obtained from the contact zone of concretions show the presence of additional reflections indicating considerable distortion of the crystal lattice and the existence of disoriented microcrystalline blocks in the Contact zone.

Among the synthesized concretions of calcium hydrosilicates (Table 1) ideal laue patterns are observed in concretions of crystals obeying Royer's structure-geometrical principle. Such are practically all cross-shaped concretions (manebach and pericline types) of crystals  $\text{C}_6\text{S}_7\text{H}$ ,  $\text{CaNaHSiO}_4$  and of microtwins of calcium chondrodite  $\text{C}_5\text{S}_2\text{H}$ .

Well-shaped Laue patterns are also displayed by penetration concretions of crystals  $\text{Na}_2\text{Ca}_3\text{Si}_2\text{O}_{10}$ . The strength of contact zone in such concretions is close to the strength of intergrown crystals (Table 2).

The obtained experimental data indicate that a strong crystalline contact in a concretion is formed in the case of apitaxial intergrowth along the general directions of anionic and cationic bonds in accordance with the principle of structure-geometrical conformity of conjugating lattices along the planes and directions of most dense packing.

Regular concretions of hydrate new formations in the hardening system are formed not as a result of intergrowth of already formed crystals, but in the process of nucleus formation - growth of nuclei from one point or one face. Strength of the contact zone characterized by microhardness in most cases is higher than the strength of the crystals forming concretions, thus pointing to a high degree of ordering in the contact zone structure (Table 2).

#### Contact Zone in Crystal Concretions of Hydrate Phases with Quartz and Calcite

Concretions were prepared by keeping quartz and calcite plates in saturated solutions of the appropriate phases for 6 months and by the diffusion method.

On all substrates, independent of solution composition, spherical particles and their aggregates are observed (Fig. 1). They do not give reflections in electron microdiffraction experiments, that suggests amorphous nature. These particles are the primary form of crystallization of hydrate new formations. Coalescence of particles and thus formation of larger aggregates is observed, indicating weak bonding with the substrate and capacity to migrate along its surface. The particles accumulate on macrodefects of the surface, steps of the cleavage surface, cracks, etc., however frequently their locations are not connected with surface topography. In this case microdefects of crystal-substrate surface play an important role. In addition to these formations crystalline particles of various morphology are observed on substrates.

Superposition of diffraction patterns of crystals comprising the concretion are observed in laue patterns of the concretion zone of portlandite with quartz and calcite. On several patterns of the concretion zone spreading and bifurcation of reflections is observed indicating the presence of stresses

Table 2

Microhardness of Contact Zone and of Hydrosilicates		Crystals of Portlandite and Calcium (data of )		
Phase	Microhardness of crystals	Microhardness of contact zone		
		structure	penetration structure	integrowth structure
Portlandite High-basic calcium hydrosilicates	49.5-258.0	140.0	290.0	84-420
	91-801	850.0	460.0	380.0

in the lattices which in its turn points to intergrowth of crystals and not simple mechanical cohesion. Many photographs also show additional reflections which are weaker and randomly distributed, indicating the presence of small disoriented single crystals in the contact zone. This suggests that at the early stages of crystallization variously oriented nuclei are formed, the growth of which is hindered by rapid growth of crystals with more favourable orientations.

Examination of the contact zone of concretions of portlandite with quartz using a scanning electron microscope confirm this suggestion. A smaller crystal grown to the substrate by the hexagonal prism face and

scaly formations, possible thin platelets of portlandite grown to the substrate by the basis face, were observed in the contact zone.

Analysis of stereographic projections constructed from laue patterns of portlandite concretions with quartz and calcite showed that intergrowth mainly occurs along faces of hexagonal prisms with angles between triad axes of portlandite and calcite crystals of  $21$  and  $42^\circ$  (Fig. 2) and between triad axes of portlandite and quartz crystals of  $0$ ,  $38$ ,  $48$  and  $90^\circ$  (Figs. 2 and 3).

A transition zone between intergrown crystals with smooth variation of Si and Ca concentrations was established by local X-ry spectral analysis in concretions of

Fig. 1. Spherical particles on the surface of aggregate

quartz with portlandite. The width of this zone is 35-50  $\mu\text{m}$ .

Crystallochemical analysis of quartz, calcite and portlandite structures points to intergrowth according to Royer's scheme along planar grids with equal or multiple parameters.

The conformity of lattice parameters may serve as a criterion of regular intergrowth of quartz with CHS crystals. In calcium hydrosilicates with rhombic or pseudohexagonal cells the parameters "a" and "b" are multiple to parameters "c" and "a" of the quartz cell which determines the possibility of formation of a regular concretion for conjugation of plane (001) of CHS with the hexagonal prism plane of quartz (Fig.4). Coincidence is also observed for conjugation of plane (001) of CHS and quartz basis (001) when the direction of (010) CHS is parallel to direction 1010 quartz. Intergrowth of CHS with the plane of hexagonal prism of quartz is observed more frequently since it possesses a larger reticular plane than the basis plane.

Fig. 2. Schemes of growing together portlandite and calcite. Thick lines - grating of portlandite, thin lines - grating of calcite

Of interest is crystallization of  $\text{C}_2\text{SH}_2$  on the calcite surface. New formations decorate slip bands on calcite faces according to a specific regularity (Fig.5). With growth of CHS on calcite conjugation of planes (001) of CHS and (100) of calcite is observed when 100 and [010] of CHS and [110] and [100] of calcite are parallel (Fig.6).

The obtained data allow to suggest the following process of contact zone formation. Nuclei of new phase are formed on the substrate in random orientation. In the case of conformity with the structure-geometric principle of Royer and for the appropriate orientation acquired due to migration along the surface, the growing crystals form a concretion with the substrate. Crystals with more favourable orientation for growth (e.g., portlandite crystals with the face of hexagonal prism oriented parallel to the substrate plane) grow more intensively, suppressing growth of nuclei with less favourable orientation. As a result, at the contact of two intergrown crystals a transition zone is formed which includes randomly

## Contact Zone in Real Hardening Systems

Intergrowth contacts were studied on mortar specimens (rods 1x1x3 cm) of composition 1:3, W/C=0.5·C<sub>3</sub>S, C<sub>2</sub>A and Portland cement were used as binders. Natural single crystals of quartz and calcite ground to 1 mm, in order to exclude the effect of granulometric composition, were used

The strength of specimens with calcite aggregate was 25-50% higher than for the quartz aggregate. In the case of C<sub>7</sub>A and cement this may be explained by formation calcium hydrocarboaluminates in the contact zone, whereas in the case of C<sub>3</sub>S increase of strength may be caused only by a larger amount of concretions between hydrate new formations and calcite than in the case of quartz.

Electron microscopic study established on the surface of aggregates in hardening paste of  $C_3S$  and Portland cement well crystallized rhombohedra of calcite which is the product of carbonization of calcium hydroxide formed during hydrolysis of  $C_3S$  (Fig. 7). The ordered arrangement of calcite crystals on surface of aggregates is clearly revealed in the patterns. Calcite rhombohedra grow onto the surface by the face (001), ribs [100] and [010] being parallel. Crystals frequently intergrow along faces (100) and (004) covering large surface areas with a continuous layer. The regular shape of the calcite crystals and their ordered arrangement on the aggregate surface indicate that their crystallization occurs at small supersaturation, presumably at late stages of hardening. Oriented calcite layers on the aggregate surface condense and strengthen the contact layers of the binder, favourably affecting the strength of the

Fig. 5. Decoration pictures on calcite surface

mortar.

Hence, in real hardening systems the contact zone is complex both in phase composition and in structure. Three main sections may be distinguished: a) sections where cohesion of the cement stone with the aggregate is purely mechanical; b) sections where the contact zone is formed by chemical interaction; c) sections where epitaxial intergrowth of crystals of hydrate new formations with crystals of aggregate occurs. All these processes may proceed simultaneously and consecutively. The different strength of cohesion of cement stone with various sections of aggregate surface is thus explained by different mechanisms of contact zone formation.

The strength may be enhanced by creating conditions for active intergrowth of crystal hydrates with each other and with aggregate crystals, i.e. by increasing the number of active centers of crystallization and influencing the surface properties. This may

Fig. 6. Schemes of growing together hydrated phases and calcite. Thick lines - grating of hydrated phases, thin lines - grating of calcite

be realized, for example, by chemical action (etching) on the crystal-substrate or by creating fresh cleavage surfaces by mechanical action. Etching removes the surface layer containing impurities which block the active centers on the surface. Moreover, etching of a polycrystalline specimen reveals crystallographic planes of single crystals most favorable for accretion of crystals of hydrate new formation (e.g., faces of hexagonal prisms of quartz crystals in a polycrystalline sample).

# Corrosion des ciments Portland par les gaz contenant du sulfure d'hydrogène

## *Portland cement hydrosulfide gas corrosion*

V.S. DANUCHEVSKI,  
A.P. TARNAVSKI, MinKh et GP Goubkine, U.R.S.S.

Dans les différentes constructions les matériaux en ciment portland entrent en contact avec les gaz d'origine naturelle ou technogène, qui contiennent l'hydrogène sulfuré en concentrations importantes. Sous hautes pressions du gaz et à la température élevée, ce qu'on observe par exemple dans les sondages à gaz, il se produit une destruction rapide du ciment portland. La corrosion par les gaz contenant le sulfure d'hydrogène a un mécanisme particulier. Lors de la dissolution du sulfure d'hydrogène dans le liquide interstitiel il se produit sa neutralisation par l'hydroxyde de calcium avec la formation de l'hydrosulfure soluble dans l'eau. Par suite des réactions d'oxydoréduction avec l'oxygène dissous dans le liquide interstitiel et les composés fortement oxydés du ciment portland (avant tout  $Fe^{III}$ ), le soufre de sulfure s'oxyde jusqu'au soufre neutre et ensuite jusqu'au soufre de sulfate. La présence de l'ion sulfate diffusé dans la profondeur de la pâte de ciment provoque la formation de l'ettringite, l'expansion et le craquelage de la pierre de ciment. Si l'hydrogène sulfuré continue d'arriver dans le liquide interstitiel, l'ettringite se détruit avec séparation du gypse. La vitesse de la corrosion est déterminée par la pression, la température, la teneur du gaz en sulfure d'hydrogène, le degré de résistance aux sulfates et aux sulfures du ciment donné.

In different building constructions portland cement materials contact with natural and industrial gases containing hydrosulfide of sufficient concentrations. At high temperature and high-pressure gases presence, as in gas-extractive boreholes, quick destruction of portland cement exists. Gas hydrosulfide corrosion has a unique mechanism. Hydrosulfide, on solution in pore liquid, is neutralized by calcium hydroxid with water-soluble hydrosulfide generation. As a result of reduction-oxidation reactions with oxygen and portland cement high-oxidized compounds (primarily with  $Fe^{III}$ ) dissolved in pore liquid, sulfid sulfur oxidizes to neutral, and then to sulfate. Diffusing in the depth of cement paste sulfate-ion presence results in ettringite generation, and then expansion and cracking of cement stone. As hydrosulfide subsequently enters the pore liquid, the ettringite becomes destroyed, gypsum being given off. Corrosion rate is determined by pressure, temperature, hydrosulfide content in gas, rate of sulfid - and sulfate - stability of the cement under consideration.

**RESUME:** Dans les différentes constructions les matériaux en ciment portland entrent en contact avec les gaz d'origine naturelle et technogène, qui contiennent l'hydrogène sulfuré en concentrations importantes. Sous hautes pressions, ce que l'on observe par exemple dans les sondages à gaz, il se produit une destruction rapide du ciment portland. La corrosion par les gaz contenant le sulfure d'hydrogène a un mécanisme particulier. Lors de la dissolution du sulfure d'hydrogène dans le liquide interstitiel il se produit sa neutralisation par l'hydroxyde de calcium avec la formation du sulfure hydraté soluble dans l'eau. Par suite des réactions d'oxydoréduction avec l'oxygène dissous dans le liquide interstitiel et les composés fortement oxydés du ciment portland (avant tout  $Fe^{III}$ ), le soufre sulfuré s'oxyde jusqu'au soufre neutre et partiellement jusqu'au soufre sulfaté. L'ion sulfate diffuse à l'intérieur du ciment durci où se conserve encore la valeur du pH du liquide interstitiel suffisante pour la formation de l'ettringite, qui s'accompagne d'une destruction de la structure interne du ciment durci, d'une expansion et d'un craquelage.

Si l'hydrogène sulfuré continue d'arriver dans le liquide interstitiel, l'ettringite se détruit avec séparation du gypse. La vitesse de la corrosion est déterminée par la pression, la température, la concentration de l'hydrogène sulfuré dans le gaz, la teneur du ciment en composés susceptibles d'entrer en réactions de réduction et en réactions avec l'ion sulfate.

Comme agent agressif envers le ciment portland l'hydrogène sulfuré est moins étudié que les sulfates, les sels de magnésium ou l'acide carbonique.

Toutefois les derniers temps dans la pratique d'utilisation du ciment portland on rencontre de plus en plus souvent des cas de son contact avec le milieu contenant le sulfure d'hydrogène. Outre les ouvrages de canalisation et d'épuration de différents types, les gaz naturels contenant l'hydrogène sulfuré et exerçant une action sur le ciment portland pour colmatage dans les sondages représentent le cas le plus caractéristique.

Dans les études précédentes (1,2) on a noté que l'hydrogène sulfuré agit sur le ciment portland comme acide faible ou comme

source de sulfates secondaires. L'étude la plus détaillée fut entreprise par O.I. Gratcheva et E.O. Barbakadzé (3,4). Ils ont étudié le processus de corrosion spécifique de réduction de  $Fe^{III}$  jusqu'à  $Fe^{II}$  détruisant les composés ferriques de la pâte durcie ainsi que la destruction de l'ettringite sans fer dans le milieu d'hydrogène sulfuré.

En procédant aux expériences où les échantillons de ciments portlands de composition différente ainsi que du liant composé de gypse et de laitier à haute teneur en alumine et du ciment alumineux étaient placés dans le gazoduc de production d'un gaz naturel contenant l'hydrogène sulfuré et ensuite étudiés par les méthodes d'analyse chimique aux rayons X et d'analyse thermique différentielle, nous avons mis en évidence que dans ces conditions de pression partielle élevée de  $H_2S$  et en l'absence de l'air a lieu

le processus de corrosion intense ayant le mécanisme spécifique. Le gaz naturel contenait en volume 1,5 à 1,6% de  $H_2S$ , de 0,5 à 0,6 % de  $CO_2$ , 0,4 g/m<sup>3</sup> de  $H_2O$ , le reste étant les hydrocarbures. La pression du gaz dans la conduite était de 12 à 14 MPa à la température de 10 à 12 °C. Les échantillons sous forme de cylindres de 18x18 mm étaient disposés dans la zone au voisinage immédiat du gazoduc.

La composition minéralogique des ciments éprouvés est donnée dans le Tableau 1.

Les données sur la variation de la résistance des échantillons à la compression en fonction de la durée de conservation sont représentées sur la figure 1.

La photo de la figure 2 montre le caractère de la destruction des échantillons.

Le Tableau 2 donne les résultats de calcul des changements de composition chimique des échantillons après 3 mois de conservation dans le gaz contenant l'hydrogène sulfuré. Le calcul était effectué sous l'hypothèse que  $SiO_2$  n'entre pas en réaction avec le milieu agressif et reste dans les échantillons en quantité invariable.

La figure 3 représente les diagrammes aux rayons X.

**Discussion des résultats.** La comparaison des données sur le changement de composition chimique avec les données concernant l'intensité de la diminution de résistance montre que la résistance diminuait plus vite pour le ciment portland n°2 qui se caracté-

risait parla somme maximale  $C_3A + C_4A$  et la teneur maximale en  $C_3A$  malgré une moindre teneur en  $Fe_2O_3$  et en CaO en comparaison du ciment n°1.

Une diminution rapide de la résistance du ciment n°2 s'accompagne d'une accumulation maximale des trois espèces du soufre. L'oxydation du soufre a lieu grâce à la réduction du fer jusqu'à  $Fe^{II}$  et à l'interaction avec l'oxygène dissous dans le liquide interstitiel (le contact avec l'oxygène de l'air lors de l'analyse des échantillons n'était pas exclu). Toutefois la comparaison des données sur la quantité du soufre oxydé et du fer réduit montre que dans les conditions données l'oxydant principal est  $Fe^{III}$ , car dans les ciments contenant peu de  $Fe^{III}$  l'accumulation de  $S^0$  et de  $SO_3$  est beaucoup plus faible. Il était naturel de supposer que l'élimination de  $Fe^{III}$  de la composition du ciment augmentera sa stabilité envers l'hydrogène sulfuré. C'est justement cette supposition qui a servi de base pour l'introduction dans le programme d'essais du ciment portland blanc (n°3). Comme il était prévu, la diminution de sa résistance était d'abord plus lente que pour les ciments portlands n°1 et 2 et s'accompagnait d'une accumulation d'une moindre quantité de  $SO_3$ . Or, vers 3 mois le degré de sa

destruction s'est avéré non inférieur à celui des autres ciments portlands. On peut l'expliquer pas sa sensibilité élevée à l'agression sulfatique à cause d'une teneur très élevée en  $C_3A$  liant  $SO_3$  en ettringite.

L'analyse aux rayons X et l'analyse thermique différentielle montrent que dans les ciments portlands soumis à l'action de  $H_2S$

on observe une diminution considérable de la teneur en  $Ca(OH)_2$ , une augmentation de la teneur en ettringite et en  $CaSO_4 \cdot 2H_2O$  et l'apparition des sulfates de calcium, d'aluminium et de fer.

À la différence de ce qui était dit, une diminution de la résistance des échantillons de liant composé de gypse et de laitier à haute teneur en alumine s'accompagne d'une décomposition de l'ettringite et d'une augmentation de la teneur en gypse (ou est due à ce fait).

Nous représentons le processus compliqué d'agression gazeuse par l'hydrogène sulfuré du ciment portland de la façon suivante.

L'hydrogène sulfuré contenu dans le gaz se dissout dans le liquide interstitiel du ciment portland solidifié. Si le gaz se trouve sous une grande pression, la quantité de  $H_2S$  dissous est assez grande. Il réagit alors avec  $Ca(OH)_2$ . Dans les conditions indiquées il se forme  $Ca(HS)_2$  facilement soluble, la valeur du pH diminue. C'est le premier processus de corrosion. Son action destructive dépend de la teneur du ciment en silicate tricalcique. Les expériences de E.O. Barbakadzé et de O.I. Gratcheva (3) montrent que les échantillons de  $\beta-C_2S$  sont beaucoup plus stables dans le milieu de  $H_2S$  que les échantillons de  $C_3S$  pur.

Le deuxième processus de corrosion est le passage  $Fe^{III} \rightarrow Fe^{II}$  avec la formation de  $FeS$  pratiquement insoluble et colorant les échantillons en noir foncé. Dans ce cas les phases  $AFm$  et  $Aft$  se détruisent, et la diminution de la résistance résultant de ce processus a lieu d'autant plus vite que la quan-

tité de ces phases dans le ciment durci est plus importante, c'est-à-dire que la somme  $C_3A + C_4AF$  est plus grande dans le ciment portland.

En même temps que la réduction  $Fe^{III} \rightarrow Fe^{II}$  a lieu l'oxydation  $S^{2-} \rightarrow S^0 \rightarrow S^{6+}$  avec la formation de  $SO_4^{2-}$ . Ceci est dû également à l'action de l'oxygène contenu dans le liquide interstitiel.

L'ion  $SO_4^{2-}$  entre en réaction avec  $Ca^{2+}$  avec la formation de  $CaSO_4 \cdot 2H_2O$ , ce qui entraîne encore un type de corrosion. L'accroissement de la teneur des échantillons en ettringite et la stabilité peu élevée du ciment 3 montrent que l'ion diffuse dans la profondeur du ciment durci où l'indice pH est encore insuffisamment élevé pour la formation de l'ettringite.

Ceci provoque la destruction des couches internes, l'apparition de fissures et y ouvre l'accès à l'hydrogène sulfuré. Tous les autres processus corrosifs se trouvent alors accélérés et dans les conditions de la diminution provoquée du pH l'ettringite se décompose. C'est pourquoi le liant composé de gypse et de laitier à haute teneur en alumine stable aux sulfates est instable dans le milieu d'hydrogène sulfuré.

#### CONCLUSIONS

1. Un ensemble complexe de processus corrosifs dans le milieu gazeux contenant l'hydrogène sulfuré comprend la transformation de  $Ca(OH)_2$  en  $Ca(HS)_2$  facilement soluble et la diminution du pH, la réduction de  $Fe^{III}$  jusqu'à  $Fe^{II}$  dans les phases AFt et AFm avec la décomposition de ces phases, la corrosion par sulfoaluminates et gypse due au sulfate secondaire. Le sulfoaluminate hydraté se décompose ensuite par l'hydrogène sulfuré pénétrant.

2. Sur le front de progression de la corrosion le processus primaire est la formation du sulfoaluminate hydraté suivie d'une formation du gypse, d'une décomposition des phases ferriques, d'une dissolution de  $Ca(OH)_2$ . La succession temporelle dans une couche fixée est l'inverse de la succession susmentionnée.

3. Le ciment stable à l'hydrogène sulfuré doit être obtenu dans le milieu réducteur, être stable aux milieux faiblement acides et à la corrosion due aux sulfates.

# A study on the action of sea water on hydrated cement pastes

## *Etude de l'action de l'eau de mer sur les pâtes de ciments hydratés*

Dr. Ch. FTIKOS, Dr. V. KASSELOURIS, Sr. S. TSIMAS, Dr. G. PARISSAKIS,  
HERACLES General Cement Co - National Technical University of Athens, Greece,  
Lab. of Inorg. and Anal. Chemistry.

RESUME : Dans le présent travail le phénomène de l'action de l'eau de mer sur les pâtes de ciment est étudié.

Les pâtes étudiées furent préparées avec des ciments Portland purs contenant différentes compositions minéralogiques, et avec les mêmes ciments mélangés avec 30 % de terre de Santorin..

L'étude montre que la détérioration des ciments conservés dans l'eau de mer n'est pas seulement due à l'attaque de  $\text{SO}_4^{2-}$  sur les composés d'aluminate de calcium hydratés, mais à une action combinée des  $\text{Mg}^{2+}$  et  $\text{Cl}^-$  contenus dans l'eau de mer sur les composés de CSH.

Les ciments avec de la terre de Santorin (pouzzolane naturelle) sont plus résistants à l'attaque de l'eau de mer.

SUMMARY : In the present work the phenomenon of the action of sea water on the cement pastes is studied.

The studied pastes were prepared from pure Portland Cements with different mineralogical composition as well as from their mixtures with 30% Santorin earth.

The study shows that the deterioration of cements cured in sea water, is not only due to the attack of  $\text{SO}_4^{2-}$  on the hydrated calcium aluminate compounds but to a combined action of  $\text{Mg}^{2+}$  and  $\text{Cl}^-$  contained in sea water on CSH compounds.

Cements with Santorin earth (natural pozzolan) are more resistant to sea water attack.

## 1. Introduction

Praxis and research have shown that sea water affects on the hydrated cement components.

This phenomenon, which has been studied by many researchers, (1-5), consists of complicated interactions due to the great number of the hydrated cement components and the ions contained in sea water.

In the present work, which is a part of an extended research program, the action of some ions contained in sea water, on Portland cement of different mineralogical composition as well as on their cogrinded mixtures with Santorin Earth (natural Pozzolan) is studied.

In pastes prepared from these cements, the above mentioned action has been studied by XRD, DTA-TG and SEM. Also, strength development has been measured.

## Experimental

The chemical composition of four Portland cements (PCI, PCII, PCIII, PCIV) as well as of Santorin Earth, is shown in table I. The mineralogical composition (according to Bogue) of Portland cements used is shown in table II.

Table I. Chemical composition of materials used.

%	PCI	PCII	PCIII	PCIV	Santorin Earth
L.O.I	0,25	0,20	0,20	1,00	2,50
I.R.	0,25	0,24	-	0,26	-
SiO <sub>2</sub>	21,72	23,73	21,55	21,08	61,50
Al <sub>2</sub> O <sub>3</sub>	4,86	5,27	5,70	4,82	15,80
Fe <sub>2</sub> O <sub>3</sub>	4,00	3,65	2,70	5,72	5,90
MgO	1,30	2,20	3,95	2,36	1,70
CaO	65,17	63,84	63,55	62,32	3,62
CaO free	3,30	1,56	-	-	-
SO <sub>3</sub>	1,42	traces	0,97	1,93	traces
K <sub>2</sub> O	traces	traces	traces	0,60	2,72
Na <sub>2</sub> O	traces	traces	traces	0,18	3,87

Table II. Mineralogical composition of cements tested (according to Bogue)

Cement type	% C <sub>3</sub> S	% C <sub>2</sub> S	% C <sub>3</sub> A	% C <sub>4</sub> AF
PCI	58	19	6	12
PCII	39	39	8	11
PCIII	50	24	10	8
PC IV	47	25	3	17

From the above mentioned cements as well as from their mixtures with 30% Santorin Earth, specimens have been prepared, according to ISO-RILEM CEMBUREAU CEN specifications, for the strength development measurement. These specimens were cured in sea water, at the area of Pagasiticos gulf, for one year.

In table III and figure 1 the results of compressive strength measurement are shown.

Table III. Compressive strengths (Kp/cm<sup>2</sup>).

Cement type	Fineness cm <sup>2</sup> /g (Blaine)	2 days	7 days	28 days	3 months	6 months	1 year
PCI	2900	186	288	388	397	437	432
PCII	2900	135	266	392	410	463	442
PCIII	2900	245	339	405	397	433	437
PCIV	3000	165	295	409	422	452	423
PCI+30%S.E	3900	135	217	315	386	391	419
PCII+30%S.E	3900	90	199	334	401	422	456
PCIII+30%S.E	3900	162	243	329	388	423	430

From the cements shown in table III pastes have been prepared with a c/w ratio 0,27 and 0,33 for the pure Portland cements and their mixtures with Santorin Earth, respectively.

In these cements, hydration phenomena have been studied by XRD, DTA-TG and SEM.

Fig. 1. Compressive strength of pure Portland Cements and their mixtures with 30% S.E.

## Study by XRD

In pure Portland cement pastes, the compounds of Ettringite, thaumasite, chloroaluminates, C<sub>4</sub>AH<sub>13</sub>, CAH<sub>10</sub>, C<sub>3</sub>S, CSH and Ca(OH)<sub>2</sub> are observed (Fig.2).

The peaks of Ettringite are more intense in the cement paste of PCI, PCII, PCIII than those of PCIV, while the peaks of chloroaluminates are more intense in the cement paste of PCII.

The nonhydrated C<sub>3</sub>S content is greater in cement pastes prepared from cements in which it is contained in high percentages.

In blended cement pastes the same compounds are observed. The intensities of the peaks of Ettringite, thaumasite, C<sub>4</sub>AH<sub>13</sub>, CAH<sub>10</sub> and Ca(OH)<sub>2</sub> are lower than those of pure cement pastes while the intensities of the peaks of CSH and chloroaluminates are higher. A part of Ettringite is transformed to monosulfate.

Fig. 2. XRD patterns for cement pastes cured in sea water for one year.

E: Ettringite  
T: Thaumate  
X: Chloroaluminates

#### Study by DTA-TG

In figure 3 thermograms are shown from cement pastes cured for one year. In all pure Portland cement pastes the compounds of Ettringite, chloroaluminates,  $C_4AH_{13}$ ,  $Ca(OH)_2$ , CSH(I) and small amounts of  $CaCO_3$  are observed.

The exothermic peak at  $620^\circ$  is attributed to thaumasite without any remarkable differentiation in its content.

The pastes of PCII are enriched in chloroaluminates compared to PCI pastes. The highest concentration of  $Ca(OH)_2$  is observed in PCI and the lowest in PCII. The presence of Ettringite is less intense in PCIV pastes.

#### Study by SEM

In figures 4,5,6' and 7 some photos are presented concerning the study by SEM of cement pastes cured for one year. In photo 1 a great number of pores are observed. Crystals of Ettringite are grown in these pores. Photo 2 depicts the reduced amount of Ettringite. The structure of CSH is not porous and the Portlandite in the center, is not deteriorated.

In photo 3 a cluster of Ettringite is observed while in photo 4 the great number of chloroaluminates, the nonporous CSH and the low dispersion of Ettringite and observed. In photo 5 the Ettringite results in the formation of some cracks around it, while in photo 6 the great cohesion in the structure and intense presence of chloroaluminates are observed.

In photo 7 the reticulated CSH and the low dispersion of Ettringite are observed.

#### Discussion and conclusion

In figure 1 which shows the strength development from 28 days up to one year, it is observed that the affect of sea water on compressive strengths appears after six months with an exception of the mixtures of PCI and PCII containing 30% Santorin Earth.

This phenomenon is more indicative in PCIV despite its low  $C_3A$  content. The above mentioned observation leads to the opinion that the sea water attack is not only due to the presence of  $C_3A$ , at least in the studied percentage of  $C_3A$ .

The study of XRD patterns and the semiquantitative estimation of hydration products by DTA-TG, show that Ettringite and thaumasite are increased in pure Portland cement pastes by increasing of the  $C_3A$  content.

Also, the presence of nonhydrated  $C_3S$  even after a curing for one year, is observed.

The blended cement pastes contain more chloroaluminates,  $C_4AH_{13}$  and CSH and less  $Ca(OH)_2$  than the pure Portland cement pastes.

Fig. 3. Thermograms for cement pastes cured in sea water for one year.

Ph. 1. M x 2000

Ph. 2. M x 2000

Fig. 4. PCI and PCI+30% S.E pastes cured in sea water for one year.

Ph. 3. M x 2000

Ph. 4. M x 2000

Fig. 5. PCII and PCII+30% S.E pastes cured in sea water for one year.

Ph. 5. M x 2000

Ph. 6. M x 2000

Fig. 6. PCIII and PCIII+30% S.E pastes cured in sea water for one year.

Ph. 7. M x 2000

Figure 7. PCIV paste cured in sea water for one year.

In addition to the above mentioned observations, the study of the same pastes by SEM, leads to two remarkable conclusions.

a). In pure Portland cements and especially in PCIII, in which  $C_3A$  is greater, the cracks are due to the decreased formation of Et-trigite and its structure.

b). The observed structure of CSH is different between the various pure Portland cement pastes as well as between the pure Portland cements and their mixtures with Santorin Earth. Reticulated CSH shows increased possibilities to be formed, in cements with high  $C_3S$  content.

The conclusion is that the deterioration of cements cured in sea water, is not only due to the attack of  $SO_4^{2-}$  or  $Cl^-$  on the calcium aluminate compounds, but to a combined action of the  $Mg^{2+}$  and  $Cl^-$  contained in sea water on the hydrated calcium silicate compounds.

$Cl^-$  ions accelerate the calcium silicate compounds hydration and lead to the formation of high C/S ratio CSH.

This high C/S ratio and the different  $K_s$  between  $Ca(OH)_2$  and  $Mg(OH)_2$  ( $Ca(OH)_2$   $K_s = 5.5 \cdot 10^{-6}$ ,  $Mg(OH)_2$   $K_s = 1.8 \cdot 10^{-11}$ ) facilitate the substitution of  $Ca^{2+}$  by the  $Mg^{2+}$  in the CSH lattice, resulting in its transformation to the reticulated form and in the formation of nonhydraulic MSH.

Cements with pozzolan are more resistant to sea water attack despite their high content in hydrated calcium aluminate compounds.

This resistancy explained by the different way of CSH formation (6,7). The CSH formed by the interaction of  $SiO_2$ , contained in pozzolan and  $Ca(OH)_2$ , is of low C/S ratio. Thus, the low concentration of  $Ca(OH)_2$  as well as the low porosity of the cement & pozzolan pastes, decrease the diffusion of the ions, and prevent the substitution of  $Ca^{2+}$  by  $Mg^{2+}$ .

# The mechanical properties of polymer modified cement paste cured under sea and tapwater

## *Les propriétés mécaniques de la pâte de ciment modifiée par l'addition de polymères, et conservée dans l'eau de mer ou dans l'eau courante*

Dr. D.I. BHATTY, Dr. D. DOLLIMORE, Professor G.A. GAMLEN and M. R.J. MANGABHAI,  
Department of Chemistry and Applied Chemistry, University of Salford, Salford - ENGLAND.

RESUME : On a effectué des recherches sur les modifications de la pâte de ciment, dues à l'addition de divers polymères, tels que le Versicol W13 (polyacrylamide), la cellulose hydroxyle-éthylque (la cellulose - éther) et le dextrane (l'amidon méthylique carboxyle). On a conservé les pâtes du ciment durci sous l'eau de mer ou sous l'eau du robinet pour déterminer leur effet sur les propriétés mécaniques de la pâte, à savoir la résistance à la compression et à la flexion.

On constate que le Versicol W13 augmente la résistance à la compression et à la flexion de la pâte du ciment durci conservée dans l'eau de mer, tandis que la cellulose hydroxyle-éthylque ne montre pas aucun effet important sur ces résistances. Ceci peut être dû à la nature de la cellulose hydroxyle-éthylque et à l'effet des conditions alcalines de la pâte du ciment. Les essais effectués sur la résistance de la pâte démontrent un comportement anormal dans l'eau de mer et dans l'eau du robinet. On a poussé plus loin les recherches pour y inclure l'effet de la durée de la conservation avec divers polymères sur les propriétés mécaniques de la pâte de ciment. On examine ensuite en détail les conséquences de ces études.

### Summary

Investigations have been carried out on the modifications of cement paste with various polymeric materials such as Versicol W13 (polyacrylamide), Hydroxyethyl cellulose (cellulose ether) and Dextran (carboxy methyl starch). The hardened cement pastes were cured under sea and tap water to determine their effect on the mechanical properties of the paste related to compressive and flexural strength.

It is shown that Versicol W13 increases the compressive and flexural strength of the hardened cement paste cured under seawater whereas Hydroxyethyl cellulose does not show any significant effect on the strength. This may be due to the nature of the Hydroxyethyl cellulose and the manner in which it is affected by the alkaline condition in the cement paste. The strength tests carried out on paste containing Dextran show anomalous behaviour in the sea and tapwater.

The investigations have been extended to include the ageing affect of the polymers on the mechanical properties of the cement paste and the consequences of these studies are discussed in detail.

## INTRODUCTION

The use of water-soluble polymers has not become established in the field of concrete, cement and mortars except in certain restricted cases (1). Polymer additives are known to affect the hydration process and the strength of the hardened paste. The environment is also a factor which affects these two parameters. At present, there are four important types of polymer modified cement systems: (1) water soluble polymers, (2) fibre-reinforced concretes, (3) polymer impregnated concretes, (4) polymer latex-modified mortars and concretes. The discussion here is confined to type (1), because water soluble polymers are used in this study.

The polymers used can be classified by the function they perform, into two categories, (1) polyorganosiloxanes and (2) polyelectrolytes and their co-polymers, and cellulose and starch ethers. The first group tend to impart impermeability qualities to the cement, whilst the second give either a plasticizing effect to the flowing cement paste or improve the strength of the hardened paste.

The first category is less important and its uses have been confined to Russia (2), where it is claimed that improvements to strength and water tightness of concretes can be made. In the second category there are two divisions:-

- (a) polyelectrolytes and their co-polymers,
- (b) cellulose and starch ethers. In this study, polymers from the second category have been used.

The use of cellulose and starch ethers in grouts, mortars and concretes was suggested earlier than the use of polyelectrolytes, but, apart from

work done for patent applications, very little has been published about them. Methyl cellulose added to the dry cement composition gives "thin-set, dry-set" mortars. Upon mixing with water there is obtained a high viscosity aqueous phase, which is inhibited (e.g., by ceramic tiles) and substrate at a lower rate than pure water, leaving the water available to the cement for the required hydration reaction (2).

## EXPERIMENTAL

### 1. Materials

The cement used was ordinary Portland cement (OPC) obtained commercially, it had a chemical composition as follows:-  $C_3S$  - 47.6%;  $C_2S$  - 22.5%;  $C_3A$  - 11.06%;  $C_4AF$  - 7.66%;  $\bar{C}SH_4$  - 4.65%. The polymers investigated were:- a) Versicol W13, a non-ionic polyacrylamide (pH = 8-9 at 20%), b) Dextran, a carboxy-methyl starch (pH = 6.0 at 1%) and c) hydroxyethyl cellulose (HEC), a nonionic cellulose ether (pH = 6.5 - 8.0 at 1%). The seawater used for curing the hardened cement paste was standard seawater (3). The moulds which were used to cast the paste into cubes and beams were made of steel. The dimensions of each cube was 2.54 cm and those of the beams were 15.24 cm x 2.54 cm x 1.27 cm.

### 2. Experimental Procedure

The w/c ratio was fixed at 0.3 because this gives a good mix which can be handled easily and gives high strength after curing under water compared to higher w/c ratios (4). A standard procedure was used for mixing the cement paste (5).

The cement paste was poured into the moulds and placed on a vibrating table for one minute. The moulds were then placed in a constant temperature room set at  $25 \pm 0.5^\circ\text{C}$  and 40% rh. The moulds

were covered with a damp hessian cloth and left for 24 hours, after which they were dismantled and the hardened pastes cured under sea water and tap water.

### 3. Mechanical Testing

3, 9 and 27 days after mixing, five cubes were taken and the compressive strength determined using an Avery-Denison Type T42U compression testing machine at a constant rate of  $30 \text{ kN min}^{-1}$  until failure occurred. The flexural strength was determined on 3, 9 and 27 day old samples using a 500 lb Howden testing machine operated manually.

### RESULTS

The mean of five readings for compressive strength and the mean of three readings for flexural strength were obtained. These results are given in Table 1 a), b) and c) for samples cured under seawater. The results for samples cured under tap water are given in Table 2 a), b) and c) (6).

### DISCUSSION

The behaviour of different polymers towards the strength of hardening cement pastes cured under sea and tap water is complex. Versicol W13 shows a general increase in compressive strength of the cubes when its concentration is higher than 0.08% by weight, and the paste is cured under seawater. The strength increases quickly within nine days and then levels off. A polymer concentration of 0.13%, however, shows unusual behaviour and seems to be affecting the compressive strength of the samples in an unexpected manner.

Investigations on the paste modified with W13 and cured under tap water show a parallel behaviour

for 0.13% polymer concentration. But the overall effect of polymer addition results in a slight reduction in the compressive strength. In the case of flexural strength of the pastes with W13, an improvement in strength is indicated when the samples are cured under seawater. The tests carried out on similar cement pastes in tap water do not show much improvement in flexural strength. The overall difference in the flexural strength of pastes aged in sea water and tap water is about 60% for pastes containing 0.18% polymer. There is a general trend of increasing strength when the polymer concentration is increased and the curing takes place under sea water.

The effect of HEC on the compressive and flexural strengths of pastes cured under sea and tap water does not show any great difference in strength. (Table 1b and 2b). The neat pastes cured under both sea and tap water have higher strengths than pastes with the addition of HEC. This may be due to the hydrolysis of the HEC by the alkali in the cement paste.

The effect of Dextran on the compressive and flexural strength is anomalous. Thus, when cured under sea water there is a slight decrease in flexural strength, while when cured in tap water there is a slight increase in flexural strength. The compressive strength decreases on samples cured under sea water, but increases on samples cured under tap water. A subsequent publication deals with surface area and adsorption properties.

# Processus de formation des minéraux et composition de phase du clinker d'alinite

## *Mineral formation processes and phase composition of alinite clinker*

M. BIKBAOU, candidat ès sciences techniques, chef de laboratoire de l'Institut des Recherches Scientifiques et des projets de construction, Tachkent, U.R.S.S.

RESUME: L'étude de la formation des minéraux du clinker d'alynite obtenu par la cuisson des matières premières en présence de la chlorure de calcium a démontré que ces processus sont assez compliqués; nous avons découvert la formation des nouvelles phases minérales: du carbonate de la chlorure de calcium, du spourrite, de l'orthosilicate et de l'alumoferrite de la chlorure de calcium. A l'étape initiale de la cuisson les phases minérales contiennent une quantité considérable d'atomes de Cl; à l'étape finale, par contre, on n'observe que les minéraux avec un faible contenu de Cl (3-4% de la masse) - l'alite et l'aluminate de la chlorure de calcium. Dans ces derniers minéraux, le chlore est solidement lié dans les positions structurales.

A part les minéraux indiqués, le clinker d'alynite contient également le bélite et le ferrite de calcium qui peuvent contenir un peu de chlore (1% de la masse environ) dans leur structure. La contenance quantitative des phases minérales dans le clinker d'alynite varie dans les limites suivantes (% de la masse):

l'alynite	60 - 80
le bélite	10 - 30
l'aluminate de la chlorure de calcium	5 - 10
le ferrite de calcium	2 - 10

Des recherches effectuées ont permis de décrire le caractère de la cristallisation des phases siliciques du clinker qui ont généralement une structure distincte à grains fins. Nous avons établi que les conditions de la cuisson et de la déchloration exercent une influence sensible sur le caractère de la cristallisation du clinker d'alynite.

Cette influence s'explique par la genèse des phases intermédiaires du spourrite, de l'alumoferrite et de l'orthosilicate de la chlorure de calcium.

SUMMARY: The investigation of mineral formation processes of alinite-clinker produced by kilning the raw material together with calcium chloride has shown their considerable complication which leads to the formation of new phases - calcium chloride carbonate, spurrite, orthosilicate and aluminoferrite of calcium chloride.

At the initial stage of kilning new phases with considerable content of the chlorine atoms (about 15% of the mass) - /orthosilicate and aluminoferrite of calcium chloride/ - are formed only the minerals containing small quantity of chlorine (3-4% of the mass) - alinite and aluminate of calcium chloride are kept at the final stage. In the above mentioned minerals the chlorine is tightly cohered in structure positions.

Besides the minerals mentioned above, the alinite clinker comprises also belite and calcium ferrite, which could comprise small quantity of chlorine (about 1.0% of the mass).

The quantitative content of mineral phases in alinite clinker varies within the following limits (% of the mass):

alinite	60 - 80
belite	10 - 30
aluminate of calcium chloride	5 - 10
calcium ferrite	2 - 10

The research data have allowed to describe crystallization of silicate phases of the clinker, which are normally characterized by clear but fine-grained structure.

Important dependence of the character of cristallization of alinite clinker upon the conditions of kilning and dechlorination has been established.

This dependence is closely connected with the genesis of intermediate phases of the clinker.

La cuisson du clinker de ciment en présence de la fusion des sels de chlorure de calcium provoque des changements radicaux: dans la cinétique des processus de la formation du clinker, ainsi que dans sa composition de phase (I). Le présent travail montre les résultats d'une étude sur la suite des processus de la formation du clinker en présence de  $\text{CaCl}_2$ , ainsi que les données sur la composition plus précise des produits intermédiaires et finales de la cuisson du clinker d'alynite; ces données n'ont pas été décrites dans les publications spéciales.

Des mélanges suivants ont été préparés:

I. Un mélange des réactifs:

$\text{CaCO}_3$	$\text{SiO}_2$	$\text{Al}_2\text{O}_3$	$\text{Fe}_2\text{O}_3$	$\text{MgO}$	$\text{CaCl}_2$
69.2	16.1	2.5	1.9	1.3	9.0

2. Un mélange de limon de loess, de cendres et des calcaires de l'usine de ciment d'Akhan-garan avec 9% de chlorure de calcium, à raison de  $\text{CS} + 0,92$ ;  $n = 2,6$ ;  $p = 3,1$ .

Des mélanges ont été préparés sous forme de granules de dimension de 7-8 mm et cuits dans un four électrique de laboratoire. La vitesse de la montée de la température était égale à  $5^\circ\text{C}$  ce qui correspond à peu près aux conditions de production industrielle. A partir de  $400^\circ\text{C}$ , un échantillon des matériaux a été pris toutes les  $50^\circ$  et refroidi en l'air. A part cela, un essai isothermique aux températures données était employé afin de déterminer la composition de phase des produits de la cuisson.

Le produit cuit a été analysé sur le contenu de l'oxyde de calcium  $\text{CO}_2$  libre et du chlore.

La suite et le contenu des processus de la formation du clinker à basse température se diffère carrément des processus analogiques de cuisson du clinker de ciment portland. La présence de la chlorure de calcium, composante supplémentaire dans le mélange brut servant à produire le clinker à basse température provoque une complication considérable des processus de la formation des minéraux. La présence de la chlorure de calcium abaisse la température du processus final de la cuisson des minéraux de sortie du clinker du ciment d'alynite aussi que tous les processus intermédiaires. Ces processus sont illustrés par les courbes de l'analyse thermique différentielle (courbe ATD) (Fig.1). A partir de  $500^\circ\text{C}$ , la courbe ATD du mélange brut du ciment change à cause de l'évaporation de l'eau des hydrates.

Nous avons utilisé une méthode d'étude de la composition de phase dans une couche mince qui a permis de découvrir le commencement de l'interaction chimique entre les composantes du mélange brut pour la formation du clinker d'alynite au niveau de  $450-500^\circ\text{C}$ .

Le processus de la formation des composés complexes commence déjà aux températures de  $530-600^\circ\text{C}$  grâce à l'interaction de  $\text{CaCl}_2$  et de  $\text{CaCO}_3$ , la carbonate de la chlorure de calcium ( $\text{CaCO}_3 \cdot \text{CaCl}_2$ ).

A  $620-640^\circ\text{C}$  ce composé se transforme en phase X qui est, peut-être, sa modification de haute température qui existe dans l'intervalle de  $630-800^\circ\text{C}$ ; leurs propriétés chimiques et les paramètres des cellules sont assez proches (voir le tableau).

Tableau I

La composition de phase des produits de la cuisson a été déterminée par les méthodes quantitative et qualitative de l'analyse optique et celle aux rayons X. La méthode de l'analyse thermique différentielle a aussi été utilisée.

Dans l'intervalle de  $650-750^\circ\text{C}$  une décarbonisation plus intense fait apparaître l'oxyde de calcium libre. A ces températures, les composantes acides entrent en action mutuelle ce qui mène à la formation du spurrite dans les produits de la cuisson.

\*CS - coefficient de saturation, n-module silicique, p-module alumineux.

Aux températures de 750-800°C les produits de la cuisson contiennent, à part le spourite prédominant, l'alumoferrite et l'aluminate de la chlorure de calcium.

1 - du spourrite;  
2 - de l'orthosilicate de la chlorure  
de calcium;  
3 - de l'aluminate de la chlorure de  
calcium.

Le changement quantitatif de la teneur des phases à chaque étape de la cuisson caractérise le mécanisme de la formation du clin-  
ker. Ainsi, la courbe du changement de la teneur d'oxyde de calcium libre dans les produits de la cuisson a deux valeurs extrêmes (fig.3). La teneur plus élevée de CaO libre due à une température plus haute

Pourtant, les températures de 700-750°C provoquent une formation intense du spourrite dont la quantité atteint le maximum à 800°C (fig.3).

La formation du spourrite s'effectue grâce à la liaison intense entre la silice et l'oxyde se libérant à la décomposition de  $\text{CaCO}_3$ :

Aux températures de 750-800°C, il est intéressant à noter la formation de l'orthosilicate de la chlorure de calcium en présence de la chlorure de calcium. La fig.4 montre les données expérimentales sur le changement de la teneur en orthosilicate de la chlorure de calcium  $2\text{Ca}_2\text{SiO}_4 \cdot \text{CaCl}_2$  dans le processus de la cuisson.

On peut supposer la possibilité de l'isomorphisme des anions au cours de la formation du spourrite et de l'orthosilicate de la chlorure de calcium quand une partie d'atomes de l'oxygène dans la molécule de la calcite du spourrite -  $2 \text{Ca}_2\text{SiO}_4 \cdot \text{CaCO}_3$  est remplacée par les atomes du chlore. Les résultats des expériences sur la séparation du chlore du spourrite synthétique synthétisé en présence de  $\text{CaCl}$  confirment que le remplacement de O par Cl dans le spourrite est possible. Ces expériences ont montré la conservation de 2% de Cl dans le minéral, probablement grâce à l'élévation du Cl dans la structure. Il n'est pas exclu que  $2 \text{Ca}_2\text{SiO}_4 \cdot \text{CaCO}_3$  et  $2 \text{Ca}_2\text{SiO}_4\text{CaCl}_2$  forment des solutions solides grâce à l'isostructure de ces composés contenant à la base une molécule de  $\text{Ca}_2\text{SiO}_4$ . Ces phases intermédiaires sont

stables dans un intervalle déterminé, car à 800-850°C le spourrite commence à se décomposer et aux températures supérieures à 950°C disparaît tout à fait.

Fig. 4. Changement du contenu de l'orthosilicate de la chlorure de calcium (I), de l'aluminate de la chlorure de calcium (2) et de l'alumoferrite de calcium (3) dans les produits de la cuisson du clinker d'alynite en fonction de la température.

Les fig. 3-5 montrent des résultats des mesures sur le changement de la teneur quantitative des phases minérales du clinker d'alynite dans le processus de la cuisson.

Elles sont effectuées à l'aide d'une analyse quantitative aux rayons X. La formation du spourrite et de l'orthosilicate de la chlorure de calcium lie l'oxyde de calcium libre se libérant au cours de la décarbonisation. Sa quantité dans l'intervalle de 700-900°C ne dépasse pas quelques pourcents. Ceci est juste pour la vitesse normale de l'élévation: 5-20% par min. Grâce au nivellement des facteurs cinétiques, le traitement isothermique prolongé aux températures 700-900°C libère tout l'oxyde de calcium du mélange brut, sauf sa quantité liée par le spourrite, l'orthosilicate, l'aluminate et l'alumoferrite de la chlorure de calcium (fig. 4); même dans ce cas la quantité de l'oxyde de calcium libre ne dépasse pas 10-12% ce qui est égal à un cinquième de sa quantité totale. Ces données sont en accord avec les résultats de la détermination de la teneur en  $\text{CO}_2$  des produits de la cuisson. L'aluminate de la chlorure de calcium commence à se former à 700-750°C; il est stable sur toutes les étapes ultérieures de la formation du clinker. Par contre, l'alumoferrite de la chlorure de calcium n'existe que dans un intervalle limité de températures. Il commence à se former à 750-800°C, mais à 950°C il se décompose en ferrite de calcium, un composé stable et en même temps il fournit l'aluminium pour la formation de l'alynite. Il est probable que ce fait explique le commencement de la cristallisation de l'alynite aux températures de l'alumoferrite de la chlorure de calcium, c'est-à-dire à 900-950°C (fig. 5).

L'hypothèse citée explique l'effet de forte minéralisation en présence de  $\text{Fe}_2\text{O}_3$  dans le

Fig. 5. Changement du contenu de l'alynite (1) et du belite (2) et la ferrite de calcium (3) en fonction de la température.

mélange brut au cours de la cuisson du clinker d'alynite. Grâce à la formation et à la décomposition de l'alumoferrite de la chlorure de calcium, l'aluminium, un des éléments principaux du réseau cristallin de l'alynite, est fourni au moment de la cristallisation de l'alynite. Cela se trouve en accord avec le fait de l'absence de l'alumoferrite de calcium dans le clinker d'alynite.

L'hypothèse proposée explique la nécessité d'une augmentation sensible de la concentration de l'aluminium dans le mélange brut utilisé au cours de la cuisson du clinker d'alynite blanc. Le belite se forme à 850-900°C, car la quantité de Cl ne suffit pas à lier toute la substance en orthosilicate de chlore (15% de chlore dans la structure), aluminate de chlore (4% de chlore dans la structure) et alumoferrite de chlore (15% de chlore dans la structure).

De cette façon, à 900°C tout le chlore est déjà pratiquement lié en composés, l'alynite se forme à partir de l'orthosilicate de la chlorure grâce à une nouvelle répartition du chlore entre lui et le belite, pendant que les  $\text{CaO}$  et  $\text{Al}_2\text{O}_3$  superflus libérés à la décomposition de l'alumoferrite, sont liés. Ainsi, la cristallisation de l'alynite est suivie du dégagement de  $\text{HCl}$  grâce à la décomposition thermique de l'alumoferrite et de l'orthosilicate de la chlorure de calcium. Une partie de  $\text{HCl}$  fournit les particules voisines et participe au processus ultérieur de la formation du minéral en homogénéisant la composition de phase du clinker; une autre partie s'en va avec les gaz grâce à la sublimation. De cette façon, une étude de la suite de la formation du clinker à basses températures a démontré une grande importance des phases intermédiaires du clinker dont la formation et la genèse, par notre opinion, exerce une influence décisive sur le caractère de la cristallisation du clinker d'alynite.

Le mécanisme des processus de la formation du clinker à basses températures que nous venons d'examiner nous permet de comprendre les particularités de la composition de

\*La composition du minéral est, probablement, la suivante:  $\text{Ca}_4\text{Al}_2\text{Fe}_2\text{Cl}_2\text{O}_9$ .

phase du clinker d'alynite.

Le clinker d'alynite est représenté par quatre minéraux (% de la masse).

1. L'alynite -  $\text{Ca}_{11}(\text{Si}, \text{Al})_4\text{O}_{18}\text{Cl}$  - 60+ 80
2. Le bélite -  $\beta - \text{C}_2\text{S}$  - 10+30
3. L'aluminat de la chlorure de calcium -  $\text{Ca}_3\text{Al}_7\text{O}_{16}\text{Cl}$  - 5+10
4. Le ferrite de calcium -  $\text{Ca}_2\text{Fe}_2\text{O}_5$  - 2+10

La formation du clinker d'alynite s'effectue dans la lutte concurrentielle des atomes et de leurs configurations pour les atomes du chlore qui sont les plus actives aux hautes températures de cristallisation du clinker; ces atomes passent facilement de la phase solide en liquide (fusion), en phase gazeuse et de nouveau solide (chloration).

Cette lutte aboutit à ce que le chlore ne reste que dans l'alynite, où il est solidement lié dans un motif structural original et entoure étroitement par huit atomes de calcium (2), ainsi que dans l'aluminat de chlorure de calcium, où il est aussi lié dans les motifs structuraux solides (3).

Le bélite et le ferrite de calcium sont identiques sur tous les indices aux minéraux portlands.

Certaines particularités de la morphologie et de la composition des cristaux sont liées à une faible solubilité du chlore (1,0-1,5% de la masse) dans le bélite et le ferrite de calcium.

Dans les clinkers obtenues à la base des matières premières aux différentes usines de ciment de l'URSS d'après la technologie de basse température avec l'utilisation de la fusion catalytique de la chlorure de calcium, l'alynite se cristallise sous forme des plaques hexagonales, des petits prismes allongés dans le même sens et des formations des rayons aiguës. On peut y observer des grains de forme des rhomboédrique et des tablettes. Les clinkers ont une structure à grains fins irréguliers, la cristallisation de l'alynite est distincte. Les dimensions des grains varient de plusieurs  $\mu\text{m}$  à 30-35  $\mu\text{m}$ . Les particules de dimension de 15-20  $\mu\text{m}$  prédominent.

On y observe des agrégats de l'alynite, quelquefois des macles des grains à l'extinction zonale caractéristique. La birefringence est basse, l'extinction est directe. Les index de réfraction varient dans les limites: 1.710 - 1.714.

Une autre phase silicique du clinker d'alynite observée dans les matériaux étudiés est représentée par le bélite (silicate basique bas), qui se diffère de l'alynite par sa forme arrondie, ovale ou celle de lentille; les débris des grains sont le plus souvent incolores, à l'extinction directe. Les index de réfraction sont  $N = 1.724 - 1.730$ . La birefringence et les index de réfraction sont les seuls indices distinctifs des études microscopiques des

phases du clinker d'alynite.

Les études minéralogiques des clinkers synthétisés à basse température sont très difficiles à accomplir à cause de la structure microcristallin des phases minérales. Les études au microscope électronique nous ont permis d'étudier le faciès et la morphologie des cristaux dans le clinker.

Le bélite est représenté dans le clinker sous forme des grains arrondis et des débris irréguliers; souvent, on l'observe sous forme des incorporations dans les cristaux de l'alynite (fig.6).

Fig.6. Stéréomicrophotographies<sup>+</sup> d'un cristal de l'alynite avec des incorporations du bélite (stéréoskew - 4). Agrandissement - 5 000.

Dans le clinker, l'alynite est représenté par les polyèdres bien cristallisés aux facettes distinctes reproduisant de différentes variétés du faciès tétragono-pyramidal (fig.7).

Une étude des microcristaux de l'alynite dans le clinker par la méthode de l'analyse microscopique du spectre aux rayons X à l'aide de l'appareil "Komeka" nous a permis de préciser la composition des éléments des cristaux de l'alynite, dont le contenu qualitatif est représenté par Ca, Si, O, Cl, Al, Fe et Mg (fig.8) et le contenu quantitatif par: Ca = 46-47 Si = 10-11 Al = 1,5-3,0 Mg = 1,0-1,5 Fe = 1,2-1,3 Cl = 2,5-3,0 O = 35-36.

#### CONCLUSIONS:

Le présent travail montre la suite de la formation et des transformations des phases intermédiaires et finales du clinker d'alynite.

À l'étape initiale du processus, les auteurs ont établi la formation du carbonate de la

<sup>+</sup>L'auteur remercie vivement mme N.Sirotkine d'avoir exécuté une analyse.

Fig.7. Variétés du faciès des cristaux de l'alynite dans le clinker: a - photos des répliques des clivages des grains de clinker prises au microscope électronique ME - 5, agrandissement de 4000, b - stéréomicrophotographies prises au microscope électronique à balayage, agrandissement de 2800.

Fig.8. Spectrogramme d'une grain d'alynite dans le clinker.

chlorure de calcium et de la phase X dont la composition est à peu près la même ils ont déterminé les paramètres de leurs cellules élémentaires. Le spourrite, l'alumoferrite et l'orthosilicate de la chlorure de calcium se forment également en tant que des phases intermédiaires du clinker d'alynite.

La contenance quantitative des phases minérales dans le clinker d'alynite varie dans les limites suivantes (% de la masse):

l'alynite	60 - 80
le bélite	10 - 30
l'aluminate de la chlorure de calcium	5 - 10
le ferrite de calcium	2 - 10

Le changement de la proportion quantitative des phases minérales intermédiaires et stables dans le processus de la formation du clinker d'alynite est démontré.

Les auteurs donnent la description du caractère de la cristallisation des phases minérales du clinker - alynite; ils soulignent sa dépendance des conditions de la cuisson des matières premières liée à la genèse des phases intermédiaires du clinker.

## Quantitative determination of the degree of conversion of high alumina cement

### *La détermination quantitative du degré de la conversion du ciment alumineux*

John BENSTED, Principal Scientist, Head of Materials Section, Blue Circle Industries Ltd. Research Division, ENGLAND.

RESUME : La détermination quantitative du degré de transformation cristalline du ciment alumineux hydraté a été faite par les différentes techniques de l'analyse thermique. Les imperfections sont discutées avec référence particulière à l'ATD. La valeur de ces mesures est en fait qualitative plutôt que quantitative, mais permet de distinguer les échantillons de ciment alumineux peu, modérément ou fortement transformés.

SUMMARY: Quantitative determination of the degree of conversion of high alumina cement by different thermal analysis techniques is discussed. The shortcomings are discussed with particular reference to DTA. The true value of these tests is shown to be qualitative rather than quantitative in being able to distinguish high alumina cement samples as little, moderately or highly converted.

Thermal analysis methods like DTA, QDTA, DTG, DSC and EGA have been used for quantitative determinations of the degree of conversion of high alumina cement (1-6). Such methods do, however, present a number of shortcomings, which are discussed here specifically for DTA, but they do correspondingly affect the applicability of the other thermal analysis techniques as well when used to obtain percentage conversion factors for high alumina cement samples.

The hydraulic aluminous component is assumed to be CA, which hydrates to CAH<sub>10</sub>. Formation of C<sub>2</sub>AH<sub>8</sub> is assumed to be negligible. In practice, C<sub>12</sub>A<sub>7</sub> is normally present in high alumina cements in amounts ~2-10%. It hydrates to give principally C<sub>2</sub>AH<sub>8</sub> together with some alumina gel that crystallises to gibbsite with time. Hydration of CA frequently gives significant C<sub>2</sub>AH<sub>8</sub> and also alumina gel which in turn crystallises to gibbsite. Consequently two generations of gibbsite are formed:

- (i) as a consequence of C<sub>2</sub>AH<sub>8</sub> formation.
- (ii) due to conversion.

Hence the height of the AH<sub>3</sub> endothermic peak, which is used as a standard for measuring conversion, is greater than can be explained by conversion alone. This would account for relatively high conversion figures being common for lower age high alumina cement concrete samples.

β-C<sub>2</sub>S can be present ~2-10% and is said to hydrate to Strätling's compound (C<sub>2</sub>ASH<sub>8</sub>) in an aluminous medium. Generally <5% is present in high alumina cements, which also contain some of their silicate in the form of melilite, a solid solution whose end members are gehlenite (C<sub>2</sub>AS) and akermanite (C<sub>2</sub>MS<sub>2</sub>). In practice significant quantities of C-S-H are occasionally present (detectable by infrared spectroscopy) and C-S-H gives an endotherm in a similar position to that of CAH<sub>10</sub>(7). Hence, when C-S-H is present, the CAH<sub>10</sub> endothermic peak is exaggerated and this can give rise to a low conversion figure.

Use of the calcium aluminate hydrates CAH<sub>10</sub>, C<sub>2</sub>AH<sub>8</sub> and C<sub>3</sub>AH<sub>6</sub> as basic analytical standards for calibration purposes is suspect, because all are highly susceptible to atmospheric carbonation. If prepared pure and used once for this purpose they are probably all right, but if used again there is likely to be significant carbonation due to more contact with air and thus lead to a more uncertain quantity of the respective calcium aluminate hydrate being present in the standard. Only CAH<sub>10</sub> is normally used as a primary standard. C<sub>3</sub>AH<sub>6</sub> is not so used owing to its high susceptibility to carbonation, which is likely to have occurred as well to at least

an appreciable extent in many specimens under test. Carbonation converts C<sub>3</sub>AH<sub>6</sub> to calcite and alumina gel, which may later crystallise as gibbsite, thereby augmenting further the AH<sub>3</sub> endotherm.

The gibbsite AH<sub>3</sub> peak is one of the basic standards of the techniques, because it is not subject to carbonation during normal atmospheric exposure (8). When conversion first takes place, alumina gel is formed which in turn crystallises to gibbsite. In practice this crystallisation process may take from several months to two years or so, so that if young high alumina cement concrete be examined the AH<sub>3</sub> peak may be depressed because of the occurrence of much alumina gel and in consequence the degree of conversion may be underestimated (9). Other forms of AH<sub>3</sub> such as nordstrandite and/or bayerite may also be present when alkaline hydrolysis has taken place and it is no longer meaningful just to consider the gibbsite peak. Complete resolution of the AH<sub>3</sub> and C<sub>3</sub>AH<sub>6</sub> endotherms does not normally take place, so that the precise effect of each one of these upon the other is not known accurately.

Sulphate attack produces ettringite and although in general the peaks due to ettringite and CAH<sub>10</sub> are clearly resolved enabling a conversion factor to be calculated, this is not always so, and in a few instances the presence of ettringite may produce a peak interfering with that of CAH<sub>10</sub>. The presence of Portland cement renders the test valueless since there is no means of ascertaining what relative contributions are made to the peak at ~100-130°C by CAH<sub>10</sub> and C-S-H.

Conversion in concrete beams is heterogeneous to a greater or lesser degree and in order to gain some representative insight into the problem, several samples need to be taken from different points in the beam under examination. Conversion at or near the edge of a beam may be greater or less than at the centre, depending upon the particular circumstances of the individual beam. Care should be taken to ensure that suitable samples are taken from the cores of beams for testing. Sampling needs careful drilling or, better, chipping, if the operator be untrained, so that any heat effects, that might themselves give rise to conversion, might be avoided.

The differential thermogram from ambient temperature to 500°C of a partially converted high alumina cement specimen is illustrated in Figure 1. The instrument used was laboratory made (7), with chromel-alumel thermocouples attached to a Kent potentiometric recorder. Dead-burnt alumina was used as the reference standard for heating. The endothermic peaks obtained are characterised in Table 1.

TABLE 1 - Endothermic Peaks for Differential Thermogram in Figure 1

<u>Peak Temperature</u> (°C)	<u>Phase Present</u>
115	CAH <sub>10</sub>
150	C <sub>2</sub> AH <sub>8</sub>
230 (shoulder)	C <sub>2</sub> ASH <sub>8</sub>
285	AH <sub>3</sub>
320	C <sub>3</sub> AH <sub>6</sub>

Fig. 1 - Differential thermogram from ambient temperature to 500°C of partially converted high alumina cement specimen.  
(Conversion = 40% by the approved DTA method).  
HEATING RATE: 20°C PER MINUTE.

The peak height method makes two assumptions (10) that are not valid in all instances:

- (i) It is assumed that the peak shapes remain the same for all samples.
- (ii) The base line is linear in all cases.

The percentage conversion figure obtained can thus in practice have a much greater uncertainty than  $\pm 5\%$  sometimes claimed. A figure of  $\pm 20\%$  is quite likely in some instances. This percentage conversion figure is not an end in itself, but simply an aid to structural tests. The rate of conversion and not the degree of conversion is what is of prime importance. There is no correlation between degree of conversion and compressive strength. Some beams have failed at low conversions; their weakness was due to the fact that such conversion as had occurred had been rapid; other beams were satisfactory at low conversions. Rate of conversion is a factor which can only be ascertained with time and cannot in consequence always be readily determined. The value of the DTA test is that a high strength highly converted beam is likely to be regarded as safe. It should be remembered that the DTA test is a calibrating and not an absolute method.

The real value of the DTA test is therefore qualitative rather than quantitative, in being able normally to grade high alumina cement samples as little, moderately or highly converted. Similar comments apply to the other thermal analysis techniques such as QDTA, DTG, DSC and EGA.

## Sulfoaluminate cement series

### *Ciments sulfoalumineux*

DENG JUN-AN, GE WEN-MIN, SU MU-ZHEN, LI XIU-YING, Engineers, Cement Research Institute The People's Republic of China.

RESUME : La formation des clinkers des ciments sulfoalumineux cuits à différentes températures, avec différentes valeurs de la saturation en chaux et avec différents rapports alumine/silice et alumine/trioxyde de soufre fut étudiée par rayons X A.T.D., microscope électronique, et analyses chimique et pétrographique. Furent également étudiées les caractéristiques d'hydratation et de durcissement des ciments fabriqués avec ces clinkers. Les résultats montrent que dans le système  $\text{CaO-Al}_2\text{O}_3\text{-SiO}_2\text{-SO}_3$ , la présence de  $\text{SO}_3$  inhibant la formation de  $\text{C}_2\text{AS}$ , et à température appropriée de cuisson,  $2\text{C}_2\text{S}\cdot\text{CaSO}_4$  étant décomposé en  $\text{C}_2\text{S}$  et  $\text{CaSO}_4$ , des clinkers à base de  $\text{C}_4\text{A}_3\text{S}$  et  $\beta\text{-C}_2\text{S}$  se sont formés. En outre, par addition de différentes quantités de gypse aux clinkers, on peut régler le temps de formation, les quantités d'ettringite et celles des autres phases d'hydratation dans la pâte de ciment, de façon à obtenir toute une série de ciments à propriétés différentes, tels que des ciments à durcissement rapide, à expansion légère, à forte expansion ou à auto-contrainte. Ces ciments qui constituent la série sulfoalumineuse sont maintenant produits sur une échelle industrielle en Chine. Le ciment à auto-contrainte est utilisé pour produire des conduites auto-contraintes, et les ciments à durcissement rapide et à expansion légère sont utilisés essentiellement pour les travaux de réparation urgente, des travaux à exécuter par temps très froid, et pour des ouvrages exigeant une bonne imperméabilité.

Summary: The formation of sulfoaluminate cement clinkers with different lime saturation values, alumina/silica ratios and alumina/sulfur trioxide ratios and burnt under different temperatures was investigated. XRD, DTA, petrographic analysis, EM and chemical analysis were employed in the study. The hydration and hardening characteristics of the cements made from the above clinkers were also studied. Results show firstly, in  $\text{CaO-Al}_2\text{O}_3\text{-SiO}_2\text{-SO}_3$  system, the presence of  $\text{SO}_3$  inhibits the formation of  $\text{C}_2\text{AS}$  and under appropriate burning temperature,  $2\text{C}_2\text{S}\cdot\text{CaSO}_4$  is decomposed into  $\text{C}_2\text{S}$  and  $\text{CaSO}_4$ . Hence clinker with  $\text{C}_4\text{A}_3\text{S}$  and  $\beta\text{-C}_2\text{S}$  as its main constituents are formed; secondly, by adding different amounts of gypsum to the clinker, the time of formation and the amounts of ettringite and other hydrated phases in the cement pastes may be so adjusted that a series of cements of different performance characters i.e., rapid hardening, slightly-expansive, expansive and self-stressing can be obtained. These cements which constitute the sulfoaluminate series are now manufactured on an industrial scale in China. Self-stressing cement is used in making self-stressing pressure pipes while slightly-expansive and rapid hardening cements are used mainly in emergency repair and permeability resisting works and under sub-zero temperatures.

## 1. Introduction

Calcium sulfoaluminate has been used as an expansive agent in cements by many investigators since the mineral was first proposed by Halstead.<sup>1-5</sup> Some investigators have used sulfoaluminate clinker to make rapid hardening cements.<sup>6-8</sup> The studies on the formation of sulfoaluminate cement clinker are mostly concentrated on  $\text{CaO-Al}_2\text{O}_3\text{-SO}_3$  system, while less work is done on  $\text{CaO-Al}_2\text{O}_3\text{-SiO}_2\text{-SO}_3$  system.<sup>9</sup> Recently there have been reports on the formation of  $2\text{C}_2\text{S}\cdot\text{CaSO}_4$  in  $\text{CaO-SiO}_2\text{-SO}_3$  system.<sup>10-11</sup>

Much investigations have been made on the hydration of  $\text{C}_4\text{A}_3\text{S}$ , with particular respect to its reaction when it is used as an expansive agent in portland cement. Xue et al.<sup>12-13</sup> put forward the view that ettringites may form and even expand under unsaturated  $\text{Ca}(\text{OH})_2$  solution. The subsequent development of calcium sulfoaluminate cement series in China<sup>14</sup> proves to support this view.

The sulfoaluminate cements as described in this paper used limestone, siliceous bauxite and gypsum as raw materials. Clinker with  $\text{C}_4\text{A}_3\text{S}$  and  $\beta\text{-C}_2\text{S}$  as its main constituents is formed in the burning. By adding different amounts of gypsum to the clinker in the

grinding cements with distinct performance characters, i.e., rapid hardening, slight-expansive, expansive and self-stressing are obtained.

More than one hundred thousand tons of sulfoaluminate cements have been manufactured since 1974. Rapid hardening cement has been used in the manufacture of concrete products (concrete ships, electric poles, railway sleepers, floor slabs, prefabricated beams and pillars and large span trusses), in emergency-repair and permeability resisting work and in frame work joints. Instances of some other applications are joints for prefabricated slabs used in reservoirs and binder for moulding sand. The cement has especial good performance under sub-zero temperatures ( $-10^\circ\text{C}$ ,  $-25^\circ\text{C}$ ,  $-35^\circ\text{C}$ ). Only simple measures are needed to acquire favorable strength gain and to assure no decrease in final strength. In the meantime, more than 2000 kilometers of self-stressing pressure pipes of various diameters have been produced using sulfo-aluminate self-stressing cement.

## II. Sulfoaluminate cement clinker

With a view to studying the clinker formation and its mineral composition, 16 raw mixes were prepared having different lime saturation values ( $C_m = \text{C}/\text{O} \cdot 7(\text{F} + \text{T} + \text{S}) + 0.55\text{A} + 1.87\text{S}$ ), alumina/silica ratios ( $N = \text{A}/\text{S}$ ) and alumina/sulfur trioxide ratios ( $p = \text{A}/\text{S}$ ). Limestone, gypsum and five siliceous bauxites with  $N=4, 2, 1, 0.2$  and one containing 13%  $\text{Fe}_2\text{O}_3$ ,

were used as raw materials.  $\text{MgO}$  and graphite powder were mixed into some of the raw mixes to study the influence of  $\text{MgO}$  and reduced atmosphere on the formation and composition of the clinker. Burning tests were carried out at first in a siliconit tube furnace and later in a small rotary kiln. Surface observation, chemical analysis, XRD and

\*Participants of the investigation are: Zheng Wan-lin, Li Pei-quan, Zhang Pei-xin and Li De-dong, Engineers, Cement Research Institute

Xue Jun-gan, Vice director, Cement Research Institute.

petrographic analysis were made on clinkers burnt under different temperatures (950, 1050, 1250, 1300 and 1400°C). Physical properties of some of the cements made from the above clinkers were examined.

Results show that under appropriate conditions clinker with  $C_4A_3\bar{S}$  and  $\beta$ - $C_2S$  as its main constituents is obtained. N value does not affect the pattern of formation of clinker minerals but it does affect the relative amount of  $C_4A_3\bar{S}$  and  $\beta$ - $C_2S$ . With  $C_m=1, p=3.82$ , the lime absorption is completed in clinker burnt under 1250°C. By introducing  $SO_3$  into

the mixes and under appropriate burning temperature, the formation of  $C_2AS$  is inhibited and the decomposition of  $2C_2S \cdot CaSO_4$  into  $C_2S$  and  $CaSO_4$  is promoted. At above 1280°C,  $C_4A_3\bar{S}$  and  $\beta$ - $C_2S$  are found to have formed and the intermediate phases  $C_2AS$  and  $2C_2S \cdot CaSO_4$  disappear. Between 1280-1400°C no appreciable changes in mineral phases have occurred. At above 1400°C,  $C_4A_3\bar{S}$  begins to decompose and  $SO_3$  to volatilize. For normal raw mixes i.e.,  $C_m=1, p=3.82$ , the clinkering temperature range is fairly wide.

Fig.1 and Fig.2 are plots of clinker

Fig.1 Clinker compositions against constituents of raw mixes at 1250°C.

Fig.2 Clinker compositions against constituents of raw mixes at 1300°C.

compositions against the constituents of raw mixes. The latter are prepared from siliceous bauxite, limestone and gypsum. XRD and petrographic analyses have been made on clinkers burnt under 1250 and 1300°C with various  $C_m$  and  $p$  values. The diagrams are schematic, yet they do illustrate the tendency of the clinker formation and its mineral composition in relation to changes in raw mix constituents.

The addition of as high as 5%  $MgO$ , which exists in clinker as extremely small periclase particles, has no distinct influence on the mineral composition of clinker. Reduced atmosphere accelerates the decomposition of  $CaSO_4$ , give rise to adverse effect on clinker formation and may even decompose  $C_4A_3\bar{S}$  already formed.

### III. The hydration, hardening and physical properties of sulfoaluminate cements.

Various types of sulfoaluminate cements have been obtained by grinding the above clinker with different amounts of gypsum.

While the amount of gypsum needed depends on the content of  $C_4A_3\bar{S}$  in the clinker, the mole ratio of  $CaSO_4 \cdot 2H_2O / C_4A_3\bar{S}$  designated as  $M$

varies from 0.5 to 6, depending on the type of cement to be made. The ratio increases in the order of rapid hardening, slightly-expansive, expansive and self-stressing cement.

In order to study the characteristics of hydration of the different types of sulfoaluminate cements, various combinations of individual minerals  $C_4A_3\bar{S}$ ,  $C_2S$  and  $CSH_2$  were

prepared. Hydration and hardening tests were made both on pastes and suspensions of cements and individual mineral combinations. Table I lists the proportioning and properties of pastes made from the individual mineral combinations. XRD, EM, DTA and chemical analysis were employed in examining specimens of different ages. Results indicate that the hydration of sulfoaluminate cements proceeds

The proportioning and properties of pastes made from individual mineral combinations.

\* d = disintegrated

as follows:

The time of formation, amount and distribution of the resultant phases determine the structure of the cement paste as well as its deformation ability. Hence they influence directly the strength, expansion, self-stressing and compactness of the cement paste. Ettringite behaves differently in different stages of hardening. By adding different amount of gypsum, the time of formation and amount of

ettringite may be so regulated that a series of cements with different properties may be obtained. In rapid hardening cement where a small amount of gypsum is added  $C_3A \cdot \bar{CS} \cdot H_{12}$  is formed besides  $C_3A \cdot 3(\bar{CS}) \cdot H_{32}$ ,  $AH_3$  and C-S-H gel.

Ettringite, one of the main hydration products of sulfoaluminate expansive cement and self-stressing cement, is the source of expansion. The  $p^H$  value of the liquid phase of the paste as determined is about 10.5. In other words, ettringite here is formed under unsaturated  $Ca(OH)_2$  solution. It expands but moderately and together with the cushion effect of  $AH_3$  gel and C-S-H gel, it imparts a

fairly large deformation ability to the cement paste of increasing structural strength. Therefore the cement has a high self-stress value with good stability.

Fig.3 shows the relationship between the proportions of the three main phases in the cements and the physical properties of the cements. The rapid hardening sulfoaluminate cement has moderate setting time. The

Fig.3 The proportions of the three main phases and the physical properties of the cements.

- II. Slightly-expansive cement area
- III. Expansive and self-stressing cement area

interval of initial set and final set is short. The compressive strength of 1:3 earthen dry mortar may attain 30 N/mm<sup>2</sup> in 12 hours and 50 N/mm<sup>2</sup> in three days. Compressive strengths in later ages still increase

and high tensile strengths are attained. (Table II). The properties of its concretes are similar to those of mortars. Both are anti-freezing and permeability resistant.

It is worth noting that the rapid hardening sulfoaluminate cement has very good performance under sub-zero temperatures. The strength of a cement frozen in early stage but later cured under normal temperature may approach that of a cement cured under normal temperature from the very beginning. By applying simple heat preservation measures, the strengths of the concrete have developed effectively under -10°C, -25°C and -35°C atmospheric temperatures at winter construction sites in Beijing and Heilungjiang.

For self-stressing sulfoaluminate cement, the self-stressing value may reach 5 N/mm<sup>2</sup> and the strength above 40 N/mm<sup>2</sup> for 1:2 mortars and 1:2 concretes while free expansion is less than 2.5% (Table III). Pressure pipes made from such cement have good performance properties in relation to water imperviousness and air tightness.

The expansion and strength values of the slightly-expansive and expansive sulfoaluminate cements are between those of rapid hardening cement and self-stressing cement. Their expansion may be regulated as required by controlling the amount of gypsum added during finish grinding. These two types of cement are mainly used in permeability resisting works and shrinkage compensating concrete works.

## The limitation of high pressure mercury porosimetry to the study of hardened cement pastes

### *Mesures de dimension des pores par pénétration de mercure dans l'étude des pâtes de ciment durci*

S. MODRY and J. HEJDUK, Building Research Institute, Praha, Czechoslovakia.

RESUME : La validité des mesures de dimension des pores, par pénétration de mercure, a fait l'objet d'études sur des pâtes durcies. Des essais de pénétration de mercure ont été effectués sur des éprouvettes vierges; puis ils ont été repris, à plus haute pression, sur les mêmes éprouvettes. Il en résulte que les fortes pressions ne provoquent pas de destructions importantes dans ces éprouvettes.

SUMMARY : The validity of results of pore size measurements by mercury intrusion was investigated on hardened cement paste. Mercury intrusion measurements were compared for virgin samples and reintruded samples after removal of mercury. Results showed no evidence of sample damage at high pressures.

Since the time the high pressure mercury intrusion porosimeter was introduced by Ritter and Drake /1/, this method has been gaining field first of all due to its undoubted advantages as e.g. relative simplicity and the speed of obtaining of the results. The mentioned properties of the method caused its many applications for investigation of pore structure of materials in many scientific and technical areas /2,3,4/. The use of the mercury porosimetry in such a broad scope was also made possible by commercially available equipments produced by several firms in Europe and in the U.S.A. /5/. The application of these instruments /in some of them can pressures reach level as high as 414 MPa/ has raised questions about the effects of high pressures on the pore structure.

This problem have been investigated and discussed by many authors as far back as Drake /1,5/ in 1949 year. From the results obtained by different authors can be concluded that a closer comparison of measured data is unfortunately rarely possible due to the fact that no detail information is available with respect to the mode of preparation etc. In general, however, it is evident that the distortion is dependent on mechanical properties of the solid phase itself, and at the same time on the shape and size of the pores and on the way of their mutual connection.

The question to what extent the pressure damages the sample and alters the pore size distribution is of utmost importance also for hardened cement pastes and concretes.

In the range of pore radii from 10 to 240  $\mu\text{m}$  results measured by mercury porosimetry were compared with those from light microscopy by Chekhovskii and Leirich /6/. Data obtained by these authors shown a reasonable agreement.

The investigation reported here was undertaken to examine the influence of high pressure on pore size distribution of pores with radii under 10  $\mu\text{m}$  in hardened cement paste.

The procedure was to determine the pore size distribution of a hardened cement paste by mercury intrusion and then to distill the mercury out of the sample and remeasure its pore size distribution. Comparison of these distributions will give an indication of any damage to the sample.

#### EXPERIMENTAL WORK

The sample selected for tests was a hardened cement paste prepared from cement with  $w/c = 0,45$ . After 7 days of the water curing specimens were dried to stop the hydration at the temperature 105  $^{\circ}\text{C}$  until they reach a constant weight. Dried specimens were crushed and granules of 2 - 3 mm in diameter were used for pore analysis.

Mercury intrusion tests on these specimens were performed with Carlo Erba porosi-

meter type 65A, capable of reaching pressures of 98,1 MPa.

Prior to intrusion the samples were outgassed at 135  $^{\circ}\text{C}$  for 7 hours under the vacuum of 0,20 Pa and were cooled to room temperature prior to loading in the porosimeter. The reason for such a temperature treatment was that after an intrusion test on a particular sample the residual mercury was removed under the same temperature and vacuum conditions.

Such a pretreatment seems to be reasonable and makes possible to differentiate changes due to temperature and due to high pressure itself. After an intrusion test a small portion of the mercury could not be removed by described technique. These samples were then retested in the porosimeter in the same manner.

For the conversion of the recorded data to pore size values cylindrical pore model was assumed. Surface tension of the mercury of 480 dyn/cm<sup>2</sup> and contact angle 140 $^{\circ}$  were assumed for calculation.

#### RESULTS

Figure 1 shows a set of mercury intrusion pore size distributions for a samples of hardened cement paste.

The curve for the "virgin" specimen /Curve A/ and the one remeasured after removal of the mercury /Curve B/ coincide the entire range of radii. The difference between the curves is comparable of even less than the experimental error.

#### CONCLUSIONS

The identical course of the integral porosity curves gives the evidence that the pressure up to 98,1 MPa has not caused measurable alteration in the sample.

## THEME VI

### $\text{Ca}(\text{OH})_2$ formation in air voids of cement pastes

#### *La formation des cristaux de $\text{Ca}(\text{OH})_2$ dans les vides des pâtes de ciment*

O.Z. CEBECI, Assistant Professor, Department of Civil Engineering, King Abdulaziz University, Jeddah, Saudi Arabia.

RESUME : Des recherches ont été faites sur l'influence des ambiances de cure, sur la formation des cristaux de  $\text{Ca}(\text{OH})_2$  dans les vides interstitiels des pâtes de ciment. Les pâtes ont été hydratées, puis conservées, soit sous enveloppe imperméable, soit en atmosphère saturée, soit immergées en eau pure ou en eau saturée en chaux. Quatre morphologies différentes de petits cristaux et de plaquettes de  $\text{Ca}(\text{OH})_2$  ont été observées au microscope électronique dans les géodes. Ceci indique que la chaux hydratée, libérée par la réaction d'hydratation du ciment, se dégage à l'intérieur des pâtes, sauf pour celles conservées en eau pure, parce qu'une partie de cette chaux migre hors de la pâte durcie.

SUMMARY : Effect of different curing media on the formation of  $\text{Ca}(\text{OH})_2$  crystals in air-voids of hardened Portland cement pastes was investigated. The pastes were hydrated in impermeable coating, humidity room, clean water and saturated lime solution. Four different morphology of deposits, ranging from small crystals to packing of  $\text{Ca}(\text{OH})_2$  plates, were observed in air voids by scanning electron microscopy. This indicated that  $\text{Ca}(\text{OH})_2$  liberated by hydration is accommodated within the pastes cured in impermeable coating, humidity room or saturated lime solution. However, curing of cement pastes in clean water may not faithfully duplicate the curing conditions of concrete in common construction practice, because part of  $\text{Ca}(\text{OH})_2$  liberated into pore solution is leached out of the hardened paste.

## INTRODUCTION

Scientists investigating the structure, properties and behaviour of hardened cement paste, mortar and concrete hydrate their samples in a variety of curing media. Furthermore, standard methods established by various institutions for testing mortar and concrete do not agree in a unique hydration practice. The most common hydration methods may be classified as follows:

1. Placing the fresh paste, with the original mixing water, in a sealed water-impermeable container (1,2).
2. Storing the samples in an environment of high relative humidity (3,4).
3. Keeping the hardened paste immersed in clean water (5,6).
4. Keeping the hardened paste immersed in saturated lime solution (7,8).

The first method is an ideal way of preserving the original water-cement mix for hydration but is not very practical especially for larger mortar and concrete specimens. The second and third methods aim at preventing the evaporation of the original mixing water, or supplying water for hydration, in an environment very similar to what common construction practice offers to concrete manufactured in the field. It is usually more convenient to immerse samples in water rather than storing them in moisture cabinets; however, calcium hydroxide liberated by the hydration of cement may be leached away from the hardened paste especially if fresh water has easy access to hydration products (9). A trend developing in recent studies is to hydrate the samples in a saturated lime solution, so that all hydration products are deposited within hardened pastes.

The present study is an attempt to evaluate the effect of different curing media on the formation of calcium hydroxide crystals in the air voids of air-entrained hardened Portland cement pastes. Scanning electron micrographs of the air voids showing various calcium hydroxide deposits are interpreted in order to help the designation of a practical curing method that faithfully represents the curing conditions of concrete in common construction practice.

## MATERIALS AND METHODS

Type I Portland cements from two different sources (an American and a Turkish factory) were used in this study. The cements were mixed with distilled water (containing commercial air-entraining agents) in a bench-top mixer at 0.5 and 0.6 water/cement ratios. The fresh pastes (containing about 6 % air by volume) were cast into glass test-tubes (diameter = 1.5 cm, height = 5 cm) and metal cubes (edge = 5 cm). The specimens were kept in a humidity room for 24 hours, then the hardened pastes were demolded. Further hydration took place under various conditions as follows:

1. HR curing in a humidity room at  $95 \pm 5$  % RH and  $23 \pm 2^\circ\text{C}$
2. SL curing by coating individual samples with an impermeable layer of epoxy.

3. FW curing in tap water by renewing the water every 2-3 days.
4. SW curing in tap water without changing the water.
5. CH curing in saturated lime solution.

SL, FW, SW and CH curing containers were also kept at  $23 \pm 2^\circ\text{C}$  in the same room as HR cured samples. After 60 days of hydration (130 days as well in case of CH curing) the hardened pastes were dried at  $105 \pm 5^\circ\text{C}$  for at least 24 hours and then broken into small pieces for visual and microscopic examination (using JEM-100 B JEOL/Jeolco, and Stereoscan S4-10, Cambridge Scientific Instruments).

## RESULTS AND DISCUSSION

Calcium hydroxide deposits observed in the air voids of hardened Portland cement pastes have been classified into four distinct morphologies shown in Figure 1. The differences in the source of cements, water/cement ratio, shape and size of specimens had no effect on the results. The voids containing the deposits (one in every 10-15 void) were randomly distributed through the cross-section of the samples.

Hydration of Portland cements is one of the major areas of great interest to cement chemists. Investigations of hydration mechanisms, hydrate structure and composition have revealed various features of calcium hydroxide crystals formed by the hydration of  $\text{C}_3\text{S}$  and  $\text{C}_2\text{S}$  (10). In general, calcium hydroxide liberated by hydration crystallizes from nuclei formed near or at the surface of cement particles (11) and surrounds air voids and aggregate particles (12,13).

In recent investigations, the interpretation of analytical data on pore solutions expressed from hardened pastes showed that these solutions are saturated with calcium hydroxide up to several months of hydration (11, 15, 16). Marchese observed calcium hydroxide plates in cavities of Portland cement pastes hydrated in tap water (5).

The results of this study implied that the crystals are deposited by capillary pore solutions saturated with calcium hydroxide (14). The solution penetrates air voids if there is a leak in the surrounding calcium hydroxide layer. In order to test this hypothesis some specimens were taken out of curing solutions and broken immediately. Optical examination of the fracture surfaces showed that the voids accommodating the deposits were filled with water whereas other voids contained neither deposits nor liquid.

The effect of curing media on the formation of deposits depends on two factors:

1. The degree of saturation of the pores with solution.
2. The degree of saturation of the pore solutions and curing solution with calcium hydroxide.

In case of SL and HR curing, the pores get unsaturated with solution as hydration continues but the solution is saturated with calcium hydroxide. Hence the result is small crystal deposition in air voids (Fig. 1-a), because the hydration products are accommodated in the vicinity of the reactants (11).

(a) HR and SL curing for 60 days

(b) FW and SW curing for 60 days.

(c) CH curing for 60 days.

(d) CH curing for 130 days.

Figure 1 - Electron micrographs showing calcium hydroxide deposits in air-voids of hardened cement pastes.

The pores are saturated with solution but the saturation of the curing solution with calcium hydroxide is limited in FW and SW curing. This increases the mobility of calcium hydroxide liberated by hydration (10); part of which is deposited within the hardened paste and in permeable air voids (Fig. 1-b); however part of calcium hydroxide is leached by curing water (9), and hence, further crystal growth in the voids is not possible.

Calcium hydroxide crystals in the air voids of CH cured pastes extended through the entire cross-section of the voids after 60 days of hydration (Fig. 1-c). The voids were packed with calcium hydroxide plates after 130 days of curing in saturated lime solution (Fig. 1-d). The pores of these samples are saturated with solution and the curing solution is saturated with calcium hydroxide. Thus, calcium hydroxide liberated into the pore solution is not leached but deposited within the hardened paste; many plates being easily accommodated in air voids.

Mortar samples were prepared according to the Rilem - Cembureau procedure, and cured in humidity room, water and saturated lime solution for 60 days. The

compressive strengths were determined as 29.31 MPa for both FW and SW cured samples and 38.04 MPa for CH cured mortars. HR curing is known to develop less strength than water curing (10). The decrease in the strength of samples cured in water (as compared to the strength of samples cured in saturated lime solution) is regarded as another demonstration of the fact that some calcium hydroxide liberated by hydration is leached away from these samples by the clean curing water.

#### CONCLUSION

The difference in the morphology of calcium hydroxide crystals deposited in air voids of hardened cement pastes hydrated in different curing media indicated that calcium hydroxide liberated by hydration is accommodated within the pastes cured in humidity room or in saturated lime solution, whereas part of calcium hydroxide is leached by curing water if the pastes are hydrated in clean water. Hence curing of cement pastes in clean water may not faithfully duplicate the curing conditions of concrete in common construction practice.

## Low temperature calorimetry as a pore structure probe

### *Détermination de la structure des pores, par calorimétrie à basse température*

Erik J. SELLEVOLD and Dirch H. BAGER, Building Materials Laboratory, Technical University of Denmark, DK-2800 Lyngby, Denmark.

#### Summary

Heat flow during cooling and heating of water saturated porous building materials have been measured at temperatures down to  $-100^{\circ}\text{C}$ . The relationship between freeze/thaw temperature and pore size is discussed. A number of experimental results, mostly on cement pastes, are given to illustrate the ability of low temperature calorimetry to detect pore structural differences.

RESUME : Des mesures ont été faites jusqu'à des températures inférieures à  $-100^{\circ}\text{C}$ , sur les flux de chaleur, dans les pores saturés d'eau des matériaux de construction, lors de cycles de refroidissement et de réchauffement. Une relation entre la température de gel et la dimension des pores a été établie et discutée. Un grand nombre de résultats expérimentaux, obtenus principalement sur des pâtes de ciment, sont donnés pour illustrer cette aptitude de la calorimétrie à basse température à détecter des différences dans la structure des pores.

## Introduction

Since 1976 a large number of calorimetric measurements of ice formation in porous building materials have been carried out at our laboratory. The experimental equipment, procedures, and a number of results have been reported previously (1, 2). In a recent report (3), calorimetric data with implications for frost resistance testing of concrete are discussed.

The present paper presents results on water saturated specimens which illustrate the potential of low temperature calorimetry as a pore structure probe. For cement products we regard this application of calorimetry as important since it may be applied without first drying the test specimen. Other types of experiments have shown that drying of hydrated cement products results in changes in their pore structures, but, as shown in this report, calorimetry provides particularly clear evidence of the character and magnitude of these changes.

## Pore Size - Freezing Point of Pore Water

The Kelvin equation relates the meniscus radius of capillary condensed water to the relative vapor pressure it exerts. An analogous equation, given by Defay et al. (4), relates the meniscus radius to the freezing point of the water. Both equations are shown in diagram form in Figure 1. If it is assumed

Figure 1. The Kelvin equation (top). The relationship between meniscus radius of capillary condensed water ( $r_K$ ) and freezing point (bottom) for two interface possibilities.

that the contact angle between water condensed in circularly cylindrical pores and the pore wall is zero, both with and without ice in the pore system, then the meniscus radius may be set equal to the pore radius, and Figure 1 may be used to interpret calorimetric ice formation data in terms of pore sizes. For example, assuming that the ice-water interface controls the state of stress in the unfrozen water, then according to Figure 1, the amount of ice formed to  $-5^\circ\text{C}$  is equal to the volume of pores with radii greater than about 11 nm (110 Å). The geometric assumptions are necessary, but not very realistic. The spreading of the ice front through a pore system with variable cross sections would be controlled by the narrowest parts: the necks. The melting of ice in such a pore system, on the other hand, would be controlled by the size of the pores rather than of the necks. Hence, the hysteresis between cooling and heating curves gives information about the continuity of the pore system.

It should be emphasized that both the calculation of amounts of ice from calorimetric data, and the interpretation of freezing temperatures in terms of pore sizes are based on many assumptions. The results must therefore not be taken too literally. In particular, simple capillary theory is only applicable in pores very large compared to the size of the water molecule. At  $-10^\circ\text{C}$  (see Fig. 1) the pore diameter is about equal to 40 molecular diameters; possibly not a "very large" number in this connection. Everett (5) suggests that such application of capillary theory is questionable below about 300 molecular diameters. Calculated pore size data are therefore most realistic at large pore sizes (high freezing temperatures). It should also be pointed out that pore size data calculated from sorption isotherms or mercury penetration are subject to many of the same uncertainties mentioned above.

## Experimental

Heat flow has been measured using a Low Temperature CALVET Micro-Calorimeter. The measurements are carried out in a scanning mode in the temperature range down to about  $-55^\circ\text{C}$ . Experiments have shown that practically no freezing takes place below this temperature. In a "normal" experiment heat flow data is collected during both cooling at  $3.3^\circ\text{C/hr}$  and heating at  $4.1^\circ\text{C/hr}$ .

The test specimens are in the form of circular cylinders with  $d \approx 15$  mm and  $l \approx 70$  mm. During an experiment the specimens are enclosed in an airtight stainless steel specimen cell, slightly larger than the specimens.

During early experiments no freezing took place (even with pure water) at temperatures greater than about  $-10^\circ\text{C}$ . The amount of super cooling was later reduced substantially by sprinkling a few mg's of AgI powder on the specimens.

The calorimeter block temperature differed of course somewhat from the specimen temperature during a test; separate experiments showed the lag to be  $0.4$  to  $0.8^\circ\text{C}$  in "normal" runs and during periods of small freeze/thaw activity, while the lag could reach several degrees during periods of high activity.

## Results and Discussion

Figure 2 shows the cumulative amounts of ice versus temperature for several water saturated materials. The curves are in qualitative agreement with our knowledge of the different pore structures; a) the standard clay brick contains large pores ( $\mu\text{m}$  range) and a very small surface area - all the pore water is freezable and freezes right after nucleation; b) the autoclaved, aerated concrete has a very large macroporosity - but also a finely divided C-S-H product with a large surface area to water. This is reflected in the freezing curve, in that there is gradual freezing down to about  $-50^\circ\text{C}$  and not all the pore water is able to freeze; c) the two mature cement pastes display very gradual freezing and at  $-55^\circ\text{C}$  only ~15% ( $w/c = 0.40$ ) and 63% ( $w/c = 0.70$ ) of the evaporable water is able to freeze.

Figure 2. Cumulative ice formation ( $W_f$ ) curves for water saturated building materials. Dotted lines indicate total evaporable water content ( $W_{es}$ ) for the materials Cool  $3.3^\circ\text{C/hr}$ .

Figure 3 shows cool and heat results for water saturated mature cement pastes. Equivalent results are shown in (1), but no AgI powder was used, which resulted in nucleation temperatures several degrees below the present ones. It is noteworthy that only a few mg's AgI powder sprinkled on the specimen surface is able to trigger ice formation in the whole specimen volume. We therefore believe that freezing takes place by the spreading of an ice front through the pore system from a few nucleation points on the surface.

w/c	Age	$W_{es}$	$W_f (-55)$	$W_{nf} (-55)$
.4	486	.213	.030	.183
.5	675	.305	.099	.206
.6	548	.379	.184	.195

Age = days of water curing

$W_{es}$  = evaporable water content at saturation

$W_f$  = frozen water content

$W_{nf}$  = non-frozen water content

All units of g/gdry.

Figure 3. Heat flow during cooling and heating for mature water saturated cement pastes. Cool  $3.3^\circ\text{C/hr}$ . Heat  $4.1^\circ\text{C/hr}$ .

The main features of the two sets of curves are similar, in spite of the different degrees of supercooling. The large hysteresis between cool and heat, and the "trimodal" nature of the cooling curves indicate the existence of restrictions or necks in the pore system in certain size ranges. The heating curves are more gradual and almost unimodal, indicating a pore size distribution of the same nature. Some details of the curves in Figure 3 differ from the previous results. Based on numerous experiments it is clear that the details of the freezing response of virgin cement pastes are quite sensitive to minor variations in w/c ratio, degree of hydration, and probably other variables. However, the main features, including the amount of "non-frozen" water at  $-55^\circ\text{C}$ ,  $W_{nf}(-55)$ , change in a very consistent manner with the main structural parameters of cement pastes.

The influence of curing time on pore structure development is shown in Figure 4, (6). After one day of curing almost all the ice forms right after nucleation, indicating few small pores. However, even in this young specimen  $W_{nf}(-55)$  is about 30% of the evaporable water. The high values of  $W_{nf}(-55)$  for cement pastes (see also Figure 1) are indications of the extreme fineness of the hydration products, whether this water is surface adsorbed, interlayer or gel water. Based on the calorimetric results the evaporable water may be divided into the categories "non-frozen" and "frozen". The cooling and heating curves both give information on the size distribution of the pores containing the latter type of water. These categories of water appear analogous to the traditional "gel" and "capillary" types proposed by Powers. The quantitative relationship between the two descriptions will be given in a future publication.

Units g/g<sub>dry</sub>. Symbols: see Figure 3.

Figure 4. Heat flow during cooling for water saturated cement pastes. 3.3° C/hr.

The curing temperature is known to have a significant influence on the pore structure of cement pastes. That this influence is large is illustrated by the calorimetric data given in Figure 5 for pastes cured at 22° C and 97° C.

The influence of  $CaCl_2$  used as an admixture to cement is illustrated in Figure 6. The total frozen and non-frozen water contents are not very different for the two specimens, but the freezing generally takes place at lower temperatures in the specimen mixed with  $CaCl_2$ . Length change data during cooling for companion specimens are included in Figure 6, to illustrate the qualitative correspondence between calorimetric and dilatometric freezing behavior. Other

Symbols: see Figures 3 and 4.

Figure 6. Heat flow (top) and length change (bottom) for water saturated cement pastes made with and without  $\text{CaCl}_2$ . No AgI used.

The "instability" of the pore structure in the virgin cement paste is shown in Figure 7. Two heat flow curves are shown in the figure; one for a virgin specimen (the curve is also shown in Figure 1), and one for a companion specimen slowly dried to 58% relative humidity over a period of one year and then resaturated. Two major changes are caused by the drying-resaturation treatment: 1)  $W_{nf}(-55^\circ\text{C})$  is decreased, i.e. more water is frozen, and 2) most of the frozen water freezes right after nucleation. The magnitude of these effects depend primarily on the drying time as long as drying takes place below about 60% relative humidity. More results will be published in the near future.

	$W_{es}$	$W_f(-10)$	$W_f(-55)$	$W_{nf}(-55)$
a	.379	.029	.184	.195
b	.378	.195	.219	.159

Symbols: see Figures 3 and 4.

Figure 7. Heat flow during cooling for a mature virgin and water saturated cement paste (a), and a companion specimen slowly dried to a water content of 0.148 g/g dry at 58% relative humidity before resaturation (b). Cool  $3.3^\circ\text{C/hr}$ .

An example of the relationship between cumulative pore size distributions derived from calorimetric (CAL) and mercury penetration (MIP) tests is shown in Figure 8. All tests were made on companion samples of mature cement mortar. The MIP specimens were dried at  $92.5^\circ\text{C}$  in the standard manner, as

were the resaturated CAL specimen before resaturation. The CAL curves were calculated assuming that the solid-liquid interface controls the freezing-melting process, see Figure 1. The curves are only calculated up to about  $-5^\circ\text{C}$ . Above this temperature the rate of heat flow is too high during both cool and heat at our standard rates to treat the curves as equilibrium curves. We have not yet carried out calorimetric runs sufficiently slowly to allow calculation of distribution curves above  $-5^\circ\text{C}$ , but it is quite possible to do so.

Figure 8. Cumulative pore size distribution curves for cement mortar calculated from mercury intrusion (MIP) and low temperature calorimetry (CAL). The mortar is mature and has a w/c ratio of 0.50. The evaporable water content was the same for all three specimens and equal to 0.093 g/g dry. See text for further details.

Figure 8 shows that there is much better agreement between MIP and CAL curves when the comparison is made for specimens treated the same way; a natural consequence of the drying-resaturation effect.

The cool-heat hysteresis is reduced by the drying-resaturation treatment, but it is still substantial. We have other experimental evidence showing that long-time drying reduces the hysteresis much further, suggesting that the "necks" are eliminated and thereby the continuity in the pore system increased.

## THEME VII

### Sulphate expansion of cement products made with aggregates containing Ca-rich feldspars

#### *Gonflement sous l'action des sulfates des ciments en contact avec des granulats calcaires riches en feldspath*

J.H.P. VAN AARDT and S. VISSER, National Building Research Institute, CSIR, Pretoria, South Africa.

SUMMARY : Work undertaken indicates that at 22°C and 40°C, cement products made with sulphate resisting portland cements and aggregates containing Ca-rich feldspars, show expansion in a 5 per cent sodium sulphate solution. There is more expansion at 40°C than at 22°C. The vulnerability to sulphate attack is probably due to the fact that Ca-rich feldspars in the aggregate and the  $\text{Ca(OH)}_2$  of the cement react to form  $\text{C}_4\text{A}$ -hydrates which in turn form ettringite in the presence of sulphates.

RESUME : L'étude ci-après montre qu'à 22 et 40° les pâtes de ciment faites avec des ciments résistant aux sulfates, et avec des granulats de calcaire riche en feldspath, gonflent lorsqu'elles sont plongées dans une solution de sulfate de soude à 5 %. Le gonflement est plus fort à 40°C qu'à 22°C. Cette vulnérabilité à l'attaque des sulfates est probablement due au fait que les calcaires riches en feldspath et la chaux hydratée du ciment réagissent pour former des hydrates  $\text{C}_4\text{A}$ , qui, à leur tour, donnent de l'ettringite en présence de sulfates.

## INTRODUCTION

It has been indicated (1,2) that feldspars react with calcium hydroxide in the presence of water. At 95°C the reaction products are the silica-containing hydrogarnet, hydrated calcium silicates and alkalies. At 39°C the alkali-feldspars produce tetracalcium aluminate hydrates, alkalies and/or calcium alkali silicate hydrates; the calcium-rich feldspars produce substantially more tetracalcium aluminate hydrates. At 22°C small amounts of the tetracalcium aluminate hydrates were detected at early ages (26 days) and substantial amounts at later ages (760 days). The tetracalcium aluminate hydrates thus formed reacted with CaSO<sub>4</sub> to form ettringite (3). Recent experiments with aggregates containing a Ca-rich feldspar seem to substantiate that the use, in the presence of sulphates, of such aggregates in mass concrete which is likely to remain continually damp and which is not likely to become carbonated, in the long term might cause distress.

## EXPERIMENTAL

The rock called "norite" used in these experiments is a medium coarse grained gabbro, grey in colour, consisting mainly of labradorite and augite optically intergrown. The augite shows twinning in seams. The feldspar shows slight sericitization.

The cements that were used, are an ordinary portland cement (OPC) and various sulphate resisting portland cements (SRPC).

The compound composition of the cements and their chemical analysis as well as the chemical analysis of the crushed norite are given in Table I.

The preparation, storage and examination of mortars made are described by van Aardt (4). Where crushed stone was substituted for natural sand the crushed material was screened and recombined to provide the same grading.

The grading of the crushed stone and of the siliceous sand, the various cements used, the curing conditions and other relevant information are given in Table II.

Since sulphate attack of portland cement concretes and mortars is usually accompanied by an expansion the dimensional change of experimental prisms of mortar and concrete were measured during storage in a sulphate solution. The dimensions of the mortar prisms were 25 x 25 x 281.25 mm and those of the concrete prisms 50 x 50 x 280 mm. The results for the mortar prisms are presented in Figures 1 and 2. Figure 3 shows the expansion observed for concrete prisms stored in a 5 per cent Na<sub>2</sub>SO<sub>4</sub> solution at 22°C. The prisms were made with a sulphate resisting portland cement, sand and crushed norite as coarse aggregate in the ratio 1:2.53:3.40.

## DISCUSSION

After it was established that Ca-rich feldspars react with  $\text{Ca(OH)}_2$  and  $\text{CaSO}_4$  to give ettringite, experiments with mortar prisms made with aggregate containing these feldspars, were started. In an attempt to rule out the role of  $\text{C}_3\text{A}$  in the cement, sulphate resisting cements (SRPC) were used. Expansion of specimens at  $40^\circ\text{C}$ , led to further experiments with various SRPC and ordinary portland cements (OPC) at 22, 40, 50 and  $80^\circ\text{C}$  and in 5 per cent sodium sulphate solutions as well as with saturated sodium sulphate solutions.

At  $80^\circ\text{C}$  none of the specimens in a solution of 5 per cent  $\text{Na}_2\text{SO}_4$  showed expansion. This is thought to be due to the fact that the reaction product at this temperature between Ca-rich feldspar and  $\text{Ca(OH)}_2$  is the silica-bearing hydrogarnet which shows resistance to sulphate attack (5). The hydrated products of cement are also different from those formed at  $22^\circ\text{C}$ . This aspect has been discussed in literature (6). The results obtained were therefore to be expected.

At  $40^\circ\text{C}$  the specimens made with norite and SRPC showed a marked expansion. Those made with OPC of course showed more severe expansion than those made with sand and OPC. Specimens made with sand and SRPC showed no expansion, see Figures 1, 2(a) and 2(b).

FIG. 1: Expansion at  $40^\circ\text{C}$  in 5%  $\text{Na}_2\text{SO}_4$  of prisms made with crushed norite fine aggregate and SRPC: K.

At  $22^\circ\text{C}$  the specimens made with norite and SRPC and also those made with sand and SRPC showed little or no expansion after 300 days. However, this exposure time appears to be too short for the prisms made with norite to show expansion because a concrete specimen made with norite (coarse aggregate) and a SRPC showed an expansion of 0.2 per cent after 1000 days at  $22^\circ\text{C}$ , see Figure 3.

FIG. 2(a) & (b): Expansion at  $22^\circ\text{C}$  and  $40^\circ\text{C}$  in 5%  $\text{Na}_2\text{SO}_4$  of prisms made with OPC: A and SRPC: G and S.

(a) Siliceous sand and (b) crushed norite fine aggregate

FIG. 3: Expansion at  $22^\circ\text{C}$  in 5%  $\text{Na}_2\text{SO}_4$  of a concrete prism made with norite coarse aggregate, sand and a sulphate resisting portland cement.

The specimens made with OPC and sand expanded less at  $40^\circ\text{C}$  than at  $22^\circ\text{C}$ . This observation has also been discussed in the literature (6). However, specimens made with norite and OPC expanded more at  $40^\circ\text{C}$  than at  $22^\circ\text{C}$ . It is concluded that a rise in temperature favours the reaction between the Ca-rich feldspar and  $\text{Ca(OH)}_2$  to produce the  $\text{C}_4\text{A}$ -hydrates in such quantities that with the addition of sulphate, large amounts of ettringite is formed thus causing distress.

Specimens made with norite and OPC which were stored at 50°C in a saturated sodium sulphate solution expanded excessively, and disintegrated completely after 500 days. Large quantities of ettringite were detected. Specimens made with norite and SRPC showed similar expansion curves as were obtained for specimens stored at 40°C in 5 per cent Na<sub>2</sub>SO<sub>4</sub>. Specimens which were made with sand and either OPC or SRPC showed little expansion in the saturated sodium sulphate solution.

It is interesting to note that the specimens made with norite and SRPC expanded as much as 1.2 per cent in 1000 days without disintegrating although cracks were clearly visible. Normally if mortar specimens made with sand and an OPC with a high C<sub>3</sub>A content expand, the expansion is usually accompanied by some localized disruptive cracks while the rest of the specimen still appears to be sound. It appears that in the case of norite mortar the expansion is more general around the grains causing the whole body to expand while in the case of a high C<sub>3</sub>A-OPC cement and sand the expansion is more disruptive at localized cracks.

This leads to the thought that exposed surfaces i.e. surface areas play an important role in the reaction between aggregate and the available Ca(OH)<sub>2</sub> from the cement and sulphate from an external source. Of course substantial quantities of C<sub>4</sub>A-hydrates had been observed after 760 days in slurry mixtures of powdered anorthite and Ca(OH)<sub>2</sub> stored at 22°C. See Figure 4.

## THEME VII

### Microtexture et résistance mécanique du ciment durci *Microtexture and mechanical resistance of hardened cement*

CHTCHOUROV A.F., Docteur ès Sciences Techniques à l'Université de Gorki, U.R.S.S.

**RESUME :** A l'heure actuelle il n'existe pas de théorie physique de la déformation et de la destruction du ciment durci. L'une des causes principales qui empêche la construction des modèles physiques de la microtexture réside dans le fait que les données expérimentales absolument sûres pour le domaine de 10 à 1000 Å constituant le maillon intermédiaire entre la structure cristallochimique et la microstructure font malheureusement défaut. Le domaine des hétérogénéités (particules et pores) des produits hydratés des minéraux de ciment inférieur à 1000 Å reste pratiquement inexploré et fait l'objet des discussions. En outre la clarté sur les mécanismes de la destruction et leur relation avec la texture à l'échelle microscopique n'est pas encore faite.

Les techniques physiques d'analyse telles que la diffraction et diffusion centrale des rayons X, la microscopie électronique et la porosimétrie à mercure, des éprouvettes hydratées dans les différentes conditions ont permis d'obtenir les données statistiques sur la microtexture et la microporosité de la pâte durci correspondant aux silicates hydratés et à un ciment Portland.

De nombreuses études, par émission acoustique et par fractographie électronique sur la fissuration des éprouvettes de pâte et de béton sous l'action de contraintes mécaniques, ont montré le rôle joué par la microtexture et ont permis de déduire la dépendance entre la résistance mécanique et des caractéristiques statistiques de texture de la pâte hydratée.

**SUMMARY :** The field of heterogeneties (particles and pores) of the cement minerals hydration products less than 1000 Å is practically not investigated and considered to be the subject of discussion. Besides, the destruction mechanism and its relationship with the texture on the microscopic level are not clear.

Physical analysis methods, such as diffraction and central diffusion of X-rays, electronic microscopy and mercury porosimetry, and also specimen, hydrated under different conditions made it possible to get statistic data about the microtexture and microporosity of hardened paste, that correspond to hydrated silicates and Portland cement.

Numerous investigations, with the help of acoustic emission and electronic fractography, of cracks formation in paste and concrete specimen under the influence of mechanic stresses, showed the role of microtexture and allowed to state the mechanic resistance dependence on statistic structural characteristics of hydrated paste.

Nous proposons dans le présent rapport de présenter les résultats de l'analyse de la microtexture du ciment durci et de montrer l'interdépendance des caractéristiques structurales et de la résistance. Pour l'étude des systèmes monophasés les principaux minéraux de ciment et leurs mélanges avec du sable quartzeux moulu ont été sélectionnés comme matériaux d'origine. La modification du rapport c/s, de même que des conditions du durcissement par autoclave a permis d'obtenir des structures presque monophasées de différente composition.

Pour l'examen de la pierre de ciment Portland nous avons fait appel à des ciments industriels. La modification de la texture a été réalisée dans une large plage des valeurs E/C, par l'emploi des additions chimiques et le changement des conditions de température et d'humidité du durcissement. Nous avons choisi pour notre travail les additions chimiques qui sont bien connues pour leur pouvoir modificateur le plus efficace:  $AC\ 1\%Na_2SO_4 + 1\%CH_3COONa + 0,2\%CDB$  et  $NNC\ 1,5\%Ca(NO_3)_2 + 1,5\%Ca(NaO_2)_2$ . L'analyse complexe de la microtexture a englobé les méthodes suivantes: diffractométrie des rayons X (DRX), adsorption de l'azote à basse température (BET), porosimétrie à mercure (PM) et microscopie électronique

ME La submicrotexture a été explorée par la diffusion centrale des rayons X (DCRX). Afin d'obtenir les caractéristiques statistiques une méthode des cordes a été développée et mise en pratique au moyen d'une calculatrice électronique (1 - 3).

En ce qui concerne le mécanisme de l'hydratation de départ des minéraux de ciment, il avait été exposé dans le travail de l'auteur(4). En vue de présenter de façon précise le modèle de formation du ciment durci nous avons mesuré les dimensions moyennes des cristallites et des degrés d'hydratation aux étapes diverses du durcissement. La périodicité du mécanisme de l'hydratation, liée à la formation des textures primaires sur la surface des particu-

les, s'est observée par la méthode électrochimique dans des conditions des rapports élevés E/C (jusqu'à 80), le pH de la solution étant en variation (S).

Ces données mettent en évidence que la croissance du cristallite élémentaire se fait directement sur la surface du grain de ciment à partir d'un centre actif; dans beaucoup de cas on peut observer les textures dans lesquelles certains cristaux élémentaires se dirigent radialement vers le centre.

Les données DCRX (tableau I) décelent que les éléments texturaux primaires sont des microcristallites aux dimensions de 20 à 60Å de section et de 100 à 600Å de longueur. Un tel cristallite, croissant depuis le centre actif et ayant atteint une certaine longueur, peut être adsorbé par la surface d'un autre grain ou bien se heurter et se souder avec un autre cristal élémentaire. L'apparition de ces actes engendre la formation par contact entraînant la croissance d'origine du module élastique.

Dès que le paquet de cristallites primaires s'opposera à la naissance des nouvelles mailles de la chaîne, les forces élastiques des chaînes en croissance le chasseront de la surface du grain. Par la suite il peut migrer dans l'espace poreux. Dans l'ensemble ce phénomène apparaît comme la désagrégation de la couche d'origine du silicate - hydraté bas moléculaire (de haute base). Si les cristaux du silicate hydraté se trouvent dans la solution ils se transforment en textures surmoléculaires secondaires. De tels pseudocristallites agrégés sont étalés aux stades avancés de  $10^3$  à  $10^4$ Å et sont bien vus sur les photos DCRX.

Par suite du durcissement prolongé à haute température des mélanges on voit apparaître la recristallisation qui fait naître des hydrates dont la microtexture est fonction de la composition, de la température et du temps. Dans le présent travail nous avons exploré les textures surmoléculaires et la

résistance de certains silicates hydratés du calcium et du ciment durci Portland (tableau I).

La diffusion centrale des rayons X est une méthode qui a de bonnes perspectives d'avenir pour l'examen de la texture à fine porosité du gel de ciment et qui permet ensemble avec les méthodes ME et PM d'obtenir l'assortiment le plus complet de caractéristiques structurales statistiques.

les courbes  $p(l)$  avec des maximums dans le domaine de 10 à 12 Å et les tailles des cristallites aux environs de 50 à 60 Å correspondent aux silicates hydratés mal cristallisés de type C-S-H dont les diffractogrammes sont démunis de pics sélectifs. En d'autres termes, dès que les couches élémentaires, parallèles à (001) deviennent ordonnées, la part des cordes de longueur de moins de 15 Å diminue fortement dans la

L'examen en commun des images de diffraction des rayons X des silicates hydratés de type tobermorite (fig.1b) et des courbes de distribution des cordes  $p(l)$  (fig.1c) révèle qu'elles sont étroitement liées ce qui réside dans le fait qu'elles reflètent l'état dispersif du système. Les distributions  $p(l)$  avec des maximums dans le domaine des pores de grandes tailles et les gros cristallites (tobermorite 11Å) correspondent aux cristallahydrates parfaits, tandis que

distribution  $p(l)$ ; et vice versa, le maximum est déplacé vers le domaine de 10 à 12 Å lorsque la structure périodique se détériore. De là découle que les cordes, définies par la méthode DCRX, sont des segments de droite, situés entre les faces de vrais cristallites qui sont composés, eux-mêmes, de couches élémentaires parfaitement paquetées. L'évacuation de l'eau de coordination conduit à un réarrangement de la microtexture, à la formation de pores de

Fig.1.-Alternance des cordes  $l$  et  $t$  du modèle de la microtexture (a), enregistrement diffractométrique (b), courbes de distribution des cordes d'après la longueur dans l'espace poreux (c): 1 et 2 - silicates hydratés semi-cristallins C-S-H(II) et C-S-H(I) respectivement; 3 - tobermorite 11 Å.

plus grande taille, de même qu'aux résultats appropriés sur les diagrammes des rayons X à petits angles. Certains éléments structuraux de grande taille, explorés dans les textures C-S-H avec la microscopie électronique, sont généralement des cristallins imparfaits, de faux cristallites, c-à-d des agrégats (paquets, etc) de petits cristallites primaires entre lesquels il y a des espaces intercristallins. De tels pores sont exclusivement décelés par la méthode DCRX. La nature des courbes de dis-

tribution des longueurs de cordes dans l'espace poreux du gel de ciment varie de façon notable en fonction des conditions de durcissement et de la présence des additions chimiques. La hausse de la température de durcissement déclenche la croissance des pores de la taille moyenne et des cristallites du gel. L'usage des additions rend impossible la croissance de gros cristallites primaires et favorise la formation d'une texture bien ordonnée lors du traitement de température et d'humidité du ciment durci.

L'analyse des données de distribution des pores et des cristallites d'après leur taille a montré que chaque rang de texture surmoléculaire est doté d'une porosité particulière, c-à-d il a son rang de pores. Les textures du ciment durci, examinées lors du travail, comportent principalement deux rangs de textures surmoléculaires et trois rangs de pores: a) le rang nul de pores ( $i=0$ ) est limité par la taille des cristallites primaires ( $l \leq t$ ); b) le premier rang de pores ( $i=1$ ) est limité par la taille des textures surmoléculaires primaires et secondaires ( $t < l \leq t_m$ ); c) le second rang de pores ( $i=2$ ) n'est pas directement lié aux textures surmoléculaires et est déterminé par les facteurs technologiques ( $l > t_m$ ).

Les variations des rapports entre les volumes des pores de gel et capillaires, qui s'observent lors du changement des conditions de durcissement, sont dues au réarrangement des textures surmoléculaires. La taille de seuil, observée dans la distribution des pores d'après la taille dans le ciment durci (6), dépend de celle des textures surmoléculaires secondaires.

L'observation du micromécanisme de la destruction, faite à l'aide de la fractographie électronique et de l'émission acoustique, a permis d'établir le rôle que des éléments structuraux jouent dans la désagrégation du ciment durci. La naissance et la croissance des fissures de cisaillement au sein de la texture cristalline constituent le microméca-

nisme essentiel à l'échelle cristallographique. Le travail, indispensable à la formation du relief de fissure sous forme de degrés et aux déformations plastiques locales apporte la contribution la plus importante à l'énergie efficace des destructions ( $\gamma^*$ ) (tableau II). L'influence de la taille des textures secondaires sur la résistance à la compression peut être exprimée par le critère modifié Griffith-Orowan:

$$R_c = K_c t_m^{-1/2} (1 - p)^n,$$

où  $P$  - porosité,  $K_c = (E \cdot \gamma^*)^{1/2}$  - coefficient d'adhérence,  $t_m$  - taille maximale des formations surmoléculaires secondaires,  $n$  - a des valeurs de 2,5 à 4,5.

Tableau II

Valeurs des coefficients d'adhérence  $K_c$  et de l'énergie efficace de destruction

Ciment durci	E/C	Durcissement normal 28 j.		Vaporisation à 80° C 3-6-10 heures	
		$K_c, N/m^{3/2}$ 10 <sup>4</sup>	$\gamma^*, J/m^2$	$K_c, N/m^{3/2}$ 10 <sup>4</sup>	$\gamma^*, J/m^2$
sans additions	0,25			45,0	3,05
	0,30	45,5	4,2	40,0	2,90
	0,35	37,6	3,2	30,7	2,10
	0,40	-	-	23,6	1,70
AC	0,30	43,2	3,8	45,3	3,80
	0,35	-	-	37,9	3,20
NNC	0,30	12,7	3,5	48,9	4,35
	0,35	-	-	39,4	3,70

A la différence de la fissure de compression celle de traction, qui apparaît sur le contour d'un gros défaut, se développe de façon instable dans le plan normal à la direction de la force appliquée tout en divisant presque instantanément l'échantillon en fragments. Aussi la résistance à la traction du ciment durci est-elle contrôlée par la taille du défaut le plus dangereux ( $d$ ) du point de vue de son pouvoir générateur de ruptures et déterminée par la formule:

$$R_p = K_c d^{-1/2}$$

Le modèle mathématique constitue un élément inséparable des essais de matériaux sans lequel il est impossible de planifier l'expérience technologique quelle que soit sa

nature. Le rôle de la texture poreuse dans la destruction a été profondément étudié dans le cadre de la mécanique de la destruction fragile, se basant sur le modèle du solide poreux fissuré, proposé par Panasuk V.V. et développé par Goldchtein P.V. et autres. Le modèle tient compte de l'interaction de toutes les fissures considérées qui atteignent le contour des pores voisins. Le modèle généralisé comprend la notion de rangs de pores: le rang nul n'a presque aucune influence sur la résistance; le premier rang est détérioré par suite de la fusion des pores de rang supérieur des champs locaux de surcharge; le second rang conditionne la naissance et la croissance des fissures instables.

La valeur limite de l'effort de compression  $q$  est déterminée par la condition où la composante de contraintes  $\sigma_y$  (l'effort de traction sur l'axe aux environs du pore), normale à la surface de fissure, satisfait à l'expression asymptotique:

$$\lim_{a \gg x \rightarrow 0} \sqrt{|x - a|} \sigma_y = \frac{K_c}{\sqrt{r}}$$

Le critère de la destruction locale pour les fissures de rupture normale  $K = K_c$  permet d'établir la dépendance de la charge limite  $q_c$  de la longueur de la fissure.

En vue de calculer les charges critiques de compression et celles de traction pour les paramètres différents de texture poreuse nous avons mis au point un algorithme et un programme pour la calculatrice électronique. Les résultats des calculs de la charge limite réduite  $q_c \sqrt{r}/K_c$  en fonction de la longueur réduite de la fissure interne  $l_1/r$  sont représentés à la fig. 2a.

Le modèle mathématique de la micromécanique destructive du silicate poreux permet de faire des estimations quantitatives des points paramétriques de la destruction avec l'application des caractéristiques de la microtexture poreuse. En outre, le modèle permet de révéler les régularités importantes du comportement d'un matériau cassant

poreux sous charge en fonction de sa texture réelle.

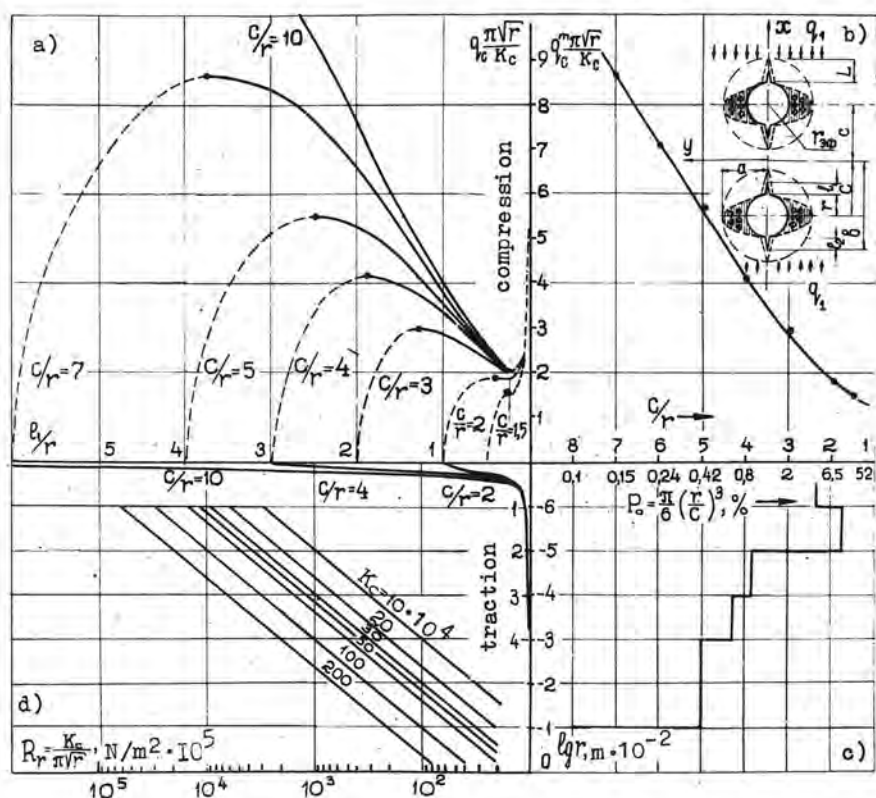

Fig. 2. Graphiques pour le modelage de la destruction du matériau poreux: a - interdépendances de la longueur de la fissure et de la charge; a - modèle du solide poreux et relation des charges maximales aux porosités partielles; c - distribution des porosités partielles suivant les rayons; d - dépendance du paramètre de résistance  $R_r$  du rayon des pores et du module d'adhérence.

1. La destruction globale instable du matériau poreux à la compression simple est due à la naissance des fissures magistrales, donnée par la fusion des pores séparés. La contrainte critique, qui assure la fusion des pores, dépend fortement de la porosité (fig.2) ce qui indique d'emblée le sens physique de la relation empirique bien connue "résistance-porosité" (7).

2. La valeur de la contrainte limite de traction est déterminée par la longueur des fissures d'origine paraissant sur le contour des pores, et dépend de la porosité faiblement. Des graphiques fig. 2a, vient que l'augmentation de la porosité fait accroître le rapport  $R_c/R_p$  ce qui est prouvé

par l'expérience.

Les deux premières conséquences mettent en évidence que les microfissures technologiques de retrait et d'autres réduisent de façon importante la tenue à la traction et sont presque négligeables pour la tenue à la compression.

3. La fusion des pores de rang inférieur des matériaux poreux aux rangs multiples ayant lieu aux endroits de concentration des contraintes (aux environs des pores de rang supérieur) n'entraîne pas de destruction globale, mais diminue la contrainte critique ce qui donne naissance aux fissures magistrales dans les pores de rang supérieur.

Le rôle primordial de la porosité capillaire et du diamètre de seuil dans la résistance du ciment durci, établi expérimentalement dans le travail (8), consiste en ce que les pores capillaires adhèrent, à partir du diamètre de seuil, au système de gros pores bulleux tout en formant avec ceux-ci une texture de destruction auto-entretenu à rangs multiples.

4. Les pores et les microfissures qui ne quittent pas les formations surmoléculaires secondaires (pour le ciment durci ce sont les pores de gel ou ceux de rang zéro) ont influence faiblement sur la résistance du ciment durci ce qui est dû au fait que leur croissance est stoppée par la texture cristalline du matériau.

5. Le module d'adhérence est généralement déterminé par les paramètres cristallochimiques et les caractéristiques de la microtexture.

Dans notre travail la vérification expérimentale des régularités principales, résultant du modèle physique de la destruction a été réalisée sur un grand nombre de silicates poreux à nature différente de la liaison chimique.

## SEMINAIRE A

### Rôle du $C_3A$ sous toutes ses formes dans l'hydratation des ciments et leur attaque par les sulfates

Président : Mme REGOURD (France)

Les 27 communications présentées par 52 auteurs au Séminaire sur l'aluminate tricalcique ont été réparties dans cinq grands thèmes :

- Thème 1 : Polymorphisme de  $C_3A$  et de ses solutions solides.  
Rapporteur Général : Miss A.E. MOORE - Grande-Bretagne.
- Thème 2 : Hydratation de  $C_3A$ .  
Rapporteur Général : Prof. H.N. STEIN - Pays-Bas.
- Thème 3 : Hydratation de  $C_3A$  dans les ciments.  
Rapporteur Général : Prof. U. LUDWIG - République Fédérale d'Allemagne.
- Thème 4 : Hydratation de  $C_3A$  en présence d'adjuvants.  
Rapporteur Général : Dr V.S. RAMACHANDRAN - Canada.
- Thème 5 : Rôle de  $C_3A$  dans l'attaque des ciments par les sulfates.  
Rapporteur Général : Prof. P.K. MEHTA - Etats-Unis d'Amérique.

Le 30 juin 1980, chaque rapporteur général a d'abord exposé les principaux résultats apparus dans les communications. Certains de ces résultats ont suscité de vives discussions.

Parmi les données nouvelles figurent :

- 1 - L'existence, dans la série des solutions solides  $C_3A + Na_2O$ , de quatre structures cristallines : deux cubiques  $C_I$  et  $C_{II}$ , une orthorhombique O et une monoclinique M. La forme de haute température des variétés O et M est orthorhombique. Cette forme, stabilisée à la température ambiante par trempe rapide, n'est que pseudo-tétragonale.
- 2 - Le rôle de  $Na_2O$ , retardateur dans l'hydratation des systèmes  $C_3A + H_2O$ , accélérateur aux tous premiers instants dans l'hydratation des systèmes  $C_3A + H_2O +$  gypse, par passage rapide en solution des ions  $SO_4^{2-}$ ,  $Na^+$ ,  $Al^{3+}$ .
- 3 - L'interaction  $C_3A - C_3S$  au cours de l'hydratation de mélanges synthétiques et de ciments industriels (formation de silico-aluminates, adsorption d'ions  $SO_3$  sur le C-S-H, développement des résistances mécaniques).
- 4 - L'interprétation de la fausse prise par une modification de la morphologie des hydrates.
- 5 - L'action des adjuvants retardateurs sur la cristallisation de l'ettringite et la conversion  $C_4AH_{13} + C_3AH_6$ .
- 6 - L'apparition à la surface des grains de  $C_3A$ , en présence d'adjuvants, de charges électriques qui, répulsives, accroissent la fluidité des pâtes.
- 7 - L'influence de la concentration d'un adjuvant sur son action accélératrice ou retardatrice de l'hydratation de  $C_3A$  dans les mélanges  $C_3A + H_2O$ ,  $C_3A + C_3S + H_2O$ , ciment + eau.
- 8 - L'amélioration de la liaison pâte de ciment-granulat calcaire par formation de carboaluminates.

Les points qui n'ont pas été élucidés et qui demandent une étude ultérieure approfondie concernent :

- 1 - L'existence de la solution solide  $NC_8A_3$  (7,6 %  $Na_2O$ ).

D'une part  $NC_8A_3$  a été observé en microscopie optique en lumière réfléchie, grâce au maillage de ses grains. D'autre part,  $NC_8A_3$  n'a pu être synthétisé qu'en présence de  $SiO_2$ . Dans la série  $C_3A - Na_2O$ , la limite de solubilité de  $Na_2O$  est atteinte à 5,9 %  $Na_2O$  quand les sites vacants du réseau cristallin de  $C_3A$  sont occupés à 75 % par les atomes de Na.

2 - La congruence de la dissolution de  $C_3A$ .

D'après l'analyse de la phase liquide, la composition de l'hydrate couvrant les grains de  $C_3A$  dans le système  $C_3A + H_2O$  correspond au rapport  $C/A = 3$ . Ce même rapport est différent de 3 d'après les mesures du potentiel Zêta. Il semble que les concentrations locales au niveau des grains de  $C_3A$  soient différentes de celles éloignées des grains anhydres. Ces différences doivent agir que la diffusion des ions en solution, la vitesse d'hydratation de  $C_3A$ , la cristallisation des hydrates, l'interaction mutuelle entre les cristaux hydratés dans la forme aqueuse.

3 - La formation de l'ettringite.

L'ettringite est soit amorphe, soit cristallisée. Elle est supposée se former à partir de la solution ou topotactiquement.

4 - L'influence des adjuvants retardateurs sur la cristallisation des hydrates.

Les complexes que forment les adjuvants sont-ils chimisorbés ou formés par l'intermédiaire de la solution puis précipités sur les cristaux de  $C_3A$  ?

5 - L'influence de la forme cristalline de  $C_3A$  sur la résistance des ciments aux eaux sulfatées.

D'après les études sur des systèmes simplifiés, (mélanges synthétiques et ciments de composition très proche), il peut apparaître que le type de  $C_3A$  affecte la vitesse de l'attaque d'un ciment par une solution sulfatée ( $Na_2SO_4$  ou  $MgSO_4$ ) mais aucune conclusion n'a pu être tirée quant à l'influence de la forme cristalline de  $C_3A$  sur la résistance à l'action de  $Na_2SO_4$  de 26 ciments portland industriels. L'hypothèse selon laquelle la porosité et la perméabilité des pâtes de ciment contenant  $C_3A$  cubique (plus réactif) réduisent l'attaque des sulfates, est à vérifier.

6 - Le mécanisme de l'expansion des pâtes de ciment dans les solutions sulfatées.

L'expansion est attribuée soit à la formation de gypse secondaire par dissolution de  $Ca(OH)_2$ , soit à la formation d'ettringite colloïdale par absorption d'eau, soit à la formation de monosulfoaluminate par échange d'ions à partir de  $C_4AH_{13}$ .

Avant d'encourager vivement toute nouvelle recherche, qu'il me soit permis de remercier ici les rapporteurs généraux, les auteurs de communications et de posters, les participants, les traducteurs, les hôtes. Chacun d'entre eux a contribué largement au succès de cette journée d'étude sur  $C_3A$ , phase mineure qui joue cependant un rôle important dans les propriétés chimiques, physiques et mécaniques du ciment portland.

Dr Micheline REGOURD  
Présidente du Séminaire A

# Theme 1 - Polymorphism of $C_3A$ and its solid solutions

## GENERAL REPORT

By MISS A.E. MOORE, Cement and Concrete Association, Materials Research Department, Slough, U.K.

### Polymorphism of $C_3A$ and its Solid solutions:

We have three papers in this section, two on the  $C_3A - NC_3A_3$  series and one on halogen-substituted  $C_{12}A_7$  compounds. I will deal with the latter first.

"Non-stoichiometry of solid solutions  $C_{11}A_7 \cdot CaX_2$ , and their properties" by Professor Timachev, Ossokine, Potapova and Nikolski.

Prof. Timachev and his colleagues have prepared  $C_{11}A_7 \cdot CaX_2$  where X is F, Cl, Br or I, together with non-stoichiometric solid solutions of the fluorine- and Chlorine-containing series.

The structure of a member of the  $CaF_2$  series was determined by Williams (1) and shown to contain a partially occupied site for fluorine, with two adjacent calcium sites also partially occupied, as shown in Fig. 1.

- F, Cl, OH or hole
- Oxygen
- Calcium
- Aluminium

Fig. 1. Co-ordination of the calcium atoms in  $C_{12}A_7$  type compounds. (Williams)

When the fluorine site is occupied the calcium atoms move towards it, to the positions shown dashed. Williams deduced the composition of his crystal to be  $C_{11.56}A_7 \cdot 0.44 CaF_2$ . It has been assumed that the asymmetric co-ordination of the calcium atoms is responsible for the hydraulic activity of compounds of this type.

Fig. 2 shows part of the phase diagram  $CaO - Al_2O_3 - CaF_2$ , with  $C_{12}A_7$ , " $C_{11}A_7$ ",  $C_{11}A_7 \cdot CaF_2$  and W the composition deduced by Williams. Compositions synthesised by Timachev et al are marked T; they represent two solid solution series, one with  $C_{11}A_7 \cdot x CaF_2$  and one with  $C_xA_7 \cdot CaF_2$ .

Fig. 2. Part of the system  $CaO - Al_2O_3 - CaF_2$  (wt%)  
T = non-stoichiometric solid solutions of  $C_{11}A_7 \cdot CaF_2$

In both cases, it is the compounds with  $C_{11}A_7 \cdot 0.9 CaX_2$  that are more reactive than those with either more or less  $CaX_2$ .

In Fig. 3(a) some properties of these compositions are shown in a diagram similar to their positions on the phase diagram. In the series with  $C_xA_7 \cdot CaF_2$  density increases and refractive index decreases as the C:A ratio increases.

Fig. 3(b) shows a comparable diagram of properties for the  $C_{11}A_7 \cdot CaCl_2$  series of non-stoichiometric compounds showing a smaller range than is possible with  $CaF_2$ .

The authors also find that only 0.7 mole of Al can be replaced by Fe in  $C_{11}A_7 \cdot CaF_2$ , giving practically no change in properties.

The C<sub>3</sub>A - NC<sub>3</sub>A<sub>3</sub> series.

Pure C<sub>3</sub>A is cubic (space group Pa 3) with  $a = 15.262$ , it has a very strong pseudo-cell at  $a/4$ , because most of the metal atoms lie on this lattice; the aluminium atoms form kinked rings of composition Al<sub>6</sub>O<sub>18</sub> with their axes parallel to the three-fold cell axes and a vacant site at the centres of the rings, which lie at  $\frac{1}{8}$ ,  $\frac{3}{8}$ ,  $\frac{5}{8}$ , and  $\frac{7}{8}$  levels in the cell.

Two non-cubic forms have been shown to occur, orthorhombic and monoclinic. An apparently tetragonal high-temperature form has been shown by Dr Maki (2) to be due to the optic axial angle (2V) becoming zero for a single wavelength of light at a specific temperature and hence the crystal appearing to be uniaxial; at other wavelengths the effect occurs at different temperatures and thus the crystal cannot be uniaxial.

In "Structural aspect of the C<sub>3</sub>A-Na<sub>2</sub>O solid solution" Professor Takeuchi, Dr Nishi and Dr Maki show that as Na<sub>2</sub>O is introduced into the system, a different cubic form, CII, occurs at 2.4% (wt.) Na<sub>2</sub>O, when the cell becomes non-centro-symmetric. (space group P2<sub>1</sub>). The position of the Al<sub>6</sub>O<sub>18</sub> rings is unchanged, but two of the calcium atoms split into groups with different Na/Ca occupancy ratios. These are the two Ca in eightfold (x,x,x) positions, of the same type as the positions of the ring centre vacancies, some of which are now occupied by Na.

The Ca polyhedra that accommodate Na become larger than the corresponding ones in CI (C<sub>3</sub>A), and rings that are occupied by Na show a contraction compared with the vacant rings in CI. This produces a decrease in cell volume from CI to CII (See Table 1 in Takeuchi et al).

When the Na<sub>2</sub>O content is increased to 3.8% (wt.) a major change in structure, to orthorhombic (Pbca) occurs. The c dimension is retained, but the true cell volume is halved, with  $a_0 \neq b_0$  both approximately  $a_c/\sqrt{2}$ . The Al<sub>6</sub>O<sub>18</sub> rings now lie with centres at  $c = 0$  and  $c = \frac{1}{2}$  only and have their axes all parallel to one pseudo-three-fold axis at  $c = 0$ , and another at  $c = \frac{1}{2}$ . (See Fig.2 in Takeuchi et al.)

The Na atoms lie partly near the centres of these rings and partly replace the calcium atoms that lie in the same planes,  $c = 0$  and  $\frac{1}{2}$ .

A further minor change in symmetry, to monoclinic (P2<sub>1</sub>/a) occurs at 5.7% (wt.) Na<sub>2</sub>O and again entails splitting of the calcium positions at  $c = 0$  and  $\frac{1}{2}$  to give partial occupancies of Na. Within this range of solid solutions, there is no change in the volume of the Al<sub>6</sub>O<sub>18</sub> rings as they become occupied by Na. The calcium polyhedra also remain constant, until they split into two groups at the change to monoclinic, when group A increase and group B decrease in size as they are progressively occupied by Na. This results in a continuous increase in cell volume.

Takeuchi et al find that the monoclinic solid solution range terminates at 5.9 wt % Na<sub>2</sub>O, apparently because the limiting occupancy of the ring centres is 75%, and the Ca sites can accept more Na only if some Si is present to replace Al. They examined one crystal with 5.535 Al and 0.475 Si (atom ratios to 18 oxygen) and found that 6.6% Na<sub>2</sub>O was accommodated, with higher replacement ratios in the Ca sites. This seems to indicate that the full 7.6% Na<sub>2</sub>O replacement for NC<sub>3</sub>A<sub>3</sub> would be possible with sufficient silica present. (See their Fig.5)

Another crystal containing both Fe and Si with 3.3 wt % Na<sub>2</sub>O was found to be orthorhombic, with less Na in ring sites and more in Ca sites than in the orthorhombic form with 3.8% Na<sub>2</sub>O only.

Prof. Tavaschi, Prof. Massazza and Dr Costa have explored the stability fields of the anisotropic forms of C<sub>3</sub>A, using reflected light microscopy on samples quenched from different temperatures.

They found that etching with 2% HNO<sub>3</sub> in alcohol gave a clear distinction between orthorhombic and monoclinic phases, revealing multiple twinning in the monoclinic phase when viewed with sufficiently high magnification.

They found that the composition NC<sub>3</sub>A<sub>3</sub>, when quenched from 1300°C or 600°C gave all orthorhombic crystals (with no free lime) and when quenched from 500°C gave all monoclinic, but that mixes richer in Na<sub>2</sub>O always showed the presence of free-lime and sodium aluminate.

The stability fields for the two forms are shown in Fig.16 of Tavaschi et al.

Thus these authors consider that the full replacement of 7.6% Na<sub>2</sub>O is possible without the presence of SiO<sub>2</sub>. This is a point of disagreement with Takeuchi et al which we should discuss.

# Thème 1 - Polymorphisme de $C_3A$ et de ses solutions solides

## RAPPORT GENERAL

A.E. MOORE, Cement and Concrete Association, Materials Research Department, Slough, U.K.

Nous avons trois communications dans ce thème, deux sur la série  $C_3A - NC_3A_3$  et une sur les composés  $C_{12}A_7$  substitués par les halogènes. Je commencerai par la dernière.

### 1) Non-stoechiométrie des solutions solides $C_{11}A_7 \cdot Ca \cdot X_2$ et leurs propriétés par le Professeur TIMACHEV et OSSOKINE, POTAPOVA et NIKOLSKI

Le Prof. TIMACHEV et ses collègues ont préparé les solutions solides  $C_{11}A_7 \cdot CaX_2$  où X est F, Cl, Br ou I et des solutions solides non-stoechiométriques de la fluorine et de la série contenant du chlore.

La structure d'un membre de la série  $C_{11}A_7 \cdot CaF_2$  a été déterminée par WILLIAMS (1) : elle contient un site partiellement occupé par le fluor avec deux sites calcium adjacents, aussi partiellement occupés, comme le montre la Figure 1. Quand le site fluor est occupé, les atomes de calcium se déplacent vers lui jusqu'aux positions hachurées. WILLIAMS en a déduit la composition de son cristal soit  $C_{11,56}A_7 \cdot 0,44 CaF_2$ . La coordination asymétrique des atomes de calcium a été supposée responsable de l'activité hydraulique des composés de ce type.

La Figure 2 montre une partie du diagramme de phase  $CaO - Al_2O_3 - CaF_2$  avec  $C_{11}A_7$ , " $C_{11}A_7$ ",  $C_{11}A_7 \cdot CaF_2$  et W la composition déduite par WILLIAMS. Les compositions synthétisées par TIMACHEV et al sont marquées T. Elles représentent deux séries de solutions solides, l'une avec  $C_{11}A_7 \cdot xCaF_2$  et l'autre avec  $C_xA_7 \cdot CaF_2$ .

Sur la Figure 3(a), quelques propriétés de ces compositions sont données dans un diagramme correspondant à leurs positions dans le diagramme de phase. Dans la série avec  $C_{11}A_7 \cdot xCaF_2$  la densité croît et l'indice de réfraction décroît quand le rapport  $\frac{C}{A}$  croît.

La Figure 3(b) montre un diagramme des propriétés de la série  $C_{11}A_7 \cdot CaCl_2$  des composés non-stoechiométriques qui présente un domaine plus étroit que celui contenant  $CaF_2$ .

Dans les deux cas, ce sont les composés  $C_{11}A_7 \cdot 0,9 CaX_2$  qui sont plus réactifs que ceux contenant plus ou moins de  $CaX_2$ .

### 2) Polymorphisme de $C_3A$ et de ses solutions solides

#### La série $C_3A \cdot NC_3A_3$

$C_3A$  pur est cubique (groupe spatial Pa 3), avec  $a = 15,262 \text{ \AA}$ . Sa structure présente une forte pseudo-maille de paramètre  $a/4$  parce que la plupart des atomes métalliques s'y trouvent. Les atomes d'aluminium forment des anneaux légèrement gauchis de composition

$Al_6O_{18}$  dont les axes sont parallèles aux axes d'ordre 3 de la maille. Un site vacant se trouve aux centres des anneaux dont les positions sont aux niveaux  $\frac{1}{8}, \frac{3}{8}, \frac{5}{8}, \frac{7}{8}$  de la maille.

Deux formes non cubiques ont été trouvées, l'une orthorhombique, l'autre monoclinique. Une forme haute température apparemment tétragonale est due, d'après le Dr MAKI (2), à la valeur de l'angle  $2V$  des axes optiques égale à zéro, pour une radiation monochromatique de la lumière, à une température spécifique. Pour les autres longueurs d'onde, cet effet se produit à des températures différentes. Le cristal ne peut donc pas être uniaxial.

#### 2.1 Dans "l'aspect structural des solutions solides $C_3A \cdot Na_2O$ ", le Professeur TAKEUCHI, le Dr NISHI et le Dr MAKI montrent qu'une seconde forme cubique

$C_{II}$  apparaît quand 2,4 %  $Na_2O$  (en poids) sont introduits dans le réseau dont la maille devient non centro-symétrique (groupe spatial  $P 2_13$ ). La position des anneaux  $Al_6O_{18}$  est inchangée mais deux des atomes de calcium se divisent en groupe de rapports d'occupation Na/Ca différents. Ce sont les deux calcium dans les positions d'ordre 8 (x,x,x) du même type que celles des sites vacants au centre des anneaux, certains d'entre eux étant maintenant occupés par Na. Les polyèdres de Ca qui accueillent Na deviennent plus grands que ceux de la structure  $C_I$  de  $C_3A$  et les anneaux qui sont occupés par Na se contractent par rapport aux anneaux vacants de  $C_I$ . Ceci entraîne une décroissance du volume de la maille de  $C_I$  à  $C_{II}$  (Tableau I).

Quand la teneur en  $Na_2O$  atteint 3,8 % (en poids), un changement important se produit dans la structure qui devient orthorhombique (Pbca). La dimension c n'est pas modifiée mais le volume de la vraie maille est divisée par deux avec  $a_0 \neq b_0$ , tous deux approximativement égaux à  $c/\sqrt{2}$ . Les anneaux  $Al_6O_{18}$  se trouvent maintenant dans les positions correspondant à  $c = 0$  et  $c = \frac{1}{2}$  seulement et ont, tous, leurs axes parallèles à  $c = \frac{1}{2}$  un pseudo-axe d'ordre 3, l'un à  $c = 0$  l'autre à  $c = \frac{1}{2}$  (Fig. 2 dans TAKEUCHI et al).

Les atomes de sodium se placent partiellement près des centres de ces anneaux et remplacent partiellement les atomes de calcium qui se trouvent dans les mêmes plans,  $c = 0$  et  $c = \frac{1}{2}$ .

Un autre changement de symétrie, mineur, se produit à 5,7 %  $Na_2O$  (en poids). La structure devient monoclinique ( $P 2_1/a$ ) ce qui entraîne à nouveau un partage des positions de calcium à  $c = 0$  et  $c = \frac{1}{2}$  pour une occupation partielle de Na. Dans ce domaine de solutions

solides, il n'y a pas de changement de volume des anneaux  $Al_6O_{18}$  quand ils sont occupés par Na. Les polyèdres de calcium restent ainsi constants jusqu'à ce qu'ils se partagent en deux groupes à la transformation orthorhombique + monoclinique. Quand la taille du groupe A croît, celle du groupe B décroît au fur et à mesure de l'occupation par Na. Ceci entraîne un accroissement continu du volume de la maille.

TAKEUCHI et al trouvent que le domaine des solutions solides se termine à 5,9 %  $Na_2O$  (en poids) apparemment parce que le taux limite d'occupation des centres d'anneaux suit la règle des 75 % et que les sites Ca ne peuvent accepter plus de Na sauf si Si est présent pour remplacer Al. Ils ont étudié un cristal avec 5,535 Al et 0,475 Si (atomes rapportés à 18 oxygène) et trouvé que 6,6 %  $Na_2O$  peuvent être logés avec des rapports de remplacement plus élevés dans les sites Ca. Ceci semble indiquer que la valeur de 7,6 %  $Na_2O$  correspondant à  $NC_8A_3$  serait possible en présence d'une quantité suffisante de silice (voir Fig. 5 TAKEUCHI et al).

Un autre cristal contenant à la fois Fe et Si avec 3,3 %  $Na_2O$  (en poids) a été trouvé orthorhombique avec moins de Na dans les sites des anneaux et plus de Na dans les sites Ca que dans la forme orthorhombique contenant seulement Na (3,8 %  $Na_2O$ ).

## 2.2 Le Prof. TAVASCI, le Prof. MASSAZZA et le Dr COSTA ont exploré les domaines de stabilité des formes anisotropiques de $C_3A$ en utilisant la microscopie en lumière réfléchie

Ils ont trouvé que l'attaque avec 2 %  $HNO_3$  dans l'alcool donne une distinction claire entre les phases orthorhombiques et monocliniques, révélant un maillage multiple dans la phase monoclinique pour un grossissement suffisamment élevé.

Ils ont également trouvé que la composition  $NC_8A_3$ , trempée à partir de 1300 °C ou de 600 °C donne des cristaux orthorhombiques (sans chaux libre) mais quand elle est trempée à partir de 500 °C, elle donne des cristaux monocliniques. Ceci est un point de discordance entre TAKEUCHI et al et TAVASCI et al qui devrait être discuté.

Les mélanges plus riches en  $Na_2O$  montrent toujours la présence de chaux libre et d'aluminate de sodium.

Les domaines de stabilité pour les deux formes sont donnés dans la Fig. 16 (TAVASCI et al).

- F, Cl, OH, ou site vacant.
- Oxygène

**RESUME :** La formation des halogéno-aluminates de calcium dans le système  $CaO-Al_2O_3-CaX_2$  (où X est F, Cl, Br, I) se produit aux températures comprises entre 900 et 1400 °C et donne lieu à une sublimation intense des halogènes. Les phases bromées et iodées ne se prêtent à la synthèse que dans une ampoule scellée.

La présence, dans la structure des aluminates de calcium, de vides spacieux est à l'origine de la formation de solutions solides à teneur variable en  $CaO$  et  $CaX_2$  et conduit au remplacement d'une partie de  $Al_2O_3$  (jusqu'à 0,7 moles) par  $Fe_2O_3$ . La sublimation des halogènes lors de la synthèse des minéraux provoque une modification des caractéristiques optiques, de la densité et de l'activité hydraulique de ces derniers. Avec l'accroissement du rayon de l'ion dans la série F - Cl - Br - I, on constate une diminution de la résistance thermique et de la densité des halogéno-aluminates et une baisse de leur température de fusion.

Les minéraux fluorés et chlorés, surtout ceux ayant une composition non stoechiométrique ( $0,9CaX_2$ ), présentent une activité hydraulique augmentée. Les propriétés des solutions solides du type  $C_{11}A_{7-x}Fe_xCaX_2$  correspondent à celles du fluoraluminate de calcium.

La régulation des conditions de la préparation des solutions solides de halogéno-aluminates de calcium et des clinkers à leur base permet d'apporter des modifications voulues à leur composition et, en conséquence, aux propriétés des liants obtenus, en modifiant notamment la durée de prise et l'intensité de la genèse de la résistance.

**SUMMARY :** In the system  $CaO-Al_2O_3-CaX_2$  (where X=F, Cl, Br, I) calcium halogen aluminates are formed in the temperature range of 900-1400 °C with intensive volatilization of halogens. Bromine- and iodine-bearing phases are synthesized only in conditions of sealed ampoule.

The presence of large voids in calcium aluminate structure causes the formation of solid solutions with variable content of  $CaO$  and  $CaX_2$  as well as part substitution of  $Al_2O_3$  (up to 0.7 moles) for  $Fe_2O_3$ . During mineral synthesis the volatilization of halogens brings about changes of optical characteristics density and hydration activity. With increasing of ion radius in the series of F-Cl-Br-I there are reduced thermal stability of halogen aluminates, their melting temperature and density.

Intensified hydraulic activity is the typical of minerals containing fluorine and chlorine and especially of non-stoichiometry ( $0.8-0.9 CaX_2$ ) composition. The properties of solid solutions of  $C_{11}A_{7-x}Fe_xCaX_2$  type correspond to calcium fluorine aluminate.

The regulation of solid solution synthesis conditions of calcium hylogenaluminates and clinkers on their basis allows to change purposely the composition and hence the properties of cements obtained that is the setting time and intensity of strength growth.

Une condition sine qua non des substitutions hétérovalentes dans le réseau des minéraux du clinker est une compensation des charges qui peut être réalisée par les procédés les plus variés. Pendant la formation de solutions solides et la dissolution d'impuretés dans les minéraux, on observe l'apparition de vacances, la formation d'associations d'atomes et l'insertion d'atomes supplémentaires dans le réseau, ce qui prête à la formation de structures défectueuses.

La présence de vides spacieux dans la structure des aluminates de calcium a pour conséquence une diversité plus grande des schémas de compensation lors des substitutions hétérovalentes, par rapport à l'alite et au bélite. Les substitutions hétérovalentes sont une des causes du dérangement de la stoechiométrie des oxydes contenus dans les minéraux du ciment. On voit ainsi apparaître un moyen de plus de la régulation orientée de la concentration de défauts dans les minéraux du clinker en vue d'augmenter leur activité hydraulique.

Le procédé le plus simple de régulation du degré d'écart à la stoechiométrie dans les halogéno-aluminates de calcium du type  $C_{11}A_7CaX_2$  (où X est un halogène) est une sublimation dosée de l'halogène au cours de la synthèse des minéraux conformément aux réactions

La formation des halogéno-aluminates de calcium d'une composition  $C_{11}A_7CaX_2$  se fait par un mécanisme de substitution de  $CaX_2$  à une molécule de  $CaO$  dans la composition du maénite, c'est-à-dire en vertu de la réaction

Le réseau des halogéno-aluminates de calcium est caractérisé par une déformation et se distingue quelque peu de la forme cubique du maénite, en provoquant des changements des caractéristiques radiographiques, illustrés pour  $C_{11}A_7CaF_2$  par les données du Tableau I. La substitution de deux atomes de fluor à un atome d'oxygène a pour effet un déplacement des atomes de fluor vers la périphérie, ce qui favorise la polarisation de la liaison et l'accroissement de l'activité hydraulique.

La vitesse de dégagement de l'halogène (en calculant en  $CaX_2$ ), lors de la cuisson des compositions stoechiométriques de  $C_{11}A_7CaF_2$  et de  $C_{11}A_7CaCl_2$ , atteint son maximum ( $2,5 \cdot 10^{-2}$  et  $4 \cdot 10^{-2}$  g/mn respectivement) à la température de fusion, alors qu'ensuite, avec l'apparition de la matière fondue, elle décroît et devient constante. Les résultats de l'analyse chimique montrent que la sublimation de l'halogène

TABLEAU I			
Caractéristiques radiographiques de $C_{12}A_7$ et de $C_{11}A_7CaF_2$			
$C_{12}A_7$		$C_{11}A_7CaF_2$	
d, Å	I/I <sub>0</sub>	d, Å	I/I <sub>0</sub>
4,895	84	4,862	55
3,791	10	3,783	10
3,201	15	3,190	24

1,600	27	1,594	31

s'effectue non seulement suivant les réactions 1 et 2, mais aussi sous forme de  $X_2$ . C'est pourquoi, pour obtenir des phases stoechiométriques, il est nécessaire de cuire les mélanges bruts dans des ampoules scellées ou bien d'introduire dans ces mélanges un excédent de  $CaX_2$  et de  $Al_2O_3$  que l'on dose suivant la durée de maintien isothermique et la température de la cuisson.

Lors de la synthèse de  $C_{11}A_7CaF_2$  et de  $C_{11}A_7CaCl_2$  selon les régimes représentés par la figure 1, on observait une réalisation à fond des processus de formation des minéraux. Pour les phases bromées et iodées, on n'est pas parvenu à faire passer intégralement à l'état combiné l'oxyde de calcium, de sorte que sa proportion s'élevait à 0,8 à 1,2 %, même dans les conditions d'une ampoule scellée. Et si la réalisation était réalisée à découvert, ces phases ne prenaient pas naissance point du tout, à cause de la faible résistance thermique des sels de calcium correspondants.

La formation des minéraux du groupe de  $C_{11}A_7CaX_2$  se fait par l'intermédiaire d'un composé intermédiaire CA.

L'élévation de la température de la synthèse et l'accroissement de la durée de cuisson provoquent un décroissement de la teneur en CA, et on voit apparaître sur les radiogrammes une structure caractéristique des halogéno-aluminates de calcium. Si l'on passe successivement du fluoraluminate à l'iodaluminate de calcium, la densité et la température de fusion (Tableau II) des composés décroissent progressivement, en fonction de l'accroissement du rayon de l'ion à implanter. La résistance thermique varie d'une façon similaire, en décroissant dans la série :  $C_{11}A_7CaF_2 \rightarrow C_{11}A_7CaCl_2 \rightarrow C_{11}A_7CaBr_2 \rightarrow C_{11}A_7CaI_2$ .

Fig. 1 - Régimes de synthèse de  $C_{11}A_7CaX_2$  où X est Cl (1) et F (2)

TABLEAU II			
Caractéristiques des halogéno-aluminates de calcium synthétisés			
Minéral	Température de fusion, °C	Densité, kg/cm <sup>3</sup>	Indice de réfraction
$C_{11}A_7CaF_2$	1550	2900	1,600
$C_{11}A_71,3CaF_2$	1550	2950	1,605
$C_{11}A_7CaCl_2$	1520	2850	1,620
$C_{11}A_71,1CaCl_2$	1520	2860	1,615
$C_{11}A_7CaBr_2$	1420	2720	1,681
$C_{11}A_7CaI_2$	1410	2690	1,693
$C_{12}A_7$	1400	2680	1,617

Les minéraux  $C_{11}A_7CaBr_2$  et  $C_{11}A_7CaI_2$  se décomposent facilement à l'air sous un chauffage relativement faible (200 °C) avec dégagement visible de vapeurs brunes de brome ou d'iode.

La variation de la stoechiométrie d'après l'halogène ne peut se produire que dans un intervalle déterminé, au-delà duquel la structure se décompose avec dégagement de  $CaF_2$ ,  $Ca$  et  $C_{12}A_7$ . La stabilité des solutions solides de  $C_{11}A_7 \cdot xCaF_2$  se maintient dans un intervalle  $0 \leq x \leq 1,3$ . Avec l'augmentation de la teneur en halogène, on voit apparaître sur les radiogrammes des crêtes caractéristiques de  $CaO$ . Les radiogrammes de ces solutions solides sont pra-

tiquement identiques et ne diffèrent l'un de l'autre que par l'importance de la crête correspondant à un espacement d'interplan de 4,88 ( $C_{11}A_7CaF_2$ ). Dans le cas des chloroaluminates de calcium, la limite supérieure de la teneur en  $CaCl_2$  est égale à 1,1. Il s'avère impossible d'évaluer ce chiffre pour  $C_{11}A_7CaBr_2$  et  $C_{11}A_7CaI_2$ , du fait d'une sublimation poussée de l'halogène. L'implantation d'une quantité excédentaire de  $CaX_2$  a pour cause non seulement l'existence de vides spacieux dans le réseau des aluminates mais aussi l'apparition éventuelle, lors de la sublimation de l'halogène, de vacances cationiques (2). La densité des solutions solides dans le domaine des fortes concentrations d'halogène est légèrement plus grande par rapport aux minéraux qui en contiennent une quantité diminuée, ce qui est confirmée par la formation des solutions solides de cette série par le mécanisme de substitution. L'implantation d'une quantité excédentaire de  $CaX_2$ , dans les conditions d'une sublimation poussée de l'halogène, conduit à la formation de solutions solides de  $C_{11}A_7CaX_2$  avec  $CaO$ .

La variation de la stoechiométrie d'après l'oxyde de calcium est limitée, pour le fluoroaluminate de calcium, à l'intervalle  $C_{10,8}A_7CaF_2 - C_{11,3}A_7CaF_2$ , au-delà duquel on enregistre l'apparition de  $CaO$  libre. Les chloroaluminates de calcium sont caractérisés par un intervalle plus étroit :  $C_{10,9}A_7CaCl_2 - C_{11,1}A_7CaCl_2$ . Le décroissement de la teneur du mélange en oxyde de calcium provoque l'apparition des minéraux  $C_3A$ ,  $CaX_2$  et  $Ca$ . La preuve de l'existence des solutions solides indiquées est une variation continue des indices de réfraction et de la densité (Tableau III).

TABLEAU III		
Caractéristiques des solutions solides du type $C_nA_7CaX_2$ à teneur variée en $CaO$		
Solution solide	Densité, kg/cm <sup>3</sup>	Indices de réfraction
$C_{10,8}A_7CaF_2$	2870	1,665
$C_{11,3}A_7CaF_2$	2920	1,595
$C_{10,9}A_7CaCl_2$	2820	1,634
$C_{11,1}A_7CaCl_2$	2850	1,615

En essayant de donner une évaluation expérimentale de la possibilité d'obtenir des halogénoferro-aluminates de calcium en vue de pouvoir modifier les propriétés des liants, on a établi que la substitution, dans le réseau du minéral  $C_{11}A_7CaF_2$ , de l'oxyde ferrique à l'oxyde d'aluminium ne se fait que jusqu'à 0,7 mole. La cuisson des compositions à teneur accrue en oxyde

ferrique (telles  $C_{11}A_6FeCaF_2$ ,  $C_{11}A_5Fe_2CaF_2$ ) conduit à la formation d'un système polyphasé comportant  $C_4AF$ , CA et  $C_{11}A_7CaF_2$ . L'augmentation de la concentration de  $Fe_2O_3$  entraîne un dégagement accru de CA. Si la teneur en oxyde ferrique ne dépasse pas 0,7 mole, une partie des cations fer se répartit dans les interstices des octaèdres de l'aluminium et le remplace en partie dans les polyèdres de coordination. Les solutions solides de la série  $C_{11}A_{7-x}Fe_xCaF_2$  (où  $x \leq 0,7$ ) présentent pratiquement les mêmes propriétés que les halogéno-aluminates.

Les calculs thermodynamiques montrent que le maillage des cristaux hydrates peut donner lieu à des germes de croissance, la facilité de la formation desquels est proportionnelle à la densité de défauts. C'est pourquoi le degré d'écart à la stoechiométrie caractérise l'activité hydraulique des minéraux. En l'occurrence, l'écart à la stoechiométrie ne traduit, au fond, autre chose que la facilité de détachement des molécules ou des ions d'avec la surface de la phase solide au cours de l'hydratation (3). L'intensité de l'hydratation est proportionnelle au dégagement de chaleur qui peut servir lui aussi d'indice d'activité hydraulique des minéraux. Les halogéno-aluminates synthétisés se sont montrés beaucoup plus actifs que le maénite (fig. 2).

Fig. 2 - Cinétique de la combinaison à l'eau des minéraux hydratables :  
1 -  $C_{11}A_7CaF_2$  ; 2 -  $C_{11}A_7CaCl_2$  ;  
3 -  $C_{11}A_7CaBr_2$  ; 4 -  $C_{11}A_7CaI_2$

Le degré d'hydratation du fluoraluminate de calcium atteint 80 % au bout de 30 à

40 mn après le gâchage, celui du chloraluminat, au bout de 6 à 8 heures.

L'hydratation du fluoraluminate de calcium se déroule schématiquement comme suit :

avec formation d'hydroaluminates de calcium lamellaires et d'un hydroxyde d'aluminium gélatineux à teneur variable en fluor. La phase liquide dégage d'abord des néoformations d'hydroaluminates de calcium :  $CAH_{10}$ ,  $C_2AH_8$ ,  $C_4AH_{13}$  (fig. 3-a) et un gel d'alumine modifié au fluor  $Al(OH)_{3-x}F_x$  (4). Au bout de 6 heures d'hydratation, il y a formation et dégagement de  $C_4AH_{19}$  et aussi un début de recristallisation des hydroaluminates de calcium métastables.  $CAH_{10}$ , dont l'état cristallin devient plus ordonné, se transforme en  $C_2AH_8$ . Ce processus s'achève à la 12-ième heure d'hydratation, ce qui est confirmé par la disparition des réflexions diffractométriques 7,16 ; 3,56 ; 2,55 Å de  $CAH_{10}$ .

Le durcissement du fluoraluminate de calcium en présence de gypse et sans celui-ci se déroule différemment, ce qui retentit sur la cinétique de l'hydratation et de la formation des phases.

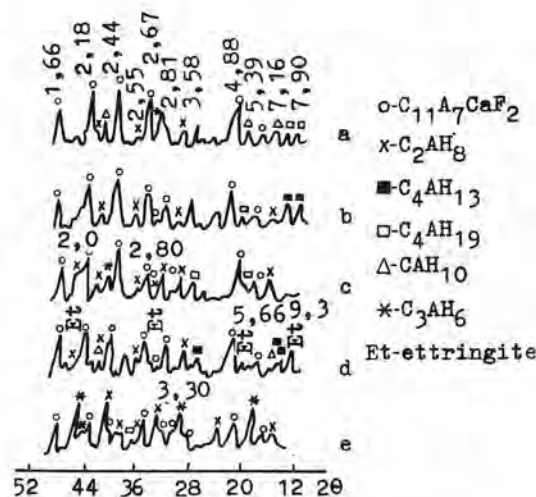

Fig. 3 - Les radiogrammes des produits d'hydratation de  $C_{11}A_7CaF_2$  qui a durci :  
a - 1 h ; b - 1 h en présence de gypse ;  
c - 1 jour ; d - 1 jour en présence de gypse ; e - 7 jours

Lors de l'hydratation de  $C_{11}A_7CaF_2$  avec 12 % de gypse à deux molécules d'eau de cristallisation, il se forme au bout d'une heure  $C_2AH_8$ ,  $C_4AH_{13}$ ,  $C_4AH_{19}$  (fig. 3-b) et un gel

d'alumine  $Al(OH)_{3-x}F_x$ . En outre, à la différence de l'hydratation de  $C_3A$  et de  $C_{12}A_7$ , il y a formation, en présence de fluor, au lieu d'ettringite, d'une solution solide d'ettringite contenant le fluor.

La formation de la composition en phase s'achève vers la 3-ème journée de durcissement et l'hydratation ultérieure ne fait qu'accumuler dans le système les phases hydratées ( $C_2AH_8$ ,  $C_3AH_6$ ,  $C_4AH_{19}$ ,  $AH_{3-x}F_x$ ) (fig. 3-e).

L'hydratation de  $C_{11}A_7CaCl_2$  s'effectue d'une manière analogue.

Les délais de la prise (en minutes) des fluoro et chloraluminates d'une composition  $C_{11}A_7O,9CaF_2$  et  $C_{11}A_7O,9CaCl_2$  sont de 4/5 et 5/7 (début/fin) contre 4/6 et 6/9 pour les compositions stoechiométriques  $C_{11}A_7CaF_2$  et  $C_{11}A_7CaCl_2$  respectivement. Les délais de la prise des bromo et iodoluminates de calcium sont proches et se chiffrent par 7/11 et 8/11 respectivement.

Le degré d'écart à la stoechiométrie a une répercussion notable sur la résistance mécanique des minéraux, les délais de la prise et l'activité hydraulique de ceux-ci (Tableau IV).

TABLEAU IV				
Résistance des halogéno-aluminates de calcium				
	Résistance à la compression, MPa			
	1	3	7	28
$C_{11}A_7CaF_2$	30,4	32,0	39,5	50,1
$C_{11}A_7O,9CaF_2$	32,5	35,0	43,0	55,0
$C_{11}A_7O,5CaF_2$	19,0	25,2	27,1	34,4
$C_{11}A_7CaCl_2$	23,5	27,0	28,4	40,7
$C_{11}A_7O,9CaCl_2$	25,0	30,3	42,1	45,6
$C_{11}A_7O,5CaCl_2$	14,3	18,2	20,7	23,5

Les minéraux caractérisés par une non-stoechiométrie considérable présentent de faibles résistance et activité hydraulique, ce qui a vraisemblablement pour cause une concentration optimale de défauts dans la structure des solutions solides. La pierre de ciment monominérale à base de  $C_{11}A_7O,9CaX_2$  avait une résistance maximale, les phases fluorées présentant les meilleures caractéristiques. L'influence de la stoechiométrie sur les propriétés hydrauliques des minéraux s'explique par l'apparition d'une quantité supplémentaire de défauts qui facilitent à l'eau l'accès de la phase à hydrater. En faisant varier la stoechiomé-

trie d'après l'halogène dans certaines limites, on parvient à réguler la résistance, alors que le degré d'écart à la stoechiométrie d'après l'oxyde de calcium donne la possibilité de modifier les délais de la prise du liant monominéral et des ciments à sa base.

#### CONCLUSIONS

1. Par suite d'une sublimation poussée des halogènes et en raison de la présence de vides spacieux dans la structure de  $C_{12}A_7$ , il se forme des solutions solides d'halogéno-aluminate de calcium à teneur variable en  $CaO$ ,  $CaX_2$  et  $Fe_2O_3$ .

2. Dans des conditions industrielles, seules les phases non stoechiométriques prennent naissance, et pour pouvoir synthétiser un liant ayant les propriétés voulues, il faut un dosage précis de la composition du mélange brut, avec prise en considération du régime de synthèse des clinkers qui est responsable du degré de sublimation des halogènes.

3. La préparation des clinkers contenant une phase aluminate d'une composition  $C_{11}A_7O,9CaX_2$  permet d'augmenter l'activité hydraulique et la résistance des ciments halogénés.

# Structural aspect of the $C_3A-Na_2O$ solid solutions

## *Etude de la structure des solutions solides $C_3A-Na_2O$*

Y. TAKEUCHI, Professor, Mineralogical Institute, Faculty of Science, University of Tokyo,  
F. NISHI, Doctor, Mineralogical Institute, Faculty of Science, University of Tokyo, and  
I. MAKI, Doctor, Nagoya Institute of Technology, Japan.

SUMMARY : The  $C_3A-Na_2O$  solid solution series has been structurally characterized based on four new structures: (i)  $a = 15.248(2)$  Å,  $P2_13$ ,  $Z = 8$ , (ii)  $a = 10.879(1)$ ,  $b = 10.845(2)$ ,  $c = 15.106(2)$ ,  $Pbca$ ,  $Z = 4$ , (iii)  $a = 10.877(6)$ ,  $b = 10.854(13)$ ,  $c = 15.135(13)$ ,  $\gamma = 90.1(1)^\circ$ ,  $P2_1/a$ ,  $Z = 4$ , and (iv)  $a = 10.844(2)$ ,  $b = 10.855(2)$ ,  $c = 15.122(4)$ ,  $\gamma = 90.38(1)^\circ$ ,  $P2_1/a$ ,  $Z = 4$ . They respectively contain 2.4, 3.3, 5.7, and 6.6  $Na_2O$  in wt. %. Among these, (ii) contains 0.45 Fe and 0.375 Si, and (iv) contains 0.465 Si per 18 oxygen atoms.

The structure (i) represents the structure type of a hitherto unreported new cubic phase, which is here denoted by CII; the  $C_3A$  phase is then denoted by CI. Thus in the  $C_3A-Na_2O$  solid solution series, there are four distinct phases, CI, CII, O, and M.

In the CII structure type, Na atoms substitute for Ca at Ca3B and Ca4B which respectively correspond to the Ca(3) and Ca(4) sites in  $C_3A$ . Excess Na atoms resulting from the replacement in the Ca/Na ratio of 1/2 go around the centers of the six-membered rings. The substitution gives rise to an expansion of the polyhedra particularly about Ca4B and a contraction of the Al - O bonds.

In the orthorhombic structure type, Na substitutes for Ca only at the Ca5 site. When Si is present in the solid solution, the Na occupancy in the rings is reduced and the solid solution range is extended towards Na-poor range. With increasing  $Na_2O$  content, the Ca5 site is differentiated into two non-equivalent sites, Ca5A and Ca5B, which accommodate Na in different amounts, thus generating the monoclinic structure type. When Si is present, Ca5B is fully occupied by Na and the monoclinic solid solution range is extended to more Na-rich region. The monoclinic - orthorhombic transition is caused by an order - disorder process of Ca and Na at the Ca5A and Ca5B sites.

RESUME : La série des solutions solides  $C_3A-Na_2O$  a été caractérisée sur la base de quatre nouvelles structures cristallines (i)  $a = 15,248(2)$  Å,  $P2_13$ ,  $z = 8$ , (ii)  $a = 10,879(1)$ ,  $b = 10,845(2)$ ,  $c = 15,106(2)$ ,  $Pbca$ ,  $z = 4$ , (iii)  $a = 10,877(6)$ ,  $b = 10,854(13)$ ,  $c = 15,135(13)$ ,  $\gamma = 90,1(1)^\circ$ ,  $P2_1/a$ ,  $z = 4$ , et (iv)  $a = 10,844(2)$ ,  $b = 10,855(2)$ ,  $c = 15,122(4)$ ,  $\gamma = 90,38(1)^\circ$ ,  $P2_1/a$ ,  $z = 4$ . Elles contiennent respectivement 2,4, 3,3, 5,7 et 6,6 %  $Na_2O$  (en poids). Parmi elles, (ii) contient 0,45 Fe et 0,375 Si et (iv) contient 0,465 Si pour 18 atomes d'oxygène.

La structure (i) représente le type de structure d'une nouvelle phase cubique qui n'a pas encore été rapportée et qui est notée ici CII ; la phase  $C_3A$  est notée CI. Ainsi, dans la série des solutions solides  $C_3A-Na_2O$ , il y a quatre phases distinctes CI, CII, O et M.

Dans le type de structure CII, les atomes Na se substituent au Ca dans Ca3B et Ca4B qui correspondent respectivement aux sites Ca(3) et Ca(4) dans  $C_3A$ . Les atomes de Na, en excès, résultant du remplacement dans le rapport Ca/Na égal à 1/2, se placent autour des centres des anneaux à six membres. La distribution entraîne une expansion du polyèdre, particulièrement autour de Ca4B, et une contraction des liaisons Al-O.

Dans le type de structure orthorhombique, Na se substitue au Ca seulement dans le site Ca5. Quand Si est présent dans la solution solide, l'occupation de Na dans les anneaux est réduite et le domaine de la solution solide s'étend vers le domaine des faibles valeurs de Na. Quand la teneur de  $Na_2O$  croît, le site Ca5 se différencie en deux sites non équivalents, Ca5A et Ca5B qui logent le Na en quantités différentes, engendrant ainsi le type de structure monoclinique. Quand Si est présent, Ca5B est occupé complètement par Na et le domaine de la solution solide monoclinique s'étend vers la région plus riche en Na. La transition monoclinique + orthorhombique est due à un processus ordre-désordre de Ca et de Na, dans les sites Ca5A et Ca5B.

## INTRODUCTION

The  $C_3A-Na_2O$  solid solution series,  $Ca_{9-x/2}Na_x[Al_6O_{18}]$ , has been structurally characterized based on four new structures having different  $Na_2O$  contents and two reported structures, one is the  $C_3A$  structure (Mondal and Jeffery (1)) and the other an orthorhombic structure ( $x=1.0$ ) (Nishi and Takéuchi (2)). The present paper is to discuss in light of them the structural features of the solid solution series.

## CRYSTAL DATA AND NOMENCLATURE

The new structures we determined include: (i) a hitherto unreported cubic structure having, unlike  $C_3A$ , a non-centric space group  $p2_13$ . (ii) an orthorhombic structure containing Si and Fe, and has a composition which falls in the two-phase region between the cubic and orthorhombic solid solutions. (iii) a monoclinic structure with  $x=1.5$ , and (iv) a monoclinic structure bearing Si and has an  $Na_2O$  content which exceeds over the compositional range for the monoclinic solid solution range. The four specimens are denoted by #1~#4 according to the increasing order of the  $Na_2O$  contents. Their chemical compositions and cell dimensions obtained from single-crystal diffractometry are listed in Table I.

We propose to designate the above new cubic phase CII and the  $C_3A$  phase CI. In addition

to the cubic phases, O (=orthorhombic phase) and M (=monoclinic phase) are known (Regourd et al., (3)). These four phases are the distinct ones in the  $C_3A-Na_2O$  series which we have so far recognized. As will be shown later, we have structurally confirmed that the high-temperature form of M is not tetragonal but orthorhombic as pointed out by Maki (4) based on optical studies.

The phases which occur in the compositional range for the orthorhombic metastable extension will be denoted O' in the present paper, and those occurring in the range for the monoclinic extension M'.

The four crystal structures were determined based on diffraction intensity data collected on four-circle single-crystal diffractometer and refined to  $R=3.7-4.9\%$ . Note that the structure types of CII and M are ordered derivatives respectively of CI and O. Therefore, in CII, for example, there are two non-equivalent six-membered rings, whereas in  $C_3A$  all rings are equivalent. Then we designated atomic sites in these derivatives in the following rule: when a site in a structure is differentiated into two non-equivalent sites in its derivative, the sites are denoted by putting A and B following the site symbol for the fundamental structure; e.g. the Ca(3) site in CI is differentiated into two distinct sites in CII which we denote Ca3A and Ca3B. Full details of the four structures will be reported elsewhere shortly (Takéuchi, Nishi and Maki (5)).

## THE CII STRUCTURE TYPE

In order to elucidate the mode of Na distribution in the cubic phase, an attempt was made of preparing cubic crystals containing maximum possible Na for that solid solution range. Electron microprobe analyses showed the product we obtained contained 2.4 Na<sub>2</sub>O in wt. per cent. These are the #1 specimens. Our X-ray study showed that the crystals had the space group, not Pa3, but P2<sub>1</sub>3 and represented a new cubic phase CII.

Of a total of 5 Na in the unit cell of the structure, 2.5 Na are located, substituting for Ca, at the positions corresponding to Ca(3) and Ca(4) sites which occur in the threefold axes in the C<sub>3</sub>A structure. The remaining Na atoms go to around the centers of the six-membered rings. The Na atoms in the rings are coordinated by bridge oxygen atoms, giving rise to a contraction of the rings compared to those in C<sub>3</sub>A; this situation makes the a periodicity of the CII structure type smaller than that of CI.

As mentioned earlier, the rings are now differentiated into two non-equivalent rings, A and B. The non-centric feature of the structure is well represented by the difference in occupancy of Na in the rings (Table II). In harmony with this, Na atoms in the cation sites mainly substitute for Ca at Ca3B and Ca4B rather than Ca3A and Ca4A. This situation would presumably be the result of attaining local charge balance.

One of marked features of the structure is that the polyhedra that accommodate Na become bigger in size compared to the corresponding ones in C<sub>3</sub>A. In particular, the Ca4B site has nine near oxygen atoms at the distances smaller than 3 Å and the coordination polyhedra are ninefold, while Ca(4) in the C<sub>3</sub>A

It is notable that the mean Al-O bond length of the #1 specimen is 1.746(2) Å and smaller than 1.752(2) Å for the C<sub>3</sub>A structure. Excepting this case of #1, we find that the mean Al-O bond lengths are almost constant throughout the C<sub>3</sub>A-Na<sub>2</sub>O solid solution series (figure 1).

Fig. 1. Variations of mean Al-O, Ca-O and Ca(Na)-O bond lengths versus Na<sub>2</sub>O content in the solid solution series. The solid solution ranges for C, O and M indicated by heavy vertical lines are those given by Regourd et al. (3); the range of C must be revised so as to indicate those of the two phases, CI and CII. The diagram is based on the data from m (Mondal & Jeffery (1)), n (Nishi & Takéuchi (2)), and #1-#4 specimens; p is a plot based on calculated Na occupancy (Takéuchi et al. (5)). The open square indicated by S is a plot of mean Al-O length corrected for the Si content in #4. The mean value of Ca(3)-O and Ca(4)-O bonds in C<sub>3</sub>A was evaluated and plotted separately from that of other Ca-O bonds in the C<sub>3</sub>A structure.

TABLE II

Specimen	#1		#2	n	#3		#4	
Ring	A	B			A	B	A	B
Occupancy of Na (%)	26(3)	37(3)	26.7(6)	50(2)	74.6(8)	75.4(8)	52(2)	75(3)
$\delta^*(\text{\AA})$			0.41(5)	0.30(4)	0.45(2)	0.52(2)	0.41(4)	0.60(4)
Average Na-O distance (Å)	2.86	2.83	2.73	2.68	2.68	2.68	2.70	2.70

n: Nishi & Takéuchi (2).

\* The separation of a pair of split Na positions.

structure has six Ca-O bonds smaller than 3 Å and three additional bonds longer than 3 Å; the coordination about Ca(4) is essentially sixfold. The mean volume (16.90 Å<sup>3</sup>) of the octahedra about Ca3A and Ca3B is likewise bigger than the volume (16.58 Å<sup>3</sup>) of the octahedron about Ca(3) in C<sub>3</sub>A. Such a 'swelling effect' of polyhedra that occurs upon replacement of Ca by Na sensibly generates structural distortion and is of basic importance to characterize the structural features of the solid solution series now considered.

This situation would probably suggest that the cubic arrangement of the six-membered rings is a stable form basically for C<sub>3</sub>A and the effect on the arrangement caused by the replacement of Ca by Na is compensated by reducing the Al-O bond lengths. With increasing Na<sub>2</sub>O content in the structure, the cubic arrangement of the rings then undergoes a drastic change to yield a new arrangement.

# THE MONOCLINIC STRUCTURE TYPE

Geometrically the crystal structure of the monoclinic structure type shares the same feature with that of the orthorhombic structure type (Nishi and Takéuchi (2)); the mode of arrangement of the six-membered rings in M is in principle the same as that of the O phase. So far the type of the arrangement of the six-membered rings is concerned, there are in the  $\text{Ca}_3\text{A-Na}_2\text{O}$  solid solution series only two different types. They are compared in figure 2.

The essential feature that characterizes the monoclinic structure type is in the mode of distribution of Na over the cation positions corresponding to Ca5 in the orthorhombic structure type. The positions are in the monoclinic structure differentiated into two different sets of positions, Ca5A and Ca5B, having different Na occupancies (Table II). Such a cation ordering gives rise to a slight distortion of the orthorhombic cell to yield a monoclinic symmetry. Compared to the Na occupancy at Ca5 (Table III) in the orthorhombic structure, that in the Ca5B in the monoclinic structure of the #3

TABLE III

#1		#3	
Site	Contents	Site	Contents
Ca3A	0.91(2)Ca 0.09(2)Na	Ca5A	0.803(4)Ca 0.197(4)Na
Ca3B	0.73(2)Ca 0.27(2)Na	Ca5B	0.447(4)Ca 0.553(4)Na
Ca4A	0.97(2)Ca 0.03(2)Na	#4	
Ca4B	0.76(2)Ca 0.24(2)Na	Ca5A	0.902(6)Ca 0.098(6)Na
#2		Ca5B	-
Ca5	0.696(3)Ca 0.304(3)Na		1.000 Na

specimen is increased, while that in the Ca5A is decreased.

In the orthorhombic structure, the Ca5 site has six near oxygen atoms at the distances smaller than 3 Å plus two additional oxygen neighbors at the distances of 3.008 Å and 3.138 Å (Nishi and Takéuchi (2)). In contrast to this, Ca5B has seven near oxygen atoms at the distances smaller than 3 Å and one additional neighbor at a distance of 3.157 Å in the case of the #3 specimen. A calculation excluding the bond lengths

Fig. 2. Two types of the arrangement of six-membered rings. (Left): the arrangement in the cubic structures. Numbers indicate in fractions of eight the height of rings. The rings shown by shaded tetrahedra correspond to B rings in CII, and those shown by open tetrahedra to A (all rings are equivalent in CI). (Right): the arrangement of rings in the non-cubic structures. The rings shown by shaded tetrahedra correspond to B rings in the monoclinic structure type (all rings are equivalent in the orthorhombic structure type). The rings drawn with light lines are at  $z=0$ , and those with heavy lines at  $z=1/2$ . The unit cell is indicated by heavy lines and subcells by broken lines.

longer than 3 Å showed that the mean Ca-O bond lengths for the Ca5B polyhedra are 2.652 Å for the #3 specimen and 2.714 Å for #4; these are considerably bigger than 2.551 Å for the Ca5 polyhedron in the orthorhombic structure. On the other hand, those for the Ca5A polyhedra are 2.521 Å for #3 and 2.622 Å for #4.

The Na atoms in the unit cell other than those in the Ca5A and Ca5B sites are located at around the centers of the six-membered rings. Occupancies of Na at around the centers of A and B rings are nearly the same. These Na atoms are each at a distance of around 3.8 Å from both Ca5A and Ca5B; the Na in the ring will therefore be exchangeable with Na at the cation sites at elevated temperatures.

Each Na atom is not exactly at the center of symmetry on which the ring is located but statistically located at a pair of positions slightly off the center. The separation,  $\delta$ , of the pair in each non-cubic structure examined is listed in Table II given previously.

The occurrence of the monoclinic structure type may be rationalized in terms of the mode of Na distribution over the Ca5A and Ca5B sites. As observed in Figure 3, the

Fig. 3 The structure of the orthorhombic type (the drawing is based on the structure reported by Nishi and Takéuchi (2)), showing the arrangements of polyhedra about cations nearly in the  $x=1/4$  level. The site symbols indicated by stars correspond to B sites in the monoclinic structure type; those not indicated by stars to A sites. Each pair of tetrahedra is portion of a six-membered ring.

Ca5A and Ca5B sites occur in the same  $z$  level and the polyhedra about these sites flank on a pair of tetrahedra of each six-membered ring. Note that they occur alternately along the  $b$  axis and also along  $c$ . If suppose that the Na occupancies at both cation sites were the same and both sets of polyhedra about these sites equally 'expand'. Then the result would bring about strain in the crystal. The mode of Na distribution at the cation sites we found in the monoclinic structure type implies an alternate arrangement of the two kinds of polyhedra about Ca5A and Ca5B, different in size. Such a situation would minimize strain in the crystal.

The monoclinic solid solution range terminates at the  $\text{Na}_2\text{O}$  content of 5.9 wt% (Fletcher et al., (6)). This limitation appears to be explainable structurally. As observed in Table II given previously, the Na-O distances decrease with increasing Na occupancy in the ring. This trend is however only in the range from zero to 50 % Na occupancies in the ring. The distances for the occupancy of 75 % Na are not significantly different from those for 50 % Na. This fact would suggest that the contraction of the six-membered ring brought about by the occupancy of 75 % Na would be the permissible limit for the distortion of the ring. Namely, the occupancy of Na in the ring appears to be limited up to around 75 %. The #3 specimen contains 5.7 %  $\text{Na}_2\text{O}$  which corresponds to the limit of the monoclinic solid solution given by Regourd et al. (3) and the occupancies of Na in the A and B rings are nearly of the same value of 75 % (Table II).

#### PHASE TRANSITION

Using a crystal piece of the #3 specimen, we recorded with a precession camera the  $hk0$  patterns at temperatures from 600°C to 900°C with an interval of 100°C. The result showed that the monoclinic structure was transformed to orthorhombic. Noting that the pair of intensities of  $8\bar{1}0$  and  $810$  reflections are one of the characteristic pairs to distinguish the orthorhombic form from monoclinic, we measured their intensities recorded at 880°C with an automated microdensitometer and compared them in Fig. 4 with those at room temperature.

Fig. 4. Portions of computer out put, showing intensities of  $8\bar{1}0$  and  $810$  reflections recorded in film at 22°C and 800°C. Contours are drawn at an arbitrary scale but with equal intervals; those at the central portion of the  $8\bar{1}0$  peak at 22°C are omitted. The ratio in observed integrated intensity of this reflection pair was 1.9 at 22°C, and 1.0 at 800°C.

When the crystals were heated above 600°C and quenched to room temperature, they exhibited lamellar twins and gave monoclinic diffraction patterns.

It is highly conceivable that the transition is caused by order-disorder of Na and Ca at the Ca5A and Ca5B sites. If the Na occupancies at these sites in the monoclinic structure type is equalized at elevated temperatures, the structure is simply transformed into orthorhombic; positional adjustment of the six-membered rings required for the transition is almost negligible.

#### ROLE OF Si IN THE STABILITY OF SOLID SOLUTIONS

A comparison between the structures of the #2 specimens and the reported orthorhombic structure of pure aluminate (Nishi and Takéuchi (2)) shows that the Na occupancy of 30 % at Ca5 in the former is slightly higher than that of the latter (25 %), while the Na occupancy in the rings of the former (Table III) is roughly half of that of the latter (50 %); the excess positive charge introduced by Si in the #2 specimen is mainly compensated by decreasing Na in the rings. It then appears that the Na occupancy in the six-membered rings is related to the stability of the orthorhombic phase. If therefore the orthorhombic structure type permits to contain more Si than that in the #2 specimen, the compositional range would be more widened towards the Na<sub>2</sub>O poor region by decreasing Na in the rings. This situation will offer a structural basis for explaining the 'meta-stable' extension of the orthorhombic phase.

Our structural study of the #4 specimen revealed that the presence of Si in the monoclinic solid solution permits the Na occupancy of 100 % at the Ca5B site (Table III) and as the result the occupancies of Na in the rings, which will otherwise increase with increasing Na<sub>2</sub>O content (Figure 5), are kept to the values less than around 75 %. As a total effect, the number of Na per cell may exceed over the number permissible for the original monoclinic range and thus the range may be extended to the Na<sub>2</sub>O content of 7.59 %.

Fig. 5. Variation of the Na occupancy in the rings versus Na<sub>2</sub>O content in the non-cubic structures. A and B represent A and B rings; q is a calculated value for the composition having Na<sub>2</sub>O of 4.6 %. Broken lines indicate assumed variations in the M' range. Entries are: 1=Nishi and Takéuchi (2), 3=#3 specimen, and 4=#4 specimen.

#### CONCLUSIONS

The conclusions drawn from the present study include:

- (i) In the C<sub>3</sub>A-Na<sub>2</sub>O solid solution series, the existence of four distinct phases, CI (=C<sub>3</sub>A), CII, O, and M, has so far been recognized.
- (ii) The monoclinic phase is transformed at around 500°C to orthorhombic and the transition is reversible. This transition is of an order-disorder type.
- (iii) When a calcium site is replaced by Na, the polyhedron about the site tends to expand. The structural changes from one phase to another with the change in Na<sub>2</sub>O contents can be explainable in terms of this effect.
- (iv) The occupancy of Na at around the center of a six-membered ring appears to be limited up to around 75 %.
- (v) When Si exists in the solid solutions, it plays a role in reducing the Na occupancy at around the centers of the six-membered rings. The extensions of the orthorhombic and monoclinic solid solution ranges can be rationalized based on such a structural characteristics.

RESUME: La composition d'équilibre des deux phases anisotropiques de l'aluminate tricalcique contenant du sodium est déterminée en fonction de la température. Ces compositions sont représentées par une couple de courbes qui se joignent en correspondance du composé  $C_8NA_3$ , dont on prouve l'existence.

SUMMARY: The equilibrium composition of the two anisotropic phases of tricalcium aluminate containing sodium is determined as a function of temperature. These compositions are represented by a couple of curves joining in the  $C_8NA_3$  compound, whose existence is proved.

## 1. INTRODUCTION

The origin of this investigation mainly lies in a sentence contained in a paper of two of us (1): "...but none of the researchers who were concerned with this subject found the two anisotropic forms at the same time" (rhombic and monoclinic phases according to Maki (2), or orthorhombic I or tetragonal and orthorhombic II according to Regourd et Al. (3)).

It lies also in that, apart from the thermochemical results, not even the mentioned investigation could distinguish the two phases. Consequently one of us proposed to re-examine the problem by using the microscopic observation by reflected light as a research method on samples quenched from different temperatures. Of course the optical properties of the phases are not determined but only their differentiation is sought through the different behaviour towards suitable reagents.

Therefore from now on the phases will be indicated as rhombic and monoclinic, for simplicity's sake, without entering upon their structure.

The starting point is represented by Maki's (2) results which slightly differ from and indeed seem to simplify Regourd, Chrony, Hjorth, Mortureux and Guinier's (3) results. In substance it is question of defining the stability field of the two rhombic and monoclinic phases by determining the couple of curves which represent the composition of the two phases in equilibrium as the temperature changes.

The extension of the rhombic phase towards the cubic one is not of interest here; on the contrary the extension of the two anisotropic phases towards  $C_8Na_3$  (\*) is considered since, of course, the two curves must join.

## 2. EXPERIMENTAL

### 2.1 Preparation of the samples

The solid solutions of sodium oxide in tricalcium aluminate were prepared by homogenizing stoichiometric quantities of r.g.  $CaCO_3$ ,  $Na_2CO_3$  and  $\gamma-Al_2O_3$  in cyclohexane by an agate jar mill. After evaporation of the liquid, the material was decarbonated for 1 hour at 900°C and afterwards re-homogenized.

Since the sodium volatility is high at the selected firing temperature (1350°C), it was necessary to introduce the material, pressed in small cylinders, into 5 mm diam. sealed platinum tubes.

To prevent the tubes from cracking owing to the thermal expansion of air, they were evacuated by a rotary pump and welded.

To reach the equilibrium with certainty, the fired samples were ground and fired again; after this treatment, their sodium content was determined by atomic absorption spectrometry and optical and X-ray examinations were carried out to ascertain their pureness.

Aliquots of each preparation were closed in platinum tubes and brought to the selected quenching temperature which was maintained for at least 12 hours. After this annealing, the samples were quenched in water. Table I shows the examined compositions expressed by the general formula  $C_{3-n}N_nA$  [for  $C_8Na_3$ , n is 0.33, exactly 0.3].

### 2.2 Microscopic observations

The microscopic observations were carried out especially on 4 mm diam., 8 mm long cylinders soaked in styrene and afterwards resinified. The cylinders were sectioned and polished along a longitudinal plane.

(\*)  $C = CaO$ ,  $N = Na_2O$ ,  $A = Al_2O_3$

The pursuit of reagents suitable to distinguish the two phases presented a considerable difficulty, given the very close analogy of the two phases. Several reagents were tried: distilled water, borax at different concentrations, alcoholic solution of  $H_2SO_4$  a.s.o., reagents studied by one of us to investigate the constitution of portland cement (4) or during subsequent research to identify the constituents of celite. The outcome was always negative: the etching was either missing or equal for the two phases. The attention was turned to stronger reagents and, among these, to "nital", an alcoholic solution of  $HNO_3$  (usually at 2%) universally used in the metallography of steels.

The result was quite positive: with an etching of about 30 seconds, one of the phases (the monoclinic) was constantly characterized by very fine stripes of polysynthetic or also multiple twinning. The observation of these stripes requires strong objectives: a numerical aperture below 0.65 is not convenient. It was noted that also this one is sometimes insufficient.

Stripes, that were visible by a 0.85 aperture objective, became undistinguishable by using a 0.65 aperture. The micrographs reproduced in this paper are all 450X (0.65 N.A. objective).

In the observation and still more in the photography, it was necessary to use all the tricks useful to eliminate blurs, sometimes very frequent, due to internal reflections of the crystals, or more generally, to drawbacks of preparation. To this purpose the photographs were taken by introducing the analyzing nicol and, except for the two last, in oblique illumination.

Coming back to the action of the reagent on the two phases, it is possible to add that the reagent simply defines the single crystals in the rhombic one; single planes of twinning are characterized by a line: no stripes. On the contrary, as regards the monoclinic phase, the reagent evidences also the stripes. However it must be noticed that the eventual lack of stripes does not mean that a given crystal is not monoclinic.

The stripes could be not resolvable by the used objective or the twinning plane could be parallel to the section.

Finally the eventual presence of free lime (or of other constituents), if limited and irregularly distributed (that is lacking in some zones) can be attributed to defects of homogenization; if systematic, it must be considered as a consequence of composition. Free lime, that the indicated reagent would strongly corrode, can be easily recognized in the simply polished specimen since it appears light against a grey background owing to its higher refractive index.

### 2.3 Results

It is natural to present them by following the development of this work.

At first the composition was simply changed by passing from  $n = 0.18$  (0.18 N) to  $n = 0.28$  (0.28 N) at an annealing temperature of  $400^{\circ}\text{C}$ . Since the first results of the observations were positive, also the ordinary temperature (slow cooling) and, for some mixes, the annealing temperature of  $1350^{\circ}\text{C}$  were considered.

Subsequently, the composition was maintained constant (0.26 N) and the annealing temperature was changed.

Given the obtained results, this operation was carried out also for  $n = 0.33$  ( $\text{CgNA}_3$ ).

In the final plot (fig. 16), the different compositions observed under the microscope are represented by rather marked spots.

FIG. 1:  $\text{C}_{2.78}\text{N}_{0.22}\text{A}$  quenched from  $400^{\circ}\text{C}$  - Nital - 450X

I) Quenching from  $400^{\circ}\text{C}$ . Fig. 1 shows the appearance of the 0.22 N mix, that is  $n = 0.22$ . Considering that the dark zone represents the styrene resin, different crystals are noted in the grains, however without stripes: this is obviously the rhombic phase.

Fig. 2 shows the appearance of the 0.26 N mix. Practically all the crystals are striped (monoclinic phase). Fig. 3 corresponds to the 0.28 N composition and, owing to the similarity of its stripes to those of the previous figure, it evidences that the phase is completely monoclinic already in 0.26 N.

In Fig. 4, corresponding to 0.24 N, some crystals have not stripes and others do, with a certain prevalence of the former: both phases are present. The monoclinic phase begins appearing at about 0.23 N.

II) Slow cooling up to ordinary temperature. The presence of the monoclinic phase begins little below 0.21 N instead of 0.23 N. Fig. 5; corresponding to 0.22 N (cmp. Fig. 1) already shows the evident presence of this phase.

FIG. 2:  $\text{C}_{2.74}\text{N}_{0.26}\text{A}$  quenched from  $400^{\circ}\text{C}$  - Nital - 450X

FIG. 3:  $\text{C}_{2.72}\text{N}_{0.28}\text{A}$  quenched from  $400^{\circ}\text{C}$  - Nital - 450X

FIG. 4:  $\text{C}_{2.76}\text{N}_{0.24}\text{A}$  quenched from  $400^{\circ}\text{C}$  - Nital - 450X

FIG. 5:  $C_{2.78}N_{0.22}A$  cooled at room temperature - Nital 450X

FIG. 6:  $C_{2.76}N_{0.24}A$  cooled at room temperature - Nital 450X

FIG. 7:  $C_{2.75}N_{0.25}A$  cooled at room temperature - Nital 450X

It clearly prevails at 0.24 N (fig. 6). It represents almost the totality at 0.25 N (compare fig. 7 with figures 2 and 3).

III) 0.26 N composition quenched from different temperatures. The rhombic phase is present at the temperature of 450°C (fig. 8). It becomes prevalent at 475°C (fig. 9). It represents the totality at 500°C (fig. 10).

Also a 0.28 N mix was quenched from 500°C. Both phases are present again in it.

IV) 0.33 N composition ( $C_8Na_3$ ) quenched from different temperatures. The two curves representing the equilibrium composition of the two phases, as defined by the above results, tend to shift rightwards as the temperature increases, nevertheless without joining for  $Na_2O$  contents considered up to now.

If the assumption of two individual phases is true, the two curves must necessarily meet in one point, which is already indicated schematically in the paper (1). This point, however, must represent the composition and transformation temperature of an only component.

FIG. 8:  $C_{2.74}N_{0.26}A$  quenched from 450°C - Nital - 450X

FIG. 9:  $C_{2.74}N_{0.26}A$  quenched from 475°C - Nital - 450X

FIG. 10:  $C_{2.74}N_{0.26}A$  quenched from 500°C - Nital - 450X

FIG. 12:  $C_{2.66}N_{0.33}A$  quenched from 400°C - Nital - 450X

The extrapolation of the two curves led to foresee their joining in the 0.33 N composition and at a temperature ranging between 500° and 600°C. Of course it was necessary to ascertain that the mass of this composition should correspond to a single compound which, at the sought temperature, must appear in two phases simultaneously.

The 0.33 N mix fired and quenched from 1350°C was lacking in free lime or other components: therefore the  $C_8NA_3$  compound exists, notwithstanding the difficulties of its preparation.

FIG. 13:  $C_{2.66}N_{0.33}A$  quenched from 550°C - Nital - 450X

FIG. 11:  $C_{2.66}N_{0.33}A$  quenched from 1350°C - Nital - 450X

Fig. 11 represents its micrographic appearance, without stripes. The small light spots inside the crystals are due to internal reflections and not to the presence of free lime that would strongly have been etched.

Fig. 12 shows the same product quenched from 400°C: the stripes are complete.

The quenching from 600°C did not produce stripes, whereas the latter were wholly present for quenching from 500°C.

FIG. 14:  $C_{2.65}N_{0.35}A$  quenched from 1350°C - Not etched - 450X

The sample quenched from 550°C (fig. 13) appeared to be extremely interesting: both phases are present. Moreover the development of striped roundish crystals of the monoclinic phase was often noticed inside crystals of the rhombic phase. Obviously the temperature of 550°C (apart from experimental errors) corresponds to the temperature of transformation of a phase into the other.

V) 0.35 N composition quenched from 1350°C. One could suppose that the two curves should not join yet at 0.33 N and that, consequently, it should be necessary to examine mixes richer in Na<sub>2</sub>O. Instead, there is no need of many quenching tests from different temperatures. The 0.35 N mix, quenched from 1350°C, showed the systematic presence of free lime and, obviously, of sodium aluminate (NA).

Fig. 14 shows that, when the specimen is simply polished, free lime appears (owing to its higher reflectivity than that of aluminate) in clearer (polygonal) grains. The NA compound, having low reflectivity, is almost undistinguishable from the dark resin in the background. Sodium aluminate could be easily evidenced by hydrofluoric acid-based reagents (which do not etch CaO) studied by one of us (4), eventually by restraining their solving action with the addition of alcohol.

FIG. 15: C<sub>2.66</sub>N<sub>0.33</sub>A quenched from 1350°C - not etched 450X

In order to assure that the 0.33 N composition does not contain free lime, the same specimen of fig. 11 is reproduced in fig. 15 which shows its not etched appearance.

The small light spots, having irregular and blurred boundaries, do not represent free lime but internal reflections of the crystals.

Here the mass among the aluminate crystals exclusively consists of resin.

After all, the two equilibrium phases show a varying composition according to two curves joining in C<sub>8</sub>NA<sub>3</sub>, as indicated in fig. 16.

### 3. CONCLUSIONS

The compound C<sub>8</sub>NA<sub>3</sub> exists. The composition of the two solid anisotropic solutions, that this compound forms as a preponderant part with C<sub>3</sub>A, varies according to two co-existence curves.

FIG. 16: Phase equilibrium in the part richest in sodium in the system C<sub>3</sub>A-C<sub>8</sub>NA<sub>3</sub>

These have a common point at 550°C corresponding to the pure C<sub>8</sub>NA<sub>3</sub> compound; they also present a decreasing trend as the temperature and the sodium content decrease.

## Theme 2 - The hydration of $C_3A$

### GENERAL REPORT

by H.N. STEIN, Laboratory of Colloid Science, Vakgroep Elektrochemie, Department of Chemical Engineering, Eindhoven University of Technology, Eindhoven, THE NETHERLANDS.

The papers which have been contributed to the present congress and which are specially related to the hydration of  $C_3A$ , concern the following problems:

- What is happening at the  $C_3A$ /water and  $C_3A/Ca(OH)_2$  solution interfaces?
  - How is the hydration of  $C_3A$  influenced by the presence of  $Na_2O$  as solid solution in the  $C_3A$ ?
  - What is the mechanism of retardation of  $C_3A$  hydration in the presence of calcium sulfate?
  - How large is the mutual interaction between calcium aluminate hydrate crystals when present in aqueous solution?
- 
- Phenomena at the  $C_3A$ /water and  $C_3A/Ca(OH)_2$  solution interfaces.

Barret and Bertrandie investigated the dissolution of  $C_3A$  in water and in  $Ca(OH)_2$  solutions by analyzing the liquid after contact with  $C_3A$ , for its increase in  $CaO$  and  $Al_2O_3$  contents. In a stagnant medium (water or dilute  $Ca(OH)_2$  solution),  $C_2AH_8$  is the first solid to precipitate, which leads to a  $\Delta CaO/Al_2O_3$  molar ratio  $> 3$  in the liquid phase. This does not, however, signify that the dissolution process itself is incongruent: after very short contact times (effected by passage of liquid through a thin layer of  $C_3A$ ), the filtrate has a  $\Delta CaO/Al_2O_3$  ratio = 3. In more concentrated  $Ca(OH)_2$  solutions ( $[CaO] > 9 \cdot 10^{-3} \text{ mol.kg}^{-1}$ ),  $C_4AH_{13}$  is the first solid to precipitate which leads to  $\Delta CaO/Al_2O_3$  molar ratios  $< 3$  in the liquid. The authors describe the dissolution as being determined by the solubility of superficially hydrated  $C_3A$ .

Thus, according to Barret and Bertrandie, the first process taking place is the formation of a hydrated layer on the  $C_3A$  itself, with  $\Delta CaO/Al_2O_3$  molar ratio = 3.

However, it has been found from electrokinetic data reported by the present author, that the calcium aluminate hydrates when formed during  $C_3A$  hydration, have a definitely non-stoichiometric surface layer deficient in aluminate ions: the  $\zeta$  potential of both hexagonal and cubical hydrates is  $> 0$  during  $C_3A$  hydration, and the corresponding surface charge increases with  $NaOH$  concentration, which indicates progressive extraction of aluminate

ions from the surfaces of the calcium aluminate hydrates.

There is no real contradiction, however, between the results reported by Barret and Bertrandie, and the  $\zeta$  potential data, because a surface charge of the required magnitude can easily originate through differences in calcium and aluminate ion dissolution rate which are too small to be detected by analyses of the aqueous solutions.

#### b. Influence of $Na_2O$ on $C_3A$ hydration

The  $\zeta$  potential data mentioned have been advanced as a support for an explanation of the influence of  $Na_2O$  on the hydration rate of  $C_3A$ : extraction of aluminate ions from the hydrated surface layer on  $C_3A$  would make its composition approach to that of  $Ca(OH)_2$ <sup>1)</sup>. This subject has been a rather controversial one. It had been studied previously by Gupta, Chatterji and Jeffery<sup>2)</sup>, by Regourd and Moretux<sup>3)</sup>, by Boikova c.s.<sup>4) 5)</sup> and by Butt c.s.<sup>6) 7)</sup> with none too consistent results. In reality, two questions are involved here: does  $Na_2O$  retard or accelerate the hydration of  $C_3A$ ; and does  $Na_2O$  present as solid solution in the  $C_3A$ , act in the same way as an equivalent amount of  $NaOH$  added separately?

Most investigators 1) 2) 3) 4) 5) report a retardation by  $Na_2O$ ; however, Butt c.s. 6) 7) found an acceleration. This discrepancy is not resolved by the contributions to the present congress: Boikova, Grishchenko and Domansky again report a retardation; Kolbassov, Kozyreva and Dobronravova on the other hand report an acceleration. From the data presented in the communications, no possible reason (e.g. differences in experimental conditions) can be extracted which may be held responsible for the discrepancy. Although part of the results reported by Kolbassov c.s. have been obtained by plastometry, which means that they are influenced not only by the degree of hydration but by the mutual interaction between the calcium aluminate hydrates as well, the authors also find a higher hydration activity of  $Na_2O$  containing  $C_3A$  by differential thermokinetic curves. Perhaps the difference in results can be explained when details on the experimental procedures employed are exchanged at this congress.

Similarly, the opinions are still divided as to whether  $\text{Na}_2\text{O}$  built into the  $\text{C}_3\text{A}$  structure acts in the same way as an equivalent amount of  $\text{NaOH}$  added separately. This question is of practical interest, since by a suitable choice of fuel it is possible to either enclose the  $\text{Na}_2\text{O}$  in a Portland cement clinker as solid solution in the  $\text{C}_3\text{A}$ , or to have it present in a separate phase ( $\text{Na}_2\text{SO}_4$ )<sup>7)</sup>.

Boikova c.s. discern three different stages in the hydration of  $\text{C}_3\text{A}$ ; during the first stage,  $\text{Na}_2\text{O}$  built into the  $\text{C}_3\text{A}$  structure retards the hydration strongly because water penetration into  $\text{C}_3\text{A}$  containing  $\text{Na}_2\text{O}$  is hindered by  $\text{Na}^+$  ions occupying holes in the  $\text{C}_3\text{A}$  crystal structure. This agrees with Regourd's view<sup>3) 8)</sup>, which is, however, not shared by Spierings and the present author<sup>1)</sup>. The latter authors report, in agreement with Gunta c.s.<sup>2) 9)</sup>, a strong retardation of  $\text{C}_3\text{A}$  hydration by  $\text{NaOH}$  added separately. Perhaps the conflicting evidence brought on this point can be conciliated by the statement that in stirred suspensions of large water to solids ratios, the action of  $\text{NaOH}$  added separately is similar to that exerted by  $\text{Na}_2\text{O}$  built into the  $\text{C}_3\text{A}$  structure, whereas in pastes of low w/s ratio local  $\text{NaOH}$  concentrations near the hydrating,  $\text{Na}_2\text{O}$  containing,  $\text{C}_3\text{A}$  are much larger than if  $\text{NaOH}$  is added separately. However, this point clearly needs further elaboration by experiments.

#### c. Retardation of $\text{C}_3\text{A}$ hydration in the presence of calcium sulfate

Local concentrations deviating from the bulk concentrations also play a dominant role in the discussions of the retardation of  $\text{C}_3\text{A}$  hydration in the presence of  $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ . To this point, part of the communication of Ghorab, Heinz, Ludwig, Meskendahl and Wolter to the present congress is devoted. The authors confirmed the topo-tactical formation of hedgehog-like ettringite layers on  $\text{C}_3\text{A}$  in pastes  $\text{C}_3\text{A} + \text{CaSO}_4 + \text{CaO} + \text{H}_2\text{O}$ , both with and without the additional presence of  $\text{CaCO}_3$  or  $\text{C}_3\text{S}$ . Probes cured at rest react (under otherwise identical curing conditions) faster than shaken ones, because in the pastes cured at rest local concentrations lead to conversion of the ettringite layer, e.g. according to:

Thus, the ettringite itself is regarded as a retarder.

This is to be contrasted with Chatterji's opinion, that not the ettringite itself, but a hexagonal hydrate layer ( $\text{C}_4\text{AH}_{13}$ ) between the  $\text{C}_3\text{A}$  and the ettringite retards the  $\text{C}_3\text{A}$  hydration; according to Chatterji, the role of ettringite is to effect a decreasing sulfate concentration from the bulk solution to the  $\text{C}_3\text{A}$  surface which results in hexagonal hydrate formation adjacent to the  $\text{C}_3\text{A}$  grains. Having reviewed different other mechanisms presented for the retardation of  $\text{C}_3\text{A}$  hydration by  $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ , Chatterji finishes by stating that "in the ultimate analysis what is considered to be an acceptable explanation depends more on the fashion of the day than anything else".

#### d. The mutual interaction between calcium aluminate hydrate crystals in aqueous solution.

This subject, a very important one for a material which is used for its mechanical properties, has just been entered upon. By the methods of colloid chemistry (measurement of coagulation rates), a value has been obtained for the so-called Hamaker constant operative between  $\text{C}_3\text{AH}_6$  crystals (about  $0.1 \times 10^{-20}$  J, rather small in comparison with other substances). More important perhaps is, that in dilute electrolyte solutions the coagulation clearly is not governed by electrostatic repulsion, and that there is, in addition to van der Waals attraction, some other agent effecting a relatively strong attraction between the  $\text{C}_3\text{AH}_6$  crystals resulting in rapid coagulation. Polyaluminate ions have been held responsible for this effect<sup>10)</sup>, but this idea needs further confirmation.

#### Final Remarks: ideas on future research

The present author does not share Chatterji's pessimism with regard to the possibility of progress in understanding the hydration reactions of  $\text{C}_3\text{A}$ . Although there are still problems to be solved, it is possible to surmount agnosticism. One leading point emerges from the foregoing discussion: the importance of local ionic concentration gradients in the aqueous phase, for determining the reactivity of  $\text{C}_3\text{A}$ . Near the  $\text{C}_3\text{A}$ /water surface, especially in a stagnant aqueous medium, apparently quite different conditions obtain than far away from  $\text{C}_3\text{A}$  grains. Thus, the importance of local concentrations in the formation or conversion of hydrates is stressed by Barret and Bertrandie, by Ghobar c.s., and by Chatterji; and the formation of different hydrates far away from and near the  $\text{C}_3\text{A}$  grains has been demonstrated convincingly by Regourd<sup>8)</sup>.

There is a problem here, however. If local concentrations different from those in the bulk solution, are to be maintained, diffusion of ions must be a slow process as compared with other processes occurring. A calculation in this respect<sup>11)</sup> about what porosity (= area available for ion transport per  $\text{cm}^2$   $\text{C}_3\text{A}$  surface) of the hydrate layer should be assumed in order to achieve this situation, leads to  $10^{-6} \text{ cm}^2$ , a rather low value as remarked by Chatterji. This particular calculation refers to  $\text{Ca}(\text{OH})_2$  diffusion; however diffusion of other electrolytes concerned is not much slower (a slow diffusion allows the porosity to become proportionally larger; diffusion coefficients of hydroxides are generally about 1.5 times larger than those of salts with other anions<sup>12)</sup>). Although the remarks made by Chatterji are not convincing (he apparently overlooks the possibilities that the number of  $\text{C}_3\text{A}$  grains decreases during hydration, and that a number of  $\text{C}_3\text{A}$  grains may be shielded from the bulk solution by a common hydrate layer; in addition, his pressure difference,  $1.5 \cdot 10^4 \text{ dyne cm}^{-2}$ , amounts to about 0.015 atmosphere which seems quite acceptable), nevertheless a porosity of  $10^{-6}$  is surprisingly low. One of the problems for

future research then appears to be, to obtain a quantitative idea about the effective porosity in hydrate layers formed under different conditions, and consisting of different hydrates.

A second problem, perhaps an even more important one, appears to me a further elaboration of the colloid chemical aspects of hardening cement. Properties such as the rheology of cement pastes and mortars, and creep of systems containing hardening cement, can only be understood if a quantitative idea can be obtained of attraction and repulsion between the hydrate particles.

# Thème 2 - Hydratation de $C_3A$

## RAPPORT GENERAL

par H.N. STEIN, Laboratory of Colloid Science, Vakgroep Elektrochemie, Department of Chemical Engineering, Eindhoven University of Technology, Eindhoven, THE NETHERLANDS.

Les communications relatives à l'hydratation de  $C_3A$  concernent les problèmes suivants :

- Que se passe-t-il aux interfaces  $C_3A$ /eau et  $C_3A$ /solution de  $Ca(OH)_2$  ?
- Comment l'hydratation de  $C_3A$  est-elle influencée par la présence de  $Na_2O$  en solution solide dans  $C_3A$  ?
- Quel est le mécanisme du retard de l'hydratation du  $C_3A$  en présence de sulfate de calcium ?
- Quelle est l'importance de l'interaction mutuelle entre les cristaux d'aluminates hydratés dans la solution aqueuse ?

### a) Phénomènes aux interfaces $C_3A$ /eau et $C_3A$ /solution de $Ca(OH)_2$

BARRET et BERTRANDIE ont étudié la dissolution de  $C_3A$  dans l'eau et dans des solutions de  $Ca(OH)_2$  en analysant la phase liquide après le contact avec  $C_3A$  car sa teneur en  $CaO$  et  $Al_2O_3$  croît. Dans un milieu stagnant (eau ou solution de  $Ca(OH)_2$  diluée)  $C_2AH_3$  est le premier solide à précipiter ce qui conduit à un rapport molaire  $CaO/Al_2O_3$  supérieur à 3 dans la phase liquide. Cependant ceci ne signifie pas que le processus de dissolution lui-même soit incongruent: après des temps de contact très courts (réalisés par passage du liquide au travers d'une couche mince de  $C_3A$ ) le filtrat a un rapport  $CaO/Al_2O_3 = 3$ . Dans des solutions de  $Ca(OH)_2$  plus concentrées ( $[CaO] > 9.10^{-3}$  mol.kg $^{-1}$ ),  $C_4AH_{13}$  est le premier solide à précipiter ce qui entraîne des rapports molaires inférieurs à 3 dans le liquide. Les auteurs décrivent la dissolution comme étant déterminée par la solubilité du  $C_3A$  superficiellement hydraté. Ainsi d'après BARRET et BERTRANDIE, le premier processus est la formation d'une couche hydratée sur le  $C_3A$  lui-même avec un rapport molaire  $CaO/Al_2O_3 = 3$ .

Cependant, le présent auteur a trouvé à partir des données électrocinétiques que les aluminates de calcium hydratés, qui se forment durant l'hydratation de  $C_3A$ , ont d'une manière définie une couche superficielle non-stoechiométrique, appauvrie en ions aluminates : le potentiel Zêta des deux types d'hydrates, hexagonaux et cubiques, est positif au cours de l'hydratation de  $C_3A$  et la charge de la surface correspondante croît avec la concentration en  $NaOH$ , ce qui indique une extraction progressive d'ions aluminates des surfaces des aluminates de calcium hydratés.

Il n'y a pas toutefois de contradiction réelle entre les résultats rapportés par BARRET, BERTRANDIE et les données du potentiel Zêta parce que la charge superficielle mesurable peut aisément provenir de

différences dans le taux de dissolution des ions calcium et aluminates qui sont trop faibles pour être détectées par les analyses des solutions aqueuses.

### b) Influence de $Na_2O$ sur l'hydratation de $C_3A$

Les données du potentiel Zêta déjà mentionnées ont été utilisées comme support d'une explication de l'influence de  $Na_2O$  sur le taux d'hydratation de  $C_3A$  : l'extraction des ions aluminates de la couche superficielle hydratée de  $C_3A$  rendrait sa composition proche de celle de  $Ca(OH)_2$  (1). Ce sujet a été plutôt controversé. Il a été étudié auparavant par GUPTA, CHATTERJI et JEFFERY (2), par REGOURD et MORTUREUX (3), par BOIKOVA et al (4, 5) et par BUTT et al (6, 7), les résultats ne sont pas concordants.

En réalité, deux questions se posent :  $Na_2O$  retarde-t-il ou accélère-t-il l'hydratation de  $C_3A$  ? ;  $Na_2O$  présent en solution solide dans  $C_3A$  agit-il de la même manière qu'une teneur équivalente en  $NaOH$  ajoutée séparément ?

La plupart des chercheurs (1, 2, 3, 4 et 5) ont rapporté un retard dû à  $Na_2O$ , cependant BUTT et al (6, 7) trouvent une accélération. Cette contradiction n'est pas résolue par les contributions à ce présent Congrès : BOIKOVA, GRISHCHENKO et DOMANSKY rapportent à nouveau un retard ; KOLBASSOV, KOZYREVA et DOBRONRAVOVA rapportent une accélération d'autre part. A partir des données présentées dans les communications, aucune raison possible (par exemple, différences dans les conditions expérimentales) ne peut être extraite qui puisse être responsable de cette contradiction. Bien qu'une partie des résultats donnée par KOLBASSOV et al ait été obtenue par plastométrie, ce qui signifie qu'ils sont influencés non seulement par le degré d'hydratation mais aussi bien par l'interaction mutuelle entre les aluminates de calcium hydratés, les auteurs trouvent aussi une activité plus grande dans le  $C_3A$  contenant  $Na_2O$ , à partir des courbes thermocinétiques différentielles. Peut-être la différence entre les résultats pourra-t-elle être expliquée quand les détails sur les procédés expérimentaux utilisés seront échangés à ce Congrès.

De la même manière, les opinions sont toujours divisées quant à savoir si  $Na_2O$  dans la structure de  $C_3A$  agit dans le même sens qu'une teneur équivalente de  $NaOH$  ajoutée séparément. Cette question est d'un intérêt pratique car par un choix approprié de fuel, il est possible, soit d'inclure le  $Na_2O$  dans le clinker de ciment portland en solution solide dans le  $C_3A$ , soit de l'avoir présent dans une phase séparée,  $Na_2SO_4$  (7).

BOIKOVA et al discernent trois stades différents dans l'hydratation de  $C_3A$  : durant le premier stade,  $H_2O$  dans la structure de  $C_3A$  retarde fortement l'hydratation parce que la pénétration de l'eau dans  $C_3A$  contenant  $Na_2O$  est empêchée par les ions  $Na^+$  occupant les trous de la structure cristalline de  $C_3A$ . Ceci est en concordance avec le point de vue de REGOURD, qui n'est cependant pas partagé par SPIERINGS et le présent auteur. Ces derniers auteurs ont rapporté en accord avec GUPTA et al (2, 9) un retard important de l'hydratation de  $C_3A$  par  $NaOH$  ajouté séparément. Peut-être le conflit évident sur ce point peut-il être concilié par l'opinion que, dans les suspensions agitées à grand rapport eau/solides, l'action de  $NaOH$  ajouté séparément est similaire à celle exercée par  $Na_2O$  dans la structure de  $C_3A$  tandis que dans les pâtes à faible  $e/s$  des concentrations locales au niveau du  $C_3A$  contenant  $Na_2O$ , qui s'hydrate, sont plus élevées que si  $NaOH$  est ajouté séparément. Cependant, ce point nécessite clairement une élaboration plus poussée par des expériences.

#### c) Retard à l'hydratation de $C_3A$ en présence de sulfate de calcium

Les concentrations locales s'écartant des concentrations globales jouent aussi un rôle dominant dans les discussions sur le retard de l'hydratation de  $C_3A$  en présence de  $CaSO_4 \cdot 2H_2O$ . A ce point est consacrée une partie de la communication à ce Congrès de GHORAB, HEINZ, LUDWIG, MESKENDAH et WOLTER. Les auteurs confirment la formation topotactique de couches d'ettringite sous forme de hérissons sur  $C_3A$  dans des pâtes  $C_3A + CaSO_4 + CAO + H_2O$  à la fois avec et sans la présence additionnelle de  $CaCO_3$  ou de  $C_3S$ . Les échantillons traités au repos (par ailleurs dans des conditions de traitement identiques) réagissent plus vite que les échantillons agités parce que dans les pâtes au repos des concentrations locales entraînent la conversion de la couche d'ettringite suivant la formule :

Ainsi l'ettringite, elle-même, est un retardateur.

Ceci contraste avec l'opinion de CHATTERJI que ce n'est pas l'ettringite elle-même mais une couche d'hydrate hexagonal ( $C_4AH_{13}$ ) entre le  $C_3A$  et l'ettringite, qui retarde l'hydratation de  $C_3A$ . D'après CHATTERJI, le rôle de l'ettringite est d'entraîner une décroissance de la concentration en sulfate de la solution à la surface de  $C_3A$  ; il en résulte une formation d'hydrate hexagonal adjacent aux grains de  $C_3A$ . Ayant revu d'autres mécanismes différents du retard de l'hydratation par  $CaSO_4 \cdot 2H_2O$ , CHATTERJI finit par énoncer "que dans l'analyse ultime, ce qui est considéré comme être une explication acceptable dépend plus du goût du jour que d'autre chose".

#### d) L'interaction mutuelle entre les cristaux d'aluminate hydratés dans la solution aqueuse

Ce sujet, très important pour un matériau qui est utilisé pour ses propriétés mécaniques, vient juste de débiter. Par les méthodes de la chimie colloïdale (mesure des taux de coagulation), une valeur a été obtenue pour la constante de Hamaker, qui agit entre les cristaux de  $C_3AH_6$  (environ  $0,1 \times 10^{-20} J$ , valeur plutôt faible en comparaison avec d'autres substances). Plus important, peut-être, dans les solutions d'électrolyte diluées, il est clair que la coagulation n'est pas gouvernée par la répulsion électrostatique et qu'il y a en plus de l'attraction VAN der WAALS, quelque autre agent responsable d'une

attraction relativement forte entre les cristaux de  $C_3AH_6$ , aboutissant à une coagulation rapide. Des ions polyaluminates ont été rendus responsables de cet effet (10) mais cette idée demande une confirmation ultérieure.

#### Remarques finales : idées sur des recherches futures

Le présent auteur ne partage pas le pessimisme de CHATTERJI concernant la possibilité de progrès dans la compréhension des réactions d'hydratation de  $C_3A$ .

Bien qu'il y ait encore des problèmes à résoudre, il est possible de surmonter l'agnosticisme. Un point principal émerge de la discussion précédente : l'importance des gradients de concentration ionique locale dans la phase aqueuse pour déterminer la réactivité de  $C_3A$ . Près de la surface  $C_3A$ /eau, spécialement dans un milieu aqueux stagnant, les conditions obtenues sont apparemment différentes de celles éloignées des grains de  $C_3A$ . Ainsi l'importance des concentrations locales dans la formation ou la conversion des hydrates est mise en valeur par BARRET, BERTRANDIE, par GHORAB et al et par CHATTERJI. La formation de différents hydrates loin et près des grains de  $C_3A$  a été démontrée de façon convaincante par REGOURD (8).

Toutefois, il y a ici un problème. Si les concentrations locales, différentes de celles de la solution sont maintenues, la diffusion des ions doit être un processus lent comparé à celui des autres processus qui ont lieu. A cet égard, un calcul concernant quelle porosité (surface utile pour le transport d'ions par  $cm^2$  du surface de  $C_3A$ ) de la couche d'hydrate serait affectée dans la réalisation de cette situation, aboutit à  $10^{-6} cm^2$ , une valeur plutôt faible comme l'a remarqué CHATTERJI. Ce calcul particulier se réfère à la diffusion de  $Ca(OH)_2$  ; cependant, la diffusion des autres électrolytes concernés n'est pas beaucoup plus faible [une diffusion faible permet à la porosité de devenir proportionnellement plus grande ; les coefficients de diffusion des hydroxydes sont généralement environ 1,5 fois plus grands que ceux des sels d'autres anions (12)] . Bien que les remarques de CHATTERJI ne soient pas convaincantes (il néglige apparemment les possibilités que le nombre de grains de  $C_3A$  décroisse pendant l'hydratation et qu'un nombre de grains de  $C_3A$  puisse être protégé de la solution par une couche d'hydrate commune ; de plus, sa différence de pression  $1,5 \times 10^4 \text{ dyne.cm}^{-2}$  s'élève à environ 0,015 atmosphère ce qui semble tout à fait acceptable), une porosité de  $10^{-6}$  est néanmoins étonnamment basse. Un des sujets de recherche future apparaît être celui d'obtenir une idée quantitative de la porosité effective dans les couches d'hydrates formées dans différentes conditions et composées de différents hydrates.

Un second problème, peut-être même le plus important, m'apparaît être une élaboration ultérieure des aspects de la chimie colloïdale du durcissement du ciment. Des propriétés telles que la rhéologie des pâtes de ciment et des mortiers et le fluage des systèmes contenant le ciment durci peuvent seulement être compris si une idée quantitative peut être obtenue sur l'attraction et la répulsion entre les particules d'hydrates.

# Hydratation de $C_3A$ en présence d'eau de chaux

## *Hydration of $C_3A$ in lime water*

P. BARRET, Professeur à l'Université de Dijon, Directeur du L.A. 23 (Réactivité des Solides),  
D. BERTRANDIE, Docteur de l'Université de Dijon, C.N.R.S. (L.A. 23) Dijon, France.

RESUME : La solubilité de  $C_3A$  calculée à partir des données thermodynamiques paraît très élevée (9). Mais ce calcul ne tient pas compte du processus d'hydroxylation superficielle par protonation comme celui décrit dans le cas de  $C_3S$  et qui est accompagné d'un abaissement notable de l'enthalpie libre, par interaction directe des molécules d'eau avec la surface du solide. Selon certains auteurs, le passage en solution des ions  $[Al(OH)_4]^-$  ainsi formés et des ions  $Ca^{2+}$  ne serait pas congruent. Si, dans un milieu stagnant, un excès d'ions  $Ca^{2+}$  autour des grains peut résulter d'une distribution ionique d'équilibre, en régime dynamique, l'expérience ne conduit pas à un rapport  $[C/A]_L$  (rapport  $CaO/Al_2O_3$  en phase liquide) croissant au-delà de 3 comme on pourrait s'y attendre si les ions  $Ca^{2+}$  passaient sélectivement en solution. Dans l'eau pure ou l'eau de chaux diluée, la précipitation préférentielle de  $C_2AH_8$  en accord avec le diagramme C,A,H, suffirait d'ailleurs à expliquer que  $[C/A]_L > 3$  même dans l'hypothèse d'une dissolution congruente ; en fait l'analyse X faite sur les échantillons solides après un contact de plusieurs minutes avec le solvant (eau ou eau de chaux) permet de déceler l'hydrate  $C_3AH_6$  avec seulement une faible proportion de monocarboaluminate de calcium. Avec l'eau ou l'eau de chaux diluée ( $[CaO] < 9.10^{-3} \text{ mol.kg}^{-1}$ ) comme solvant, on observe  $[\Delta C/A]_L \geq 3$  mais avec de l'eau de chaux plus concentrée ( $[CaO] > 9.10^{-3} \text{ mol.kg}^{-1}$ )  $[\Delta C/A]_L \approx 2$ .

Les essais effectués par flux continu de solvant à travers une couche mince de  $C_3A$  sur filtre ont permis également de tracer la partie de la courbe de supersolubilité des hydrates riches en  $CaO$  aux grands rapports  $[C/A]_L$  ; cette courbe vient compléter la partie que nous avons déterminée, notée (I) dans le domaine des  $[C/A]_L$  voisins de 1. La similitude avec la courbe (I) que nous avons également construite à partir de  $C_3S$  sur le diagramme C,S,H est évidente ce qui établit une analogie fondamentale entre les deux diagrammes, la différence de comportement venant de ce que, dans le cas de  $C_3A$ , des hydrates de rapport  $[C/A]_S \geq 3$  peuvent précipiter ce qui entraîne  $[C/A]_L < 3$ , tandis que, à partir de  $C_3S$ , ce sont des C-S-H de rapport  $[C/S]_S < 3$  qui précipitent de sorte que  $[C/S]_L$  ne peut aller qu'en augmentant jusqu'à la précipitation de l'hydroxyde de calcium.

SUMMARY : The  $C_3A$  solubility calculated from thermodynamic data seems to be very high (9). But, such a calculation does not take in account superficial hydroxylation process by protonization like that described with  $C_3S$  and accompanied by a decrease of free enthalpy due to the direct interaction of the solid surface with the water. The dissolution of  $[Al(OH)_4]^-$  and  $Ca^{2+}$  ions coming from this hydroxylated surface is considered as uncongruent. But, if in a stagnant medium, an excess of  $Ca^{2+}$  ions around the grains may result from an equilibrium ionic distribution, in a dynamic state, the experiment did not lead to a  $[C/A]_L$  ( $CaO/Al_2O_3$  ratio in liquid phase) becoming higher and higher than 3 by a selective transfer of  $Ca^{2+}$  ions into solution. In pure water or in diluted lime water, an excess of  $C_2AH_8$  in the precipitate can explain that  $[\Delta C/A]_L > 3$  according to the C,A,H diagram even if the congruent dissolution is assumed ; in fact by X ray diffraction on solid samples in contact with the solvent (water or lime water) for several minutes,  $C_3AH_6$  cubic hydrate was detected with only a few amount of calcium monocarboaluminate. With water or diluted lime water ( $[CaO] < 9.10^{-3} \text{ mol.kg}^{-1}$ ) as solvent  $[\Delta C/A]_L \geq 3$  was observed but with more concentrated lime water ( $[CaO] > 9.10^{-3} \text{ mol.kg}^{-1}$ )  $[\Delta C/A]_L \approx 2$ .

The part of the supersolubility curve of the hydrate rich in lime, corresponding to the high values of  $[C/A]_L$  ratio, could be plotted from the results obtained by a continuous flow of solvent through a thin layer of  $C_3A$  on a filter. The first part of this curve, noted (I) had been previously determined in the range of  $[C/A]_L$  close to 1. A similar curve was plotted on the  $C_3S$  diagram too. This shows a real analogy between the two kinds of diagram, the difference of behaviour being essentially that, with  $C_3A$ , hydrates of  $[C/A]_S > 3$  ratio may precipitate leading to  $[C/A]_L < 3$ , whereas with  $C_3S$ , hydrates of  $[C/S]_S < 3$  can only precipitate, leading to  $[C/S]_L > 3$ , this ratio increasing by lime accumulation in liquid phase till precipitation of calcium hydroxyde.

## INTRODUCTION

Tadros, Jackson et Skalny (1) considèrent la dissolution de  $C_3A$  dans l'eau comme non congruente : les ions  $Ca^{2+}$  passant préférentiellement en solution. Ils interprètent ainsi leurs résultats expérimentaux obtenus d'une part, par agitation dans l'eau pendant une minute de  $C_3A$  dans un rapport solide/liquide ( $\ell/s$ ) compris entre 25 et 250, d'autre part, par analyse ESCA et Auger de la surface du solide résiduel. Or, les mesures des concentrations en  $CaO$  et  $Al_2O_3$  que nous avons effectuées sur  $C_3A$ , tant par agitation dans l'eau pendant la même durée que par flux de solvant (eau et eau de chaux de diverses concentrations) à travers une couche mince de  $C_3A$  sur filtre ne sont pas en accord avec ces résultats. C'est pourquoi nous proposons dans ce mémoire de replacer le problème de la dissolution de  $C_3A$  et de la précipitation des hydrates dans le cadre du diagramme chaux-alumine-eau ( $C,A,H$ ) complété par les concepts cinétiques que nous avons développés aussi bien dans le cas de  $CA$  que dans celui de  $C_3S$  et qui paraissent avoir une portée générale : stade cinétique d'hydroxylation superficielle par interaction directe entre le solide et l'eau, accompagné d'un abaissement de l'enthalpie libre et donc d'une réduction de solubilité ; dissolution congruente en régime établi ; conservation de la congruence pour la dissolution dans l'eau de chaux ; caractère complexe de la réaction globale de formation des hydrates et existence d'un réseau de réactions simultanées ; définition sur les diagrammes d'équilibre de courbes de supersolubilité des phases hydratées délimitant les domaines à nucléation spontanée et les domaines conditionnellement instables et dans ceux-ci, de courbes d'instabilité minimale marquant la transition entre deux hydrates. Il était donc intéressant d'étudier le comportement de  $C_3A$  au contact de solutions de plus en plus concentrées en chaux et de chercher à faire apparaître dans les interprétations une unité conceptuelle valable aussi bien pour les systèmes chaux-silice-eau que pour les systèmes chaux-alumine-eau.

## ETUDE EXPERIMENTALE

Celle-ci a consisté d'abord à reprendre le même type d'essais que ceux effectués par Tadros, Jackson et Skalny cités ci-dessus (1) et dont les auteurs ne donnent qu'un résultat :  $[Ca^{2+}]/[Al^{3+}] = 1,9$  pour  $[Ca^{2+}] = 10,5 \cdot 10^{-3} \text{ mol.kg}^{-1}$  après 1 min d'agitation dans l'eau, ( $25 < \ell/s < 250$ ). Ceci donne un rapport  $[C/A]_{\ell} = 3,8$  au lieu de la valeur 3 correspondant à la congruence. Nos essais ont été effectués avec  $\ell/s = 12,5, 25, 50, 100$  et  $250$ . Ils ont été complétés par des essais de même nature sur un échantillon ayant déjà été agité dans l'eau avec un rapport  $\ell/s = 25$  pendant une minute puis lavé à l'acétone et à l'éther et remplacé sur un nouveau filtre, ceci afin d'éliminer la chaux non combinée. Le nouvel essai a été effectué également avec  $\ell/s = 25$ . Puis un ensemble d'essais en système ouvert a été effectué dans le but d'étudier la composition du filtrat prélevé à des instants successifs et celle du filtrat total. Pour cela, a été utilisé un filtre millipore sous pression, d'aire  $a = 13,85 \text{ cm}^2$ . Le flux de solvant était assuré au moyen d'une pompe péristaltique capable d'entretenir une pression hydrostatique de 5 bar. Le flux était réglé à une valeur maximale de :  $0,60 \text{ ml.s}^{-1} \cdot \text{cm}^{-2}$ . Nous avons déjà donné dans d'autres publications, par exemple (2), la définition de ce que nous appelons le temps de contact  $\theta$  entre chaque tranche de liquide traversant le lit pulvérulent d'épaisseur  $h$  et d'aire  $a$  avec un débit  $q$  supposé cons-

tant au cours d'une période  $\Delta t$ . Le temps de contact  $\theta = ah/q$  est celui pendant lequel un plan du liquide traverse la couche d'épaisseur  $h$ . Le solvant ne se charge pratiquement en ions du solide que pendant ce temps de contact qui peut être réglé très bref en agissant sur le flux  $q/a$  et sur l'épaisseur  $h$  du solide pour une section  $a$ . Le temps de passage  $\tau$  est le temps total pendant lequel le flux de solvant dure. L'échantillon solide résiduel est susceptible de réagir et de se dissoudre pendant tout ce temps. Si, au cours de la traversée du lit solide, chaque fraction du liquide a le temps d'atteindre une composition telle que la nucléation d'un précipité survienne spontanément, celui-ci reste sur filtre, mais il se peut que la sursaturation du filtrat soit encore suffisante pour que celui-ci soit le siège d'une nouvelle nucléation exigeant une période d'induction plus longue.

Dans chaque prélèvement de filtrat, toute évolution est bloquée en ajoutant une proportion connue d'acide chlorhydrique. Les concentrations en chaux et en alumine sont déterminées par spectrométrie atomique d'absorption de flamme à mieux que  $10^{-4} \text{ mol.kg}^{-1}$ .

L'intérêt d'une telle méthode vient de ce qu'un état stationnaire ou quasi stationnaire est réalisé, en ce sens que l'attaque du solide est constamment renouvelée au cours du temps par du solvant de même composition.

Une variante de la méthode a été également mise en œuvre en envoyant sur l'échantillon un flux de solvant finement pulvérisé et réglé de telle façon qu'aucune accumulation de gouttelettes ne puisse avoir lieu. Les conditions de faible  $\ell/s$  qui règnent dans une pâte sont ainsi réalisées approximativement.

L'analyse des filtrats est complétée par celle des solides résiduels sur filtre par diffraction X afin de tenter d'identifier les phases hydratées qui sont apparues. En outre des essais d'analyse quantitative de  $Ca$  et  $Al$  par microsonde à dispersion d'énergie dans le cas où les dépôts d'hydrates sur les grains sont d'épaisseur suffisante pour masquer le substrat sont actuellement en cours. Les aspects caractéristiques des différents hydrates sont également recherchés par microscopie électronique à balayage (SEM).

## RESULTATS

$C_3A$  agité 1 min dans l'eau : Les résultats des dosages en  $CaO$  et  $Al_2O_3$  sont rassemblés dans le tableau I

masse $C_3A$ g	$\ell/s$	$CaO$ $10^{-3} \text{ mol.kg}^{-1}$	$Al_2O_3$ $10^{-3} \text{ mol.kg}^{-1}$	$[C/A]_{\ell}$
1	12,5	9,87	2,32	4,25
"	25	9,57	2,75	3,48
"	50	9,10	3,25	2,80
"	100	6,97	2,57	2,71
"	250	6,40	2,20	2,91
"	25 bis	7,72	2,67	2,89

pour des essais effectués à 20°C sur 1 g de C<sub>3</sub>A et à différentes valeurs du rapport pondéral l/s. L'essai sur l'échantillon ayant subi un premier lavage à l'eau à l/s = 25 est noté 25 bis dans la colonne l/s.

#### Essai d'évolution en système ouvert :

a) Flux de solvant à travers 1,5 g de C<sub>3</sub>A sur filtre: L'aire du filtre était a = 13,85 cm<sup>2</sup> et l'épaisseur initiale du lit de poudre h = 0,11 cm. Le flux diminue au cours du temps par suite d'un colmatage progressif du filtre par les produits d'hydratation, ce qui conduit à une augmentation du temps de contact  $\theta$  du solvant avec le solide. Le volume de filtrat correspondant à chaque prélèvement était de 30 ml dont 2 utilisés pour le dosage de Ca et 25 pour celui de Al. A titre indicatif, avec le débit maximum, q = 8,31 ml.s<sup>-1</sup>, la durée d'un prélèvement était de 3,6 s.

Deux séries d'essais notés 1 et 2 ont été effectués avec l'eau distillée décarbonatée comme solvant ; leurs résultats sont rassemblés dans le tableau II (essais a). D'autres essais ont été faits en utilisant successivement comme solvant de l'eau de chaux aux concentrations suivantes exprimées en 10<sup>-3</sup> mol.kg<sup>-1</sup> : 1) 3,10, 2) 6,06, 3) 8,31, 4) 9,37, 5) 10,87, 6) 14,00. Les résultats sont consignés dans le tableau III.

vement de 7 l et 5,5 l ; les concentrations en CaO et Al<sub>2</sub>O<sub>3</sub> de ces filtrats ont été : essai 1 : [CaO] = 1,25.10<sup>-3</sup> mol.kg<sup>-1</sup> ; [Al<sub>2</sub>O<sub>3</sub>] = 0,48.10<sup>-3</sup> mol.kg<sup>-1</sup> ; [C/A]<sub>l</sub> = 2,60. Essai 2 : [CaO] = 2,72.10<sup>-3</sup> mol.kg<sup>-1</sup> ; [Al<sub>2</sub>O<sub>3</sub>] = 0,94.10<sup>-3</sup> mol.kg<sup>-1</sup> ; [C/A]<sub>l</sub> = 2,89. Les masses de solide résiduel sur filtre ont été respectivement de 0,6654 g et 0,1164 g et les pourcentages d'eau liée par rapport au produit hydraté : 22,4 et 27,5 %.

b) Solvant pulvérisé : Les essais ont seulement été effectués avec l'eau distillée décarbonatée en utilisant le pulvérisateur de l'appareil de spectrométrie atomique d'absorption de flamme et un diaphragme disposé de telle façon qu'aucune gouttelette ne puisse se déposer sur les parois de l'entonnoir à filtration. L'aspiration de la trompe à eau était mise en route avant le début de la pulvérisation. Les essais ont eu lieu sur des lits de C<sub>3</sub>A pulvérisés à raison de 0,5 g uniformément réparti sur l'aire de 12,56 cm<sup>2</sup> du filtre millipore. Les résultats sont donnés dans la partie b du tableau II. Chacun des deux essais a été effectué sur un lit de C<sub>3</sub>A frais, avec des temps

de passage  $\tau$  respectivement de 2 min et 2 min 15 s.

Analyse X du résidu solide sur filtre : L'analyse par diffraction X des résidus solides sur filtre a fait apparaître essentiellement l'hydrate cubique  $C_3AH_6$  accompagné d'un peu de carboaluminate de calcium en raison de la difficulté d'éliminer complètement  $CO_2$ . Il est frappant de constater, aussi bien avec l'eau de chaux de diverses concentrations qu'avec l'eau distillée comme solvant que les raies de diffraction de  $C_2AH_8$  et de  $C_4AH_{13}$  sont absentes du spectre des échantillons utilisés dans les essais de filtration continue. Les analyses X ont eu lieu seulement à la fin de ces essais qui ont duré respectivement 36 à 65 min avec l'eau comme solvant, mais seulement 10 min avec l'eau de chaux à diverses concentrations. Ce résultat est à rapprocher de celui rappelé par Spierings dans sa thèse (2) d'après Breval (3) et Ciach et Swenson (4). Nous espérons être en mesure de donner oralement des indications complémentaires à partir des études actuellement en cours au moyen de la sonde à dispersion d'énergie.

Courbe de supersolubilité des hydrates : La méthode d'étude par filtration continue permet d'obtenir un filtrat débarrassé des germes dont la nucléation a été pratiquement instantanée. La composition de ce filtrat est donc celle d'une solution sursaturée dans laquelle un faible accroissement des concentrations en chaux et en alumine provoquerait une précipitation immédiate. On peut donc admettre, avec une légère erreur par défaut, que la courbe tracée sur le diagramme C,A,H en joignant les points représentant les concentrations maximales dans de tels filtrats en fonction de la concentration en chaux du solvant est proche de la courbe de supersolubilité des hydrates dans le domaine considéré (Fig. 1). Cette courbe constitue le prolongement de celle que nous avons tracée (2, 6) dans le domaine des concentrations plus faibles en ions calcium et plus élevées en ions aluminates, par adjonction de chaux à des solutions d'aluminate monocalcique.

## DISCUSSION

En ce qui concerne les résultats des essais d'agitation de  $C_3A$  dans l'eau pendant 1 min, on n'obtient pas, contrairement aux conclusions de Tadros, Jackson et Skalny (1) une valeur de 3,8 pour  $[C/A]_l$  à toute valeur de  $l/s$  comprise entre 25 et 250. À  $l/s = 50, 100, 250$ , on peut constater que  $[C/A]_l \approx 3$  avec de petites variations de part et d'autre de cette valeur que l'on peut attribuer en partie aux incertitudes expérimentales. C'est seulement pour les valeurs de  $l/s$  les plus petites (12,5, 25) que  $[C/A]_l$  est nettement supérieur à 3 : respectivement 4,25 et 3,48 à  $l/s = 12,5$  et 25. Mais le fait que  $[C/A]_l$  apparaisse d'autant plus grand que  $l/s$  est plus petit conduit à se demander si de la chaux résiduelle non combinée, lors de la préparation de  $C_3A$ , ne pourrait être responsable de cet excédent. C'est pour répondre à cette question qu'un essai complémentaire a été fait en opérant sur un échantillon séché à l'acétone puis à l'éther après un premier contact de 1 min avec l'eau à  $l/s = 25$ .

Le résultat est significatif, puisque, dans ces conditions (Tableau II, b),  $[C/A]_l$  est nettement inférieur à 3. On doit donc craindre que, dans les essais d'agitation dans l'eau pendant un court instant, les résultats ne soient faussés par le passage en solution de chaux non combinée; même si elle se trouve en très faible proportion.

Fig. 1 - Courbes de solubilité : (0) gel d'alumine, (1)  $CAH_{10}$ , (2)  $C_2AH_8$ , (3)  $C_3AH_6$ , (4)  $C_4AH_{13}$ . La partie supérieure de la courbe (I) est complétée à l'aide des points expérimentaux obtenus en filtration continue : \* . La courbe  $mt_{\infty}$  définie par analogie avec  $mt_2$ , courbe d'instabilité minimale entre  $C_2AH_8$  et  $AH_3$ , apparaît comme une courbe de transition possible entre  $C_4AH_{13}$  et  $C_2AH_8$ . A droite de cette courbe,  $C_4AH_{13}$  n'a pas tendance à se transformer en  $C_2AH_8$ .  $C_3Ash$  : courbe de solubilité hypothétique.

Les essais en système ouvert par filtration continue ne présentent pas cet inconvénient, car la chaux libre résiduelle est éliminée dans les premières secondes par le flux de solvant.

Les conclusions suivantes se dégagent de ces essais : 1) Les dosages successifs, échelonnés dans le temps, du filtrat qui est passé sur le même échantillon donnent une valeur du rapport  $[\Delta C/A]_l$  assez constante et reproductible dans le temps bien que les valeurs absolues des concentrations en chaux et en alumine et donc de l'écart  $\Delta C$  diminuent régulièrement en même temps que le flux, en raison du colmatage occasionné par la formation des hydrates.

2) Le rapport  $[\Delta C/A]_l$  qui est voisin de 3 avec de petites fluctuations en plus ou en moins dans l'eau pure comme solvant, a tendance à décroître lorsque la concentration en  $CaO$  augmente et particulièrement lorsque celle-ci est supérieure à  $9.10^{-3} \text{ mol.kg}^{-1}$ . Pour une concentration de  $10,87.10^{-3} \text{ mol.kg}^{-1}$   $[\Delta C/A]_l = 2$  et ce rapport devient même inférieur à 2 ( $\approx 1,6$ ) lorsque la concentration en  $CaO$  dans le solvant est de l'ordre de  $14.10^{-3} \text{ mol.kg}^{-1}$ .

Ces résultats montrent clairement, qu'en régime dynamique, une dissolution sélective du calcium de  $C_3A$  n'a pas lieu. Les résultats expérimentaux sont au contraire en bon accord avec l'hypothèse d'une disso-

lution congruente de  $C_3A$ , non seulement dans l'eau, mais également dans les solutions de chaux.

Cela n'exclut pas que, dans un milieu stagnant un équilibre puisse s'établir entre la phase liquide et la surface hydroxylée de  $C_3A$ , de telle sorte qu'un certain écart à la stoechiométrie, par exemple par lacunes d'ions  $Ca^{2+}$ , s'instaure dans la couche superficielle ; mais il paraît exclu que cet écart augmente indéfiniment. Du point de vue cinétique, une autorégulation doit s'établir conduisant au transfert interfacial en solution des ions calcium et aluminates dans des proportions quasi stoechiométriques.

Dans nos expériences, le rapport 3 est à peu près conservé tant que la concentration en  $CaO$  du solvant est inférieure à  $9.10^{-3}$  mol.kg $^{-1}$ , bien qu'un précipité d'hydrate se forme. Mais comme celui-ci est constitué par  $C_3AH_6$ , le rapport  $[C/A]_e$  après précipitation n'a pas changé. La précipitation d'une petite fraction de monocarboaluminate  $3CaO, Al_2O_3, CaCO_3, H_2O$  peut contribuer à faire tendre le rapport  $[C/A]_e$  vers une valeur inférieure à 3. Si la formation de  $C_3AH_6$  passe par l'intermédiaire de  $C_2AH_8$  et de  $C_4AH_{13}$ , il faut supposer que les proportions de ces deux aluminates sont celles de la réaction stoechiométrique :

Il convient également de remarquer, en se rapportant au diagramme C,A,H (Fig. 1) que la courbe (I) se situe en partie dans le domaine sous-saturé par rapport à  $C_4AH_{13}$ .

Reprenons la construction graphique que nous avons proposée et utilisée par ailleurs (2, 7), pour représenter sur le diagramme C,A,H les variations de composition de la phase liquide accompagnant les processus de dissolution et précipitation : l'hypothèse de la dissolution congruente de  $C_3A_{sh}$  (superficiellement hydroxylé) se traduit, lorsque le solvant est l'eau, par la circulation du point M (Fig. 1) sur la droite  $[C/A]_e = 3$  passant par l'origine. La précipitation d'aluminates hydratés tels que  $C_2AH_8$ ,  $C_4AH_{13}$ ,  $C_3AH_6$  entraîne des changements de composition représentés respectivement par des vecteurs tels que  $MN_2$ , parallèle à la droite  $C/A = 2$ ,  $MN_4$ , parallèle à la droite  $C/A = 4$ ,  $MN_3$ , colinéaire de la droite  $C/A = 3$ . La combinaison de la dissolution congruente de  $C_3A_{sh}$  et de la précipitation de l'un ou l'autre de ces hydrates a comme conséquence que le rapport  $[C/A]_e$  reste égal à 3 si le précipité est formé de  $C_3AH_6$  seul ou d'un mélange équimoléculaire de  $C_2AH_8$  et de  $C_4AH_{13}$  qu'il devient  $> 3$  si ce mélange est plus riche en  $C_2AH_8$  qu'en  $C_4AH_{13}$  et  $< 3$  dans le cas contraire. Les conclusions restent les mêmes lorsque le solvant est de l'eau de chaux, à condition de remplacer le rapport  $[C/A]_e$  par le rapport  $[\Delta C/A]_e$  où  $\Delta C$  est l'accroissement de concentration en  $CaO$  ; le point M circule alors sur une parallèle à la droite  $[C/A]_e = 3$  passant par l'abscisse correspondant à la concentration initiale de l'eau de chaux.

Avec l'eau comme solvant, aux résultats expérimentaux obtenus aussi bien par agitation de  $C_3A$  à différentes valeurs de  $\ell/s$  que par filtration continue correspondent des points N situés au voisinage ou au-dessous de la courbe (I) avec des valeurs de  $[C/A]_e$  très voisines de 3 par excès ou par défaut. Ces valeurs peuvent être justifiées soit par la précipitation directe de  $C_3AH_6$  ce qui est thermodynamiquement possible, soit par celle du mélange quasi équimoléculaire  $C_2AH_8$  et  $C_4AH_{13}$ . Cela suppose alors

que le point M pénètre largement dans le domaine métastable sursaturé par rapport à  $C_4AH_{13}$ , à droite du prolongement en pointillés de la courbe de solubilité (4) de cet hydrate. Mais, dans ce domaine, des considérations expérimentales et théoriques nous ont conduit à prévoir l'existence d'une courbe de transition  $mt_{\infty}$  entre  $C_4AH_{13}$  solide et  $C_2AH_8$  correspondant à l'équation chimique :

Sur cette courbe, les valeurs du degré de sursaturation de la solution par rapport à chacun de ces hydrates sont égales et en constituent un minimum commun (8).

Si une telle transition a lieu effectivement, cela signifie que le point M doit aller au-delà de cette courbe pour que se produise la précipitation effective de  $C_4AH_{13}$ , ce qui suppose que la solubilité de  $C_3A_{sh}$  soit suffisante. (Courbe hypothétique sur le diagramme).

Il existe donc des raisons théoriques pour que  $C_2AH_8$  précipite préférentiellement ce qui permettrait d'expliquer que  $[C/A]_e > 3$  sans recourir à l'hypothèse d'une dissolution non congruente de  $C_3A_{sh}$ .

Avec l'eau de chaux comme solvant, la même situation se présente, mais va en s'atténuant à mesure que la concentration de cette eau de chaux s'approche, par valeurs croissantes de la valeur  $[C] = 11.10^{-3}$  mol.kg $^{-1}$ , donnée par l'intersection de l'axe des abscisses avec la parallèle à la droite  $[C/A]_e = 3$  passant par le point d'intersection des courbes d'équilibre de solubilité de  $C_2AH_8$  et  $C_4AH_{13}$ . En effet, au-delà de cette valeur, le point M pénètre en premier lieu dans le domaine sursaturé par rapport à  $C_4AH_{13}$  avant de traverser le prolongement dans le domaine métastable de la courbe de solubilité de  $C_2AH_8$ . En outre, le point M est immédiatement au-delà de la courbe de transition  $mt_{\infty}$ , de sorte qu'une précipitation préférentielle de  $C_4AH_{13}$  peut être prévue. Mais, naturellement, la solution est également sursaturée par rapport à  $C_3AH_6$  qui peut précipiter. Il est donc logique de s'attendre, en utilisant l'eau de chaux comme solvant, à ce que :  $[\Delta C/A]_e > 3$  lorsque sa concentration initiale  $[C]^0 < 11.10^{-3}$  mol.kg $^{-1}$  et à ce que :  $[\Delta C/A]_e < 3$  lorsque  $[C]^0 > 11.10^{-3}$  mol.kg $^{-1}$ . C'est bien une telle conclusion qui paraît devoir être dégagée des résultats expérimentaux en filtration continue.

En ce qui concerne la solubilité dans l'eau de  $C_3A$  selon l'équation :

elle a été exprimée par H.N. Stein (9) à partir de données thermodynamiques permettant de remonter aux valeurs des  $\Delta G_{98}^0$  de formation des partenaires de cette réaction. Le produit de solubilité est  $3.10^8$  ou  $4.10^{10}$  suivant la valeur choisie pour  $\Delta G_{C_3A}^0$ . En prenant la plus petite de ces deux valeurs, on peut se rendre compte de l'ordre de grandeur atteint par  $xy^{\pm}$  où  $x$  représente la concentration molaire massique en  $Ca_{aq}^{2+}$  et  $y^{\pm}$  le coefficient d'activité ionique moyen.

Si l'on appelle  $y$  et  $\psi$  les concentrations molaires massiques des ions  $[Al(OH)_4]_{aq}^{-}$  et  $OH_{aq}^{-}$ , la relation d'électroneutralité impose :

$$\frac{\psi}{2x} + \frac{y}{2x} = 1 \text{ que l'on peut écrire } X + Y = 1.$$

La loi d'action de masse s'écrit alors :

$$64(x\gamma^{\pm})^9 X^4 (1-X)^2 = 4.10^{10}$$

Dans l'hypothèse d'une dissolution congruente :

$$[C/A]_e = 3, \text{ soit } x/y = 1,5, \text{ ou encore :}$$

$$1/2(1-X) = 1,5. \text{ On en tire } X = 0,67, \text{ d'où :}$$

$$x\gamma^{\pm} = \left[ \frac{2,61.10^8}{64.(0,67)^4.(0,33)^2} \right]^{1/9} = 8,295 \text{ mol.kg}^{-1}$$

Il faudrait  $\gamma^{\pm} > 1$ , de l'ordre de 2,75 pour obtenir  $x = 3 \text{ mol.kg}^{-1}$ , ce qui correspondrait à une solubilité  $S_{C_3A} = 1 \text{ mol.kg}^{-1}$

En fait, le mécanisme d'hydroxylation superficielle que nous avons proposé doit contribuer à réduire notablement cette valeur, mais les données nécessaires pour le calcul font défaut. On peut néanmoins en poser le principe :

L'équation quasi chimique de l'hydroxylation superficielle peut s'écrire en éléments de structure :

et la réaction de transfert interfacial en solution :

La somme de ces deux réactions donne évidemment l'équation globale (1). Mais ce qui est en équilibre à la saturation, c'est la réaction (3), d'où  $\Delta G_3 = 0$ . Comme  $\Delta G_1 = \Delta G_2 + \Delta G_3$ , il en résulte que  $\Delta G_2 = -\Delta G_1$ .

L'abaissement d'enthalpie libre correspondant à la formation de l'état superficiellement hydroxylé (équation 2) est égal à celui de l'équation globale (1), mais avec une valeur de  $x\gamma^{\pm} < a$  la valeur d'équilibre et qui rendrait positive l'affinité chimique de cette réaction.

Rappelons à titre indicatif que dans le cas de CA, les concentrations d'équilibre avec l'état superficiellement hydroxylé sont mesurables en raison de la durée de vie importante de la solution métastable. Un calcul semblable a donné comme valeur de l'abaissement d'enthalpie libre accompagnant la réaction d'hydroxylation superficielle (10) :

$$\Delta G' = -14,71 \text{ KJ.mol}^{-1}$$

et  $\Delta G'' = -12,83 \text{ KJ.mol}^{-1}$  comme valeur de la chute d'enthalpie libre correspondant à la précipitation de  $\text{CAH}_{10}$  à partir de cette solution.

La valeur de  $x\gamma^{\pm}$  calculée pour la solubilité théorique de CA anhydre est  $0,078 \text{ mol.kg}^{-1}$ . Elle tombe à  $0,0113 (\gamma^{\pm} = 0,57)$  pour celle de  $\text{CA}_{\text{sh}}$ , soit à  $x = 0,020 \text{ mol.kg}^{-1}$ .

## CONCLUSION :

Les observations et les arguments théoriques ci-dessus développés sont en faveur d'une dissolution congruente, mais de celle de  $\text{C}_3\text{A}_{\text{sh}}$  (superficiellement hydroxylé), aussi bien dans l'eau de chaux à diverses concentrations que dans l'eau distillée. En régime dynamique l'accumulation d'ions  $\text{Ca}^{2+}$  en solution comme cela se produit avec  $\text{C}_3\text{S}$ , semble exclue. Bien au contraire, le rapport  $[C/A]_e$  voisin de 3 par dissolution de  $\text{C}_3\text{A}_{\text{sh}}$  dans l'eau distillée ou l'eau de chaux diluée, tend à diminuer lorsque la concentration de l'eau de chaux utilisée comme solvant augmente. La raison de cette différence de comportement entre  $\text{C}_3\text{A}$

et  $\text{C}_3\text{S}$  doit être recherchée, non dans une dissolution incongruente, mais dans le fait qu'il existe des aluminates hydratés susceptibles de précipiter dans lesquels  $[C/A]_s \geq 3$ , tandis que cela n'est pas le cas pour les C-S-H dont le rapport  $[C/S]_s$  est toujours  $< 3$ .

Ce travail a été fait en coopération avec la Société LAFARGE à laquelle nous exprimons nos remerciements.

# The colloid chemistry of calcium aluminate hydrates

## *La chimie colloïdale des aluminates de calcium hydrates*

H.N. STEIN, Laboratory of Colloid Science, Vakgroep Elektrochemie, Department of Chemical Engineering, Eindhoven University of Technology, Eindhoven, THE NETHERLANDS.

### SUMMARY

A review is given on colloid chemical data for calcium aluminate hydrates, both with regard to the state of the surface of the hydrate crystals in aqueous solutions, and with regard to the interaction between hydrate crystals dispersed in aqueous electrolyte solutions. On the basis of these data, some cement chemical problems are discussed.

### RÉSUMÉ

On donne une revue sur les données de chimie colloïdale pour les aluminates de calcium hydratés, tant par rapport à l'état de la surface des cristaux des hydrates dans les solutions aqueuses, que par rapport à l'interaction entre les cristaux des hydrates dispersés dans les solutions aqueuses des électrolytes. En se basant sur ces données, on discute quelques problèmes de la chimie des ciments.

## 1. INTRODUCTION

Colloid chemistry is a discipline dealing with the properties of systems in which interfaces between phases play an important role. In cement chemistry, the following problems are related to colloid chemistry and can be studied with profit by the experimental methods available in this science:

- a. The mechanical and rheological properties of pastes consisting of solid particles embedded in a liquid are influenced by attraction and repulsion between the particles. Colloid chemistry, since the introduction of the well-known Derjaguin-Landau-Verweij-Overbeek theory <sup>1) 2)</sup>, enables us to determine quantitative parameters for these effects.
- b. The reactivity of hydrating cement compounds is connected with the physical and chemical character of their surfaces. Colloid chemical data are specifically connected with the situation at the surface, and can thus give evidence about problems such as the retardation of C<sub>3</sub>A hydration by hydrate formation, the character of the C<sub>3</sub>S surface during the dormant state of C<sub>3</sub>S hydration, etc.

In spite of these obvious connections, cement chemists have only occasionally paid attention to colloid chemistry, and colloid chemists have only occasionally paid attention to cement chemistry. The reasons for this latter statement may be understood: the solids encountered in cement chemistry, being isolators, do not allow easy application of some experimental methods employed in colloid science. Thus, AgJ, a solid studied extensively by colloid chemists, is so good a conductor that a AgJ electrode can be made relatively easily; by means of this electrode, changes in overall potential difference over the solid/electrolyte solution interface can be registered. However, with isolating solids such as are encountered in cement chemistry, this is very difficult. Furthermore, the electrolyte concentrations in the aqueous phases present in hydrating cement pastes are rather large as compared with those usually dealt with in colloid chemistry.

Nevertheless, the present author hopes to show that some colloid chemical methods can be used with advantage in cement chemistry.

## 2. THE NATURE OF THE SURFACE OF CALCIUM ALUMINATE HYDRATES, DISPERSED IN AQUEOUS SOLUTIONS

One colloid chemical parameter, which is readily measured even with isolators as dispersed phases, is the so-called  $\zeta$ -potential, i.e., the difference in electrical potential between two points in the aqueous phase: one situated in the "bulk" aqueous phase far away from the solid; the other situated at the "slipping plane", the locus where the liquid loses its movability with regard to the solid. The first layer of liquid is attached rigidly to the solid ("no slip" condition, universally accepted in hydrodynamics <sup>3)</sup>), and only at the slipping plane the liquid can be moved towards the solid.

The  $\zeta$  potential can be calculated from elektrokinetic data <sup>4)</sup> (from the relative motion of solid and liquid under influence of an electric field as e.g., in electrophoresis, electroosmosis, streaming potential, etc.). From it, the net surface charge behind the slipping plane can be calculated; for a solid suspended in a solution of a symmetrical electrolyte (NaCl, MgSO<sub>4</sub>, etc.) by the formula <sup>5)</sup>:

$$\sigma = \sqrt{2\epsilon_r \epsilon_0 n k T} \left[ \exp\left(\frac{ze\zeta}{2kT}\right) - \exp\left(-\frac{ze\zeta}{2kT}\right) \right]$$

where

- $\epsilon_r$  = the dielectric constant of the liquid phase
- $\epsilon_0$  = the permittivity of vacuum (=  $8.85 \cdot 10^{-12}$  C.V<sup>-1</sup>m<sup>-1</sup>),
- $n$  = the concentration of the electrolyte (ions per m<sup>3</sup>),
- $k$  = the Boltzmann constant ( $1.38 \cdot 10^{-23}$  J.K<sup>-1</sup>),
- $T$  = the absolute temperature,
- $z$  = the valency of the ions in the electrolyte solution,
- $e$  = the charge of a proton.

It should be realized that the surface charge thus calculated is in general not equal to the surface charge on the solid itself, since ions present in the liquid layer between the phase boundary and the slipping plane will be counted as belonging to the "solid" when the surface charge is calculated from elektrokinetic data.

Thus, if the charge on a solid is negative in say, 0.01 NaOH solution, addition of Ca<sup>2+</sup> ions will decrease the  $\zeta$  potential (in absolute sense); the latter may even become positive ("charge reversal"). However, careful planning of experiments is necessary in order to ascertain whether the Ca<sup>2+</sup> ions are taken up by the solid itself or are only strongly adsorbed ("chemisorbed") on it. It has been reported <sup>6)</sup> that C<sub>3</sub>A hydrating in excess water has a positive surface charge ( $\zeta \approx +34$  mV), which can be

reduced to  $\zeta = 0$  but not reversed to a negative surface charge, by adding  $\text{SO}_4^{2-}$  ions. The finding itself is significant, but it cannot with any claim on certainty be understood in the absence of additional data on the hydrates present on the  $\text{C}_3\text{A}$  surface.

Fig. 1 shows the  $\zeta$  potential of the hydrates formed during  $\text{C}_3\text{A}$  hydration in NaOH solutions of various concentrations (w/s = 100) 7) 8). The data refer to two reaction stages, the first one corresponding to the metastable point of coexistence of  $\text{Ca}_2\text{Al}_2(\text{OH})_{10} \cdot 3\text{H}_2\text{O}$  ( $=\text{C}_2\text{AH}_8$ ) and  $\text{Ca}_2\text{Al}(\text{OH})_7 \cdot 6\text{H}_2\text{O}$  ( $=\text{C}_4\text{AH}_{19}$ ) with solution 9). The second stage occurs when the reaction comes finally practically to a standstill 10) 11).

During stage I, the hexagonal hydrates  $\text{Ca}_2\text{Al}_2(\text{OH})_{10} \cdot 3\text{H}_2\text{O}$  and  $\text{Ca}_2\text{Al}(\text{OH})_7 \cdot 6\text{H}_2\text{O}$ , and the cubical  $\text{Ca}_3\text{Al}_2(\text{OH})_{12}$  ( $=\text{C}_3\text{AH}_6$ ) are present. The  $\zeta$  potential is positive at all NaOH concentrations investigated. In spite of significant differences between these solids as regards their crystal structure, no difference was noted between them in electrophoresis (the individual particles observed in electrophoresis can be identified by their habitus as being hexagonal or cubical).

During stage II, the cubical hydrate predominates. The  $\zeta$  potential is still positive, though somewhat less than at stage I. Fig. 2 shows the  $\zeta$  potential as a function of reaction time, in 0.01 M NaOH solution. The "dip" of the  $\zeta$  potential after 5 - 10 hours corresponds to conditions shortly after the conversion of the hexagonal hydrates into  $\text{Ca}_3\text{Al}_2(\text{OH})_{12}$ . It is found at other NaOH concentrations as well (cf. fig. 1).

Although the  $\zeta$  potential decreases with increasing NaOH concentration, the net surface charge behind the slipping plane increases (see fig. 3) for both reaction stages.

The large positive  $\zeta$  potentials and the increasing  $\sigma_s$  with increasing NaOH concentration indicate that there exists on the hydrate particles a surface layer, in which the charge of the  $\text{Ca}^{2+}$  ions is not fully balanced by that of the anions (aluminate and  $\text{OH}^-$  ions). Such a layer can be envisaged to originate either by withdrawal of aluminate ions from, and only partial replacement of them in the hydrates, by  $\text{OH}^-$ , or by chemisorption of  $\text{Ca}^{2+}$  and  $\text{Ca}(\text{OH})^+$  ions from the solution (chemisorption of  $\text{Na}^+$  ions to the extent required is unknown on oxidic surfaces). It is true that the crystal structure of the hexagonal hydrates would give rise to a positive surface charge if layers with overall composition  $\text{Ca}_2\text{Al}(\text{OH})_6^+$  12) form the outermost part of the crystal. However, the increasing positive net surface charge with increasing NaOH concentration cannot be explained by this model. Moreover, a net positive surface charge is observed on  $\text{Ca}_3\text{Al}_2(\text{OH})_{12}$  as well, at least in non-equilibrium solutions such as are obtain-

ed during  $\text{C}_3\text{A}$  hydration 10) 11).

Fig. 1

The  $\zeta$  potential of calcium aluminate hydrates during the reaction of  $\text{C}_3\text{A}$  with NaOH solutions versus the NaOH concentration 8).

I : reaction stage I (both hexagonal hydrates and  $\text{Ca}_3\text{Al}_2(\text{OH})_{12}$ ),  
II : reaction stage II ( $\text{Ca}_3\text{Al}_2(\text{OH})_{12}$ ).

Fig. 2

Fig. 3

(for legends of fig. 3 see page 4)

Fig. 3

The net charge behind the slipping plane versus the NaOH concentration for reaction stages I and II (as in fig. 1) 8).

In equilibrium solutions, however,  $\text{Ca}_3\text{Al}_2(\text{OH})_{12}$  has a negative surface charge (fig. 4) which increases in absolute sense (= becomes more negative) with increasing NaOH concentration. The transition of positive into negative surface charge, with gradual establishment of equilibrium, can be followed by registering the  $\zeta$  potential as a function of time after introduction of  $\text{Ca}_3\text{Al}_2(\text{OH})_{12}$  into a 0.01 M NaOH solution previously saturated towards that compound, (fig. 5). If the  $\text{Ca}_3\text{Al}_2(\text{OH})_{12}$  had been prepared in an autoclave, the transition of the  $\zeta$  potential into negative values is relatively rapid (curve A). If the  $\text{Ca}_3\text{Al}_2(\text{OH})_{12}$  had been obtained by room temperature hydration of  $\text{C}_3\text{A}$ , the transition is slower (curve B). If  $\text{Ca}_3\text{Al}_2(\text{OH})_{12}$  obtained in an autoclave is placed in a metastable solution obtained during  $\text{C}_3\text{A}$  hydration in 0.01 M NaOH after 6 hours, which is supersaturated towards  $\text{Ca}_3\text{Al}_2(\text{OH})_{12}$  and  $\gamma\text{Al}(\text{OH})_3$ , a very slow transition is found (curve C). The result can be interpreted as indicating that the surface layer becomes disordered similar to that of  $\text{Ca}_3\text{Al}_2(\text{OH})_{12}$  formed during the reaction. The recrystallization is very slow, but at a certain point it is so far advanced that precipitation from the solution can occur; indeed concentration changes have been observed in the solution at that stage.

### 3. INTERACTION BETWEEN CALCIUM ALUMINATE HYDRATES

Colloid chemistry enables us to draw conclusions on the mutual attraction or repulsion, between solid particles embedded in a liquid. The experimental data concerned consist of measurements of the coagulation rate 13) 14) as a function of electrolyte concentration.

A transition is seen between two regimes:

- a) "slow coagulation" at low concentration, dependent on the electrostatic repulsion between two solids with surface charge of equal sign, and consequently characterized by a dependency on electrolyte concentration.
- b) "fast coagulation" at large electrolyte concentration, where electrostatic repulsion is absent 1) 2) and where the coagulation rate is independent on the electrolyte content of the solution.

Fig. 6 shows, as an example, some typical data for AgJ in  $\text{H}_2\text{O}$  + ethylene glycol mixtures, with  $\text{KNO}_3$  as an electrolyte 16). The coagulation is followed by measuring the light extinction (E) as a function of time (t); a large value of  $dt/dE$  corresponds to a very slow coagulation rate, hence to a stable dispersion. The transition between "slow" and "fast" coagulation is situated at the critical coagulation concentration, at the intersection between the two straight lines drawn through the experimental data at low and high concentrations, respectively. Thus, for a mixture with  $x_{\text{EG}}$ , the mole fraction of

ethylene glycol, = .403, the transition is found at  $\log c_{\text{RbNO}_3} = 1.85$ , which means  $[\text{RbNO}_3] = 0.071$  M.  $c_{\text{RbNO}_3}$  is the concentration expressed in  $\text{m mol.l}^{-1}$ .

For  $\text{Ca}_3\text{Al}_2(\text{OH})_{12}$  in water, different curves are found (fig. 7) 17). Here, the concentration is expressed by the parameter

$$\kappa = \left( \frac{e \sum N_i z_i^2}{\epsilon_r \epsilon_0 kT} \right)$$

well-known from the Debye-Hückel theory of electrolyte solutions. For  $\text{NaNO}_3$  at relatively large concentrations ( $\kappa > 10^9 \text{ m}^{-1}$ , i.e.  $[\text{NaNO}_3] > 0.1 \text{ M}$ ), the expected decrease in dispersion stability with increasing electrolyte concentration is found; transition from "slow" to "fast" coagulation is situated at  $\kappa \approx 2 \cdot 10^9 \text{ m}^{-1}$ , from which the constant describing the mutual attraction between  $\text{Ca}_3\text{Al}_2(\text{OH})_{12}$  crystals in water ("the Hamaker constant") can be calculated to be about  $0.1 \cdot 10^{-20} \text{ J}$ .

For  $\text{NaOH}$ , the stability decrease is shifted towards higher electrolyte concentrations. This is not unexpected because  $\text{OH}^-$  ions act as "potential determining ions" for oxidic materials 18) so that the surface potential increases in absolute sense (= becomes more negative) with increasing  $\text{NaOH}$  concentrations. Consistent with this idea are the data on the  $\zeta$  potentials of  $\text{Ca}_3\text{Al}_2(\text{OH})_{12}$  shown in fig. 5. The increasing potential between  $\text{Ca}_3\text{Al}_2(\text{OH})_{12}$  surface and bulk liquid counteracts coagulation.

The most interesting part of fig. 7, however, is the destabilisation of the  $\text{Ca}_3\text{Al}_2(\text{OH})_{12}$  dispersions with decreasing electrolyte concentration, found at low electrolyte content of the solution. This effect is independent of the type of electrolyte employed being the same for  $\text{NaNO}_3$ ,  $\text{KNO}_3$ ,  $\text{NaOH}$  and  $\text{Ca}(\text{OH})_2$ ; it is also independent of the surface potential. It leads to a very low value of  $dt/dE$ , i.e. to large coagulation tendency, for  $\text{Ca}_3\text{Al}_2(\text{OH})_{12}$  dispersed in water. Although a definite explanation of this phenomenon cannot at present be given, it has been suggested that it is connected with the formation of polyaluminate ions in the solution of low electrolyte content. The polyions are thought to form bridges between the particles, thus enhancing coagulation. The increasing stability of the dispersion with increasing electrolyte concentration in the concentration range concerned has been ascribed tentatively to the polyions being progressively broken down with increasing  $\kappa$ ; the absence of a special role of  $\text{OH}^-$  ions can be understood if it is assumed that the average charge per Al-ion in a polyion is independent of the degree of polymerization. But at present no independent confirmation of these ideas has been obtained.

Fig. 6  
Rates of coagulation of AgJ sols by  $\text{KNO}_3$  in water-ethylene glycol mixtures, 16).  $pJ = 4.6$ ;  $x_{\text{EG}}$  = mole fraction of ethylene glycol in the liquid.

#### 4. APPLICATION OF THE DATA TO SOME CEMENT CHEMICAL PROBLEMS

##### a. The Conversion of $C_4AH_{19}$ and $C_2AH_8$ into $C_3AH_6$

$Ca_3Al_2(OH)_{12}$  nuclei accelerate the transition of the hexagonal hydrates into the cubical one <sup>11)</sup>. Nevertheless, the aqueous phase which is present when the  $C_3A$  hydration comes practically to a standstill, is supersaturated towards the two stable solids:  $Ca_3Al_2(OH)_{12}$  and  $\gamma-Al(OH)_3$ , in spite of  $Ca_3Al_2(OH)_{12}$  crystals being present in abundance <sup>10)</sup>. From the results reported in the present paper on the surface of  $Ca_3Al_2(OH)_{12}$  crystals it is clear that the latter become inactive as nuclei during the  $C_3A$  hydration, because they are covered by a disordered layer.

##### b. The retardation of $C_3A$ hydration by hydrates

One of the old problems in cement chemistry is: why does  $CaSO_4$  retard the hydration of  $C_3A$ ? Coverage by ettringite crystals <sup>19)</sup> <sup>20)</sup> and inactivation of the  $C_3A$  surface by adsorbed  $SO_4^{2-}$  ions <sup>6)</sup> are among the theories advanced, the most recent data <sup>21)</sup> being in favour of an ettringite coating. However, ettringite layers as formed in hydrating pastes are too incoherent for complete screening of the  $C_3A$  <sup>22)</sup>.

It has been remarked <sup>23)</sup> that there is no need to assume such a complete screening. If ettringite is the sole hydrate formed, and counteracts the transport of ions from the bulk solution towards the vicinity of the  $C_3A$  sufficiently for a concentration gradient to exist between those regions, there will arise a local  $SO_4^{2-}$  shortage near the  $C_3A$ . If initially the solution is saturated towards  $CaSO_4 \cdot 2H_2O$ ,  $H_2O$  and  $CaSO_4$  reach the  $C_3A$  in a weight to weight ratio of 400 : 1; if ettringite precipitates as the sole hydrate,  $H_2O$  and  $CaSO_4$  are withdrawn from the solution in a weight to weight ratio of 14 : 1. Thus, predominant ettringite formation leads to a local  $SO_4^{2-}$  shortage near the  $C_3A$ . Nevertheless, the reactivity of  $C_3A$  is lower than in  $SO_4^{2-}$  free pastes. It has been suggested <sup>23)</sup> that amorphous  $Al(OH)_3$  is formed because the ettringite crystals tend to grow further when there is no  $SO_4^{2-}$  at hand, with  $2OH^-$  replacing  $SO_4^{2-}$ , causing a locally low pH and  $Ca^{2+}$  concentration near the  $C_3A$ . Although mixed crystals  $Ca_2Al_2(OH)_{12}(SO_4^{2-})_{3-x}(OH^-)_{2x} \cdot 25H_2O$  are not known, the effect suggested here may be a surface effect rather than a bulk effect.

Earlier <sup>24)</sup> it was supposed that the amorphous  $Al(OH)_3$  precipitates from the solution. It would be more in line with the colloid chemical data presented in the present paper, to think of a disturbed surface layer on the  $C_3A$  similar to the one shown to be present on  $Ca_3Al_2(OH)_{12}$ . This layer might be formed by preferential extraction of  $Ca^{2+}$  from the  $C_3A$  and its replacement by  $H^+$ .

However, it is very difficult to obtain any direct evidence for such a layer, at least in alkaline solution where the  $C_3A$  is covered by hydrates. Further research may perhaps bring evidence on this point.

RESUME : La présente étude porte sur le rôle du  $C_3A$  et du  $NC_8A_3$  (identifié comme une combinaison indépendante) dans les réactions initiales de l'hydratation du ciment et dans les modèles représentant ces réactions.

La formation simultanée de plusieurs phases hydratées, au voisinage et à la surface du  $C_3A$  et du  $NC_8A_3$ , au tout début de l'hydratation, montre l'interdépendance de ces réactions initiales avec la composition, la symétrie et le degré de saturation de la phase liquide à ce moment, ainsi qu'avec la vitesse de diffusion des ions et les propriétés physiques des minéraux.

La présence de  $NC_8A_3$  dans le clinker est indésirable, car elle peut entraîner une diminution des résistances du ciment hydraté.

SUMMARY: The role of  $C_3A$  and  $NC_8A_3$  (identified as an independent compound) is investigated in primary competing reactions of initial process of cement hydration in the systems modelling this process.

Simultaneous formation different hydrate phases near and on the surface of  $C_3A$  and  $NC_8A_3$  in first moments of hydration prove the interdependence of primary reactions and composition, symmetry, the degree of oversaturation of primary liquid phase, rate of diffusion of ions and physical properties of minerals.

Presence of  $NC_8A_3$  in Portland cement clinker is undesirable as it may favour the decrease of strength of hardening system "cement-water".

It is known that  $C_3A$  and its alkali analogue  $NC_8A_3$  play an important role in initial reactions of cement hydration particularly in the formation of primary structures of hardening in the processes lying in the basis of "false" setting of cement [1].

To detalize the role of  $C_3A$  and alkali calcium aluminates in the initial hydration process of cement and to investigate primary competing reactions, the scientists of MCTI named after D.I. Mendeleev carried out some research works of the initial processes of  $C_3A$  and  $NC_8A_3$  hydration (by means of a number of physico-chemical methods) in the systems modelling the processes taking place during cement hydration.

Identification of synthesized minerals was carried by means of chemical, optical, X-ray diffractometry, differential thermal analyses and by means of electronic microscope.

The following facts state that  $NC_8A_3$  is an independent mineral with the ordered arrangement of ions Na in  $C_3A$  lattice. The presence of 7% of sodium in the above mentioned mineral, the effect of anisotropy change of refraction index from  $N^m = 1.714 \pm 0.03$  to  $N_x = 1.700 \pm 0.003$  and  $N_y = 1.712 \pm 0.003$ ; change of frequency and intensity of amplitude in the ranges of  $430-540 \text{ cm}^{-1}$  and  $700-900 \text{ cm}^{-1}$ ; the appearance of endothermic effect ( $t = 1285^\circ\text{C}$ ) and exothermic ( $t = 1370^\circ\text{C}$ ) the appearance of unstable regions on the surface of dendrites of  $NC_8A_3$ :

New reflections of 4.93; 4.426; 3.432; 3.401; 2.719; 2.625; 2.435; 2.316; 2.050; 1.915; 1.397 Å; instead of completely disappeared reflections of  $C_3A$  (4.604, 3.501, 3.332; 3.262, 3.120, 2.993, 2.581, 2.512, 2.138, 2.097; 2.078 Å could be clearly seen on the X-ray diffractograms.

Two reflections of 2.050 and 2.035 appear instead of reflection 2.040 Å. From the remaining group of  $C_3A$  reflections the following reflections remain. A group of reflections of  $C_3A$  shifts in  $NC_8A_3$  in the following way. for  $C_3A$ : 1.405, 1.390, 1.3649, 1.3596, 1.3491, 1.3336, 1.3190; for  $NC_8A_3$ : 1.397, 1.348, 1.345, 1.339, 1.337 Å the range of 1.211-1.198 we have poorly formed similar picks 1.1899 and 1.0979 Å of two minerals simultaneously.

The experiments carried out by means of electronic microscope and electron-diffraction microscope aimed at the investigation of initial stages of hydration  $C_3A$  and  $NC_8A_3$  beginning with the moment of cement and water interaction (1-5 sec) in rather short intervals of time (1, 5, 15 and 30 sec; 1, 5, 15 and 30 minutes; 1, 2, 3 and 6 hours) allowed to analyse morphological and phase changes, taking place in the systems, modelling initial processes of hydration [2].

In  $C_3A-H_2O$  system calcium hydroaluminates  $C_4AH_x$  ( $x=19-13$ ) and  $Al(OH)_3$  are formed be-

Fig.1. The surface of the mineral  $C_3A$  before hydration (x 20 000).

Fig.2. The surface of the mineral  $NC_8A_3$  before hydration (x 20 000).

ginning with the moment of interaction and they dominate up to 2-3 hours with the following forming of  $C_3AH_6$ .

Analysing electron-diffraction photographs (period 1 sec - 1 hour of hydration) we can see reflections as diffusion rings 2.88, 2.50, 1.65, 1.60 and 1.24 Å and dot reflexes 1.87, 1.80, 1.60, 1.57, 1.40 Å corresponding in general to  $C_4AH_{19}$  and  $Al(OH)_3$ .

In the system  $C_3A-CaSO_4 \cdot 2H_2O-H_2O$  in the moment of mineral and water interaction the formation of prismatic  $C_3A \cdot 3CaSO_4 \cdot 31H_2O$  and plate like  $C_4AH_{13}$ ,  $C_3A \cdot CaSO_4 \cdot 12H_2O$  is typical (Fig.4).

They are characterised by the reflections on the electron-diffraction photographs 3.58-2.95; 3.00-2.87; 2.50-2.45; 2.15-1.80 and 1.71-1.68 Å. They all have the form

of diffusion rings and have the following dot-reflexes 3.23; 3.19; 2.95; 2.86; 1.87; 1.62; 1.59; 1.52 and 1.49 Å.

Fig.3. The surface  $C_3A$  after 5 seconds of hydration in the system  $C_3A-H_2O$  (x 40 000).

Fig.4. The surface of  $C_3A$  after 5 seconds of hydration in the system  $C_3A-CaSO_4 \cdot 2H_2O-H_2O$  (x 20 000).

The presence of ions of  $Ca^{2+}$  and  $SO_4^{2-}$  in the preliminary liquid leads to simultaneous formation of  $C_3A \cdot 3CaSO_4 \cdot 31H_2O$ ,  $C_3A \cdot CaSO_4 \cdot 12H_2O$ ;  $C_4AH_x$  and  $Al(OH)_3$  on the surface of grains of  $C_3A$ . This is the evidence of the fact that there are different conditions for crystal formation on the surface of the mineral. The formation of  $C_4AH_x$  in the system with two-water gypsum and in the system with the nuclei of  $C_3A \cdot 3CaSO_4 \cdot 31H_2O$  proves that the reaction of  $C_3A$  solving with the formation of calcium hydroaluminates is the very primary stage. Besides it, it reaffirms the idea that

$C_3A \cdot 3CaSO_4 \cdot 31H_2O$  is not the only phase that forms on the  $C_3A$  grains in the presence of  $CaSO_4 \cdot 2H_2O$  and that this phase exists after all  $SO_4^{2-}$  ions have disappeared from the solution.

In the system with two-water gypsum two main reactions aimed at the formation  $C_3A \cdot 3CaSO_4 \cdot 31H_2O$  and  $C_4AH_x$  take place and in some local parts of the system if there are not enough  $SO_4^{2-}$  ions and in the base of the less oversaturations of the liquid phase. The formation of  $C_3A \cdot CaSO_4 \cdot 12H_2O$  takes place.

Investigations of  $NC_8A_3$  in analogical conditions revealed the difference of the initial process of hydrates formation compared to that of  $C_3A$ , i.e. by 5 sec of hydration almost the whole surface of  $C_3A$  is covered by hydrates of this or that composition depending on the system. In case of pure  $NC_8A_3$  the hydrates usually have plate-like form and only some parts of the surface are covered by them.

Fig.5. Surface of  $NC_8A_3$  after 5 seconds of hydration in the system  $NC_8A_3-H_2O$  (x10000).

In the presence of two-water gypsum the formation of  $C_3A \cdot 3CaSO_4 \cdot 31H_2O$  is not noticed, and plate-like phase with the composition  $C_4AH_x$ ,  $C_3A \cdot CaSO_4 \cdot 12H_2O$  dominates.

The formation of various hydrate phases near and on the surface of the minerals under investigation proves the fact that there is a certain dependence of primary hydration reactions and crystal formation on the composition, symmetry and the degree of oversaturation of the environment, i.e. on the initial liquid phase, rate of diffusion of ions, formed in the process of solving of the basic adhesive mineral and physical properties of the basic mineral.

Fig.6. Surface of  $NC_8A_3$  after 5 seconds of hydration in the system  $NC_8A_3-CaSO_4 \cdot 2H_2O-H_2O$  ( $\times 10\ 000$ ).

The investigation of hydration activity of minerals, kinetics of their solving and heat liberation allowed to find substantial differences in the character of these changes [3].

Plastometry analyses of monomineral pastes during 10 hours reveal differences in structure formation on hydration products of  $C_3A$  and  $NC_8A_3$ . The formation of primary structure takes place quicker in the system with the sodium analogue. But after six hours of hydration the increase of plastic strength is more intensive in the system with  $C_3A$ .

The curve is divided into two parts, which may be referred to the formation of the primary structure and then to the process of mass crystallization typical for the second period of hydration. Gypsum added to hardening systems (5% of gypsum) influence differently on the structure formation of  $C_3A$  and  $NC_8A_3$ . Thus resistance to shift deformations is increased by 2 or 3 times in case of  $C_3A$ , and in the second case it decreases by 2 times. As the mentioned above investigations by means of electronic microscope show the formation of  $C_3A \cdot 3CaSO_4 \cdot 31H_2O$  is not found on the grains of  $NC_8A_3$  and this may lead to a "false" setting.

Differential thermokinetic curves show that in the first 30 minutes the rate of heat liberations of  $NC_8A_3$  is higher. On the curves only one maximum during four hours is fixed. After 1.5 hours the rate of heat liberations decreases 4 times for instance during 4 hours 560.3 kJ/kg and as to  $C_3A$  549.9 kJ/kg was liberated; and as to  $NC_8A_3$  hydration occupies only some parts of the surface.

Thus alkali analogue of  $C_3A$  in early periods of hydration forms a structure differing from  $C_3A$ . Characteristic properties of

this structure show that probably there may be formed "false" unstable structures.

Data concerning the change of composition of water medium prove it. When  $C_3A$  is hydrated in a suspension with  $m/s = 340$  during 672 hours the concentration of calcium oxide in the solution changes in a "wave-like" way. On the curve we may see 3 maximum points after 2 minutes of mineral and water mixing (0.67 g/l). After 6 hours - 1.11 g/l and after 168 hours - 1.15 g/l. In case of  $NC_8A_3$  the amount of  $CaO$  in the solution is 3-4 times lower and does not change in a "wave-like" manner. It changes with a constant velocity and the concentration of  $Al_2O_3$  is 4-5 times as great as in  $C_3A$  system in the first minute of contacting with water. Then for  $C_3A$  the amount of  $Al_2O_3$  remains insignificant 0.07-0.9 mg/l compared to  $NC_8A_3$  where its amount is 50-60 mg/l.

After 72 hours of hydration the amount of  $Na_2O$  remains constant (6-7 g/l). The excess of  $Al_2O_3$  in the solution prevents hydrolyzation of  $NC_8A_3$  by forming sodium aluminate.

The data given above prove the facts that alkali oxides take part in sorption and hydrate formation processes in the formation of strong structure during the hydration of the minerals  $C_3A$  and  $NC_8A_3$  which takes place at different parameters pH of the liquid medium. In case of  $NC_8A_3$  pH is 12.9

after 1 min of hydration and after 592 hours of hydration - 13.4 and as to  $C_3A$  hydration these parameters are as follows 11.9 and 12.1.

Various primary conditions of hydration lead to the formation of different primary structures of hardening and influence the kinetics of hydration and this in turn influence the difference in strength parameters.

Thus  $C_3A$  mineral by 672 hours of hydration has strength 2.8 MPa (small samples -  $1 \times 1 \times 3$  cm), and when folding - 1.1 MPa  $NC_8A_3$  mineral (though its setting is extremely quick) loses its strength as time goes (as if they become liquid) and it leads to the following: in 24 hours it is difficult to take the samples out of the forms and later they do not become strong even in 2 years.

**CONCLUSION** In  $C_3A$  hydration in systems modelling the processes of cement hydration the formation of calcium hydroaluminates proves the fact that the reaction of  $C_3A$

solving is a primary one. Besides it proves that in the system various local conditions for hydrate formation in the moment of mixing are created. In the system  $C_3A-CaSO_4$ .

$2H_2O-H_2O$  the reactions with the formation of  $C_4AH_x$ ,  $C_3A \cdot 3CaSO_4 \cdot 31H_2O$ ,  $C_3A \cdot CaSO_4 \cdot 12H_2O$  and  $Al(OH)_3$  are primary ones.

$\text{NC}_8\text{A}_3$  is an independent mineral. The characteristic features of hydration of this mineral differ greatly from those of  $\text{C}_3\text{A}$ .

The presence of  $\text{NC}_8\text{A}_3$  in Portland cement clinker is obviously undesirable as in the first moments of hardening its presence may give rise to a "false" setting and later it may favour continuous loss of strength of hardening system "cement-water".

### RESUME :

Des phases aluminates de composition complexe analogues aux phases des clinkers industriels ont été synthétisées et étudiées. Elles représentent des solutions solides multicomposants de  $C_3A$  avec  $Na_2O$ ,  $K_2O$ ,  $MgO$ ,  $Fe_2O_3$ ,  $SiO_2$  et avec de petites quantités de  $Cr_2O_3$ ,  $TiO_2$ ,  $P_2O_5$ . On a étudié aussi des solutions solides de  $C_3A$  avec  $Na_2O$ ,  $SiO_2$ ;  $C_3A + K_2O + SiO_2$ ;  $C_3A + Na_2O + K_2O + SiO_2$ .

On obtient les phases homogènes quand la quantité totale des impuretés n'excède pas 12 à 13 % en poids. Dans les échantillons contenant plus de 5 % en poids de  $Fe_2O_3$ , certaines quantités d'aluminoferrites de calcium cristallisent avec les aluminates.

La phase contenant plus de 3 % en poids de  $Na_2O + K_2O$  se trouve être orthorhombique. Les aluminates avec une petite quantité d'alcalins sont cubiques. Les paramètres cristallins et les densités des aluminates sont donnés.

On a étudié l'hydratation à court et à long terme. On montre que le processus d'hydratation de  $C_3A$  et des solutions solides  $C_3A + Na_2O$  peut être considéré comme un modèle par rapport à l'hydratation des solutions solides multicomposants. Les courbes cinétiques d'hydratation permettent de distinguer trois stades du processus. Les particularités d'hydratation à chaque stade sont prédéterminées par un nombre de facteurs corrélés.

L'hydratation des aluminates en présence d'aluminoferrites se poursuit avec moins d'intensité et ne peut être complète même après des temps prolongés.

Dans le cas général, les éléments mineurs en solution solide ainsi que la présence d'autres phases retardent considérablement l'interaction des aluminates avec l'eau. Le degré d'hydratation peut être deux ou trois fois plus faible que dans le  $C_3A$  pur.

**SUMMARY :** Aluminate phases of complicated composition analogous to the phases of commercial clinkers have been synthesized and studied. They represent polycomponent solid solutions of  $C_3A$  with  $Na_2O$ ,  $K_2O$ ,  $MgO$ ,  $Fe_2O_3$ ,  $SiO_2$  and small amounts of  $Cr_2O_3$ ,  $TiO_2$ ,  $P_2O_5$ . Studies have also been made of the solid solutions of  $C_3A$  with  $Na_2O$ ,  $SiO_2$ ;  $C_3A$  with  $K_2O$ ,  $SiO_2$ ;  $C_3A$  with  $Na_2O$ ,  $K_2O$ ,  $SiO_2$ .

The homogeneous phases were obtained when the total amount of impurity oxides did not exceed 12-13 wt %. In samples containing more than 5 wt %  $Fe_2O_3$  some amounts of calcium aluminoferrites crystallized together with the aluminates.

The phase containing more than 3 wt %  $Na_2O + K_2O$  appeared to be orthorhombic. Aluminates with a less content of alkalis are cubic. The unit cell parameters and densities of the aluminates are given.

Hydration at early and later ages was studied. It is shown that the hydration process of  $C_3A$  and its solid solutions with  $Na_2O$  can be regarded as a model with respect to the hydration of polycomponent solid solutions. The hydration kinetic curves permit to distinguish three stages of the process. The peculiarities of hydration at each stage are predetermined by a number of interrelated factors.

Hydration of the aluminates in the presence of aluminoferrites proceeds less intensely and cannot be completed even after long times.

In general case, the impurity components of the solid solution as well as the presence of other phases slow down considerably the interaction of the aluminates with water. The degree of hydration in this case can be twice or thrice as low as in pure  $C_3A$ .

## ON THE ALUMINATE PHASE IN CEMENT CLINKER

Polycomponent solid solutions of  $C_3A$  with  $Na_2O$ ,  $K_2O$ ,  $MgO$ ,  $Fe_2O_3$ ,  $SiO_2$  are constituents of the aluminate phase of clinker. They can also contain small amounts of other oxides:  $Cr_2O_3$ ,  $Mn_2O_3$ ,  $TiO_2$ ,  $P_2O_5$ ,  $SO_3$ .

Due to the peculiarities of structure, the aluminate phase contains the greatest amount of impurities compared to other cement phases. The presence in the  $C_3A$  crystal lattice of a large  $Ca^{2+}$  cation and holes exceeding in size any cation provides, on the one hand, the distribution of foreign ions with large radii and, on the other hand, promotes the realization of the different and numerous schemes of heterovalence isomorphic substitutions.

As known, the crystal structure of  $C_3A$  is most convenient for  $Na^+$  substituting  $Ca^{2+}$ . The compensating additional  $Na^+$  is distributed in the holes. When the aluminate phase is formed in the clinker rich in  $SiO_2$ , the balanced substitution  $Ca^{2+}Al^{3+} \rightleftharpoons Na^+Si^{4+}$  is possible. That's why the aluminate phases contain considerable amounts of  $Na_2O$  and  $SiO_2$ ; the amount of potassium is smaller, as a rule, compared to sodium.

$Fe^{3+}$  is always present in the aluminate due to the wide-spread substitution  $Al^{3+} \rightleftharpoons Fe^{3+}$ ;  $Mg^{2+}$  can also enter the structure as a result of substitutions  $Ca^{2+} \rightleftharpoons Mg^{2+}$ ,  $2Al^{3+} \rightleftharpoons Mg^{2+}Si^{4+}$ ,  $3Mg^{2+} \rightleftharpoons 2Al^{3+}$  and occupy positions both of  $Ca^{2+}$  and  $Al^{3+}$ . Much less are the amounts of  $Cr^{3+}$ ,  $Mn^{3+}$ ,  $Ti^{4+}$ ,  $P^{5+}$ ,  $S^{6+}$ , first of all as they are present in the clinker in small quantities. Besides,  $Cr$ ,  $Mn$ ,  $Ti$  prefer the crystal lattice of aluminoferrites, and  $P$  and  $S$  that of belite.

All the foreign ions mentioned were found in the aluminate phase of clinker by means of electron-probe microanalysis. The maximum contents of them depend on the possibilities of the crystal lattice of  $C_3A$  and are limited.

However, attention is drawn to the fact that the total amounts of impurity oxides determined by different authors differ considerably and are within the limits of 10-20 wt %. Data obtained by us on the amounts of the main and secondary impurity oxides present in the aluminate phases are as follows:

$Na_2O$	0.3-4.0	$TiO_2$	0.1-0.4
$K_2O$	0.3-0.8	$P_2O_5$	0.04-0.1
$MgO$	0.8-1.7	$SO_3$	0.1-0.5
$Fe_2O_3$	2.9-7.8		
$SiO_2$	3.5-5.6		

The indicated maximum amount of  $Fe_2O_3$  exceeds, in our opinion, the amount of this oxide that can be distributed in the polycomponent solid solution.

The laboratory syntheses of the aluminate phases of complicated composition analogous to the phases of industrial clinkers showed that homogeneous samples could be obtained when the total amounts of impurity oxides did not exceed 13 wt %. It was observed in this case that if the initial batch con-

tained more than 5 wt %  $Fe_2O_3$ , some amount of the aluminoferrite phase always appeared in the synthesis product. Most often the aluminoferrite phase crystallized in the form of thin intergrowths with the aluminate phase.

## SYNTHETIC ALUMINATE PHASES OF COMPLICATED COMPOSITION

Table I gives compositions of the aluminate phases synthesized according to the data of chemical analysis. The compositions of samples I, II, VII were chosen using the data of electron-probe microanalysis of the phases of industrial clinkers. The composition of phase VI containing the impurity oxides  $SiO_2$ ,  $Fe_2O_3$ ,  $MgO$ ,  $Na_2O$ ,  $K_2O$  most characteristic of the aluminate was chosen according to [1]. Phases III, IV, V are solid solutions of  $C_3A$  with  $Na_2O$ ,  $K_2O$ ,  $SiO_2$ .

X-ray and microscopic investigations permitted to establish that only the aluminate phase VI containing more than 3 wt % of alkali oxides is orthorhombic, all the others are cubic. According to X-ray analysis, all aluminates resemble each other and are derivatives of pure  $C_3A$  (Fig. 1). The X-ray diffraction pattern of the orthorhombic aluminate differs from those of  $C_3A$  and cubic phases only with splitting of reflections at angles  $2\theta$  of 32-34°, 47-49°, 58-60°.

Table II represents unit cell parameters of cubic aluminates and their densities determined by pycnometer method.

The unit cell parameters of orthorhombic aluminate VI are:  $a=10.879(4)$  Å;  $b=10.841(4)$  Å;  $c=15.134(5)$  Å. The density is 3.18 g/cm<sup>3</sup>. The greater value of density of the aluminates I, II, VI, VII compared to III, IV, V is due to the presence of iron in their crystal lattice.

Samples I, VI, VII contain small amounts of calcium aluminoferrite which increase with increasing amount of  $Fe_2O_3$  in the initial batch. The greatest amount of aluminoferrite was found in sample VI. According to [1] the total contents of impurity oxides in this sample should be 19 % with 7.8 %  $Fe_2O_3$  included. However, we failed to obtain the homogeneous aluminate phase of this composition.

In sample VI the compositions of aluminate and aluminoferrite were determined by us using electron microprobe. The data are given in Table III.

The results of the analysis of the aluminate and aluminoferrite formed during the simultaneous crystallization are of interest as evidence of the preferable distribution of the elements in these two phases.

The amount of  $Fe_2O_3$  in the aluminate is about 5 %. This is considerably less compared to clinker aluminates. The same refers to  $SiO_2$ .

Of special attention is the behaviour of  $MgO$ . In the aluminate crystals analyzed no magnesium was found. In the clinker aluminate phases we also found crystals

which sometimes contained no magnesium. The fact that among all cement minerals magnesium is distributed first of all in the aluminoferrite is visibly demonstrated by microprobe analysis. As should be expected,

sodium is present in a greater amount in the aluminate.

#### HYDRATION

Hydration kinetic curves for the aluminate phases obtained by means of X-ray diffraction are shown in Fig. 2a. For comparison, the hydration curves for C<sub>3</sub>A and crystalline forms of solid solutions of C<sub>3</sub>A with Na<sub>2</sub>O/2/ are also shown. Analogous results were simultaneously published in /3/.

The hydration process of C<sub>3</sub>A and its solid solutions with Na<sub>2</sub>O can be regarded as a model which permits the description of the hydration course of any derivative of C<sub>3</sub>A.

According to the kinetic curves, three stages of hydration are clearly distinguished at early interaction with water.

The first stage is characterized by an intense reaction course accompanied by a considerable heat liberation and is completed after a short period (to ~ 15 minutes). The intense start of the hydration is due to the peculiarities of the crystal structure of C<sub>3</sub>A, first of all to large holes /4/. The decrease of the degree of hydration with increasing amount of sodium in the C<sub>3</sub>A crystal lattice and consequently the increase in number of the occupied holes are evidence of the predominant role of the latter at early hydration.

In case of either substitution of Ca<sup>2+</sup> or Si<sup>4+</sup> by elements of other valency (what takes place during the formation of the aluminate phase in clinker) the charge balance can be realized not only by Na<sup>+</sup> but also by other ions. This is one of the reasons of a lower value of the degree of hydration of the aluminate phases of complicated composition (Fig. 2a,b), although the Na<sub>2</sub>O content in them is less than in the cubic solid solution of C<sub>3</sub>A with Na<sub>2</sub>O. In other words, together with sodium, other compensating ions can be located in the crystal lattice holes of the aluminate phase.

The second stage of hydration that is completed after ~ 80-100 minutes from the beginning of the process is characterized by a sharp retardation of the reaction and is diffusion-controlled /2,5/. The reason of retardation is a layer of hydration products formed on the surface of hydrated particles. After completion of the period of intense

Fig. 2 - Kinetic hydration curves for : (a) aluminate phases of complicated composition (numbers of curves correspond to those of phases in Table I); (b) C<sub>3</sub>A (curve I) and solid solutions with Na<sub>2</sub>O : curve II - cubic solid solution (2.4 wt % Na<sub>2</sub>O); III - orthorhombic (3.8 wt % Na<sub>2</sub>O); IV - tetragonal (4.8 wt % Na<sub>2</sub>O); V - monoclinic (5.7 wt % Na<sub>2</sub>O).

reaction the thickest layer of hydrates forms on the surface of  $C_3A$  particles. The greater the amount of ions filling the crystal lattice holes of the solid solution, the lower the degree of hydration, the thinner the layer of hydration products that hinders the penetration of the liquid phase into the non-interacted substance.

The third, delayed completing stage is predetermined by the two preceding stages and depends also on the newly formed factors, namely on the kind of reaction products, on the growth of crystallohydrates, their size, orientation, recrystallization etc.

Due to a thinner layer of reaction products on the surface of the solid solution with the maximum filling of the holes, its hydration at the third stage will proceed more intensely compared to any other solid solution. As a result, the curves of degree of hydration can intersect after certain periods of time different for the different samples.

The analysis of the values of degree of hydration shows that after one day hydration the aluminates of the simplest composition containing sodium (samples IV, V) practically hydrated. The degree of hydration for them was  $\sim 90\%$ . An analogous sample containing potassium (III) showed a  $70\%$  degree of hydration. The samples of aluminate phase containing  $Fe_2O_3$  (I, II, VI, VII) showed a clear tendency to retardation of the hydration process at the third stage. The aluminate phase with the least amount of  $Fe_2O_3$  (sample II) showed the highest value of degree of hydration after one day hydration and longer to six months (the term to which the observation was made).

The presence of aluminoferrite, although it does not change the general character of hydration, retards much more the hydration at the later stage, as shown by kinetic curves for sample VI. This is probably due to the fact that the layer of a mixture of hydration products of the aluminate and aluminoferrite is more dense compared to the products of hydration of the aluminate alone. As a result, the mineral can remain non-hydrated. Completeness of the reaction in this case depends to a considerable extent on the grain size.

#### CONCLUSIONS

The clinker aluminate phase is a polycomponent solid solution of  $C_3A$  with the oxides of constituent elements of raw materials.

The maximum amount of impurity oxides to be contained in the aluminate phase during the clinker formation does not exceed  $12-13\text{ wt}\%$  at a  $Fe_2O_3$  content not more than  $5\%$ .

In structural respect, the clinker aluminate phases are derivatives of  $C_3A$  and can possess the same crystal forms as solid solutions of  $C_3A$  with  $Na_2O$ .

The hydration of the aluminate phases proceeds by analogy with  $C_3A$  and crystal forms of its solid solutions with  $Na_2O$ . However, other components of the solid solution as

well as other phases retard considerably the hydration.

The course of hydration at different stages is predetermined by a number of interrelated factors. However, at each stage only some of them play the decisive role.

Thus, in the initial period the hydration activity of the different crystal forms of solid solution depends mainly on the occupancy of lattice holes with foreign ions. The degree of hydration of the solid solution with the highest occupancy of the holes can be twice or thrice as low as in pure  $C_3A$ .

At subsequent stages the peculiarities of the interaction process with water depend on the thickness and the nature of the layer of hydration products, on the presence of other phases.

Each of the impurities also plays a definite role. Thus,  $Fe^{3+}$  ions, wherever they were (in the lattice of the aluminate solid solution or in the composition of the calcium aluminoferrite), retard the hydration of the aluminate phase. Aluminates of a simple composition containing  $Na^+$  (along with  $K^+$  and  $Si^{4+}$ ) possess a greater value of the degree of hydration at the third stage compared to all phases investigated.

The choice of a set of impurities in the polycomponent solid solution permits wide variations of the degree of hydration of the aluminate phases of complicated composition.

# Mechanisms of retardation of $C_3A$ : a critical evaluation

## *Evaluation critique des mécanismes de ralentissement de l'hydratation de $C_3A$*

S. CHATTERJI, M.Sc., D. Phil., Research Scientist, H + H Industri A/S, Lyngby, Denmark.

SUMMARY: The original papers were critically evaluated in order to differentiate between three proposed mechanisms of retardation of  $C_3A$  hydration.

(i) Retardation due to "alumina-rich" layer formation:-

From the hydration characteristics of dilute suspensions of  $C_3A$  in water and acid, it was concluded that "alumina-rich" layers form on  $C_3A$  grains which retard further hydration. Analyses of experimental conditions and results indicate the formation of expected alumina gels. The relevance of these results to pastes of  $C_3A$ , particularly in alkaline media, is uncertain especially as, contrary to practice,  $CaCl_2$  was found not to influence the induction (retardation) period".

(ii) Retardation due to alumina gel formation:-

From the hydration characteristics of  $C_3S+C_3A$ +gypsum+water pastes, it was concluded that  $C_3A$  grains, protected by layers of hydration products which hinder the flow of  $Ca^{2+}$  and  $OH^-$  but not water, hydrate in a dilute  $Ca(OH)_2$  solution forming  $C_4AH_x$  and alumina gel and this gel is the actual retarding agent. Subsequently it was calculated that only  $3.2 \times 10^2$  dyne·cm<sup>-2</sup> pressure differential across the protective layer is sufficient to maintain the required water flow. In the above calculation the number of  $C_3A$  grains was underestimated. The insertion of the proper number, without any other change, yields about  $1.5 \times 10^4$  dyne·cm<sup>-2</sup>. Moreover there was no direct evidence of alumina gel formation.

(iii) Retardation due to water shortage at  $C_3A$  surface:-

An electron microscopic study showed that additives, especially  $Ca(OH)_2$ , reduce the size of hydration products in  $C_3A$  pastes. It was postulated that the smaller the hydration products the higher their resistance to water flow and hence smaller volume of water will reach the  $C_3A$  grains for further reaction. The presence of  $C_4AH_{13}$  instead of  $C_4AH_9$  in virgin moist pastes substantiates this water shortage. Effects of  $CaCl_2$  and organic additives can be easily explained.

RESUME: Les études originales ont fait l'objet d'une évaluation critique afin de différencier les trois mécanismes de ralentissement de l'hydratation du  $C_3A$ .

(i) Ralentissement dû à la formation de couches "riches en alumine"

Selon les caractéristiques de l'hydratation des suspensions diluées de  $C_3A$  dans l'eau et les acides, on a conclu que les couches riches en alumine se forment à partir de granules  $C_3A$ , ce qui ralentit toute hydratation ultérieure. L'analyse des conditions expérimentales et des résultats obtenus indique la formation de gels d'alumine. La pertinence de ces résultats en ce qui concerne les pâtes de  $C_3A$ , particulièrement en milieu alcalin, peut être mise en doute, surtout après avoir découvert que, contrairement à la pratique, "le  $CaCl_2$  n'avait aucune influence sur la période d'induction (ralentissement)".

(ii) Ralentissement dû à la formation de gel d'alumine:-

Selon les caractéristiques de l'hydratation des pâtes  $C_3S+C_3A$ +gypse+eau, on a conclu que les granules  $C_3A$ , protégés par les couches de produits de l'hydratation qui empêchent les flux de  $Ca^{2+}$  et de  $OH^-$  tout en laissant l'eau s'hydrater dans une solution diluée de  $Ca(OH)_2$  et forment du  $C_4AH_x$  et un gel d'alumine qui est l'agent véritable du ralentissement. En conséquence on a calculé qu'une pression différentielle de  $3.2 \times 10^3$  dyne·cm<sup>-2</sup> à travers les couches protectrices est suffisante pour maintenir le flux d'eau nécessaire. Dans ce calcul, on a sous-estimé le nombre de granules  $C_3A$ . L'introduction du nombre exact, sans faire intervenir d'autres changements, donne une pression de  $1.5 \times 10^4$  dyne·cm<sup>-2</sup> environ. De plus, il n'y avait pas de preuves directes de formation de gel d'alumine.

(iii) Ralentissement dû au manque d'eau à la surface du  $C_3A$ :-

Une étude au microscope électronique a montré que les additifs, notamment le  $Ca(OH)_2$ , réduisent le volume des produits d'hydratation dans les pâtes  $C_3A$ . On a postulé que plus les produits d'hydratation sont faibles, plus leur résistance au flux de l'eau est grande, ce qui entraîne une baisse du volume d'eau qui atteindra les granules de  $C_3A$  pour la réaction ultérieure. La présence de  $C_4AH_{13}$  au lieu de  $C_4AH_9$  dans les pâtes humides vierges confirme ce manque d'eau. On peut facilement trouver une explication à l'action du  $CaCl_2$  et des additifs organiques.

It is known that finely ground clinker of commercial Portland cement react with water with considerable evolution of heat and the paste is quick setting. In commercial practice the high rate of heat evolution and the quickness of set are controlled by co-grinding clinker and gypsum; although other chemicals can also be used for this purpose. It is generally conceded that  $C_3A$  or related phases are responsible for quick setting. As a result the hydration of  $C_3A$  and the effects of different chemicals on its hydration have been studied extensively; and different mechanisms have been proposed to explain the observed effects. The object of this paper is to differentiate among three current mechanisms of retardation of  $C_3A$  hydration.

As any reaction mechanism can only be evaluated by comparing its corollaries with observations, so certain aspects of paste hydration of  $C_3A$  have been collected below:

(1)  $C_3A-H_2O$  system: Hedin was the first to show that about 40% of  $C_3A$  hydrates within 3 minutes of water addition but the subsequent hydration rate is much slower (1). Recent quantitative x-ray diffraction (QXRD) results confirmed it (2,3). Fig. 1 is taken from reference 2 and shows this effect clearly. Electron microscopic studies show that well formed hexagonal crystals of  $C_2AH_8$  and  $C_4AH_{13}$  form within 4 minutes of water addition (4,5). With the passage of time, hexagonal crystals grow in size and proportion and  $C_3AH_6$  appears.

Fig. 1

Rates of  $C_3A$  hydration in different media

(2)  $C_3A-Ca(OH)_2-H_2O$  system: QXRD and other studies showed that the addition of  $Ca(OH)_2$  lowers the rate of  $C_3A$  hydration (1,2,4,5,6). Plates of hexagonal aluminates, smaller and thinner than in  $C_3A-H_2O$  paste, could definitely be identified in a 3 hours sample (4,5); though their formation within 4 minutes could be inferred.

(3)  $C_3A-CaSO_4-H_2O$  system: QXRD results show that the addition of gypsum does not affect the early rate of  $C_3A$  hydration (2). According to Hedin, gypsum is less effective than  $Ca(OH)_2$  (1), but according to Collepardi et al gypsum is more effective than  $Ca(OH)_2$  (6). Thus the results are not in concordance. Ettringite is the main hydration product in the presence of gypsum although a small amount of hexagonal aluminate could be detected at all times (4,5,6,7). In a 3 hours old sample hexagonal crystals were as thin as in the  $C_3A-Ca(OH)_2-H_2O$  paste. Monosulfate forms when  $SO_4$  ion concentration in the liquid phase drops below that required by ettringite.

(4)  $C_3A-Ca(OH)_2-CaSO_4-H_2O$  system: It is generally been accepted that lime-gypsum combination is a better retarder than either of the components (1,2,5,6). Ettringite is the main hydration product in the presence of gypsum although hexagonal aluminates can be found at all times. (4,5,6,7). Sizes of the hydration products are very much reduced in this system (5,8).

(5)  $C_3A-CaCl_2-H_2O$  system: The effect of  $CaCl_2$  on  $C_3A$  hydration depends on its concentration (1,5). For the same retardation a lower amount of  $CaCl_2$  is needed than  $Ca(OH)_2+CaSO_4\cdot 2H_2O$  combination; however at a higher concentration  $CaCl_2$  is an accelerator (1). Electron microscopic and x-ray diffraction studies show that hexagonal monochloride ( $C_3A\cdot CaCl_2\cdot xH_2O$ ) forms at low  $CaCl_2$  concentration and needle shaped trichloroaluminate ( $C_3A\cdot 3CaCl_2\cdot yH_2O$ ) forms at high  $CaCl_2$  concentration (5).

With the above background information it is now possible to analyse and differentiate between different mechanisms of retardation of  $C_3A$  hydration.

#### (A) Retardation due to "alumina-rich" layer formation:

This mechanism has been proposed by Tadros and Skanly (9,10). The authors concluded that  $C_3A$  dissolves incongruently in water or dilute acid solutions forming alumina-rich surfaces on  $C_3A$  grains. Calcium ions get adsorbed on this layer forming positively charged particles. "The formation of a structure consisting of an aluminium-rich surface with adsorbed calcium ions, appears to minimize the active dissolution sites and results in reduced rates of dissolution". "In the presence of sulfate ions, adsorption on the positively charged sites further reduces the rate of dissolution. This effect is probably achieved via the blocking effects of sulfate ions on coordination sites which would otherwise be occupied by hydrogen or hydroxyl ions, known to be able to catalyze the dissolution of alumina...". In order to appreciate their conclusions, it is necessary to analyse their experimental technique and results:

(i)  $C_3A$ -water suspensions: In these suspensions water/solid ratios varied between 25 to 250. The liquid phase after one minute of mixing contained  $1.05 \times 10^{-2} M$  Ca

ions and  $5.5 \times 10^{-3} \text{ M}$  Al ions. As Ca/Al ratio was 1.9 instead of 1.5 of  $\text{C}_3\text{A}$  the authors concluded that  $\text{C}_3\text{A}$  dissolves incongruently. However an examination of  $\text{Ca}(\text{OH})_2\text{-Al}(\text{OH})_3\text{-H}_2\text{O}$  phase diagram (11) shows that a liquid phase containing  $1.05 \times 10^{-2} \text{ M}$  Ca ions in equilibrium can contain only  $1.96 \times 10^{-3} \text{ M}$  Al ions i.e. the analysed solution was already 2.8 times supersaturated with Al ions. A congruent solution of  $\text{C}_3\text{A}$ , if all Al ions could be kept in solution, would have yielded a Al ion supersaturation of 3.6. It is highly unlikely that such a supersaturation could be achieved in practice. Whether from the above analyses of the liquid phase one can conclude incongruent solubility of  $\text{C}_3\text{A}$  is another matter altogether. In this context it is of interest to note that Hedin who arranged  $\text{C}_3\text{A}$ /water ratio so that both Ca and Al ions could be kept in solution, found Ca/Al ratio of 1.5 over a period of 20 minutes (1).

(ii)  $\text{C}_3\text{A}$ -dilute acid suspensions: Figs. 2 and 3 are taken from reference 9 and show representative results. The time interval between pH 4 and about 11.2 has been termed "induction period". It can be seen that the induction period has been lengthened by  $\text{SO}_4$  ions. In some experiments  $\text{CaCl}_2$  was used instead of  $\text{CaSO}_4$  and "CaCl<sub>2</sub> was found not to influence the induction period". A quantitative analysis of these results will be informative. Consider the case of pure 0.166M HCl first.

Fig. 2 - Rates of dissolution of 2g  $\text{C}_3\text{A}$  in 75 ml. of 0.166M HCl

(a) From Fig. 3 it can be seen that the initial Ca ion concentration was just below 0.06M and that of Al ion just above 0.02M; for the sake of simplicity assume them to be 0.06 and 0.02 respectively. From Fig. 2, the pH of the solution at that time was 4. If both the metals were in their fully ionized state then Ca ions would have required 0.12M Cl ions and Al ions would have required 0.06M Cl ions i.e. altogether 0.18M Cl ions; whereas the solution contained only 0.166M Cl ions. If the pH of the solution is taken into consideration, a higher Cl ion concentration will be needed to neutralize the positive ions.

It is thus obvious that not all the metals in the solution were in their fully ionized state i.e. at least a part of Al was in a hydrolyzed state

Fig. 3 - Dissolution of 2g  $\text{C}_3\text{A}$  in 75 ml of 0.166M HCl. (a) and (c) for  $[\text{Ca}^{2+}]$  and [aluminium]; (b) and (d) for  $[\text{Ca}^{2+}]$  and [aluminium] in the presence of  $1.55 \times 10^{-3} \text{ M}$   $\text{CaSO}_4$  respectively.

(b) Fig. 2 shows that between 2 and 12 minutes the pH of the solution rose slightly above 4. Fig. 3 shows that in the same period Ca ion concentration was effectively constant, however Al ion concentration dropped from 0.02 to 0.01M. A removal of Al ion from the solution should have been accompanied by a change in positive ions i.e. changes in pH and/or Ca ion concentration. In the absence of either, one is forced to think that at least a part of Al was in a finely divided state at the time of the first filtration but had grown subsequently and was removed at the second filtration. This interpretation is consistent with the fact that Al ions start to hydrolyse at pH3 (12,13) and that the solubility of  $\text{Al}(\text{OH})_3$  at pH4 is  $1 \times 10^{-4} \text{ mol/l}$  (14). It is only natural that freshly formed  $\text{Al}(\text{OH})_3$  will need time to grow sufficiently to be removed by filtration. Incidentally the measured Ca ion concentration of 0.06M is just short of that required to neutralize 0.166M HCl to pH4. It will thus appear that a major part, if not all, of Al released by the action of HCl was hydrolyzed to  $\text{Al}(\text{OH})_3$  in a very short time. It is expected that adjacent to  $\text{C}_3\text{A}$  grains the pH will be higher than in the bulk liquid phase and a major part of hydrolysis and precipitation of  $\text{Al}(\text{OH})_3$  will occur there i.e.  $\text{C}_3\text{A}$  grains will be covered by  $\text{Al}(\text{OH})_3$  layers. The difficulty of material transport through this  $\text{Al}(\text{OH})_3$  layer will explain the "induction period".

Dissolution of  $\text{C}_3\text{A}$  in HCl in the presence of  $\text{SO}_4$  ions could not be analysed in detail, the reason being that Figs. 2 and 3 report results of two different  $\text{SO}_4$  concentrations.

However qualitatively the effectiveness of  $\text{SO}_4$  ions could be explained on the basis of Schulze-Hardy rule, which states that divalent  $\text{SO}_4$  ions will be very effective in precipitating positively charged  $\text{Al}(\text{OH})_3$  gel (15). A tightly packed  $\text{Al}(\text{OH})_3$  gel will hinder the flow of materials through it more than a loosely packed layer.

The authors definitely got  $\text{Al}(\text{OH})_3$  layers on  $\text{C}_3\text{A}$  grains in their experiments. However their results and hypothesis are at variance with the following characteristics of  $\text{C}_3\text{A}$  paste:

- (i) in  $\text{C}_3\text{A}$  pastes hexagonal aluminates or/and ettringite were found from 30 sec. onwards whereas the authors could not find them,
- (ii) the hypothesis suggests that high concentration of  $\text{Ca}(\text{OH})_2$ , in the absence of  $\text{SO}_4$  ions, should dissolve aluminous layer thereby increasing  $\text{C}_3\text{A}$  hydration, whereas in practice  $\text{Ca}(\text{OH})_2$  is a retarder,
- (iii) it is difficult to explain the higher efficiency of  $\text{Ca}(\text{OH})_2 + \text{CaSO}_4 \cdot 2\text{H}_2\text{O}$  mixture,
- (iv)  $\text{CaCl}_2$ , which the authors found to be ineffective, is in practice a very effective agent.

In view of the above contradictions, the relevance of this experimental set up and the hypothesis to paste hydration of  $\text{C}_3\text{A}$  especially in alkaline medium is very uncertain.

(B) The hypothesis of retardation due to an aluminous hydroxide layer formation:

This hypothesis was proposed by Stein et al (16,17). According to this hypothesis "when  $\text{C}_3\text{A}$  reacts with water, both  $\text{C}_2\text{AH}_8$  and  $\text{C}_4\text{AH}_{13}$  are formed" (17). However when  $\text{C}_3\text{A}$  reacts in a solution containing Ca and OH ions the nucleation of  $\text{C}_4\text{AH}_{13}$  is favoured leading to a local shortage of Ca and OH ions near  $\text{C}_3\text{A}$  grains and formation of  $\text{Al}(\text{OH})_3$  gel layers on the grains. This gel layer needs a protective layer of  $\text{C}_4\text{AH}_x$  to hinder the flow of Ca and OH ions but not water.

From the measured heat liberation data and the known enthalpy of the following reaction

Stein calculated that for a 0.75g  $\text{C}_3\text{A}$  + 0.25g  $\text{C}_3\text{S}$  paste if  $\text{C}_4\text{AH}_x$  layer had a porosity less than  $10^{-6} \text{ cm}^2/\text{cm}^2$  of  $\text{C}_3\text{A}$  surface the shortage of Ca and OH ions would be the rate determining factor. Inserting the above porosity and calculated water flow through  $\text{C}_4\text{AH}_x$  layer to maintain the rate of heat liberation in the Hagen-Poiseuille equation Stein calculated that a pressure differential of  $3.2 \times 10^3 \text{ dynes}\cdot\text{cm}^{-2}$  across the  $\text{C}_4\text{AH}_x$  layer would be needed. This low figure indicated the absence of water shortage (17).

In the above calculation Stein used  $10^{-6}$  as the radius of the individual pores. A division of the total pore area by  $\pi r^2$  gives  $3.18 \times 10^6$  as the total number of pores in the paste. From the characteristics of their starting materials it can be calculated that 0.75g  $\text{C}_3\text{A}$  contained  $1.42 \times 10^9$  equal spheres of radius  $3.46 \times 10^{-4} \text{ cm}$ . Note that the number of spheres is larger than the number of pores. An assumption of size distribution in  $\text{C}_3\text{A}$  should increase the number of particles. From Stein's other data it can be calculated that during the initial stages of hydration the volumes of individual particles were reduced by about 30% i.e. there was no reduction of particle number. The use of this number in the Hagen-Poiseuille equation without any other change gives a pressure differential of  $1.5 \times 10^4 \text{ dyne}\cdot\text{cm}^{-2}$ . This is also the pressure on the pore walls tending to disrupt them i.e.  $\text{C}_4\text{AH}_x$  layer. One may wonder if the above assumption of one pore per particle is reasonable especially as Fig. 4 taken from reference 18, shows several pores per  $400 \mu\text{m}^2$  surface of  $\text{C}_4\text{AH}_x$  layer. The use of pro rata number of pore gives an enormous pressure differential. It is also to be noted that in the case of no water shortage  $\text{C}_4\text{AH}_{13}$  and not  $\text{C}_4\text{AH}_{13}$  should form. The assumptions of the number of pores and the rigidity of  $\text{C}_4\text{AH}_x$  layer depend on ones personal belief. However the followings are independent of personal belief:

- (i) there is no independent evidence of  $\text{Al}(\text{OH})_3$  formation,
- (ii) there is independent x-ray evidence of  $\text{C}_4\text{AH}_{13}$  formation in moist paste indicating a water shortage (19),
- (iii) as  $\text{Al}(\text{OH})_3$  is not expected to form in  $\text{C}_3\text{A}$ -water paste (17), this hypothesis can not explain the drop in the rate of  $\text{C}_3\text{A}$  hydration after about 3 minutes,
- (iv) it is also difficult to explain the effects of  $\text{CaCl}_2$  on  $\text{C}_3\text{A}$  hydration.

Fig. 4 -  $\text{C}_3\text{A}$  hydrated for 10 minutes in paste ( $w/s = 1$ ).

(C) The hypothesis of water shortage as the cause of retardation of  $C_3A$  hydration:

In this hypothesis (20,21) it has been assumed that (i) the hydration of  $C_3A$  depends on the availability of water at the grain surfaces, (ii) water has to flow through hydration products which form round the grains, (iii) the resistance to water flow varies directly with the thickness of the reaction product layer and inversely as the particle size of the product i.e. the flow follows a Kozeny-Carman type equation, (iv) thin plates e.g.  $C_4AH_{13}$  offer higher resistance than needles e.g. ettringite. These authors showed that the addition of  $Ca(OH)_2$ , gypsum,  $Ca(OH)_2 + CaSO_4 \cdot 2H_2O$  mixture to  $C_3A$  paste causes reduction in the particle size of the reaction products compared to pure  $C_3A$  paste. They also showed that at low  $CaCl_2$  concentration hexagonal plates of monochloride form and at high  $CaCl_2$  concentration needles of trichloride form.

From the above hypothesis it follows that  $C_3A$ -water paste will need a thick layer of hydration products before a water shortage will cause a lowering of the hydration rate i.e. the initial hydration rate will be high and once a sufficiently thick layer of hydration products has formed the rate will drop. The retarding and the accelerating effects of  $CaCl_2$  at different concentrations can be explained on the basis of the plate and needle shapes of the product, respectively. In the case of  $C_3A$ - $Ca(OH)_2$ -gypsum paste, the formation and persistence of hexagonal aluminate phases suggests a decreasing gradient of  $SO_4$  ion from the bulk solution to  $C_3A$  surface. This gradient results in the formation of the hexagonal phase adjacent to the grains and on top of which a layer of ettringite. Better performance of  $Ca(OH)_2 +$  gypsum mixture has been attributed to the observed smallness and thinness of the hexagonal crystals.

It should be noted that no other ad-hoc assumption is necessary to explain the actions of lignosulfonate, NaOH etc. (21,22). The direct x-ray evidence of a water shortage at  $C_3A$  grain surface has already been referred to (19).

Recently Collepardi et al suggested a modified version of the water shortage hypothesis (6). These authors proposed that the ettringite layer, which forms in the presence of gypsum, has a better retarding effect than a layer of thin and small hexagonal aluminates. Fig. 5, which has been taken from ref. 6, shows that the heat liberation rate of  $C_3A$ -gypsum paste has an early peak at about 5 minutes. "After 15 minutes of hydration a peak (in DTG curves) at  $120^\circ C$  assigned to  $C_3A \cdot 3CS \cdot H_{12}$  is recorded. Traces of calcium aluminate hydrate can be observed". Fig. 5 also shows that the heat liberation rate accelerates again at about 1.5 hours and peaks at about 4.5 hours; the rate has another inflexion at about 6 hours.

Fig. 5 - Heat evolution in the system  $C_3A + Ca(OH)_2 + CaSO_4 \cdot 2H_2O + H_2O$ .

"At 3-4 hours ettringite is the principal product of hydration while traces of gypsum and hexagonal hydrate can also be observed. At 6-24 hours ettringite tends to decrease and a large peak at  $220^\circ C$  assigned to  $C_3A \cdot CS \cdot H_{12}$  appears". As ettringite was the principal product upto 3-4 hours, it is obvious that the accelerating rate of heat liberation between 1.5 and 3-4 hours must be due to the accelerating rate of ettringite formation. As ettringite tends to decrease at 6-24 hours monosulfate must also be forming at that time i.e. the inflexion of the heat liberation curve at about 6 hours is due to monosulfate formation. It is rather surprising that a thin layer of ettringite, which according to the authors, could retard  $C_3A$  hydration between 0.25 and 1 hour but a thicker ettringite layer could not retard between 1.5 and 3-4 hours. No explanation of this anomaly has been offered.

It is to be noted that the authors have confirmed the formation of hexagonal aluminate hydrate from 15 minutes onwards. The formation of ettringite as the principal product upto 3-4 hours shows that the bulk liquid phase had a high  $SO_4$  ion concentration upto that time. The persistent formation of hexagonal aluminate then means a persistent decreasing gradient of  $SO_4$  ions from the bulk solution to  $C_3A$  surface and that the hexagonal aluminates must have formed in between  $C_3A$  and ettringite layer. One can of course always claim that an ettringite layer, which can not stop hexagonal aluminate formation, is a more effective retarder than the layer of hexagonal aluminate which forms between the layer of ettringite and  $C_3A$  grain. However on the above basis it will be difficult to explain the higher retarding efficiency of hexagonal monochloride over needle shaped trichloride.

The type of analyses carried out in this paper can be further extended and merits or otherwise of different hypothesis can be evaluated. However in the ultimate analysis what is considered to be an acceptable explanation depends more on the fashion of the day, than anything else.

# Theme 3 - Hydration of $C_3A$ in cements

## GENERAL REPORT

by UDO LUDWIG, Institut für Gesteinshüttenkunde, Rwth Aachen, R.F.A.

With the above theme eight papers are submitted for presentation and they deal with

- (I) the reactivity of cubic, orthorhombic and monoclinic  $C_3A$  (1)
- (II) the formation of mono- and trisilicoaluminate hydrates (1, 2)
- (III) the hydration of  $C_3A$  in pure systems with  $C_3S$ ,  $C_5S$ ,  $C_6$  and  $K_2S$  (1, 3, 4, 5)
- (IV) the hydration of  $C_3A$  and  $C_2(A,F)$  in cements (1, 5, 6, 7, 8)

REGOURD, HORNAIN and MORTUREUX (1) studied the rate of hydration of both cubic and orthorhombic forms of  $C_3A$  in the presence of  $C_3S$  and gypsum by XRD with a normal paste of 0.35 to 0.5 W/S ratio. They found that in the initial stages of reaction the cubic form was more reactive than that of orthorhombic. The use of NaOH solution instead of distilled water showed no effect on the reactivity of  $C_3A$ . From these observations, the authors concluded that the higher density of the orthorhombic form of  $C_3A$  is responsible for the lower reactivity. Addition of 3 wt.-%  $K_2SO_4$  to  $C_3A-C_3S-C_5H_2$  paste accelerates the hydration of both the cubic as well as the orthorhombic form of  $C_3A$ . - The lower hydration rate of orthorhombic as well as monoclinic  $C_3A$  was also observed in pastes hydration of industrial clinker.

J.H.P. VAN AARDT and S. VISSER (2) synthesized a monosilicoaluminate hydrate (10,0 Å) analogous to the calcium monosulphoaluminate hydrate (10.3 Å) by reaction of amorphous silica and lime with a slurry of  $C_4AH_{19}$  (10.6 Å) at 50°C. The reaction was followed by XRD.

$C_4AH_{19}$  was prepared from  $C_3A$  and  $Ca(OH)_2$  at 50°C, which contained a little amount of  $C_3AH_6$  and 8.2 Å hydrate. On the addition of silica or silica with  $Ca(OH)_2$ , the following reactions took place.

1. silica and  $Ca(OH)_2$  formed CSH and
2. silica replaced the OH groups in  $C_4AH_{19}$  to form the silicoaluminate hydrate.

On the addition of increasing amounts of silicoaluminate hydrate is formed readily especially when no extra  $Ca(OH)_2$  is added. The addition of CSH did not produce the 10 Å hydrate.

At later ages of hydration or by raising the temperature from 50°C to room temperature, 10,0 Å hydrate is converted into  $C_2ASH_8$  (12.6 Å) and CSH.

Under normal conditions, the formation of silicoaluminate hydrate is unlikely in hydrated Portland cement because of the excess  $Ca(OH)_2$  present.

On the otherhand with the help of electron microanalysis of the polished sections of the following two hydrated mixtures

76 wt.%  $C_3S$  + 19 wt.%  $C_3A$  + 5 wt.% gypsum and  
80 wt.%  $C_3S$  + 20 wt.%  $C_3A_C$ .

M. REGOURD, H. HORNAIN and B. MORTUREUX (1) found the following two silicoaluminate hydrates

$C_4ASH_{12}$  and  $C_3A \cdot 3CS \cdot H_{31}$ .

After seven days of hydration, the formation of poorly crystalline trisilicoaluminate hydrate was observed as pseudomorph of the anhydrous  $C_3A$ . The monosilicoaluminate hydrate is formed outside the original  $C_3A$  boundary. The  $C_3A_C$  reacts faster than  $C_3A_0$ .

J. JAMBOR (3) studied the binding properties of  $C_3A$  in the presence of  $CaCO_3$ . The fineness of  $C_3A$  and  $CaCO_3$  were respectively 2800 and 2480  $cm^2/g$  (Blaine). The experiment was carried out with 2 cm cubes with mixtures of

1.  $C_3A$  with graded amounts of  $CaCO_3$
2.  $C_3A$  with graded amounts of quartz sand and
3. 73 wt.-%  $C_3A$  and 27 wt.-%  $CaCO_3$  and graded amounts of quartz sand.

After 1 and 28 days curing, bulk density and compressive strengths were determined in wet and dry states (100°C drying). In addition to this the total porosity, average radius of the micropores and ignition loss at 600°C were also determined for dried specimens. The specimens were analysed by XRD, thermal analyses and scanning electron microscopy. The usual hydration products of  $C_3A$  form only loose structures with low binding capacity whereas due to additions of  $CaCO_3$ , the strength is increased 300 times in the wet state. Maximum strength was found to be 29 MPa for a paste with  $C_3A/CaCO_3$  ratio of 60/40. XRD and thermal analyses confirmed that the formation of mainly  $C_3A \cdot CaCO_3 \cdot H_n$  and the higher rate of hydration of  $C_3A$  in the presence of  $CaCO_3$  is the cause of increased strength.

I. ODLER (4) studied the interaction between the CSH phase formed in  $C_3S$  hydration in the presence of gypsum and the ability of bound gypsum to react

with  $C_3A$ . The maximum amount of bound gypsum was found to be 9.8 g/100 g  $C_3S$  after 1 day of hydration in a paste with 10 wt.-% calcium sulphate. This ratio of 1 mol  $SO_3$  per 6.1 moles  $C_3S$  hydrated corresponds well with the results in literature. Increase in  $C_3S$  hydration takes place upto 10 wt.-% of gypsum additions. The bound gypsum can not be detected by DTA and XRD but can easily be quantitatively extracted by lime water or can react with  $C_3A$  to form ettringite. The bond between calcium sulphate and CSH phase is weak and the author assumes that the calcium sulphate is physically adsorbed at the surface of CSH gel. -

H. Y. GHORAB, D. HEINZ, U. LUDWIG, T. MESKENDAHL and A. WOLTER (5) did new research on the stability of calcium aluminate sulphate hydrates in pure systems and in cements. - Suitable additions of calcium sulphates to cements prevent false setting by formation of an ettringite layer preferably on the surfaces of the  $C_3A$ . Investigations in pure systems with  $C_3A$ , gypsum or anhydrite and lime with and without additional  $CaCO_3$  or  $C_3S$  and with industrial plain or blended Portland cements confirm or indicate that ettringite and carboaluminate hydrate are the stable phases at room or lower temperatures. Monosulphate hydrate is the stable phase at elevated temperatures. In consequence an interim formation of instable monosulphate hydrate at normal temperatures or specially at direct, delayed or repeated, wanted or unwanted heat treatment of cement pastes mortars or concretes can cause damage by subsequent ettringite formation accompanied by expansion, cracking and decreased strength. Calcium carbonate additions can increase the damage. Portland cements with limited or without  $C_3A$  or Portland cements blended with granulated blast furnace slags or suitable puzzolanas in appropriate amounts reduce or even prevent damage. - But reduction or prevention of damage should not be regarded as the sole task. One should look ahead making use of the knowledge of the reactions of the calcium aluminate hydrates, for instance, for the chemical prestressing of concrete.

B. F. COTTIN (6) studied the kinetics of hydration of the following four different industrial clinkers.

Cement	$C_3S$	$C_2S$	$C_3A$	$C_4AF$	$C_{free}$	Alkali-sulphate	$CaSO_4$
A	67	19	8	1	4.4	0.2	0.2
B	59	16	13	7	1.0	1.8	1.5
C	62	19	2	14	1.9	0.7	0.1
D	60	20	7	10	1.1	0.5	0

The clinkers were mixed with 0, 1, 2.5 and 5 wt.-%  $SO_3$  in the forms of gypsum, hemihydrate and burned and natural anhydrite and ground to a fineness of 3000  $cm^2/g$  (Blaine). The W/C ratio during the hydration was kept at 0.5. The kinetics of hydration was followed by an isothermal calorimeter. The calorimetric curves show three exothermic peaks with changing intensity and time of occurrence due to

1. early hydration of  $C_3A$  (influenced by the presence of  $C_3S$  and sulphates)
2.  $C_3S$  hydration
3. total sulphate consumption.

The addition of calcium sulphate always lead to a decreased intensity of the first peak except clinker C with hemihydrate. But from the results it seems impossible to have a general correlation between the decrease in heat liberation and the quantity and the nature of the added sulphates. For all clinkers the optimum gypsum content lies between 2.5 to 5 wt.-% of the added  $SO_3$ . With the exception of clinker B, sulphate additions resulted in an increased and early heat liberation second peak. This peak which is mainly due to  $C_3S$  hydration occurs at early hydration time even in the plain clinker B without any sulphate additions because the clinker itself contains a lot of alkali sulphates. The third peak which is due to total  $SO_3$  consumption was generally very weak and broad. With natural anhydrite this peak was absent.

I. ODLER and R. WONNEMANN (7) studied the effect of different forms of calcium sulphate on the hydration of  $C_3A$  present in a laboratory burned clinker. The clinker contained 15 wt.-%  $C_3A$  and 5 wt.-%  $C_2(A,F)$ . The clinker was ground with 3 wt.-% of  $SO_3$  in the form of anhydrite, hemihydrate or gypsum to a fineness of 3000  $\pm$  100  $cm^2/g$  (Blaine) and hydrated with W/S = 0.5.

The ettringite formation was determined up to 30 minutes by DTA. The unreacted fraction of gypsum and hemihydrate was determined by DTA that of anhydrite by QXRD. - The results indicate, that there is no significant influence of the additions and of the form of added sulphate on the hydration kinetics of  $C_3A$ . With sulphate addition ettringite is the first hydration product of  $C_3A$  to be converted later on to monosulphate hydrate. The ettringite formation is reduced and the conversion to monosulphate hydrate is delayed with anhydrite. - The flash setting of pure clinker (<1 minute) is not a consequence of rapid  $C_3A$  hydration but a consequence of an altered morphology of the hydration products as already suggested by LOCHER, RICHARTZ and SPRUNG. With hemihydrate the measured fast setting is related to the conversion to dihydrate. The higher water requirement with anhydrite is due to the formation of a significant amount of different calcium aluminate hydrates than ettringite.

E. S. JONS and B. OSBAECK (8) investigated the influence of  $C_3A$  in cements. They prepared three clinkers each with 60 wt.-%  $C_3S$  and 22 wt.-%  $C_2S$ . The  $C_3A$  and  $C_4AF$  contents in each clinker varied respectively from 0 to 16 and 2 to 18 wt.-%. Three cements were made from each clinker by the addition of different amounts of  $SO_3$  in the form of a mixture of equal amounts of gypsum and hemihydrate. Clinkers mixed with sulphates were ground in a ball mill for 15 min. Differences in fineness reflect differences in grindability and remained without consideration. On the other hand corrections were made for strength values arising from the contribution to the measured fineness by the added sulphate. The maximum correction amounts to 6 MPa. Further correction was made for decreased bulk density with increased  $C_3A$  content of the clinker. The largest correction attributable to entrained air was 5 MPa. The strength development curves show an optimum amount of both  $C_3A$  and added  $SO_3$ . There is a positive effect of  $SO_3$  addition on the early hydration of  $C_3S$  which corresponds well with the work of other researchers with pure  $C_3S$  or alites. The strong retarding effect of excess  $SO_3$  on  $C_3A$  hydration is significant. It appears that large amounts of  $C_3A$  have a negative effect on  $C_3S$

hydration. By plotting logarithm of compressive strength vs reduced porosity by  $C_3S$  hydration, the authors conclude that  $C_3A$  gives an independent positive contribution to strength during the entire period of examination. Negative effects are the air entrainment in the mortars and the lower rate of  $C_3S$  hydration at more advanced stages of hydration.

Summarizing the submittal papers, the following conclusions can be made:

The orthorhombic and monoclinic  $C_3A$  are less reactive as compared to the cubic form. Analogous results are obtained both in pure systems and hydrated cements.

In the presence of water, the reaction between  $C_4AH_{19}$  and amorphous silica and as well as between  $C_3A$  with  $C_3S$  or  $C_2S$  showed the formation of

$C_2A \cdot CS \cdot H_{12}$ . In the reaction of  $C_3A$  with  $C_3S$  or  $C_2S$ , the formation of  $C_3A \cdot 3CS \cdot H_{32}$  was also observed. The formation of silicoaluminate hydrates has also been observed in hydrated Portland cements.

In systems containing sufficient amounts of sulphate ions, the immediate formation of a gel like ettringite layer on the surface of  $C_3A$  grains hinders false setting. The monosulphoaluminate hydrate and its solid solutions, formed subsequently, are partly unstable at room or lower temperatures. A renewed ettringite formation, without and - increased - with interim heat treatment, was also observed at later ages. Additional  $CaCO_3$  increases this reaction. The renewed ettringite formation was also observed during cement hydration and this can cause damage by expansion, decreased strength and cracking. The Portland cements with limited  $C_3A$  or blended cements are less susceptible to this damage.

The sulphate adsorbed on the surface of CSH gel from the reaction of  $C_3S$ ,  $CS$  and water can react subsequently with  $C_3A$  to form ettringite.

The form and amount of calcium sulphate added to cements will influence the early hydration but it will not change the hydration kinetics significantly.

The hydration products of  $C_3A$  will contribute to the strength formation.

# Thème 3 - Hydratation de $C_3A$ dans les ciments

## RAPPORT GENERAL

par UDO LUDWIG, Institut für Gesteinshüttenkunde, Rwth Aachen, R.F.A.

Dans ce thème, 8 contributions sont présentées et traitent de :

- 1) la réactivité de  $C_3A$  cubique, orthorhombique et monoclinique (1),
- 2) la formation de mono et trisilicoaluminate hydratés (1, 2),
- 3) l'hydratation de  $C_3A$  dans des systèmes purs avec  $C_3S$ ,  $C_2S$ ,  $C_4A$  et  $K_2S$  (1, 3, 4, 5),
- 4) l'hydratation de  $C_3A$  et  $C_2(A,F)$  dans les ciments (1, 5, 6, 7, 8).

REGOURD, HORNAIN et MORTUREUX (1) ont étudié le taux d'hydratation des formes à la fois cubique et orthorhombique de  $C_3A$  en présence de  $C_3A$  et de gypse par DRX dans une pâte normale de rapport eau/ciment égal soit à 0,35 ou à 0,5. Ils ont trouvé que dans les stades initiaux de réaction, la forme cubique est plus réactive que la forme orthorhombique. L'utilisation d'une solution de NaOH à la place d'eau distillée ne montre aucun effet sur la réactivité de  $C_3A$ . De ces observations, les auteurs ont conclu que la plus forte densité de la forme orthorhombique de  $C_3A$  est responsable de la plus faible réactivité. L'addition de 3%  $K_2SO_4$  à la pâte  $C_3A-C_3S-C_2S$  accélère l'hydratation de la forme cubique aussi bien que celle de la forme orthorhombique. Le taux d'hydratation plus faible de la forme orthorhombique et de la forme monoclinique de  $C_3A$  a aussi été observé dans l'hydratation de pâtes de clinker industriel.

J.H.P. VAN AARDT et S. VISSER (2) ont synthétisé un monosilicoaluminate hydraté (10,0 Å) analogue au monosulfoaluminate de calcium hydraté (10,3 Å) par réaction d'une silice amorphe et de chaux avec des traces de  $C_4AH_{19}$  (10,6 Å) à 5 °C. La réaction a été suivie par DRX.  $C_4AH_{19}$  a été préparé à partir de  $C_3A$  et  $Ca(OH)_2$  à 5 °C, il contenait une faible quantité de  $C_3AH_6$  et un hydrate à 8,2 Å. L'addition de silice ou de silice et de  $Ca(OH)_2$  donne les réactions suivantes :

- 1) la silice et  $Ca(OH)_2$  forment C-S-H et
- 2) la silice remplace les groupes OH dans  $C_4AH_{19}$  pour former le silicoaluminate hydraté.

En présence de teneurs croissantes en silice, le silicoaluminate hydraté est formé rapidement, spécialement quand  $Ca(OH)_2$  n'est pas ajouté en sus. L'addition de C-S-H ne produit pas l'hydrate à 10 Å.

A plus long terme de l'hydratation ou en élevant la température de 5 °C à la température ambiante, l'hydrate à 10,0 Å est transformé en  $C_2ASH_8$  (12,6 Å) et C-S-H. Dans les conditions normales, la formation d'un silicoaluminate hydraté est peu probable dans le ciment portland hydraté à cause de la présence d'un excès de  $Ca(OH)_2$ .

D'autre part, à l'aide de la micro-analyse électronique de sections polies des deux mélanges hydratés suivants :

- 76 %  $C_3S$  + 19 %  $C_3A$  + 5 % gypse et  
80 %  $C_3S$  + 20 %  $C_3A$  (en poids)

M. REGOURD, H. HORNAIN et B. MORTUREUX (1) ont trouvé deux silicoaluminates hydratés :

Après sept jours d'hydratation, la formation d'un trisilicoaluminate hydraté mal cristallisé a été observée comme un pseudomorphe du  $C_3A$  anhydre. Le monosilicoaluminate hydraté est formé à l'extérieur de la bordure du  $C_3A$  original. Le  $C_3A$  réagit plus vite que  $C_3AO$ .

J. JAMBOR (3) a étudié les propriétés liantes de  $C_3A$  en présence de  $CaCO_3$ . Les finesse de  $C_3A$  et  $CaCO_3$  étaient respectivement de 2800 et 2480  $cm^2 \cdot g^{-1}$  (Blaine). L'expérience a été effectuée sur des cubes de 2 cm avec les mélanges de :

- 1)  $C_3A$  avec des quantités de  $CaCO_3$  calibré,
- 2)  $C_3A$  avec des quantités de sable de quartz calibré et
- 3) 73 %  $C_3A$  et 27 %  $CaCO_3$  (en poids) et des quantités de sable de quartz calibré.

Après 1 et 28 jours de traitement, la densité volumique et les résistances à la compression ont été déterminées à l'état humide et sec (séchage à 100 °C). En addition à ceci, la porosité totale, le rayon moyen des micropores et la perte au feu à 600 °C ont été aussi déterminés sur les échantillons séchés. Les échantillons ont été analysés par DRX analyses thermiques et microscopie électronique à balayage. Les produits d'hydratation habituels de  $C_3A$  forment seulement des structures lâches avec une faible aptitude liante tandis que grâce aux additions de  $CaCO_3$ , la résistance est accrue 300 fois à l'état humide. Le maximum de résistance trouvé a été de 29 MPa pour une pâte avec un rapport  $C_3A/CaCO_3$  de 60/40. La DRX et les analyses thermiques confirment que la formation de  $C_3A \cdot CaCO_3 \cdot H_n$  principalement et le taux d'hydratation plus élevé de  $C_3A$  en présence de  $CaCO_3$  est la cause de l'accroissement de la résistance.

I. ODLER (4) a étudié l'interaction entre la phase C-S-H formée dans l'hydratation de  $C_3S$  en présence du gypse et l'aptitude du gypse lié à réagir avec  $C_3A$ . La teneur maximale de gypse lié a été trouvée égale à 9,8 g/100 g de  $C_3A$  après un jour d'hydratation dans une pâte avec 10 % de sulfate de calcium. Ce rapport de 1 mol  $SO_3$  pour 6,1 moles de  $C_3S$  hydraté correspond bien aux résultats déjà publiés.

Le taux d'hydratation de  $C_3S$  croît jusqu'à une addition de 10 % de gypse (en poids). Le gypse lié ne peut être détecté ni par ATD ni par DRX mais peut être facilement extrait quantitativement par une eau de chaux, ou peut réagir avec  $C_3A$  pour former de l'ettringite. La liaison entre le sulfate de calcium et la phase C-S-H est faible et l'Auteur assume que le sulfate de calcium est adsorbé physiquement à la surface du gel de C-S-H.

M. Y. GHORAB, D. HEINZ, U. LUDWIG, T. MESKENDAH et A. WOLTER (5) ont fait une nouvelle recherche sur la stabilité des sulfoaluminates hydratés dans des systèmes purs et dans les ciments. Des additions appropriées de sulfates de calcium aux ciments empêchent la fausse prise par formation d'une couche d'ettringite, de préférence sur les surfaces de  $C_3A$ . Les études de systèmes purs avec  $C_3A$ , gypse ou anhydrite, et chaux, avec ou sans  $CaCO_3$  ou  $C_3S$ , et avec des ciments portland avec ajouts, confirment ou indiquent que l'ettringite et le carboaluminate hydraté sont les phases stables à la température ambiante. Le monosulfate hydraté est la phase stable aux températures élevées. Par conséquent, une formation provisoire de monosulfate hydraté, instable à la température normale ou spécialement au cours d'un traitement thermique (direct, retardé ou répété, désiré ou indésiré) de pâtes de ciments, mortiers ou bétons, peut entraîner des dommages par formation ultérieure d'ettringite accompagnée d'expansion, de fissuration et de chute de résistance. Des additions de carbonate de calcium peuvent accroître la détérioration. Les ciments portland à teneur limitée en  $C_3A$  ou sans  $C_3A$  ou les ciments portland au laitier de haut fourneau granulé ou aux pouzzolanes appropriées en quantités convenables, réduisent ou même empêchent la dégradation. Mais la réduction, ou l'empêchement du dommage, ne devrait pas être considéré comme la seule tâche. On devrait aller plus loin en utilisant la connaissance des réactions des aluminates de calcium hydratés, par exemple, pour la précontrainte chimique du béton.

B. COTTIN (6) a étudié la cinétique de l'hydratation des quatre clinkers industriels suivants :

Ciment	$C_3S$	$C_2S$	$C_3A$	$C_4AF$	$C_{libre}$	Sulfate alcalin	$CaSO_4$
A	67	19	8	1	4,4	0,2	0,2
B	59	16	13	7	1,0	1,8	1,5
C	62	19	2	14	1,9	0,7	0,1
D	60	20	7	10	1,1	0,5	0

Les clinkers ont été mélangés avec 0,1, 2,5 et 5 % (en poids) de  $SO_3$  sous les formes gypse, hémihydrate, anhydrite naturelle et surcuite, broyées à une finesse de  $3000 \text{ cm}^2 \cdot \text{g}^{-1}$  (Blaine). Le rapport e/c a été gardé égal à 0,5 pendant l'hydratation. La cinétique d'hydratation a été suivie par calorimétrie isotherme. Les courbes calorimétriques montrent trois pics exothermiques d'intensité variable et dont le temps d'apparition est dû à

- 1) l'hydratation initiale de  $C_3A$  (influencée par la présence de  $C_3S$  et des sulfates),
- 2) l'hydratation de  $C_3S$ ,
- 3) la consommation totale du sulfate.

L'addition du sulfate de calcium entraîne toujours une décroissance de l'intensité du premier pic, excepté dans le clinker C avec l'hémihydrate. Mais

à partir des résultats, il semble impossible d'avoir une corrélation générale entre la décroissance de la chaleur dégagée et la quantité et la nature des sulfates ajoutés. Pour tous les clinkers, la quantité optimale de gypse se place entre 2,5 et 5 % en poids de  $SO_3$  ajouté. A l'exception du clinker B, les additions de sulfate entraînent l'accroissement d'intensité et l'apparition plus précoce du second pic de dégagement de chaleur. Ce pic qui est dû principalement à l'hydratation de  $C_3A$  se produit plus tôt, même dans le clinker B sans aucune addition de sulfate, parce que le clinker lui-même contient beaucoup de sulfates alcalins. Le troisième pic qui est dû à la consommation totale de  $SO_3$ , est généralement très faible et large. Dans le cas de l'anhydrite naturelle, ce pic est absent.

I. ODLER et R. WONNEMANN (7) ont étudié l'effet de différentes formes de sulfate de calcium sur l'hydratation de  $C_3A$  présent dans un clinker préparé en laboratoire. Le clinker contenait 15 % de  $C_3A$  et 5 % de  $C_2(A,F)$  (en poids). Le clinker a été broyé avec 3 % de  $SO_3$  (en poids) sous la forme d'anhydrite, d'hémihydrate et de gypse à une finesse de  $3000 \pm 100 \text{ cm}^2 \cdot \text{g}^{-1}$  (Blaine) et hydraté avec un rapport e/c = 0,5. La formation d'ettringite a été déterminée, par ATD, jusqu'à 30 minutes. La fraction de gypse et d'hémihydrate qui n'a pas réagi a été déterminée par ATD et celle d'anhydrite par diffraction des rayons X. Les résultats indiquent qu'il n'y a pas d'influence significative de l'addition et de la forme du sulfate ajouté sur la cinétique d'hydratation de  $C_3A$ . Par addition de sulfate, l'ettringite est le premier produit hydraté de  $C_3A$ , qui se convertit plus tard en monosulfate hydraté. La formation d'ettringite est réduite et la conversion en monosulfate hydraté est retardée avec l'anhydrite. La fausse prise du clinker pur (inférieure à 1 minute) n'est pas une conséquence de l'hydratation rapide de  $C_3A$  mais une conséquence de l'altération de la morphologie des produits hydratés comme l'ont déjà suggéré LOCHER, RICHARTZ et SPRUNG. Avec l'hémihydrate, la prise rapide est reliée à la conversion en dihydrate. La demande en eau plus élevée avec l'anhydrite est due à la formation d'une quantité significative de différents aluminates de calcium hydratés plutôt que d'ettringite.

E.S. JØNS et B. OSBAECK (8) ont étudié l'influence de  $C_3A$  dans les ciments. Ils ont préparé trois clinkers l'un avec 60 %  $C_3S$  et 22 %  $C_2S$  (en poids). Les teneurs en  $C_3A$  et  $C_4AF$  de chaque clinker variaient respectivement de 0 à 16 et de 2 à 18 % (en poids). Trois ciments ont été préparés à partir de chaque clinker par addition de différentes quantités de  $SO_3$  sous la forme d'un mélange en quantité égale de gypse et d'hémihydrate. Les clinkers mélangés avec les sulfates ont été broyés dans un broyeur à boulets pendant 15 minutes. Les différences de finesse reflètent les différences de broyabilité mais peuvent ne pas être prises en considération. D'autre part, les valeurs de résistance ont été corrigées en tenant compte de la contribution de la finesse mesurée et de l'addition de sulfate. La valeur maximale de la correction était de 6 MPa. Une correction supplémentaire a été faite tenant compte de la décroissance de la densité volumique en fonction de la croissance de la teneur en  $C_3A$  du clinker. La correction la plus élevée, attribuée à l'air entraîné, était de 5 MPa. Les courbes de variation de résistance mettent en évidence une teneur optimale de  $C_3A$  et de  $SO_3$  ajouté. Il y a un effet positif de l'addition de  $SO_3$  sur l'hydratation initiale de  $C_3S$  qui correspond bien aux résultats d'étude d'autres chercheurs sur le  $C_3S$  pur et les alites. L'effet retardateur important d'un

excès de  $\text{SO}_3$  sur l'hydratation de  $\text{C}_3\text{A}$  est significatif. Il apparaît que des quantités importantes de  $\text{C}_3\text{A}$  ont un effet négatif sur l'hydratation de  $\text{C}_3\text{S}$ . En traçant la courbe du logarithme de la résistance à la compression en fonction de la réduction de la porosité par l'hydratation de  $\text{C}_3\text{S}$ , les Auteurs concluent que  $\text{C}_3\text{A}$  apporte une contribution positive et indépendante, à la résistance, pendant la totalité de la durée de l'étude. Les effets négatifs sont l'entraînement d'air dans les mortiers et le taux plus faible de l'hydratation de  $\text{C}_3\text{S}$  à des stades plus avancés de l'hydratation.

Résumant les contributions ci-dessus, les conclusions suivantes peuvent être tirées :

- Les  $\text{C}_3\text{A}$  orthorhombiques et monocliniques sont moins réactifs comparés à la forme cubique. Des résultats analogues ont été trouvés à la fois dans des systèmes purs et dans des ciments hydratés.

- En présence d'eau, la réaction, entre  $\text{C}_4\text{AH}_{19}$  et la silice amorphe et aussi bien entre  $\text{C}_3\text{A}$  et  $\text{C}_3\text{S}$  ou  $\text{C}_2\text{S}$ , entraîne la formation de  $\text{C}_3\text{A.CSH}_{12}$ . Dans la réaction de  $\text{C}_3\text{A}$  avec  $\text{C}_3\text{S}$  ou  $\text{C}_2\text{S}$ , la formation de  $\text{C}_3\text{A.3CS.H}_{32}$  a aussi été observée. La formation des silicoaluminates hydratés a aussi été trouvée dans les ciments portland hydratés.

- Dans les systèmes contenant des teneurs suffisantes en ions sulfate, la formation immédiate à la surface des grains de  $\text{C}_3\text{A}$  d'un gel, tel qu'une couche d'ettringite, empêche la fausse prise. Le monosulfate hydraté et ses solutions solides, formés ensuite, sont partiellement instables à la température ambiante ou aux plus basses températures. Une formation nouvelle d'ettringite sans, et (accrue) avec un traitement thermique transitoire, a aussi été observée à plus long terme. L'addition de  $\text{CaCO}_3$  favorise cette réaction. La formation nouvelle a aussi été observée au cours de l'hydratation du ciment et elle entraîne des détériorations, par expansion, chute de résistance et fissuration. Les ciments portland à teneur limitée en  $\text{C}_3\text{A}$  ou les ciments avec ajouts sont moins sensibles à cette dégradation.

- Le sulfate adsorbé à la surface du gel de C-S-H au cours de la réaction entre  $\text{C}_3\text{S}$ ,  $\text{CS}$  et l'eau peut réagir ensuite avec  $\text{C}_3\text{A}$  pour former l'ettringite.

- La forme et la quantité du sulfate de calcium ajouté au ciment influencent l'hydratation initiale mais ne changent pas la cinétique d'hydratation d'une manière significative.

- Les produits d'hydratation de  $\text{C}_3\text{A}$  contribuent au développement de la résistance.

# Hydratation de $C_3A$ dans des mélanges synthétiques et dans des ciments portland industriels

## *Hydration of $C_3A$ in synthetic mixtures and in industrial portland cements*

M. REGOURD, H. HORNAIN, B. MORTUREUX, Département Microstructures C.E.R.I.L.H. - Paris, France

### Résumé

L'hydratation de  $C_3A$  et de ses solutions solides avec  $Na_2O$  a été suivie par diffraction des rayons X, microscopie électronique à balayage et microsonde électronique. Ces différentes méthodes ont toutes révélé une réactivité décroissante de la forme cubique à la forme monoclinique aux brèves échéances. L'interaction  $C_3A-C_3S$  au cours de l'hydratation de mélanges  $C_3A + C_3S +$  gypse a été mise en évidence par la formation de silicoaluminates autour des grains de  $C_3A$  et par le taux d'hydratation plus élevé de  $C_3S$  dans les mélanges  $C_3S + C_3A$  cubique. Cette interaction a été retrouvée dans les ciments portlands industriels et le silicoaluminate a été observé également dans des mélanges  $C_2S + C_3A$ .

### Summary

The hydration of  $C_3A$  and its solid solutions with  $Na_2O$  has been followed by X-ray diffraction, scanning electron microscopy and electron probe microanalysis. These various methods have all shown a decreasing early reactivity from the cubic form to the monoclinic form. The  $C_3A-C_3S$  interaction during hydration of  $C_3A + C_3S +$  gypsum mixtures has been put in evidence by the formation of silicoaluminates around the  $C_3A$  grains and by the higher degree of hydration in the  $C_3S +$  cubic  $C_3A$  mixtures. This interaction has been found again in industrial portland cements and the silicoaluminate has also been observed in  $C_2S + C_3A$  mixtures.

## 1. INTRODUCTION

$\text{Ca}_3\text{Al}_2\text{O}_6$ , cubique à l'état pur (1), forme des solutions solides notamment avec les alcalins Na et K qui peuvent entraîner des changements de symétrie, cubique + orthorhombique + monoclinique (2, 3). Dans les ciments portlands,  $\text{C}_3\text{A}$  est cubique ou orthorhombique. La forme monoclinique est rarement observée (4).

Les solutions solides synthétiques  $\text{C}_3\text{A} + \text{Na}_2\text{O}$  ont une réactivité hydraulique inférieure à celle de l'aluminate cubique (5, 6). Il existe, en outre, une interaction  $\text{C}_3\text{A}-\text{C}_3\text{S}$  : le taux d'hydratation de  $\text{C}_3\text{S}$  dépend de la réactivité de  $\text{C}_3\text{A}$  d'une part, il se forme autour des grains de  $\text{C}_3\text{A}$  des silicoaluminates de calcium d'autre part (7, 8).

Dans cette communication, nous précisons la réactivité de  $\text{C}_3\text{A}$  en relation avec sa teneur en alcalins. Nous étudierons ensuite la formation de silicoaluminates dans des mélanges  $\text{C}_3\text{A} + \text{C}_3\text{S}$  et  $\text{C}_3\text{A} + \text{C}_2\text{S}$ .

## 2. REACTIVITE DE $\text{C}_3\text{A}$

Les échantillons étudiés sont des mélanges synthétiques et des ciments portlands. Les produits synthétisés en laboratoire ont une granulométrie comprise soit entre 25 et 40  $\mu\text{m}$  soit entre 40 et 63  $\mu\text{m}$ . Le  $\text{C}_3\text{S}$  est triclinique, le  $\text{C}_3\text{A}$  cubique est pur et le  $\text{C}_3\text{A}$  orthorhombique contient 4,8 %  $\text{Na}_2\text{O}$ . Les poudres sont convenablement homogénéisées et gâchées sous forme de minicylindres de 1 cm de hauteur et 1  $\text{cm}^2$  de section. Différents rapports eau/solide sont utilisés ( $e/c = 0,35, 0,40$  et  $0,50$ ). La conservation des éprouvettes a lieu dans l'eau à 20 °C. A chaque échéance choisie, 3 minicylindres sont prélevés et broyés. L'hydratation est arrêtée par lavage à l'acétone-éther et l'eau interstitielle évaporée par cryosublimation. Le taux d'hydratation est mesuré par diffraction des rayons X.

Deux séries de mélanges synthétiques sont étudiées : 80 %  $\text{C}_3\text{S}$  + 20 %  $\text{C}_3\text{A}$  et 76 %  $\text{C}_3\text{S}$  + 19 %  $\text{C}_3\text{A}$  + 5 % gypse. Afin de définir le rôle exact de  $\text{Na}_2\text{O}$  (dans le réseau cristallin ou dans la solution aqueuse) le taux d'hydratation de  $\text{C}_3\text{A}$  a été comparé d'une part dans deux mélanges 76 %  $\text{C}_3\text{S}$  + 19 %  $\text{C}_3\text{A}$  + 5 % gypse contenant l'un  $\text{C}_3\text{A}$  cubique pur, l'autre  $\text{C}_3\text{A}$  orthorhombique, d'autre part dans une pâte du mélange contenant  $\text{C}_3\text{A}$  cubique, gâchée avec une solution de soude contenant l'équivalent des 4,8 %  $\text{Na}_2\text{O}$  de la solution solide orthorhombique, soit 0,55 M NaOH par litre. Les résultats sont groupés dans le Tableau I.

Temps d'hydratation	$\text{C}_3\text{A}$ eau distillée	$\text{C}_3\text{A}$ sol. NaOH	$\text{C}_3\text{A}_0$ eau distillée
7 jours	0,45	0,47	0,22
14 jours	0,63	n.d.	0,63

Tableau I - Comparaison des taux d'hydratation  $\alpha$  de  $\text{C}_3\text{A}$  gâché avec une solution de soude (4,8 % eq.  $\text{Na}_2\text{O}$ ) et de  $\text{C}_3\text{A}$  et  $\text{C}_3\text{A}_0$  gâchés avec de l'eau distillée (mélanges 76 %  $\text{C}_3\text{S}$  + 19 %  $\text{C}_3\text{A}$  + 5 % gypse).  $e/c = 0,35$  ; granulométrie 40-63  $\mu\text{m}$ .

Le tableau I indique qu'à 7 jours,  $\text{C}_3\text{A}$  est plus hydraté que  $\text{C}_3\text{A}_0$ . Les taux d'hydratation pratiquement égaux de  $\text{C}_3\text{A}$  gâché à l'eau distillée et de  $\text{C}_3\text{A}$  gâché avec la solution de soude montrent que les différences de réactivité entre  $\text{C}_3\text{A}$  et  $\text{C}_3\text{A}_0$  sont, à cette échéance,

dues à la présence de  $\text{Na}_2\text{O}$  dans un réseau cristallin plus compact que celui de l'aluminate pur. Une deuxième série d'essais effectuée sur des pâtes  $\text{C}_3\text{S} + \text{C}_3\text{A}$  + gypse, de granulométrie 25-40  $\mu\text{m}$  et gâchée à l'eau distillée confirme la plus grande réactivité de  $\text{C}_3\text{A}$  cubique dès les premières échéances (fig. 1).

Fig. 1 : Taux d'hydratation de  $\text{C}_3\text{A}$  dans un mélange synthétique  $\text{C}_3\text{A} + \text{C}_3\text{S}$  + gypse.  $\text{C}_3\text{A}$  cubique s'hydrate plus vite que  $\text{C}_3\text{A}_0$  (4,8 %  $\text{Na}_2\text{O}$ ).

Il existe par ailleurs une corrélation très nette entre le taux d'hydratation de  $\text{C}_3\text{A}$  et celui de  $\text{C}_3\text{S}$  : à une hydratation plus rapide de  $\text{C}_3\text{A}$  correspond une réactivité plus grande de  $\text{C}_3\text{S}$ , (Tableau II).

Taux d'hydratation $\alpha$	$\text{C}_3\text{S} + \text{C}_3\text{A} + \text{G}$	$\text{C}_3\text{S} + \text{C}_3\text{A}_0 + \text{G}$
$\text{C}_3\text{A}$	0,63	0,34
$\text{C}_3\text{S}$	0,58	0,47

Tableau II - Corrélation entre le taux d'hydratation  $\alpha$  de  $\text{C}_3\text{A}$  et celui de  $\text{C}_3\text{S}$  ; 28 jours ;  $e/c = 0,40$ .

Afin de nous rapprocher de la composition de ciments portlands dans lesquels le potassium se partage entre  $\text{C}_3\text{A}$ ,  $\text{C}_2\text{S}$  et  $\text{K}_2\text{SO}_4$ , nous avons ajouté 3 % de  $\text{K}_2\text{SO}_4$  aux mélanges  $\text{C}_3\text{A} + \text{C}_3\text{S}$  + gypse. Dans ce cas,  $\text{C}_3\text{A}_0$  s'hydrate aussi rapidement que  $\text{C}_3\text{A}$  dans les pâtes sans  $\text{K}_2\text{SO}_4$ . La différence de réactivité entre  $\text{C}_3\text{A}$  et  $\text{C}_3\text{A}_0$  subsiste cependant si les aluminates sont tous deux hydratés en présence de  $\text{K}_2\text{SO}_4$  (fig. 2). Le Tableau III montre que  $\text{K}_2\text{SO}_4$  est aussi accélérateur de  $\text{C}_3\text{S}$ .

Fig. 2 : Influence de  $K_2SO_4$  sur le taux d'hydratation de  $C_3A$  dans un mélange  $C_3A + C_3S +$  gypse.

Taux d'hydratation $\alpha$	$C_3AC$	$C_3AC + K_2SO_4$	$C_3A_0 + K_2SO_4$
$C_3A$	0,25	0,46	0,26
$C_3S$	0,20	0,30	0,30

Tableau III - Taux d'hydratation  $\alpha$  de  $C_3A$  et  $C_3S$  dans les mélanges  $C_3S + C_3A +$  gypse ( $e/c = 0,40$ ) à 8 heures.

Les différences de réactivité des solutions solides de  $C_3A$  et l'interaction  $C_3A-C_3S$  ont été également observées dans des ciments industriels. Ainsi dans 3 ciments contenant respectivement 7 % de  $C_3A$  cubique, 13 % d'un mélange  $C_3A$  cubique + orthorhombique, et 16 % de  $C_3A$  orthorhombique, les taux de réaction de  $C_3A$ , après 7 jours, sont de 0,65 pour  $C_3AC$ , 0,42 pour le mélange  $C_3AC + C_3A_0$  et 0,35 pour  $C_3A_0$ .

Des essais ont aussi été effectués sur deux clinkers industriels A et B de compositions voisines (Tableau IV) mais renfermant l'un 12 % de  $C_3A$  orthorhombique, l'autre 12 % de  $C_3A$  monoclinique. Les taux d'hydratation mesurés par DRX sont rassemblés dans le Tableau V, qui montre que, d'une part  $C_3A$  monoclinique s'hydrate plus lentement que  $C_3A$  orthorhombique, d'autre part le taux de réaction de  $C_3S$  aux courtes échéances est plus élevé dans le cas du ciment A contenant  $C_3A_0$  que dans le cas du ciment B contenant  $C_3A_M$ .

Clinker	$C_3S$	$C_2S$	$C_3A$	$C_4AF$	CaO libre
A	61	20 < 15 $\beta$ 5 $\alpha$	12 O	5	1,5
B	60	24 < 15 $\beta$ 9 $\alpha$	12 M	3	0,7

Tableau IV - Composition minéralogique déterminée par DRX des deux clinkers industriels A et B testés.

$\alpha$	Echéances	A ( $C_3A_0$ )	B ( $C_3A_M$ )
$C_3S$	8 heures	0,50	0,42
	24 "	0,64	0,55
	48 "	0,70	0,70
$C_3A$	7 jours	0,66	0,55

Tableau V - Taux d'hydratation de  $C_3S$  et de  $C_3A$  dans les deux clinkers industriels A et B ;  $e/c = 0,50$  ; granulométrie 40-63  $\mu m$ .

### 3. FORMATION DE SILICOALUMINATES DANS LES MELANGES $C_3S-C_3A$ ET $C_2S-C_3A$

L'interaction  $C_3A-C_3S$  se manifeste également par la formation de silicoaluminates, trisilicoaluminate  $C_3A \cdot 3CaSiO_3 \cdot 31H_2O$  ( $C_4AS_3H_{31}$ ) et monosilicoaluminate  $C_3A \cdot CaSiO_3 \cdot 12H_2O$  ( $C_4ASH_{12}$ ) qui ont été mis en évidence dans des mélanges synthétiques  $C_3S + C_3A$  et  $C_2S + C_3A$ .

Ces deux hydrates, déjà signalés par FLINT et WELLS (8), peuvent être considérés comme faisant partie de deux séries de composés de formules générales (9) :

avec  $X = CO_3, SO_4, S_2O_3 \dots$ ,  $Y = OH, Cl, SiO_3 \dots$  et  $m = 30 \text{ à } 32$ ,  $n = 10 \text{ à } 12$ .

Avec l'anion  $SO_4^{2-}$  on obtient les deux sulfoaluminates bien connus : trisulfoaluminate  $C_3A \cdot 3CaSO_4 \cdot 31H_2O$  (ettringite) et monosulfoaluminate  $C_3A \cdot CaSO_4 \cdot 12H_2O$ . De même l'aluminate hexagonal  $C_4AH_{13}$  peut être assimilé au composé  $C_3A \cdot Ca(OH)_2 \cdot 12H_2O$ . FLINT et WELLS ont mis en évidence les deux silicoaluminates dans des solutions où ils ont fait varier le rapport molaire  $CaO/Al_2O_3$  entre 1 et 4. Dans ces solutions se forment d'abord des plaquettes hexagonales correspondant au monosilicoaluminate  $C_3A \cdot CaSiO_3 \cdot 12H_2O$  homologue du monosulfoaluminate  $C_3A \cdot CaSO_4 \cdot 12H_2O$ . Le monosilicoaluminate se transforme ensuite lentement en trisilicoaluminate  $C_3A \cdot 3CaSiO_3 \cdot 31H_2O$  sous forme de fines aiguilles de structure identique au trisulfoaluminate  $C_3A \cdot 3CaSO_4 \cdot 31H_2O$ . FLINT et WELLS ont également obtenu le trisilicoaluminate dans des mélanges  $C_2S\beta + C_4AF, C_2S\beta + C_3A, C_3S + C_4AF$ , en suspension dans des solutions saturées de  $CaO$ . Ils n'ont pas observé de silicoaluminate dans les suspensions de  $C_3S + C_3A$ . Plus récemment, MITUZAS, KAMINSKAS et MITUZAS (10) ont déduit à partir d'analyses chimiques que le composé  $C_3A \cdot 3CaSiO_3 \cdot aq$  devait exister dans les ciments portlands hydratés. Dans ce sens, nous avons observé les mêmes éprouvettes que celles mentionnées au paragraphe précédent et nous avons étudié également des pâtes  $C_2S + C_3A$  traitées dans les mêmes conditions.

#### 3.1 Mélanges 76% $C_3S$ + 19 % $C_3A$ + 5 % gypse

Les examens de sections polies à l'aide de la microsonde de Castaing indiquent que les échantillons évoluent de la façon suivante :

- à deux jours les grains de  $C_3A$  sont entourés de cristaux d'ettringite contenant une petite quantité de  $SiO_2$ ,
- à partir de 7 jours, il se forme par pseudomorphose progressive des grains de  $C_3A$  une double couche de silicoaluminates : trisilicoaluminate en contact avec  $C_3A$  anhydre, monosilicoaluminate dans la partie externe du grain transformé. A l'extérieur du grain, en

contact avec le silicoaluminate on observe d'abord de l'ettringite qui est remplacée peu à peu par un mélange monosulfoaluminate  $C_4AH_{13}$  (fig. 3). Les rapports molaires mesurés à l'aide de la microsonde électronique, à différentes échéances, sont rassemblés dans le Tableau VI - après 10 mois, seul le monosilicoaluminate est observé. Sa composition semble évoluer ; la concentration en  $SiO_2$  diminue lorsqu'on passe de l'extérieur vers l'intérieur du grain. En outre dès 3 mois, une couronne de monosulfoaluminate est susceptible de se former autour du centre encore anhydre de  $C_3A$  par diffusion d'ions  $SO_4$  à travers la couche de silicoaluminate (fig. 4). D'une façon générale on constate que la formation des silicoaluminates est plus rapide avec  $C_3A$  cubique que  $C_3A$  orthorhombique. A 28 jours, la couche de silicoaluminates est plus importante autour des grains de  $C_3A$ . A cette échéance les deux silicoaluminates y sont déjà détectés alors que pour  $C_3A_0$ , seul le trisilicoaluminate est observé.

En contact avec les grains de  $C_3S$ , existe une couche pseudomorphique de silicates de calcium hydratés

Phase	Echéances*	C/S	C/A	S/A	C (S + A)
Trisilicoaluminate (zone interne)	28 j	2,1	5,6	2,7	1,5
	3 m	1,7	4,4	2,5	1,2
	6 m	2,4	6,2	2,6	1,7
Monosilicoaluminate (zone externe)	28 j	4,0	3,6	0,9	1,9
	3 m	3,7	3,3	0,9	1,7
	6 m	5,2	3,8	0,7	2,2
Monosilicoaluminate centre bord	10 m	6,3	3,2	0,5	2,1
	10 m	4,4	3,3	0,8	1,9

\* j : jour ; m : mois.

Tableau VI - Rapports molaires mesurés dans les silicoaluminates des mélanges 76 %  $C_3S$  + 19 %  $C_3A$  + 5 % gypse ;  $e/c = 0,35$  ; granulométrie 40-63  $\mu m$ . (résultats à  $\pm 0,2$  près).

Fig. 3 : Section polie d'un mélange  $C_3A$  +  $C_3S$  + gypse. 1  $C_3A$  ; 2 Trisilicoaluminate ; 3 Monosilicoaluminate ; 4 Monosulfoaluminate.

Fig. 4 : Section polie d'un mélange  $C_3A_0$  +  $C_3S$  + gypse. 1  $C_3A$  ; 2 Monosulfoaluminate ; 3, 4 Silicoaluminate ; 5 Monosulfoaluminate.

C-S-H dont la composition est différente suivant que le grain de  $C_3S$  se trouve à proximité ou loin d'un grain de  $C_3A$  : près des grains de  $C_3A$  les C-S-H sont plus pauvres en  $SiO_2$  et plus riches en chaux ; le rapport molaire  $CaO/SiO_2$  déterminé par microsonde électronique est de 1,4-1,5. Loin de  $C_3A$  la teneur en  $SiO_2$  augmente et celle de la chaux diminue ; le rapport molaire est de l'ordre de 0,8 à 1,0. La quantité d' $Al_2O_3$  dans les C-S-H est d'environ 2 à 3 %.

### 3.2 Mélange 80 % $C_3S$ + 20 % $C_3A$ cubique

Dans ce mélange la formation des deux silicoaluminates est plus rapide qu'en présence de gypse. A 34 jours la zone de silicoaluminate en contact avec  $C_3A$  est très large. A l'extérieur du grain cristallise l'aluminate hexagonal  $C_4AH_{13}$ . Par diffraction des

rayons X il a été possible de mettre en évidence le monosilicoaluminate qui donne un diagramme identique à celui du monosulfoaluminate (fig. 5). Par contre il n'a pas été observé de pics pouvant être attribués au trisilicoaluminate dont le spectre X serait analogue à celui du trisulfoaluminate. Les examens par microsonde électronique à balayage montrent que, d'une façon générale, les deux silicoaluminates observés dans toutes les pâtes  $C_3S$  +  $C_3A$  gypsées ou non, ont une apparence amorphe ou faiblement cristallisée. (fig. 6 et fig. 7).

### 3.3 Mélanges 67 % $C_3S$ + 16,5 % $C_3A$ + 16,5 % gypse.

En présence d'une forte proportion de gypse, les silicoaluminates ne se forment pas. Seuls l'ettringite et  $C_4AH_{13}$  sont observés en contact des grains de  $C_3A$ .

Phase	Echéances	C/S	C/A	S/A
Trisilico-aluminate	7 jours	2	5	2,4
Trisilico-aluminate	28 jours	2,1	6,1	3,0

Tableau VII - Rapports molaires mesurés dans les silicoaluminates des mélanges 76 % C<sub>2</sub>S + 19 % C<sub>3</sub>A + 5 % gypse ; e/c = 0,35 (erreur moyenne absolue  $\pm 0,2$ ).

Bien que rapide, la formation du silicoaluminate se limite donc au seul trisilicoaluminate (C/S = 2), jusqu'à 28 jours. Elle est peut-être en relation avec la valeur plus faible du rapport C/S du silicate bicalcique comparée à celle du silicate tricalcique qui, à la même échéance, donne déjà du monosilicoaluminate (C/S = 4). Elle implique également une interaction importante entre C<sub>2</sub>S et C<sub>3</sub>A liée à une diffusion de la silice à travers la solution.

Fig. 5 : Diffractogramme de rayons X pas à pas d'un échantillon contenant C<sub>3</sub>ASH<sub>12</sub>.

Fig. 6 : a) Trisilicoaluminate (1) au contact de C<sub>3</sub>A anhydre (2).  
b) Aspect amorphe du trisilicoaluminate.

Fig. 7 : Monosilicoaluminate

Par ailleurs les silicoaluminates C<sub>4</sub>ASH<sub>13</sub> et C<sub>4</sub>ASH<sub>12</sub> ne sont pas stables dans les solutions fortement chargées en sulfates telles que l'eau de mer. Il se forme de l'ettringite.

### 3.4 Mélanges 76 % C<sub>2</sub>S + 19 % C<sub>3</sub>A + 5 % gypse

Dans ces mélanges, les silicoaluminates apparaissent plus rapidement. Après 7 jours, il s'est déjà formé une couche relativement épaisse de silicoaluminate de composition proche du trisilicoaluminate, associé à C<sub>4</sub>AH<sub>13</sub> et au monosulfoaluminate. Après 28 jours, contrairement à ce qui avait été observé dans les mélanges avec C<sub>3</sub>S, seul le trisilicoaluminate est présent. Le monosilicoaluminate n'est pas observé (fig.8). Les résultats de l'analyse des silicoaluminates obtenue à l'aide de la microsonde de Castaing exprimés en rapport molaires sont groupés dans le Tableau VII.

Fig. 8 : Formation de trisilicoaluminate (1) au contact de C<sub>3</sub>A (2) dans un mélange de 76 % C<sub>2</sub>S + 19 % C<sub>3</sub>A + 5 % gypse, hydraté 7 jours. Monosulfoaluminate (3) à l'extérieur du grain.

## DISCUSSION

La réactivité de l'aluminate tricalcique dans les mélanges  $C_3A + C_3S +$  gypse est en relation avec sa structure cristalline due à la présence d'alcalins en solution solide. Les mêmes résultats ont été obtenus, dès les premières échéances (10 minutes), par BOIKOVA, DOMANSKY, STAVITSKAYA ET NIKUSHCHENKO (6) qui ont étudié quatre solutions solides contenant 2,4, 3,8, 4,8 et 5,7 %  $Na_2O$  et dont ils ont comparé la réactivité à celle du  $C_3A$  pur. D'après SPIERINGS et STEIN (11), la réactivité de  $Na_{2x}.Ca_{3-x}.Al_2O_3$  ne diffère pas d'une manière significative de celle de  $C_3A$  pur car un mélange, à part égale, de solutions solides avec  $x = 0,5$  et  $x = 0,25$  donne les mêmes résultats que l'échantillon avec  $x = 0,15$ , prouvant ainsi que seule la concentration de  $NaOH$  dans la phase liquide est le facteur déterminant du taux d'hydratation de l'aluminate. Dans le même sens, MASSAZZA et COSTA (12) n'ont mis en évidence aucune influence de la forme cristalline sur les enthalpies de formation des solutions solides  $3(CaO,Na_2O).Al_2O_3$ . Ces résultats, en apparence contradictoires, sur l'influence du sodium dans le réseau cristallin ou dans la phase aqueuse, demandent à être discutés au cours de ce séminaire.

L'interaction  $C_3A-C_3S$  est clairement mise en évidence au cours des réactions d'hydratation. Elle est surtout sensible à court terme. Elle se manifeste également par la formation de silicoaluminates. Toutefois la morphologie de ces composés ne correspond pas à celle décrite par FLINT et WELLS (8) : plaquettes hexagonales isomorphes du monosulfoaluminate pour le monosilicoaluminate et cristaux aciculaires isomorphes de l'ettringite pour le trisilicoaluminate. Nos observations au microscope électronique à balayage ont montré que les silicoaluminates apparaissent peu ou pas cristallisés. Seules les analyses par diffraction des rayons X ont indiqué la présence de monosilicoaluminate cristallisé. La formation de ces silicoaluminates est due à une diffusion importante d'ions silicates hydratés à partir des grains de  $C_3S$  vers les grains de  $C_3A$ . La diffusion inverse des ions aluminates de  $C_3A$  vers  $C_3S$  est beaucoup plus limitée. Néanmoins, les C-S-H peuvent contenir 2 à 3 % de  $Al_2O_3$ . Au stade initial de la réaction, dans les pâtes gypsées, c'est l'ettringite qui se forme en premier mais la présence de silice dans cette ettringite prouve que la diffusion de  $SiO_2$  est déjà amorcée. Cette diffusion devient ensuite prépondérante et on observe le trisilicoaluminate au contact des grains de  $C_3A$ . Par suite de l'accroissement de la couche de C-S-H entourant les grains de  $C_3S$  et de la diminution du silicate anhydre, la diffusion de la silice est fortement ralentie. Le trisilicoaluminate se transforme progressivement en monosilicoaluminate. La diffusion des ions  $SO_4^{2-}$  à travers la couche de silicoaluminate vers le grain anhydre de  $C_3A$  redevient prépondérante et il se forme au contact de  $C_3A$  une couronne de monosulfoaluminate vraisemblablement aux dépens des sulfoaluminates externes.

Les silicoaluminates sont particulièrement bien mis en évidence dans les mélanges synthétiques  $C_3S-C_3A$  ou  $C_2S-C_3A$ , de granularité régulière. Ces échantillons constituent un ensemble de microsystemes (grain de  $C_3A$ -grain de  $C_3S$ ) dans lesquels se produisent des échanges ioniques par l'intermédiaire de la solution : les propriétés électrocinétiques, caractérisées par le potentiel Zéta, attribuent une charge superficielle positive à  $C_3A$  (13) et une charge négative à  $C_3S$  (14). Nous n'avons pu mettre en évidence aucun des deux silicoaluminates dans les ciments portlands à l'aide de nos techniques physiques d'analyse. En fait, la pâte de ciment est un système beaucoup plus complexe que nos mélanges

synthétique  $C_3A + C_3S$ . Chaque grain de clinker est polyphasé et la granularité de ses différentes phases est assez étendue. Dans la phase interstitielle, l'aluminate tricalcique est souvent finement cristallisé avec l'aluminoferrite et l'analyse de la zone hydratée autour des grains de  $C_3A$  n'est pas aisée. Cependant, d'une part le silicium est détecté dans l'ettringite et l'aluminium dans le C-S-H d'autre part, MITUZAS, KAMINSKAS et MITUZAS (10) ont, à partir des résultats de leur analyse chimique par attaques sélectives, suggéré l'existence du trisilicoaluminate de calcium.

# Synthesis of a calcium silicoaluminate hydrate at 5° C

## *Synthèse d'un silicoaluminate de calcium hydraté à 5° C*

J.H.P. VAN AARDT and S. VISSER, National Building Research Institute, CSIR, Pretoria, South Africa.

SUMMARY : A calcium monosilicoaluminate hydrate analogous to calcium monosulphoaluminate hydrate has been synthesized at 5° C from a mixture of  $C_3A$ , calcium hydroxide and amorphous silica. The thin hexagonal plates have a basal d-spacing of 10,0 Å in contrast to the d-spacing of 10,3 Å for the monosulphoaluminate at 5° C. It does not show a clear shift to lower d-spacings like the calcium monosulphoaluminate {10,3 Å (5° C) to 9,6 Å (25° C)} when the temperature is raised from 5° C to 25° C; substances with higher d-spacings, i.e. higher than 10,0 Å, are produced on raising the temperature and in some instances  $C_2AH_8$  (Stratling's compound) and C-S-H hydrates are produced.

RESUME : On a effectué la synthèse d'un monosilicoaluminate de calcium hydraté analogue au monosulfoaluminate de calcium hydraté, à une température de 5° C, à partir d'un mélange de  $C_3A$ , d'hydroxyde de calcium et de silice amorphe. La distance-d des plaques minces hexagonales est de 10,0 Å par contraste avec celle du monosulfoaluminate, qui est de 10,3 Å à 5° C. On ne voit pas de déplacement évident aux faibles distances d comme dans le cas du monosulfoaluminate de calcium {de 10,3 Å (5° C) à 9,6 Å (25° C)} quand on élève la température de 5 à 25° C; on obtient des substances avec des distances-d plus élevées, c'est-à-dire de plus de 10,0 Å, quand on élève la température, et dans certains cas on obtient  $C_2ASH_8$  (composé de Stratling) et des C-S-H hydratés.

## INTRODUCTION

Numerous calcium aluminate complexes of the general formulae  $3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot 3\text{CaX} \cdot 30\text{--}32\text{H}_2\text{O}$  and  $3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{CaX} \cdot 8\text{--}12\text{H}_2\text{O}$  (X represents an acid radical) have been synthesized at ambient temperatures. In 1944 Flint and Wells (1) reported the existence of silico-aluminates. Since then various workers have reported on the presence of these compounds in hydrated mixtures of calcium silicates plus aluminates and in hydrated portland cement (2,3). Van Aardt (4) reported on tetracalcium hydroxyaluminate hydrates and sulphoaluminate hydrates observed at early hydration times of  $\text{C}_3\text{A}$  or  $\text{C}_3\text{AH}_6$  with  $\text{Ca}(\text{OH})_2$  and  $\text{CaSO}_4$  at low temperature ( $5^\circ\text{C}$ ). The sulphoaluminate hydrate (10,3 Å)<sup>†</sup> was synthesized by adding  $\text{CaSO}_4$  to  $\text{C}_4\text{AH}_1$  (10,6 Å). Subsequently, a silicoaluminate hydrate (10,0 Å) was obtained in a similar manner by adding amorphous silica.

## EXPERIMENTAL

$\text{C}_3\text{A}$  (135 mg) was reacted with  $\text{Ca}(\text{OH})_2$  (37 mg) in water (100 ml) at  $5^\circ\text{C}$  for 19 days. The presence of  $\text{C}_4\text{AH}_1$  (10,6 Å) was established by wet X-ray diffraction. To this slurry was then added :-

1. 30 mg  $\text{SiO}_2$  + 37 mg  $\text{Ca}(\text{OH})_2$
2. 60 mg  $\text{SiO}_2$  + 74 mg  $\text{Ca}(\text{OH})_2$
3. 90 mg  $\text{SiO}_2$  + 111 mg  $\text{Ca}(\text{OH})_2$
4. 90 mg  $\text{SiO}_2$  + 74 mg  $\text{Ca}(\text{OH})_2$
5. 30 mg  $\text{SiO}_2$  +
6. 60 mg  $\text{SiO}_2$  +

The reaction was followed by means of X-ray diffraction. Some solid was filtered off and excess liquid was removed between sheets of filter paper before the still humid solid was scanned. No precaution was taken to keep the temperature at  $5^\circ\text{C}$  since no shifting to a lower d-spacing, as with calcium sulphoaluminate hydrate (4,5,6), was observed at ambient temperatures.

## RESULTS AND DISCUSSION

Although the reaction between  $\text{C}_3\text{A}$  and  $\text{Ca}(\text{OH})_2$  at  $5^\circ\text{C}$  gave mainly  $\text{C}_4\text{AH}_1$  (10,6 Å), a little  $\text{C}_3\text{AH}_6$  and the 8,2 Å phase were also present.

On adding amorphous  $\text{SiO}_2$  or amorphous  $\text{SiO}_2$  plus  $\text{Ca}(\text{OH})_2$  to  $\text{C}_4\text{AH}_1$ , see experiments 1 to 6 above, two reactions took place namely  $\text{Ca}(\text{OH})_2$  and silica reacted to form C-S-H compounds and silica replaced the OH-group in  $\text{C}_4\text{AH}_1$  to form a silicoaluminate hydrate phase with a d-spacing of 10,0 Å. Table 1 lists the main compounds detected after 240 days for experiments 1 to 4 and after 120 days for experiments 5 and 6. Figure 1 gives the XRD-traces.

<sup>†</sup>The d-spacing attributed to the 001 reflection or basal interference of the compound named.

TABLE 1

Oxide ratios of silica and calcium added to one mole of  $\text{C}_4\text{AH}_1$ , and the compounds detected after 120 and 240 days reaction time at  $5^\circ\text{C}$

Exp. No.	Time (days)	$\text{C}_4\text{AH}_1$	$\text{SiO}_2$	$\text{CaO}$	Compounds identified by XR-diffraction				
					10,0 Å phase	$\text{C}_4\text{AH}_1$	C-S-H	8,2 Å phase	$\text{C}_3\text{AH}_6$
1	240	1	1	1	-	xxxxx*	x	x	x
2	240	1	2	2	x	xxx	x	x	x
3	240	1	3	3	xxx	x	x	x	x
4	240	1	3	2	xxxx	x	x	x	-
5	120	1	1	-	xxx	xx	-	x	-
6	120	1	2	-	xxxx	-	-	x	-

\*Number of x's are in relation to quantity of relevant compound

Fig. 1 - XRD-traces for experiments 1 to 4 after 240 days and experiments 5 and 6 after 120 days

The  $C_4AH_1$  compound persisted where the  $Ca(OH)_2$  was in excess, i.e. experiments 1, 2 and 3. With increasing silica additions the 10,0 Å phase seemed to form more readily. In experiments 5 and 6 where no extra  $Ca(OH)_2$  was added, the 10,0 Å phase formed much more readily and was detected in large quantities at much earlier times. After 120 days the presence of  $C_4AH_1$  could hardly be detected especially in experiment 6. At later ages the 10,0 Å phase seemed to decompose and it produced  $C_2ASH_8$  (Stratling's compound) and C-S-H. Figure 2 shows the reaction products for experiment 5 at 240 days; here the breakdown can be detected. The basal reflection of 12,6 Å for Stratling's compound can be seen. Figure 3 gives XRD-traces comparing  $C_4AH_1$  (10,6 Å),  $C_4ASH_x$  (10,3 Å) and  $C_4ASH_x$  (10,0 Å). The marked difference between the 10,3 Å phase and the 10,0 Å phase becomes pronounced when comparing the higher order of the basal reflections as can be seen from Figure 3.

Fig. 2 - XRD-trace for experiment 5 after 240 days showing the presence of  $C_2ASH_8$  and C-S-H

Fig. 3 - XRD-traces for (a)  $C_4AH_1$ , (b)  $C_4ASH_x$  and (c)  $C_4ASH_x$

SEM with energy X-ray dispersive analysis shows that the hexagonal crystals obtained in experiment 6 contain silica in their structure. Figure 4 shows the hexagonal morphology of the crystals and Figure 5 shows the energy dispersive analytical results.

Raising the temperature from 5°C to room temperature and higher did not shift the basal reflection of the 10,0 Å phase to lower d-values but a breakdown to  $C_2ASH_8$  and C-S-H was observed.

Fig. 4 - SEM of the 10,0 Å phase showing hexagonal crystals

Fig. 5 - Energy-dispersive analysis of the above crystals

In an experiment where  $Ca(OH)_2$  and amorphous silica in the ratios of 1  $Ca(OH)_2$  to 1  $SiO_2$  and 2  $Ca(OH)_2$  to 3  $SiO_2$  were added together and kept at 5°C, C-S-H compounds were formed and no  $Ca(OH)_2$  was observed after 100 days. As can be expected from the previous experiments the addition of the C-S-H compounds to  $C_4AH_1$  did not produce the 10,0 Å phase. There appears to be a competition between the  $C_4AH_1$  and the  $Ca(OH)_2$  for the silica and the formation of C-S-H compounds is dominant in the system. Also if the ratio of  $Ca(OH)_2$  to  $Al_2O_3$  was high no Stratling's compound,  $C_2ASH_8$ , was formed. The delicate balance between reactants to produce the 10,0 Å phase and the meta-stability of its existence is further illustrated by the fact that even when some 10,0 Å phase was present in the initial stages it decomposed at equilibrium i.e. after long periods of storage. These observations could explain why workers in the past had difficulty in preparing the silicon bearing phase. Furthermore, it is unlikely that the phase will exist under normal conditions in hydrated portland cement because of the presence of excess  $Ca(OH)_2$ .

# Influence of $3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{CaCO}_3 \cdot n\text{H}_2\text{O}$ on the structure of cement paste

## *L'influence de $3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{CaCO}_3 \cdot n\text{H}_2\text{O}$ sur la structure de la pâte de ciment*

J. JAMBOR, Ing. Dr. Dr. Sc. Institute of Construction and Architecture, Slovak Academy of Sciences, Bratislava, Tchécoslovaquie.

RESUME : Tenant compte des connaissances sur l'influence de  $\text{CaCO}_3$  sur l'hydratation de l'aluminate tricalcique  $\text{C}_3\text{A}$ , aussi bien que des expériences acquises par la pratique de la technologie du béton, l'auteur a réalisé une recherche dont le but était de vérifier l'influence de la formation de l'aluminate de chaux carbonaté hydraté  $\text{C}_3\text{A} \cdot \text{CaCO}_3 \cdot n\text{H}_2\text{O}$  dans la pâte liante, sur sa structure et sa résistance.

Pour la recherche, on a utilisé des pâtes-liants faites des mélanges de  $\text{C}_3\text{A}$  à teneur variable en  $\text{CaCO}_3$  broyé et en sable siliceux, qui étaient traitées de la manière habituelle. Après avoir établi les caractéristiques principales des propriétés physico-mécaniques, les pâtes durcies ont été soumises à l'analyse de leur composition de phase et de leur structure poreuse.

Les résultats ont confirmé que, contrairement au sable siliceux,  $\text{CaCO}_3$  participe activement à l'hydratation de  $\text{C}_3\text{A}$  en causant la formation de  $\text{C}_3\text{A} \cdot \text{CaCO}_3 \cdot n\text{H}_2\text{O}$  comme le produit d'hydratation principal. En comparaison avec des produits habituels d'hydratation de  $\text{C}_3\text{A}$ , c'est à dire  $\text{C}_3\text{AH}_6$  ou  $\text{C}_4\text{AH}_{19}$  -  $\text{C}_2\text{AH}_8$ , c'est  $\text{C}_3\text{A} \cdot \text{CaCO}_3 \cdot n\text{H}_2\text{O}$  qui présente une capacité liante très élevée. Sa formation dans la pâte liante de  $\text{C}_3\text{A}$  lui donne une structure plus compacte, ayant une valeur jusque 10 fois plus petite du rayon moyen des micropores et une résistance à la compression même jusque 100 fois plus importante.

Ces constatations permettent d'éclaircir les expériences acquises par la technologie du béton, qui indiquent une influence favorable de l'addition de  $\text{CaCO}_3$ , broyé ou de l'emploi des agrégats calcaires sur la résistance du béton. En même temps elles montrent des possibilités nouvelles de l'amélioration de la capacité liante des ciments portland à teneur élevée en  $\text{C}_3\text{A}$ .

SUMMARY : Taking into consideration the experience concerning the influence of  $\text{CaCO}_3$  on the hydration of tricalcium aluminate -  $\text{C}_3\text{A}$  as well as the experience acquired in the concrete technology, an investigation was carried out, the aim of which was to clarify the influence of the forming of calcium aluminate carbonate hydrate -  $\text{C}_3\text{A} \cdot \text{CaCO}_3 \cdot n\text{H}_2\text{O}$  in the binder paste on its structure and strength.

The hardened binder pastes made of the mixtures of  $\text{C}_3\text{A}$  with a graded amount of ground  $\text{CaCO}_3$ , or quartz sand, cured in usual way, were used for the investigation. After ascertaining the basic physico-mechanical properties the phase composition and the character of pore structure of the tested pastes were investigated.

The achieved results have confirmed, that unlike the quartz sand, the  $\text{CaCO}_3$  participates in the hydration process of  $\text{C}_3\text{A}$  and causes forming of  $\text{C}_3\text{A} \cdot \text{CaCO}_3 \cdot n\text{H}_2\text{O}$  as a main hydration product. In comparison with the usual hydration products of  $\text{C}_3\text{A}$  - i.e.  $\text{C}_3\text{AH}_6$  or  $\text{C}_4\text{AH}_{19}$  -  $\text{C}_2\text{AH}_8$  - the  $\text{C}_3\text{A} \cdot \text{CaCO}_3 \cdot n\text{H}_2\text{O}$  possesses a spectacularly higher binding capacity. The forming of this compound in the hydrating  $\text{C}_3\text{A}$  paste causes a more compact structure - with up to 10-times smaller average micropore radius and up to 100-times higher compressive strength.

These findings permit to explain the experience acquired in practical concrete technology, that indicate a positive effect of ground  $\text{CaCO}_3$  admixture, or of an use of calcite aggregate on the concrete strengths. At the same time, they provide new possibilities of an improvement of the binding capacity of the portland cements with a higher  $\text{C}_3\text{A}$  content.

## INTRODUCTION

Experience shows, that the tricalcium aluminate  $C_3A$  and its hydration products of the type  $C_3AH_6$ , or  $C_4AH_{19} - C_2AH_8$  contribute only very little to the binding properties of portland cement and in addition to it they affect negatively some other technically important properties of hardened cement paste and concrete [1,2]. For this reason effort is developed to modify the hydration of  $C_3A$  in such a way as to obtain hydration products with a much higher binding capacity. This effect comes true partly already by using gypsum as a retarding admixture to the cement. Due to its influence calcium aluminate sulphate hydrates with a higher binding capacity are formed from a part of  $C_3A$  present during the hydration process. Taking into consideration the experience acquired in the concrete technology we drew our attention to the investigation of the influence of  $CaCO_3$  on the hydration of  $C_3A$  and especially of the influence of the developed calcium aluminate carbonate hydrate on the structure and strength of hardened binder pastes.

The effect of various carbonates on the hydration of calcium aluminates and the conditions of forming as well as the relative stability of calcium aluminate carbonate hydrates have been studied by G. Schippa and R. Turriziani [3], P.P. Budnikow, W.M. Kolbassow and A.S. Pantelejew [4], K.T. Greene [5], E.T. Carlson and H.A. Berman [6], R.F. Feldman, V.S. Ramachandran and P.J. Sereda [7] and others [8,9]. These authors have proved, that due to the effect of the soluble as well as insoluble carbonates the calcium aluminate monocarbonate hydrate -  $C_3A.CaCO_3.H_{11}$  is formed by the hydration of  $C_3A$  and  $C_4AF$  at a normal temperature. The amount of bound water in this compound is given mostly by the value of  $n = 10-12$  in dependence on the relative humidity of the medium. Some authors suppose the forming of calcium aluminate tricarbo-nate hydrate -  $C_3A.3CaCO_3.H_{32}$  - under specific condition too, although this assumption was hitherto not confirmed generally.

The influence of the formed  $C_3A.CaCO_3.H_n$  on the structure and strength of hardened binder pastes has been investigated relatively little so far. P.P. Budnikow and coworkers have proved, that the forming of  $C_3A.CaCO_3.H_{11}$  causes in  $C_3A$  paste a spectacular increase of its strength, whereas in  $C_4AF$  paste it does not appear significantly [4]. E. Spohn and W. Lieber have demonstrated a positive influence of the formed  $C_3A.CaCO_3.H_{10}$  on the strengths in  $C_3A$  pastes as well as in  $C_4AF$  pastes. In connection with these findings the mentioned authors have proved the positive influence of the  $CaCO_3$  admixture on the strengths of portland cement mortars and concretes, too [9].

## MATERIALS AND METHODS USED

The following materials were used for the

tests:

a/  $C_3A$  - prepared by five times repeated burning at  $1400^\circ C \pm 20^\circ C$  of pressed mixture of chemically pure  $CaCO_3$  and  $Al_2O_3$  in molar proportion 3:1. The  $C_3A$  was ground to the maximum grain size of 90 microns.

b/  $CaCO_3$  - prepared by grinding of selected lumps of natural marble to the maximum grain size of 90 microns.

c/ Standard quartz sand for testing of cement corresponding to the specifications of the standard ISO/R 697-1968, or IS 650-1966.

The composition of used materials is given in Table I.

	$C_3A$	$CaCO_3$
Ignit. loss at $1000^\circ C$ %	0.30	43.63
Insoluble residue %	1.03	0.34
CaO %	61.42	55.32
$Al_2O_3$ %	37.24	-
$R_2O_3$ %	-	0.32
MgO %	-	0.38
Free CaO %	0.20	-
Main phase - approx.	98% $C_3A$	98% $CaCO_3$
Specific density $g/cm^3$	3.151	2.582
Blaine fineness $cm^2/g$	2796	2483

For the investigation 2 cm edge test cubes made of thirteen binder pastes were used. Three types of mixtures were used for the preparation of pastes and test specimens: mixtures of  $C_3A$  with a graded amount of  $CaCO_3$ , mixtures of  $C_3A$  with a graded amount of quartz sand and mixtures with a graded amount of quartz sand containing the compound of 73%  $C_3A$  and 27%  $CaCO_3$  as a binder. The pastes and the test specimens were prepared and cured in usual way. After 1 and 28 days of hardening at  $20^\circ C$  twelve specimens of each paste were used for the determination of their bulk density and compressive strength, six of them being tested in their original wet state and six after their drying at  $100^\circ C$ . After the strength tests the crushed specimens were used for the investigation of their phase composition as well as their pore structure.

Compressive strength, bulk density, specific density and total porosity of the test specimens were determined by using usual methods. The phase composition of hardened pastes was investigated by means of X-ray diffraction phase analysis and complex thermal analysis - using a Philips diffractograph with a PW 1050 goniometer and Derivatograph of type OD 102 delivered by MOM Budapest. The pore size distribution was determined by the Guyer - Böhlens method using a Carlo Erba mercury intrusion porosimeter of model 70 H. A stereoscan made by

#### RESULTS AND THEIR DISCUSSION

The composition of the binder pastes and the ascertained basic properties of test specimens after their 1 and 28 days hardening are given in Table II.

The results of tests prove a decisive influence of the CaCO<sub>3</sub> presence in the mixture on the properties of hardened paste. All hardened pastes without CaCO<sub>3</sub> and containing only C<sub>3</sub>A as a binder - i.e. pastes No. 1, 7, 8 and 9 have shown in original wet state as well as after drying at 100°C very low compressive strengths only; likewise a very little increase of strength and decrease of total porosity during their 28 days hardening. A relatively coarse-pore

structures with an average micropore radius above 1400 nm have been ascertained in these pastes by porosimetric analysis. These results have proved, that C<sub>3</sub>A alone and its usual hydration products form only a relatively little compact structure of the paste and possess a very low binding capacity only.

On the other hand all hardened pastes containing CaCO<sub>3</sub> in addition to C<sub>3</sub>A have shown in wet state as well as after drying up to 100-times higher compressive strengths than compared pastes without CaCO<sub>3</sub>. The pastes with CaCO<sub>3</sub> have also manifested a spectacular increase of compressive strength and bulk density as well as a corresponding decrease of their total porosity during 28 days hardening. In all these pastes a substantially higher content of the water bound in the hydration products has been

ascertained. The porosimetric analyses have proved a more compact fine-pore structure of these pastes - with the values of average micropores radius up to 10-times smaller than those in the pastes without  $\text{CaCO}_3$ . A spectacular difference in the pore structure character of the tested pastes containing  $\text{CaCO}_3$  and without  $\text{CaCO}_3$  is shown in Fig. 1, in which the integral pore size distribution curves of pastes No. 2, 3, 4, 6 and pastes No. 1, 8 after 1 day of their hardening are illustrated.

Fig. 1 - Integral pore size distribution curves of pastes No. 1, 2, 3, 4, 6 and 8 after 1 day hardening.

The given results already indicate, that in the pastes prepared of the  $\text{C}_3\text{A}$  with  $\text{CaCO}_3$  mixtures another type of the hydration products is formed, than that formed in the pastes containing only  $\text{C}_3\text{A}$  as a binder. This has been confirmed by the results of XRD - analysis and complex thermal analysis.

In pastes No. 1, 7, 8 and 9, prepared with  $\text{C}_3\text{A}$  only as a binder, after their 1 and 28 days hardening, the  $\text{C}_3\text{AH}_6$  as the main hydration product has been identified. Beside that the non-hydrated  $\text{C}_3\text{A}$ ,  $\text{C}_4\text{AH}_{10}$  and a small amount of  $\text{C}_3\text{A} \cdot \text{CaCO}_3 \cdot \text{H}_2\text{O}$  - formed probably due to the effect of  $\text{H}_2\text{O}$  -  $\text{CO}_2$  - have been ascertained in these pastes. In the pastes No. 7, 8 and 9  $\beta$ -quartz have been present.

In pastes No. 2, 3, 4, 5, 6, 10, 11, 12 and 13 prepared of the  $\text{C}_3\text{A}$  with  $\text{CaCO}_3$  mixtures the  $\text{C}_3\text{A} \cdot \text{CaCO}_3 \cdot \text{H}_2\text{O}$  as the main hydration product has been identified after their 1 and 28 days hardening. The non-hydrated  $\text{C}_3\text{A}$ ,  $\text{C}_3\text{AH}_6$ ,  $\text{CaCO}_3$  and  $\beta$ -quartz /in the pastes No. 10, 11, 12, 13 only/ in a variable content have been determined in these pastes as the secondary phases. In no paste the presence of  $\text{C}_3\text{A} \cdot 3\text{CaCO}_3 \cdot \text{H}_2\text{O}$  has been ascertained. The highest relative amount of the  $\text{C}_3\text{A} \cdot \text{CaCO}_3 \cdot \text{H}_2\text{O}$  has been found in the pastes No. 3 and 4 prepared of the mixtures, in which the original proportion of  $\text{C}_3\text{A}$  to  $\text{CaCO}_3$  was closed to that in the compound  $\text{C}_3\text{A} \cdot \text{CaCO}_3 \cdot \text{H}_2\text{O}$ . The characteristic diffractometer traces of the pastes No. 1, 3, 5, 8, 11 in their original wet state after 1 day hardening are illustrated

in Fig. 2.

Fig. 2 - Diffractometer traces of pastes No. 1, 3, 5, 8 and 11 after 1 day.

The results of XRD-analyses have been fully confirmed by the results of complex thermal analyses of tested pastes. The characteristic DTA - curves of the pastes No. 1, 2 and 4 after their 1 day hardening are demonstrated in Fig. 3. DTA curve of the paste No. 1 is typical of the  $\text{C}_3\text{AH}_6$ , whereas the DTA curve of the paste No. 4 shows the presence of  $\text{C}_3\text{A} \cdot \text{CaCO}_3 \cdot \text{H}_2\text{O}$  as the main phase in the paste.

The spectacular differences in the type of hydration products and in the character of the structure of the pastes prepared with or without  $\text{CaCO}_3$  have been demonstrated by electron scanning microscopy, too. In Fig. 4 a typical structure of paste No. 1 formed mostly of  $\text{C}_3\text{AH}_6$  and in Fig. 5 a more compact and fine-porous structure of the paste No. 4 formed mostly of  $\text{C}_3\text{A} \cdot \text{CaCO}_3 \cdot \text{H}_2\text{O}$ , is shown.

These results have confirmed, that the forming of  $\text{C}_3\text{A} \cdot \text{CaCO}_3 \cdot \text{H}_2\text{O}$  is the main cause of the relatively high strengths of the pastes made of  $\text{C}_3\text{A}$  with  $\text{CaCO}_3$  mixtures. This finding is confirmed indirectly also by the relationship between the compressive strength of the pastes No. 2 to 6 and the relative proportions of  $\text{C}_3\text{A}$  and  $\text{CaCO}_3$  in the mixtures used for the preparation of these pastes - as illustrated by Fig. 6. This relationship confirms that the highest compressive strengths have been exhibited by

Fig. 3 - DTA curves of pastes No. 1, 2 and 4 after 1 day hardening.

Fig. 4 - Fracture surface of hardened paste No. 1.

the pastes made of the mixtures containing 60 to 70%  $C_3A$  and 30-40%  $CaCO_3$ . The fact, that the highest strengths have been obtained in pastes with a moderately higher  $CaCO_3$  content than corresponding to the theoretical composition of  $C_3A \cdot CaCO_3 \cdot H$  may in this case be explained by imperfect reaction of the  $CaCO_3$  grains with  $C_3A$ .

Fig. 5 - Fracture surface of hardened paste No. 4.

Fig. 6 - Relationship between compressive strength of the paste and composition of used  $C_3A$ - $CaCO_3$  mixture.

#### CONCLUSION

The achieved results have confirmed, that finely ground  $CaCO_3$  in hydrating  $C_3A$  - pastes participates in the hydration process and causes forming of  $C_3A \cdot CaCO_3 \cdot H$  as a main hydration product. The amount of formed

$C_3A \cdot CaCO_3 \cdot H$  depends on the proportion of  $C_3A$  and  $CaCO_3$  in the hydrating mixture and the relatively highest share of this phase has been formed in mixtures containing 60-70%  $C_3A$  and 30-40%  $CaCO_3$ . In comparison to the usual hydration products of  $C_3A$  - i.e.  $C_3AH_6$  or  $C_4AH_{19}$ - $C_2AH_8$ - the  $C_3A \cdot CaCO_3 \cdot H$  possesses spectacularly higher binding capacity and its forming in the hydrating  $C_3A$  paste causes a more compact structure of the paste - with up to 10-times smaller average micropore radius and up to 100-times higher compressive strength. This finding permits to explain the cause of the usually higher strengths of the concretes made of calcite aggregate and provides new possibilities for improvement of the binding capacity of the portland cements with a higher  $C_3A$  content.

# Interaction between gypsum and the C-S-H phase formed in $C_3S$ hydration

## *Interaction entre le plâtre et la phase C-S-H, formée pendant l'hydratation de $C_3S$*

I. ODLER, Institut für Stein und Erden - Clausthal-Zellerfeld, R.F.A.

### RESUME :

L'interaction entre le plâtre et la phase C-S-H, qui s'est formée pendant l'hydratation de  $C_3S$ , a été étudiée. La quantité de plâtre lié et l'aptitude de ce gypse à réagir avec le  $C_3A$  ont été déterminées.

### ABSTRACT :

The interaction between the C-S-H-phase formed in  $C_3S$  hydration and gypsum was studied. The amount of gypsum bound and the ability of bound gypsum to react with  $C_3A$  were determined.

In the study of the kinetics of hydration of a series of portland cements we observed that ettringite was formed even after the total supply of free calcium sulfate in form of gypsum or anhydride, as determined by DTA and/or XRD, was depleted. We tentatively assumed that at this stage calcium sulfate bound to the CSH-phase formed in  $C_3S$  hydration can serve as source of  $SO_4^{2-}$ -ions needed for ettringite formation. To test this hypothesis the interaction between gypsum and the CSH-phase formed in the hydration of pure tricalcium silicate was studied.

In the first part of our work pastes prepared from pure  $C_3S$  and from blends of  $C_3S$  and gypsum ( $w/s = 0.7$ ) were allowed to hydrate in small polyethylene bottles for different periods of time. After stopping the hydration process by D-drying the resultant material was further analysed. The gypsum content as determined by DTA (Mettler 200 apparatus, 10 mg sample  $10^\circ C/min$   $N_2$  atm) and the non reacted  $C_3S$  fraction as determined by quantitative XRD on samples preignited to  $600^\circ C$  are shown in Tab. I. It can be seen that the amount of gypsum detectable by DTA declined with progressing  $C_3S$  hydration and disappeared completely in pastes with long enough hydration time and small enough gypsum additions. Similar results were obtained when gypsum was determined by XRD. Thus it appears that gypsum is bound by the  $C_3S$  hydration products in a way that makes it undetectable by the two methods employed. If expressed per unit of  $C_3S$  hydrated the amount of "missing" gypsum was not constant. It increased with increasing amount of gypsum added to the original paste and declined with progressing hydration. The maximum amount of bound gypsum i.e. 9.8 g/100 g  $C_3S$  found after 1 day of hydration in a paste with 10% calcium sulfate added corresponds to a molar ratio of 1 mol  $SO_4^{2-}$  per 6.1 mols  $C_3S$  hydrated. This value is in good agreement with those found earlier by Copeland and coworkers (1) on a  $C_3S$  paste milled 11 days with 20% gypsum, by Bentur (2) on  $C_3S$  pastes hydrated to a degree of hydration of 70% with up to 9% gypsum added, and by Mehta and coworkers (3) on alite cement pastes with 3 and 6% gypsum added.

As to the effect of gypsum on the rate of  $C_3S$  hydration it was found that the fraction of  $C_3S$  hydrated after any hydration time increased with increasing amount of gypsum added up to 10%  $CaSO_4$ . These data have to be compared with those of Bentur (2) who also found a positive effect of gypsum on  $C_3S$  hydration however only up to about 2-3% gypsum added.

In subsequent work it was tested whether gypsum bound to the CSH-phase and detectable neither by DTA nor XRD can serve as source of  $SO_4^{2-}$ -ions for ettringite formation. To do so pastes made from  $C_3S$  and gypsum hydrated for various periods of time were ground to a fine powder, blended with  $C_3A$  (Mol  $C_3A$  : Mol  $CaSO_4 = 1 : 3$ ) and mixed with additional water to obtain thin paste consistency. After different times of further hydration the pastes were dried at  $35^\circ C$  to constant weight and further investigated by DTA and XRD. As an example, results obtained on a sample of  $C_3S + 2.5\% CaSO_4$  prehydrated for 28 days and subsequently allowed to react with  $C_3A$  for additional 7 days are shown in Fig. 1. It can be seen that within 28 days the endothermic peak belonging to gypsum disappeared; instead a broad endothermic area belonging to the CSH-phase formed in  $C_3S$  hydration became apparent. After adding  $C_3A$  and further hydration a new peak belonging to ettringite developed. After ad-

ditional gypsum addition this compound was again detectable as a separate peak. XRD studies confirmed the formation of ettringite after  $C_3A$  addition. Similar results were obtained on all pastes studied. A comparison of samples that were allowed to react with  $C_3A$  for different periods of time revealed that the ettringite peak reached its final intensity within about 3 hours. In samples in which an excess of  $C_3A$  was added monosulfate and calcium aluminate hydrate rather than ettringite were detectable.

In the final part of our experimental work the amount of sulfate ions that can be recovered by extraction of the paste with a saturated calcium hydroxide solution was measured. To do so finely ground  $C_3S$  pastes containing 2.5 calcium sulfate and hydrated 3, 7 and 28 days were repeatedly extracted for 1 hour with a 100 fold excess of a saturated calcium hydroxide solution. After filtering the concentration of  $SO_4^{2-}$  in the liquid phase was determined. About 40 - 60% of  $SO_4^{2-}$  present in the paste was recovered in the first extraction; between 3 and 6 additional extractions were needed to recover more than 95% of the total amount of sulfates.

From the data obtained one has to conclude that significant, however not unlimited, amounts of calcium sulfate can be taken up by the hydration products in the hydration of  $C_3S$  in presence of gypsum. As a reaction between calcium sulfate and calcium hydroxide, i.e. one of the  $C_3S$  hydration products, can be excluded one has to assume that the disappearing of gypsum from the system is due to a reaction of the latter substance with the second product of  $C_3S$  hydration i.e. the CSH-phase. From the observation that the "missing" sulfate can be rather readily recovered by extraction of the paste and can even serve as source of  $SO_4^{2-}$  ions for ettringite and monosulfate formation one has to conclude that the bond of calcium sulfate to the CSH-phase is rather weak. It had been suggested by Copeland and coworkers (1) that in the hydration of  $C_3S$  in presence of calcium sulfate a CSH-gel is formed in which silicone is partially substituted by the sulphur of sulfate ions. Mehta and coworkers (3) postulated an "absorption" of gypsum by the precipitating calcium silicate hydrates. It seems however unlikely that sulphur atoms bound firmly within the structure of the CSH-phase could enter the liquid phase as quickly and react with tricalcium aluminate as readily as observed in our experiments. Thus we believe that the sulfate ions are just physically adsorbed to the large surface of the CSH-phase and an equilibrium exists between the amount of sulfate ions adsorbed and the calcium sulfate concentration in the liquid phase.

In the light of the results reported the formation of ettringite in portland cement pastes at a time when free calcium sulfate is not detectable anymore becomes understandable. It can be assumed that also here calcium sulfate bound by the CSH-phase can serve as source of  $SO_4^{2-}$ -ions for ettringite formation as originally postulated.

## Conclusions

1. In the hydration of  $C_3S$  in presence of gypsum up to  $1/6$  mol  $SO_4^{2-}$  per 1 mol  $C_3S$  hydrated is bound by the hydration products. The bound gypsum can be detected neither by DTA nor by XRD.

2. The gypsum bound by the CSH-phase can be almost quantitatively extracted by water saturated with calcium hydroxide and can react with  $C_3A$  to form ettringite.

### RESUME :

Dans des systèmes secs ou humides, l'ettringite se décompose déjà à 18 °C dans le vide de  $10^{-6}$  bar, à 74 °C à l'humidité et sous la pression atmosphérique ordinaire, à 82,5 °C sous le nitrogène humide, mais il résiste au traitement dans l'eau de 100 °C après que l'équilibre ait été obtenu.

Les produits de déshydratation forment des pseudomorphes de l'ettringite avec une porosité ouverte élevée. Sous l'attaque du gaz carbonique, le plâtre, la bayerite et l'aragonite se forment. La porosité ouverte augmente de 46 % en volume par rapport au volume de l'ettringite.

Dans des systèmes humides, des additions convenables de sulfates de calcium aux ciments empêchent la fausse prise par la formation d'une couche d'ettringite sur les surfaces du  $C_3A$ . Des recherches récentes sur des systèmes purs avec  $C_3A$ , gypse ou anhydrite et chaux et avec ou sans  $CaCO_3$  ou  $C_3S$  supplémentaire et des recherches sur des ciments industriels confirment ou montrent la formation instantanée de l'ettringite, sa recristallisation postérieure et sa dissolution accompagnée de la formation de monophases avec la réaction du  $C_3A$  encore présent et une formation topochemique de l'ettringite renouvelée. Il est montré que dans les systèmes de ciment contenant des sulfates, l'ettringite et le carboaluminate hydraté sont les hydrates plus stables à la température ordinaire et à basse température. Aux températures plus élevées, le monosulfate hydraté devient l'hydrate stable. C'est pourquoi, un traitement thermique direct, retardé ou répété, désiré ou accidentel, des mortiers de ciment ou des bétons peut causer des dégâts sous forme d'expansion, de fissuration et de chute de résistance. Le remplacement total ou partiel du ciment portland ordinaire par du ciment sans  $C_3A$  ou par du ciment à faible teneur en  $C_3A$ , par des laitiers granulés ou par des pouzzolanes peut réduire ou éviter ces dégâts.

D'autre part, la connaissance de ces corrélations ne devrait pas être utile seulement pour réduire ou éviter des dégâts, mais devrait être utilisée, par exemple, pour la précontrainte du béton.

### SUMMARY :

In both dry and moist systems, ettringite already decomposes at 18 °C under vacuum of  $10^{-6}$  bar, at 74 °C under normal humidity and pressure conditions, at 82.5 °C under wet  $N_2$ -gas but resists treatment with 100 °C water after equilibrium is reached. The dehydration products form pseudomorphs of ettringite with high open porosity. At  $CO_2$ -attack gypsum, bayerite and aragonite are formed. The open porosity increases by 46 vol.-% related to the ettringite volume.

In wet systems suitable additions of calcium sulphate to cements prevent false setting by formation of an ettringite layer preferably on the surfaces of  $C_3A$ . New investigations in pure systems with  $C_3A$ , gypsum or anhydrite and lime with and without additional  $CaCO_3$  or  $C_3S$  and with industrial cements confirm or indicate the immediate formation of ettringite, its later recrystallization and dissolution accompanied by formation of monophases with reaction of still present  $C_3A$  and a renewed topochemical ettringite-formation. It is confirmed that in sulphate bearing cement systems ettringite and the carboaluminate hydrate are the more stable hydration products at normal and lower temperatures, whereas monosulphatehydrate at elevated temperatures comes to be the more stable hydration product. Therefore, direct, delayed or repeated, wanted or unwanted heat treatment of cement mortars and concretes can cause damage in the form of expansion, cracking and decreased strengths. Complete or partial replacement of normal portland cement by portland cement without or with limited  $C_3A$  content, by granulated blast furnace slags or pozzolanas can reduce or prevent damage.

On the other hand, the knowledge on the given correlations should not only be sufficient to reduce or prevent damage but to make use of it, for instance, for the prestressing of concrete.

## INTRODUCTION

The setting retardation of cement pastes is caused by the added calcium sulphates. They form a hedgehog-like layer of ettringite ( $C_3A \cdot Cs_3 \cdot H_{32}$ ) on the surfaces of the quick reacting clinker component  $C_3A$ .<sup>1)</sup> This layer scarcely influences the interdependent mobility of the particles and this prevents quick setting (1-3). Without addition of calcium sulphates the transformation of  $C_3A$  was just as high. The formation of a cards' house-like macro structure, which causes quick stiffening, was observed, however (2).

Hydration in the system  $C_3A - C\bar{E} - C - H$  of Portland cements produces, after an initial formation of ettringite, a decomposition of the same and formation of tricalcium aluminate monosulphate hydrate ( $C_3ACSH_{12}$ ) or solid solutions with tetracalcium aluminate hydrate ( $C_4AH_{13}$ ), respectively and hydration of the residual  $C_3A$  (4,5). After 60 days' further wet storage at room temperature in some cases a renewed formation of ettringite was observed. The high stability of ettringite at room temperature could be derived from the earlier investigations in the pure system  $CaO - Al_2O_3 - CaSO_4 - H_2O$  (6,7) and  $CaO - Al_2O_3 - CaSO_4 - CaCO_3 - H_2O$  (8). But no great importance was attached to these observations.

Damage to heat treated concrete products and thick concrete walls of reactors and the observation of interim lower bending strength of mortar bars encouraged further work on the thermal and chemical stability of the calcium aluminate sulphate hydrates and the related compounds.

- \*The experimental work is subdivided into three parts
  - thermal dehydration of ettringite,
  - chemical stability of calcium aluminate sulphate hydrates in pure systems and
  - influence of heat treatment on cement mortars.

## THERMAL DEHYDRATION OF ETTRINGITE

### Experimental

The ettringite used was prepared by mixing  $C_3A$  and gypsum in the stoichiometric ratio and excess water in a vibrating mill. Its chemical composition was  $C_2.8AC_2.7H_{31.4}$ . The isothermic dehydration was carried out

- under normal air pressure at temperatures from 50 to 900°C,
- under wet nitrogen gas at temperatures from 46 to 180°C and
- under vacuum at temperatures from 18 to 180°C.

Moreover, the dehydration of ettringite was carried out under normal pressure and humidity conditions dynamically with a heating rate of 5°C/min up to 1000°C and quasi-isothermally (9) up to 900°C by thermo-analytical measurements.

Finally the solubility of ettringite was investigated in the temperature range between 20 and 100°C. More details are given in (10).

1) The following abbreviations are used:  
 A -  $Al_2O_3$ ; F -  $Fe_2O_3$ ; C -  $CaO$ ; S -  $SiO_2$ ;  
 CS -  $CaSO_4$ ;  $C\bar{E}$  -  $CaCO_3$ ; H -  $H_2O$

## Results

The isothermic dehydration of the ettringite under normal pressure and humidity conditions at temperatures of between 50 and 144°C is shown in Fig. 1.

Fig. 1 Isothermic dehydration of ettringite under normal pressure and humidity

To a great extent the curves follow a  $\sqrt{t}$ -law. That means the dehydration is diffusion-controlled. This corresponds well with the model of the ettringite structure (11). Increased temperature leads to an increased dehydration velocity.

The dehydration isotherms under normal pressure and humidity, under wet nitrogen and under vacuum are shown in Fig. 2. The enrichment of the rinsing gas with water vapour effects only a small displacement

Fig. 2 Isothermic dehydration of ettringite

of the dehydration temperature to higher values. The temperature range from 46 to 50°C effects a loss of 1.4 m  $H_2O$ . From 50 to 125°C a further 22 m  $H_2O$  are emitted. In the range of 110 to 146°C a hydrate with a residual water content of 8 moles is recognizable.

Between 160 and 180°C a second hydrate stage with 6 m H<sub>2</sub>O is observed. At 900°C dehydration is complete. - Lowering of the total pressure to 10<sup>-6</sup> bar already leads to a water content of only 9 moles at 18°C. In the range of 39 to 85°C the water content amounts to only 8 and up to 120°C to 5.7 moles of water.

The results of the thermo-gravimetric dehydration are shown in Fig. 3. The accurate corresponding of the quasi-isothermic with the dynamic dehydration is evident.

Fig. 3 Dynamic and quasi-isothermic dehydration of ettringite

X-ray diagrams show that the structure of ettringite is already destroyed in a vacuum of 10<sup>-6</sup> bar at 18°C, at 74°C under normal pressure and at 82.5°C under wetted nitrogen. The restorage to 90 % r.h. leads to the rehydration of ettringite and in the presence of CO<sub>2</sub> from the air to the decomposition products gypsum, bayerit and aragonite. The molecular weight of the decomposition products amounts to only 54 % of that of the ettringite. That means that the carbonization effects a corresponding increase of the open porosity. The decomposition products from dehydration and carbonization products form ettringite-shaped pseudo-morphs.

The solubility of ettringite was investigated at 20, 40, 80 and 100°C. It was established that the values of solubility at temperatures  $\geq 40^\circ\text{C}$  increase very much with the reaction period and that the equilibrium has not yet been reached after 21 or 49 days stirring. At this time ca. 30 wt.-% of ettringite were solved.

#### CHEMICAL STABILITY OF CALCIUM ALUMINATE HYDRATES IN PURE SYSTEMS

##### Experimental

The chemical compositions and the surface areas (BET) of the starting materials are given in Table 1. The investigated systems, the molar ratios of the systems, water/solid-ratios (w/s-ratios), temperatures, reaction periods and curing conditions are given in Table 2. More details are published in (10).

Tab. 2 Systems, mixtures and curing conditions

##### Results

The investigations on the stability of the calcium aluminate sulphate hydrates in the three systems

result overall in the ascertainment that ettringite is at room and lower temperature the most stable phase. The topochemical formation of ettringite in lime-saturated solutions is confirmed. Increasing temperatures accelerate the ettringite formation and the recrystallisation of the hedgehog-like layer of very small ettringite particles on the surface of the C<sub>3</sub>A grains. At rest cured probes react under otherwise identical curing conditions much faster than shaken ones since the micro heterogeneities in the first case support an earlier formation through solution of monophases under dissolution of the originally topochemically formed ettringite and rapid reaction of the residual C<sub>3</sub>A corresponding, for example, to the following mechanisms:

The use of equivalent amounts of anhydrite instead of gypsum leads under otherwise identical conditions, because of the slower solution velocity, to a decrease or prevention of the layer formation and thereby to an increase of  $C_3A$ -hydration (1,3,13). The  $C_2(A,F)$ -components of the clinker react in a similar way but with decreased velocity at decreased alumina content (1,13).

The differentiation of the various monophases in the examined systems was done by drying the samples at equilibrium humidities ranging from 11 to 90 % (Tab.3).

Monophase	Drying [% r.h.]	X-ray d0001 [Å]	Thermal analysis
$C_3A \cdot C\bar{S} \cdot aq$	11	8.8	OH at 440°C
$C_3A \cdot (Cs, CH) \cdot aq$ ( $CO_2$ -free)	33-90 11	8.8 8.15	OH at 440°C and 470°C
$C_3A \cdot (CH, C\bar{E}) \cdot aq$ ( $CO_2$ -bearing)	11	8.15 - 8.2	OH at 440°C $CO_2$ at 740°C

Tab. 3 Differentiation of monophases

It is well known that the  $CO_2$ -free tetra calcium aluminate hydrate forms solid solutions with monosulphate hydrate. The basic interference of the mixed crystal appears at equilibrium humidities of 11 % at 5.15 Å and at humidities ranging from 33 to 90 % at 8.8 Å. Increased carbonization leads to increased formation of  $CO_2$  containing tetra calcium aluminate hydrate with a basic d-value at 8.1 to 8.2 Å. This interference remains unaffected by humidities between 11 and 90 %. Further carbonization leads to the formation of monocarbo aluminate hydrate. That is at room temperature the most stable monophase. The basal d-value of the monosulphate hydrate at 8.8 Å remains unaffected at 11 % r.h.. Additional differentiation of the monophases are possible by thermoanalytical investigation, mainly by dehydration of portlandite and decarbonization of calcium carbonate. With 0.6 molar  $C_3A/C\bar{S}$  ratio the renewed formation of ettringite was established after a curing period of 90 d at a constant 20°C (12).

In the system  $C_3A - C\bar{S} - C - H$  the mixtures with 0.6 and 0.8 molar  $C_3A/C\bar{S}$ -ratio after complete formation of monophases were cured at 5°C. After four month curing a formation of ettringite was established. In the presence of  $CaCO_3$  or  $C_3S$  the renewed formation of ettringite was found after 1 d curing at 80°C and further wet curing at room temperature.

Fig. 4 shows the renewed formation of ettringite in the system with  $CaCO_3$  addition by X-ray diagrams. The starting sample contains ettringite, monocarbo-aluminate hydrate ( $C_3AC\bar{C}H_{12}$ ), portlandite and small amounts of monosulphate hydrate. The one day at 80°C cured sample shows only the interference at 8.8 Å. It remained unaffected at 11 % r.h. and belongs to the monosulphate hydrate. Under these conditions the carboaluminate hydrate and the ettringite are unstable. After only three days curing at room temperature renewed formation of ettringite from monosulphate hydrate is established.

Fig. 5 shows the renewed formation of ettringite in the system with  $C_3S$ . After one day's curing at 80°C the X-ray diagram shows the interferences of ettrin-

Fig. 4 X-ray diagrams of samples with  $CaCO_3$  cured at 80 and 20°C

$M$  = monophases  $MS = C_3A \cdot C\bar{S} \cdot H_{12}$

$Mc = C_3A \cdot C\bar{E} \cdot H_{11}$

Fig. 5 X-ray diagrams of samples with  $C_3S$  cured at 80 and 20°C

gite, monophases and portlandite. After 28 days' storage at 20°C the ettringite was totally converted into monophases. After 60 days' a renewed formation of ettringite was visible. The intensity of the interferences increases up to 90 and 236 days. This behaviour of C<sub>3</sub>S-containing mixes was observed for all of the proved mixes with molar C<sub>3</sub>S/C<sub>3</sub>A-ratios from 0.5 to 3.

## INFLUENCE OF HEAT TREATMENTS ON CEMENT MORTARS

### Experimental

The investigations on cement mortars were done with two different series of experiments.

The first series was done to prove the influence of the temperature of heat treatment on cement mortars with a high early strength cement type 55. The temperatures used are 60, 70, 80, 90 und 100°C. The hot curing period varied from 12 to 72 h. The weights, lengths and resonance frequencies dependent on the curing period were measured. More details are given in (14).

In the second series special heat treatment was carried out that, with cements that are sensitive to heat treatment, doubtlessly leads to severe expansion and damage to the structure. Fig. 6 shows the treatment used together with an industrial treatment programme. The work was done with the above mentioned

Fig. 6 Heat treatment programmes in practice and in this work

PZ 55. The cement was partly or totally substituted by a Portland cement type 45 HS (high sulphate resistant), by granulated blast furnace slag and by puzzolanas (Bavarian trass and fly ash). The sulphate content of the blended cements was kept at the same value as the type 55 Portland cement. The heat treatment was carried out as shown in Fig. 6 after 1 d, after 1 a or as a renewed treatment on mortars that had already been heat treated. Measurements of weights, lengths, resonance frequencies and strengths were carried out. X-ray diagrams were prepared from enriched cement stone from the mortars.

### Results

The results of the investigations on the influence of the period of heat treatment and of the temperature in Fig. 7 show that expansions with the Portland cement type 55 are measured after curing at temperatures

Fig. 7 Influence of heat treatment on cement mortar with type 55 Portland cement

>80°C. The early expansion is increased by increased curing periods and temperatures. After an 11 months' curing period at 20°C the expansions amount to from 6 to 9 mm/m. Analogous to the expansions a lowering of the resonance frequencies was measured. This is a measure for the loss in strength.

The results of the investigations under use of the treatment programme from Fig. 6 are in Fig. 8 to 12.

Fig. 8 shows the behaviour of the PZ 55 at direct, subsequent and renewed heat treatment. First of all it is recognizable that expansions are accompanied by decreased resonance frequencies. A subsequent heat treatment leads to more severe expansions and more reduced resonance frequencies and a repeated heat treatment at later curing stages leads to renewed expansions accompanied by strength's loss and decrease of resonance frequencies. The more severe damaging of the specimens at delayed or repeated heat treatment is caused by the reduced elasticity of the structure at this later stage.

The results of investigations with partial or full exchange of PZ 55 by PZ 45 HS are given in Fig. 9. Expansions and loss in resonance frequencies are even increased by the replacement of 25 and 50 wt.-% of the PZ 55. Only 75 wt.-% replacement gives up to this stage of the investigation (10 months) a sharply reduced reaction. With PZ 45 HS up to now no sign of a reaction is visible. The explanation of the increased reaction, specially with 25 wt.-% replacement of the PZ 55, lies in the compensated sulphate content in the cement. That means that the relative sulphate content related to the C<sub>3</sub>A content is higher while the reduced C<sub>3</sub>A content is not yet effective.

Fig. 8 Expansion and resonance frequency of mortar bars with PZ 55 at direct, delayed and repeated heat treatment

Fig. 9 Expansion, resonance frequency and final compressive strength of mortar bars with partial and full replacement of PZ 55 by PZ 45 HS

A drastically reduced or prevented reaction is achieved by the replacement of the PZ 55 by 25 or 50 wt.-% blast furnace slag (Fig. 10).

Fig. 10 Expansion, resonance frequency and final compressive strength of mortar bars with partial replacement of PZ 55 by blast furnace slag

The replacement of 15 wt.-% Portland cement by Bavarian trass causes a lowering of the intensity of the reaction accompanied by a shifting of the starting point of the visible reaction to a shorter curing period (Fig. 11). 30 wt.-% exchange of PZ 55 by the trass prevents the reaction totally.

The replacement of PZ 55 by 15 or 30 wt.-% of fly ash is a very effective provision to reduce or prevent sensitiveness against heat treatment (Fig. 12).

The expansions and the loss in strength are caused by the renewed topochemical formation of ettringite from the unstable sulphate-containing monophases. Favoured by a heat treatment, the ettringite formed in the early hydration period becomes unstable and forms monosulphate hydrate and its solid solutions with tetracalcium aluminate hydrate that are themselves unstable at lower temperatures and give rise to the renewed formation of ettringite. Fig. 13 shows in each case on the left (a) the d-values of hydrates formed at a constant curing temperature of 20°C and on the right (b) those of interim heat treated samples. If permanent 20°C curing the basic d-values at 9.7 Å are more or less present at all states of the curing period. This is one of the main interferences of ettringite. - Contrary to this, directly after the heat treatment at a total curing period of three days this interference of the ettringite is not present. With increasing additional curing at 20°C

Fig. 11 Expansion, resonance frequency and final compressive strength of mortar bars with partial replacement of PZ 55 by Bavarian trass

Fig. 12 Expansion, resonance frequency and final compressive strength of mortar bars with partial replacement of PZ 55 by fly ash

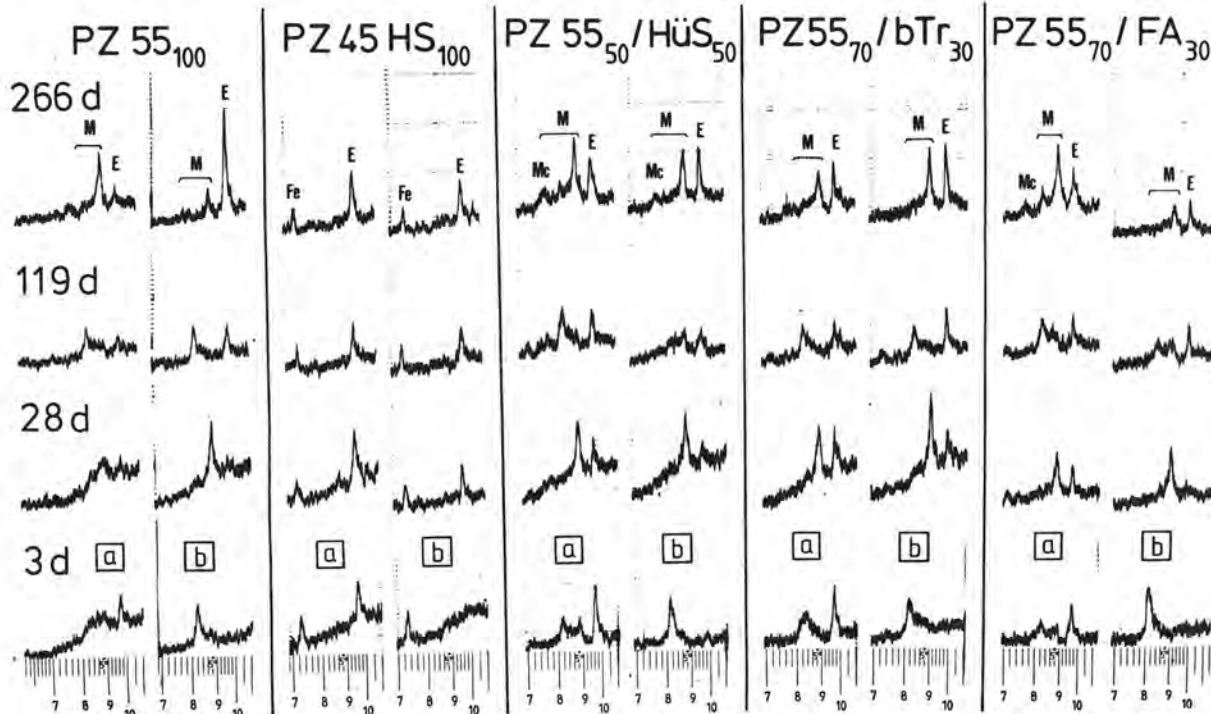

Fig. 13 X-ray diagrams of samples (a) constantly cured at 20°C and (b) interim heat treated. Mortar bars DIN 1164, abbr. accord. to Fig. 4 and 5, Fe = C<sub>2</sub> (A,F) HüS = granulated blast furnace slag, bTr = Bavarian trass, FA = fly ash

this ettringite interference becomes visible and grows with curing time.

## CONCLUSION

The dehydration of ettringite is a diffusion-controlled process which corresponds well with the model of the structure (8). The dehydrated product has the same habitus as the formed ettringite with a very open structure sensitive to carbonization. The volume loss of carbonated ettringite amounts to 46 % and a corresponding decrease of strength.

Ettringite is a very important cement hydration product. It is formed mainly topochemically with the added calcium sulphates and serves the required workability of cement mortars and concretes. This first or early ettringite formation is harmless as long as it is finished in the plastic state of the mortar or concrete. Elongation of ettringite formation period leads to lowering of the early strength accompanied by expansion (12).

The new investigations on pure systems and with plain and blended Portland cement show that ettringite and carboaluminate hydrate are the stable phases at room and lower temperatures and monosulphate hydrate is the stable phase at elevated temperatures. In consequence an interim direct, delayed or repeated, wanted or unwanted heat treatment of cement pastes, mortars or concretes can cause damage by expansion, cracking and decreased strength. Calcium carbonates can increase the damage. Portland cement with limited or without  $C_3A$  or Portland cements blended with granulated blast furnace slags or suitable puzzolanas in appropriate amounts reduce or even prevent damage. - On the other hand, reduction or prevention of damage should not be regarded as the sole task. One should look ahead making use of the knowledge of the reactions of the calcium aluminate sulphate hydrates and related compounds.

## ACKNOWLEDGEMENT

We are grateful to W. Boenicke and D. Ganser for preparation and measurement on mortar bars and to the Deutsche Akademische Austauschdienst and to the Deutsche Forschungsgemeinschaft in Bonn for the financial support.

# Certaines interactions entre $C_3A$ et $C_3S$ lors de l'hydratation des ciments portland

## *Some interactions between $C_3A$ and $C_3S$ during cement portland hydration*

B.F. COTTIN, Chef de Service, Laboratoire de Recherche Générale, Lafarge S.A. France.

RESUME : Quatre clinkers de ciment Portland industriels, de compositions très différentes, ont été broyés à 3000  $\text{cm}^2/\text{g}$  Blaine et gypsés aux taux de 0 - 1 - 2,5 et 5 % de  $\text{SO}_3$  à l'aide de gypse - semi hydrate - surcuit ou anhydrite naturelle. La cinétique d'hydratation des ciments obtenus a été suivie par calorimétrie isotherme.

Les spectres de calorimétrie des ciments Portland révèlent en général trois pics dont l'intensité et l'échéance montrent respectivement l'hydratation d'une partie de  $C_3A$  (modifiée par la présence de  $C_3S$  et de sulfate de calcium) - l'hydratation de  $C_3S$  (influencée par l'hydratation du  $C_3A$  : empoisonnement) - la consommation totale des ions  $\text{SO}_4$  (dont l'échéance est liée aux deux premières réactions).

Les principales conclusions sont les suivantes :

- Le premier pic (hydratation de  $C_3A$ ) est toujours diminué par le gypsage. Mais il ne paraît pas possible de dégager une loi générale entre cette diminution et la nature et la quantité de sulfate de calcium ajouté.
- Dans tous les cas, le gypsage optimum se situe entre 2,5 et 5 % de  $\text{SO}_3$  ajoutés, même avec le clinker le plus riche en  $C_3A$ .
- Sauf pour ce dernier clinker, qui est aussi le plus riche en sulfates alcalins, le "déempoisonnement" de  $C_3S$  par le gypsage est caractérisé par un pic calorimétrique plus précoce et plus intense. Il est vrai que l'échéance du pic de  $C_3S$  du clinker riche en  $C_3A$  et sulfates alcalins est inhabituellement précoce.
- Le pic révélant le moment où la consommation des ions  $\text{SO}_4$  est complète n'existe pas lorsque le gypsage est réalisé par addition d'anhydrite naturelle. Dans les autres cas, il est le plus souvent très peu intense et étalé dans le temps.
- L'interaction silicates - aluminates - sulfates de calcium est très complexe. D'autres paramètres interviennent très probablement, comme la teneur et la nature des sels alcalins du clinker, le procédé et l'intensité de la cuisson. C'est la raison pour laquelle les quelques essais réalisés, loin de tout expliquer, soulèvent un lot de nouvelles questions auxquelles seules de nombreuses études pourraient répondre de façon satisfaisante.

SUMMARY : Four industrial Portland cement clinkers were chosen owing to their quite different compositions. They were ground at 3000  $\text{cm}^2/\text{g}$  Blaine and calcium sulphate added with gypsum - hemi hydrate - anhydrous  $\text{CaSO}_4$  or native anhydrite at 1 - 2,5 - 5 %  $\text{SO}_3$  levels. The kinetics of hydration of these mixes were analysed by isothermal calorimetry.

Generally, the calorimetric curves obtained with Portland cement show three exothermic peaks whose intensity and time of occurrence correspond respectively :

- to hydration of a part of the  $C_3A$  (modified by the presence of the  $C_3S$  and the calcium sulphate)
- to  $C_3S$  hydration (possibly "poisoned" by the  $C_3A$ )
- to total consumption of  $\text{SO}_4$  ions (at a time depending on the two previous reactions).

Our main conclusions are as follows :

- Adding calcium sulphate results always in diminishing the intensity of the first peak ( $C_3A$  hydration). But it does not seem possible to define a general law between this decrease in heat liberation and the nature or the quantity of calcium sulphate added.
- In every case, optimum gypsum content takes place between 2,5 and 5 % of added  $\text{SO}_3$ , even with the  $C_3A$  richest clinker.
- Except for this last clinker, which is also the highest in alkaline sulphates, the "dispoisoning" of the  $C_3S$  due to calcium sulphate adding results in an earlier and more intense calorimetric peak. It is true that the  $C_3S$  peak of the  $C_3A$  and alkaline sulphates rich clinker is abnormally early.
- The total consumption  $\text{SO}_4$  peak is not present when the added sulphate is native anhydrite. In other cases, this peak is generally very weak and broad.
- The calcium silicates - aluminates - sulphates interaction is very intricate. Probably, other parameters affect the phenomena, as alkaline salts content of the clinker, or the process and intensity of the burning. For this reason, it is not possible to explain everything by our few tests which raise new questions for many future studies to be carried out in this field.

L'influence primordiale de l'aluminate tricalcique sur les propriétés du ciment Portland n'est plus à démontrer. Ce constituant agit en particulier :

a - sur l'aptitude à la mise en place des pâtes, mortiers ou béton, qui peut devenir totalement impossible à cause de l'hydratation très rapide de  $C_3A$ . C'est le phénomène de prise rapide ou flash universellement combattu par l'addition de sulfate de calcium.

b - sur leurs cinétiques d'hydratation et de durcissement. En effet, par nature, l'aluminate tricalcique réagit extrêmement rapidement avec l'eau. Ces réactions se déroulent avec un passage plus ou moins important d'alumine en solution, selon la composition globale du ciment. Or, les ions aluminiques en solution ont une forte tendance à retarder l'hydratation des silicates de calcium, par empoisonnement de leur surface.

c - sur leurs propriétés physiques et chimiques. La teneur en  $C_3A$  du ciment Portland a des répercussions importantes sur les variations dimensionnelles (retrait hygrométrique ou gonflement sous eau) sur la tenue aux solutions agressives ...

Les essais, dont nous donnons les résultats et qui ne représentent qu'une petite contribution à la connaissance de ces phénomènes, avaient pour but d'étudier les deux premiers points a et b, c'est-à-dire les cinétiques de réaction à courte échéance. En particulier, nous désirions voir comment interviennent sur ces cinétiques les variations de compositions des ciments dues à des provenances différentes de clinkers industriels et à des "sulfatages" différents (taux d'addition de sulfate de calcium et nature de ce sulfate).

#### PARAMETRES CHOISIS

Nous avons choisi quatre clinkers de compositions aussi différentes que possible :

Clinker A : riche en  $C_3S$  et en chaux libre, pauvre en alcalins solubles et en  $SO_3$

Clinker B : à forte teneur en  $C_3A$  et sulfates alcalins. Il y a un net excédent de  $SO_3$  par rapport aux alcalins solubles.

Clinker C : sans  $C_3A$  et riche en aluminoferrites. Les teneurs en  $SO_3$  et alcalins solubles sont relativement faibles.

Clinker D : d'analyse moyenne. La teneur en  $SO_3$  est insuffisante pour combiner tous les alcalins solubles.

Le tableau n° 1 donne les analyses chimiques et les compositions potentielles, calculées selon Bogue, de ces clinkers. Les sulfates alcalins ont été calculés d'après les teneurs en alcalins solubles, et le  $CaSO_4$  d'après le taux de  $SO_3$  résiduel.

Nous n'avons pas retenu la finesse du clinker comme paramètre, car il est trop évident que la consommation du sulfate de calcium est accélérée par l'augmentation de la surface de réaction. Nous avons adopté la finesse de 3000 Blaine obtenue au broyeur à boulets de laboratoire de capacité 5 kg.

Les taux de  $SO_3$  ajoutés par l'apport de sulfate de calcium ont été de 0 - 1 - 2,5 et 5 % pour chaque clinker. Les quatre sulfates de calcium utilisés furent le gypse pur - le semi hydrate pur - le surcuit pur - une anhydrite naturelle à 96 % de  $CaSO_4$ .

Les mélanges clinkers - sulfate de calcium ont été très soigneusement réalisés au tamis. Leurs cinétiques d'hydratation ont été suivies en continu jusqu'à 24 heures à l'aide d'un calorimètre isotherme du type CERILH, à la température de 25°C. La quantité d'eau distillée injectée sur le

	Clinker A	Clinker B	Clinker C	Clinker D

TABEAU 1 : Analyse et composition des clinkers

ciment au temps 0 correspondait à un E/C de 0,5.

Après les 24 heures d'hydratation, les pâtes hydratées étaient examinées par diffraction X qualitative, et leur eau liée déterminée par perte au feu après lavage acétone-éther.

#### RESULTATS OBTENUS

Nous ne donnerons que les résultats qui nous paraissent les plus intéressants.

##### Aspect habituel d'un thermogramme de ciment Portland

Les courbes calorimétriques habituellement obtenues avec les ciments Portland comportent toujours (Graphique 1)

- un premier pic de dégagement de chaleur rapide et limité dans le temps. Son interprétation est complexe car il comprend les chaleurs de mouillage et de dissolution. Mais celles-ci doivent être relativement faibles puisque, pour certains clinkers ou ciments, le premier pic est peu important, alors qu'il n'y a pas de raison que les chaleurs de mouillage et de dissolution soient très différentes d'un échantillon à l'autre. Les variations relatives de ce premier pic sont donc en grande partie dues à une réaction d'hydratation pratiquement instantanée et de courte durée.

FIG. 1 - Aspect classique d'un thermogramme de ciment Portland

- une période relativement athermique, souvent appelée période dormante.

- un second pic exothermique correspondant à un dégagement de chaleur beaucoup plus important que celui du premier pic, mais très étalé dans le temps. Ce pic est attribué à l'hydra-

tation proprement dite, en particulier des silicates de calcium.

- parfois un troisième pic, toujours peu intense, dont l'échéance est variable, c'est-à-dire que le maximum de ce pic peut se situer avant ou après celui du deuxième pic. Ce pic est attribué aux phénomènes qui se déroulent lorsque le sulfate de calcium a été complètement consommé pour faire l'et-

tringite. Ces phénomènes sont attribuables, soit à une recristallisation de l'ettringite déjà formée qui ne se trouve plus en équilibre avec la solution appauvrie en  $\text{SO}_4^{--}$ , soit à la reprise de l'hydratation de  $\text{C}_3\text{A}$  de nouveau disponible par la modification de structure de la couche protectrice d'ettringite, soit à la transformation de l'ettringite en monosulfoaluminate de calcium hydraté.

FIG. 2 - Clinkers témoins

#### Résultats obtenus sur clinkers non sulfatés

Les courbes sont tout à fait conformes au modèle classique. Elles sont reportées sur le graphique 2 (dans lequel les échelles sont modifiées après la première heure : multipliées par 2 pour les dégagements de chaleur, divisées par 10 pour les temps).

L'intensité du premier pic varie beaucoup d'un clinker à l'autre. Ces variations peuvent être attribuées en grande partie à l'hydratation de  $\text{C}_3\text{A}$ , comme le montre le graphique 3 a : hauteur du premier pic en fonction de la teneur en  $\text{C}_3\text{A}$ .

L'intensité et l'échéance du maximum du second pic sont elles aussi très variables. Mais il paraît a priori difficile de définir avec certitude une loi reliant ces valeurs aux divers paramètres chimiques mesurés. Nous avons pu prouver, par des essais antérieurs faisant appel à des techniques tout à fait différentes, que, en absence de sulfate, le  $\text{C}_3\text{A}$  laisse passer en solution suffisamment d'alumine pour empoisonner le  $\text{C}_3\text{S}$ , c'est-à-dire le retarder. Nous avons aussi montré que le sulfate de calcium (ou de potassium) supprime le passage de l'alumine en solution, probablement par formation d'ettringite protectrice autour de  $\text{C}_3\text{A}$ . Si nous appliquons ces théories aux quatre clinkers étudiés ici,

FIG. 3 a - Relation entre la hauteur du 1er pic de calorimétrie et la teneur en  $\text{C}_3\text{A}$  des clinkers non gypsés

nous devrions trouver une relation entre l'échéance du maximum du second pic et la teneur en alumine du clinker corrigée par la teneur en  $SO_3$ . Le graphique 3 b montre que cette

FIG. 3 b - Temps du 2ème pic de calorimétrie en fonction de  $C_3A - 3 SO_3$  des clinkers non gypsés

relation paraît convenable pour  $A - 3 SO_3$  (sans que l'on puisse affirmer qu'il y ait une relation entre ce coefficient 3 de  $SO_3$  et le rapport  $A/SO_3 = 3$  dans la formule de l'ettringite).

Les autres constatations que nous avons pu relever sur l'étude de ces clinkers non sulfatés sont les suivantes :

- Les quantités d'eau liée à 24 heures sont aussi très variables d'un clinker à l'autre (20,5 % pour le clinker A - 9,8 % pour le clinker C) et proportionnelles à l'intensité du maximum du second pic de calorimétrie.

- Il est plus difficile de se faire une opinion générale sur l'hydratation des aluminates. Comme il est normal, c'est pour le clinker B que l'on a observé la plus grande quantité d'ettringite après 24 h. d'hydratation. Le clinker A révèle dans les mêmes conditions un très large pic de diffraction X au niveau de  $C_4AH_n$ .

#### Influence du "sulfatage" sur le premier pic de calorimétrie

Le graphique 4 fournit tous les résultats obtenus avec les quatre clinkers et les divers types de "sulfatage".

Le cas du clinker A paraît le plus simple à expliquer : dans tous les cas, la hauteur du premier pic de calorimétrie est diminuée, les extrêmes étant obtenus avec les additions de semi hydrate (le plus soluble et le plus actif) et d'anhydrite naturelle (la moins active car moins rapidement soluble). La proportion d'addition de sulfate ne joue pas significativement. A noter qu'avec les additions de 2,5 et 5 % de semi hydrate, on observe nettement le pic d'hydratation en gypse vers 2 h.

FIG. 4 - Intensité du 1er pic de calorimétrie en fonction du taux de  $SO_3$  ajouté

☆ témoin non sulfaté, ● gypse, □ semi hydrate, × surcuit, ○ anhydrite

Le cas du clinker B est plus complexe à analyser : le gypse diminue la hauteur du premier pic proportionnellement à son addition, les résultats obtenus avec le surcuit sont assez dispersés, par contre c'est l'anhydrite naturelle qui révèle l'action la plus importante, indépendante du pourcentage ajouté. Ce dernier résultat est surprenant compte tenu des caractéristiques de solubilité de ce sulfate de calcium. Les phénomènes sont faussés avec l'addition du semi hydrate dont l'hydratation en gypse est accélérée par la présence du sulfate de potassium dans le clinker : le pic correspondant s'ajoute au premier pic d'hydratation du ciment, et augmente sa hauteur.

Le clinker C non "sulfaté" donne un premier pic de faible intensité. Les additions de sulfate de calcium le laisse à un

niveau très bas, sauf lorsqu'il s'agit de semi hydrate à cause de son hydratation rapide en gypse.

Le premier pic du clinker D est relativement peu modifié par toutes les additions de sulfate de calcium réalisées. L'hydratation du semi hydrate est moins accélérée qu'avec les clinkers B et C, de sorte que le pic correspondant n'apparaît que vers 50 minutes, et n'influence pas le premier pic de calorimétrie.

#### Influence du "sulfatage" sur le second pic de calorimétrie

Le graphique 5 donne l'échéance du maximum du pic dit "des silicates" pour tous les essais réalisés.

Avec le clinker A, ce temps est toujours diminué de 2 à 3 h.

FIG. 5 - Temps du maximum en fonction du taux de  $\text{SO}_3$  ajouté

☆ témoin non sulfaté, ● gypse, □ semi hydrate, × surcuit, ○ anhydrite

sauf avec la plus faible addition de gypse et de semi hydrate. On peut noter aussi que par rapport au témoin non sulfaté, la hauteur de ce pic est inchangée avec toutes les additions à 1 % de  $\text{SO}_3$ , mais augmentée de 40 à 50 % avec les additions à 2,5 et 5 % de  $\text{SO}_3$ .

Le clinker B se comporte de façon tout à fait différente : alors que le témoin non sulfaté présente un pic d'hydratation des silicates anormalement précoce à 5 heures, tous les essais de "sulfatage" conduisent à rallonger de 3 à 4 heures l'échéance de ce maximum. L'intensité de ce pic reste du même ordre de grandeur.

Les comportements des clinkers C et D sont analogues : le "sulfatage" accélère toujours le pic des silicates, l'action du semi hydrate étant plus importante que celle des autres sulfates de calcium. La hauteur de ce pic est toujours pratiquement doublée par l'addition du sulfate de calcium.

D'une manière générale, on retrouve bien le "désempoisonnement" des silicates lorsque le sulfate de calcium permet de précipiter rapidement l'alumine. Celui-ci se traduit par une accélération du second pic, d'autant plus sensible que le clinker témoin était plus lent, et plus importante avec l'addition de semi hydrate. Une exception cependant à signaler, et qui concerne le clinker B dont le témoin non adjuté présente un pic des silicates anormalement rapide, dû peut-être à la grande quantité de sulfates alcalins contenus dans ce produit. L'addition des sulfates de calcium ramène un pic de silicate dont la cinétique est analogue à celles des autres clinkers "sulfatés".

#### Influence sur le "sulfatage optimum"

La notion de "sulfatage" optimum résulte d'un compromis entre deux phénomènes :

- L'addition de sulfate de calcium permet une hydratation des silicates non entravée par l'alumine en solution, et conduit à la formation d'ettringite très volumineuse, favorable aux résistances. Ces deux actions bénéfiques sont évidemment d'autant plus importantes que le taux d'addition de sulfate est plus grand, jusqu'à une proportion limite à partir de laquelle se produit :

- Un blocage des réactions d'hydratation des aluminates et des sulfates, d'autant plus important que le taux d'addition de sulfate dépasse cette limite. Il reste alors, après le début de durcissement, du sulfate de calcium libre qui finit par s'hydrater en donnant des sulfoaluminates expansifs.

Cette limite, qui correspond aux meilleures résistances initiales et aux variations de dimensions ultérieures minimales des éprouvettes, est appelée "sulfatage optimum". Elle correspond, en première approximation, à un taux d'addition de sulfate de calcium tel que ce sulfate soit complètement consommé en sulfoaluminates de calcium hydratés en moins de 24 heures.

Il paraît logique de penser que le "sulfatage optimum" dépende de la réactivité du sulfate ajouté et de celle du clinker (au moins ses phases alumineuses). Nous n'avons pas la prétention de déterminer le niveau de "sulfatage optimum" à partir de trois essais seulement, mais nous avons été surpris de constater, par diffraction X, que dans tous les cas le "sulfatage optimum" se situe entre 2,5 et 5 % de  $\text{SO}_3$  ajouté. En effet, après 24 heures d'hydratation, nous ne trouvons, dans les pâtes hydratées, du sulfate de calcium que pour l'addition correspondant à 5 % de  $\text{SO}_3$  : sous forme de gypse avec le gypse et le semi hydrate, sous forme d'anhydrite avec le surcuit et l'anhydrite naturelle.

Par ailleurs, comme nous l'avons expliqué dans la description générale des courbes calorimétriques obtenues sur les ciments, le moment où tout le sulfate de calcium est consommé se traduit parfois par un pic exothermique. Celui-ci n'a évidemment jamais été visible sur nos essais à 5 % de  $\text{SO}_3$  ajoutés, puisque le sulfate n'était pas entièrement consommé à 24 heures, fin de nos enregistrements.

Mais dans les autres cas, ils ont été relativement peu souvent mis en évidence, comme le montre le tableau 2 : Ce pic "sulfatés" n'a jamais été observé avec l'anhydrite naturelle, ni avec le clinker C. C'est avec le clinker A qu'il a été le plus souvent rencontré. Il paraît difficile de tirer des conclusions ou des tentatives d'explication de ces quelques résultats.

Sulfate ajouté	% SO <sub>3</sub>	Clinker A	Clinker B	Clinker C	Clinker D
Gypse	1	très net 3 h	large 10 h	invisible	invisible

TABLEAU 2

## CONCLUSIONS

Les comportements des quatre clinkers étudiés vis-à-vis du "sulfatage" sont très différenciés, et le nombre d'essais réalisés est trop restreint pour pouvoir tirer des lois générales sur les interactions entre constitution du clinker - niveau de "sulfatage" - nature du sulfate de calcium. Ceci est d'autant plus vrai que nous ne connaissons pas tous les paramètres susceptibles d'agir.

Les principales conclusions que l'on peut tirer de ces essais sont les suivantes :

- Le premier pic d'hydratation est toujours diminué, mais on ne peut tirer de loi générale reliant cette diminution d'intensité à la nature ni à la quantité de sulfate ajouté.

- Le semi hydrate est très actif pour régulariser la prise du C<sub>3</sub>A. Mais son hydratation en gypse peut occasionner des raidissements, ou fausse prise sulfate. Il apparaît, d'après nos essais, que si le semi hydrate est pur (exempt de gypse) et si le clinker est pauvre en composés susceptibles d'activer la germination du gypse (sulfate alcalins par exemple), la fausse prise sulfate n'apparaîtra qu'à une échéance où elle ne gênera plus la mise en place.

- Nous confirmons que l'addition de sulfate de calcium empêche bien l'"empoisonnement" des silicates par l'alumine en solution. Cela se traduit par l'obtention d'un deuxième pic de calorimétrie dont l'échéance du maximum est raccourcie et ramenée à peu près au même temps de 8 à 12 heures. Cependant il existe une exception, avec le clinker B riche en sulfates alcalins, pour lequel le maximum du second pic est anormalement précoce, mais ramenée à une valeur habituelle par addition de sulfate de calcium.

- Le troisième pic d'hydratation (pic des sulfates) apparaît rarement. Il est plus visible avec le ciment A, le plus pauvre en sulfates alcalins. Il n'est jamais mis en évidence lorsque le sulfate ajouté est l'anhydrite naturelle : nous supposons que sa lenteur relative de passage en solution ne doit pas lui permettre de s'épuiser rapidement.

- Nous avons observé par diffraction X un blocage relatif de l'hydratation des aluminates avec les plus fortes additions de sulfate, qui se traduit par une plus grande quantité d'anhydres résiduels après 24 h d'hydratation.

La complexité des phénomènes explique le fait que nous n'ayons trouvé aucune loi valable entre composition de clinker et "sulfatage" d'une part, et cinétique d'hydratation d'autre part.

Nous avons cependant été surpris par le fait que, malgré sa faible réactivité avec l'eau, l'anhydrite naturelle se comporte le plus souvent, vis-à-vis de l'hydratation des aluminates et des silicates, de la même façon que le gypse et le surcuit.

Il reste donc beaucoup à apprendre sur le gypsage du ciment Portland, surtout si l'on songe que la température, l'énergie de malaxage, les adjuvants ou additions doivent jouer un rôle non négligeable sur le déroulement des phénomènes.

# Hydration of $C_3A$ in portland cement in the presence of different forms of calcium sulfate

## *L'hydratation de $C_3A$ de ciment portland en présence de diverses formes du sulfate de calcium*

I. ODLER, Institut für Stein und Erden - Clausthal-Zellerfeld, R.F.A.  
R. WONNEMAN

### RESUME :

L'influence du sulfate de calcium, sous forme d'anhydrite, d'hémihydrate et de gypse sur l'hydratation de  $C_3A$ , constituante d'un clinker préparé en laboratoire, a été étudiée. La cinétique d'hydratation et les phases formées ont été déterminées.

### ABSTRACT :

The effect of calcium sulfate in the form of anhydride, hemihydrate and gypsum on the hydration of  $C_3A$  present in a laboratory made portland clinker was studied. The kinetics of the hydration process and the phases formed were determined.

Within our work the effect of anhydrite  $\text{CaSO}_4$  ( $\text{CS}$ ), of calcium sulfate hemihydrate  $\text{CaSO}_4 \cdot 1/2\text{H}_2\text{O}$  ( $\text{CSH}_{0.5}$ ) and of gypsum  $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$  ( $\text{CSH}_2$ ) on the hydration of tricalcium aluminate  $3\text{CaO} \cdot \text{Al}_2\text{O}_3$  ( $\text{C}_3\text{A}$ ) present in a portland clinker was studied. The aim of the work has been to determine whether the rate of the hydration process and the quality of the hydration products formed is affected by the form of the sulfate employed.

### Experimental

The cements studied were prepared from a laboratory burned clinker (1 h at  $1350^\circ\text{C}$ ) containing 68,9%  $\text{CaO}$ , 21,9%  $\text{SiO}_2$ , 5,9%  $\text{Al}_2\text{O}_3$  and 3,3%  $\text{Fe}_2\text{O}_3$  (all other oxides  $<0,1\%$ ). The clinker contained 15%  $\text{C}_3\text{A}$  and 5%  $\text{C}_2$  ( $\text{AF}$ ) as determined by XQRD after concentrating these phases by dissolving the calcium silicates in methanolic maleic acid. The cements tested contained each 3,0%  $\text{SO}_3$  in form of anhydrite, hemihydrate and gypsum. For comparison a cement made from pure clinker without calcium sulfate added was studied as well. All cement were ground to a spec. surface area of  $3000 \pm 100 \text{ cm}^2/\text{g}$  (Blaine). The cements were allowed to hydrate in paste form ( $w/s = 0,50$ ) for different periods of time at  $20^\circ\text{C}$ . The hydration process was stopped by grinding the paste with acetone, filtering the resultant suspension and washing the residue with acetone and then with ethyl ether.

The non reacted fraction of  $\text{C}_3\text{A}$  was determined by XQRD after igniting the sample for 1 hour to  $600^\circ\text{C}$  by measuring the intensity of the peak  $d = 2,70\text{\AA}$ . This way the  $\text{C}_3\text{A}$  content of the sample could be determined with an accuracy of about  $\pm 0,5 \text{ g}/100 \text{ g}$  cement.

For quantitative determination of ettringite formed in the hydration of  $\text{C}_3\text{A}$  in the presence of calcium sulfate the DTA method can be employed only in pastes hydrated short time, as in the further course of hydration the endothermic peak belonging to ettringite gets overlapped by an endothermic region having its origin in the decomposition of the  $\text{CSH}$ -phase formed in the hydration of calcium silicates. Consequently in our experiments ettringite was determined by DTA only up to 30 min of hydration (Mettler 2000 apparatus, sample 10 mg,  $10^\circ\text{C}/\text{min}$ ,  $\text{N}_2$  atm.). For measuring the ettringite content in pastes with longer hydration times the area or the XRD peak  $d = 9,75\text{\AA}$  was determined and the obtained peak area was compared with the area of the 30 min peak for which the corresponding ettringite value has been already known on the basis of DTA determination. The non reacted fraction of calcium sulfate was determined by DTA (gypsum and and hemihydrate) or XQRD (anhydrite).

### Results

Fig. 1 shows the amount of  $\text{C}_3\text{A}$  used up in the hydration process as function of hydration time. In the absence of calcium sulfate about 1,5 g  $\text{C}_3\text{A}/100 \text{ g}$  cement was used up within the first 15 min of hydration; the hydrated amount stayed almost constant up to about 10 hours and started to increase again in the further course of hydration.

The three calcium sulfates affected the rate of  $\text{C}_3\text{A}$  hydration only insignificantly; here again an initial rapid hydration was followed by a dormant period and a renewed faster hydration after several hours.

Fig. 2: Shows the ettringite content of the pastes as function of hydration time. In all three cements the ettringite content rose up to a maximum and decreased in the further course of hydration. The beginning of the decline of the ettringite content coincided with the appearance of the monosulfate peak at  $d = 8,92\text{\AA}$  in the XRD diffraction pattern of the paste. The rate at which ettringite was formed was not uniform in the three cements. It was slowest in the cement containing anhydrite and about equally fast in the two remaining cements. In addition to that the maximum amount of ettringite formed was lower and the beginning of monosulfate formation was delayed in the cement containing calcium sulfate in the anhydrous form. The delayed formation of ettringite and monosulfate in presence of anhydrite as compared to cements containing hemihydrate and gypsum is obvious also from Fig. 3 in which the DTA curves of the cement pastes studied determined after different hydration times are shown.

Fig. 4: Shows the content of nonreacted calcium sulfate as function of hydration time. It appears that the rate at which calcium sulfate was used up was about identical in the case of hemihydrate and gypsum and significantly slower in the case of anhydrite. It may be also noted that, in addition to reacting with  $\text{C}_3\text{A}$ , the hemihydrate was gradually converted to dihydrate; this conversion was completed within about 30 min.

Finally in Tab. I the setting of the cements studied as determined by the Vicat needle penetration test is shown. It appears that both the amount of water needed to obtain normal consistency as well as the beginning and end of setting depended on the form of calcium sulfate present in the system.

### Discussion

A comparison of the hydration rates of  $\text{C}_3\text{A}$  in absence and presence of the three calcium sulfates revealed that the rate at which  $\text{C}_3\text{A}$  was used up was not altered significantly by the presence of any of the calcium sulfates in the system. This finding is contrary to the general view (1, 2, 3, 4, 5, 6) however in line with observations of Locher and coworkers (7) who found equal  $\text{C}_3\text{A}$  hydration rates in absence and presence of gypsum.

Unlike the  $\text{C}_3\text{A}$  hydration rate, the rate of ettringite formation was found to be different in the presence of different calcium sulfate forms, this phase being formed slowliest in the presence of anhydrite and about equally fast in presence of hemihydrate and gypsum. This difference may be due to the slower dissolution rate of the former compound in water. The extended duration of ettringite formation, the slower rate of  $\text{SO}_3$  depletion and the delayed beginning of monosulfate formation in the cement containing anhydrite were probably additional consequences of the lower dissolution rate of this calcium sulfate form.

In Fig. 5 the amount of ettringite formed v.s. amount of  $\text{C}_3\text{A}$  used up in the hydration is plotted. The straight line in the figure gives the amount of ettringite formed if the amount of  $\text{C}_3\text{A}$  shown on the abscissa is quantitatively converted to this phase. It can be seen from the figure that in the cements

containing hemihydrate or gypsum a significant fraction of  $C_3A$  used up in the hydration process formed ettringite. On the other hand less than one third of  $C_3A$  was converted to this phase in the cement containing the same amount of  $SO_3$  in form of anhydrite. It has to be assumed, that in the latter case, most of the  $C_3A$  hydrated to calcium aluminate hydrate due to an insufficient dissolution rate of this form of calcium sulfate.

From a comparison of the setting time determination data with the results of quantitative phase determination it appears that the setting time has been not only a function of the amount of  $C_3A$  hydrated and that other factors were involved as well. The flash setting of pure clinker was obviously not a consequence of excessive  $C_3A$  hydration as about similar amounts of  $C_3A$  hydrated in the three cements containing calcium sulfate did not cause setting. The reason for the instant setting of this cement is not obvious; it is conceivable that this phenomenon may be related to an altered crystall morphology of the hydration products formed under these conditions as suggested by (7). In the case of the cement containing hemihydrate one has to assume that its relatively fast setting is related to the conversion of hemihydrate to gypsum rather than to reactions involving  $C_3A$ . The shorter setting time and higher water requirements of the cement containing anhydrite as compared to the one with gypsum are probably due to the conversion of a significant part of  $C_3A$  to calcium aluminate hydrate rather than to ettringite in the hydration of the former cement.

#### Conclusions

1. In the hydration of finely ground portland cement clinker in absence of calcium sulfate an intensive hydration of  $C_3A$  takes place right after contact with water; the fast initial reaction is succeeded by a dormant period of rather slow hydration and a renewed fast hydration after several hours. An addition of  $SO_3$  in form of anhydrite, hemihydrate or gypsum does not alter the kinetics of  $C_3A$  hydration significantly.
2. In the presence of any of the calcium sulfates ettringite is formed as the first product of  $C_3A$  hydration to be converted later on to monosulfate. The rate of ettringite formation is significantly reduced and the beginning of the conversion to monosulfate is delayed if anhydrite, rather than hemihydrate or gypsum is employed as  $SO_3$  source.
3. The flash setting of portland cement in absence of calcium sulfate does not appear to be due to excessive  $C_3A$  hydration as equal amounts of  $C_3A$  hydrated in presence of calcium sulfates do not produce cement setting.

B. OSBAECK, DK-2500 Valby Copenhagen, Denmark.

RESUME : L'évolution des résistances des ciments Portland est influencée par leur teneur en  $\text{C}_3\text{A}$ . La cause de cette influence n'est cependant pas entièrement établie; elle peut être due à des modifications tant de la composition des hydrates constitués que de leur quantité. La quantité d'hydrates peut être affectée tant par la propre hydratation du  $\text{C}_3\text{A}$  que par les modifications de l'hydratation du  $\text{C}_3\text{S}$  provoquées par le  $\text{C}_3\text{A}$ .

Pour connaître l'importance relative de ces divers effets possibles, plusieurs clinkers cuits en laboratoire ont été examinés. Ces clinkers ont été broyés avec des proportions variables de  $\text{SO}_3$ . L'évolution des résistances des mortiers et l'allure de l'hydratation des pâtes ont été suivies en recourant à la diffractométrie quantitative par Rayons X.

Il ressort des résultats obtenus que le  $\text{C}_3\text{A}$  de tous les ciments examinés contribue positivement, de lui-même, aux résistances des ciments. En même temps, il semble que le  $\text{C}_3\text{A}$  exerce une influence négative sur le taux d'hydratation du  $\text{C}_3\text{S}$ . Cet effet est dominant pour une forte teneur en  $\text{C}_3\text{A}$  et en fin de prise. Dans cet article sont expliquées les causes possibles des effets ainsi observés.

SUMMARY: The strength development of Portland cements is influenced by their contents of  $\text{C}_3\text{A}$ . The cause of this influence, however, is still controversial and can be due to changes both in the composition, and in the amount, of the hydrates formed. The amount of hydrates can be affected both by the hydration of  $\text{C}_3\text{A}$  itself and by changes in  $\text{C}_3\text{S}$  hydration induced by  $\text{C}_3\text{A}$ .

To elucidate the relative importance of these possible effects, a series of laboratory-burned clinkers have been investigated. From the clinkers, cements with different  $\text{SO}_3$ -contents have been prepared. The development of strength has been followed in mortars, and the course of hydration in pastes, using quantitative X-ray-diffraction.

From the results obtained it appears that  $\text{C}_3\text{A}$  in all amounts examined gives an independent positive contribution to the strength-producing properties of the cements. Simultaneously, however,  $\text{C}_3\text{A}$  seems to have a negative influence on the rate of  $\text{C}_3\text{S}$  hydration. This effect dominates at high  $\text{C}_3\text{A}$  levels and at late ages. Possible explanations for the observed effects are given.

## INTRODUCTION

It is well established that the presence of  $C_3A^*$  in Portland cement affects its strength producing properties. Qualitatively,  $C_3A$  raises the early strength, an effect still observable at 7 and 28 days curing (20°C), but seems to have a negative influence at late ages. The quantitative effect is dependent on which component  $C_3A$  is replacing in the cement (1), and also on the amount of  $SO_3$  and alkalis present. A recent review on this topic is given by Schrämli (2).

Many of the explanations given for the effect of  $C_3A$  take as a starting point an observed acceleration of  $C_3S$  hydration, due to the presence of  $C_3A$ . The independent contribution from  $C_3A$  to the overall degree of hydration is viewed as unimportant, or even harmful to the strength of the product. (3, 5).

This paper is a further contribution to the understanding of the effect of  $C_3A$ , with special reference to the interrelationship between the rates of hydration of  $C_3A$  and  $C_3S$  in Portland cement.

The following three potential clinker compositions were formulated to permit observations of the hydration-related effects of partial or total replacement of  $C_4AF$  by  $C_3A$ :

TABLE 1			
Planned Clinker Compositions			
	BA	B	BF
$C_3S$	60	60	60
$C_2S$	22	22	22
$C_3A$	16	8	0
$C_4AF$	2	10	18

## EXPERIMENTAL

The raw mixtures were formulated from 75% of an industrial material, corrected with 25% analytical grade reagents to the desired compositions. Each mixture was ground to pass a 90  $\mu m$  sieve.

The heat treatment was carried out in 300 g batches of powdered raw meal in an open platinum crucible. After calcination for 30 min. at 1050°C the crucible was placed in an electric furnace preheated to the desired reaction temperature.

\* Throughout the paper the oxide abbreviations  $C_3S$ ,  $C_2S$ ,  $C_3A$ , and  $C_4AF$  are used to designate the solid solutions of the four major clinker minerals.

The bottom of the crucible reached the reaction temperature after about 20 min. Clinker BF and B were kept for 40 min. at 1450°C, while clinker BA required 80 min. at 1500°C to attain a free lime level below 1.5%. The crucible was cooled to 1300°C during 20-25 min. in the furnace; then air-cooled from 1300°C to ambient.

The composition of the clinkers was characterized by the following techniques: Total chemical analysis by X-ray fluorescence, mineralogical composition by X-ray diffraction, chemical composition of the clinker minerals by scanning electron microscopy with EDAX-analyzer, and structure description by optical microscopy.

Three cements were made from each clinker with different levels of  $SO_3$  added as equal amounts of calciumsulphate-dihydrate and calciumsulphate-hemihydrate. The precrushed clinkers (~1 mm) were mixed with the desired amount of  $SO_3$  and ground in a ball mill for 15 min. The differences in fineness thus reflect differences in grindability.

The cements were characterized by determinations of grain size distribution, using Laser granulometry, specific surface according to Blaine, and the total sulphur content.

The strength development of the cements was determined in mortars according to the ISO-RILEM procedure (sand-cement-water, 3 : 1 : 0.5), except that the specimen dimensions were 2 x 2 x 5 cm<sup>3</sup>, and the mixing and casting procedures differed slightly. The method used gives results approximately 25% higher than the standard ISO-RILEM procedure. The bulk density of the mortars was measured after 1 day of curing. The compressive strength was determined after 1, 3, 7, 28, and 90 days.

The course of hydration was followed in pastes, using X-ray diffraction. The cements were mixed with 10% analytical grade  $CaF_2$  as internal standard, and cast with a water-cement-ratio of 0.44 in 1 cm<sup>3</sup> cylinders. The paste specimens were cured at 100% relative humidity, which resulted in weak carbonation during hardening.

The residual unhydrated  $C_3S$ ,  $C_3A$ , and  $C_4AF$  were determined after 1, 3, and 28 days' during at 20°C. At each fixed time, four cylinders were broken to determine the compressive strength. The results were in agreement with the mortar results, but gave inferior reproducibility.

The crushed specimens were ground with isopropanol and dried at 65°C. (Residual  $C_3S$  was determined from the peaks at 30.102° and 51.702° ( $Cu-K\alpha$ -radiation); then the samples were treated with salicylic acid-methanol to remove anhydrous silicates. After a quantitative filtration and drying,  $C_3A$  and  $C_4AF$  were determined in the residue.

Attempts to develop a sufficiently reproducible procedure for the determination of  $C_2S$  consumption were not successful.

## RESULTS

The results are shown in figures 1-3 and in tables 2-5. From table 2 it appears that the desired clinker compositions were obtained.

The microanalysis of the clinker minerals in table 3 show that the contents of  $Al_2O_3$  and  $Fe_2O_3$  in the silicate phases depend nearly linearly on the composition of the interstitial phase. The molar sum of  $Al_2O_3$  and  $Fe_2O_3$  (A+F in table 3) seems to be independent of the  $Al_2O_3/Fe_2O_3$ -ratio and the fraction of  $Al_2O_3$  ( $f_A$  in table 3) is almost the same in the three measured phases.

The X-ray-diffraction patterns in fig. 1 show that the  $C_2S$  is in the  $\beta$ -modification in the high  $Al_2O_3$  clinker (BA), but is stabilized in a high-temperature modification in the  $Fe_2O_3$ -rich clinker (BF). From table 3 it appears that the difference cannot be explained from differences in the  $K_2O$  contents.

Fig. 2 shows the micro-structure of the BA and BF clinkers. The  $C_3S$ -borders in clinker BA are diffuse, and surrounded by small crystals of  $C_2S$ , while the  $C_3S$ -borders of the BF clinker appear unaffected. The effect has been described earlier (8) as due to the corrosive behaviour of high  $Al_2O_3$ -melts on  $C_3S$  during the cooling.

Data obtained from cement testing are shown in table 4. The grain-size distribution are approximated by Rosin-Rammler-distributions, from which the steepness ( $n$ ) and the calculated

residue on  $20\ \mu m$  ( $R_{20\mu}$ ) are given in the table. Also given in the table are the measured specific surface of the cement, bulk density of mortar and the compressive strength.

However, to obtain more comparable strength results, two corrections have been applied, one correcting for differences in fineness, and the other for differences in bulk density. Fig. 3 shows the corrected strength results, together with the measured data. The corrections do not alter the qualitative results, but give the relevant data, which are suitable for direct quantitative comparison.

In order to correct strength values to equal clinker fineness, the contribution to the measured fineness from the added  $SO_3$  is calculated using linear regression. From this a specific surface of each cement is calculated as if it contained 4% added "mixed" gypsum, designated as Blaine, 4% in table 4. These values are used to correct the strength to a 'constant clinker fineness' basis, using empirical constants of  $0.045\ MPa/m^2/kg$  at 1 and 90 days and  $0.09\ MPa/m^2/kg$  at 3, 7, and 28 days. The largest correction in this set of data is  $70 \cdot 0.09\ MPa = 6\ MPa$ .

Corrections for air entrained during mixing and casting are made by adding 5% to the strength value for each 1% air entrained equivalent to a 1% reduction in mortar density. The largest correction attributable to entrained air in the set of data is  $5 \cdot (2300 - 2263) / 23 = 8.0\% = 5 \text{ MPa}$ , taking  $2300 \text{ kg/m}^3$  as the reference density for all mortars.

Finally, table 5 shows the measured extents of reaction of five selected cements, together with the relevant strength data, corrected for bulk density but not for fineness deviations. As mentioned earlier, reproducible methods to assess the extent of hydration of C<sub>2</sub>S have not been developed. However, for the measurements carried out, there was no measurable reduction in the amount of anhydrous C<sub>2</sub>S after 1 or 3 days. The degree of reaction after 28 days averaged 0.25.

#### DISCUSSION

The replacement of C<sub>4</sub>AF by C<sub>3</sub>A has simultaneously changed the composition and structure of the silicates. The importance of these changes with respect to cement hydration characteristics cannot be derived from the data given here. However, preliminary results (9) from experiments intended to give such information have not shown measurable effects from changes in C<sub>3</sub>S-composition. As regards C<sub>2</sub>S the question is open.

The strength development curves from fig. 3 which are in accordance with the results of Celani and Ish-Shalom (3,10), show a complex pattern with an optimum amount of both  $C_3A$  and added  $SO_3$ , indicating that several mechanisms act together; some of them can be understood by comparing the results of fig. 3 and table 5, as follows:-

The positive effect of  $SO_3$  on the early hydration age (1 and 3 days) of  $C_3S$  is seen by comparing early strengths of cement BF 1 with those of BF 4. (7). Also the retarding influence of  $SO_3$  on the early hydration of  $C_3A$  is seen by comparing strength results of cement BA 4 with BA 8 (6). The parameter with the greatest influence on the early strength, thus seems to be the content of added  $SO_3$ . The effect of  $C_3A$  is less clear.

28 days	10.5	5	-15	-17
90 days	7	2	-17.5	-19.5

The quantitative effect of  $C_3A$  is seen in table 6. Comparison of the results of BF 2 - BF 4 with B 2 - B 4 shows that B-cements are superior at all ages. However, half of the potential strength gain is lost due to air entrainment. The magnitude of this effect depends on the casting and mixing procedure.

The observed potential strength gains can be explained by the hydration data for BF 4 (0%  $C_3A$ ) and B 4 (8%  $C_3A$ ). Since there is no significant difference in degree of reaction of  $C_3S$  between the two samples, the strength differences can best be attributed to a larger contribution to the overall degree of hydration from  $C_3A$  than from  $C_4AF$ .

Further, large substitutions of  $C_3A$  for  $C_4AF$  give no further strength gains, as seen from a comparison of the strengths of B 4 - B 6 and of BA 4 - BA 6. On the contrary a strength loss is seen at late ages. From the hydration data in table 5 this can be explained as a result of the generally lower degree of reaction of  $C_3S$  in BA-cements, which only at early ages can be compensated for by a larger contribution to the overall degree of hydration from  $C_3A$ .

It seems, therefore as if  $C_3A$  in large amounts has a negative influence on the rate of hydration of  $C_3S$ . A possible explanation is that  $C_3A$  competes with  $C_3S$  for the available water in the mortar. Although  $C_3A$  makes up only 16% of the cement, it would require 1/3 of the water in the mortar to be completely converted to monosulphate hydrate, which is the hydrate consuming the least water. This could well lead to local depletion of free water near  $C_3S$  surfaces. Consistent with this explanation it is reasonable that the degree of hydration of  $C_3S$  at 28 days is larger in BA 8 than in BA 4, since  $C_3A$  has been retarded for a longer period in BA 8. The lack of water thus is felt somewhat later in BA 8.

Summing up we propose the effect of  $C_3A$  as being composed of three different partial effects:

The positive effect of  $C_3A$  is that it reacts faster than  $C_4AF$ , leading to a larger contribution to the overall degree of hydration. This is demonstrated in fig. 4. The initial amount of  $C_3S$  ( $f_{C_3S}$ ) and the degree of reaction of  $C_3S$  ( $\alpha_{C_3S}$ ) are used to calculate the reduction in porosity associated with the consumption of  $C_3S$ : ( $\theta$  = porosity,  $w/c$  = 0.5)

$$(1-\theta)_{C_3S} = \frac{0.25 \cdot f_{C_3S} \cdot \alpha_{C_3S} + 31.75}{31.75 + 50.00}$$

In fig. 4, this parameter,  $(1-\theta)_{C_3S}$ , is plotted against the logarithm of the strength results, corrected for bulk density, from table 5. It is seen that the data fall in groups according to the  $C_3A$  contents of the cements, demonstrating that  $C_3A$  gives an independent positive contribution to strength at all ages.

Fig. 4 - Illustration of the independent contribution from  $C_3A$  to the mortar strength.

The unfavourable effects of  $C_3A$  observed are the entrainment of air in the mortars and the negative influence on  $C_3S$  consumption at late ages as seen in the BA-cements.

No unambiguous evidence of a positive influence of  $C_3A$  on the early hydration of  $C_3S$  was found. It seems as if the major accelerator of the early  $C_3S$ -hydration is the cement  $SO_3$ .

In this attempt to account for the effect of  $C_3A$  on strength primarily in terms of differences in the overall degree of hydration, the authors do not ignore the importance of hydration product quality aspects. These have, however, not been the subject of this investigation.

#### CONCLUSIONS

When  $C_3A$  is substituted for  $C_4AF$  in Portland cement it will contribute positively to mortar strength at all ages due to its higher reactivity.

This positive effect is, however, counteracted by two negative effects of increasing the  $C_3A$ -content in the cement:

- a tendency of increasing air entrainment, an effect which must be expected to be rather dependent on the testing procedure, and
- a negative influence on the degree of hydration of  $C_3S$  at late ages, an effect which could be due to the high water needs of  $C_3A$ -hydration.

The present investigation does not provide evidence to a positive effect of  $C_3A$  on  $C_3S$  hydration; however, a positive effect of cement  $SO_3$  is seen.

#### ACKNOWLEDGEMENTS

The efficient technical assistance of Dorthe Lotz Clasen and Margrethe Møller is gratefully acknowledged. F. MacGregor Miller's critical remarks helped to clarify linguistic and conceptual difficulties.

# Theme 4 - Hydration of $C_3A$ in the presence of admixtures

## GENERAL REPORT

by V.S. RAMACHANDRAN, Division of Building Research, National Research Council of Canada, Ottawa, Ontario, CANADA.

This report summarizes six papers. Although the amount of  $C_3A$  present in portland cement is relatively low in comparison with other phases, it exerts a significant influence on the heat development, setting property and early strength development.

COLLEPARDI, CORRADI, BALDINI and PAURI investigated two sets admixtures, namely,  $Na_2CO_3$  + Na-lignosulphonate and sulphonated naphthalene formaldehyde on the hydration of  $C_3A$  + CH and  $C_3A$  + CH +  $C_2SH_2$  systems, respectively. At different hydration periods, varying between 5 min and 7 days, the products were examined by DTA, DTG, TG and XRD. Zeta potential measurements were also carried out using a  $C_3A$ /solution ratio of 10.

In the  $C_3A$ -CH- $H_2O$  system, monitoring of  $C_3A$  peak intensity by XRD indicated that the addition of  $Na_2CO_3$  + Na-lignosulphonate retarded the hydration of  $C_3A$ . Significant changes in the Zeta potentials were observed in mixtures containing the admixtures. In  $C_3A$ - $H_2O$  system, the value was 37.4 mV and by the addition of the admixture combination, it attained a value of -41.5 mV, indicating high dispersion. The change in the Zeta potential was less remarkable when the admixtures were not used in combination. In the  $C_3A$ - $C_2SH_2$ - $H_2O$  system, the effect of sulphonated naphthalene formaldehyde showed that it neither modifies the rate of formation of ettringite and its subsequent conversion of the low sulphoaluminate, nor the type of hydration products. This admixture changes the Zeta potential from -8.5 to -30.9 mV.

It can be concluded that the flowability in the  $C_3A$ -CH- $H_2O$  or  $C_3A$ - $C_2SH_2$ -CH- $H_2O$  system containing  $Na_2CO_3$  + Na-lignosulphonate or sulphonated naphthalene formaldehyde depends on Zeta potential changes, retardation of the initial stages of reaction and possibly water/solid ratio.

MASSAZZA and COSTA have reported the effect of Na-lignosulphonate or alkyl naphthalene sulphonate formaldehyde on the hydration of  $C_3A$  +  $CaSO_4 \cdot 2H_2O$  mixtures. The products formed within a few minutes and those up to 3 days were examined by XRD, TG, DSC, thermoluminescence, adsorption and electron microscopic and conduction calorimetric techniques.

Admixtures retarded the hydration reactions. For example, in the absence of admixtures, gypsum is consumed in the reaction in 4 h, in the presence of 1% naphthalene sulphonate formaldehyde gypsum disappears after 7 h and in the presence of 1% Na-lignosulphonate gypsum persists up to 36 h. Adsorption of these admixtures carried out on ettringite and monosulphonate in a non-aqueous medium showed that substantial amounts were adsorbed. An electron microscopic examination revealed that, whereas ettringite

fibres formed in the absence of the admixtures, smaller size crystals of ettringite, appearing as fine felts, covered the  $C_3A$  grains in the presence of the admixtures.

It is concluded that the flowability in the  $C_3A$  +  $CaSO_4 \cdot 2H_2O$  +  $H_2O$  system is caused by the retardation of ettringite in the presence of admixtures, resulting in a decrease in the water demand. In addition, the admixtures, by decreasing the interlocking of ettringite crystals, enhance the flowability of pastes.

RAMACHANDRAN, in an elucidation of the role of lignosulphonates on the hydration of  $C_3A$ , has studied the hydration and adsorption-desorption isotherms of systems containing  $C_3A$ ,  $C_3S$ ,  $C_4AH_{13}$ - $C_2AH_8$ ,  $C_3AH_6$  and  $C_3S$ , in the presence of Ca- and Na-lignosulphonates. The products were examined by XRD, DTA and SEM.

In the system  $C_3A$ - $H_2O$ -Ca-lignosulphonate, treated with 15, 30, 50, 100 and 200% CLS, a complex gelatinous product is formed containing  $Al^{3+}$ . In an aqueous medium both hexagonal and cubic aluminate hydrates adsorb lignosulphonate irreversibly. An evidence for a complex and interlayer adsorption was also obtained in the hexagonal aluminate hydrate. In the non-aqueous medium, only the hexagonal phase irreversibly adsorbs lignosulphonate. Consequently it is suggested that the present tendency of explaining the retardation action on the basis of adsorption of lignosulphonate on  $C_3A$  should be altered to "consumption of lignosulphonate by the hydrating  $C_3A$ ". The influence of the small amounts of calcium aluminate and its hydrates on the hydration of  $C_3A$  in the presence of calcium lignosulphonate can be explained by the relative adsorption effects which are in the order of  $C_3A > \text{hexagonal phase} > \text{cubic phase}$ . As  $C_3A$  adsorbs substantial amounts of lignosulphonate it should follow that in commercial lignosulphonates containing sugars, the lignosulphonate should play an important role in retardation effects. Data have been presented to show the sugar-free Na- or Ca-lignosulphonate is as effective as the commercial lignosulphonates in retarding the hydration of  $C_3A$ .

It has been concluded that  $C_3A$  can interact with lignosulphonate in the presence of water to form a complex compound. Both hexagonal and cubic aluminate hydrates adsorb lignosulphonate irreversibly in an aqueous medium. In a non-aqueous medium, only the hexagonal phase adsorbs lignosulphonate, indicating that for adsorption or interaction of lignosulphonate with  $C_3A$  the presence of water is necessary. Sugar-free Ca- or Na-lignosulphonate retards the hydration of  $C_3A$  as efficiently as commercial lignosulphonates.

ZIELINSKA and ZIELINSKI investigated the effect of  $\text{Na}_2\text{S}_2\text{O}_3$  on the hydration of  $\text{C}_3\text{A}$  alone and in portland cement clinker. The mixtures were hydrated to different times between 1 h and 28 days and subjected to examination by XRD, TG, IR and SEM.

In the hydration of  $\text{C}_3\text{A}$ ,  $\text{Na}_2\text{S}_2\text{O}_3$  retards the formation of hexagonal phases and their conversion to the cubic phase, changes the morphology of the cubic aluminate hydrate. Complex compounds of the AFm type containing  $\text{S}_2\text{O}_3^{2-}$  group are formed; the deformed agglomerates of hexagonal phase also result. The polyhydrons of large dimension of  $\text{C}_3\text{AH}_6$ , evident without admixture, are converted to small octahedrons of  $\text{C}_3\text{AH}_6$  in the presence of  $\text{Na}_2\text{S}_2\text{O}_3$ . In the clinker,  $\text{Na}_2\text{S}_2\text{O}_3$  seems to accelerate the hydration of  $\text{C}_3\text{A}$ . At 8 h in the presence of the admixtures, needles analogous to ettringite are formed, probably a complex compound of the AFt type containing  $\text{S}_2\text{O}_3^{2-}$  groups.

It is concluded that  $\text{Na}_2\text{S}_2\text{O}_3$ , although a retarder for the hydration of  $\text{C}_3\text{A}$ , acts as an accelerator of  $\text{C}_3\text{A}$  when it is present in the clinker. Certain morphological changes of the hydration products and formation of complex compounds containing  $\text{S}_2\text{O}_3^{2-}$  groups are also indicated.

SERSALE, SABATELLI and VALENTI examined the effect of Na-gluconate, copper acetate and aluminum phosphate on the hydration of  $\text{C}_3\text{A}$  up to 48 h, utilizing XRD, DTA, TG and SEM techniques.

All the admixtures retarded the hydration of  $\text{C}_3\text{A}$ , Na-gluconate being the most efficient retarder. At 48 h, the degree of hydration was almost constant in the presence of all admixtures but this value was still lower than that observed for sample hydrated without an admixture. Comparison of the products at 50% hydration showed that in the presence of retarders, hexagonal rather than the cubic phase was present. The micrographs of samples hydrated to the same degree do not show any significant differences.

It is concluded that Na-gluconate, copper acetate and aluminum phosphate retard the hydration of  $\text{C}_3\text{A}$  by stabilization of the hexagonal calcium aluminate hydrate. These admixtures do not alter the morphological features of the products.

REGOURD, MORTUREUX and HORNAIN studied the effect of  $\text{CaCl}_2$  and sucrose on the hydration of  $\text{C}_3\text{A}$ ,  $\text{C}_3\text{S}$ ,  $\text{C}_3\text{A} + \text{C}_3\text{S} + \text{gypsum}$  and portland cement utilizing XRD and electron microscopic techniques.

Tricalcium aluminate hydrates to hexagonal phase followed by the cubic phase in two days. In the presence of  $\text{CaCl}_2$ , chloroaluminate is formed but the rate of hydration is not affected. Sucrose is a retarder and inhibits the hydration after two days, forming ill-crystallized  $\text{C}_4\text{AH}_{13}$ . A product enveloping the  $\text{C}_3\text{A}$  grains was indicated in the SEM. In the  $\text{C}_3\text{S} + \text{C}_3\text{A} + \text{gypsum}$  system, ettringite forms initially and is converted to monosulphate and finally to a solid solution of monosulphate and  $\text{C}_4\text{AH}_{13}$ . Calcium chloride is an accelerator for  $\text{C}_3\text{S}$  hydration up to seven days. The microstructure of C-S-H is also modified. It is also observed that  $\text{CaCl}_2$  is a better retarder than gypsum for  $\text{C}_3\text{A}$  hydration. In the presence of  $\text{CaCl}_2$ , hexagonal plates of chloroaluminate are formed. Sucrose retards the hydration of  $\text{C}_3\text{S}$  up to two days and then acts as an accelerator. Sucrose, although a retarder for  $\text{C}_3\text{A}$  hydration, is less effective than  $\text{CaCl}_2$ . In portland cement,  $\text{CaCl}_2$  acts as an accelerator and sucrose as a retarder between four and sixteen hours. After twenty-four hours, portland cement alone or that with the admixtures shows the same rate of

hydration.

It is considered that  $\text{CaCl}_2$  affects the hydration of cement at the outset by influencing the nucleation of C-S-H and CH. In  $\text{C}_3\text{A}$ -gypsum- $\text{CaCl}_2$  system, competition exists between gypsum and  $\text{CaCl}_2$ . Calcium chloride is a better retarder than gypsum up to twenty-eight days. The formation of a coating of chloroaluminate may explain the retardation. Sucrose is a retarder of  $\text{C}_3\text{A}$  hydration and forms ill-crystallized aluminate hydrates.

B. CASU, M. CHIRUZZI, F. TEGIACHI and G. ZOPETTI studied the effect of aqueous solutions of some carbohydrates and the corresponding aldonates on the hydrating  $\text{C}_3\text{A}$ . Techniques such as optical rotation, potentiometer, NMR and IRA were used to follow changes occurring from 1 min to 100 min. Within a few minutes after contact of  $\text{C}_3\text{A}$  with reducing glucose and maltose, precipitation occurred. Evidence was obtained for the formation of complexes in solution between  $\text{C}_3\text{A}$  and sodium gluconate and this preceded the precipitation on  $\text{C}_3\text{A}$ . The protective layer thus formed retarded the hydration and set.

#### CONCLUDING REMARKS

Although  $\text{C}_3\text{A}$  content in portland cement is low, it influences significantly many physical, chemical and mechanical properties of the cement such as setting rheology, early strength, sulphate attack, heat effect, carbonation, etc. Since  $\text{C}_3\text{A}$  seems to adsorb large amounts of different admixtures, it is very essential to study the role of  $\text{C}_3\text{A}$  and  $\text{C}_3\text{A} + \text{gypsum} + \text{CH}$  systems and their interaction with admixtures. The importance of such studies becomes evident from the number of new admixtures (93, 71, 73 and 88 in 1976, 1977, 1978 and 1979, respectively) that have been developed.

One of the problems encountered in the study of systems containing  $\text{C}_3\text{A}$  is the variation of results reported by different workers. One of the obvious problems is that the hydration is relatively fast. Many factors influence the reaction rate and these include the shape of the bulk sample, size of the material taken for a particular study, pre-exposure conditions, effect of impurities, the difference in the reactivity of samples apparently of same particle size, the W/S ratio, temperature, etc. This becomes more complex when admixtures and admixture combinations are added to  $\text{C}_3\text{A}$  systems. The influence of the molar concentrations of admixtures in solutions is often neglected and comparisons are generally made on the basis of a particular percentage of admixture with respect to solid  $\text{C}_3\text{A}$ .

It is very important to investigate the influence of admixtures on  $\text{C}_3\text{A}$  and  $\text{C}_3\text{A} + \text{gypsum}$  systems but often these results may not be directly applicable to portland cement systems because of the role of other phases and also because  $\text{C}_3\text{A}$  in portland cement contains Na in solid solution.

The limitation of various techniques should also be considered in evaluating results. One of the necessary requirements should be that all published reports should contain the essential information that would characterize the materials and experimental conditions. This may be a starting point for eventual comparison of results obtained in different laboratories and for answer to many questions.

# Thème 4 - Hydratation de $C_3A$ en présence d'adjuvants

## RAPPORT GENERAL

par V.S. RAMACHANDRAN, Division of Building Research National, Research Council of Canada, Ottawa, Ontario, CANADA.

Ce rapport résume sept contributions. Bien que la teneur en  $C_3A$  présent dans le ciment portland soit relativement faible comparée à celle d'autres phases, elle exerce une influence significative sur le dégagement de chaleur, la prise et le développement des premières résistances.

COLLEPARDI, CORRADI, BALDINI et SAURI ont étudié deux séries d'adjuvants, à savoir  $Na_2CO_3$  + lignosulfonate de Na et formaldéhyde de naphthalène sulfoné, sur l'hydratation des systèmes  $C_3A$  + CH et  $C_3A$  + CH +  $C_5H_2$  respectivement. A différentes périodes d'hydratation, variant entre 5 minutes et 7 jours, les produits ont été examinés par ATD, DTG, TG et DRX. Les mesures de potentiel Zêta ont aussi été effectuées en utilisant un rapport  $C_3A$ /solution égal à 10.

Dans le système  $C_3A$  - CH -  $H_2O$ , l'évolution de l'intensité du pic de  $C_3A$  par DRX indique que l'addition de  $Na_2CO_3$  + lignosulfonate retarde l'hydratation de  $C_3A$ . Des changements significatifs dans les potentiels Zêta ont été observés dans les mélanges contenant les adjuvants. Dans le système  $C_3A$  -  $H_2O$ , la valeur était de 37,4 mV et par addition de la combinaison d'adjuvants, il atteignait une valeur de -41,5 mV, avec une dispersion élevée. Le changement du potentiel Zêta était moins marqué quand les adjuvants n'étaient pas utilisés en combinaison.

Dans le système  $C_3A$  -  $C_5H_2$  -  $H_2O$ , l'effet du formaldéhyde de naphthalène sulfoné montre qu'il ne modifie ni le taux de formation de l'ettringite ni sa conversion ultérieure en monosulfoaluminate ni le type des produits d'hydratation. L'adjuvant change le potentiel Zêta de -8,5 à -30,9 mV.

On en conclut que la fluidité des systèmes  $C_3A$  - CH -  $H_2O$  ou  $C_3A$  -  $C_5H_2$  - CH -  $H_2O$  contenant  $Na_2CO_3$  + lignosulfonate de Na ou le formaldéhyde sulfoné dépend des changements du potentiel Zêta, du retard des stades initiaux de la réaction et peut-être du rapport eau/solide.

MASSAZZA et COSTA ont rapporté l'effet du lignosulfonate de Na et du formaldéhyde d'alkyl naphthalène sulfoné sur l'hydratation de mélanges  $C_3A$  +  $CaSO_4 \cdot 2H_2O$ . Les produits formés en quelques minutes et ceux formés pendant les trois premiers jours ont été examinés par DRX, TG, DSC, thermoluminescence, microscopie électronique, adsorption isotherme et calorimétrie à conduction. Les adjuvants retardent les réactions d'hydratation. Par exemple, en absence d'adjuvants, le gypse est consommé dans la réaction en 4 heures; en présence de 1 % de formaldéhyde de naphthalène sulfoné, il disparaît après 7 heures et en présence de 1 % de lignosulfonate de Na, il persiste jusqu'à 36 heures. L'adsorption de ces adjuvants effectuée dans un milieu non aqueux montre que des quantités substantielles sont adsorbées, sur l'ettringite ou le monosulfate. Un examen au microscope électronique révèle que, en absence d'adjuvants, l'ettringite cristallise en fibres tandis qu'en présence d'adjuvants, des cristaux

de plus petite taille forment un feutrage fin couvrant les grains de  $C_3A$ .

On en conclut que la fluidité du système  $C_3A$  +  $CaSO_4 \cdot 2H_2O$  est due au retard de la formation d'ettringite en présence d'adjuvants qui entraîne une demande d'eau plus faible. De plus, en réduisant l'enchevêtrement des cristaux d'ettringite, les adjuvants améliorent la rhéologie des pâtes.

RAMACHANDRAN a étudié l'hydratation et les isothermes d'adsorption-désorption des systèmes contenant  $C_3A$ ,  $C_3S$ ,  $C_4AH_{13}$  -  $C_2AH_8$ ,  $C_3AH_6$  et  $C_3S$ , en présence de lignosulfonates de Ca et de Na afin d'expliquer leur rôle sur l'hydratation de  $C_3A$ . Les produits ont été examinés par DRX, ATD et MEB.

Dans le système  $C_3A$  -  $H_2O$ , traité avec 15, 30, 50, 100 et 200 % de lignosulfonate de Ca, il se forme un complexe gélatineux contenant  $Al^{3+}$ . Dans un milieu aqueux, les hydrates d'aluminate à la fois hexagonaux et cubiques adsorbent le lignosulfonate irréversiblement. Un complexe interlamellaire d'adsorption a aussi été mis en évidence dans les aluminates hydratés hexagonaux. Dans un milieu non aqueux, seule la phase hexagonale adsorbe irréversiblement le lignosulfonate. Par conséquent, on peut suggérer que l'action retardatrice fondée sur l'adsorption du lignosulfonate sur  $C_3A$  puisse être modifiée en "consommation du lignosulfonate par le  $C_3A$  qui s'hydrate". L'influence de petites quantités d'aluminate de calcium et de ses hydrates, sur l'hydratation de  $C_3S$  en présence de lignosulfonate de Ca, peut être expliquée par les effets relatifs d'adsorption qui sont dans l'ordre,  $C_3A$  > phase hexagonale > phase cubique. Comme  $C_3A$  adsorbe des quantités substantielles de lignosulfonates, ceux contenant des sucres, devraient jouer un rôle dans les effets retardateurs. Des résultats publiés montrent que le lignosulfonate de Na ou de Ca, sans sucre, est aussi efficace dans le retard de l'hydratation de  $C_3A$  que les lignosulfonates commerciaux.

On en conclut que  $C_3A$  peut interagir avec le lignosulfonate en présence d'eau pour former un composé complexe. Les aluminates hydratés à la fois hexagonaux et cubiques adsorbent irréversiblement le lignosulfonate dans un milieu aqueux. Seule la phase hexagonale adsorbe le lignosulfonate indiquant que pour l'adsorption ou l'interaction du lignosulfonate avec  $C_3A$ , la présence d'eau est nécessaire. Le lignosulfonate de Ca ou de Na, sans sucre, retarde l'hydratation de  $C_3A$  aussi efficacement que les lignosulfonates commerciaux.

ZIELINSKA et ZIELINSKI ont étudié l'effet de  $Na_2S_2O_3$  sur l'hydratation de  $C_3A$  seul et dans le clinker de ciment portland. Les mélanges ont été hydratés à des temps différents entre 1 heure et 28 jours et examinés par DRX, TG, IR et MEB.

Dans l'hydratation de  $C_3A$ ,  $Na_2S_2O_3$  retarde la formation des phases hexagonales et leur conversion

en phase cubique et change la morphologie de l'aluminate hydraté cubique. Il se forme des composés complexes du type AFm contenant le groupe  $S_2O_3^{2-}$ . Il en résulte des agglomérats de phase hexagonale. Les polyèdres de  $C_3AH_6$ , de grandes dimensions, mis en évidence sans adjuvants, sont couverts de petits octaèdres de  $C_3AH_6$  en présence de  $Na_2S_2O_3$ . Dans le clinker,  $Na_2S_2O_3$  semble accélérer l'hydratation de  $C_3A$ . A 8 heures, en présence d'adjuvant, des aiguilles analogues à l'ettringite se forment, elles sont probablement un composé complexe du type Aft contenant des groupes  $S_2O_3^{2-}$ .

On en conclut que  $Na_2S_2O_3$  bien que retardateur de l'hydratation de  $C_3A$  agit comme un accélérateur de  $C_3A$  quand il est présent dans le clinker. Certains changements morphologiques des produits d'hydratation et la formation de composés complexes contenant des groupes  $S_2O_3^{2-}$  sont aussi indiqués.

SERSALE, SABATELLI et VALENTI ont étudié l'effet du gluconate de sodium, de l'acétate de cuivre et du phosphate d'aluminium sur l'hydratation de  $C_3A$  jusqu'à 48 heures, en utilisant la DRX, l'ATD, la TG et le MEB.

Tous les adjuvants retardent l'hydratation de  $C_3A$ , le gluconate de Na étant le retardateur le plus efficace. A 48 heures, le degré d'hydratation est presque constant en présence de tous les adjuvants mais cette valeur est plus faible que celle observée dans l'échantillon sans adjuvant. La comparaison des produits à 50 % d'hydratation montre qu'en présence de retardateurs, la phase hexagonale est présente plutôt que la phase cubique. Les micrographies des échantillons, au même degré d'hydratation, ne montrent pas de différences significatives.

On en conclut que le gluconate de sodium, l'acétate de cuivre et le phosphate d'aluminium retardent l'hydratation de  $C_3A$  en stabilisant l'aluminate de calcium hydraté hexagonal. Ces adjuvants n'altèrent que les caractéristiques morphologiques des hydrates.

RÉGOURD, MORTUREUX et HORNAIN ont étudié l'effet de  $CaCl_2$  et du saccharose sur l'hydratation de  $C_3A$ ,  $C_3S$ ,  $C_3A + C_3S +$  gypse et du ciment portland en utilisant la DRX et le MEB.

L'aluminate tricalcique s'hydrate en phase hexagonale suivie par la phase cubique en deux jours. En présence de  $CaCl_2$ , le chloroaluminate est formé mais le taux d'hydratation n'est pas affecté. Le sucre est un retardateur et inhibe l'hydratation après deux jours, formant  $C_4AH_{13}$  mal cristallisé. Un produit enveloppant les grains de  $C_3A$  est observé au MEB. Dans le système  $C_3S + C_3A$ ,  $CaCl_2$  agit comme un accélérateur de l'hydratation de  $C_3A$  jusqu'à 1 jour. La formation de chloroaluminate semble retarder l'hydratation ultérieure. Le sucre est un retardateur de l'hydratation à la fois de  $C_3A$  et de  $C_3S$  aux stades initiaux. Dans le système  $C_3S + C_3A +$  gypse, l'ettringite se forme initialement puis se convertit en monosulfate et finalement en une solution solide monosulfate -  $C_4AH_{13}$ . Le chlorure de calcium est un accélérateur de l'hydratation de  $C_3S$  jusqu'à 7 jours. La microstructure de C-S-H est modifiée et il se forme des plaquettes hexagonales de chloroaluminates. On observe aussi que  $CaCl_2$  est un meilleur retardateur de l'hydratation de  $C_3A$  que le gypse. Le sucre retarde l'hydratation de  $C_3A$  jusqu'à 2 jours et ensuite agit comme un accélérateur. Le sucre, bien que retardateur de l'hydratation de  $C_3A$  est moins efficace que  $CaCl_2$ . Dans le ciment portland,  $CaCl_2$  agit comme un accélérateur et le sucre comme un retardateur entre 4 et 16 heures. Après 24 heures, le ciment portland seul ou celui avec les adjuvants présente le même taux d'hydratation.

On estime que  $CaCl_2$  affecte l'hydratation du ciment au début en influençant la nucléation de C-S-H et de CH. Dans le système  $C_3A -$  gypse -  $CaCl_2$ , une compétition existe entre le gypse et  $CaCl_2$ . Le chlorure de calcium est un meilleur retardateur que le gypse jusqu'à 28 jours. La formation d'une couche de chloroaluminate peut expliquer le retard. Le sucre est retardateur de  $C_3S$  initialement et aussi de  $C_3A$  et forme des aluminates hydratés mal cristallisés.

B. CASU, M. CHIRUZZI, F. TEGIACCHI et G. ZOPETTI ont étudié l'effet, sur l'hydratation de  $C_3A$ , des solutions aqueuses de quelques carbohydrates et des aldones correspondants. Les techniques telles que la rotation optique, la potentiométrie, la RMN et l'IR ont été utilisées pour suivre les changements se produisant entre 1 et 100 minutes. Dans les premières minutes après le contact de  $C_3A$  avec le glucose et le maltose réducteurs, une précipitation se produit. La formation en solution de complexes entre  $C_3A$  et le gluconate de sodium a été mise en évidence et elle précède la précipitation sur  $C_3A$ . La couche protectrice ainsi formée retarde l'hydratation et la prise.

#### CONCLUSIONS ET REMARQUES

Bien que la teneur en  $C_3A$  dans les ciments portland soit faible, elle influence, d'une manière significative, les propriétés physiques, chimiques et mécaniques du ciment telles que la prise, la rhéologie, les premières résistances, l'attaque au sulfate, le dégagement de chaleur, la carbonatation, etc... Etant donné que  $C_3A$  semble adsorber de grandes quantités d'adjuvants différents, il est essentiel d'étudier le rôle de  $C_3A$  et des systèmes  $C_3A +$  gypse + CH et leur interaction avec les adjuvants. L'importance de telles études devient évidente en raison du nombre de nouveaux adjuvants qui se sont développés (93, 74, 73 et 88, respectivement en 1976, 1977, 1978 et 1979).

Un des problèmes rencontrés dans l'étude des systèmes contenant  $C_3A$  est la variation des résultats rapportés par les différents chercheurs. Un des problèmes évident est celui de la vitesse relativement rapide de l'hydratation. De nombreux facteurs influencent le taux de réaction et ceux-ci incluent la forme de l'échantillon, la taille du matériau pris dans une étude particulière, les conditions de prétraitement, l'effet des impuretés, les différences de réactivité des échantillons apparemment de particules de même taille, de rapport e/c, de température, etc... Ceci devient plus complexe quand les adjuvants ou les combinaisons d'adjuvants sont ajoutés aux systèmes  $C_3A$ .

L'influence des concentrations molaires des adjuvants en solution est souvent négligée et les comparaisons sont généralement faites sur la base d'un pourcentage particulier d'adjuvants par rapport au  $C_3A$  solide.

Il est très important d'étudier l'influence des adjuvants sur  $C_3A$  et sur les systèmes  $C_3A +$  gypse mais souvent ces résultats ne peuvent être directement applicables aux systèmes du ciment portland à cause du rôle des autres phases et aussi parce que  $C_3A$  dans le ciment contient Na en solution solide.

Les limitations des différentes techniques devraient aussi être considérées dans l'évaluation des résultats. Tous les rapports publiés devraient contenir l'information caractérisant les matériaux et les conditions expérimentales ; c'est une exigence indispensable. Ceci pourrait être le point de départ d'une comparaison éventuelle de résultats obtenus dans différents laboratoires et la réponse à de nombreuses questions.

# Hydration of $C_3A$ in the presence of lignosulfonate-carbonate system or sulfonated naphthalene polymer

## *Hydratation du $C_3A$ en présence de lignosulfonate et de carbonate ou de polymère de naphthalène sulfoné*

### SUMMARY :

The combined addition of water soluble lignosulfonate and carbonates to Portland clinker without gypsum has been proposed to prepare flowable pastes with low water/cement ratios. On the other hand sulfonated naphthalene polymer (SNP) based admixtures are normally used as superplasticizers to obtain concretes with low w/c ratios.

In the present paper the influence of sodium lignosulfonate (LGS) and carbonate (NC) on the hydration of  $C_3A$  with lime and without gypsum was examined. The  $C_3A$  hydration rate is retarded by the simultaneous addition of LGS (0.6%) and NC (0.6%), and for some minutes the hydration is completely blocked. It may be speculated that this effect combined with the change in the zeta potential caused by LGS and NC could contribute to the flowability of clinker pastes. By  $C_3A$  hydration, hexagonal calcium aluminate hydrates are initially formed and then they are transformed into the cubic hydrate. The same products are obtained in the presence of LGS and NC.

The effect of SNP (0.6%) on the hydration of  $C_3A$  with lime and gypsum was also studied. No substantial change in the  $C_3A$  hydration rate is observed. The same products (ettringite and then monosulfate) are formed with and without SNP. Changes in zeta potential caused by SNP are recorded. It can be assumed that this is substantially responsible for the increase in flowability of cement pastes.

### RESUME :

On a suggéré de préparer des pâtes très fluides avec un faible rapport eau/ciment en additionnant simultanément du lignosulfonate et du carbonate, solubles dans l'eau, au clinker portland sans gypse. Par ailleurs, des adjuvants à base de polymère de naphthalène sulfoné (PNS) sont déjà utilisés pour obtenir des bétons très fluides.

Dans cet article, on a examiné l'influence du lignosulfate de sodium (LGS) et du carbonate de sodium (NC) sur l'hydratation du  $C_3A$  avec de la chaux et sans gypse. La vitesse d'hydratation du  $C_3A$  est ralentie par l'addition simultanée de LGS (0,6%) et de NC (0,6%) et, pour quelques minutes, l'hydratation est complètement bloquée. On pourrait déduire que la combinaison de cet effet avec le changement du potentiel Zêta, causé par le LGS et le NC, pourrait contribuer à rendre fluide les pâtes de clinker. Lors de l'hydratation du  $C_3A$  se forment d'abord les aluminates de Ca hydratés hexagonaux qui sont ensuite transformés en hydrate cubique. Les mêmes produits se forment en présence de LGS et de NC.

L'effet du PNS (0,6%) sur l'hydratation du  $C_3A$  avec chaux et gypse a également été étudié. On ne note aucune modification significative dans la vitesse d'hydratation du  $C_3A$ . Les mêmes produits (ettringite et ensuite monosulfate) se forment avec et sans PNS. On a enregistré des modifications du potentiel Zêta dues au PNS. On peut considérer que ces modifications sont la principale cause de l'accroissement de la fluidité des pâtes de ciment.

## INTRODUCTION

The so called superplasticizers are largely used, particularly in Europe and Japan, as additives that permit a concrete to have 20-30% of the mixing water removed without reduction in workability (1) or a strong increase in workability (for instance : from 20 to 220 mm in slump) without significant change in all the properties of the hardened concrete (2). They are substantially based on sulfonated-naphthalene-formaldehyde polymers (SNP) or sulfonated melamine-formaldehyde polymers (3). On the other hand, Brunauer and coworkers (4) studied the combined effect of water soluble lignosulfonates and carbonates on pastes from ground Portland clinker without gypsum. Therefore, superplasticizers based on SNP can be considered as liquefying agents for Portland cement pastes, whereas lignosulfonate-carbonate combinations act as both set regulator and liquefying agent for ground Portland clinker without gypsum. The purpose of the present work was to study the influence of SNP on the  $C_3A$  hydration in the presence of lime and gypsum, and the effect of lignosulfonate-carbonate combination on the  $C_3A$  hydration in the presence of lime without gypsum. The two systems correspond to the  $C_3A$  hydration in Portland cement and Portland clinker respectively.

## EXPERIMENTAL

### Materials and methods

Tricalcium aluminate (free lime = 0.1% and Blaine fineness of about 3,500  $cm^2/g$ ) was prepared according the method described in a previous paper(5). It was blended with reagent grade calcium hydroxide (CH) in order to simulate the aqueous phase present in Portland cement of Portland clinker pastes. The  $C_3A/CH$  weight ratio was 5:1 for all the mixes, whereas reagent grade gypsum ( $CS_2H_2$ ) was present (20% by weight of  $C_3A$ ) only in mixes C and D as shown in Table I. Reagent grade sodium carbonate (NC), sodium lignosulfonate (LGS), said to be free of sugars or other carbohydrates, and SNP, produced as dry powder by MAC, were dry-mixed with the other ingredients. The percentages of NC, LGS and SNP were 0.6% by weight of  $C_3A$ . By taking into account the  $H_2O/C_3A$  ratio (0.5) the concentration of the additives in the liquid phase was 12 g/l.

Table I - Composition (in grams) of mixes for paste hydration ( $H_2O/C_3A = 0.5$ )

Mix	$H_2O$	$C_3A$	CH	$CS_2H_2$	NC	LGS	SNP
A	5	10	2	-	-	-	-
B	5	10	2	-	0.06	0.06	-
C	5	10	2	2	-	-	-
D	5	10	2	2	-	-	0.06

Hydration at 20°C of these pastes was examined. After a certain time (5 min - 7 days) the hydration was stopped by grinding the pastes with methyl alcohol. The filtered solids were dried at 60°C and analyzed by a Netzsch apparatus in which DTA, DTG and TG curves are obtained simultaneously. Only DTG curves are shown in the present paper. XRD analysis was also carried out by a Philips apparatus and the intensity of the  $C_3A$  peak at 1.56 Å was determined.

Zeta potential measurements were performed using a Laser Zee Meter by Pen Kem Inc. which is based on electrophoretic technique (7) and gives the results directly in millivolt. The samples for zeta potential measurements were prepared by mixing for 5 min 100 g of lime saturated water solution with 10 g of  $C_3A$ , with or without 2 g of  $CS_2H_2$ , 1.2 g of NC, LGS or SNP as shown in Table II. Therefore, the concentration of NC, LGS and SNP in the liquid phase (12 g/l) was the same as used for the paste samples. The liquid phase was separated by vacuum filtration. A small portion of the solid sample was added to the filtered liquid phase and a suspension (10 mg/20 ml) was obtained with the same ionic strength of the original suspension and diluted enough to be observed by the microscope of the Laser Zee Meter.

Table II - Composition (in grams) of mixes for zeta potential measurements

Mix	CH saturated water solution	$C_3A$	$CS_2H_2$	NC	LGS	SNP	Zeta potential (mV)
A'	100	10	-	-	-	-	+ 37.4
B'	100	10	-	1.2	1.2	-	- 41.5
C'	100	10	2	-	-	-	- 8.5
D'	100	10	2	-	-	1.2	- 30.9

## RESULTS AND DISCUSSION

### C<sub>3</sub>A - CH system

In Fig. 1 the XRD intensity peak of C<sub>3</sub>A as a function of time is shown. When C<sub>3</sub>A hydrates in the presence of lime without gypsum the reaction rate is very high. The addition of 0.6 % of LGS and NC to the C<sub>3</sub>A-CH system retards the reaction between C<sub>3</sub>A and water particularly during the initial period of hydration.

Fig. 1 - XRD intensity peak as a function of hydration time. All the mixes contain CH.

The DTG curves of Fig. 2 confirm this effect and show that the initial hydration of C<sub>3</sub>A is substantially blocked by the addition of NC and LGS for 5 min. Similar results are obtained when NC and LGS (0.625%) are added to C<sub>4</sub>AF-CH system as the C<sub>4</sub>AF hydration is substantially blocked for about 30 min (8). By C<sub>3</sub>A hydration (Fig. 2.A) hexagonal calcium aluminate hydrates (C<sub>4</sub>AH<sub>5</sub> and C<sub>2</sub>AH<sub>8</sub>) are initially formed with DTG peaks at about 200 and 270°C. The peak at about 100°C, recorded in a previous paper (5), is not observed in the present work as the hydrated samples were dried for a longer time at 60°C before being analysed by DTG. Some cubic hydrate (C<sub>3</sub>AH<sub>6</sub>) with a DTG peak at about 320°C and a smaller one at about 500°C appears immediately. However, the transformation of the hexagonal calcium aluminate hydrates into the cubic hydrate occurs remarkably after 1 day only. The same products are observed when C<sub>3</sub>A hydrates in the presence of NC and LGS (Fig. 2.B) although there

is a retardation during the initial period of hydration.

The data reported in Table II show that the zeta potential of C<sub>3</sub>A in a lime saturated solution is positive (37.4 mV). This result agrees very well with the data of Tadros et al (9) who found a value of 34 mV for suspensions of 8 g of C<sub>3</sub>A in 100 ml water. The high zeta potential would indicate that the C<sub>3</sub>A suspension (Mix A' in Table II) is a well dispersed system. The deflocculation of Mix A' was actually confirmed by the difficulty in centrifugal sedimentation and vacuum filtration. On the other hand, the C<sub>3</sub>A paste (Mix A in Table I) is a stiff system. It may be speculated that by going from Mix A' to Mix A the ionic strength is changed and the zeta potential decreases towards to zero by favouring thus the flocculation. Alternatively, one could think that Mix A' and Mix A have approximately the same zeta potential, but the clusters formation in

Fig. 2 - DTG curves for C<sub>3</sub>A + CH pastes without (A) and with (B) NC and LGS.

the paste - due to hexagonal calcium aluminate hydrates - plays a prominent role in the stiffening of the system. On the other hand, the initial hydration products in Mix A' (Table II) and Mix A (Table I) are different, as the cubic hydrate is mainly formed in the C<sub>3</sub>A suspension (Mix A') instead of the hexagonal hydrates in the C<sub>3</sub>A paste (Fig. 2:A at 5 min). Traetterberg and Grattan-Bellew (10) and Collepardi et al (11) have found that when, for some reason, the transformation of the hexagonal calcium aluminate hydrates into the cubic phase occurs during the initial period of hydration, the C<sub>3</sub>A paste changes from a stiff system to a fluid one. In the present work it seems that a high water/solid ratio, such as that of Mix A', favours the transformation of the hexagonal hydrates into the cubic phase having a high positive zeta potential.

A sharp change of zeta potential to a negative value of -41.5 mV (Mix B' in Table II) is obtained in the presence of NC and LGS (12 g/l). Incidentally, in the presence of LGS (12 g/l) without NC a less remarkable change in zeta potential to about -20 mV is obtained. On the other hand the change in zeta potential caused by NC addition is still weaker. Similar results were obtained for the C<sub>4</sub>AF-CH system (8).

#### C<sub>3</sub>A - CH - C $\bar{S}$ .H<sub>2</sub> system

The C<sub>3</sub>A hydration is remarkably retarded by the addition of gypsum to the C<sub>3</sub>A-CH system particularly during the first 6 hours (Fig. 1). During this period the amount of ettringite (with a DTG peak at about 130°C) increases, whereas the amount of C $\bar{S}$ .H<sub>2</sub> (with a DTG peak at about 160°C) proportionally decreases (Fig. 3.C). Then ettringite is transformed into monosulfate (with DTG peaks at about 220 and 270°C) at 6 - 24 hours (Fig. 3.C) and C<sub>3</sub>A hydration is remarkably accelerated (Fig. 1). Similar results were obtained by studying the influence of lime and gypsum on the C<sub>3</sub>A hydration by an isothermal conduction calorimeter and DTG (5).

The addition of SNP to the C<sub>3</sub>A-CH-C $\bar{S}$ .H<sub>2</sub> system does not substantially change either the hydration rate (Fig. 1) or the hydration products (Fig. 3.D). Massazza et al (12) found that a SNP based superplasticizing admixture retarded the C<sub>3</sub>A hydration. A different composition of the admixture used by Massazza et al could explain the apparent disagreement with the results of the present work.

The zeta potential of the C<sub>3</sub>A-CH-C $\bar{S}$ .H<sub>2</sub> system (Table II) changes from -8.5 mV to -30.9 mV by addition of SNP (12 g/l). So, the effect of SNP on the zeta potential of the C<sub>3</sub>A-CH-C $\bar{S}$ .H<sub>2</sub> system seems to be less remarkable than that of LGS + NC on the zeta potential of the C<sub>3</sub>A-CH system. On the other hand, the influence of SNP on the zeta potential seems to be more remarkable in Portland cement paste

Fig. 3 - DTG curves for C<sub>3</sub>A + CH + C $\bar{S}$ .H<sub>2</sub> pastes without (C) and with (D) SNP.

than in the C<sub>3</sub>A-CH-C $\bar{S}$ .H<sub>2</sub>-H<sub>2</sub>O system. When the concentration of SNP in the liquid phase is 7.5 g/l, the zeta potential of Portland cement is about -50 mV (6), so that a still more negative value could be expected with a higher concentration of SNP (12 g/l) as that of the present work.

#### CONCLUSIONS

By paste hydration of C<sub>3</sub>A in the presence of lime, hexagonal calcium aluminate hydrates (C<sub>4</sub>AH<sub>x</sub> and C<sub>2</sub>AH<sub>8</sub>) are initially formed and then they are transformed into the cubic hydrate (C<sub>3</sub>AH<sub>6</sub>) after 1 day. The same products are obtained when LGS and NC (both 0.6% by weight of C<sub>3</sub>A) are added to the C<sub>3</sub>A-CH system. However, the C<sub>3</sub>A hydration is retarded by addition of LGS and NC and in particular the reaction is completely blocked for some minutes. The zeta potential - determined on a C<sub>3</sub>A suspension - is remarkably changed from a positive value (37.4 mV) to a negative one (-41.5). Similar effects on the hydration rate and

zeta potential were caused by NC and LGS in the C<sub>4</sub>AF-CH system (8). It may be speculated that both the change in zeta potential and the retardation of the initial hydration of C<sub>3</sub>A and C<sub>4</sub>AF could substantially contribute to the flowability of Portland clinker pastes containing NC and LGS. The high negative value of zeta potential on all the Portland clinker compounds - possibly including C<sub>3</sub>S and C<sub>2</sub>S - due to the addition of NC and LGS, could cause the mutual repulsion of clinker particles and then their dispersion (13). On the other hand, the formation of large clusters of hexagonal calcium aluminate hydrates sticking together could cause lower workability in a Portland clinker paste without gypsum (14, 15). When this aggregation is prevented, as the C<sub>3</sub>A and C<sub>4</sub>AF hydrations are completely blocked, more flowable clinker pastes could be obtained. Therefore, the liquefying effect of NC and LGS in Portland clinker pastes without gypsum could be partly ascribed to both the dispersing action caused by a negative zeta potential and the retardation in C<sub>3</sub>A and C<sub>4</sub>AF hydrations.

In the presence of lime and gypsum ettringite is initially (0-6 hours) formed causing retardation in C<sub>3</sub>A hydration (5). When ettringite is transformed into monosulfate (6-24 hours) the C<sub>3</sub>A hydration rate is accelerated. No substantial change either in the C<sub>3</sub>A hydration rate, type of products or transformations are caused by the addition of SNP (0.6% by weight of C<sub>3</sub>A). Therefore, it can be assumed that - as far as the C<sub>3</sub>A-CH-CS<sub>2</sub>H<sub>2</sub> system is concerned - the increase in flowability of Portland cement pastes, caused by SNP addition, is mainly due to a change in zeta potential resulting in a mutual repulsion of cement particles and then in their dispersion.

# Effect of superplasticizers on the $C_3A$ hydration

## *Effet des superfluidifiants sur l'hydratation du $C_3A$*

F. MASSAZZA, Professor of Applied Chemistry, Italcementi, Laboratorio Chimico Centrale Bergamo, Italy,  
U. COSTA, B. Ch. Italcementi, Laboratorio Chimico Centrale, Bergamo, Italy.

RESUME : On a étudié l'hydratation de mélanges de  $C_3A$  et de gypse en présence de lignosulfonate de sodium et de condensat de naphthalène sulfoné et de formaldéhyde dans le but d'éclaircir les causes de l'action fluidifiante exercée par ces substances sur les pâtes de ciment. Les adjuvants ralentissent la vitesse de formation de l'ettringite, mais cela ne devrait pas être attribué à leur interaction avec  $C_3A$ . En effet l'aluminate non encore hydraté n'adsorbe pas les adjuvants et ne subit même pas de modifications structurales au niveau des centres actifs en thermoluminescence.

Au contraire, les sulfoaluminates hydratés adsorbent des quantités considérables de ces adjuvants et cela cause des modifications morphologiques dans les cristaux d'ettringite. Dans ce cas ils apparaissent, au microscope électronique, sous forme de petites aiguilles et pas comme de gros faisceaux fibreux représentant leur aspect normal en l'absence d'adjuvants.

Ces morphologies différentes peuvent expliquer, au moins partiellement, l'action exercée par ces superfluidifiants sur la rhéologie des pâtes de ciment. Leur présence cause la formation d'un feutre microcristallin sur les grains de  $C_3A$ , en empêchant son hydratation. Vice-versa, la morphologie normale, caractérisée par de gros cristaux d'ettringite joignant les différentes particules, justifie la perte rapide de plasticité des pâtes qui s'hydratent en l'absence d'adjuvants. En définitive, l'action des deux fluidifiants sur les ciments peut être attribuée à la réduction initiale de la demande d'eau du ciment et à la plus petite interconnexion entre les particules en cours d'hydratation.

SUMMARY: The hydration of mixes of  $C_3A$  and gypsum in the presence of sodium lignosulphonate and naphthalene sulphonate formaldehyde condensate was studied in order to explain the causes of the fluidizing action exerted by these substances on cement pastes.

The admixtures slow down the rate of formation of ettringite but this does not seem to be attributed to their interaction with  $C_3A$ . In fact the not yet hydrated aluminate does not adsorb the admixtures and does not even undergo structural changes concerning the active sites in thermoluminescence.

On the contrary sulphoaluminate hydrates adsorb considerable amounts of these additives and this causes evident morphological changes in the ettringite crystals. In this case they appear, under the electron microscope, in the form of small needles and not as large fibrous bundles representing their usual aspect in the absence of admixtures.

These different morphologies can explain, at least partly, the action exerted by these superplasticizers on the rheology of the cement pastes. Their presence causes the formation of a microcrystal felt on the grains of  $C_3A$ , hampering its hydration. Viceversa the normal morphology, characterized by large fibrous ettringite crystals connecting the different particles, justifies the rapid loss of plasticity of the pastes hydrating without admixtures. After all the action of the two plasticizers can be attributed to the initial reduction in the water demand of cement and the lower interlock among the hydrating particles.

## 1. INTRODUCTION

Plasticizers and superplasticizers have usually been employed for some time in the manufacture of concrete but, despite the several studies performed, the mechanism of their action has not yet quite been explained.

Many works reported in the most recent reviews (1) (2)(3) were carried out on the hydration of  $C_3A$  since this compound affects to a great extent setting times, water demand, workability and generally rheology of cement pastes.

A more limited number of works was performed on the action of these admixtures on the  $C_3A$  hydration in the presence of gypsum.

This work, which is part of a research programme on the mechanism of action of superplasticizers, reports the results obtained in the study of the  $C_3A$  hydration in the presence of gypsum, sodium lignosulphonate (L.S.S.) and naphthalene sulphonate formaldehyde condensate (N.S.F.). Lignosulphonate does not appreciably modify the initial rate of reaction of  $C_3A$  with gypsum but retards the conversion of ettringite to monosulphate and the formation of aluminate hydrates (4). This retarding action depends on the admixture content (5) and was confirmed by differential thermal analysis (6) and electron microscopic observations (7).

Lignosulphonate does not alter the sequence of the reactions but modifies the morphology of the hexagonal hydrates appearing when gypsum is depleted (8). Observations by the scanning electron microscope showed that also ettringite undergoes morphological changes (9) like those noticed in the presence of sugar (10).

As for the N.S.F. action, information was not found in the available literature.

## 2. EXPERIMENTAL

### 2.1 Materials

Synthetic  $C_3A$ , natural  $CaSO_4 \cdot 2H_2O$ , purified sodium lignosulphonate and commercial alkyl naphthalene sulphonate formaldehyde condensate were used in the present work.

The tests were carried out on mixes consisting of 100 parts of  $C_3A$  and 20 parts of  $CaSO_4 \cdot 2H_2O$  hydrated with pure water or 1% solutions of the admixtures.

### 2.2 Course of the hydration reaction

The hydration process was followed by a conduction calorimeter (11) recording the heat evolved by pastes consisting of 1 g mix and 1 ml pure water or containing the admixtures.

The heat evolution curves (figs. 1 and 2) show two peaks: the former, intense but of short duration, is due to the rapid reaction of  $C_3A$  with water, the latter, which appears when gypsum is exhausted, indicates the conversion of ettringite to monosulphate (12). Type and dosage of the admixtures affect intensity and position of the latter peak but not those of the former.

### 2.3 Identification of the phases in the pastes

The identification of the phases present at different stages of reaction was performed by X-ray diffraction, thermogravimetric analysis (TG) and differential scanning calorimetry (DSC).

The hydration was stopped at the established times by dispersing the paste in agate mortar with acetone. However this treatment caused the removal of some water of crystallisation of ettringite, monosulphate and tetracalcium aluminate hydrate. This fact was pointed

out by the change in the intensity and the position of the X-ray diffraction peaks. Ettringite showed extremely weak and broad peaks in some samples.

FIG. 1: Heat evolution curves recorded on pastes of  $C_3A$  + 20% gypsum containing N.S.F.

To restore the original structure, the samples were stored for some hours at 23°C and 100% R.H. (13). After this treatment, the samples gave X-ray diffraction patterns corresponding to ettringite  $32H_2O$ , monosulphate  $12H_2O$  and tetracalcium aluminate  $19$  and  $13H_2O$ . The last was partially carbonated (14).

FIG. 2: Heat evolution curves recorded on pastes of  $C_3A$  + 20% gypsum containing L.S.S.

The phases identified by X-rays (table I) are in agreement with those detected by DSC (fig. 3). Ettringite is the first hydration product forming and remains the only one as long as gypsum is present in the paste.

Calcium sulphate disappears in the pastes without admixtures after about 4 hours whereas it should disappear after about 7 hours in the presence of 1% N.S.F., according to the results obtained by conduction calorimetry. On the contrary in the presence of L.S.S., gypsum is found up to 36 hours. The depletion of calcium sulphate is followed by the appearance of monosulphate forming at the expense of

FIG. 3: DSC curves obtained on pastes of  $C_3A + 20\%$  gypsum: a) without admixture, b) with N.S.F., c) with L.S.S.

ettringite. Then the hydration of the still present  $C_3A$  proceeds with the formation of hexagonal hydrates  $C_4AH_{19}$  and partially carbonated  $C_4AH_{13}$ . The lattice constants of ettringite do not undergo changes due to the presence of the admixtures, whereas those of monosulphate slightly vary, as it is shown by the line  $d(0001)$  passing from 8.84 to 8.93 Å.

#### 2.4 Dosage of ettringite in the pastes

The ettringite content in the hydrating pastes was determined by DSC or TG. The enthalpic effect related to the dehydration peak, that the compound shows at  $115^\circ\text{C}$ , was measured by the former method and the corresponding weight loss by the latter. The obtained calorimetric data were converted to concentration on the basis of the known value of the dehydration enthalpy of ettringite (213.9 Kcal/mole (15)). The ettringite content was calculated from the weight loss measured between 50 and  $120^\circ\text{C}$ ; at this temperature the compound loses 70% of its water (13). At the selected rate of heating ( $5^\circ\text{C}/\text{min}$ ), gypsum slightly affects the exactitude of the ettringite determination since it begins decomposing as from about  $120^\circ\text{C}$ . As table II shows, ettringite is already present in considerable amount after 30 minutes. The content is maximum in the sample without admixtures and minimum in the sample containing L.S.S..

#### 2.5 Interaction among admixtures, $C_3A$ and hydration products

2.5.1 Thermoluminescence (TL) was used to evidence an eventual interaction between admixtures and an

hydrous  $C_3A$ . In fact the aim was to verify whether

the crystal defects always present in this compound (16) could constitute preferential sites for the hydration or adsorption of the admixtures. To obtain this information, an apparatus with evacuated cell enabling heating rates up to 2°C/s was used. The intensity of the light emission was measured between 20 and 250°C by a single photon counting instrument provided with a photomultiplier sensitive in the 250-680 nm range.

\*) Complete reaction of gypsum gives a maximum of 35.5% by weight of ettringite

The active centres were excited as far as saturation by the X-rays produced by a tube with chrome anticathode. All the TL curves showed only the two maxima of light emission, belonging to C<sub>3</sub>A, which as many electron traps related to crystal defects corresponded to (16).

The characteristics of the traps, namely:

E = depth of the trap (eV)

S = frequency factor (s<sup>-1</sup>)

p = probability of escape of trapped electrons at 25°C (s<sup>-1</sup>)

t = lifetime of trapped electrons (s) = 1/p

were calculated according to Randall and Wilkins' formalism, already successfully applied to the study of the thermoluminescence of the portland cement constituents (17).

Table III shows that the values of the fundamental parameter E, which the others derive from, undergoes random variations attributable to the measurement error. Therefore there are not evident modifications of the active sites of C<sub>3</sub>A present in the different samples. The constancy of the characteristics of the traps and the progressive reduction in the intensity of the TL peaks, observed as the C<sub>3</sub>A hydration proceeds (18), would lead to exclude that these traps or centres of luminescence play a role in the reactions occurring during the hydration of C<sub>3</sub>A with gypsum in the presence or absence of the considered admixtures.

2.5.2 The interaction between admixtures and hydration products of C<sub>3</sub>A was studied by determining the adsorption isotherms obtained by dispersing the hydrates in solutions of dimethylsulphoxide (DMSO), already used in similar studies (19). Ettringite was prepared according to J. D'ANS and H. EICK's (20) method. Monosulphate was obtained by reaction between solutions saturated with calcium hydroxide and calcium sulphate and a solution obtained by shaking CA in water (20)(21). After filtration in at

mosphere of inert gas, the precipitates were washed with acetone which was eliminated by vacuum evaporation. The samples were controlled by X-ray diffraction and thermal analysis. One mole of ettringite contained 25+26 moles of water whereas one of monosulphate did 10 moles.

Anhydrous DMSO is considerable hygroscopic and causes a partial dehydration of sulphaaluminate hydrates.

To eliminate this inconvenience, a small amount of water (8%) was added to the solvent. It proved to be sufficient to stabilize the hydration products without modifying other characteristics.

The adsorption of the admixtures on the hydrates was determined by continuously recording the variations of the electric conductivity of the suspensions.

In fact the electric conductivity of the solutions of the admixtures in DMSO is proportional to their concentration in a rather large range of concentrations (0-10 g/l). All the measurements were performed at 20°C by using a thermostatic conductivity cell connected to a conductimeter working at 400 Hz. They were protracted as far as the attainment of the equilibrium indicated by the stabilization of the electric conductivity.

The equilibrium conductivity was also confirmed in the liquid obtained by filtering the suspensions.

Figures 4 and 5 show that at the equilibrium concentration of 9 g/l, the adsorption values are, for L.S.S., 5.9 wt % of ettringite and 4.3% of monosulphate. For N.S.F. the corresponding values are 4.7% of ettringite and 3.1% of monosulphate.

Monosulphate, differently from ettringite, showed an appreciable increase in its lattice distances after adsorption (18).

The increase in the lattice distances of monosulphate and the invariability in those of ettringite correspond to what occurs for the two compounds when they pass from 10 to 12 and from 10 to 32 water molecules respectively (22)(13).

TAB. III: Characteristics of the electron traps of C<sub>3</sub>A

Sample	Hydrat. time	TRAP I				TRAP II			
		E (eV)	S (s <sup>-1</sup> ) × 10 <sup>10</sup>	p (s <sup>-1</sup> ) × 10 <sup>-6</sup>	t (s) × 10 <sup>5</sup>	E (eV)	S (s <sup>-1</sup> ) × 10 <sup>10</sup>	p (s <sup>-1</sup> ) × 10 <sup>-6</sup>	t (s) × 10 <sup>5</sup>
Anhydrous C <sub>3</sub> A		1.05	91	1.4	7.1	1.15	44	1.4	7.1
Pastes without admixtures	0.5 h	0.90	0.6	5.9	1.7	0.94	0.12	14	0.71
	4 h	0.97	6.2	2.4	4.2	1.29	1200	0.14	71
Pastes with 1% N.S.F.	0.5 h	1.07	135	0.9	11	1.25	447	0.26	38
	15 h	0.88	0.45	5.5	1.8	0.95	0.15	11	0.91
Pastes with 1% L.S.S.	0.5 h	1.19	7300	0.5	20	1.28	1600	0.38	26
	24 h	1.12	650	0.7	14	1.18	86	0.97	10

After all the adsorption data seem to indicate that the admixtures can replace some water in the lattice of sulphaaluminate hydrates. It was ascertained that anhydrous C<sub>3</sub>A shows no adsorption.

## 2.6 Morphology of the hydration products

The morphology of the hydration products was examined by observing the broken surfaces of the pastes under the scanning electron microscope.

The most interesting results concern the first stag-

es of reaction during which the main hydration product is ettringite. After 30 minutes its morphology has appeared considerably affected by L.S.S. and N.S.F.

FIG. 4: Adsorption isotherms of N.S.F. and L.S.S. dissolved in DMSO on ettringite

FIG. 5: Adsorption isotherms of N.S.F. and L.S.S. dissolved in DMSO on monosulphate

The micrograph of fig. 6, relevant to a mix with pure water, shows the presence of large fibrous crystals of ettringite forming a sort of tridimensional branching which joins the different grains. On the contrary the appearance of the pastes made with solutions of the two admixtures is quite different: the ettringite crystals have considerably smaller sizes, they prevailingly appear as a fine felt (figs. 7 and 8) covering the  $C_3A$  and gypsum particles but seem unable to form strong and broad interlocks.

These differences can be considered as the consequence of introducing admixture molecules into the lattice of ettringite. This explanation is based on the results of the adsorption of the admixtures dissolved in dimethylsulphoxide and it is reasonable to extend it to the aqueous solutions.

### 3. CONCLUSIONS

The tests carried out showed that sodium linnosulphonate and naphtalene sulphonate formaldehyde slow down the formation of ettringite. From this standpoint the action of L.S.S. is higher than that of N.S.F.. Whilst  $C_3A$  does not adsorb the admixtures dissolved in DMSO, sulphaaluminate hydrates can adsorb appreciable amounts. As for monosulphate, the adsorption is accompanied by a noticeable variation of the lattice distances.

This adsorption is likely to be the cause of the mor

FIG. 6: Large ettringite bundles in pastes of  $C_3A + CaSO_4 \cdot 2H_2O$  hydrated for 30 minutes with pure water. 3000 X

phological changes noticed in the ettringite crystals. The fine structure of its crystals observed in the pastes containing the admixtures can, in its turn, justify the slowing down underwent by the  $C_3A$  hydration.

FIG. 7: Ettringite needles in pastes of  $C_3A + CaSO_4 \cdot 2H_2O$  hydrated for 30 minutes with 1% N.S.F. solution. 5000 X

In fact ettringite in the form of small crystals protects the  $C_3A$  grains from the action of water more than it does when it consists of large fibrous crystals.

Viceversa, the large fibrous crystals can exert a more effective mechanical action of interlock among the grains forming the paste.

To conclude, the fluidizing action caused by the two examined products on cement pastes can be attributed, at least partly, to the two following effects:

1. Slowing down of the rate of formation of ettringi

- te and therefore reduction in the water demand of cement
2. Decrease in the interlock performed by the ettringite bridges connecting the solid particles and consequent improvement in the rheology of the paste.

FIG. 8: Ettringite needles in pastes of  $C_3A + CaSO_4 \cdot \frac{1}{2}H_2O$  hydrated for 30 minutes with 1% L.S.S. solution. 5000 X

# Elucidation of the role of calcium lignosulfonate in the hydration of $C_3A$

## *Eclaircissement du rôle du lignosulfonate de calcium dans l'hydratation du $C_3A$*

V.S. RAMACHANDRAN, Senior Research Officer of Building Research, National Research Council of Canada,  
Ottawa, Ontario K1A 0R6 Canada.

RESUME: L'auteur obtient des isothermes d'adsorption et de désorption en exposant de l'aluminate tricalcique ( $C_3A$ ), de l'aluminate calcique hexagonal ( $C_4AH_{13}$ - $C_2AH_8$ ) et de l'hydrate d'aluminate cubique ( $C_3AH_6$ ) à des solutions de lignosulfonate de calcium (CLS) dans de l'eau ou du diméthylsulfoxyde. Dans le milieu non aqueux, le  $C_3A$  et le  $C_3AH_6$  absorbent peu ou pas de lignosulfonate; la phase hexagonale adsorbe à peu près 2.2% de CLS. Dans une solution aqueuse contenant une grande quantité de CLS, le  $C_3A$  forme un complexe de CLS basique qui est insoluble dans l'eau. Les boucles de balayage dans les isothermes pour le système aluminate hexagonal-CLS- $H_2O$  montrent une complète irréversibilité avec une adsorption de 10% à une concentration d'équilibre de 0.10% de CLS. Une adsorption rapide et irréversible de 2.05% de CLS se produit dans le système  $C_3AH_6$ -CLS- $H_2O$ . Les phases  $C_3A$ ,  $C_4AH_{13}$ - $C_2AH_8$  et  $C_3AH_6$  agissent comme des absorbants pour le CLS dans l'hydratation du  $C_3S$  contenant du CLS; l'hydratation du  $C_3S$  qui est complètement inhibée en présence de 0.8% de CLS peut être rétablie par l'addition de ces phases d'aluminate. L'efficacité relative avec laquelle l'addition de 5% de ces additifs annule l'influence inhibitrice du CLS est de l'ordre de  $C_3A > C_4AH_{13}$ - $C_2AH_8 > C_3AH_6$ .

Le Ca et le Na-lignosulfonate ne contenant aucun sucre agissent de façon similaire au lignosulfonate commercial et retardent l'hydratation du  $C_3A$ .

SUMMARY: Adsorption-desorption isotherms were obtained by exposing tricalcium aluminate ( $C_3A$ ), hexagonal calcium aluminate ( $C_4AH_{13}$ - $C_2AH_8$ ) and cubic aluminate hydrate ( $C_3AH_6$ ) to calcium lignosulfonate (CLS) solutions in water or dimethyl sulfoxide. In the non-aqueous medium  $C_3A$  and  $C_3AH_6$  adsorb little, if any, lignosulfonate; the hexagonal phase adsorbs about 2.2% CLS. In an aqueous medium containing large amounts of CLS,  $C_3A$  forms a basic CLS complex that is insoluble in water. Scanning loops in the isotherms for the hexagonal aluminate-CLS- $H_2O$  system show complete irreversibility with an adsorption of 10% at an equilibrium concentration of 0.10% CLS. A rapid irreversible adsorption of 2.05% CLS occurs in the  $C_3AH_6$ -CLS- $H_2O$  system. The  $C_3A$ ,  $C_4AH_{13}$ - $C_2AH_8$  and  $C_3AH_6$  phases act as sinks for CLS in the hydration of  $C_3S$  containing CLS; the hydration of  $C_3S$  that is completely inhibited in the presence of 0.8% CLS can be restored by the addition of these aluminate phases. The relative effectiveness with which the addition of 5% of these additives counteracts the inhibitive influence of CLS is in the order of  $C_3A > C_4AH_{13}$ - $C_2AH_8 > C_3AH_6$ .

Both Ca and Na-lignosulfonates containing no sugar behave in a manner similar to the commercial lignosulfonate in retarding the hydration of  $C_3A$ .

## INTRODUCTION

Lignosulfonic acid and its salts are widely used as water-reducing and retarding admixtures in concrete. They are known to reduce water requirements by about 5 - 10% and setting times by 30 - 60%.

Since only small amounts of lignosulfonate are needed to influence the water-reducing and retarding properties of concrete, it has been concluded that the action of this admixture involves the phenomenon of adsorption. Some attempts have been made to study the adsorption of admixtures on portland cement and the individual cement minerals, viz.,  $C_3S$ ,  $C_2S$ ,  $C_3A$  and  $C_4AF$ . Since the  $C_3A$  phase plays an important role in the early stages of hydration, considerable work has been directed to a study of the adsorption of lignosulfonate on this phase. In most studies, the amount of the admixture adsorbed by  $C_3A$  under so-called equilibrium conditions has been determined by exposure to an aqueous solution. In this method the hydration of  $C_3A$  could not have been avoided and, consequently, conclusions drawn from such experiments are questionable.

Another unresolved question concerns the role of lignosulfonate in the retardation of cement hydration. Commercial lignosulfonates invariably contain sugars and it is generally thought that they are, in fact, responsible for the retarding action (1-3). There is strong evidence, however, that lignosulfonate is adsorbed by the hydrating minerals (4-12). This would indicate that the lignosulfonate molecule in a commercial sample should play an important role in the dispersion and retardation of hydration of  $C_3A$ .

In view of these questions, it was thought that a more realistic approach to study the adsorption isotherms of lignosulfonates on the aluminate phases should involve measurements under conditions in which the adsorbent does not undergo hydration. This condition could be achieved by using a non-aqueous solvent, viz, dimethyl sulfoxide and adsorbents  $C_3A$ ,  $C_4AH_{13}$ - $C_2AH_8$  and  $C_3AH_6$  or using aqueous solutions of lignosulfonate with  $C_4AH_{13}$ - $C_2AH_8$  and  $C_3AH_6$ . Thus, adsorption-desorption scanning branches emanating at different points on the main adsorption curve would enable a study of the type of surface interaction occurring in the system.

For a further evaluation of the role of lignosulfonate, purified sugar-free lignosulfonate salt of Ca or Na was prepared from the corresponding salts of commercial products and its effect on the relative rates of hydration of  $C_3A$  was followed by differential thermal technique.

## EXPERIMENTAL

**Materials** - Tricalcium aluminate was obtained by calcining a mixture of  $CaCO_3$  and  $Al_2O_3$ ; it had a Blaine surface area of 4350  $m^2/g$ . Tricalcium silicate was prepared by calcining a mixture of  $CaCO_3$  and  $SiO_2$ ; it had a Blaine surface area of 3310  $m^2/g$ . The hexagonal calcium aluminates comprising  $C_4AH_{13}$  and  $C_2AH_8$  (referred to as the hexagonal phase) were prepared by the hydration of  $C_3A$  at 20°C for 5 days. The cubic calcium aluminate hydrate  $C_3AH_6$  (referred to as the cubic phase) was prepared by steam curing  $C_3A$  at a pressure of 0.69 MN/ $m^2$  for 24 h. Calcium lignosulfonate sample in the form of powder was supplied by Lignosol Chemical Ltd., Quebec. The sample had 4.5% reducing bodies. Sugar-free Ca or Na lignosulfonates were obtained by fractionation of commercial lignosulfonates by continuous diffusion using a Dowex 50WX2 resin.

**Methods** - Amounts of lignosulfonate adsorbed by the aluminates were determined by estimation of lignosulfonate, before and after adsorption, by a Perkin Elmer double beam UV spectrophotometer at a wavelength of 275  $\mu m$ . Details of the method are described in another publication (13).

Differential thermal analysis (DTA) was carried out in  $N_2$  using a Du Pont 900 Thermal Analyser. X-ray diffractograms (XRD) were obtained by a Hilger and Watts unit using  $CuK\alpha$  source. Electron microscopic examination was carried out by a Cambridge Stereoscan Mark 2A instrument.

## RESULTS AND DISCUSSION

### Tricalcium Aluminate-Calcium

#### Lignosulfonate-Water System

Tricalcium aluminate hydrates to the metastable hexagonal hydrate and finally to the cubic form. In the presence of calcium lignosulfonate (CLS) conversion to the hexagonal and cubic hydrate proceeds more slowly, depending on the dosage of CLS (Table I). In portland cement containing 10%  $C_3A$ , incorporation of 3% CLS is equivalent to 30% with respect to the  $C_3A$  phase and hence it was of interest to study the effect of the addition of 15, 30, 50, 100 and 200% CLS on the hydration of  $C_3A$ .

TABLE I - Influence of Calcium Lignosulfonate on the hydration of  $C_3A$

Ligno-sulfonate, %	Products Formed			
	1 day	7 days	14 days	28 days
0	cubic	cubic	cubic	cubic
0.5	cubic	cubic	cubic	cubic
1.0	hexagonal	hexagonal + cubic	cubic	cubic
3.0	hexagonal	hexagonal	hexagonal	hexagonal + cubic

A gelatinous mass formed at concentrations equivalent to and greater than 50% CLS. Electron microscopic examination revealed the gel to be a fluffy mass typical of a non-crystalline material, which appeared different from CLS or  $C_3A$  (Figs. 1a, b, d) (13). In samples treated with an aqueous solution containing 30% CLS with respect to  $C_3A$ , the resultant material exhibited a honeycomb structure (Figure 1c). Using surface area, chemical analysis, DTA and X-ray methods, it was concluded that the gel formed at higher concentrations of CLS was a basic CLS containing some  $Al^{+++}$ . Very high adsorption values reported in the  $C_3A$ -CLS- $H_2O$  system by Reh binder and Segalova can be explained by the formation of such a complex (14). In the presence of <30% CLS, a non-crystalline complex results, and this is related to that formed between CLS and the hexagonal phase.

### Hexagonal Aluminate Hydrate-Calcium

#### Lignosulfonate-Water System

Adsorption-desorption isotherms of CLS on the hexagonal phase are shown in Figure 2 (15). After a rapid adsorption, the curve tapers off between equilibrium concentrations of 0.05 and 0.15% CLS. The scanning isotherms obtained from various points show complete irreversibility.

Fig. 1a - Tricalcium aluminate

Fig. 1b - Calcium lignosulfonate

Fig. 1c - C<sub>3</sub>A treated with 30% calcium lignosulfonate

Fig. 1d - Gel-like material from C<sub>3</sub>A + 100% calcium lignosulfonate

Figure 3 represents X-ray diffractograms of the hexagonal phase and CLS-treated samples on the desorption branch corresponding to a net adsorption value of 10% CLS (15). The hexagonal phase shows a peak at  $7.90\text{\AA}$  for  $\text{C}_4\text{AH}_3$  and two characteristic peaks for  $\text{C}_2\text{AH}_8$  at  $10.5\text{\AA}$  and  $5.23\text{\AA}$ . The sample containing 10% CLS exhibits a sharp peak of larger magnitude at  $10.5\text{\AA}$  but one of reduced intensity at  $7.90\text{\AA}$ . The surface area measurements indicated that whereas the hexagonal phase had a value of  $11.1\text{ m}^2/\text{g}$ , that which had adsorbed 10% CLS had an area of  $15.3\text{ m}^2/\text{g}$ . The hexagonal phase containing the irreversibly adsorbed CLS was found to be unmistakably different from the normal phase on examination by DTA, thermogravimetric analysis and electron microscopy. These results could be interpreted as follows. A complete irreversibility up to an adsorption value of 10% CLS was due to the formation of a complex between CLS and the hexagonal phase. The increase in the intensity of the  $10.5\text{\AA}$  peak and a decrease in the intensity of that at  $7.9\text{\AA}$  in XRD may be due to an increase in the C-axis spacing, as a consequence of CLS entering the interlayer position. Thus, it seems possible that retardation of conversion of the hexagonal to the cubic phase is due to CLS existing as a complex with the hexagonal phase. The interlayer complex may

Fig. 2 - Adsorption-desorption isotherms of calcium lignosulfonate on the hexagonal and cubic phases of calcium aluminate hydrates

restrict the free movement of the interlayer ions for conversion to the cubic form.

#### Tricalcium Aluminate Hexahydrate-Calcium

##### Lignosulfonate-Water System

Adsorption-desorption scanning isotherms of this system are presented in Figure 2. After a rapid, initial adsorption the amount remains almost constant at 2.05%. Scanning isotherms from different points show irreversibility. Surface areas of  $C_3AH_6$  before and after adsorption of CLS were 4.71 and 9.38  $m^2/g$ , respectively. It appears that in the presence of CLS, dispersion of  $C_3AH_6$  and chemi-sorption of CLS are promoted.

##### Adsorption of Calcium Lignosulfonate on $C_3A$ and its Hydrates in a Non-aqueous Medium

Figure 4 gives the typical adsorption isotherms of CLS (using dimethyl sulfoxide (DMSO) as a non-aqueous solvent) on the hexagonal phase (16). After a rapid adsorption, the value tapers off to a value of 2.2%. The irreversibility, even at low concentrations of CLS, indicates that CLS is strongly complexed with the hexagonal phase. The amount of adsorption of CLS in an aqueous medium is much higher than in DMSO because of the possibility of water with a higher dipole moment entering the interlayer positions and enabling more CLS to enter. In a non-aqueous medium, practically no adsorption of CLS occurs on  $C_3A$  or  $C_3AH_6$  phase. The relatively lower surface areas of  $C_3A$  and  $C_3AH_6$ , the nature of the surfaces and absence of interlayer spaces are probably responsible for the lack of adsorption.

##### Tricalcium Silicate-Calcium Lignosulfonate-Water System in the Presence of Tricalcium Aluminate and its Hydrates

The adsorption-desorption experiments have shown that the relative amounts of adsorption of CLS in the aluminate phases are in the decreasing order  $C_3A > C_4AH_{13}-C_2AH_8 > C_3AH_6$ . *Ceteris Paribus*  $C_3A$  hydrates faster than  $C_3S$  and, therefore, in cements the hydrating aluminate may act as a sink for CLS. A few experiments were performed to investigate the effect of 5% of these aluminate phases on the hydration of  $C_3S$  containing 0.8% CLS. Addition of 0.8% CLS to  $C_3S$  completely inhibits its hydration, as evidenced by the absence of  $Ca(OH)_2$  formation (Figure 5, A-2) (17). Addition of 5%  $C_3A$  is sufficient to promote hydration slowly at first and normally after 3 days because  $C_3A$  has the capacity to react with large quantities of CLS (Figure 5, B-2). The hexagonal phase, adsorbing less CLS than the  $C_3A$  phase, is relatively less efficient in counteracting the inhibitive action of CLS; the cubic phase is practically ineffective (Figure 5, C-1, C-2, D-1 and D-2). The greater inhibitive action of CLS (on the hydration of  $C_3S$ ) when added to cements after 5 min of hydration may be explained on the basis of the hydrated products of  $C_3A$  consuming less CLS than  $C_3A$  itself.

##### Hydration of Tricalcium Aluminate in the Presence of Sugar-free Calcium and Sodium Lignosulfonates

Figures 6, 7 and 8 compare the thermograms of  $C_3A$  hydrated in the presence of 0.1, 0.5, 1.0 or 3%

Fig. 3 - X-ray diffractogram of hexagonal phase and that treated with calcium lignosulfonate

Fig. 4 - Adsorption-desorption isotherms of calcium lignosulfonate on the hexagonal phase

commercial Ca-lignosulfoaluminate (CLS), sugar-free Ca-lignosulfonate (Sf-CLS) and sugar-free Na-lignosulfonate (Sf-NLS), for periods ranging from 1 to 60 days (18). The thermal behaviour of  $C_3A$  hydrated in the absence of admixtures (not shown in the figure) indicates, even at 15 min, a large endothermal effect at 300°C denoting the presence of the cubic phase. Slight retardation in the early stages of hydration occurs in the presence of 0.1% admixtures but at 1 day the cubic hydrate is the only dominant phase present. At 0.5% addition, Sf-NLS seems to be the best retarder,

Fig. 5 - Kinetics of the hydration of  $C_3S$  in the presence of calcium lignosulfonate,  $C_3A$  or its hydrates.

A-1 =  $C_3S+H$ ; A-2 =  $C_3S+CLS+H$ ;  
 B-1 =  $C_3S+C_3A+H$ ; B-2 =  $C_3S+C_3A+CLS+H$ ;  
 C-1 =  $C_3S+\text{hexagonal phase}+H$ ;  
 C-2 =  $C_3S+\text{hexagonal phase}+CLS+H$ ;  
 D-1 =  $C_3S+C_3AH_6+H$ ; D-2 =  $C_3S+C_3AH_6+CLS+H$ .

Fig. 6 - DTA of  $C_3A$  hydrated in the presence of commercial  $Ca$  lignosulfonate.

Fig. 7 - DTA of  $C_3A$  hydrated in the presence of sugar-free  $Ca$  lignosulfonate.

Fig. 8 - DTA of  $C_3A$  hydrated in the presence of sugar-free  $Na$  lignosulfonate.

as evidenced by the presence of only the hexagonal phase at 1 day (Figure 8). In the presence of 1.0% lignosulfonate, the conversion of the hexagonal to the cubic phase is retarded in all samples. A much more efficient retardation occurs at an addition of 3% admixture. These results demonstrate that sugar-free lignosulfonate, which is presumably adsorbed irreversibly by  $C_3A$  and its hydrates, is as efficient as the commercial lignosulfonate in retarding the hydration and interconversions in the  $C_3A-H_2O$  system. The XRD and TGA data on these samples were in fair agreement with those obtained by DTA.

## CONCLUSIONS

In the  $C_3A$ -calcium lignosulfonate (CLS)- $H_2O$  system, at low concentrations of CLS, a surface complex containing  $C_3A$ , CLS and  $H_2O$  may form, but at higher concentrations of CLS a highly basic CLS compound containing some  $Al^{3+}$  results. In the hexagonal aluminate-CLS- $H_2O$  system, scanning loops in the isotherms indicate complete irreversibility due to the formation of an interlayer complex that may be responsible for the retardation of the conversion of the hexagonal to the cubic phase. In the  $C_3AH_6$ -CLS- $H_2O$  system, a rapid irreversible adsorption is followed by dispersion.

In the non-aqueous medium, in contrast to the aqueous medium the  $C_3A$  does not adsorb CLS. Thus the present tendency of explaining the retarding action on the basis of adsorption of CLS on  $C_3A$  should be altered in favour of the concept "the consumption of CLS by the hydrating  $C_3A$ ."

The inhibitive action of CLS on the hydration of  $C_3S$  is modified by incorporation of  $C_3A$ , the hexagonal phase or the cubic phase. The phase consuming larger amounts of CLS lowers the inhibitive action of CLS on the hydration of  $C_3S$ . Thus, when prehydrated  $C_3A$  is added to the  $C_3S$ -CLS- $H_2O$  system there is less adsorption of CLS on aluminate phases, and hydration of  $C_3S$  is inhibited or retarded more than by the addition of  $C_3A$ .

Calcium and sodium lignosulfonates, deplete of sugars, are as effective as the commercial lignosulfonates in retarding the hydration of  $C_3A$ , indicating thereby that adsorption of lignosulfonate by the cement compounds is an important mechanism by which hydration is retarded.

## ACKNOWLEDGEMENTS

The author thanks G.M. Polomark for the experimental assistance. This paper is a contribution from the Division of Building Research, National Research Council of Canada, and is published with the approval of the Director of the Division.

# Influence du thiosulfate de sodium sur l'hydratation du $C_3A$

## *Influence of sodium thiosulphate on the hydration of $C_3A$*

E. ZIELINSKA, Professeur-adjoint, Ecole Polytechnique de Varsovie,

B. ZIELINSKI, Docteur ès Sciences Chimiques, Ecole Polytechnique de Varsovie, Pologne.

**RESUME:** Parmi les constituants du clinker du ciment portland c'est le  $C_3A$  qui est le plus actif dans le sens de la vitesse d'hydratation et de la réactivité chimique. Comme son hydratation peut sensiblement être atteinte par la présence d'un autre composé chimique, surtout au début du processus, l'auteur a étudié l'influence exercée sur son cours par le thiosulfate de sodium ( $Na_2S_2O_3$ ), qui d'après ses expériences s'est montré un accélérateur efficace du durcissement des ciments portland.

Les recherches étaient poursuivies sur les pâtes du  $C_3A$  pur à l'aide des RX, de la thermogravimétrie, la spectrométrie IR et la microscopie électronique TEM. On a essayé aussi de démontrer l'influence du  $Na_2S_2O_3$  sur l'hydratation du  $C_3A$  dans le clinker du ciment portland.

On a constaté que le thiosulfate de sodium retarde l'hydratation du  $C_3A$  pur durant les premières 24 heures, change la composition de la pâte et modifie la morphologie de l'hydroaluminate de calcium cubique. Les résultats de recherches font suggérer aussi que le  $C_3A$  forme, en présence du  $Na_2S_2O_3$  des sels doubles, avant tout du type AFm, contenant des groupes  $S_2O_3^{2-}$ .

Dans le cas de l'hydratation du clinker le thiosulfate de sodium n'exerce aucune influence retardatrice envers le  $C_3A$ , tout au contraire il semble l'accélérer. La cristallisation accélérée de l'hydroaluminate de calcium cubique est un fait incontestable, ainsi que l'est sa morphologie différente de la morphologie de l'hydroaluminate analogue se formant sous l'action du  $Na_2S_2O_3$  dans les pâtes du  $C_3A$  pur. La présence du  $Na_2S_2O_3$  mène aussi à la cristallisation des formes caractéristiques de morphologie analogue à celle de l'ettringite, et étant d'après toute probabilité un sel double du type Aft, comprenant des groupes  $S_2O_3^{2-}$ .

**SUMMARY:** Among the minerals of the clinker of Portland cement,  $C_3A$  is the most active in the sense of speed of hydration and of chemical reactivity. Since its hydration may undergo significant changes in the presence of other chemical compounds, particularly in the early stages, the authors examined the possible influence of  $Na_2S_2O_3$ , which according to her earlier research proved to be an effective activator of hardening of Portland cements.

Research was carried out on pastes of pure  $C_3A$  by means of X-ray analysis, thermogravimetry, IR-spectroscopy, and electronic microscopy TEM. An attempt was also made to determine the influence of  $Na_2S_2O_3$  on hydration of  $C_3A$  in Portland cement clinker.

It was found that  $Na_2S_2O_3$  retards the hydration of pure  $C_3A$  during the first 24 hrs, changes the phase composition of the paste, and modifies the morphology of the resulting cubic calcium hydroaluminate. The results also indicate that in the presence of  $Na_2S_2O_3$ ,  $C_3A$  forms complex compounds, primarily of the AFm type, containing the  $S_2O_3^{2-}$  group.

In the case of clinker,  $Na_2S_2O_3$  does not retard the hydration of  $C_3A$ , and indeed seems to accelerate it. Without doubt the appearance of cubic hydroaluminate is accelerated, and their morphology differs from the morphology of analogous hydroaluminate appearing in pure  $C_3A$  pastes under the influence of  $Na_2S_2O_3$ . In the presence of  $Na_2S_2O_3$  characteristic crystalline forms appear, morphologically analogous to ettringite, which are probably complex compounds of the Aft type, containing  $S_2O_3^{2-}$  groups.

Le thiosulphate de sodium qui s'est montré un accélérateur efficace du durcissement des ciments portlands (1) exerce une action spécifique sur le processus de leur hydratation, se manifestant avant tout au début de celui-ci et paraissant influencer le plus la phase interstitielle. C'est pourquoi, en vue d'éclaircir plus précisément le mécanisme d'action du  $\text{Na}_2\text{S}_2\text{O}_3$  on a poursuivi tout d'abord les recherches concernant l'hydratation du  $\text{C}_3\text{A}$  en présence du  $\text{Na}_2\text{S}_2\text{O}_3$ , pendant les premiers 28 jours. Les essais ont été faits pour le  $\text{C}_3\text{A}$  pur ainsi que pour le clinker du ciment portland.

#### MATERIAUX ET METHODES

Les recherches sur l'hydratation du  $\text{C}_3\text{A}$  ont été effectuées sur les pâtes monominérales, préparées avec 50% d'eau et additionnées de  $\text{Na}_2\text{S}_2\text{O}_3$  (3% par rapport au  $\text{C}_3\text{A}$ ) ainsi que sur les pâtes sans addition, comme témoins.  $\text{C}_3\text{A}$  était synthétisé par traitement thermique à partir des mélanges des oxydes. Finesse du  $\text{C}_3\text{A}$  =  $2900 \text{ cm}^2/\text{g}$ . Les observations de l'hydratation du  $\text{C}_3\text{A}$  dans le clinker étaient poursuivies sur des pâtes pareilles, préparées du clinker portland broyé jusqu'à la finesse =  $2680 \text{ cm}^2/\text{g}$ . La composition minéralogique du clinker: 67,4%  $\text{C}_3\text{S}$ , 9,5%  $\text{C}_2\text{S}$ , 10,2%  $\text{C}_3\text{A}$ , 8,5%  $\text{C}_4\text{AF}$ . La concentration du  $\text{Na}_2\text{S}_2\text{O}_3$  dans l'eau de gâchage du clinker était la même que dans le cas des pâtes du  $\text{C}_3\text{A}$  pur.

Les recherches étaient poursuivies à l'aide des RX, de la thermogravimétrie et techniques associées, la spectrométrie IR et la microscopie électronique TEM. L'évolution de la morphologie et microstructure de phases hydratées était étudiée dans le cas du  $\text{C}_3\text{A}$  pur - sur pâtes, et dans le cas du clinker - sur les fractures de grains hydratées dans une solution de  $\text{Na}_2\text{S}_2\text{O}_3$  et, parallèlement dans l'eau.

#### RESULTATS ET DISCUSSION

##### I. Hydratation du $\text{C}_3\text{A}$

Conformément aux résultats obtenus, dans les pâtes témoins - sans addition du  $\text{Na}_2\text{S}_2\text{O}_3$  les phases essentielles sont: l'hydroaluminat hexagonal  $\text{C}_2\text{AH}_8$  et l'hydroaluminat cubique  $\text{C}_3\text{AH}_6$ . En outre on décèle la gibbsite et le carboaluminat de calcium. La teneur des hydroaluminates appréciée d'après les courbes ATD, DTG et TG varie dans le temps: la quantité de  $\text{C}_2\text{AH}_8$  diminue de 14% au bout de 24 heures d'hydratation aux valeurs difficiles à déterminer d'après la méthode ci-dessus, tandis que la quantité de  $\text{C}_3\text{AH}_6$  monte de 47% (au bout de 24 heures) à 51% au bout de 28 jours. Dans les pâtes avec le  $\text{Na}_2\text{S}_2\text{O}_3$ , se trouvent comme phases essentiels: l'hydroaluminat hexagonal  $\text{C}_4\text{AH}_{13}$  et l'hydroaluminat cubique  $\text{C}_3\text{AH}_6$  accompagné aussi de gibbsite et de carboaluminat. La teneur en  $\text{C}_3\text{AH}_6$  varie dans le temps dans un sens inverse par rapport aux échantillons témoins - sa quantité diminue de 34% après 24 h jusqu'à 21% après 28 jours d'hydratation. La quantité de  $\text{C}_4\text{AH}_{13}$  diminue de 44% après 8 h à

12% après 28 jours. En même temps on observe l'accroissement de la teneur en eau libre de 6% à 14%.

Sur les courbes ATD des pâtes avec  $\text{Na}_2\text{S}_2\text{O}_3$  se fait remarquer dès les premières heures d'hydratation un pic exothermique avec un maximum à  $460^\circ\text{C}$  d'une intensité croissante dans le temps (figure 1). Aucun changement

Fig. 1 - Courbes ATD du  $\text{C}_3\text{A}$  hydraté: A - sans  $\text{Na}_2\text{S}_2\text{O}_3$ , B - avec  $\text{Na}_2\text{S}_2\text{O}_3$ ; 1-8 heures, 2-24 heures, 3-28 jours d'hydratation

de poids ne correspond à cet effet, qui, de plus ne subit nulle modification si les essais sont exécutés dans l'atmosphère d'azote - ce qui fait penser à une cristallisation d'un produit partiellement déhydraté.

Des différences marquantes se font voir aussi entre les spectres IR des pâtes avec et sans  $\text{Na}_2\text{S}_2\text{O}_3$  (figure 2). Dans le cas des pâtes additionnées on observe tout d'abord la persistance des bandes du  $\text{C}_3\text{A}$  anhydre, notamment pendant les premières 24 heures, ce qui prouve un retardement de l'hydratation du  $\text{C}_3\text{A}$  (confirmé d'ailleurs par les RX). Une attention spéciale attire l'apparition sur les courbes du  $\text{C}_3\text{A} + \text{Na}_2\text{S}_2\text{O}_3$  des bandes à  $996, 1015, 1130, 1145 \text{ cm}^{-1}$  qui, bien que situées dans le domaine des vibrations des groupes  $\text{S}_2\text{O}_3^{2-}$  ne peuvent être attribuées au  $\text{Na}_2\text{S}_2\text{O}_3$  pur (figure 3). On note aussi l'absence de la bande  $\nu_2$  de  $\text{S}_2\text{O}_3^{2-}$  à

Fig. 2 - Spectres IR du  $C_3A$  hydraté sans  $Na_2S_2O_3$  (1, 1', 1'') et avec  $Na_2S_2O_3$  (2, 2', 2'')

Fig. 3 - Spectre IR du  $Na_2S_2O_3 \cdot 5H_2O$

$600\text{ cm}^{-1}$  et des changements dans la région de  $3400\text{ à }3600\text{ cm}^{-1}$ . Les bandes en question évoluent dans le temps: après 28 jours on n'observe presque plus celle à  $996\text{ et à }1149\text{ cm}^{-1}$ , par contre celles à  $1015\text{ et à }1130\text{ cm}^{-1}$  paraissent plus intenses et mieux formées. Au plus dans le domaine  $3400\text{--}3600\text{ cm}^{-1}$ , caractéristique de vibration  $\nu_1$  et  $\nu_3$  de  $H_2O$  ainsi que  $\nu_{OH^-}$  se forment nettement des bandes à  $3622, 3550, 3475\text{ et }3400\text{ cm}^{-1}$ .

L'ensemble d'observations des spectres IR fait supposer l'existence éventuelle d'un composé du type Afm renfermant des groupes

$S_2O_3^{2-}$ . Les résultats de l'analyse thermique - l'apparition d'un effet exothermique sur les courbes ATD du  $C_3A + Na_2S_2O_3$  et, avant tout la diminution de la quantité de  $C_3A$  et  $C_4AH_{13}$  parallèlement à l'accroissement de l'eau libre dans ces échantillons font envisager aussi une telle possibilité. Le composé en question pourrait se former du  $C_4AH_{13}$  (2) à partir d'un mécanisme proposé pour les transformations des aluminates hydratés en présence du gypse, celles-ci menant à la formation du monosulphate de calcium (3,4). La formation d'un sel du type Afm expliquerait aussi le retardement de l'hydratation du  $C_3A$  par le thiosulphate de sodium. L'hypothèse présentée semble être confirmée par les observations microscopiques des produits d'hydratation dans les pâtes du  $C_3A$  pur et avec  $Na_2S_2O_3$ . C'est seulement dans les pâtes additionnées qu'on observe, outre les plaquettes de  $C_4AH_{13}$  un nombre important de grandes plaquettes hexagonales fortement déformées, constituant une caractéristique structure stratifiée (figure 4). On remarque aussi que le thiosulphate de sodium modifie la morphologie de l'hydroaluminat cubique. Dans les pâtes du  $C_3A$  pur le  $C_3AH_6$  paraît sous forme de polyèdres (figure 5) de grande dimension, tandis qu'en présence du  $Na_2S_2O_3$  - sous forme d'octaèdres de beaucoup plus petit (figure 6).

Fig. 4 - Pâte de  $C_3A + Na_2S_2O_3$  durcie 24 heures. Agglomérat de plaquettes hexagonales fortement déformées

Fig. 5 - Pâte de  $C_3A$  pur durcie 24 heures. Polyèdres de  $C_3AH_6$

Fig. 6 - Pâte de  $C_3A + Na_2S_2O_3$  durcie 24 heures; octaèdres de  $C_3AH_6$

#### HYDRATATION DU CLINKER

Les observations de l'hydratation du  $C_3A$  dans un mélange tel que clinker présentent certaine difficulté. Néanmoins les recherches faites ont put démontrer quelques mode d'action du  $Na_2S_2O_3$  sur le  $C_3A$ .

Tout d'abord aucune action retardatrice du  $Na_2S_2O_3$  n'est remarquée. Sur les courbes ATD du clinker hydraté en présence du  $Na_2S_2O_3$  (figure 7) on ne voit pas l'effet

Fig. 7 - Courbes ATD du clinker hydraté: (A) - sans  $Na_2S_2O_3$ , (B) - avec  $Na_2S_2O_3$  1-8 heures, 2-24 heures, 3-28 jours d'hydratation

exothermique à  $460^\circ C$  présent dans le cas des pâtes du  $C_3A + Na_2S_2O_3$ ; l'effet exothermique avec un maximum à  $620^\circ C$  est lié à l'interaction du  $Na_2S_2O_3$  avec les silicates (5). Tout-demême l'apparition d'un pic endothermique avec un maximum à  $320^\circ C$  indique une modification d'hydratation de la phase interstitielle par le  $Na_2S_2O_3$ .

En comparant les spectres IR du clinker hydraté en présence du  $Na_2S_2O_3$  (figure 8) aux spectres du  $C_3A + Na_2S_2O_3$  on a attiré une

Fig. 8 - Spectres IR du clinker hydraté sans  $Na_2S_2O_3$  (1, 1', 1'') et avec  $Na_2S_2O_3$  (2, 2', 2'')

attention toute particulière sur le domaine des vibrations du groupe  $S_2O_3^{2-}$  et la région  $3400-3600\text{ cm}^{-1}$ . On a noté les différences suivantes: Après 8 heures sur les spectres du clinker apparaît une bande déformée ("shoulder") à  $1100-1300\text{ cm}^{-1}$  et de très faibles bandes à:  $1015$ ,  $995$  et  $670\text{ cm}^{-1}$ . Cette dernière n'a pas été aperçue dans le cas des spectres des pâtes du  $C_3A + Na_2S_2O_3$  ou par contre apparaissait une bande à  $1145\text{ cm}^{-1}$ , absente dans le cas du clinker. Après 28 jours la bande à  $670\text{ cm}^{-1}$  a disparu et la bande à  $990\text{ cm}^{-1}$  a fortement diminué. Dans la région  $1100-1130\text{ cm}^{-1}$  on a pu voir une bande très nette avec un maximum à  $1130\text{ cm}^{-1}$ . Dans la région  $3400-3600\text{ cm}^{-1}$  la bande apparaissant sur les courbes du  $C_3A$  additionné à  $3530\text{ cm}^{-1}$  c'est déplacé sur  $3540\text{ cm}^{-1}$ , en outre on n'observe pas la bande à  $3470\text{ cm}^{-1}$ .

L'ensemble des observations fait supposer, que dans le clinker hydraté avec le  $Na_2S_2O_3$  se forme, d'après toute probabilité aussi un sel double contenant des groupes  $S_2O_3^{2-}$ , mais du type Aft.

Les images des produits d'hydratation obtenus à l'aide du microscope électronique TEM confirme cette suggestion. En cas du clinker hydraté dans la solution du  $Na_2S_2O_3$

apparaît un grand nombre de cristaux à la morphologie caractéristique, analogue à celle de l'ettringite (figure 9). Les observations microscopiques laissent aussi

Fig. 9 - Fracture de grain de clinker hydraté 8 heures dans une solution de  $\text{Na}_2\text{S}_2\text{O}_3$ . Aiguilles analogues à l'ettringite

constater que la cristallisation des hydroaluminates hexagonaux est accélérée en présence du  $\text{Na}_2\text{S}_2\text{O}_3$ . Après 15 min déjà on note la présence de plaquettes hexagonales bien formées, tandis que les produits d'hydratation du clinker hydraté dans l'eau apparaissent dans le même temps uniquement sous forme de gel.

Comme c'était le cas du  $\text{C}_3\text{A}$ , le  $\text{Na}_2\text{S}_2\text{O}_3$  change la morphologie du  $\text{C}_3\text{AH}_6$ , bien que d'une autre façon.

Dans les produits d'hydratation du clinker le  $\text{C}_3\text{AH}_6$  se cristallise sous forme de cubes (figure 10), soudés et formant une structure granuleuse.

Fig. 10 - Fracture de grain de clinker hydraté 8 heures dans une solution de  $\text{Na}_2\text{S}_2\text{O}_3$ . Cubes de  $\text{C}_3\text{AH}_6$

## CONCLUSIONS

Les recherches poursuivies ont permis de constater que le thiosulphate de sodium modifie d'une façon marquante l'hydratation du  $\text{C}_3\text{A}$ , dans les pâtes monominérales ainsi que dans le clinker. Cette modification est différente dans les deux cas.

En cas du  $\text{C}_3\text{A}$  en pâte monominérale  $\text{Na}_2\text{S}_2\text{O}_3$  retarde son hydratation, change le type de l'hydroaluminate hexagonal ainsi que la morphologie de l'hydrate cubique  $\text{C}_3\text{AH}_6$ . La pré-

sence du thiosulphate de sodium mène aussi, d'après toute vraisemblance, à la formation d'un sel double du type AFm contenant des groupes  $\text{S}_2\text{O}_3^{2-}$ .

En cas du  $\text{C}_3\text{A}$  dans le clinker on n'observe aucune action retardatrice du  $\text{Na}_2\text{S}_2\text{O}_3$ . Le thiosulphate de sodium accélère la cristallisation des aluminates hydratés hexagonaux et modifie aussi la morphologie du  $\text{C}_3\text{AH}_6$ . En présence du  $\text{Na}_2\text{S}_2\text{O}_3$  semble se former aussi un sel double contenant des groupes  $\text{S}_2\text{O}_3^{2-}$ , mais du type AFt.

# Influence of some retarders on the hydration, at early ages, of tricalcium aluminate

## *Influence des retardateurs sur l'hydratation, en tout début, de l'aluminate tricalcique*

R. SERSALE, Professor, Institute for Applied Chemistry, Faculty Engineering, University of Naples,  
V. SABATELLI, Assistant Professor,  
and G.L. VALENTI, Assistant Professor, Italie.

**SUMMARY:** The Authors give an account of the preliminary results of an experimental research carried out for the purpose of carefully investigating the influence of some set-retarders on the hydration process of tricalcium aluminate pastes.

The evaluation of the hydration degree of the starting product, as well the characterisation of hydration products, has been carried out via X-ray diffraction analysis, while scanning electron microscopy and thermal analysis have been used as complementary techniques.

The effects of the different retarders have been assessed with reference to the same hydration degree of the pastes and some information has been collected on the mechanism involved in the reaction.

**RESUME:** Les Auteurs rapportent les résultats préliminaires d'une recherche sur l'influence de quelques adjuvants retardateurs de la prise, sur l'hydratation de pâtes d'aluminate tricalcique.

A l'aide de la diffractométrie des rayons X on a évalué le degré d'hydratation des produits de départ, en caractérisant aussi les produits d'hydratation. L'analyse thermique différentielle et la microscopie électronique à balayage ont été utilisées comme techniques de référence.

Les effets des différents retardateurs ont été évalués à égalité de degré d'hydratation, en recueillant des informations sur le mode d'action des retardateurs employés.

## 1. INTRODUCTION.

The study of the chemistry of the hydration of Portland cement, in the presence of additives, preliminarily requires the careful investigation of the behaviour of the individual phases entering in its composition, even if one must act very cautiously afterwards in extending the results to the more complex system (1).

The purpose of this investigation is therefore to give a contribution to the knowledge on the hydration of tricalcium aluminate in the presence of set retarders, taking into account that this compound, whose content in Italian Portland cements runs upon 7-10%, plays an important role in the whole hydration process and also affects some determinant characteristics of these hydraulic binders.

This investigation attempts therefore to find a correlation between the retardation effect of some chemical products and the nature and morphology of the hydration products of tricalcium aluminate. The selection, restricted at the present to only three retarders, includes: a soluble salt of a complex organic acid: the sodium gluconate; a soluble salt of a simple inorganic acid: the copper acetate; an insoluble salt of a inorganic acid: the aluminium phosphate, which are all indicated in the literature as possible industrial additives (2) and therefore suitable for use in an alkaline environment, such as that characterizing hydraulic binders.

These chemicals have been employed in the form of laboratory reagent grade, in order to prevent the influence of some impurities (3); while two of them are, at least up now, among the additives whose behaviour has been very little investigated.

The study has been carried out on pastes, using the same product with no additives, <sup>as reference</sup> with the samples investigated, containing different amounts of additive, hydrated for different time intervals, always within the limits of the early ages, although the comparison of its behaviour concerns a very similar hydration degree. This condition, in our opinion, favours a more homogeneous comparison of the relative results, both in terms of intrinsic characteristics of the pastes (4) and, possibly, in terms of action mechanism.

Recently very interesting investigations have been indeed carried out on the hydration chemistry of the clinker constituent which is more responsible for setting: the C<sub>3</sub>A (5), but the most complete works concern the effect of gypsum as set retarder (1) (6) or the effect of sugars and their oxidation products (7). Moreover, the question of the action mechanism is still open, namely, whether the action is to be connected to delay in the nucleation process of the hydration products (8) rather than to the formation of a protective coating (9) which at a definite moment loses its efficiency. Nor is a possible interaction between hydration products and additive to be rejected, resulting in the formation of complexes (10)

having a stability which depends on the pH of the environment.

## 2. EXPERIMENTAL.

### 2.1. Material

Tricalcium aluminate was prepared by heating a stoichiometric mixture of calcium carbonate and aluminium oxide, both reagent grade, ground previously in an agate ball mill, for four hours at 1375°C. Thereafter the mixture was heated again during twice four hours at 1500°C. Between all firings, the product was ground and the end product was brought to a specific Blaine surface of 3500. The X-ray diffractogram (fig.3) of the product agrees completely with the data mentioned in the literature (11). The percentage of free CaO was less than 1% by weight.

### 2.2. Pastes preparation.

The pastes were prepared using synthetic tricalcium aluminate as previously reported, with a water/solid ratio of 0.6. When soluble, the additive was added in solution. The relative amounts, referred to the weight of tricalcium aluminate, were: 0.10% for sodium gluconate and 3.0% for copper acetate. The water insoluble aluminium phosphate was instead added as powder, in amount of 5% of the weight of aluminate. The above mentioned amounts were determined by means of experimental tests, in order to keep the values of the hydration degree in a rather restricted band, so as to compare systems having very similar hydration degree.

The pastes containing the retarders, as well those with no additives, were aged for time intervals within 48 hours, in a thermostat at the temperature of  $20 \pm 1^\circ\text{C}$ , in polythene envelopes, hermetically sealed.

At established times of expiry, the hydration process has been stopped by means of acetone treatment, grinding and successive filtration, followed by washing with ethyl ether. Such treatment furnished the powders that were employed in the different investigations.

X-ray investigation has been carried out by means of a Philips diffractometer, using CuK $\alpha$  radiation, scanning speed  $0.5^\circ\text{C}$  20/min., time constant 8 secs. Quantitative evaluation of the percentage of hydrated C<sub>3</sub>A were made using the method worked out by Daugherty and Kowalewski (12).

Thermal differential analysis has been made with a Du Pont thermalanalyser, heating rate  $10^\circ\text{C}/\text{min}$ .

Thermogravimetric analysis has been made by means of a Stanton thermobalance Massflow Mod. MF/H5/20, heating rate  $6.6^\circ\text{C}/\text{min}$ , using 80 mg of powder.

Scanning electron microscopy analysis has been carried out by means of a Leitz-AMR 1200, using samples previously metallized with carbon and successively with a gold-palladium alloy.

### 2.3. Results.

The course of the hydration process of the pastes containing the selected additives in the above mentioned percentages, is reported in fig.1. Term of reference is always the paste of tricalcium aluminate with no additive (curve n.4). Besides the retardation effect which is more intense if sodium gluconate is used (curve n.3), one should notice the long induction period in the hydration process, which follows the addition of this retarder, as clearly appears from curve n.3. Fig.1 shows that while the samples prepared using

Fig.1 - Hydration degree (%) of  $C_3A$  pastes with or without retarders, versus reaction time (hours).

aluminium phosphate (curve n.2) or copper acetate (curve n.1), aged for about five hours, obtain a hydration degree of about 50%, those made with sodium gluconate, tested in the same condition, hardly reach one of 10%.

On the contrary, samples aged 48 hours show that the influence of all the selected additives, in the percentages indicated above, appears to be pretty similar, with a slight inversion for the action of sodium gluconate. The hydration degree of pastes prepared with this retarder surpasses, indeed, even if very little, those of the pastes prepared with the other two additives, respectively.

Fig.2 shows the results of thermal differential analysis, carried out on fraction of pastes prepared with no additives, aged for time intervals within 10 min. and 48 hours. The following five endothermal peaks are to be seen: the first, declining with the increase of the aging and showing considerable amplitude at very early hydration ages, with a maximum between 170 and 180°C, more intense for ages between 30 and 66 min., which can be attributed to dicalcium aluminate hydrated (13); the second, very weak and with a maximum around 250-255°C, this, too, declining with the increase of the aging, which can be attributed to the tetracalcium aluminate hydrated (13); the third, increasing with the aging, with a maximum between 280 and 320°C, which can be attributed to tricalcium aluminate hydrated (13); the fourth, which can be recognized after aging of about seven hours, increasing with the length of aging, with a maximum between 480 and 505°C, which can be attributed to the dehydration of calcium hydro-

xide, deriving from thermal decomposition of tricalcium aluminate hydrated (13); the fifth, very weak with a

Fig.2 - DTA traces of  $C_3A$  pastes with no retarders, aged for: a=10; b=30; c=66 min.; d=7; e=48 hours.

maximum around 760°C, which can be attributed to the presence of slight quantities of calcium carbonate, deriving from thermal decomposition of calcium carboaluminate (14), recognized by X-ray diffraction. The figure, which represents a useful reference for evaluating the behaviour of the starting product in presence of additives, shows that in the experimental conditions that have been selected, the formation of tricalcium aluminate hydrated, together with di- and tetracalcium aluminate hydrated, is to be recognized, just after 10 min of reaction with water. Moreover, after hydration times running about seven hours, the rate at which tricalcium aluminate hydrated is generated, exceeds the rate at which dicalcium aluminate, as well tetracalcium aluminate hydrated, is produced.

Fig.3, 4 and 5 show a selection of the more interesting results of the investigations on pastes prepared with the retarders in the amounts that have been indicated above. Term of reference is always a paste of tricalcium aluminate hydrated with no additive. As has been emphasized above, the comparison is made at a pretty similar hydration degree, in order to restrict the numbers of the factors affecting the behaviour of the system.

Each of the three figures refers chronologically: to a paste containing copper acetate (n.1); aluminium phosphate (n.2); sodium gluconate (n.3), as well to a paste prepared with no additive (n.4). The relative aging are indicated by the points marked in fig.1. In fig.3 the diffractogram of the unhydrated product is

reported in order to make the comparison more easy (n.0).

Fig.3 - X-ray patterns of C<sub>3</sub>A pastes having similar hydration degree (see fig.1).

The examination of the diffractograms in fig.3 shows that in the presence of additives, the neo-formed phases are characterized by a relative low degree of crystallinity. The only phases that can be recognized are: C<sub>3</sub>A·CaCO<sub>3</sub>·H<sub>12</sub> (lines at 11.63; 23.39; 31.24 °2θ) and C<sub>4</sub>AH<sub>13</sub> (lines at 11.19; 22.49; 31.12 °2θ), excluding the lines that can be attributed to the fraction not yet hydrated and recognizable by a comparison with the diffractogram n.0.

The lines at 17.27; 19.94; 26.50; 28.40; 31.77, etc. 2°θ, in the diffractogram of the paste with no additive (n.4), show the presence of C<sub>3</sub>AH<sub>6</sub>, together with the phases just indicated.

The diffractograms of the same pastes, aged for times different from those that are mentioned above, show the same lines as these just indicated; the only difference is that C<sub>3</sub>AH<sub>6</sub> does not appear when the length of the hydration falls under 66 min.

Fig.4 shows the following endothermic peaks: a peak with maximum at 175-180°C, which can be attributed to the presence of C<sub>2</sub>AH<sub>3</sub>; a peak, with a maximum between 240-270°C, which can be attributed to the presence of

C<sub>4</sub>AH<sub>13</sub>; a peak, with maximum at 320°C, which in the presence of sodium gluconate appears at 280°C, attributable to the presence of C<sub>3</sub>AH<sub>6</sub>.

Fig.4 - DTA traces of C<sub>3</sub>A pastes having similar hydration degree (see fig.1).

As a significant difference in the presence of additives, there is to be noticed the appearance of peak with maximum around 80°C, which can be attributed to the presence of C<sub>4</sub>AH<sub>19</sub> (7). Its evolution in C<sub>4</sub>AH<sub>13</sub> seems indeed to be inhibited, in normal conditions of drying, by the presence of the three retarders selected.

Fig.5 allows one to verify precisely, on the basis of the relative losses of weight, the presence of the phases individuated by X-ray diffraction analysis (fig.4). A lack of the slight loss of weight, before 100°C, in the diagram of the paste with no additive (n.4) is to be seen. This loss can be attributed to the dehydration of C<sub>4</sub>AH<sub>19</sub> and has been observed only in the presence of additives. According to X-ray results, in the temperature interval of 200-300°C (fig.5), there is to be noticed the slight difference in the profile of curves 1 and 2, in comparison to curve 3. Only for this curve may one observe the insertion of a second localized loss at about 280°C, on the continuous loss which begins at about 200°C, according to the two endothermic distinct peaks at about 255 and 280°C in fig.4.

It seems therefore correct to ascribe the anticipation

at 280°C of the dehydration effect of  $C_3AH_6$ , which usually can be found at 320°C, to the poor crystallinity of this compound because of the presence of sodium gluconate. Such an interpretation seems to be very

Fig.5 - TGA traces of  $C_3A$  pastes having similar hydration degree (see fig.1).

likely, on the basis of the profile of the differential thermal diagrams a and b in fig.2, concerning the dehydration of pastes without retarders, at very early ages, between 10 and 30 min.

Fig.6 shows a selection of the examination of  $C_3A$  pastes with or without retarders, by scanning electron microscopy.

Micrographs a and b concern pastes with no additive. Micrograph a shows the presence of irregular lamellar forms and secondarily of forms attributable to a cubic lattice, in a paste aged for about one hour. On the basis of X-ray diffraction analysis and of the complementary techniques, the lamellar forms can be attributed to the calcium aluminates hydrated:  $C_2AH_8$  and  $C_4AH_{13}$  (15), the others to tricalcium aluminate hydrated. The last forms become more evident for aging running about 48 hours (micrograph b).

Micrographs c, d and e concern, chronologically, the pastes prepared with sodium gluconate, copper acetate and aluminium phosphate, respectively, in the above mentioned amounts. The comparison of the microstructures is made, as just emphasized, at pretty similar degree of hydration. The microstructures appear to be very similar and the absence of forms attributable to a cubic lattice can be observed. This remark also con-

cerns aging of about 48 hours, as it has been observed, for example, in the micrograph f (paste with aluminium phosphate).

### 3. DISCUSSION.

Among the three different retarders that have been used in this study, sodium gluconate seems the most active chemical. Its action not only appears to be more effective, but concerns the whole process which in turn seems to be characterized by a long induction period before the chemical decreases its activity. The complex phenomenon seems to involve the nature of the neo-formed phases, too, since if in the presence of all the retarders used we have always observed phases attributable to calcium aluminates hydrated:  $C_2AH_8$  and  $C_4AH_{13}$ , only in the presence of sodium gluconate has it been possible to reveal the probable, rapid formation of tricalcium aluminate hydrated, as soon as the induction period stops.

Owing to the mode of formation, this aluminate is characterized by a low crystallinity degree, of the type of phase which it is possible to detect, at very early ages, by hydration of tricalcium aluminate with no retarder.

The selected additives favour the stabilisation of a calcium aluminate hydrated which, according to the temperature of dehydration, could be classified as  $C_4AH_{19}$  (7).

The retarders that have been employed do not seem to favour single morphological modifications that are possible to reveal by scanning electron microscopy examination on pastes; so that the microstructure appears to be similar in all the samples prepared with the three different retarders.

In spite of the different chemical nature, the mechanism of the three additives can be brought back to the same pattern and supports the more reliable theory (16) of a stabilisation of hexagonal calcium aluminates hydrated.

The questions concerning the main mechanism responsible for the retardation and the research of the reasons which at a precise moment cancel the stabilising effect, are therefore still open, so investigations in the field must be encouraged.

### Résumé

L'étude de l'hydratation de C<sub>3</sub>A seul et dans les mélanges synthétiques C<sub>3</sub>A + C<sub>3</sub>S + gypse a été effectuée en présence d'un accélérateur de C<sub>3</sub>S, le chlorure de calcium et d'un retardateur de C<sub>3</sub>A, le saccharose. Le taux d'hydratation a été mesuré par diffraction des rayons X et la morphologie des hydrates observée par microscopie électronique à balayage.

Il existe une compétition gypse-CaCl<sub>2</sub> dans l'hydratation de C<sub>3</sub>A jusqu'à 28 jours (formation de sulfoaluminate et de chloroaluminate). L'interaction C<sub>3</sub>A-C<sub>3</sub>S, trouvée dans les conditions normales d'hydratation, est également mise en évidence en présence d'adjuvants accélérateurs et retardateurs.

### Summary

Hydration study of C<sub>3</sub>A and C<sub>3</sub>A in synthetic mixtures C<sub>3</sub>A + C<sub>3</sub>S + gypsum has been done with an accelerator of C<sub>3</sub>S (calcium chloride) and a retarder of C<sub>3</sub>A (saccharose). The hydration ratio has been measured by X-ray diffraction and the morphology of the hydrates observed by scanning electron microscopy.

There is a competition between gypsum and CaCl<sub>2</sub> during hydration of C<sub>3</sub>A up to 28 days (formation of sulfoaluminate and chloroaluminate). The C<sub>3</sub>A-C<sub>3</sub>S interaction found in normal conditions of hydration, is also shown with admixtures, accelerators and retarders.

## 1. INTRODUCTION

L'action des adjuvants sur l'hydratation du ciment portland est complexe car elle fait intervenir un grand nombre de paramètres (composition chimique et teneur de l'adjuvant, composition minéralogique et temps d'hydratation du ciment, température) (1).

Afin de décomposer les interactions adjuvant-ciment, des études ont été entreprises sur le rôle des accélérateurs et des retardateurs sur l'hydratation de chacun des constituants du ciment portland (C3S, C2S, C3A, C4AF) puis sur des mélanges C3S + C3A (les deux phases qui s'hydratent en premier) et C3S + C3A + gypse, enfin sur des produits industriels.

Le taux d'hydratation de chaque minéral a été déterminé par diffraction des rayons X (DRX) par la méthode de l'étalon interne. La microstructure des pâtes, au cours de la prise et du durcissement, a été observée par microscopie électronique à balayage (MEB).

L'étude a porté principalement sur le rôle d'un accélérateur, le chlorure de calcium, et d'un retardateur, le saccharose.

## 2. PREPARATION DES ECHANTILLONS

Afin d'assurer une meilleure répartition de l'adjuvant, celui-ci a toujours été dissous dans l'eau de gâchage. Sa quantité a été mesurée en % pondéral par rapport au poids du ciment (rapport e/c = 0,5).

Fig. 1 : C3A hydraté 2 jours. Dodécaèdres rhomboïdaux de C3AH6 et plaquettes de C4AH13.

Les phases pures préparées au laboratoire sont broyées et tamisées de façon à obtenir une granulométrie comprise entre 25 et 40 µm.

Le ciment utilisé provient d'un clinker broyé à la finesse de 3570 cm<sup>2</sup>.g<sup>-1</sup> et additionné de 5 % de gypse.

Les échantillons se présentent sous la forme de micro-éprouvettes cylindriques (phases pures) ou cubiques (ciments). Les éprouvettes sont conservées pendant deux jours dans une atmosphère à 100 % d'humidité relative puis immergées dans l'eau à 20 °C. A l'échéance prédéterminée, elles sont plongées dans l'azote liquide afin d'arrêter les réactions d'hydratation, l'eau est évaporée par cryosublimation. Dans chaque série, les échantillons adjuvés sont comparés à un échantillon témoin.

Nous retiendrons de l'étude générale des deux adjuvants sur les phases du clinker, l'action du saccharose et du chlorure de calcium sur C3A seul puis sur C3A dans les mélanges C3A + C3S, C3A + C3S + gypse et enfin dans un ciment portland.

## 3. HYDRATATION DE C3A SEUL

L'aluminate tricalcique réagit très rapidement avec l'eau en donnant les hydrates hexagonaux C2A H8 et C4A H13 qui se transforment en hydrate cubique C3A H6. A deux jours, le témoin est presque entièrement hydraté en gros cristaux (dodécaèdres rhomboïdaux) de C3A H6 (fig. 1).

Fig. 2 : Taux d'hydratation α en fonction du temps et de l'adjuvant.

Fig. 3 : Pâte de C3A hydraté 28 jours. Enregistrements diffractométriques X obtenus sur C3A pur et sur C3A + CaCl<sub>2</sub>.

- (1)  $\text{CaCl}_2$  n'a pas d'influence sensible sur le taux d'hydratation de C3A (fig. 2). Les hydrates formés diffèrent cependant de ceux du témoin : chloroaluminates  $\text{C}_3\text{A} \cdot \text{CaCl}_2 \cdot 12\text{H}_2\text{O}$  et  $\text{C}_2\text{AH}_8$  identifiés par diffraction des rayons X à 28 jours. Dans le témoin, seuls sont détectés  $\text{C}_3\text{AH}_6$  et  $\text{C}_4\text{AH}_{13}$  (en faible teneur) (fig. 3).

- (2) Le saccharose est retardateur de C3A (fig. 2). En présence de 1% de saccharose, la prise est instantanée mais l'hydratation est pratiquement bloquée jusqu'à 2 jours. La réaction est ensuite très lente et le taux d'hydratation plafonne à 50% entre 7 et 28 jours. A cette dernière échéance  $\text{C}_3\text{AH}_6$  est en très faible proportion d'après la DRX qui, par contre, caractérise l'aluminate  $\text{C}_4\text{AH}_{13}$  par une raie très élargie, preuve d'une moins bonne cristallisation que dans le témoin (fig. 4).

Fig. 4 : DRX - C3A + saccharose hydraté 28 jours.

Le MEB révèle dans les premiers instants la présence d'une membrane qui enrobe tous les grains de C3A (fig. 5), et qui semble être la cause du retard de l'hydratation aux premiers âges. En se fissurant par la suite, elle permet au grain anhydre sous-jacent de s'hydrater mais la réaction reste plus lente que dans le cas du témoin. Les aluminates sont mal cristallisés et la conversion en aluminate cubique est sinon empêchée, du moins considérablement retardée. La formation d'un aluminate hydraté contenant dans son réseau un complexe organique interlamellaire a été suggérée par YOUNG (2), RAMACHANDRAN et FELDMAN (3), MILESTONE (4,5), VAN WALLENDIAEL et MAHIEU (6).

Fig. 5 : Pâte C3A + 1% saccharose.  
Membrane recouvrant les grains de C3A.

#### 4. HYDRATATION DU MELANGE C3S (80%) + C3A (20%)

Le C3A du témoin s'hydrate uniquement en cristaux hexagonaux de  $\text{C}_4\text{AH}_{13}$ . L'interaction C3A-C3S y est très nette : C3A s'hydrate plus lentement que lorsqu'il est seul (75% du C3A hydraté à 28 jours) ; C3S s'hydrate plus rapidement (45% dès 7 jours contre 30%).

Le taux d'hydratation pondéré du mélange C3S + C3A est donné sur la figure 6. L'action des deux adjuvants appelle les remarques suivantes :

- (1)  $\text{CaCl}_2$  est accélérateur de C3A à 1 jour. Ensuite, les chloroaluminates qui apparaissent en amas autour des grains de C3A retardent son hydratation (fig. 7). Le pourcentage d'anhydre (environ 10%) reste constant entre 2 et 28 jours, l'hydratation est moins avancée que sur le témoin. Les aluminates hydratés se présentent sous forme d'un mélange de chloroaluminates et de  $\text{C}_4\text{AH}_{13}$ .

- (2) Le saccharose maintient un effet retardateur jusqu'à 1 jour pour un pourcentage pondéral de 0,1% et jusqu'à 4 jours pour 0,2%. Ensuite, il devient nettement accélérateur et le taux d'hydratation dépasse celui des deux autres échantillons (fig. 8 a & b).

L'interaction C3A-C3S est également très nette. L'allure des courbes de variation du taux d'hydratation est la même pour C3S et C3A.

Fig. 6 : Pâtes C3S + C3A - Taux d'hydratation global  $\alpha$  en fonction du temps.

Fig. 7 : Pâte C3S + C3A + 1%  $\text{CaCl}_2$ .

Fig. 8 : Pâtes C3S + C3A - Taux d'hydratation  $\alpha$  de C3S et de C3A en fonction du temps.

#### 5. HYDRATATION DU MELANGE C3S (76%) + C3A (19%) + GYPSE (5%)

L'hydratation se rapproche de celle d'un ciment portland. Le gypse est un régulateur de prise. Il retarde la cristallisation des aluminates hydratés hexagonaux par la formation de sulfoaluminates : d'abord, le trisulfoaluminate  $C_3A \cdot 3CaSO_4 \cdot 32H_2O$ , puis le monosulfoaluminate  $C_3A \cdot CaSO_4 \cdot 12H_2O$ , enfin une solution solide  $C_3A \cdot CaSO_4 \cdot 12H_2O - C_4AH_13$  (fig. 9).

- (1) L'action de  $CaCl_2$  doit être considérée séparément sur C3S et C3A.  $CaCl_2$  a un rôle accélérateur de C3S jusqu'à 7 jours (fig. 10). Cet effet apparaît clairement sur les diagrammes de diffraction des rayons X du mélange avec et sans  $CaCl_2$  à l'échéance de 2 jours (fig. 11). Par rapport à la raie de l'étalon interne Si, celles de C3S anhydre sont beaucoup moins intenses en présence de  $CaCl_2$ . La chaux  $Ca(OH)_2$  est caractérisée par les deux raies à 3,11 et 2,63 Å alors qu'elle est à peine détectée sur le témoin.  $CaCl_2$  modifie la microstructure du C-S-H qui est réticulé en raison de la présence d'ions  $Cl^-$  dans son réseau cristallin. La différence est pratiquement inexistante en ce qui concerne C3A.

Le gypse (témoin) est moins retardateur de l'aluminate tricalcique que  $CaCl_2$ .

Ces résultats sont illustrés par la figure 12 où sont comparés les taux d'hydratation de C3A dans divers cas : les courbes 1 et 4 montrent l'effet retardateur du gypse ; les courbes 4 et 5 le rôle retardateur de  $CaCl_2$  par rapport au gypse.

Dans le témoin les premiers hydrates formés sont de l'ettringite en fines aiguilles disséminées. Dans l'éprouvette contenant  $CaCl_2$  on observe des assemblages de plaquettes hexagonales de chloroaluminate  $C_3A \cdot CaCl_2 \cdot 12H_2O$ .

- (2) Le saccharose retarde l'hydratation de C3S jusqu'à 2 jours puis l'accélère, par rapport au témoin, jusqu'à 7 jours. A partir de cette dernière échéance, les deux échantillons (témoin et adjuvanté) ont un taux d'hydratation comparable.

Le C3A est aussi retardé mais moins qu'avec  $CaCl_2$ . Le taux d'hydratation moindre par rapport au témoin est mis en évidence par la présence d'ettringite à 7 et 28 jours (fig. 13) alors que le témoin contient déjà des monosulfoaluminates (fig. 9).

Fig. 9 : Pâte C3S + C3A + gypse, 7 jours, monosulfoaluminates.

## 6. HYDRATATION DU CIMENT PORTLAND

Le ciment portland étudié contient 62% C3S et 15% C3A. Les résultats des mélanges C3S + C3A + gypse s'appliquent au ciment :  $\text{CaCl}_2$  est accélérateur, le saccharose est nettement retardateur entre 4 et 16 heures. On note qu'avec  $\text{CaCl}_2$  la différence affecte surtout C3S comme l'indique le diagramme de diffraction des rayons X

à l'échéance de 4 heures (fig. 14) : la raie de C3A a sensiblement la même intensité que dans le témoin. A partir de 24 heures, les trois échantillons, le témoin et les deux adjuvants (1%  $\text{CaCl}_2$ , 0,1%  $\text{C}_{12}\text{H}_{22}\text{O}_{11}$ ) suivent la même courbe d'hydratation. Cependant, les échantillons contenant le saccharose sont moins compacts que les deux autres, la fracture observée au MEB est plus intergranulaire que transgranulaire.

Fig. 14 : CPA. DRX - Enregistrements pas à pas obtenus sur le CPA avec et sans  $\text{CaCl}_2$ . (G = gypse)

Fig. 15 : CPA. Taux d'hydratation global  $\alpha$  en fonction du temps.

L'hydratation des grains de clinker est plus irrégulière. L'effet retardateur de 0,1% de saccharose sur le C3A dans le ciment portland est détectable par DRX, il est faible jusqu'à 1 jour. Les deux adjuvants considérés ici ont, surtout en présence de gypse, un effet sur C3S (fig. 15).

#### DISCUSSION

Le chlorure de calcium intervient dans la période précoce de l'hydratation du ciment. Il affecte essentiellement la nucléation des silicates hydratés C-S-H et de la portlandite  $\text{Ca}(\text{OH})_2$ , hydrates du C3S. Au cours de l'hydratation de C3A il existe une compétition gypse- $\text{CaCl}_2$ . Jusqu'à 28 jours, le sulfate est moins retardateur que le chlorure. Celui-ci forme aux premières échéances un chloroaluminate protecteur dont l'effet retardateur apparaît beaucoup moins en présence de gypse : les courbes de la figure 16 mettent bien en évidence cette influence des deux adjuvants  $\text{CaCl}_2$  et saccharose en présence et en l'absence de gypse, sur l'hydratation d'un mélange C3S (80%) + C3A (20%). Les courbes 1, 2, 3 représentent le taux d'hydratation pondéré en l'absence de gypse et les courbes 4, 5, 6 le taux d'hydratation en présence de gypse : l'effet des deux adjuvants est très nettement atténué et  $\text{CaCl}_2$  agit globalement comme un accélérateur.

Le saccharose est retardateur de C3S aux brèves échéances. Il est également retardateur de C3A par formation d'aluminates mal cristallisés (raie de diffraction des rayons X très élargie à 8,2 Å).

#### CONCLUSION

La diffraction des rayons X et le microscope électronique à balayage ont permis de suivre l'évolution de la microstructure des produits adjuvantés (phases pures, mélanges synthétiques et ciments industriels). Ces techniques mettent bien en évidence d'une part l'influence des adjuvants accélérateurs et retardateurs sur la cristallisation et la composition des hydrates du ciment, d'autre part l'action différente de ces adjuvants sur un minéral à l'état isolé ou inclus dans un système polyphasé. Dans un ciment, le rôle d'un adjuvant doit tenir compte des interactions C3A-C3S et gypse-adjuvant.

# Interaction of aluminates with carbohydrates and aldonates

## *Interaction des aluminates avec les hydrates de carbone et les aldonates*

B. CASU\*, M. CHIRUZZI\*\*, F. TEGIACCHI\*\* and G. ZOPPETTI\*, Research Chemists.

\* « G. Ronzoni » Research Institute and \*\* Grace Italiana S.p.A., Milan, Italy.

**SUMMARY:** The interaction of  $C_3A$  (both alone and in cement compositions) with some carbohydrates and the corresponding aldonates, was investigated using optical rotation, potentiometric, NMR and IR methods. Evidence was obtained that stable complexes form first in solution and then precipitate, coating the  $C_3A$  granules. The complexing ability of the carbohydrate was correlated with the flow and resistance properties of cement pastes added of the carbohydrate.

Blocking the anomeric center by formation of a methyl glucoside substantially reduced the complexing ability of the carbohydrate and its water-reducing properties on cement pastes, on the contrary, this ability was substantially enhanced by the corresponding aldonates. The strength of the cement-pastes appear to be affected in a more complex way.

The carboxylate group as well as all the hydroxyl groups of the aldonates, are involved in complexing with  $C_3A$ . The availability of suitably oriented hydroxyl groups on contiguous units of disaccharides also appear to favour the formation and stability of the complexes.

**RESUME:** L'interaction du  $C_3A$  (soit lui-même, soit comme composant du ciment) avec quelques hydrates de carbone et les aldonates correspondants fut étudiée en adoptant des méthodes de rotation optique, potentiométriques, NMR et IR. Il fut mis en évidence que les complexes stables se forment tout d'abord en solution et ensuite précipitent en revêtant les granules de  $C_3A$ .

La capacité complexante des hydrates de carbone a été mise en relation avec les caractéristiques de résistance et d'ouvrabilité des pâtes de ciment contenant des hydrates de carbone.

Au moment où on bloque le centre anomérique, avec la formation d'un méthyl glucoside, on réduit substantiellement la capacité complexante des hydrates de carbone et leurs propriétés de réduction d'eau sur les pâtes du ciment; au contraire, cette capacité était récupérée substantiellement avec les aldonates respectifs. La résistance du ciment semble être influencée d'une façon plus complexe.

Les groupes carboxyliques, d'ailleurs tous les groupes hydrosiliciques des aldonates sont mêlés dans la complexation avec le  $C_3A$ .

La disponibilité des groupes oxhydriques orientés convenablement sur les unités contigues des disaccharides semble favoriser aussi la formation et la stabilité des complexes.

## INTRODUCTION

Carbohydrates are well-known set-retarders of cement, and to some extent they also improve the flow properties of cement pastes (1). Although there is a general agreement on the concept that carbohydrates, as well as the corresponding aldonates, act as set-retarders by coating the cement granules thus retarding the hydration of its components, it is still not clear whether the additives are just adsorbed by the granules or precipitate on the granules after complexation with cement components that went into solution. Conflicting conclusions have also been drawn from different types of experiments as regards the role played in the set-retarding process by the "aldehydo" (in fact, hemiacetal) groups of reducing sugars, and of the hydroxyl groups alpha to the carboxylate groups of hydroxyacids (2-7).

To elucidate some of the above aspects, the present work was focused on the interaction of some carbohydrates (and the corresponding aldonates) with cement components in solution, in the presence of an excess of these components in the solid state. Since the effects of additives on the first stages of hydration primarily involve interaction with tricalcium aluminate ( $C_3A$ ), this component was investigated in more detail. However, experiments were also made with the silicates ( $C_3S$  and  $C_2S$ ) and ferroaluminates ( $C_4AF$ ).

The investigated carbohydrates were reducing monosaccharides (typically, D-glucose), the di-saccharide maltose ( $\alpha$ -D-glucopyranosyl-1,4-D-glucose) and the corresponding aldonates. The non-reducing monosaccharide methyl- $\alpha$ -D-glucoside was used as a model, to investigate the effect of blocking the hemiacetal group. Aldonates other than D-gluconate (D-galactonate and D-mannonate) were also investigated, in order to evaluate the influence of a change in configuration at carbons-4 and -2 relative to D-gluconate.

The influence of the  $-CH_2OH$  group at C-6 was indirectly evaluated using an aldonate lacking this group, i.e. D-xylonate.

The structure of D-glucose, maltose and the corresponding aldonates are shown in Figure 1.

The present approach involved monitoring several physico-chemical parameters of the aqueous phase containing the additive contacted with cement components (especially  $C_3A$ ), as a function of the time of contact. The main parameter considered was optical rotation. In the absence of complexation with solubilized cement components, the optical rotation values provide a sensitive determination of the optically-active additives that remain in solution at any given time of contact.

In case of an interaction with cement components in solution, these values are also a function of the type and extent of complexing. Together with independent measurements of total (free+complexed) additive in solution, the optical rotation measurements are thus a measure of the extent of involvement of the additive in complexing with solubilized cement components. Total additive was measured by colorimetric and potentiometric methods.

The extent of solubilization of cement components in the presence of the additive was determined by measuring total calcium (by atomic absorption). "Free" calcium was evaluated by potentiometric measurements, using both a calcium-specific electrode and a standard pH electrode. Soluble complexes were also investigated by  $^1H$ -NMR spectroscopy, and solid complexes by IR spectroscopy.

## MATERIALS AND METHODS

Monosaccharides, maltose and sodium D-gluconate were chromatographically pure commercial samples (Merck, Darmstadt and C. Erba, Milan). The aldonates of D-galactose, D-mannose, D-xylose and maltose were prepared starting from the corresponding aldoses (8).  $C_3A$ ,  $C_3S$ ,  $C_2S$  and  $C_4AF$ , were prepared by standard procedures.

The optical rotation was measured with a Perkin-Elmer Mod. 141 photoelectric polarimeter, at 436 nm. Use of this wavelength, which doubles the sensitivity as compared with the sodium D-line, was especially required at the lowest concentrations of the aldonates.

The potentiometric experiments were made with a Metrohm pH-meter. The pH was measured with a standard glass electrode, and the  $Ca^{++}$  activity with an Orion ion-specific electrode.

The atomic absorption measurements on  $C_3A$ -carbohydrate solutions were made on a Perkin-Elmer Mod. 303 spectrophotometer, equipped with a calcium lamp. The IR spectra of solid samples of  $C_3A$  + additive (as KBr pellets) were obtained with a Perkin-Elmer Mod. 337 grating spectrophotometer. After contacting with  $H_2O$  or carbohydrate (aldonate) solutions, the  $C_3A$  granules were air-dried before preparing the pellets. The spectra of the soluble complexes were obtained after evaporating the solvent under vacuum, after filtering the solutions as described for the optical rotation measurements.

The  $^1\text{H}$ -NMR spectra of sodium gluconate solutions were obtained with a 90 MHz Perkin-Elmer Mod. R-32 spectrometer. A 10% (w/v) solution of gluconate in  $\text{D}_2\text{O}$  (99.7%), alone and saturated with  $\text{C}_3\text{A}$ , was evaporated under vacuum, and the residue redissolved in  $\text{D}_2\text{O}$ . The evaporation-solubilization process was repeated three times, to exchange with deuterium most of active hydrogens of the samples. The spectra of the gluconate- $\text{C}_3\text{A}$  solutions were obtained within 30' from their preparation, before precipitation of any solid complex.

The physico-chemical parameters of the aqueous systems were measured as follows:

4 g aluminate (or silicate, clinker or cement) were introduced in a 400 ml beaker containing 200 ml  $\text{H}_2\text{O}$  (or the same volume of a solution containing from 0.2 to 10% (w/v) carbohydrate or aldonate). For the optical rotation and atomic absorption measurements, 10 ml aliquots were taken from the solution (vigorously stirred with a magnetic stirrer) at given time intervals, with a syringe equipped with a Milipore 0.45  $\mu$  filter.

pH and  $\text{Ca}^{++}$  activity measurements were made with the electrodes directly immersed in the suspensions. Typical measurements were made after 1', 3', 5', 10', 20', 30', 60', 100' and (occasionally) 1000'.

The total concentration of carbohydrate in solution was determined by the colorimetric anthrone (9) method, on filtered aliquots of the suspensions. Total aldonates in solution were similarly determined by potentiometric titration with 0.1N NaOH, on the eluates from a column of IR-120 ( $\text{H}^+$ ) resin.

The effect of the additives on the flow and strength properties of cement pastes was evaluated on a Portland cement, using standard tests (UNI 7102).

## RESULTS

The optical rotation of the reducing carbohydrates suddenly decreased at the very early stages (within a few minutes) of contacting with  $\text{C}_3\text{A}$ . Being paralleled by a concurrent decrease of the carbohydrate concentration (colorimetric analysis), this behaviour clearly reflect precipitation of the carbohydrate. On the contrary, the non-reducing carbohydrate methyl

$\alpha$ -D-glucoside did not precipitate (no changes in optical rotation over a period of 100' of contacting with  $\text{C}_3\text{A}$ ).

The optical rotation of sodium gluconate solutions is dramatically affected by contacting the solution with solid  $\text{C}_3\text{A}$ . An increase of up to 5 times the original rotation value ( $[\alpha]_{436} = +23$ ) was in fact observed, the actual increase being a function of the time of contact with  $\text{C}_3\text{A}$ . Such a behaviour is illustrated in Figure 2, where the optical rotation changes of solutions of different gluconate content (from 0.2 to 5% w/v) are plotted vs the time of contact with  $\text{C}_3\text{A}$ .

(For the sake of presentation, the curves are "normalized", i.e. the  $\alpha$  values are divided by the corresponding concentration of gluconate, and vertically displaced by the same amount relative to each other.)

Fig. 2 - Optical rotation ( $\alpha_{436}$ ) of solutions at different concentrations of sodium gluconate, as a function of the time of contact with  $\text{C}_3\text{A}$ . (The curves are normalized and vertically displaced with respect to each other (see text). The arrow indicates the  $\alpha$  value for the 0.2% gluconate solution at time zero).

As shown in the figure, the relative increase in optical rotation at any given time of contact with  $\text{C}_3\text{A}$  is also a function of the gluconate concentration. For 0.2% gluconate solutions, a maximum value of  $\alpha$  was already reached after 1 minute contacting with  $\text{C}_3\text{A}$ . The optical rotation then steadily decreased with time, reaching a minimum value after 100'.

As the original gluconate concentration increased from 0.3 to 3%, the maximum  $\alpha$  value was displaced toward longer times, followed by a progressively steeper decrease. Potentiometric analyses indicated that practically all the gluconate present before contacting with  $\text{C}_3\text{A}$  remained in solution up to the time at which a decrea

se of  $\alpha$  is observed, and that the drop in  $\alpha$  values is clearly associated with disappearance of the gluconate, as it precipitates from the solution. (Such a precipitation was currently observed after a while even from filtered solution, i.e. non longer contacted with  $C_3A$ .)

In the presence of  $C_3A$  granules, precipitation occurred after 1' for 0.2% gluconate solutions, - 3' for 1% and - 25' for 3% solutions. At 5% gluconate, all  $C_3A$  used in these experiments (2g) went into solution after - 10', originating a clear stable gel.

As shown in Figure 3, also other clinker components produced an increase in optical rotation of gluconate solutions. However, such an increase was observed at times considerably longer than for  $C_3A$ . The maximum  $\alpha$  values were at - 40' for  $C_3S$ , - 1000' for  $C_4AF$  and more than 1000' for  $C_2S$ . Also, the relative increase of  $\alpha$  (as measured on contacting the gluconate solutions with the same amount of each clinker component) was substantially lower than observed for  $C_3A$ .

Fig. 3 - Apparent concentration of gluconate as calculated from  $\alpha_{436}$  values before contacting with  $C_3A$ , as a function of the time of contact with  $C_3A$  and other cement components, for a 1% solution of Na gluconate. The curve for a reconstituted clinker (see text) is also shown.

Fig. 3 also illustrates the behaviour of clinker (in fact, a "reconstituted" composition consisting of 4%  $C_3A$ , 55%  $C_3S$ , 25%  $C_2S$  and 16%  $C_4AF$ ), contacted with 1% gluconate under the same experimental conditions used for the isolated components. It is noteworthy that this experimental  $\alpha/t$  curve (with a maximum at - 60') does not correspond to the one calculated by adding up the relative contributions of the individual clinker components.

The calculated curve consists in fact of two curves, with maxima corresponding to the maxima of  $C_3A$  (the component that produces the largest increase in  $\alpha$ ) and of  $C_3S$  (the most abundant component in the clinker). As the concentration of gluconate is decreased (to 0.2%) and the  $C_3A$  content of the clinker increased (to 14%), the separate contributions of  $C_3A$  and the other components clearly show up in the experimental curves for reconstituted clinkers.

Addition of gypsum to  $C_3A$  shifts the  $\alpha/t$  curves toward longer times, without substantially affecting the maximum  $\alpha$  values. (For 0.2% gluconate in the presence of 2% solid  $C_3A$  + 1% gypsum, the maximum of the curve shifts from - 1' to - 4'.)

Fig. 4 - Optical rotation ( $\alpha_{436}$ ) and calcium ion activity for a 0.2% Na gluconate solution, as a function of the time of contact with  $C_3A$ .

The curves showing total calcium in the gluconate solutions as a function of the time of contact with the cement components are closely similar to the optical rotation curves.

On the contrary, as shown in Figure 4 for the 0.2% gluconate solution, curves for free calcium are complementary to the optical rotation (and total calcium) curves, i.e. the  $Ca^{++}$  activity is minimum for the maximum  $\alpha$  value, and levels-off when the  $\alpha$  values (and the gluconate concentration) fall below a certain level.

Such a levelling-off of free calcium is quite different from that observed in the absence of additive. In fact, in additive-free systems the  $Ca^{++}$  activity is somewhat higher than in the presence of gluconate up to - 10' contacting with  $C_3A$ , then sharply

increases with a maximum at  $\sim 80'$ ; at  $1000'$ , it becomes again close to the values at time zero. The pH of the gluconate solutions contacted with  $C_3A$  increase in parallel with the concentration of free calcium. (An increase from 12.5 to  $\sim 13$  was observed for 1-3% gluconate solutions, with a maximum pH value reached after  $10'$ .)

As shown in Figure 5 all the  $^1H$ -NMR signals of Na gluconate are affected by addition of  $C_3A$ . (Assignments (10) refer to hydrogens on carbons at different distances from the carboxylate group.)

Fig. 5 -  $^1H$ -NMR spectra (90 MHz) of a  $D_2O$  solution of Na gluconate (a) and Na gluconate added of  $C_3A$  (b).

Also aldonates other than D-gluconate interact with  $C_3A$  and other cement components. The  $\alpha/t$  curve of D-gluconate was quite close to that of D-gluconate. The D-mannonate curve is also to be considered similar to the one of D-gluconate, in spite of its being reversed in sign, as expected because of the different configuration at C-2. On the contrary, D-xylonate did not show any significant changes of  $\alpha$  in the presence of  $C_3A$ . Maltobionate showed a  $\alpha/t$  curve similar to the one of D-gluconate, with somewhat bigger  $\Delta\alpha$  values at the same molar concentration.

The effect of glucose, maltose and the corresponding aldonates on the flow and strength properties of a

Portland cement is illustrated in Table I. Data for methyl  $\alpha$ -D-glucoside are also included. While this latter additive did not cause any significant variation in the flow and strength of the cement paste, the other additives substantially increased the flow and retarded the strength development.

Table I - Percent variation of flow and strength of a Portland cement added of 0.1% carbohydrate or aldonate (referred to a blank without additive)

	flow	compressive strength after 1 day
D-glucose	+ 9	- 21
maltose	+ 12	- 38
methyl $\alpha$ -D-glucoside	+ 1	- 3
sodium D-gluconate	+ 16	- 43
malto-aldobionate	+ 13	- 54

#### DISCUSSION

The above results clearly indicate that the reducing carbohydrates glucose and maltose precipitate from their solutions at the very beginning of contacting with  $C_3A$ . This behaviour prevented to ascertain whether any complex is formed in solution before the carbohydrate deposits on the  $C_3A$  granules. Interaction with  $C_3A$  was prevented by blocking the anomeric center by a methyl group, such as in methyl  $\alpha$ -D-glucoside.

On the other hand, a clear evidence that complexes in solution are formed was obtained for Na gluconate. The complex with  $C_3A$ , which is formed within a few minutes especially for the most dilute gluconate solutions, precipitate on the undissolved granules in a short time after its formation. This time increases with increasing concentration of the gluconate, up to 5% gluconate, which forms a stable gel.

Preliminary IR measurements on the  $C_3A$  granules after contacting with aldonate solutions as well as on the aldonate +  $C_3A$  recovered from the aqueous phase have confirmed that the gluconate is indeed in a complexed form both in solution and in the solid phase precipitated on the granules.

$C_3S$ ,  $C_2S$  and  $C_4AF$  also form soluble complexes with gluconate. However, these complexes are formed at longer times and are associated to smaller variation of optical rotation than with  $C_3A$ . Since also sodium aluminate formed a similar complex with  $C_3A$ , it is suggested that the complex involves the aluminate part and not the calcium part of this cement component. On the other hand, since the concentration of total calcium in solution parallels the concentration of gluconate (and the optical rotation values), it is inferred that  $C_3A$  binds to gluconate as a complexion.

It should be noted that formation of the well-known calcium complex of gluconate brings about a much smaller change in optical rotation than observed for aluminates (i.e., only -17% increase of  $\alpha$  as compared with the -500% increase observed in the present experiments with  $C_3A$ .)

Aluminates were recently shown to form strong complexes with carbohydrates(11). It is not surprising that aldonates, which retain all the hydroxyl groups of the original carbohydrate except the anomeric one (which is replaced by a good coordinating group such as the carboxylate) can form even stronger complexes. Preliminary experiments with D-glucitol (sorbitol) have shown that this analog of D-gluconate, having a primary hydroxyl group instead of the carboxylate, complexes  $C_3A$  less strongly (and affects the flow and resistance of cement substantially less) than gluconate. It is relevant that the  $^1H$ -NMR spectral shifts on addition of  $C_3A$  indicate that all the hydroxyl groups of gluconate are involved in the complex. (A significant effect of simple  $Ca^{++}$  salts was observed only for the  $\alpha$  and  $\beta$  hydrogens). It is therefore not surprising that D-xylonate, missing the hydroxyl group at C-6, does not significantly interact with  $C_3A$ . On the contrary, an inverted configuration of the hydroxyl group at C-2 (such as in D-mannose) does not prevent the formation of stable complexes.

Maltobionate (consisting of a non-reducing sugar and an aldonate) also forms strong complexes with  $C_3A$ , suggesting that the non-reducing, intact glucose ring participates in some way in coordination of the complex aluminate ions, possibly involving suitably oriented hydroxyl groups. Also the better complexability observed for the disaccharide maltose as compared to glucose is likely attributable to the above possibility, clearly shown by inspection of molecular models.

Data in Table I show that the additives that complex  $C_3A$  improve the flow properties of cement pastes. This complexing ability qualitatively correlates also with the retarding effect on the strength development of the pastes at the early stages.

#### CONCLUSION

The above findings throw some light on the mechanism of carbohydrate-derived cement additives, the formation of a complex in solution precedes precipitation of the additive on the undissolved granules, and formation of the protective layer that retards hydration (and setting) of cement.

ACKNOWLEDGEMENT. The authors would like to thank Prof. A.Rio of Rome University for the stimulating and helpful discussion. Thanks are also due to G.Torri and M.Morrone of Ronzoni Institute, and C. Rossetti of Grace Italiana, for their fine work in performing the experiments.

# Theme 5 - The role of $C_3A$ in sulfate attack on cements

## GENERAL REPORT

by P.K. METHA, University of California, Berkeley, U.S.A

A review of four papers on the role of  $C_3A$  in sulfate attack on cements is given in this report. Two papers present new information in the field since the Moscow Congress. The third paper presents test results of sulfate attack on a large number of portland and blended portland cements. The fourth paper contains a literature review on the mechanism of expansion associated with the sulfate attack.

The first paper reviewed here describes an investigation on the significance of the differences in the rates of hydration of various forms of  $C_3A$  in regard to attack by magnesium sulfate, which is the principal source of sulfate in seawater. The second paper describes a study in which two hydrated cements were exposed to a sodium sulfate solution, the  $C_3A$  in one of the cements being in the cubic form and in the other being predominantly in the orthorhombic form. The third paper describes an investigation on the relative sulfate resistance of 26 different portland cements and several portland pozzolan cements. The last paper presents a critical review of the literature in order to show that it is not the formation of ettringite but monosulfate hydrate which is responsible for expansions associated with sulfate attack on cements.

According to the paper authored by M. REGOURD, H. HORNAIN and B. MORTUREUX, 4 different types of  $C_3A$  were synthesized for making cements by mixing 50 % alite, 30 % quartz powder, 5 % gypsum and 15 % of any one of the four types of  $C_3A$ . The following types of  $C_3A$  were used: pure  $C_3A$  in cubic form, orthorhombic  $C_3A$  containing 4.8 %  $Na_2O$ , cubic  $C_3A$  containing 5 %  $Fe_2O_3$  and orthorhombic  $C_3A$  containing 4.8 %  $Na_2O$  and 5 %  $Fe_2O_3$ . Minicylinders (1 cm diameter by 1 cm height) of neat cement paste corresponding to 0.35 water-cement ratio were moist-cured for 3 days and then immersed in a 5 %  $MgSO_4$  solution. After 7 days of sulfate immersion all the specimens showed large expansions and were badly cracked. Formation of gypsum, ettringite and brucite in the deteriorated material was confirmed by X-Ray diffraction analysis. It was concluded by the authors that in the presence of quartz, the porosity of the specimens was so high that it was not possible to detect the differences in the sulfate resisting characteristics of the different forms of  $C_3A$ . Four new cement compositions were synthesized in which the quartz fraction was replaced with a granulated blastfurnace slag of 3000  $cm^2/g$  Blaine. Also, the authors investigated the effect of two different periods of moist curing, namely 48 hours or 6 hours in fresh water, on the subsequent behavior of cements in sulfate solution. XRD and DTA were used to monitor the rates of hydration of  $C_3A$  at various intervals. Evaluation of the degree of sulfate attack was done by visual examination.

For the pastes cured in water for 48 hours, prior to sulfate immersion, it was observed that those made from the cement containing the pure  $C_3A$  in cubic form performed better during the sulfate attack. The pastes from the other three cements showed evidence of more sulfate attack. The pastes from the other three cements showed evidence of more sulfate attack which, according to the XRD and DTA data, was due to the transformation of  $Ca(OH)_2$  and monosulfate hydrate into gypsum and ettringite, respectively. The authors also found significant differences in the rates of hydration of  $C_3A$  present in the 4 cements. For instance, DTA of the pastes hydrated for 3 hours (Fig. 2 of the REGOURD et al paper) shows that more ettringite was present in the cement paste containing pure  $C_3A$  in cubic form than in the cement paste containing  $C_3A$  in the orthorhombic form (4.8 %  $Na_2O$ ). Similarly, the data from XRD analyses (Fig. 3 of the REGOURD et al paper) show that in the pastes cured for 48 hours, the degree of hydration of  $C_3A$  for the cement containing pure  $C_3A$  in cubic form was about 70 % as compared to 55-60 % for the cements containing the other types of  $C_3A$ . It was concluded by the authors that the superior performance to sulfate attack of the cement containing pure  $C_3A$  in cubic form resulted from the lower porosity of the paste due to the higher rate of hydration of  $C_3A$  in the cement.

In the second series of tests in which the pastes were cured in fresh water for 6 hours only prior to the sulfate immersion, it was found that both the cements containing  $C_3A$  with 5 %  $Fe_2O_3$  performed better than the cement containing pure  $C_3A$  in cubic form or the orthorhombic  $C_3A$  containing 4.8 %  $Na_2O$ . According to the authors, this was due to the fact that only a small fraction of the  $C_3A$  was hydrated in all the cements prior to sulfate immersion. Therefore, the lower reactivity of the anhydrous  $C_3A$  containing  $Fe_2O_3$  was favourable for sulfate resistance than the higher reactivity of the others types of  $C_3A$  which did not contain  $Fe_2O_3$ . The authors concluded that the porosity of a cement paste, as affected by hydration characteristics of the constituents compounds, and history of curing prior to sulfate exposure, are the most important factors in determining its sulfate resistance.

According to the paper authored by P.K. METHA, two cements containing  $C_3A$  in different forms were investigated for relative sulfate resistance. The cements were made from a high-alkali industrial clinker containing 13.6 % potential  $C_3A$ . The  $C_3A$  in the clinker was predominantly in the orthorhombic form. Cement "A" was made by grinding this clinker with 5 % gypsum to 4000  $cm^2/g$  Blaine. Another clinker having the same potential compound composition, but with  $C_3A$  present in the cubic form only, was obtained by heating the industrial clinker at 1350 °C for 30 minutes in a la-

boratory furnace. Cement "B" was made from this heat-treated clinker by grinding it with 5 % gypsum to the same fineness as Cement "A". The sulfate resisting characteristics of the cements were evaluated by an accelerated test procedure according to which neat cement paste cubes and mortar prisms, normally cured for 14 days, were immersed in a 4 %  $\text{Na}_2\text{SO}_4$  solution. The solution was maintained at a constant pH and sulfate concentration by automatic and continuous titration against N/10  $\text{H}_2\text{SO}_4$ . Changes in compressive strength of the neat cement paste cubes and expansion of the mortar prisms during a 5-week sulfate immersion period were used as criteria for evaluation of the sulfate resistance of the cements. X-Ray diffraction analyses of the neat cement pastes at regular intervals, both before and during the sulfate immersion, were carried out in order to monitor the mineralogical changes.

The compression strength data from the neat cement paste cubes and the expansion data from the mortar prisms (Fig. 2 of the MEHTA paper) showed that these were significant differences between the rates of sulfate attack of the two cements. For instance, the sudden increase in the expansion rate of Cement "A" during the third week of sulfate immersion was not observed in Cement "B" until the fifth week. From the XRD data of the pastes prior to the sulfate immersion (Fig. 4 of the MEHTA paper), it was concluded that the main alumina-containing compounds in the paste of Cement "A" were ettringite and monosulfate hydrate, whereas in Cement "B", besides ettringite, a calcium aluminosilicate was detected. The deteriorated portions of Cement "A" after the 28-day period of sulfate immersion contained more ettringite and less monosulfate hydrate than were present before the sulfate immersion. Also, like REGOURD et al, the author found that Cement "B" (the cement containing the cubic  $\text{C}_3\text{A}$  only) hydrated faster, produced most of the potential ettringite within 1 day of normal hydration, and was 15 % stronger in compression than Cement "A" (the cement containing the orthorhombic  $\text{C}_3\text{A}$ ).

On the basis of his experimental results, the author concluded that the process of expansion and cracking of high- $\text{C}_3\text{A}$  portland cement pastes in a sulfate solution can be divided into two stages. In the first stage, called the dormant stage, the chemical reaction between the sulfate solution and unreacted aluminate and aluminate hydrates present in the cement paste is associated with increase in the amount of monosulfate hydrate, and is not accompanied by expansion. This is followed by the second stage during which expansion and cracking occur as a result of conversion of the monosulfate hydrate into ettringite. It was also concluded by the author that high- $\text{C}_3\text{A}$  portland cements, regardless of the type of  $\text{C}_3\text{A}$ , would eventually show deleterious expansion in sulfate solution, however the rate of sulfate attack was slower in the cement containing cubic  $\text{C}_3\text{A}$ . This was mainly due to the rapid rate of hydration of cubic  $\text{C}_3\text{A}$  which made the cement paste stronger and less permeable, and also led to the formation of aluminosilicate hydrate which was found more resistant to sulfate attack than the monosulfate hydrate.

K. MATHER reported the results of an investigation on relative sulfate resistance of 26 industrial portland cements, and several pozzolan cements made from some of the portland cements used in the investigation. Five portland cements contained no potential  $\text{C}_3\text{A}$  content, 6 contained  $\text{C}_3\text{A}$  in orthorhombic and/or tetragonal form, 8 contained  $\text{C}_3\text{A}$  in cubic and orthorhombic or tetragonal form, and 7 had  $\text{C}_3\text{A}$  in cubic

form only. Nine of the portland-pozzolan cements contained fly ash from burning of bituminous, sub-bituminous or lignite coals, one contained a calcined natural pozzolan of high silica and glass content, and one consisted of a silica dust which is a byproduct of the ferrosilicon alloy industry. By continuous immersion in 5 %  $\text{Na}_2\text{SO}_4$  solution, the sulfate resistance was evaluated from changes in length and fundamental transverse frequency of 25.4 mm by 25.4 mm by 285.8 mm prisms made with mortars, containing one part of cement to 2.75 parts graded sand to 0.485 parts of water by weight. The mortar prisms were cured for 24 hours in sealed molds at 35°, then demolded and thereafter cured in saturated lime water at  $23 \pm 1.7^\circ$  until the comparison mortar cubes showed  $20.7 \pm 1.0$  MPa compressive strength. At this time the prisms were immersed in the 5 %  $\text{Na}_2\text{SO}_4$  solution. Changes in length and fundamental transverse frequency were measured at 7, 14, 21, 28, 56 and 90 days, and thereafter as needed. Each time the prisms were measured for length, the sulfate solution was changed. The criterion for fracture by increase in length was chosen as 0.1 %.

In regard to the portland cements, all the zero- $\text{C}_3\text{A}$  cements were found sulfate resisting except one which showed 0.085 % expansion in 180 days (and may show more than 0.1 % expansion at one year). The author suspected that the large expansion shown by this cement may be related to hydration of periclase, since the cement contained 4.53 %  $\text{MgO}$  by chemical analysis. All the 6 cements containing orthorhombic and/or tetragonal  $\text{C}_3\text{A}$  failed except one cement which showed 0.057 % expansion at 180 days of sulfate immersion. Since this cement contained only 2 %  $\text{MgO}$ , the author seems to suggest that the overall expansion in the test for sulfate attack is influenced by the amount of periclase in cement. At the time of reporting the results, the author found that 7 of the 8 cements containing  $\text{C}_3\text{A}$  in cubic and orthorhombic or tetragonal form had failed by exceeding the 0.1 % expansion limit. Similarly, 5 of the 7 cements containing only cubic  $\text{C}_3\text{A}$  had also failed. From this the author concluded that, contrary to the observations of some earlier investigations, there was no correlation between the type of  $\text{C}_3\text{A}$  present in portland cement and the resistance of the cement to sulfate attack. The author also made interesting observations on the strain capacity (increase in length without fracturing) of various cements. Expansions could not be related directly to the  $\text{C}_3\text{A}$  of the cements because due to rapid strength gain, the cements with higher  $\text{C}_3\text{A}$  content possessed lower strain capacity.

In regard to the effect of the type of pozzolan on the sulfate resistance of portland-pozzolan cements containing from 0.4 to 14.6 % potential  $\text{C}_3\text{A}$ , it was shown (Fig. 1 of the MATHER paper) that 30 % cement replacement by volume with either of the 2 reactive pozzolans, namely the calcined volcanic pozzolan and the silica dust from the ferrosilicon industry, made the cements highly resistant to sulfate attack. On the contrary, at this level of cement replacement, none of the 8 sub-bituminous and lignitic fly ashes were able to reduce the expansion in mortar prisms to less than 0.1 % when portland cement of either 13.1 % potential  $\text{C}_3\text{A}$  content (RC 714) or 14.6 % potential  $\text{C}_3\text{A}$  content (RC 756) were used in making the pozzolan cement (Fig. 2 and 3 of the MATHER paper). In fact many of the sub-bituminous and lignitic fly ashes increased the sulfate expansion of the central portland cement instead of reducing it. This type of behavior was observed from fly ashes which contained less than 50 % silica, 16 to 26 %  $\text{Al}_2\text{O}_3$  and 5 to 30 %

CaO. The increase in sulfate expansion of portland-pozzolan cements made with high- $C_3A$  clinkers and fly ashes of high alumina and lime content is attributed to formation of ettringite from the readily available  $Al_2O_3$  and CaO in fly ash.

With portland cement containing 9.4 % potential  $C_3A$ , 2 of the 8 fly ashes of the sub-bituminous-lignitic group were able to reduce the sulfate expansion to less than 0.1 % at 365 days (Fig. 4 of the MATHER paper). Portland-pozzolan cements made with clinkers containing up to 11 % potential  $C_3A$  and about 20 % bituminous fly ash showed substantial improvement in sulfate resistance of mortars as compared to the control portland cements made from the same clinkers. In conclusion, the author has shown that the ability of portland cements and portland-pozzolan cements to resist sulfate attack is affected by the  $C_3A$  content of the portland cement and the composition, reactivity, and amount of pozzolan used.

In his paper containing a critical appraisal of the cement literature on mechanism of sulfate expansion, S. CHATTERJI presents arguments challenging the widely held belief that the expansion in portland cement pastes on exposure to sulfate solutions is associated with ettringite formation. He also presents arguments in support of CHATTERJI and JEFFERY's hypothesis according to which the formation of monosulfate hydrate from  $C_4AH_{13}$ , by ion exchange in portland cement pastes exposed to sulfate ions, is responsible for expansion. The literature survey on sulfate generated expansion divided into two categories: free expansion, and restrained expansion. In regard to free expansion, the author cites his own work as well as the work of SELIGMANN and GREENING on considerable free expansions observed in  $C_3A$ -gypsum-lime systems in which monosulfate rather than ettringite was the stable product. Also, from an examination of MATOUSEK and SAUMAN's work on expansion of mixtures containing portland cement, metakaoline and gypsum, the author notes that at least 20 % expansion occurred after the formation of ettringite had ceased. Citing MEHTA's studies on restrained expansions of Type K, M and S cements, the author points out that the expansions continued even beyond the time when formation of ettringite had ceased and, in fact, ettringite was being transformed into the monosulfate hydrate. In further support of his case for sulfate expansion due to the monosulfate formation, the author notes that there is no expansion in the sulfate resisting portland cement because they do not contain the monosulfate hydrate on hydration. In conclusion, the author says: "It is possible to set down evidence for this or that hypothesis but in the ultimate analysis ones prejudices determine which hypothesis one believes".

Summarizing the main points from the 4 contributions on the role of  $C_3A$  in sulfate attack, REGOURD et al and MEHTA have shown that the rate of sulfate attack in cements can be influenced by the type of  $C_3A$  present. Hydrated pastes made from cements containing cubic  $C_3A$  were attacked at a slower rate by sulfate solutions than the pastes made from cements

containing  $C_3A$  in more densely packed structurals. The differences in the rates of sulfate attack were attributed mainly to the more rapid hydration of cubic  $C_3A$  which produced stronger and probably less permeable paste prior to the immersion in sulfate solution. MEHTA also demonstrated the formation of a calcium aluminosilicate hydrate in the pastes of a portland cement containing cubic  $C_3A$ . He suspected that the relatively superior resistance of the calcium aluminosilicate hydrate may be partially responsible for the slower rate of sulfate attack on portland cements containing cubic  $C_3A$ . MATHER has shown that the high alumina and lime present in lignitic and sub-bituminous fly ashes can increase rather than reduce the sulfate resisting behavior of pozzolan cements made from such fly ashes. MATHER's test results did not confirm the finding of other investigation that the type of  $C_3A$  present in a portland cement can influence its resistance to sulfate attack.

In the opinion of this reporter, the contradiction between the findings of REGOURD and al, and MEHTA on one hand, and MATHER on the other, is not real. Whereas MATHER's conclusion was drawn from sulfate immersion up to 365 days, the former investigators made their comments on the basis of 4 to 5 weeks of sulfate immersion. It appears that the type of  $C_3A$  affects only the rate of sulfate attack but not the eventual degree of attack. Evidently, more work is needed to confirm the hypothesis that reduced porosity and permeability of the pastes made from cements containing cubic  $C_3A$  is responsible for slower rate of sulfate attack on these cements. Also, the need for accelerated and reliable test methods for evaluation of sulfate resistance of cements is self evident. Different curing periods, size of specimens, sulfate solutions, and failure criteria were used in the three investigations reported above, CHATTERJI's contribution makes the point that the question of mechanism of expansion accompanying sulfate attack also deserves more attention in the future. Most of his criticism on the ettringite expansion hypothesis is based on continuing expansion of pastes even after the formation of ettringite has ceased. This argument, instead of being against the ettringite-expansion hypothesis, can be used in support of the hypothesis if the mechanism of expansion is due to swelling of colloidal ettringite by water adsorption. MEHTA and HU reported that maximum expansions as a result of swelling of ettringite were not observed in their experiment until after about 45 days of exposure of ettringite to water. Clearly, more experimental studies are needed to settle this controversy. CHATTERJI is, therefore, correct in stating that ones prejudices often determine which hypothesis one would like to believe. This reporter hopes that before the next Congress the researchers interested in the mechanism of sulfate generated expansion in portland cements pastes, including CHATTERJI, would cast aside their personal prejudices and undertake conclusive experimental studies to shed better light on the subject.

# Thème 5 - Le rôle de $C_3A$ dans l'attaque des ciments par les sulfates

## RAPPORT GENERAL

par P.K. METHA, Université de Californie, Berkeley U.S.A.

Une revue de quatre communications sur le rôle de  $C_3A$  dans l'attaque des ciments par les sulfates est donnée dans ce rapport. Deux communications présentent des informations nouvelles dans ce domaine, depuis le Congrès de Moscou. La troisième communication présente les résultats des essais de l'attaque par les sulfates d'un grand nombre de ciments portland et de ciments portland avec ajouts. La quatrième communication contient une revue de la littérature sur le mécanisme de l'expansion associée à l'attaque par les sulfates.

La première communication revue ici décrit une recherche sur la signification des différences dans les taux d'hydratation des formes variées de  $C_3A$  à l'égard de l'attaque par le sulfate de magnésium qui est la source principale de sulfate dans l'eau de mer. La seconde communication décrit une étude dans laquelle deux ciments hydratés ont été exposés à une solution de sulfate de sodium, le  $C_3A$  dans l'un des ciments étant sous la forme cubique et dans l'autre étant principalement sous la forme orthorhombique. La troisième communication décrit une étude sur la résistance relative aux sulfates de 26 ciments portland différents et de quelques ciments portland aux pouzzolanes. La dernière communication présente une revue critique de la littérature afin de montrer que ce n'est pas la formation de l'ettringite mais celle du monosulfate hydraté qui est responsable des expansions associées à l'attaque des ciments par le sulfate.

D'après la communication de M. REGOURD, H. HORNAIN et B. MORTUREUX, quatre types différents de  $C_3A$  ont été synthétisés pour faire des ciments en mélangeant 50 %  $C_2S$ , 30 % de poudre de quartz, 5 % de gypse et 15 % d'un des quatre types de  $C_3A$ . Les différents types de  $C_3A$  utilisés sont les suivants :  $C_3A$  pur cubique,  $C_3A$  orthorhombique contenant 4,8 %  $Na_2O$ ,  $C_3A$  cubique contenant 5 %  $Fe_2O_3$  et  $C_3A$  orthorhombique contenant 4,8 % et 5 %  $Fe_2O_3$ . Des minicylindres (1 cm de diamètre et 1 cm de hauteur) de pâte pure de ciment correspondant à un rapport eau/ciment = 0,35 ont été conservés en atmosphère humide pendant 3 jours et ensuite immergés dans une solution à 5 %  $MgSO_4$ . Après 7 jours d'immersion dans l'eau sulfatée, tous les échantillons montraient des gonflements importants et étaient très fissurés. La formation de gypse, d'ettringite et de brucite dans le matériau détérioré, était confirmée par l'analyse par diffraction des rayons X. Les Auteurs ont conclu qu'en présence de quartz, la porosité des échantillons était si élevée qu'il n'était pas possible de détecter les différences des caractéristiques de la résistance au sulfate des différentes formes de  $C_3A$ . Quatre nouvelles compositions, dans lesquelles la fraction quartz a été remplacée par du laitier de haut fourneau granulé de surface spécifique Blaine égale à  $3000 \text{ cm}^2/\text{g}^{-1}$ , ont été synthétisées. Les Auteurs ont aussi étudié l'effet de deux périodes différentes de traitement en atmosphère humide, à savoir 48 heures et 6 heures dans l'eau, sur le comportement ultérieur des ciments dans la solution de sulfate. La DRX et l'ATD ont été utilisées pour connaître les taux d'hydratation de  $C_3A$  à différentes échéances. Le degré de l'attaque par le sulfate était évalué par observation visuelle.

Pour les pâtes conservées dans l'eau pendant 48 heures avant l'immersion dans le sulfate, il a été

observé que celles qui contiennent le ciment avec  $C_3A$  pur sous la forme cubique résistent mieux à l'attaque du sulfate. Les pâtes des trois autres ciments mettent en évidence une attaque plus forte par le sulfate qui, d'après les données de la DRX et l'ATD, est due à la transformation de  $Ca(OH)_2$  et du monosulfate hydraté respectivement en gypse et ettringite. Les Auteurs ont aussi trouvé des différences significatives dans les taux d'hydratation de  $C_3A$  présent dans les 4 ciments. Par exemple, le thermogramme des pâtes hydratées pendant 3 heures (Fig. 2, REGOURD et al) montre plus d'ettringite dans la pâte de ciment contenant  $C_3A$  pur cubique que dans la pâte de ciment contenant  $C_3A$  sous la forme orthorhombique (4,8 %  $Na_2O$ ). D'une manière similaire, les données des analyses DRX (Fig. 3, REGOURD et al) montrent que dans les pâtes traitées pendant 48 heures, le degré d'hydratation de  $C_3A$  pour le ciment contenant  $C_3A$  pur sous la forme cubique était d'environ 70 % comparé à 55-60 % pour les ciments contenant les autres types de  $C_3A$ . Les Auteurs en concluent que la performance supérieure à l'attaque par le sulfate du ciment contenant  $C_3A$  pur sous forme cubique est le résultat d'une plus faible porosité de la pâte due à un taux plus élevé d'hydratation dans le ciment.

Dans la seconde série d'essais dans laquelle les pâtes ont été traitées dans l'eau potable pendant 6 heures seulement avant leur immersion dans le sulfate, il a été trouvé que les deux ciments contenant  $C_3A$  avec 5 %  $Fe_2O_3$  résistent mieux que le ciment contenant  $C_3A$  pur sous la forme cubique ou le  $C_3A$  orthorhombique contenant 4,8 %  $Na_2O$ . D'après les Auteurs, ceci est dû au fait qu'une petite fraction seulement de  $C_3A$  s'était hydratée dans tous les ciments avant leur immersion dans le sulfate. Donc, la réactivité plus faible du  $C_3A$  anhydre contenant  $Fe_2O_3$  était plus favorable à la résistance au sulfate que la réactivité plus forte des autres types de  $C_3A$  qui ne contenaient pas de  $Fe_2O_3$ . Les Auteurs concluent que la porosité d'une pâte de ciment affectée par les caractéristiques de l'hydratation de ses constituants et l'histoire du traitement avec l'exposition au sulfate sont les facteurs les plus importants dans la détermination de la résistance au sulfate.

D'après la communication de P.K. MEHTA, deux ciments contenant  $C_3A$  sous différentes formes ont été étudiés quant à leur résistance au sulfate. Les ciments ont été préparés à partir d'un clinker industriel à haute teneur en alcalins contenant 13,6 % de  $C_3A$  potentiel. Le  $C_3A$  dans le clinker était d'une manière prépondérante sous la forme orthorhombique. Le ciment "A" a été obtenu en broyant ce clinker avec 5 % de gypse à  $4000 \text{ cm}^2/\text{g}^{-1}$  Blaine. Un autre clinker ayant la même composition potentielle mais avec  $C_3A$  présent sous la forme cubique seulement a été obtenu par chauffage du clinker industriel à  $1350^\circ\text{C}$  pendant 30 minutes dans un four de laboratoire. Le ciment "B" a été préparé à partir du clinker traité thermiquement en le broyant avec 5 % de gypse de la même finesse que celle du ciment "A". Les caractéristiques de la résistance au sulfate des ciments ont été évaluées par un test accéléré dans lequel des cubes de pâte pure de ciment et des prismes de mortiers traités normalement pendant 14 jours sont immergés dans une solution à

4 % de  $\text{Na}_2\text{SO}_4$ . La solution est maintenue à une concentration en sulfate et un pH constants par une titration automatique et continue à l'aide de  $\text{H}_2\text{SO}_4$  à N/10. Les changements dans la résistance à la compression des cubes de pâte pure de ciment et l'expansion des prismes de mortier durant une période d'immersion dans le sulfate de 5 semaines ont été utilisés comme critères d'évaluation de la résistance des ciments aux sulfates. Les analyses par diffraction des rayons X des pâtes pures de ciments, à intervalles réguliers, à la fois avant et pendant l'immersion dans le sulfate, ont été effectuées afin de suivre les changements minéralogiques.

Les données de la résistance à la compression des cubes de pâte pure de ciment et les données de l'expansion des prismes de mortier (Fig. 2, MEHTA) montrent qu'il y a des différences significatives entre les taux d'attaque au sulfate des 2 ciments. Par exemple, l'accroissement brusque du taux d'expansion du ciment "A" durant la troisième semaine d'immersion dans le sulfate n'est pas observé dans le ciment "B" et ce jusqu'à la cinquième semaine. Des données de la DRX des pâtes avant leur immersion dans le sulfate (Fig. 4, MEHTA), il a été conclu que les principaux composés contenant de l'alumine dans la pâte de ciment "A" étaient l'ettringite et le monosulfate hydraté tandis que dans la ciment "B" un aluminosilicate de calcium a été détecté à côté de l'ettringite. Les fragments détériorés du ciment "A", après une période de 28 jours d'immersion dans le sulfate, contenaient plus d'ettringite et moins de monosulfate hydraté qu'avant l'immersion dans le sulfate. Comme REGOURD et al, l'Auteur trouve aussi que le ciment "B" (le ciment contenant le  $\text{C}_3\text{A}$  cubique seulement) s'hydrate plus vite et produit plus d'ettringite potentiellement pendant un jour d'hydratation normale et que la résistance en compression est 15 % plus forte que celle du ciment "A" (le ciment contenant  $\text{C}_3\text{A}$  orthorhombique).

Sur la base de ses résultats expérimentaux, l'Auteur conclut que le processus d'expansion et de fissuration de pâtes de ciment portland à haute teneur en  $\text{C}_3\text{A}$  dans une solution de sulfate peut être divisé en deux étapes. Dans la première étape, appelée période dormante, la réaction chimique, entre la solution de sulfate et l'aluminate anhydre et les aluminates hydratés présents dans la pâte de ciment, est associée à l'accroissement du taux de monosulfate hydraté et n'est pas accompagnée d'expansion. Ceci est suivi du second stade dans lequel l'expansion et la fissuration apparaissent comme le résultat de la conversion du monosulfate hydraté en ettringite.

L'Auteur conclut aussi que les ciments portland à haute teneur en  $\text{C}_3\text{A}$ , sans tenir compte du type de  $\text{C}_3\text{A}$  montreraient éventuellement une expansion délétère dans la solution sulfatée. Cependant le taux de l'attaque par le sulfate était plus faible dans le ciment contenant du  $\text{C}_3\text{A}$  cubique. Ceci est dû principalement à la vitesse rapide d'hydratation du  $\text{C}_3\text{A}$  cubique qui rend la pâte plus résistante et moins perméable et aussi entraîne la formation d'un aluminosilicate hydraté qui a été trouvé plus résistant à l'attaque par le sulfate que le monosulfate hydraté.

K. MATHER rapporte les résultats d'une recherche sur la résistance relative au sulfate de 26 ciments portland industriels et de quelques ciments pouzzolaniques préparés à partir de quelques uns des ciments portland utilisés dans cette recherche. Cinq ciments portland ne contenaient pas de  $\text{C}_3\text{A}$  potentiel, six contenaient  $\text{C}_3\text{A}$  sous forme orthorhombique ou tétragonale, huit contenaient  $\text{C}_3\text{A}$  sous les formes cubique et orthorhombique ou tétragonale et sept avaient  $\text{C}_3\text{A}$  sous la

forme cubique seulement. Neuf des ciments portland pouzzolaniques contenaient des cendres volantes provenant du chauffage de charbons bitumineux, sous-bitumineux ou de lignite, un contenait une pouzzolane naturelle calcinée à haute teneur en verre et en silice et un consistait en une poussière de silice qui est un sous-produit de l'industrie des alliages de ferrosilicium. Par immersion continue dans une solution à 5 %  $\text{Na}_2\text{SO}_4$ , la résistance au sulfate a été évaluée à partir des variations de longueur et de la fréquence fondamentale transversale de prismes de  $25,4 \times 25,4 \times 285,8$  mm de mortiers contenant une part de ciment pour 2,5 parts de sable calibré et de 0,485 part d'eau, en poids. Les prismes de mortier ont été conservés, à 35°, pendant 24 heures dans des moules scellés, puis démoulés et ensuite traités dans une eau de chaux saturée à  $23 \pm 1,7^\circ$  jusqu'à ce que les cubes de mortier de comparaison présentent une résistance à la compression de  $20,7 \pm 1,0$  MPa. A ce moment, les prismes ont été immergés dans la solution à 5 %  $\text{Na}_2\text{SO}_4$ . Les variations de longueur et la fréquence fondamentale transversale ont été mesurées à 7, 14, 21, 28, 56, 90 jours et plus si nécessaire. La solution de sulfate était changée chaque fois que la longueur des prismes était mesurée. Le critère de dégradation par accroissement de longueur a été choisi à 0.1 %.

Dans les ciments portland, tous les ciments à 0 %  $\text{C}_3\text{A}$  ont été trouvés résistants au sulfate excepté un ciment qui a présenté une expansion de 0,085 % à 180 jours (et pouvait montrer plus de 0,1 % d'expansion à un an). L'Auteur soupçonne que le gonflement important de ce ciment pourrait être relié à l'hydratation du périclase puisque le ciment contenait 4,53 %  $\text{MgO}$  d'après l'analyse chimique. Les six ciments contenant  $\text{C}_3\text{A}$  orthorhombique ou tétragonal se sont dégradés, excepté un ciment qui présentait 0,057 % d'expansion après 180 jours d'immersion dans le sulfate. Ce ciment contenant seulement 2 %  $\text{MgO}$ , l'Auteur semble suggérer que l'expansion totale dans l'essai de l'attaque par le sulfate est influencée par la quantité de périclase dans le ciment. A l'époque de ses derniers résultats, l'Auteur a trouvé que 7 des 8 ciments contenant  $\text{C}_3\text{A}$  sous la forme cubique, orthorhombique ou tétragonale se sont dégradés en dépassant la limite d'expansion de 0,1 %. De la même manière, 5 des 7 ciments, contenant seulement  $\text{C}_3\text{A}$  cubique, se sont également détériorés. De ceci, l'Auteur conclut que, contrairement aux observations précédentes de certains chercheurs, il n'y a pas de corrélation entre le type de  $\text{C}_3\text{A}$  présent dans le ciment portland et la résistance du ciment à l'attaque par le sulfate. L'Auteur a aussi fait des observations intéressantes sur l'aptitude à la déformation (expansion linéaire sans fissuration) de ciments différents. Les expansions ne peuvent pas être reliées directement à la quantité de  $\text{C}_3\text{A}$  dans les ciments en raison de la croissance rapide de la résistance, les ciments plus riches en  $\text{C}_3\text{A}$  possèdent une aptitude à la déformation plus faible.

En ce qui concerne l'effet du type de pouzzolane sur la résistance au sulfate des ciments portland aux pouzzolanes contenant de 9,4 à 14,6 %  $\text{C}_3\text{A}$  potentiel, il a été montré (Fig. 1 MATHER) que le remplacement de 30 % de volume de ciment par l'une ou l'autre des 2 pouzzolanes réactives, à savoir la pouzzolane volcanique calcinée et la poussière de silice de l'industrie du ferrosilicium, rend les ciments hautement résistants à l'attaque par le sulfate. Au contraire, à ce taux de remplacement du ciment, aucune des 8 cendres volantes sous-bitumineuses ou de lignite n'est capable de réduire l'expansion dans les prismes de mortier à moins de 0,1 % quand le ciment portland con-

tenant soit 13,1 % de  $C_3A$  potentiel (RC 714) ou 14,6 % de  $C_3A$  potentiel (RC 758) est utilisé pour fabriquer ces ciments aux pouzzolanes (Fig. 2 et 3, MATHER). En fait, beaucoup de cendres volantes sous-bitumineuses ou de lignite accroissent l'expansion au sulfate du ciment portland étalon au lieu de la réduire. Ce type de comportement a été observé à partir de cendres volantes qui contenaient moins de 50 % de  $SiO_2$ , 16 à 26 %  $Al_2O_3$  et 5 à 30 % de  $CaO$ . L'accroissement de l'expansion au sulfate des ciments portland aux pouzzolanes contenant des clinkers riches en  $C_3A$  et des cendres à haute teneur en alumine et en chaux est attribué à la formation d'ettringite à partir de  $Al_2O_3$  et de  $CaO$  disponibles dans la cendre volante.

Avec le ciment portland contenant 9,4 % de  $C_3A$  potentiel, 2 des 8 cendres volantes du groupe sous-bitumineux et de lignite ont été capables de réduire l'expansion au sulfate à moins de 0,1 % à 365 jours (Fig. 4, MATHER). Les ciments portland pouzzolaniques fabriqués avec des clinkers contenant jusqu'à 11 % de  $C_3A$  potentiel et environ 20 % de cendres volantes bitumineuses montrent une amélioration substantielle à la résistance des mortiers au sulfate comparée à celle des ciments portland étalons fabriqués avec les mêmes clinkers. En conclusion, l'Auteur a montré que l'aptitude à la résistance au sulfate des ciments portland et des ciments portland aux pouzzolanes est affectée par la teneur en  $C_3A$  du ciment portland par la composition, la réactivité et la teneur de la pouzzolane utilisée.

Dans sa communication contenant une évaluation critique de la littérature en cours sur le mécanisme de l'expansion au sulfate, S. CHATTERJI présente des arguments contestant la croyance largement reconnue que l'expansion dans les pâtes de ciment portland exposées aux solutions de sulfate est associée à la formation de l'ettringite. Il présente aussi des arguments supportant l'hypothèse de CHATTERJI et JEFFERY suivant laquelle la formation de monosulfate hydraté à partir de  $C_4AH_{13}$ , par échange ionique dans les pâtes de ciment portland exposées aux ions sulfate, est responsable de l'expansion. Une vue d'ensemble de la littérature sur les expansions dues au sulfate révèle une division en deux catégories : expansion libre et expansion restreinte. En ce qui concerne l'expansion libre, l'Auteur cite son propre travail aussi bien que celui de SELIGMANN et GREENING sur les expansions libres considérables observées dans des systèmes  $C_3A$  - gypse - chaux dans lesquels le monosulfate, plutôt que l'ettringite, était le produit stable. A partir également de l'examen du travail de MATOUSEK et SAUMAN, sur l'expansion de mélanges contenant ciment portland, métakaolinite et gypse, l'auteur note qu'une expansion d'au moins 20 % se produit après que la formation d'ettringite ait cessé. Citant les études de MEHTA sur les expansions restreintes des ciments de Type K, M et S, l'Auteur signale que les expansions continuent dans le temps, après que la formation de l'ettringite ait cessé et, en fait, l'ettringite est transformée en monosulfate hydraté. Un support supplémentaire de l'expansion au sulfate due à la formation de monosulfate, noté par l'Auteur, est qu'il n'y a pas d'expansion dans le ciment portland résistant au sulfate parce qu'il ne contient pas de monosulfate hydraté au cours de l'hydratation. En conclusion, l'Auteur dit : "Il est possible de considérer comme évidente telle ou telle hypothèse mais en dernière analyse, l'hypothèse retenue l'est en fonction d'idées préconçues".

Résumant les points principaux des 4 contributions sur le rôle de  $C_3A$  dans l'attaque au sulfate, REGOURD et al, et MEHTA ont montré que la vitesse de

l'attaque des ciments par le sulfate peut être influencée par le type du  $C_3A$  présent. Des pâtes hydratées de ciments contenant  $C_3A$  cubique ont été attaquées à une vitesse plus lente par les solutions de sulfate que les pâtes de ciment contenant  $C_3A$  dans des structures plus denses. Les différences dans les taux d'attaque par le sulfate ont été attribuées principalement à l'hydratation plus rapide du  $C_3A$  cubique qui produit une pâte plus résistante et probablement moins perméable avant l'immersion dans la solution de sulfate. MEHTA a aussi démontré la formation d'un aluminosilicate de calcium hydraté dans les pâtes de ciment portland contenant  $C_3A$  cubique. Il soupçonne que la résistance relativement supérieure de l'aluminosilicate hydraté, comparée à celle du monosulfate hydraté, puisse être partiellement responsable du taux plus faible de l'attaque, par le sulfate, des ciments portland contenant  $C_3A$  cubique. MATHER a montré que les teneurs élevées en alumine et chaux, présentes dans les cendres volantes de lignite et les cendres sous-bitumineuses, peuvent accroître plutôt que réduire le comportement au sulfate des ciments pouzzolaniques fabriqués avec de telles cendres volantes. Les résultats des essais de MATHER ne confirment pas les conclusions d'autres chercheurs d'après lesquels le type de  $C_3A$  présent dans un ciment portland peut influencer sa résistance à l'attaque par le sulfate.

D'après le rapporteur, la contradiction entre les résultats de REGOURD et al et MEHTA d'une part, de MATHER d'autre part n'est pas réelle. Tandis que la conclusion de MATHER est tirée d'une immersion dans le sulfate jusqu'à 365 jours, les premiers chercheurs commentent sur la base de 4 à 5 semaines. Il apparaît que le type de  $C_3A$  affecte seulement la vitesse d'attaque par le sulfate mais pas le degré éventuel de l'attaque. Evidemment, un travail supplémentaire est nécessaire pour confirmer l'hypothèse que la porosité et l'imperméabilité réduites des pâtes de ciment contenant  $C_3A$  cubique sont responsables de la vitesse plus faible de l'attaque de ces ciments par le sulfate. La nécessité de tests accélérés et dignes de confiance pour l'évaluation de la résistance des ciments au sulfate est aussi évidente. Différentes périodes de prétraitement, de taille des échantillons, de solutions de sulfate et différents critères de dégradation ont été utilisés dans les trois études rapportées ci-dessus. La contribution de CHATTERJI fait ressortir que la question du mécanisme de l'expansion accompagnant l'attaque par le sulfate mérite plus d'attention dans le futur. La plus grande partie de sa critique sur l'hypothèse de l'expansion due à l'ettringite est fondée sur l'expansion continue des pâtes, même après que la formation de l'ettringite ait cessé. Cet argument, au lieu d'être contre l'hypothèse de l'expansion due à l'ettringite, peut être utilisé comme support de l'hypothèse si le mécanisme de l'expansion est dû au gonflement d'une ettringite colloïdale par adsorption d'eau. MEHTA et HU ont rapporté que les expansions maximales résultant du gonflement de l'ettringite n'ont été observées, dans leur expérience, qu'après environ 45 jours d'exposition à l'eau de l'ettringite.

Des nouvelles études expérimentales sont clairement nécessaires pour régler cette controverse. CHATTERJI est, néanmoins, correct en déclarant "Les idées préconçues souvent déterminent quelle hypothèse on aimerait retenir". Le présent rapporteur espère qu'avant le prochain Congrès, les chercheurs intéressés par le mécanisme d'expansion au sulfate des pâtes de ciment, CHATTERJI compris, se débarrasseront de leurs préjugés personnels et entreprendront des études expérimentales concluantes pour éclairer le sujet.

# Rôle de $C_3A$ dans l'attaque des ciments par les eaux sulfatées

## *Role of $C_3A$ in the attack on cements by sulfate solutions*

B. MORTUREUX, H. HORNAIN, M. REGOURD, Département Microstructures,  
C.E.R.I.L.H. - Paris, France

### Résumé

L'évolution de mélanges synthétiques  $C_3A + C_3S +$  gypse et de ciments portland à différentes teneurs en  $C_3A$  a été suivie par diffraction des rayons X, microscopie électronique à balayage et microsonde électronique. Les facteurs étudiés sont la forme cristalline de  $C_3A$  (cubique, orthorhombique), la composition élémentaire des grains de  $C_3A$  (teneur en  $Na_2O$ ,  $K_2O$ ,  $Fe_2O_3$ ), l'interaction  $C_3A - C_3S$ .

Les résultats montrent que la résistance aux eaux agressives des pâtes de ciment et des mortiers dépend avant tout de leur compacité. A brève échéance,  $C_3A$  cubique s'hydrate plus vite que  $C_3A$  orthorhombique et donne un matériau moins vulnérable si l'échantillon est immergé dans la solution agressive après un temps d'hydratation suffisamment long. Le rôle bénéfique du fer en solution solide dans  $C_3A$  a été confirmé.

### Summary

The evolution of synthetic mixtures  $C_3A + C_3S +$  gypsum and portland cements with different amounts of  $C_3A$  has been followed by X-ray diffraction, Scanning Electron Microscopy and Electron Micro Probe Analysis. The factors which have been studied are the crystalline form of  $C_3A$  (cubic, orthorhombic), the elemental composition of  $C_3A$  grains (amount of  $Na_2O$ ,  $K_2O$ ,  $Fe_2O_3$ ), the  $C_3A - C_3S$  interaction.

The results show that the resistance of cement pastes and mortars to aggressive waters depends before all on their compacity. At short time, cubic  $C_3A$  hydrates more rapidly than orthorhombic  $C_3A$  and gives a less vulnerable material if the sample is immersed into the aggressive solution after a sufficient time of hydration. The beneficial role iron in solid solution in  $C_3A$  has been confirmed.

Les études sur la réactivité de  $C_3A$  et de ses solutions solides avec les alcalins ont montré que l'aluminate tricalcique pur cubique s'hydrate plus rapidement que  $C_3A$  dopé au sodium sous les formes orthorhombique ou monoclinique (1, 2, 3, 4). Dans les produits industriels,  $C_3A$  peut insérer, dans son réseau cristallin, d'autres ions que le sodium : le potassium, le silicium et le fer par exemple.

Le rôle bénéfique du fer dans la résistance des ciments à l'eau de mer ayant été mis en évidence par FRIGIONE et MARRA (5), nous avons essayé de comparer le comportement, dans une solution de  $MgSO_4$ , de mélanges synthétiques  $C_3S + C_3A +$  gypse dans lesquels nous avons fait varier la composition de  $C_3A$  ( $C_3A + Na_2O$ ,  $C_3A + Fe_2O_3$ ,  $C_3A + Na_2O + Fe_2O_3$ ). La résistance aux eaux sulfatées des ciments et mortiers étant fonction de leur imperméabilité, nous avons aussi comparé l'influence du temps de traitement avant l'immersion dans l'eau agressive. L'évolution des réactions chimiques et de la microstructure du matériau a été suivie par ATD, diffraction des Rayons X et microscopie électronique à balayage.

#### Préparation des échantillons

Des minicylindres de mélanges synthétiques  $C_3S + C_3A +$  gypse ont été préparés avec un rapport eau/solide = 0,35, conservés 24 heures en atmosphère humide puis deux jours dans l'eau potable, enfin immergés dans une solution à 5 % de  $MgSO_4$ .

Les quatre compositions de  $C_3A$  utilisées sont les suivantes :

1.  $C_3A$  cubique pur,
2.  $C_3A$  orthorhombique avec 4,8 %  $Na_2O$ ,
3.  $C_3A$  cubique avec 5 %  $Fe_2O_3$  (limite de solubilité de  $Fe_2O_3$  dans le réseau cristallin de  $C_3A$ ),
4.  $C_3A$  orthorhombique avec 4,8 %  $Na_2O$  et 5 %  $Fe_2O_3$ .

Une première série d'éprouvettes est constituée de 50 %  $C_3S + 15$  %  $C_3A + 30$  % quartz + 5 % gypse. La granularité de  $C_3S$  et de  $C_3A$  est comprise entre 20 et 40  $\mu m$ , celle du gypse inférieure à 40  $\mu m$ , ceci afin de faciliter les observations microscopiques, le quartz a une surface spécifique de 3000  $cm^2.g^{-1}$ .

Dans la seconde série, le quartz a été remplacé par du laitier et deux temps de prétraitement ont été étudiés (2 jours et 6 heures dans l'eau potable).

#### Etude des mélanges $C_3S$ (50 %) + $C_3A$ (15 %) + quartz (30 %) + gypse (5 %).

Après 7 jours d'immersion dans l'eau sulfatée, tous les échantillons sont en très mauvais état (gonflement et fissuration). La diffraction des Rayons X montre la formation de  $Mg(OH)_2$  et de  $CaSO_4.2H_2O$  secondaire (Fig. 1). Ces deux nouvelles phases sont dues à la réaction de  $MgSO_4$  sur  $Ca(OH)_2$  libéré par l'hydratation de  $C_3S$ .

Il n'est pas possible de différencier la résistance des différentes formes de  $C_3A$  dans ces mélanges dont la porosité devait être trop élevée au moment de leur immersion dans l'eau agressive. Afin de diminuer cette porosité, nous avons remplacé le quartz par du laitier.

Fig. 1 - Diffraction des Rayons X.

Formation de gypse secondaire et de  $Mg(OH)_2$  dans un mélange  $C_3S$  (50 %) +  $C_3A$  (15 %) + quartz (30 %) + gypse (5 %) après 7 jours d'immersion dans une solution à 5 %  $MgSO_4$ .

E = ettringite, G = gypse, Qz = quartz.

#### Etude des mélanges $C_3S$ (50 %) + $C_3A$ (15 %) + laitier (30 %) + gypse (5 %)

Mis à part le laitier qui remplace le quartz, la composition chimique des échantillons reste la même que dans la première série mais deux temps de prétraitement ont été étudiés (2 jours et 6 heures dans l'eau potable après 24 heures en atmosphère humide).

#### Mélanges $C_3S + C_3A$ + laitier + gypse : 48 heures dans l'eau

La différence de réactivité hydraulique entre les quatre formes de  $C_3A$  est montrée dans le thermogramme de la Figure 2 et dans la courbe de la Figure 3 tracée à partir des données de la diffraction des Rayons X. Avant l'immersion dans l'eau sulfatée,  $C_3A$  cubique pur est le plus hydraté. Après 26 jours dans  $MgSO_4$ ,  $C_3A$  cubique pur est hydraté à 80 % et  $C_3A + 5$  %  $Fe_2O_3$ , également cubique, à 64 %.

$C_3S$  est aussi hydraté différemment dans les quatre échantillons. En raison de l'interaction  $C_3A-C_3S$  (4, 6),  $C_3S$  est hydraté à 60 % dans l'échantillon ① et 50 % dans les échantillons ② et ④ à la fin du prétraitement.

L'échantillon ① est en bon état après 26 jours en eau sulfatée. Les autres échantillons présentent une certaine expansion qui peut être reliée à la dissolution de  $Ca(OH)_2$  et à sa transformation en  $Mg(OH)_2$  d'une part, à la formation d'ettringite d'autre part. L'ATD (Fig. 4) et la diffraction des Rayons X (Fig. 5) montrent clairement ces transformations.

Il semble donc que dans cette série, l'échantillon ①, plus hydraté que les autres, ait acquis une

Fig. 2 - Enregistrements ATD des mélanges  $C_3S + C_3A$  + laitier + gypse après 3 heures dans l'eau : le mélange ① avec  $C_3A$  cubique a donné plus d'ettringite et de C-S-H que le mélange ② avec  $C_3A$  orthorhombique.  
G = gypse, E = ettringite.

Fig. 3 - Taux d'hydratation  $\alpha$  des mélanges  $C_3S$  (50 %) +  $C_3A$  (15 %) + laitier (30 %) + gypse (5 %), conservés 48 heures dans l'eau puis 26 jours dans la solution à 5 %  $MgSO_4$ .

Fig. 4 - Enregistrement ATD d'un mélange  $C_3S + C_3A$  + laitier - gypse après 2 jours dans l'eau (A) puis 7 jours dans une solution à 5 %  $MgSO_4$  (B).  
M = monosulfoaluminate, E = ettringite

Fig. 5 - Diffraction des Rayons X. Mélanges  $C_3S + C_3A$  + laitier + gypse, après 7 jours dans  $MgSO_4$ . Comparaison entre le mélange ① avec  $C_3AC$  et le mélange ④ avec  $C_3AO$  ( $Na_2O + Fe_2O_3$ ) :  $Ca(OH)_2$  est partiellement transformé en  $Mg(OH)_2$  dans l'échantillon ④ seulement.

Fig. 6 - Diffraction des Rayons X.  
Evolution du mélange (4)  $C_3S + C_3A$  (4,8 %  $Na_2O + 5\%$   $Fe_2O_3$ ) + laitier + gypse dans la solution de  $MgSO_4$  après 6 heures dans l'eau potable. La corrosion est visible à 28 jours : décroissance de  $Ca(OH)_2$  et apparition de  $Mg(OH)_2$ , croissance de l'ettringite et décroissance du monosulfoaluminate. Cette corrosion est faible, il reste  $Ca(OH)_2$  et le gypse secondaire n'est pas visible.

E = ettringite, M = monosulfoaluminate

Imperméabilité suffisante avant l'agression de  $MgSO_4$ . Contrairement au quartz, le laitier a réagi. Activé par  $Ca(OH)_2$ , ses grains se sont entourés d'une mince couche de C-S-H favorable à la cohésion.

Mélanges  $C_3S + C_3A$  + laitier + gypse : 6 heures dans l'eau

Afin de vérifier l'hypothèse de l'influence de la compacité de l'échantillon (due à un taux d'hydratation élevé de  $C_3S$  et  $C_3A$ ) sur la résistance au sulfate, nous avons immergé une seconde série d'éprouvettes après un temps de traitement plus court, soit 24 heures en atmosphère humide et 6 heures dans l'eau potable.

Avant immersion dans la solution sulfatée,  $C_3A$  est hydraté à 30 % dans l'échantillon (1) avec  $C_3A$  cubique pur et à 20 % dans les échantillons (2) et (4) avec  $C_3A$  orthorhombique. Après 5 et 28 jours dans la solution sulfatée, les échantillons (3) et (4) sont en meilleur état que les échantillons (1) et (2) les premiers (3) et (4) ne montrent aucune fissure externe, tandis que les derniers (1) et (2) ont partiellement éclaté.

Dans ce cas, il semble que la réactivité de  $C_3A$  ait joué un rôle plus important que dans la série précédente. Les mesures par diffraction des Rayons X du taux d'hydratation de  $C_3A$  montrent que  $C_3A + Fe_2O_3$  réagit moins vite que  $C_3A$  pur entre 1 et 28 jours dans  $MgSO_4$  :

Echantillon	Après 1 jour dans $MgSO_4$	Après 28 jours dans $MgSO_4$
1. $C_3A_c$ pur	58 %	74 %
2. $C_3A_o$ (4,8 % $Na_2O$ )	53 %	67 %
3. $C_3A_c$ (5 % $Fe_2O_3$ )	65 %	67 %
4. $C_3A_o$ (4,8 % $Na_2O + 5\%$ $Fe_2O_3$ )	53 %	54 %

Après 28 jours dans l'eau sulfatée, on observe une différence importante entre les échantillons (1) et l'échantillon (4). La couche superficielle de l'échantillon (1) est composée d'ettringite, de gypse secondaire et de  $Mg(OH)_2$ ; le monosulfoaluminate et la portlandite ont disparu. Au contraire, la couche superficielle de l'échantillon (4) contient encore du monosulfoaluminate et  $Ca(OH)_2$  (Fig. 6). Dans ce cas, la réactivité plus faible de  $C_3A + Fe_2O_3$  est plus favorable que celle de  $C_3A$  pur qui, peu hydraté avant son immersion dans l'eau sulfatée, a réagi trop rapidement avec  $MgSO_4$  et a formé trop d'ettringite expansive.

#### CONCLUSION

La comparaison entre les différentes séries d'échantillons  $C_3S + C_3A +$  gypse + quartz et  $C_3S + C_3A +$  gypse + laitier montre clairement que la porosité de l'éprouvette est le facteur le plus important de la résistance du ciment à l'attaque par les sulfates. Une compacité suffisante peut être obtenue à partir d'un  $C_3A$  réactif tel que  $C_3A$  cubique pur après un temps d'hydratation suffisamment long avant l'immersion dans l'eau agressive. Parce qu'il existe une interaction  $C_3A - C_3S$ ,  $C_3S$  est aussi plus hydraté et

contribue à une réduction de la porosité des échantillons. La dégradation est faible, elle est reliée à la transformation du monosulfoaluminate en ettringite.

Dans le cas d'un temps d'hydratation en eau potable relativement court avant l'immersion dans la solution agressive, la réactivité de  $C_3A$  semble être un facteur important. Le  $C_3A$  cubique pur s'hydratant plus rapidement que le  $C_3A$  orthorhombique contenant du sodium forme, très vite, de l'ettringite qui est expansive.

Bien que de symétrie cubique,  $C_3A$  contenant du fer s'hydrate plus lentement que  $C_3A$  pur et paraît plus favorable dans le cas d'un prétraitement court.

Ces résultats, obtenus sur des mélanges synthétiques sont très partiels, ils montrent que la composition de  $C_3A$  dans les ciments peut jouer un rôle dans la résistance aux sulfates mais d'autres facteurs influençant la perméabilité doivent être étudiés simultanément (temps de prétraitement, granularité, température, ...).

# Influence of different crystalline forms of $C_3A$ on sulfate resistance of portland cement

## *Influence des différentes formes cristallines de $C_3A$ sur la résistance aux sulfates du ciment portland*

P. K. MEHTA, Professor of Civil Engineering,  
University of California, Berkeley, California 94720, USA

**SUMMARY:** A preliminary investigation was made to determine the effect of different crystalline forms of  $C_3A$  present in portland cement on the sulfate resistance of the cement. An industrial portland-cement clinker containing 13 percent potential  $C_3A$ , predominantly in the orthorhombic form, was used for this study. In order to redistribute the alkalies and to convert the orthorhombic  $C_3A$  into the cubic  $C_3A$ , a portion of the clinker was heat treated at 1350°C in a laboratory furnace. The cements made by grinding the two clinkers separately with 5 percent gypsum were evaluated for relative sulfate resistance, using an accelerated test procedure developed at the University of California. According to the test procedure, neat cement paste cubes and small mortar prisms were immersed in 4 percent  $Na_2SO_4$  solution which was held at a constant pH by automatic titration against dilute  $H_2SO_4$ . From preliminary results it is seen that the strength loss and expansion due to sulfate attack occurred earlier in the cement containing the orthorhombic  $C_3A$ . Higher initial strength of the cement containing the cubic  $C_3A$  is considered partially responsible for the lower sulfate resistance shown by this cement.

**RÉSUMÉ:** Une étude préliminaire a été réalisée afin de déterminer l'effet des différentes formes cristallines de  $C_3A$  présentes dans le ciment Portland sur la résistance du ciment aux sulfates. Un clinker de ciment Portland industriel contenant 13 %  $C_3A$ , principalement sous la forme orthorhombique, a été utilisé dans cette étude. Afin de redistribuer les alcalins et de convertir le  $C_3A$  orthorhombique en  $C_3A$  cubique, une partie du clinker a été traitée à 1350°C dans un four de laboratoire. Les ciments préparés par broyage des deux clinkers séparément avec 5 % de gypse ont été évalués en ce qui concerne leur résistance relative aux sulfates à l'aide d'un test accéléré développé à l'Université de Californie. D'après la procédure de ce test, des petits prismes de mortier et des cubes de pâte de ciment sont immergés dans une solution à 4% de  $Na_2SO_4$  qui est tenue à un pH constant par une titration automatique avec  $H_2SO_4$  dilué. A partir des résultats préliminaires, on voit que l'expansion et la chute de résistance due à l'attaque des sulfates se produisent plus tôt dans le ciment contenant  $C_3A$  orthorhombique. Une résistance initiale plus élevée du ciment contenant du  $C_3A$  cubique est considérée comme partiellement responsable de la résistance aux sulfates plus faible, trouvée dans ce ciment.

## INTRODUCTION

It is well known that chemical composition of raw materials and processing conditions influence the crystal structure of the principal compounds of portland cement. It is also known that the differences in hydration characteristics of the various crystalline forms of a cement compound can affect the setting and hardening properties of the cement, and in some instances, its durability in aggressive environments. The results of an experimental investigation on the effect of sulfate attack on two portland cement samples containing different crystalline forms of  $C_3A$  is described in this paper.

Several investigators including Moore (1), Maki (2), Regourd and Guinier (3), and Baikova et al (4) have shown that substitution of alkalis in  $C_3A$  lattice changes the crystal symmetry. With increasing amount of alkalis, the crystal structure of  $C_3A$  changes from cubic  $\rightarrow$  orthorhombic  $\rightarrow$  tetragonal  $\rightarrow$  monoclinic. For instance, Baikova et al (4) reported 2.42, 3.80, 4.83, and 5.70 percent  $Na_2O$  in cubic, orthorhombic, tetragonal, and monoclinic  $C_3A$  respectively. According to Regourd (5),  $C_3A$  is usually cubic or orthorhombic/tetragonal, but rarely monoclinic in industrial clinkers. Splitting of the 440,008, and 844 X-ray diffraction lines of the cubic  $C_3A$  can be used for detection and quantitative determination of the various crystalline forms of  $C_3A$  present in a cement. Regourd used the splitting of the 440 line for this purpose. According to the author (5), this line splits to a doublet (040, 400) and a single line (224) for the orthorhombic form, and to two lines (040 and 224) for the tetragonal form. The ratio of peak intensities of the 040 and 224 lines is indicative of the amount of orthorhombic or tetragonal  $C_3A$  present. This ratio is about 0.5 when no cubic  $C_3A$  is present in the cement.

There is some published data on the differences in the hydration behavior of the various crystalline forms of  $C_3A$ . Regourd (5) reported that the hydration rates in water are:  $C_3A$  cubic  $>$   $C_3A$  orthorhombic  $>$   $C_3A$  tetragonal. Baikova et al (4) explained that plugging of the structural holes in cubic  $C_3A$  by increasing amounts of alkali ions slows down the initial hydration reaction. Both investigators (4,5) found that the differences in hydration rates were confined to early ages, 1 and 3 days, only. After 3 days hydration small differences in the degree of hydration of the four crystalline forms of  $C_3A$  were observed. After 28 days there was hardly any difference. Regourd (5) also showed that the presence of alkali sulfates considerably accelerated the hydration of all forms of  $C_3A$ .

Regourd (6) reported that the rapid hydration of the cubic  $C_3A$  was associated with a corresponding rapid hydration of the  $C_2S$ . This probably accounted for the presence of large zones of the trisilicoaluminate hydrate,  $C_3A \cdot 3CaSiO_3 \cdot 32H_2O$ , around the cubic  $C_3A$  grains in the 28-day old specimens which were examined by scanning electron microscopy. Much smaller zones of the silicoaluminate hydrate were detected around the tetragonal  $C_3A$  grains in which  $C_3S$  hydration was slower. The existence of silicoaluminates of the type,  $C_3A \cdot xCaSiO_3 \cdot yH_2O$  in hydrated cements had been envisaged for a long time, and the silicoaluminate isomorphs of both the monosulfate hydrate and the trisulfate hydrate (ettringite) are suggested in the literature. Except for Regourd's

(6) work on the action of sea water on cements, there is little published data regarding the effect of different crystalline forms of  $C_3A$  on durability of cement to aggressive environments, such as sulfate attack.

FIG. 1 X-RAY DIFFRACTION ANALYSIS OF MALEIC ACID RESIDUES OF CLINKERS

## MATERIALS AND PROCEDURE

An industrial clinker containing 20.9%  $\text{SiO}_2$ , 6.8%  $\text{Al}_2\text{O}_3$ , 2.6%  $\text{Fe}_2\text{O}_3$ , 63.9%  $\text{CaO}$ , 2.9%  $\text{MgO}$ , 1.2%  $\text{SO}_3$ , 1.1%  $\text{K}_2\text{O}$ , and 0.4%  $\text{Na}_2\text{O}$  was used for making the two cements of this investigation. The potential  $\text{C}_3\text{A}$  in clinker, as determined by the Bogue equation, was 13.6 percent. After dissolving out the silicates by maleic acid, the residue showed that in addition to some cubic  $\text{C}_3\text{A}$ , there was a large quantity of the orthorhombic  $\text{C}_3\text{A}$  present. Another clinker having the same compound composition, but with  $\text{C}_3\text{A}$  present only in the cubic form, was obtained by heating this industrial clinker at  $1350^\circ\text{C}$  for 30 minutes in a laboratory furnace. The X-ray diffraction analysis of the maleic acid residue of the heat-treated clinker confirmed that the orthorhombic  $\text{C}_3\text{A}$  had converted to the cubic form. The diffraction patterns of the two clinkers are shown in Fig. 1.

From the peak intensity ratio of 040 and 224 lines in Fig. 1, it was determined that the industrial clinker without the additional heat treatment contained about 60% orthorhombic  $\text{C}_3\text{A}$  and 40% cubic  $\text{C}_3\text{A}$ . Also, by chemical analysis of the heat-treated clinker, it was determined that the total alkali content remained unchanged by the heat treatment. Since the aphtitalite,  $\text{NaK}_3\text{S}_4$ , peaks became stronger after the heat treatment, probably it was due to the high sulfate content in clinker that the orthorhombic-cubic conversion occurred by redistribution of alkali in the clinker rather than by alkali loss through volatilization. Both the clinkers were ground separately in a laboratory ball mill, with 5 percent added gypsum. The cement containing  $\text{C}_3\text{A}$  predominantly in the orthorhombic form was designated as 'Cement A', and the cement which contained  $\text{C}_3\text{A}$  in the cubic form only was designated as 'Cement B'. Both the cements conformed to about 4,000  $\text{cm}^2/\text{g}$  Blaine fineness.

The sulfate resistance characteristics of the cements were evaluated by an accelerated test procedure described elsewhere in detail by this author (7,8). According to the procedure, 13 by 13 mm cubes of neat cement paste, and 15 by 15 by 100 mm mortar prisms, both cured for 14 days at room temperature, were immersed in a 4 percent  $\text{Na}_2\text{SO}_4$  solution which was kept at a constant hydrogen-ion and sulfate concentration by automatic titration against N/10  $\text{H}_2\text{SO}_4$ . The pH of the immersion solution, which was stirred constantly, was maintained at  $7 \pm 0.5$ , and it was replaced by a fresh solution every week. In addition to the small specimen size and the constant sulfate and hydrogen ion concentrations, the acceleration of the sulfate attack was achieved by high permeability of the specimens. For this purpose the neat cement paste cubes were made with 0.5 water-cement ratio, and the mortar prisms were made with 1:1:0.6 proportions by weight of cement, coarse sand (600-850  $\mu\text{m}$ ), and water, respectively. Changes in visual appearance and compressive strength of the neat cement paste cubes, and expansion of the mortar prisms were used as criteria for evaluation of sulfate resistance of the cements. X-ray diffraction data was obtained using Cu K $\alpha$  radiation at 40 kV and 30 mA.

## RESULTS AND DISCUSSION

Average values from the compressive strength tests and expansion measurements are plotted in Fig. 2.

FIG. 2 EFFECT OF SULFATE IMMERSION ON EXPANSION AND STRENGTH

From the mortar expansion data in Fig. 2 it can be seen that Cement A showed only a slight expansion during the first 2 weeks of sulfate immersion; however, during the 3rd week there was a sudden increase in expansion from about 0.1 to 1.0 percent. On the other hand for Cement B, a similar increase in expansion did not occur until the 5th week. Visual appearance and strength changes in neat cement paste cubes also confirmed that the rate of sulfate attack was faster on Cement A than on Cement B. For instance, Cement A showed a gradual loss of compressive strength on the order of about 10 percent during the first 3 weeks of sulfate immersion but, thereafter, during the 3-5 week period lost about 33 percent of the original strength. On the contrary, Cement B showed little strength loss during the first 3 weeks of immersion, thereafter, only 6 percent strength loss was recorded until the end of the test period. Since the strength loss tends to lag behind expansion, further strength loss was expected to occur on prolonging the immersion period. However, it is evident from the test data that Cement A was attacked more readily in the sulfate solution than Cement B.

The first cracks at the corners and edges of the neat Cement A paste specimens appeared at the 18th day of sulfate immersion, which is consistent with the expansion date. Thereafter, the cracks widened rapidly and resulted in surface spalling. The spalled layers of the paste were weak and could easily be broken with fingers. With regard to Cement B, after 4 weeks of sulfate immersion the cement paste cubes were still sound, with sharp edges and corners. A photograph of the typical specimens of Cement A and B on the 28th day of the sulfate immersion is shown in Fig. 3.

FIG. 3 CEMENT PASTE CUBES AFTER 28 DAYS SULFATE IMMERSION

X-ray diffraction analyses of the neat cement pastes at regular intervals, both before and after the sulfate immersion, were carried out in order to explain the differences between the two cements with regard to their behavior on sulfate attack. On hydration the 1-day old pastes showed ettringite peaks of considerable intensity from Cement B, whereas no such peaks were observed during the same period from hydration of Cement A. This showed that the  $C_3A$  in Cement B hydrated faster than the  $C_3A$  in Cement A. Also, from examination of peak intensities for alite and  $Ca(OH)_2$ , Regourd's (6) observation was confirmed that the rate of hydration of alite was closely associated with the  $C_3A$  hydration rate, i.e., relatively more alite hydrated in the Cement B paste after 1 day hydration. At 3, 7, and 14 days, some ettringite was detected in the pastes of Cement A, but at no time the peak intensities became as high as they were in the pastes of Cement B. Already at 3 days some low sulfate,  $C_3A \cdot CSH_{1.2}$ , was detected in Cement A, and much higher peak intensities of this component were found in the 7 and 14-day old samples. On the contrary, the low sulfate peaks were not detected in the 3, 7, and 14-day old pastes of Cement B. Interestingly, instead of low sulfate, another phase corresponding to 8.66 Å d-spacing ( $10.2^\circ 2\theta$ , Cu Ka) was observed in the 7 and 14-day hydrated pastes of Cement B. According to the ASTM card file, this peak appears to belong to a calcium aluminosilicate hydrate of the composition,  $Ca_6(AlSiO_4)_{12} \cdot 30H_2O$ . The calcium aluminate hydrates and carboaluminate hydrates do not have peaks in this position, but other calcium aluminosilicate hydrates of the type,  $C_3A \cdot x CaSiO_3 \cdot yH_2O$ , may have main peaks in this region. Regourd (6) reported large zones of  $C_3A \cdot 3 CaSiO_3 \cdot 32H_2O$  around the hydrating cubic  $C_3A$  grains, but their identification by X-ray diffraction analysis was difficult. Thus, assuming that the 8.66 Å peak is due to a calcium aluminosilicate hydrate, it can be concluded that prior to the sulfate immersion the main alumina-containing compounds in the hydrated paste of Cement B were ettringite and a calcium aluminosilicate hydrate, whereas the corresponding compounds in the hydrated paste of Cement A were ettringite and low sulfate hydrate. This is illustrated in Figs. 4-I and 4-II.

The changes in compound composition as a result of sulfate attack on the hydrated cement pastes were followed by X-ray diffraction analyses of the outer 3 mm thick portions of the specimens. During the first 2 weeks of sulfate immersion, there was no change in the intensity of ettringite peaks in the pastes of both Cements A and B. At the same time there was some increase in low sulfate for Cement B, however, there was a considerable increase in the intensity of low sulfate peaks for Cement A. After two weeks of sulfate immersion, the low sulfate peaks in Cement A started to decrease, with a corresponding increase in the intensity of ettringite peaks. It should be noted that a sudden increase in expansion of the mortar prisms of Cement A was recorded during the same period.

For Cement B, during the first 3 weeks of sulfate immersion there was no change in the intensity of ettringite and the aluminosilicate peaks. However, a gradual increase in the low sulfate peak was observed. After three weeks some decrease in the low sulfate and the aluminosilicate peaks was recorded, with a corresponding increase in ettringite. And this was the same period during which the mortar

FIG. 4 X-RAY DIFFRACTION PATTERS OF:

- I. HYDRATED CEMENT 'B', 14 DAYS
- II. HYDRATED CEMENT 'A', 14 DAYS
- III. SPALLED LAYER OF CEMENT 'A' AFTER 28 DAYS SULFATE IMMERSION

prisms of Cement B started to show large expansion. It appears from the x-ray diffraction data that, from the standpoint of expansion and cracking of hydrated cements in sulfate solutions, there is an initial dormant period associated with increase in the low sulfate hydrate as a result of chemical reaction between the sulfate and unreacted aluminates or aluminate hydrates present. This dormant period is followed by a period of expansion, cracking and strength loss associated with the conversion of the low sulfate hydrate to ettringite. Also, it appears that transformation of the low sulfate hydrate to ettringite occurred more readily than the similar transformation involving the low aluminosilicate hydrate.

Finally, Fig. 4-III shows X-ray diffraction analysis of a spalled layer of Cement A after four weeks of sulfate immersion. In addition to ettringite and low sulfate, gypsum peaks were detected in the sample. During advanced stage of sulfate attack formation of gypsum, as a result of decomposition of C-S-H and  $Ca(OH)_2$ , is accompanied by serious weakening of the cementing properties. This is why the spalled material was weak and easily friable. The diffraction pattern from a spalled layer of Cement B exposed to the sulfate solution for 5 weeks also showed peaks due to gypsum and ettringite. Although gypsum peaks were present in the specimen, it was noted that the 8.66 Å peak due to the aluminosilicate hydrate was still present. This showed that the compound was more sulfate resistant than the low sulfate hydrate.

On the basis of this work the author believes that at least three factors were involved in the superior sulfate resistance of the cement which contained

C<sub>3</sub>A in the cubic form alone, and alkalies present mainly as sulfates. Firstly, the higher reactivity of the cubic C<sub>3</sub>A, which was further enhanced by considerable amount of aphtthalite present, was responsible for the formation of most of the potential ettringite during the early hydration period, i.e., within 1 day, when the cement paste was less stiff. Consequently, the tensile stress induced would have been low and the ettringite thus formed contributed to strength, rather than to disruptive expansion. Secondly, since more alite hydrated under these conditions this also contributed to the higher strength of the paste at the time of sulfate immersion (Cement B paste was about 15 percent stronger than Cement A paste). Finally, the hydration characteristics of the cement containing C<sub>3</sub>A in the cubic form alone were such that a significant proportion of the aluminate was tied up as aluminosilicate hydrate, rather than the aluminosulfate hydrate or low sulfate (C<sub>3</sub>A·C<sub>2</sub>SH<sub>12</sub>). The former was found to be more resistant to conversion to ettringite when the hydrated pastes were exposed to the sulfate solution. A combination of the three factors appears to be responsible for the slower rate of sulfate attack on the cement which contained C<sub>3</sub>A in the cubic form alone, as compared to the cement containing the orthorhombic C<sub>3</sub>A.

#### CONCLUSIONS

On the basis of a laboratory study on sulfate resistance of two cements having the same compound composition, but with C<sub>3</sub>A present either in the cubic form alone or in predominantly orthorhombic form, it is concluded that the rates of expansion, cracking, and strength loss associated with ettringite formation in high-C<sub>3</sub>A portland cements can be affected by the crystalline form of C<sub>3</sub>A.

Under normal curing conditions it was found that the cement containing the cubic C<sub>3</sub>A alone hydrated faster, produced most of the potential ettringite in 1 day, and was 15 percent stronger at the time of immersion in the sulfate solution. Also, the hydration products of this cement, prior to the sulfate immersion, contained a complex calcium aluminosilicate hydrate, which was found to be more resistant to sulfate attack than the low sulfate hydrate present in the hydration products of the cement containing the orthorhombic C<sub>3</sub>A. A combination of these factors appears to be responsible for the slower rate of sulfate attack on the cement which contained C<sub>3</sub>A in the cubic form alone, as compared to the cement which contained the orthorhombic C<sub>3</sub>A.

# Factors affecting sulfate resistance of mortars

## *Facteurs affectant la résistance au sulfate des mortiers*

KATHARINE MATHER, Chief, Engineering Sciences Division, Structures Laboratory,  
U.S. Army Engineer Waterways Experiment Station, Vicksburg, MS 39180, USA.

**SUMMARY :** The ability of a mortar made using portland cement, fine aggregate, and water to resist attack by sulfates is affected by the proportions of the mortar (water-cement ratio and cement content), by the maturity, by the amount of tricalcium aluminate in the portland cement, the presence of tricalcium aluminate-sodium oxide solid solutions with different structures and reactivities, and by the composition, reactivity, and amount of pozzolan used together with the portland cement.

Cements investigated included portland cements of Types I, II, III, and V meeting ASTM C 150, blended cements including Type IP's meeting ASTM C 595 that were made from the same clinkers as the Type I's, and Type I's blended with pozzolans including fly ashes produced by burning bituminous, subbituminous, and lignitic coals, calcined natural volcanic glass high in silica, and silica fume. Silica fume forms glassy microspheres that may contain over 90 percent  $\text{SiO}_2$ ; it is a by-product of the production of silicon metal.

Some of the fly ashes produced from subbituminous and lignitic coals replacing 30 percent by volume of cements increased the expansion of mortars containing the blends when stored in sulfate solutions. This behavior reflects  $\text{SiO}_2$  below 50 percent,  $\text{Al}_2\text{O}_3$  16 to 26 percent, and  $\text{CaO}$  5 to 30 percent. Other investigations show that  $\text{Al}_2\text{O}_3$  and  $\text{CaO}$  in the fly ash glass are readily available to form ettringite. With cement of lower  $\text{C}_3\text{A}$  content some of the subbituminous and lignitic fly ash blends improved the sulfate resistance of mortars, except when  $\text{SiO}_2$  in the fly ashes was 38 percent or less.

Type IP blended cements made with portland-cement clinkers containing up to 11 percent calculated  $\text{C}_3\text{A}$  and about 20 percent fly ash show substantial improvement in sulfate resistance of mortars compared with Type I cements made from the same clinkers.

**RÉSUMÉ :** La résistance au sulfate des mortiers est affectée par le rapport eau/ciment et la teneur en ciment (dont il n'est pas parlé) ainsi que par la quantité d'aluminate tricalcique dans le ciment portland, la présence des solutions solides du sodium dans l'aluminate tricalcique de structures et de réactivités différentes, par la composition, la métastabilité thermique et la quantité de pouzzolane employée pour remplacer une partie du ciment portland dans le but d'augmenter la résistance au sulfate du mortier.

Les ciments hydrauliques étudiés comprenaient les Types I, II, III, et V répondant à la spécification ASTM C 150, les ciments de Type IP répondant à la spécification ASTM C 595 fabriqués à partir des mêmes clinkers que les ciments de Type I, et du Type I comportant de la pouzzolane, y compris les cendres volantes produites par la combustion de charbons bitumineux, subbitumineux et lignitiques, le verre volcanique naturel calciné à haute teneur en silice et les fumées de silice. Les fumées de silice forment des microsphères vitreuses pouvant contenir plus de 90 pour cent de  $\text{SiO}_2$ ; elles sont un sous-produit de la production de métal au silicium.

Les cendres volantes produites par les charbons subbitumineux et lignitiques remplaçant 30 pour cent du volume des ciments à haute teneur en  $\text{C}_3\text{A}$  cubique augmentèrent l'expansion due au sulfate de sodium des mortiers contenant les mélanges. Ce comportement représente  $\text{SiO}_2$  au-dessous de 50 pour cent,  $\text{Al}_2\text{O}_3$  de 16 à 26 pour cent et  $\text{CaO}$  de 5 à 30 pour cent. D'autres analyses indiquent que  $\text{Al}_2\text{O}_3$  et  $\text{CaO}$  présents dans le verre de cendre volante peuvent permettre la formation d'ettringite. Dans le cas des ciments à plus faible teneur en  $\text{C}_3\text{A}$  cubique les mélanges de cendres volantes subbitumineuses et lignitiques améliorent la résistance au sulfate des mortiers, sauf lorsque la proportion de  $\text{SiO}_2$  dans les cendres est de 38 pour cent ou moins. Les effets de mélanges de  $\text{C}_3\text{A}$  cubique et orthorhombique I et de  $\text{C}_3\text{A}$  orthorhombiques ou tétragonaux seront également étudiés.

Les ciments mélangés du Type IP produits à partir de clinkers contenant jusqu'à 11 pour cent de  $\text{C}_3\text{A}$  calculé environ 20 pour cent de cendres volantes démontrent une amélioration sensible dans la résistance au sulfate des mortiers par rapport aux Types I produits à partir des mêmes clinkers.

## INTRODUCTION

The chemical resistance of pastes, mortars, and concretes made using portland cement is affected by the proportions of the mixture (water-cement ratio and cement content), by the presence and amount of various solid solutions of  $C_3A$  with different structures and containing  $Na_2O$ ,  $K_2O$ ,  $SiO_2$ ,  $Fe_2O_3$ ,  $MgO$ , etc. If a pozzolan is used together with the portland cement, its composition, reactivity, and proportion in the mixture will affect for good or evil the sulfate resistance of the system.

## CEMENTITIOUS MATERIALS

In the work upon which this paper is based, the sulfate resistance of mortars containing portland cements complying with the requirements for Types I, II, III, and V of ASTM C 150-78, Standard Specification for Portland Cement, and also cements complying with the requirements for Types IP and IS of ASTM C 595, Standard Specifications for Blended Hydraulic Cements, were investigated. In most cases we were able to test the Type I and the Type IP and the Type I and Type IS sampled at the same time from the same plant. We also tested four bituminous fly ashes, three sub-bituminous fly ashes, four lignitic fly ashes, a calcined natural volcanic glass, a glassy silica fume of high silica content that is a waste product in the production of silicon metal, and a sample of Santorin earth. Some of the materials studied are not reported on here.

## MORTARS

The mortars were made with one part of cement to 2.75 parts graded standard sand to 0.485 parts of water, by weight. When other materials were used, the water content was changed until the flow of the mortar was equal to that of the mortar containing portland cement alone. Reductions were necessary with some of the portland-pozzolan cements; one pozzolan having very high surface area increased the water-cement ratio by about 3 percent.

## TEST SPECIMENS AND INITIAL TESTS

All the specimens cast were 25.4 mm by 25.4 mm by 285.8 mm long with gage studs at both ends. All were cured for 24 hr in sealed molds in water at  $35^\circ \pm 3^\circ C$ , then removed from the molds. The initial gage length,  $254 \pm 2.5$  mm, was determined; the fundamental transverse frequency was measured, and the bars were cured in water saturated with CH at a temperature of  $23^\circ \pm 1.7^\circ C$ . The same procedure was used for curing cubes of the same mortar which were broken in compression at various ages until the cubes reached the desired strength at which age the mortar bars were to be placed in 0.352 molar  $Na_2SO_4$  solution. Before the bars were placed in sulfate solution, the length and fundamental transverse frequency of each bar was again measured. The strengths at which the bars were placed in sulfate solution were equalized as well as possible so that cements compared in the test for sulfate-resistance would be at the same maturity as measured by compressive strength. The first tests were made with bars having a compressive strength of  $27.6 \pm 1.4$  MPa as measured in equivalent cubes; the next series at  $24.1 \pm 1.4$  MPa; the final choice of strengths was  $20.7 \pm 1.0$  MPa. The decision to lower the strength level was made because many portland, portland-pozzolan, and several portland blast-furnace

slag cements survived the test for one year and did not fail by breaking although they expanded well over 1.0 percent of the gage length. There thus seems to be a wide variation in the strain capacity of mortar bars made with different portland, portland-pozzolan, and portland blast-furnace slag cements as well as among those made using blends of different portland cements with 30 or 35 percent replacement of cement by absolute volume of pozzolan.

## LATER TESTS

The bars were subsequently measured for length change and tested for fundamental transverse frequency at 7, 14, 21, 28, 56, and 90 days. Thereafter the schedule for measurements was adjusted to the rate at which the expansion was increasing and the relative dynamic modulus of each group of mortar bars was decreasing. Each time the bars were measured, the sulfate solution was changed and since the measurement interval was not constant throughout the test it was not to be expected that a constant amount of sulfate was available to attack the bars during each interval between readings. The volume of sulfate solution to bars was maintained at 3.9 to 1 throughout the test.

## FAILURE CRITERIA

The criterion for failure by increase in length was chosen as 0.10 percent; some cements failed by having all of the mortar bars break at expansions which were not determined because the failure occurred between two readings and we only know for example that after an expansion of 0.44 percent at 28 days every bar was broken at 56 days, the time of the next reading. The earliest failures by fracture of any of the bars took place at 28 days. Failures by fracture occurred thereafter at ages up to 180 days, but there was a tendency among the portland cements for failures to occur at relatively low expansions at ages below 90 days or for failures to occur at markedly larger expansions where the bars would already have been judged to have failed simply on the basis of expansion.

## TRICALCIUM ALUMINATE DETERMINATIONS

We investigated the form of  $C_3A$  or  $C_3A$  solid solution with sodium oxide, potassium oxide, magnesium oxide, or silicon dioxide (1) by X-ray diffraction using a diffractometer with nickel-filtered copper radiation; in all cases the portion of the cement examined had been treated with maleic acid in methanol solution stirred for 30 min and then filtered (2).

We have followed the method in Appendix A of Mander et al (2) except that we use as-received cement samples and stir for 30 min in the maleic acid-methanol solution, followed by vacuum filtration over a small piece of nylon stocking under No. 50 Whatman filter paper in a Büchner funnel, three washes with methanol, and evaporation to free-flowing dryness under an infrared lamp. Sulfates are removed by a 10 percent solution of ammonium chloride in water, stirred at laboratory temperature with a magnetic stirrer for 45 min, filtered, and evaporated to free-flowing dryness as are the maleic-acid residues. Mander et al (2) and Regourd, Chromy, et al (4) provide X-ray diffraction spacings for cubic and orthorhombic  $C_3A$  and solid solutions of  $C_3A$  and sodium oxide. Regourd and Guinier (5) provide more information; we have assumed that Orthorhombic II mentioned

by Regourd et al (4) is equivalent to "Monoclinic" in Regourd and Guinier (5) and Maki (6) except for the necessary differences in indexing. Like Kristmann (7) the diffractometer available to us resolved doublets in the relevant angular ranges of  $C_3A$  and solid solutions in  $C_3A$  but did not resolve triplets. Therefore, we used in our separations of  $C_3A$  the lines in the angular region from 21 to 21.84 degrees two-theta. As a consequence we believe that the separation of cubic  $C_3A$  from other  $C_3A$  is reliable as is the absence of  $C_3A$  from the malic acid residue. The distinction of the cubic and orthorhombic or tetragonal  $C_3A$  from orthorhombic and tetragonal or orthorhombic or tetragonal we suspect may be less reliable.

#### EFFECTS OF TRICALCIUM ALUMINATE CONTENT

Initially let us consider cements in which no  $C_3A$  was detected by X-ray diffraction. Five such portland cements were found. Only one had been tested for one year and it had expanded only to 0.065 percent at that time. The other four cements in which no  $C_3A$  was detected have been tested to 180 days at which time one which contains 4.53 percent M by chemical analysis has expanded to 0.085 percent, although it may expand more than 0.10 percent at one year, the influence of the periclase content hydrating to  $Mg(OH)_2$  is believed to be the significant feature explaining the expansion of this cement. All of the other three cements contain less possible periclase. Six cements were recognized as containing orthorhombic or tetragonal or orthorhombic and tetragonal  $C_3A$ . These include one which in one year reached an expansion of 2.88 percent in mortar bars.

The strain capacity (i.e., the increase in length without fracturing) of this particular cement was the largest shown by any of the portland cements tested. Another cement reached an expansion of 0.861 percent at 146 days but was not measurable at 180 days. Clearly, the strain capacity was substantial but well below that of the cement just discussed. Three other cements reached expansions over 0.10 percent by 180 days. One of those which exceeded 0.10 percent at 180 days contained 4.36 percent M by chemical analysis. The sixth cement which contains slightly over 2 percent M expanded to 0.057 percent at 180 days. The question of the strain capacity of the mortar bars of four of these cements has not yet been answered since all are still under test and none in the four sets has fractured. Cements containing cubic and orthorhombic or tetragonal  $C_3A$  or cubic  $C_3A$  and one of the other two forms in this group made up eight cements. Seven of those tested have failed by exceeding 0.10 percent expansion and three have failed in fracture, two at quite low expansions, and the others at expansions above 0.58 percent.

Seven portland cements contained only cubic  $C_3A$ . One of these reached an expansion of 1.77 percent at 365 days with no mortar bars broken. Another at 90 days had expanded to 0.61 percent with four mortar bars broken. Another has achieved the same expansion at 180 days without any failures by fracture. A fourth expanded to 0.29 percent at 90 days and was unreadable at 146 days. A fifth has expanded beyond 0.20 percent at 180 days without failures in fracture. Two other cements have not failed. One is expected to because although it contains the least cubic  $C_3A$  detected it also contains 3.63 percent M by chemical analysis and has expanded to 0.085 percent at 180 days. While we endeavored to find out which substances were present in the 26 portland cements

tested, our tests so far suggest, but do not confirm, the opinions of Regourd and Chromy et al (4) that cubic  $C_3A$  is more active than the forms with denser packing. Certainly the amount of  $C_3A$  in the cement as ranked by X-ray diffraction is not invariably correlated with maximum expansion, usually because the cements with the highest  $C_3A$  contents also are cements of quite rapid strength gain and low strain capacity, so that they may fail in 56 to 90 days by exceeding 0.10 percent expansion and by having all of the mortar bars fail in fracture.

#### BEHAVIOR OF PORTLAND-POZZOLAN CEMENTS

A comparison has been made between  $C_3A$  and solid solutions of the several crystal forms ranked by relative amount and the companion IP cements made with the same portland cement clinker and an addition ranging from 15 to possibly 25 percent of fly ash in the cements containing the most cubic  $C_3A$ . In the group of portland cements containing the largest amounts of cubic  $C_3A$  and their companion IP cements, all of the portland cements failed by expanding from 0.289 percent at 90 days where all fractured, up to as much as 1.77 percent where the bars survived to one year but relative  $E$  had fallen to 57 percent. Only one of the three companion IP cements expanded as much as 0.10 percent. One reached one year with an expansion of 0.035; it was the companion of the portland cement that expanded 1.77 percent. The other two cements are still under test with no apparent relation between the expansion of their companion portlands and those of the IP's. In the group of cubic  $C_3A$  cements, one portland with a relatively low amount of  $C_3A$  has a companion IP. The portland had expanded 0.61 percent at 180 days while the IP expanded 0.06 percent at the same age. In the group containing cubic and either orthorhombic or tetragonal  $C_3A$  solid solution or both, two portland cements have in one case two companion IP cements, one made with fly ash and one experimental cement with bottom ash. The other portland cement had a companion portland blast-furnace slag cement. The portland with IP companions is still under test but has substantially exceeded the failure criterion of 0.10 percent expansion. The companion IP still under test at the same age as the portland has expanded 0.08 percent while the experimental cement with bottom ash has already expanded over 0.90 percent at the same age. The portland cement with the companion portland blast-furnace slag cement expanded over 1 percent and failed by cracking and warping at 146 days with a relative  $E$  of 49 percent. The portland blast-furnace slag cement reached an expansion of 0.08 percent at 292 days and was terminated. Among cements containing relatively small amounts of cubic and orthorhombic or tetragonal  $C_3A$  or solid solutions one Type I cement survived to an age of one year at an expansion of 1.40 percent; the companion cement expanded 0.43 percent at one year. The second portland cement is still under test but has exceeded the failure criterion of 0.10 percent expansion. It had two companion IP cements with different amounts of fly ash in each. One has expanded 0.04 percent and the other 0.05 percent at the same age as the portland; all three are continuing in test. In cements containing orthorhombic or tetragonal solid solutions or both one cement containing an intermediate amount of total  $C_3A$  expanded to 2.9 percent at one year with a relative  $E$  of 64 percent at that time. Its companion IP expanded 0.11 percent at one year with a relative  $E$  of 150 percent. Within the same group of  $C_3A$  solid solutions one containing a relatively small amount of total  $C_3A$  expanded 0.10 percent at 280 days and is still in test. Its companion which has been in

test for 180 days has expanded 0.05 percent. In the same group of  $C_3A$  solid solutions the cement containing the least total aluminate phase has expanded to 0.86 percent at 146 days and was thereafter unreadable. Its companion IP has expanded 0.14 percent and is still under test. Summarizing these results shows that out of a total of 12 portland cements with companion blended cements, almost all blended with fly ash, 11 of the blended cements had expansions substantially reduced from those of the portland cements but in one case the addition of fly ash increased the total expansion but prolonged the life of the blended cement mortar bars from 90 days when all of the portland cement bars had broken to 270 days and the blended cement is still under test. Thus we have a clear case for the utility of Type IP cements.

#### BEHAVIOR OF BLENDS WITH HIGH-SILICA POZZOLANS

Three cements: RC 756 with 14.6 percent  $C_3A$  as calculated from chemical composition, RC 714 with 13.1, and RC 744 with 9.4 were tested alone and with 30 percent replacement by solid volume of each of two high-silica pozzolans. The  $C_3A$  in 756 was indicated by X-ray diffraction to be cubic, that in 714 and 744 to be cubic and orthorhombic. The high-silica pozzolans were AD 518, a calcined volcanic glass, and AD 536, a silica fume.

As shown on Fig. 1, the three cements tested alone behaved as follows: RC 714 showed 0.515 percent expansion at 56 days and all the bars disintegrated before the next test age; RC 756 showed 0.868 percent expansion at 90 days and all the bars disintegrated before the next test age; and bars made with RC 744 all survived to 365 days at which time the expansion was 0.808 percent after which the bars began to warp.

Figure 1

With 30 percent silica fume (AD 536), the expansions at 365 days with the three cements were insignificant and insignificantly different: 0.019, 0.016, and 0.018, respectively. With 30 percent calcined volcanic glass the expansions with the three cements remained in the order of expansion of the cements alone but were well below failure at one year being 0.057, 0.041, and 0.034, respectively. It is concluded that either of these two pozzolans at 30 percent replacement can effectively control sulfate expansion using any of these cements in this test; the silica fume is more effective and equally effective with all three cements. The volcanic glass still allows the cements to manifest their inherent differences in sulfate resistance but the expansion is at an innocuous level in all cases.

#### BEHAVIOR OF CEMENT 714 WITH FLY ASHES

Cement 714, by itself survived to 56 days, had expanded then 0.515 percent, and then disintegrated (Fig. 2). When replaced by 30 percent of each of eight fly ashes the effects varied. With fly ash 509 the specimens only survived 28 days after which they disintegrated, but at 28 days the expansion (0.040 percent) was less than when 511 was used. With fly ashes 506, 510, 511, and 513 the bars survived to 56 days but with widely different expansions at that point (0.427, 0.229, 0.417, and 0.056, respectively) and then disintegrated. With fly ashes 505, 507, and 512 the bars survived to 90 days, again with widely different expansions (1.167, 1.172, and 0.385, respectively). It is concluded that none of the eight fly ashes tested would control sulfate expansion of this cement in this test at 30 percent replacement. It is not positively shown however that any of the eight fly ashes made sulfate resistance significantly worse than it was when the cement was used alone.

Figure 2

# BEHAVIOR OF CEMENT 756 WITH FLY ASHES

Cement 756, by itself survived to 90 days at which time its expansion was 0.867 (Fig. 3). When replaced by 30 percent of each of eight fly ashes, as was to be expected, the effects varied. Five of the fly ashes had an adverse effect on sulfate resistance. In four cases the specimens only survived 56 days at which time their expansions were:

506: 0.634      510: 0.276  
509: 0.209      513: 0.031

In the fifth case, with 505, the bars survived to 90 days but with higher expansion (0.039) than the cement by itself. In the other three cases the bars survived as long as the cement by itself, but no longer, and had lesser but still large expansions (0.199, 0.392, and 0.500). It is concluded that none of these fly ashes will control sulfate expansion of this cement in this test at 30 percent replacement; five of the eight actually make the system less sulfate resistant.

Figure 3

# BEHAVIOR OF CEMENT 744 WITH FLY ASHES

Cement 744, by itself survived to 365 days (Fig. 4), at which time its expansion was 0.808 percent. When replaced by 30 percent of each of eight fly ashes the effects varied. In contrast to the behavior of these fly ashes with cement 714, here two of them (510 and 513) did significantly increase the sulfate susceptibility of the system; with both of these fly ashes the specimens only survived to 202 days. With all the other six fly ashes the specimens survived to 365 days and, in all cases, with reduced expansions as compared with cement 744 by itself. However only with 505 and 512 was the expansion at 365 days reduced below 0.10 percent, the failure criterion. It is concluded that

of the eight fly ashes, the use of two made the sulfate resistance worse, with two others the sulfate expansion was reduced to a possibly tolerable amount, and with the other four expansion was reduced but by not sufficient to provide protection in the test.

Figure 4

Based on the behavior of these ten pozzolans with the three cements (714, 756, 744), they may be ranked from best to worst with regard to their effects on sulfate resistance as follows:

	With Cement			Weighted	
	714	756	744	Average	
Best	536	536	536	536	(silica fume)
	518	518	518	518	(volcanic glass)
	512	512	512	512	(subbituminous)
	505	511	505	505	(subbituminous)
	507	507	507	507	(subbituminous)
	513	505	511	511	(bituminous)
	510	513	509	513	(lignite)
	511	509	506	509	(lignite)
	506	510	513	510	(lignite)
Worst	509	506	510	506	(lignite)

# CONCLUSIONS

1. Although it is possible by the use of an X-ray diffractometer to separate cubic  $C_3A$  from solid solutions of  $C_3A$  with alkalis and silica when the solid solutions have crystal structures other than cubic, without special provisions to improve resolution of the use of monochromatic radiation, the separation of cubic from not cubic is the most reliable unless a step-scanner

can be used on the diffractometer or a Guinier camera is available.

2. The cubic and orthorhombic I group following the nomenclature of Regourd, Chromy, et al (4) is probably the next most reliable separation as made with a diffractometer, on the basis of the experimentation by Maki (6) that shows that the partial solid solution in cubic  $C_3A$  passes with increasing substituents into mixed cubic and orthorhombic solid solutions as the substituents increase to a level of 7 percent  $Na_2O$ , modified in commercial portland cements by the  $SiO_2$  content and  $K_2O$  content.

3. We had hoped in this work to provide evidence to support or refute the belief of Regourd, Chromy, et al (4) that cubic  $C_3A$  should be more reactive than any of the solid solutions with  $Na_2O$  which have denser structures. However, our results are not clear regarding this particular question because it developed that bars made using mortars prepared in accordance with ASTM Designation C 109 with constant water-cement ratio and proportions proved to have very different strain capacities, probably as a consequence of the rate of strength gain of the cements even when the  $C_3A$  contents were similar. For example, cement 756, containing the most cubic  $C_3A$  of any of the cements we tested (14.6 percent  $C_3A$  calculated from chemical analysis) in mortar bars exposed in 5 percent  $Na_2SO_4$  solution survived to 90 days and reached an expansion of 0.868 percent; the bars disintegrated before the next reading. When that cement was replaced by 30 percent by volume of each of eight fly ashes, the expansions were reduced in four cases but failure by disintegration of the bars took place earlier than that of the cement; in one case the bars survived as long as the cement by itself but the expansion was greater. In three other cases the bars containing fly ash survived as long as the bars containing the straight portland cement but disintegrated at lower expansions. In this group, only one fly ash increased the strain capacity. Cement 714 contained 13.1 percent  $C_3A$ , a smaller amount than in cement 756. In C 109 mortar bars it expanded to 0.515 at 56 days and then disintegrated. As compared with cement 756, it had less strain capacity because the bars disintegrated earlier at a lower expansion. If it were possible to exchange the cubic  $C_3A$  of 756 with the lower cubic and orthorhombic  $C_3A$  of 714, leaving the rest of each cement as it was, would the greater strain capacity of 756 with the  $C_3A$  of 714 lead to a larger expansion of that combination before the bars disintegrated? Would the smaller strain capacity of 714 be further decreased by the larger amount of cubic  $C_3A$  from 756? Does strain capacity in sulfate exposure depend on the formation of ettringite and gypsum and the development of tensile strength and creep capacity all *pari passu*? Does failure by disintegration occur when expansion, strength gain, and creep depart in rate from each other by more than a certain, at present unknown, rate? Cement 744, with 9.4 percent cubic plus orthorhombic  $C_3A$ , less than either 756 or 714, survived in bars exposed in sodium sulfate to 365 days when it had expanded to 0.81 percent. Two fly ashes increased the sulfate susceptibility; one caused earlier failure at lower expansion and the other failure at 365 days at lower expansion. Cement 744 is concluded to have the greatest strain capacity of these three cements, but contained less  $C_3A$ .

4. Because we did not find cements of equal  $C_3A$  content in the cubic, cubic and orthorhombic I, and orthorhombic or tetragonal, or orthorhombic or

tetragonal groups, and we did find cements of equal strain capacities in these groups, we can neither confirm nor refute the belief of Regourd, Chromy, et al (4) that cubic  $C_3A$  is more reactive than solid solutions of other crystal forms.

# Mechanism of sulfate expansion : A reappraisal of literature

## *Mécanisme de l'expansion due au sulfate : une réestimation de la littérature*

S. CHATTERJI, M. Sc., D. Phil., Research Scientist. H + H-INDUSTRI A/S, Lyngby, Denmark

**SUMMARY:** The expansion of Portland cement concrete due to  $\text{SO}_4$  ion attack has been attributed either to ettringite formation or formation of monosulfate from pre-existing  $\text{C}_4\text{AH}_x$ . The two mechanisms can be distinguished by noting whether the expansion follows ettringite formation or if it continues even when the proportion of ettringite is decreasing. The relevant literature has been critically surveyed to ascertain the validity of either of the above relationships. In this survey a distinction will be made between free expansion and expansion against a constraint.

**The literature on free expansion:** Chatterji has noted that in a  $\text{C}_3\text{A}$ -gypsum- $\text{Ca}(\text{OH})_2$  paste expansion can occur even when ettringite was disappearing. Analyses of quantitative results of Greening as well as Sauman show that most of the expansion occurs when ettringite is disappearing.

**The literature on expansion against a constraint:** Mehta has done extensive work on this aspect using all types of expansive cements. Analyses of his papers show that:

- (i) M and S type expansive cements develop about half the total expansion at maximum ettringite content; the rest occurs when ettringite is disappearing.
- (ii) In K type expansive cement a third of the total expansion occurs by the time free  $\text{CaSO}_4$  has reacted. During the rest of expansion ettringite and some unstated calcium aluminate hydrate, in the ratio 1:8, form from  $\text{C}_4\text{A}_3\text{S}$ .
- (iii) Hydration of  $\text{C}_4\text{A}_3\text{S}$  in the presence of  $\text{Ca}(\text{OH})_2$  yields monosulfate and  $\text{C}_4\text{AH}_x$ .
- (iv) The expansion continues when either ettringite is decreasing and/or monosulfate is forming.

It is to be noted that ettringite causes no expansion in a sulfate resistant Portland cement.

The role of ettringite in sulfate expansion is uncertain especially as a number of workers, including Mehta, have reported the formation of hexagonal aluminate hydrate even when gypsum is present in the system. In other words, even the early expansion of expansive cements may be due to monosulfate formation. It is to be noted that in a sulfate resistant Portland cement monosulfate does not form.

**RESUME:** L'expansion du béton de ciment Portland due à l'action des ions  $\text{SO}_4$  a été attribuée soit à la formation d'ettringite, soit à la formation de monosulfates à partir de  $\text{C}_4\text{AH}_x$  pré-existant. Que l'expansion suive la formation d'ettringite ou bien qu'elle continue pendant que la proportion d'ettringite diminue, il est impossible de distinguer entre les deux mécanismes. Les ouvrages pertinents sur ce sujet ont été soumis à une lecture critique pour assurer la validité des deux relations décrites plus haut. Dans cette étude nous ferons une distinction entre l'expansion libre et l'expansion soumise à une contrainte.

**Les ouvrages sur l'expansion libre:** Chatterji a remarqué que dans un  $\text{C}_3\text{A}$ -plâtre- $\text{Ca}(\text{OH})_2$  il peut se produire une expansion de la pâte, même pendant la disparition de l'ettringite. Les analyses des résultats quantitatifs obtenus par Greening et Sauman montrent que la plus grande partie de l'expansion se produit quand l'ettringite disparaît.

**Les ouvrages sur l'expansion soumise à une contrainte:** Mehta a fait une étude approfondie sur ce sujet en utilisant différents types de ciments expansifs. Une analyse de son travail montre que:

- (i) Les ciments expansifs de type M et S développent la moitié de leur expansion totale quand la teneur en ettringite est maximale. Le reste se produit quand l'ettringite disparaît.
- (ii) Les ciments expansifs de type K développent un tiers de leur expansion totale pendant le temps de réaction du  $\text{CaSO}_4$  libre. Pendant le reste de l'expansion, il se forme de l'ettringite et des hydrates d'aluminate de calcium indéterminés à partir de  $\text{C}_4\text{A}_3\text{S}$  dans le rapport 1:8.
- (iii) L'hydratation du  $\text{C}_4\text{A}_3\text{S}$  en présence de  $\text{Ca}(\text{OH})_2$  forme des monosulfates et du  $\text{C}_4\text{AH}_x$ .
- (iv) L'expansion continue quand l'ettringite diminue et/ou quand il y a formation de monosulfate.

Il faut remarquer que l'ettringite ne cause pas d'expansion dans les ciments Portland résistants aux sulfates.

Le rôle de l'ettringite dans l'expansion des sulfates est hypothétique, notamment depuis que Mehta et d'autres ont constaté une formation d'aluminates hydratés hexagonaux, même en présence de plâtre dans le système. Autrement dit, l'expansion du début des ciments expansifs peut être due à la formation de monosulfate. On remarquera qu'il ne se forme pas de monosulfate dans les ciments Portland résistants aux sulfates.

it is known that structures containing some types of calcerious cements expand and disintegrate when exposed to sulfate bearing water. For both economic and scientific reasons, the processes leading to the above breakdown, also known as sulfate expansion, have been extensively studied. It is a commonly held belief that the expansion is related to the formation of calcium sulfoaluminate hydrate. There are two calcium sulfoaluminate hydrates namely monosulfate (low sulfoaluminate) and trisulfate (ettringite); and each of these has been implicated in sulfate expansion. The main object of this paper is to critically evaluate the relevant literature in order to differentiate between the two conflicting hypotheses.

As a preliminary to this evaluation it is in order to recapitulate the salient points of the two opposing hypotheses.

#### (1) The hypothesis involving monosulfate:

This hypothesis postulates that in a hydrating paste,  $C_4AH_{13}$  forms from alumina bearing phases. If exposed to  $SO_4$  ions  $C_4AH_{13}$  first changes over to monosulfate by an ion-exchange process. When  $SO_4$  ion concentration increases, monosulfate changes over to ettringite by a "through-solution" process. The conversion of  $C_4AH_{13}$  to monosulfate is accompanied by a volume expansion. Depending upon the presence or absence of excess  $Ca(OH)_2$ , the hardened paste may or may not expand. The formation of ettringite may give rise to second order expansive forces (1).

#### (2) The hypothesis involving ettringite:

According to this hypothesis the formation of ettringite from alumina bearing phases is responsible for the expansion. The exact mechanism by which ettringite causes the expansion has been variously attributed to (a) a solid state formation of ettringite (2,3), (b) a crystal growth pressure (4), (c) an adsorption of water by colloidal ettringite which forms in the presence of  $Ca(OH)_2$  (5). More will be said about each of the above explanations later on. However it is generally been accepted that the presence of free  $Ca(OH)_2$  is necessary for expansion (1,2,5).

Since both the hypotheses accept ettringite as the stable calcium sulfoaluminate hydrate in the presence of excess or stoichiometric amounts of sulfate, its presence under these circumstances does not constitute evidence for or against any of these hypotheses. Moreover, as in one of the hypotheses the formation of monosulfate has been given a role analogous to that of free radicals in organic reaction mechanisms, an appropriate experiment has to be performed to reveal its importance. The two hypotheses can be differentiated by

- (i) a continued expansion when ettringite formation has stopped especially when it is disappearing or disappeared.

- (ii) the absence of expansion in a system containing excess  $Ca(OH)_2$  in which ettringite but not monosulfate form. The relevant literature on sulfate expansion has been critically surveyed keeping the above two criteria in mind. In this evaluation a distinction has been made between free and restrained expansion measurements.

#### (A) Literature on the free expansion measurements:

It appears that Chatterji was first to report that in  $C_3A-Ca(OH)_2$ -gypsum-water system, expansion continues even when ettringite is disappearing and monosulfate is forming (1). However a similar inference can be drawn from Meissener's work on sulfate unsoundness of cement (6). Meissener had added upto about 4.9%  $SO_3$  to different types of cements and measured lengths of wet cured mortar prisms made with those cement samples. Unsoundness appeared by about 90 days, long after all gypsum had been consumed.

Matousek and Sauman have reported the expansion characteristics of expanding cements based on Portland cement, metakaolinite and gypsum (7).

FIG. 1  
Influence of the addition of metakaolinite on the volume changes of the cement with a constant gypsum content (10%).

Fig. 1 has been taken from their paper. An analysis of the results (8) indicated that in the mixture containing 20% metakaolinite, complete consumption of gypsum had occurred between 7 and 10 days. From Fig. 1 it can be seen that the expansion continued upto the 14th day i.e. even after ettringite formation had stopped. The last 20% or so expansion occurred against a higher cohesive strength of the cement i.e. the expansive force was stronger than that at the beginning.

However, the most interesting results are those of Seligmann and Greening (9). These authors measured volume changes of wet pastes against a small Hg head in the system  $C_3A-Ca(OH)_2$ -gypsum having varying  $SO_3/Al_2O_3$  ratios; they also followed their hydration by using an x-ray diffraction technique.

Fig. 2  
Expansion characteristics  
of  $C_3A-CaSO_4-Ca(OH)_2$  pastes

Fig. 2 shows their volume expansion results. In the figure 1/2 etc. denote  $SO_3/Al_2O_3$  ratios. In the mixture 1/4 it took about 6 hours for the complete consumption of gypsum and that of ettringite about 9 hours. However from Fig. 2 it can be seen that the expansion continued upto about 40 hours; moreover it also shows that only a minor fraction of the total expansion occurred whilst ettringite was forming and most of the expansion occurred whilst it was disappearing. This is also true for the mixture marked 3/4. The authors stated "The expansion continued during stages II (consumption of ettringite to form monosulfate) and III (formation of monosulfate- $C_4AH_x$  solid solution) hydration ....."

The results of Seligmann and Greening and Chatterji are of particular interest as the expansion could not be attributed to any other compound and they show that expansion occurs when ettringite is disappearing and monosulfate or its solid solution is forming.

#### (B) Literature on restrained expansion:

On this aspect Mehta and his co-workers have done extensive work using both pure components and expansive cements of different types.

Fig. 3  
Expansion characteristics  
of expansive cements

Fig. 3 and table 1 have been taken from one of their papers (10). In this paper Mehta and Lesnikoff have studied the expansion characteristics of water cured pastes of K, M and S type expansive cements as well as their hydration reaction by x-ray diffraction technique. The expansive cements were produced by grinding small amounts of expansive agents with Portland cement clinker. Analyses of these results will start with S type cement and end with K type cement.

(i) S type expansive cement: Table 1 shows that ettringite had reached its maximum proportion in between 7 and 10 days. The proportions of ettringite and  $C_3A$  decreased between 10 and 14 days. Fig. 3 shows that about half of the total expansion occurred by 10 days and the expansion continued thereafter apparently with acceleration. In other words the later part of the expansion and disappearance of ettringite occurred simultaneously.

(ii) M type expansive cement: In this cement the proportion of ettringite was highest on the 3rd day. Thereafter its proportion decreased as did those of  $C_3A$  and CA. Fig. 3 shows that about half of the observed total expansion occurred by the 3rd day and the rest subsequently. Here again the expansion continued whilst ettringite was disappearing. This cement deserves further attention. In this case, the complete consumption of  $CaSO_4$  took about 3 days. In the presence of excess  $Ca(OH)_2$ , the continued hydration of  $C_3A$  and CA must have produced  $C_4AH_x$ . Mehta has previously shown that  $C_4AH_x$  reacts very fast with ettringite to produce monosulfate (11). For some unknown reasons Mehta and Lesnikoff could not detect the formation of monosulfate or  $C_4AH_x$  until about 14 days. Thus half of the total expansion was occurring concurrently with the disappearance of ettringite and formation of  $C_4AH_x$  and/or monosulfate.

(iii) K type expansive cement: This is a very interesting case. Table 1 shows that  $CaO$  was completely hydrated by 6 hours and in the 24-hour sample no free  $CaSO_4$  could be detected. Proportions of  $C_4A_3S$  and  $C_3A$  decreased and that of ettringite increased monotonously with time. This is the only cement sample where the proportion of ettringite increased all the time.

Now  $SO_4$  ions needed for the formation of ettringite after 24 hours must have come from  $C_4A_3S$ . This is somewhat surprising as Mehta and Kline have previously shown that mixtures of  $C_4A_3S$ ,  $CaO$  and  $CS$  under similar conditions form monosulfate (mix. nos P and R of ref. 3). However that may be, the stoichiometry of ettringite formation from  $C_4A_3S$  is informative. As equation 1 shows, each "molecule" of ettringite formation is accompanied by the liberation of 8 "molecule" of  $Al_2O_3 \cdot nH_2O$  and 6 of  $Ca(OH)_2$

Table 1  
Relative XRD Peak Intensities of  
Hydrated Cement Pastes

Age of Hydration/ Type of Cement	CaO	C <sub>2</sub> H <sub>2</sub>	C <sub>2</sub> H <sub>1</sub> /2	C <sub>2</sub> S	C <sub>4</sub> A <sub>3</sub> S	C <sub>3</sub> A	CA	Ettringite

10 d	-	-	-	-	-	33	-	25
14 d	-	-	-	-	-	32	-	23

As the cement already had enough Ca(OH)<sub>2</sub> both from CaO and Portland cement hydration, it is expected that the above "nascent" Al<sub>2</sub>O<sub>3</sub>·nH<sub>2</sub>O will form C<sub>4</sub>AH<sub>x</sub>. Furthermore, the continued hydration of C<sub>3</sub>A after 24 hours will add more C<sub>4</sub>AH<sub>x</sub> to the stock. It is also expected that C<sub>4</sub>AH<sub>x</sub> will react with ettringite to form monosulfate (11). Thus it is doubly surprising that in this cement the proportion of ettringite went on increasing and no monosulfate or hexagonal calcium aluminate hydrate could be detected until about 14 days.

Fig. 3 shows that about 30% of the total expansion occurred within 24 hours when ettringite may be claimed to be the main sulfoaluminate and the rest, about 70%, occurred when ettringite was forming along with another calcium aluminate hydrate in the ratio 1:8.

Attribution of the continued expansion to ettringite or the other calcium aluminate hydrate depends on ones prejudices. When one notes that the particular K type studied contained CaO as a component, one may wonder if the expansion upto 24 hours logically can be attributed solely to ettringite. It is known that CaO can cause expansion after it has been fully hydrated (12).

It will thus appear that the major part of the restrained expansion of any expansive cement occurs when monosulfate is forming and/or ettringite is disappearing. It is not even certain that the expansion at the initial stages of hydration can be attributed to ettringite. A number of authors including Mehta have reported the formation of monosulfate at the initial stages of hydration even in the presence of excess calcium sulfate (1,3,11,13,14,15). Undetected monosulfate, as it must have happened in the cases of M and K types of expansive cements, might have caused the initial expansions.

#### (c) Ettringite formation without expansion:

Any theory of sulfate expansion must explain the absence of expansion in the case of sulfate resistant Portland cement. Like ordinary Portland cement, it liberates Ca(OH)<sub>2</sub> on hydration and forms ettringite on reacting with sulfate (4,16,17). The particle size of ettringite is similar to those in ordinary Portland cement (18) if not smaller (4). It is difficult to explain why ettringite formation does not cause any expansion in sulfate resistant Portland cement as it does in ordinary Portland cement.

It will be of interest to know if monosulfate forms in sulfate resistant Portland cement. In a cooperative research programme none of the seven participating laboratories could detect it by DTA any time upto 365 days of hydration (19). Kalousek and Benton had previously published similar results (20,21,22). A maximum of two, out of seven cooperative laboratories, could detect trace or possible trace amount of monosulfate at any time upto 365 days by x-ray diffraction technique (23). Noting that the strongest line of monosulfate is at 8.9A and that ettringite has a line of moderate intensity at 8.84A, the detection of trace amounts of monosulfate in the presence of larger amounts of ettringite is somewhat uncertain especially when the intensity of 8.9A line was varying erratically with time. The absence of monosulfate in sulfate resistant Portland cement has been previously noted (16). If this general inability to detect monosulfate in any quantity in sulfate resistant Portland cement is taken at its face value then the absence of expansion in this type of cement is very straightforward - no monosulfate no expansion.

#### Some comments on the proposed explanations as to how ettringite causes expansion:

Various authors have proposed various explanations as to how the formation of ettringite causes expansion in cements. Some of these will be examined in this section.

(i) Solid state formation of ettringite:

It was proposed that expansion occurs only when ettringite forms through a solid state reaction from alumina-bearing phases in a saturated  $\text{Ca(OH)}_2$  solution (2). Both transmission and scanning electron microscopic studies showed that ettringite formation is a "through-solution" process irrespective of  $\text{Ca(OH)}_2$  concentration (5,16, 24). Moreover this does not explain the case of sulfate resistant Portland cement.

(ii) Crystal growth pressure:

It can be shown that a crystal, in contact with its supersaturated solution, will exert a pressure against any constraint provided there is no other crystal in the same system which can grow unhampered. This proviso is difficult to satisfy in any cement paste. Neither can the crystal growth pressure hypothesis explain the observations of Chatterji and those of Seligmann and Greening.

(iii) Expansion due to water adsorption by colloidal ettringite:

This is one of the latest proposals (5,25). According to this proposal ettringite forms in a colloidal state in the presence of  $\text{Ca(OH)}_2$  and this colloidal ettringite adsorbs a large amount of water on its surface causing expansion. However, there seems to be some confusion as regards to the experimental evidence for it. In his 1967 paper questioning the validity of monosulfate hypothesis, Mehta had shown that lime free  $\text{C}_3\text{A}-3\text{CSH}_2$  paste of water/solid ratio of 0.6 (the theoretical w/s ratio for complete reaction is 0.59) can expand i.e. ettringite which had formed in the absence of  $\text{Ca(OH)}_2$  and had no access to an external source of water could expand. (11). In his 1973 paper proposing the colloidal ettringite hypothesis, Mehta has shown that "a stoichiometric mixture of  $\text{C}_4\text{A}_3\text{S}_3\text{CSH}_2$ , and quicklime ..... with more than enough water to form ettringite" could not expand significantly in the absence of extra water (5). Thus it is difficult to predict for a given case if ettringite will need  $\text{Ca(OH)}_2$  and/or water to expand or not.

In spite of above confusion, the results of Mehta and Hu (25) deserve closer examination. In this work a stoichiometric mixture of  $\text{C}_4\text{A}_3\text{S}_3$ ,  $\text{CS}$ , lime and water, to produce ettringite, was cast in a steel cylinder which was closed at the bottom. After about 1 hour, when the mix had set, a small plastic plate was placed on the top of the mix and a dial gage was brought in contact to measure the subsequent length change continuously.

The mix was allowed to hydrate for 7 days to complete ettringite formation during which time there was a volume decrease. After complete reaction, excess water was added to the top of the paste which then gradually expanded by about 54%. As the paste expanded

so much it has to be assumed that most of the ettringite must have formed in the presence of  $\text{Ca(OH)}_2$ , in other words, for most of the time, the reaction condition was similar to mix No. J of ref. 3, which according to Mehta and Kline develop poor bonding property. Furthermore the observed 54% expansion itself is an indication of the poor bonding property of the mix. Present day dial gauges exert a spring load of about 100 g. As in the above experiment this 100 g load was distributed by the plastic plate over the paste surface, it may be inferred that the expansion occurred against a very low pressure. A force which causes an expansion in a low cohesive paste against a low pressure may not be able to expand a high cohesive paste i.e. the experiment has very little relevance to sulfate expansion. Another indication of this irrelevance is that colloidal ettringite can not cause any expansion in sulfate resistant Portland cement.

The irrelevance of the above type of experiments to sulfate expansion is best illustrated by the results of Collepardi et al (15). Using the above experimental technique these authors have shown that a  $\text{C}_3\text{A}$ -gypsum paste can expand even when no  $\text{Ca(OH)}_2$  is present. Following Mehta and HU these authors have attributed the expansion to water adsorption by ettringite though they could detect hexagonal aluminate in their samples from 15 minutes onwards. If the force monitored by their experiment has any relevance to sulfate expansion then one would expect sulfate expansion in  $\text{Ca(OH)}_2$  free cement like supersulfated cement, aluminous cement, pozzolana cement etc. Absence of sulfate expansion in any of the above cements illustrates how irrelevant this type of experiment is to sulfate expansion.

A prediction from monosulfate hypothesis:

In a subject as technological as sulfate expansion, a method of decreasing the sulfate expansion of a given ordinary Portland cement will be highly desirable. The monosulfate hypothesis suggests that the addition of finely ground  $\text{CaCO}_3$  to ordinary Portland cement will decrease its sulfate expansion by decreasing monosulfate formation. This suggestion was found to be valid (26).

In conclusion it can be said that it is possible to set down evidence for this or that hypothesis but in the ultimate analysis ones prejudices determine which hypothesis one believes.

## RESUMES DE POSTERS

V. BABOUCHKIN, (Kharkov) et A. KOLOMATSKI, Institut Technologique, (Belgorod) - U.R.S.S.

"Thermodynamique de l'hydratation de  $C_3A$  et le rôle des hydrates d'aluminium dans les changements de volume de la pierre de ciment pendant le durcissement et la corrosion du sulfate".

Ayant précisé les données thermodynamiques pour les aluminates hydratés  $C_2AH_8$ ,  $C_4AH_{13}$ ,  $C_3AH_6$  et pour les sulfoaluminates hydratés de calcium  $C_3ACSH_{12}$ ,  $C_3ACSH_{32}$ , on a fait des calculs thermodynamiques dans les systèmes  $C_3A-H_2O$  et  $C_3A-Cs-H_2O$  à la température normale et élevée.

On a établi les domaines de température de la stabilité thermodynamique des sulfoaluminates hydratés de calcium et on a démontré la possibilité de leur transformation réciproque selon les conditions de la réaction.

Dans le système  $C_3A-Cs-H_2O$ , on a analysé la préférence des réactions de formation des sulfoaluminates hydratés de calcium en différentes proportions quantitatives des constituants réactifs à l'intervalle des températures 298-398 °K.

On a examiné les conditions de la stabilité de la forme monosulfate du calcium pendant le durcissement et la corrosion du sulfate. On a montré le rôle de l'ettringite dans ce processus, y compris les changements de volume et la destruction.

"Hydratation du  $C_3A$  dopé au sodium".

Les auteurs ont étudié quatre échantillons de  $C_3A$  dopés par différentes quantités de  $Na_2O$ . Le dosage a été réalisé en incorporant diverses teneurs de  $Na_2O$  aux matières premières avant la synthèse thermique de  $C_3A$ .

L'hydratation des échantillons a été suivie par les techniques ci-après : diffraction des R.X., microcalorimétrie isotherme, l'évolution de la concentration des ions de la phase aqueuse et analyse thermogravimétrique.

L'ensemble des résultats permet de constater qu'en absence de gypse, les échantillons dopés sont d'autant moins réactifs que la teneur en  $Na_2O$  est plus élevée.

Par contre, la présence de gypse inverse cette séquence.

Notons encore la disparition quasi instantanée du gypse lors de l'hydratation des échantillons dopés.

Ces résultats ont conduit les auteurs à proposer une interprétation originale sur le rôle des ions contrôlant la cinétique de l'hydratation du  $C_3A$  en présence de gypse.

M. CONJEAUD, Lafarge, (Trappes) - France.

"Processus d'attaque des ciments portland hydratés par le sulfate de magnésium".

La résistance au sulfate de magnésium de cinq CPA industriels et d'un  $C_3S$  synthétique a été testée sur mortier 1/3 à des échéances allant jusqu'à 3 ans. La concentration de la solution agressive est 50 g/l  $MgSO_4$ , 7  $H_2O$ , soit 1,6 %  $SO_3$  dans la solution, et celle-ci est renouvelée tous les mois. L'analyse des phases formées et de la microstructure a été effectuée par diffraction X et microscopie à balayage. La stabilité des mortiers, comme celle des bétons, dépend de paramètres physiques et chimiques. La compacité et la perméabilité jouent un rôle considérable imbriqué à celui des paramètres chimiques. Le processus d'attaque chimique des mortiers et bétons par  $MgSO_4$  passe par la formation bien connue d'ettringite à partir du  $C_3A$  résiduel, avec augmentation de volume consécutive. Mais il est mis en évidence que cette ettringite se décompose ensuite rapidement (ce qui s'explique, d'après LEA, par l'instabilité de l'ettringite en présence de  $MgSO_4$ ) en chaux, alumine et gypse avec libération d'eau et création de porosité. D'où une première accélération du processus d'attaque. Puis, on observe la décomposition du C-S-H qui réagit avec la chaux, l'alumine et le gypse, pour former de la "Si-ettringite" gonflante en quantité très importante, et la dégradation du béton devient complète. Dans un tel processus, le  $C_3A$  joue un rôle initiateur, d'où son importance.

Mais il faut noter que tous ces résultats ne doivent être extrapolés à d'autres milieux, même contenant  $MgSO_4$  comme l'eau de mer, qu'avec beaucoup de précautions, car d'autres phénomènes entrent en jeu ainsi que l'ont montré d'autres études que nous avons faites.

S. DIAMOND, Purdue University, (Lafayette) - U.S.A.

"Hydration reactions of  $C_3A$  and anhydrite present within a high-calcium flyash".

A high CaO - content flyash having  $C_3A$ , free CaO and  $CaSO_4$  as soluble components was found to set hydraulically in pastes consisting only of flyash and water. SEM micrographs displayed show rapid development of ettringite supplemented by calcium monosulfaluminate bridging between individual flyash spheres to produce a rigid structure. Some C-S-H gel is produced at later ages.

"Formation de silicoaluminates dans des mélanges gypsés  $C_3A + C_3S$  et  $C_3A + C_2S + C_3A$ ".

La formation de silicoaluminates de calcium dans des mélanges synthétiques gypsés  $C_3A + C_3S$  et  $C_3A + C_2S$  a été mise en évidence par analyse à la microsonde électronique de Castaing et observation au microscope électronique à balayage. Cette formation est due à une diffusion importante d'ions silicates à partir des grains de  $C_3S$  ou  $C_2S$  vers les grains de  $C_3A$ . Au début de la réaction, la diffusion de la silice se manifeste déjà par la présence de silicium dans la couche d'ettringite qui se forme initialement autour des grains de  $C_3A$ . Cette diffusion devient ensuite prépondérante et se traduit par la formation d'abord de trisilicoaluminate  $C_6AS_3H_{31}$ , puis de monosilicoaluminate  $C_3ASH_{12}$ , par pseudomorphose des grains de  $C_3A$ .

" $C_3A$  dans les clinkers industriels".

L'aluminate tricalcique de 30 ciments portland industriels a été analysé par diffraction des rayons X, microscopie optique et microsonde électronique. Les formes cristallines cubiques et orthorhombiques sont les plus fréquentes, elles coexistent souvent. Une forme monoclinique a été trouvée dans deux cas, elle est riche en alcalins,  $SiO_2$  et  $Fe_2O_3$ .

La stabilisation de  $C_3AC$ ,  $C_3AO$  ou  $C_3AM$  dépend du taux d'alcalins mais aussi du taux de  $SO_3$  du clinker.

B. MORTUREUX, H. HORNAIN, M. REGOURD, C.E.R.I.L.H., (Paris) - France.

"Comportement de pâtes  $C_3S + C_3A +$  gypse et de ciments portland dans les solutions sulfatées".

L'évolution de mélanges synthétiques  $C_3A + C_3S +$  gypse et de ciments portland à différentes teneurs en  $C_3A$  a été suivie par diffraction des rayons X et microscopie électronique à balayage. Les paramètres étudiés sont la forme cristalline de  $C_3A$  (cubique, orthorhombique), la composition élémentaire des grains de  $C_3A$  (teneur en  $Na_2O$ ,  $K_2O$ ,  $Fe_2O_3$ ).

Les résultats montrent que la résistance aux eaux agressives des pâtes de ciment et des mortiers dépend avant tout de leur compacité. A brève échéance,  $C_3A$  cubique s'hydrate plus vite que  $C_3A$  orthorhombique et donne un matériau moins vulnérable si l'échantillon est immergé dans la solution agressive après un temps d'hydratation suffisamment long.

W. RICHARTZ, Forschungsinstitut der Zementindustrie, (Düsseldorf) - Federal Republic of Germany.

"Reactivity of  $C_3A$  and setting of cement".

Immediately after mixing the cement with water a reaction starts in which a small amount of the tricalcium aluminate  $C_3A$  and the calcium sulfate added as set-controlling agent take part. After approximately 10 to 15 minutes this initial reaction stops to restart again after a "dormant period" of several hours.

On principle, the pattern of this initial reaction is the same with all cements. In the first few minutes there are, however, differences in the amount of  $C_3A$  taking part in the reaction. The reason for this is the differing reactivity of the  $C_3A$  of the various portland cements. To achieve setting according to the standard, the supply of the sulfate must be adjusted to the reactivity of the  $C_3A$  at the start of the hydration. In this case the sole reaction product is ettringite which forms in a thin layer on the surface of the cement grains only. Too low a sulfate supply leads to the formation of monosulfate, too much sulfate to secondary gypsum. In both cases the result is early setting, because monosulfate and gypsum crystallize as relatively large plates or laths in the pore space between the cement grains. The adjustment of the sulfate supply to the reactivity of the  $C_3A$  may be achieved by the use of a suitably proportioned mix of natural anhydrite  $CaSO_4$  and gypsum  $CaSO_4 \cdot 2H_2O$ . During the grinding process of the cement the gypsum should be dehydrated completely to hemihydrate  $CaSO_4 \cdot 1/2H_2O$  so that at the start of the hydration there is a suitable mix of anhydrite and hemihydrate.

## POSTER

# A Progress report on analytical electron microscopy studies of the hydration of tricalcium aluminate

## *Rapport d'avancement sur les études par microscopie électronique analytique de l'hydratation d'aluminate tricalcique*

J.E. BAILEY, Professor, Department of Metallurgy and Materials Technology,  
University of Surrey - GUILDFORD SURREY,  
D. CHESCOE, Great-Britain.

### SUMMARY :

Analytical electron microscopy has proved a useful tool in the study of hydrating cement particles. Apart from morphology detail in both TEM and SEM, it is possible with this technique to obtain elemental analysis and diffraction from a single fibre.

In previous work on the hydration of OPC, several different fibre types were observed, of which the most predominant designated type II, were hollow amorphous calcium aluminate sulphate hydrates.

To obtain a greater understanding of the hydration mechanism, tricalcium aluminate was hydrated with varying quantities of gypsum.

Examination in TEM of hydrated  $C_3A$  revealed the expected hexagonal hydrates. As the quantity of gypsum was increased, in addition to the hexagonal calcium aluminate hydrates, fibrous calcium aluminate sulphate hydrates were observed. With low concentration of gypsum, these CASH precipitates were remote from the  $C_3A$  particles, but as the concentration increased, so fibres emanating from a  $C_3A$  particle surface were observed. It was found, that although the elemental concentration of the remote and surface associated fibres were similar, those emanating from the  $C_3A$  were amorphous, this evidence increasing the understanding of the growth mechanism of these fibres.

### RESUME :

La microscopie électronique analytique s'est révélée un outil pratique dans l'étude de l'hydratation des particules de ciment. A part le détail morphologique, il est possible d'obtenir avec le M.E.T. (Microscope Electronique à Transmission) et le M.E.B. (Microscopie Electronique à Balayage) l'analyse élémentaire et la diffraction d'une seule fibre.

Dans un travail précédent sur l'hydratation du ciment portland, plusieurs types de fibres ont été observés, le plus fréquent étant le type II, c'est-à-dire des hydrates de sulfo-aluminate de calcium creux et amorphes.

Pour mieux comprendre le mécanisme de l'hydratation, l'aluminate tricalcique a été hydraté avec différentes quantités de gypse.

L'examen au "M.E.T." du  $C_3A$  hydraté a révélé les hydrates hexagonaux attendus. Quand la quantité de gypse croît, on constate la présence, non seulement d'hydrates hexagonaux d'aluminate de calcium, mais aussi de sulfo-aluminates de calcium hydratés fibreux. A faible concentration de gypse, ces précipités de CASH se trouvent loin des particules de  $C_3A$ , mais à forte concentration des fibres émanant de la surface d'une particule de  $C_3A$  ont été observées. Bien que la concentration élémentaire des fibres éloignées et superficielles soit la même, celles émanant du  $C_3A$  sont amorphes, cette évidence accroissant la compréhension du mécanisme de croissance de ces fibres.

## 1. INTRODUCTION

This paper is in the form of a brief report of some recent studies on the nature of the structure of the hydration products obtained from calcium aluminate in the presence of gypsum.

In a recent paper, a technique for examining directly the morphology, crystallinity and chemical composition of hydrated Portland cement was described, see Bailey and Chescoe (1). Three morphologically distinct fibrillar hydration products were observed to form at the surface of Portland cement particles. Perhaps surprisingly, two of these were found to be predominantly calcium aluminate sulphate compositions and were distinctly amorphous and one of these fibres referred to as type II was clearly tubular in form (1).

In this short report, some further observations on the hydration behaviour of calcium aluminate in the presence of gypsum are presented which demonstrate the validity of the technique and demonstrate the ability of the technique to distinguish between amorphous and crystalline products.

## 2. SPECIMEN PREPARATION AND EXPERIMENTAL TECHNIQUES

For this work tricalcium aluminate ( $C_3A$ ) was prepared from calcium carbonate and Linde, A alumina and fired to  $1400^\circ\text{C}$  for several hours. The Portland cement used was an ordinary Portland cement (OPC), details given below :

	CaO	SiO <sub>2</sub>	Al <sub>2</sub> O <sub>3</sub>	SO <sub>3</sub>	Fe <sub>2</sub> O <sub>3</sub>	MgO	(Na <sub>2</sub> O+K <sub>2</sub> O)Free	Lime
OPC	63.90	19.70	7.00	3.00	2.10	1.3	0.77	1.3

Calculated (Bogue) percentage compounds:

	$C_3S$	$C_2S$	$C_3A$	$C_4AF$
OPC	46.5	21.4	15.0	6.4

Specimens for examination in the electron microscope were prepared by coating electron microscope grids with a formvar film. Droplets of the required cement/water mix were pipetted onto these grids which were positioned on a glass microscope slide and then contained by a coverslip after removal of air bubbles. The system was then sealed with a quick-setting epoxy resin. After hydration the seal was broken and the electron microscope grid transferred to a carbon coating vacuum unit and a thin layer of carbon deposited to stabilise the grid for electron microscopy. Specimens of  $C_3A$  and  $C_3A$  + gypsum were prepared in a similar manner except that for the latter, the materials were ground together before water was added. In all of these experiments the water/cement mix ratio was approximately 0.3.

All specimens were examined in a JEOL 200CX electron microscope. An operating voltage of 100kV was normally used and all specimens were examined

in transmission electron microscopy for morphological and electron diffraction studies. In addition to TEM, specimens were always examined in SEM to check the region of interest was on the upper surface of the support film. If the hydration product was on the lower surface, the elemental ratio could be distorted due to absorption of x-rays within the support film. X-ray microanalysis was always performed at low beam current to minimise beam damage to the specimen. It was found, that although the counting statistics were obviously improved at higher beam currents, there was migration of elements along the fibre and the fibre was damaged.

## 3. RESULTS

A striking example of the fibrillar hydration products observed in Portland cement is shown in Figure 1. The prominent large fibres which have extruded reaction products at their ends are the hollow type II, reported previously (1).

FIGURE 1: OPC Hydrated for 24 Hours

An elemental analysis of the fibres themselves show that they are predominantly calcium aluminate sulphate in composition and the extruded product contains largely calcium, see table 1. Selected area electron diffraction from these areas give only very diffuse rings, indicating an amorphous nature.

In order to investigate further the origin of these tubular growths, a study has been initiated of the hydration of tricalcium aluminate and the effect of gypsum and lime on its hydration behaviour. The hydration products obtained for  $C_3A$  are shown in Figure 2. Hexagonal platelets and related structures are observed dispersed randomly and not specifically related to any interface i.e.  $C_3A$  surface. Furthermore, the precipitates are crystalline. X-ray microanalysis of these precipitates gives an average Ca/Al ratio of  $\sim 3$  (see table 1).

Table 1

TYPE OF HYDRATE	ELEMENTAL RATIOS	
	Ca/S	Ca/Al
CASH in OPC	2.58±0.95	2.59±0.65
EXTRUSION PRODUCT IN OPC	22.2	24.6
CAH in C <sub>3</sub> A		3.19±0.59
CASH in C <sub>3</sub> A/C $\bar{S}$	1.97±0.82	2.84±1.21

\*Typical  
valueFIGURE 2: C<sub>3</sub>A Hydrated for 30 Hours

When C<sub>3</sub>A is hydrated in the presence of small amounts of gypsum i.e. a molar ratio of 1.5, two types of precipitate are observed remote from the C<sub>3</sub>A interface. The two forms of precipitate can be seen in Figure 3. The precipitates at A are crystalline calcium aluminate hydrates as confirmed by elemental analysis (see table 1) and electron diffraction. The precipitates at B were found to be calcium aluminate sulphate and electron diffraction showed them to be crystalline. Figure 4 shows the result of increasing the gypsum content further, the molar ratio being 1. In this case two forms of calcium aluminate sulphate were observed. The interfacial fibrous growths at C were shown to be similar in composition to the type II fibres observed in ordinary Portland cement (OPC). Electron diffraction confirmed that these fibres were amorphous in nature. Once again, the fibres remote from the interface were found to be crystalline and of approximately ettringite composition.

FIGURE 3: C<sub>3</sub>A/C $\bar{S}$  = 1.5 Hydrated for 43 HoursFIGURE 4: C<sub>3</sub>A/C $\bar{S}$  = 1 Hydrated for 3½ Hours

#### 4. DISCUSSION

As reported previously, (1) the observation of amorphous tubular filaments of calcium aluminate sulphate composition in Portland cement leads to the suggestion that amorphous films of CASH form at C<sub>3</sub>A surfaces and that these are ruptured by osmotic swelling to produce the tubular filaments. Lea (2), when reviewing explanations of the effects of gypsum on the set of Portland cement suggested such a mechanism by analogy with Power's (3) osmotic pressure model for calcium silicate hydration although in neither case was the formation of tubular filaments proposed. The attractiveness of the membrane precipitation/osmosis model has recently been emphasised by Birchall, Howard and Double (4) and the lack of direct evidence of crystalline ettringite at the C<sub>3</sub>A surface does not favour models based on the rupturing of crystalline platelets at that surface and indeed these latter theories do not explain the tubular fibrous growths observed. Skalny and Young (5) in their review of C<sub>3</sub>A hydration come to somewhat similar conclusions, commenting that the

evidence indicates that after initial hydrolysis, a CASH gel forms which causes retardation. The osmosis model merely suggests that the gel is ruptured by osmotic pressure to form the observed tubular filaments and possibly other crumpled shapes although direct evidence of the latter have not been observed to date.

In order to study the reactions between  $C_3A$  and  $CS$  we are examining more closely the nature of the precipitated hydration products. As seen in Figure 2, the transmission electron micrographs of hydrated  $C_3A$  show an abundance of precipitates remote from  $C_3A$  surfaces, favouring a "through solution" precipitation mechanism. There is no evidence in these studies to date of nucleation of aluminate hydrates at a  $C_3A$  surface but combined transmission and scanning electron microscopy may provide further information. The elemental analysis was carried out on an area containing a number of individual precipitates and the observed calcium/aluminium ratio of 3 is an average. These precipitates appear hexagonal in nature and the average may result from the presence of the two hexagonal hydrates referred to in the literature, i.e.  $C_4AH_{13}$  and  $C_2AH_8$ . Further work will be required to determine whether this interpretation is correct or whether in fact conversion to  $C_3AH_6$  has occurred.

At  $C_3A/CS$  molar ratios of 1.5 which may be comparable to those found in Portland cement, both crystalline calcium aluminate hydrates and crystalline calcium aluminate sulphate hydrates have been observed remote from  $C_3A$  surfaces, see Figure 3. It seems reasonable to conclude that in this case also the crystalline calcium aluminate sulphate precipitates have resulted from a "through solution" precipitation mechanism but clearly more detailed work is required.

A small increase in gypsum content, i.e.  $C_3A/CS = 1$  leads to the observation of two types of calcium aluminate sulphate precipitates suggesting a change in precipitation mechanism and the interesting observation of the simultaneous precipitation of both the amorphous and crystalline CASH compositions, one interfacial and one apparently precipitated from solution, would suggest competing mechanisms.

One important conclusion from these observations is that the analytical electron microscopy technique is able to quite clearly distinguish between amorphous and crystalline forms of these aluminate sulphate hydrates and we have independently demonstrated this by preparing crystalline ettringite by adding calcium sulphate to a solution of sodium aluminate. When examined in the electron microscope this material was crystalline. These observations will be reported elsewhere. It is premature to speculate in detail on the chemical reactions and processes involved until more detailed observations have been made but it would seem from these earlier results that competing mechanisms may be operating in determining the structure and form of the resulting calcium aluminate sulphate hydrates.

## 5. CONCLUSIONS

It is concluded from these preliminary results that :

- (1) The analytical electron microscopy of samples hydrated "in situ" on electron microscope grids is capable of revealing detailed information on the elemental composition, structure and form of the precipitating hydrates in these hydraulic cements.
- (2) In Portland cements an amorphous form of calcium aluminate sulphate hydrate precipitates at  $C_3A$  surfaces and in part this is tubular in form providing strong support for membrane precipitation/osmosis models of hydration.
- (3) The experiments reported on  $C_3A$  hydration in the presence of calcium sulphate clearly show that two forms of CASH are observed; one crystalline and one amorphous, which leads to the view that there may be competing mechanisms i.e. membrane precipitation vs "through solution" precipitation, depending upon the chemical and environmental conditions.
- (4) The observations on  $C_3A$  hydration may explain why both amorphous and crystalline ettringite have been observed in Portland cement.

## POSTER

### Fibrous growth products in the hydration of portland cement and related systems

#### *Produits de croissance en fibres dans l'hydratation du ciment portland et des systèmes correspondants*

A. GHOSE, H.M. JENNINGS, P.L. PRATT and P. BARNES - London, England.

#### ABSTRACT :

Microscopic observations of hollow fibres in cement hydration lends credence to the idea of osmotic driving forces being responsible for such growths. However, the present results indicate that these fibrous growths are intimately associated with the hydration of the aluminate phases rather than the silicates whose hydration mechanism is different.

#### RESUME :

Les observations microscopiques de fibres creuses, dans l'hydratation du ciment, confortent l'idée des forces de pression osmotique responsables de telles croissances. Cependant, les résultats présents indiquent que ces croissances en fibres sont intimement associées à l'hydratation des phases aluminates plutôt que des silicates dont le mécanisme d'hydratation est différent.

# FIBROUS GROWTH PRODUCTS IN THE HYDRATION OF PORTLAND CEMENT AND RELATED SYSTEMS

A. Ghose, H.M. Jennings and P.L. Pratt,

Department of Metallurgy and Materials Science,  
Imperial College, London, SW7, England

and

P. Barnes,

Department of Crystallography, Birkbeck College,  
London, WC1, England.

The observation of hollow tubular growths in cement pastes by Double et al (1) has aroused much interest recently. In their work, hydration was studied "in situ" in a wet cell of a high voltage (1 MeV) microscope using a very high water to cement ratio (about 10:1) though tubular growths have also been observed (2-4) in more realistic cement pastes. A "reverse silica garden" osmotic pump model has been envisaged by Double et al (1) to account for such tubular growths.

The present note reports on the electron-optical investigations of three systems - ordinary Portland cement (O.P.C.), synthetic  $C_3S$  and synthetic  $C_2A$  in presence of gypsum - undertaken in an effort to pinpoint the origin of hollow cement tubes. The results are summarised below:

## 1. O.P.C.

Hydration in this system (w/c between 0.5 to 0.7) points to the presence of both hollow and solid fibres (Figures 1-2) after about 4 hours. Many of the hollow fibres exhibited evidence of a past or present internal liquid meniscus (or multiple menisci on occasions - Figure 2) with liquid turbulence being induced inside on concentration of the electron beam. The skeletal morphology of some of the fibres in Figure 1 is a result of beam and vacuum damage in the TEM. Microanalysis of these fibres (both solid and hollow) revealed the presence chiefly of Ca, Al and S in variable proportions with K, Si and Fe being occasionally present (Table 1). These fibres thus appear to be far closer in composition to Aft rather than C-S-H as required by the "reverse silica garden" model. Outgrowths of C-S-H were however observed with a crumpled foil morphology (Figure 3) which in places rolled up to give the appearance of fibrillar growths. The more squat and solid rod-like growths in this micrograph are Aft and they appear like fibre bundles.

## 2. Synthetic $C_3S$

Hollow tubular growths have never been seen in this system in our observations. C-S-H fibrillar growths have been observed as with O.P.C. but they do not appear to be hollow (Figure 4). Microanalysis revealed the presence of Ca and Si only in widely varying proportions (Table 1).

Figure 1

Figure 2  
TEM micrographs of O.P.C. hydrated for 1 day at w/c 0.6 illustrating both hollow and solid fibrillar Aft growths.

Figure 3. TEM micrograph of O.P.C. hydrated for 5 days at w/c 0.5 illustrating Aft and C-S-H growths.

Figure 4. TEM micrograph of synthetic  $C_3S$  hydrated for 1 day at w/c 0.6 illustrating the crumpled foil-fibrillar C-S-H morphology.

### 3. Synthetic $C_3A$ + 20% Gypsum

Hollow and solid fibres (composition close to Aft as revealed by microanalysis - Table 1) were visible in this system after 15 minutes of hydration (Figures 5 and 6). These fibres are morphologically similar to those observed in the hydration of O.P.C.

Our results thus indicate that hollow fibrillar growths is intimately associated with the hydration of the aluminate phase (in conjunction with gypsum) rather than with the silicates as required by the "reverse silica garden" model and that the hydration mechanism of the silicates in fact differs from this. However the concept of osmotic driving forces being responsible for hollow tubular growths appears to account for the presence of hollow Aft fibres. The presence of both hollow and solid Aft fibres is indicative of a combined "through solution" and "topochemical" growth (5), with a topochemically formed layer of ettringite on the aluminate grains possibly acting as the semi-permeable membrane in the osmotic growths.

The ranges of atomic composition quoted are overall ranges for each atomic species and normalised to 6 Ca atoms.  
Details concerning specific compositions are given elsewhere (5).

## POSTER

### Possibility of a catalytic role of $C_3A$ in the hardening of portland cements

#### *Possibilité d'un rôle catalytique de $C_3A$ dans le durcissement des ciments portland*

Sandor POPOVICS, Professor, Department of Civil Engineering,  
Drexel University, Philadelphia, Pennsylvania 19104 U.S.A.

#### SUMMARY :

This paper demonstrates that there is an interaction between the calcium silicates and the  $C_3A$  in portland cements. It also shows that the effect of  $C_3A$  on the strength development of portland cement mortars and concretes can be calculated as if the  $C_3A$  acted as catalyst on the calcium silicates. Finally, a quantitative form is proved for the fact widely known in the qualitative form that high  $C_3A$  content accelerates the strength development at early ages but hinders it later.

#### RESUME :

Cet article démontre qu'il y a une interaction entre les silicates de calcium et le  $C_3A$  dans les ciments portland. Il montre aussi que l'effet de  $C_3A$  sur le développement des résistances des mortiers et bétons peut être calculé comme si  $C_3A$  jouait le rôle d'un catalyseur sur les silicates de calcium. Enfin, une forme quantitative est donnée à la forme qualitative bien connue d'après laquelle une haute teneur en  $C_3A$  accélère le développement de la résistance aux brèves échéances mais le gêne plus tard.

## Is There Interaction Between the Calcium Silicates and $C_3A$ ?

When the first attempts were made for the development of a numerical relationship between the strength development of a portland cement and its compound composition (1)-(3), it was a natural assumption that the main constituents contribute their intrinsic strengths without any interaction between each other. This means mathematically that the pertinent formulas are linear creating a linear cement model. It has become obvious later, however, that experimental data do not support adequately either the original linear cement model or its linear modifications, as discussed in details elsewhere in the Proceedings of this Congress. (4) For instance, Figure 1 shows that the effect of the  $C_3A$  content on the strength development in a portland cement mortar is much stronger than proportional. Furthermore, Figure 2 demonstrates that the effect of the  $C_3A$  content on the ultimate compressive strength, that is, on the strength obtained after very long wet curing, depends also on the  $C_3S$  content. This is again a clear indication of an interaction between these two compounds. In addition, an increasing amount of other evidence has been reported that the hydration processes of the calcium silicates are interacted by the  $C_3A$ . (9)-(17)

In the light of all this unambiguous evidence, this writer believes that the real question is not any more whether there is interaction between the calcium silicates and aluminate but rather (a) what is the nature of this interaction; and (b) how can one estimate quantitatively the effect of this

interaction on the strength development of a portland cement. One would expect that research would answer first the (a) portion of this question and then develop a method for the estimation of its effect; however, it did not happen in this order. While there is no generally accepted view yet concerning the nature of interaction between the calcium silicates and  $C_3A$ , the effect of  $C_3A$  on the strength development of portland cement, essentially calcium silicates, can be calculated quite well with the exponential cement model.

## The Exponential Cement Model

The exponential cement model, probably the first non-linear cement model for the representation of hardening, was introduced in 1967. (5) (6) The mathematical form of this model provides a relationship between the strength developing capability of a portland cement and its simplified compound composition, as follows:

$$f_{rel} = 100 \frac{1 - pe^{-a_1 t} - (1-p)e^{-a_2 t}}{1 - pe^{-28a_1} - (1-p)e^{-28a_2}} \quad (1)$$

where

$f_{rel}$  = relative strength of portland cement paste, mortar, or concrete, percent of the 28-day strength,

$t$  = age of the specimen at testing, days,

$p$  = computed  $C_3S$  content of the portland cement, percent/100,

Figure 1 Comparison of experimental and computed values to illustrate the effect of  $C_3A$  content on the kinetics of the hardening of portland cement in 1:2.75 mortars. Experimental values are represented by points, and values calculated by Eq. (1) with  $a_1 = 0.0067C_3A + 0.10$  and  $a_2 = 0.0018C_3A + 0.005$ , by lines (5) (6)

Figure 2 Final relative compressive strength of portland cements in mortars as a function of the compound composition (7) (8)

$a_1$  and  $a_2$  = rate parameters of the two hardening components which are independent of the strength, age, and  $C_3S$  content, but may be a function of the  $C_3A$  content, and any other factor that influences the course of hydration (fineness, gypsum content, admixtures, water-cement ratio, temperature, curing and testing methods, etc.), 1/day.

Equation 1) was obtained from the following conditions:

(a) The model consists only of two hardening components; the first component is the  $C_3S$ , the second component is a mixture of the other cement ingredients, mainly  $C_2S$ .

(b) These two components hydrate simultaneously as first order reactions with differing rates but without any interaction with each other.

(c) The final strength developed by  $C_3S$  is the same as the final strength of the second component.

The proportionality factors, which are the  $a$  parameters in Equation 1), represent the specific rates of hardening, that is, (rate of hardening)/(remaining strength at a given age). The squares of these parameters represent specific decelerations of hardening. The more intensive the early hardening process, the greater is the value of  $a_1$ ; and the longer and larger is the hardening after 28 days, the smaller becomes the value of  $a_2$  up to a certain limit.

For the sake of simplicity, the model does not take into consideration directly the effect of diffusion on the strength development.

Numerically, the  $a$  parameters can be obtained by applying a suitable statistical method to pertinent experimental data. For instance, by applying Equation 1) to the previously mentioned test results by Gonnerman (3), the following  $a_1$  and  $a_2$  values were obtained for the compressive strength of 1: 2.75 Ottawa sand mortars with wet curing:

$$a_1 = 0.0067C_3A + 0.10 \quad 2)$$

and

$$a_2 = 0.0018C_3A + 0.005 \quad 3)$$

where  $C_3A$  represents the percent of the potential tricalcium aluminate in the portland cement computed according to the Bogue method.

The application of the presented formulas will be illustrated below.

#### Example

The compositions of three of Gonnerman's cements are shown in Figure 1. The computed  $C_3S$  contents of all three cements are practically the same but the  $C_3A$  contents differ.

Illustrate the effect of  $C_3A$  content on the relative strength development at various ages by using Eq. 1) along with

Eqs. 2) and 3).

The  $a$  parameters of cement No. 24 are calculated by Equations 2) and 3):

$$a_1 = 0.14 \quad \text{and} \quad a_2 = 0.018$$

By substituting these values into Eq. 1) the following is obtained:

$$f_{rel,24} = 100 \frac{1 - 0.41e^{-0.14t} - 0.59e^{-0.018t}}{1 - 0.41e^{-3.92} - 0.59e^{-0.50}} = 100(1.58 - 0.65e^{-0.14t} - 0.93e^{-0.018t})$$

Similarly, the equations of the curves for relative compressive strength versus age for the cements Nos. 1 and 7, respectively, are

$$f_{rel,1} = 100 (1.25 - 0.54e^{-0.22t} - 0.71e^{-0.037t}),$$

and

$$f_{rel,7} = 100 (2.12 - 0.89e^{-0.10t} - 1.23e^{-0.005t})$$

A group of values calculated by these formulas are presented in Figure 1 by lines along with observed results by points from Gonnerman's experiments.

Note that (a) the  $a_1$  and  $a_2$  values of these three cements are affected strongly by the  $C_3A$  content in these formulas; and (b) the fit in Figure 1 between experimental and calculated strengths is good, that is, the exponential model reflects the non-linear effect of  $C_3A$  on the strength development quite accurately from the age of one day to two years.

Equation 1) can also be used for the estimation of the ultimate strength, that is, the strength obtained after very long wet curing, expressed as a percentage of the 28-day strength. This equation takes on the following form for great  $t$  values (7) (18):

$$f_{rel}^{\infty} = \frac{100}{1 - pe^{-28a_1} - (1 - p)e^{-28a_2}} \approx \quad 4)$$

$$\approx \frac{100}{0.98 - (1 - p)e^{-28a_2}} \quad 5)$$

where  $f_{rel}^{\infty}$  = relative ultimate strength, percent of the 28-day strength. The other symbols are the same as the symbols of Eq. 1).

As another numerical illustration for the reliability of the exponential model, Figure 2 presents also the calculated relationship between the compound composition of portland cement and the relative ultimate compressive strength. Points represent experimental values reported by Gonnerman (3) for cements of approximately 40 and 60 percent  $C_3S$  contents, respectively, with constant (1.8%)  $SO_3$  content, and the same fineness (1440  $cm^2/g$  by air permeability). The lines designate

values that were calculated from Eq. 5) for 40 and 60 percent  $C_3S$  contents, respectively, with the  $a_2$  value of Eq. 3). Considering the satisfactory goodness of fit in Figure 2, one may say that Eqs. 1) and 3) not only provide numerically the detrimental effect of the higher  $C_3A$  content on the ultimate strength but also show that this effect depends simultaneously on the  $C_3S$  content.

Incidentally, a cement model based on the dimensionless relative strength is more suitable for the exploration of the roles of the cement compounds in hardening than one based on actual strength, that is, strength expressed, say, in MPa. This is so because the interfering effects of factors other than the compound composition, such as the conditions of clinking of the cement, cooling, etc. on the strength development are considerably reduced by the ratio-structure of the model. Note also that  $f_{rel}$  is what can be called the "age factor", that is, its product with the actual 28-day strength provides the strength at any  $t$  age.

It can be seen from the evidence presented here and elsewhere (5)(6)(19)(20) that the interaction between the calcium silicates and the  $C_3A$  is represented quite well numerically by the  $a$  factors as exponents in Eq. 1). Even more important, however, is that the formula reveals the nature of this interaction in the cement model, as shown below.

#### $C_3A$ as Catalyst

As has been shown in Eqs. 2) and 3), the general forms obtained for the two  $a$  factors for Eq. 1) were found to be linear

$$a = k + m(C_3A) \quad (6)$$

where

$k$  and  $m$  = parameters which are independent of the strength,  $C_3S$  and  $C_3A$  contents, and age but may be a function of other factors that influence the strength and hydration,

$C_3A$  = computed tricalcium aluminate content of the portland cement, percent.

In certain cases  $k$  or  $m$  can be negligibly small; but when  $m$  is greater than zero, that is, when the  $a$  factor contains the  $C_3A$  term, this means according to the theory of first-order reactions that the  $C_3A$  acts as a catalyst on the  $C_3S$  and/or on the second component of the portland cement model the majority of which is  $C_2S$ . In other words, the paste of this cement model hardens as if the  $C_3A$  acted on the calcium silicates as a catalyst. (21)

Experimental results discussed above support the applicability of the exponential model within wide limits, which is unlikely to have happened to such extent without a similarity between the hardening process represented by the model and the actual process. Therefore, it may be instructive to summarize what this cement model has to say about the role of  $C_3A$  in the hardening process of portland cement.

The strength of a portland cement paste comes from the hardening of two, more or

less, hypothetical components, namely the calculated  $C_3S$ , and the rest of the cement which is essentially  $C_2S$ .

These two components hydrate simultaneously in the model as first-order reactions, the  $C_3A$  acting as catalyst on both components. This means that either the  $C_3A$  does act, in reality, as a catalyst on the calcium silicates during hydration, or that the complex role of  $C_3A$ , for instance the one advanced by Hansen (9), can be approximated statistically on the basis as if the  $C_3A$  acted as such a catalyst.

Each component has a rate of hardening:  $a_1$  for the  $C_3S$  and  $a_2$  for the second component. These are predetermined by the  $C_3A$  content and fineness of the cement as well as by the composition of the strength specimen, and the curing and testing conditions.

The values of  $a_1$  for different portland cements are about seven to ten times higher than those for  $a_2$  within the usual range of  $C_3A$  content.

The squares of the  $a$  parameters represent the specific decelerations of hardening of the components, that is, (deceleration of hardening)/(remaining strength development), at a given age. (22) Consequently, the specific rate of hardening is a linear function, and the specific deceleration of hardening is a quadratic function of the  $C_3A$  content with a reasonable degree of approximation. In other words, an increase in the  $C_3A$  content increases the early strength through an increased specific rate of hardening, but, simultaneously, it increases the deceleration of the hardening quadratically, thus the final strength will be less.

Note that the possibility of fundamental similarities between the hypothetical hardening process of the exponential cement model and the actual hardening process of a portland cement can help cement chemists to aim their research at new, promising goals, such as to establish directly the role of  $C_3A$  in the cement hydration and hardening by focusing the investigation to its possible catalytic action.

#### Conclusion

On the basis of the available experimental evidence it is safe to say that there is interaction between the  $C_3A$  and the calcium silicates in a portland cement. The effect of this interaction on the strength development can be estimated by the exponential cement model. Whether the interaction is catalytic as in the model, or some other process the effect of which can be approximated by the assumption of catalytic action is still a question the answer for which is left for future research. In any case, the interaction casts doubts to efforts where experience obtained with the hydration or hardening of pure  $C_3S$  or  $C_2S$  is attempted to be transferred to portland cement.

## POSTER

### Hydratation de l'aluminate tricalcique dopé à l'oxyde de sodium *Hydration of tricalcium aluminate doped by sodium oxide*

N. BILANDA, P. FIERENS, J. TIRLOCQ, Université de Mons,  
et N. TENOUTASSE, Université Libre de Bruxelles, Belgique.

RESUME : Des échantillons d'aluminate tricalcique pur et d'aluminates tricalciques dopés par  $\text{Na}_2\text{O}$ , à des teneurs variables, ont été synthétisés et caractérisés.

L'hydratation de ces échantillons a été suivie par les techniques ci-après : diffraction des RX, microcalorimétrie isotherme, analyse de la phase aqueuse et thermogravimétrie.

En absence de gypse la vitesse d'hydratation est de plus en plus réduite au fur et à mesure que la teneur en  $\text{Na}_2\text{O}$  augmente. Par contre, en présence de gypse une séquence inverse est observée.

Dès que la concentration en ions sodium s'élève dans la phase aqueuse, on assiste à la consommation quasi instantanée du gypse et à la formation simultanée de tous les composés hydratés.

Pour les échantillons fortement dopés, la production d'ettringite est inhibée par la carence en ions calcium. Ces résultats montrent l'importance de la composition de la phase aqueuse sur la cinétique de l'hydratation de l'aluminate tricalcique dopé au  $\text{Na}_2\text{O}$ .

SUMMARY : Different samples of pure and  $\text{Na}_2\text{O}$  doped tricalcium aluminate have been synthesized and characterized.

Their hydration has been followed by several techniques : XR diffraction, isothermal microcalorimetry, aqueous phase analysis and thermogravimetry.

Hydration rate, without gypsum, decreases when  $\text{Na}_2\text{O}$  concentration increases. On the other hand, in hydration with gypsum, a reverse behaviour is observed.

When  $\text{Na}^+$  ions amount increases in the aqueous phase, gypsum vanishes immediately and the different hydrates appear at the same time.

In the highest doped  $\text{C}_3\text{A}$  hydration, ettringite grow is inhibited because of a lack of calcium ions.

Our results show that the aqueous phase composition is an important factor which governs the rate of hydration of  $\text{C}_3\text{A}$  doped by  $\text{Na}_2\text{O}$ .

## 1. Introduction

Le présent travail a pour but d'examiner systématiquement l'effet du  $\text{Na}_2\text{O}$  sur l'hydratation de l'aluminate tricalcique ; dans le présent article, le sodium se trouve incorporé sous forme de solution solide dans l'aluminate tricalcique.

Des travaux antérieurs effectués par Regourd (1), Butt (2), Spiering (3), Boikova (4), Collepardi (5), et autres ne semblent pas aboutir à des conclusions unanimement acceptées quant à l'effet du sodium sur l'hydratation de l'aluminate tricalcique.

Dans cette étude, nous avons fait appel aux techniques ci-après :

- la Diffraction des RX, la Thermogravimétrie Différentielle (TGD), la Microcalorimétrie et l'analyse de la phase liquide par Absorption atomique et par Néphélométrie.

L'effet du  $\text{Na}_2\text{O}$  sera examiné, lors des hydratations, en eau pure ou après addition de gypse (20 % en poids de  $\text{C}_3\text{A}$ ).

## 2. Résultats expérimentaux

### 2.1. Synthèse et caractérisation des produits anhydres.

La synthèse de l'aluminate tricalcique pur par la technique classique n'a pas posé de problème (6,7).

Par contre, celle des échantillons dopés à l'oxyde de sodium, sans formation de chaux libre en excès a été peu aisée, d'abord à cause de la volatilité de l'oxyde alcalin observée déjà à  $650^\circ\text{C}$ , ensuite à cause de la présence de traces de  $\text{C}_{12}\text{A}_7$  résultant de l'hétérogénéité subséquente du système synthétisé (8).

Trois échantillons d'aluminate tricalcique dopés à l'oxyde de sodium ont été synthétisés à  $1350^\circ\text{C}$  avec des teneurs variables en  $\text{Na}_2\text{O}$  :

(I) 1,2 % ; (II) 4,6 % et (III) 5,8 %.

La teneur en sodium, après la synthèse, a été dosée par spectrométrie d'absorption atomique. La chaux libre a été mesurée par la méthode de Franke (9), et la surface spécifique de nos échantillons broyés, déterminée par la méthode de BET (10).

La surface spécifique du gypse, finement broyé, a également été mesurée et vaut  $0,7 \text{ m}^2/\text{g}$ .

La variété allotropique de chaque échantillon de  $\text{C}_3\text{A}$  a été déterminée par diffraction des RX au laboratoire du C.E.R.I.L.H. (M. Regourd).

Les caractéristiques des échantillons sont résumées au tableau suivant :

Produits	%CaO libre	% $\text{Na}_2\text{O}$ dans le réseau	Surface Spécif. $\text{m}^2/\text{g}$ .	Variété allotropique
$\text{C}_3\text{A}$ pur	0,30	0	0,30	Cubique
$\text{C}_3\text{A}$ dopé I	0,13	1,2	0,24	Cubique
$\text{C}_3\text{A}$ dopé II	0,15	4,6	0,41	Orthorhomb. I
$\text{C}_3\text{A}$ dopé III	0,13	5,8	0,48	Orthorhomb.

### 2.2. Cinétique d'hydratation de $\text{C}_3\text{A}$ sans gypse

L'effet du sodium sur l'hydratation de  $\text{C}_3\text{A}$ , dans l'eau distillée, a été suivi à  $25^\circ\text{C}$  avec un rapport Eau/Solide = 1, par TGD et par DRX. (Diffraction des RX) (6,7).

Dans tous les cas examinés, l'hydrate cubique ( $\text{C}_3\text{AH}_6$ ) est présent dès la première minute d'hydratation et son pic de TGD qui apparaît aux environs de  $300^\circ\text{C}$  (11) croît en fonction du temps d'hydratation. Les hydrates hexagonaux instables, bien visibles dès le début de l'hydratation, disparaissent progressivement au cours des trois premières heures, dans le cas de l'hydratation du  $\text{C}_3\text{A}$  pur.

Mais, dans celui des échantillons dopés, la présence des hydrates hexagonaux est permanente et simultanée à celle de  $\text{C}_3\text{AH}_6$  durant les périodes d'hydratation examinées.

De plus, nous avons observé que le spectre DRX du produit hydraté obtenu à partir du  $\text{C}_3\text{A}$  pur ne montre pas la présence de  $\text{Ca}(\text{OH})_2$ , tandis que cet hydroxyde est toujours présent dans les hydrates des échantillons dopés dès les premiers instants d'hydratation.

A partir de la stoechiométrie de formation de  $\text{C}_3\text{AH}_6$ , on peut définir un degré d'avancement  $\alpha$  de la réaction et dresser les courbes cinétiques reprises à la figure 1.

Fig. 1 - Cinétique d'hydratation de  $\text{C}_3\text{A}$  par TGD.

On constate que la cinétique d'hydratation de l'aluminate tricalcique décroît à mesure que la teneur en sodium incorporé dans le réseau augmente ; ce qui conduit à la séquence suivante (3) :

$\text{C}_3\text{A}$  pur >  $\text{C}_3\text{A}$  dopé I >  $\text{C}_3\text{A}$  dopé II =  $\text{C}_3\text{A}$  dopé III.

Par DRX, nous avons suivi la décroissance de l'intensité de la raie principale à  $d = 2,700 \text{ \AA}$  du  $\text{C}_3\text{A}$  en fonction du temps d'hydratation.

Des courbes cinétiques, représentées à la figure 2 ont été établies, dans chaque cas, grâce à une courbe d'étalonnage construite à partir de mélanges  $\text{C}_3\text{A}-\text{C}_3\text{AH}_6$ .

Le processus d'hydratation de nos systèmes obéit au modèle de mécanisme réactionnel par diffusion

Fig. 2 - Cinétique d'hydratation de  $C_3A$  par DRX.

de Jander (12), qui répond à l'équation suivante :

$$D_3(\alpha) = (1 - \sqrt{1-\alpha})^2 = kt$$

$\alpha$  = degré d'avancement de la réaction.

$k$  = constante cinétique de la réaction.

$t$  = temps d'hydratation.

Les graphiques sont illustrés à la figure 3 et les constantes cinétiques au tableau II.

Fig. 3 - Modèle cinétique.

Tableau II : Constantes cinétiques				
Réaction d'hydratation de :	$C_3A$ pur	$C_3A$ dopé I	$C_3A$ dopé II	$C_3A$ dopé III
Constante cinétique ( $\text{min}^{-1}$ )	$6,5 \cdot 10^{-5}$	$1,8 \cdot 10^{-5}$	$1 \cdot 10^{-5}$	$3,6 \cdot 10^{-6}$

Au bout de quelques minutes d'hydratation, tous les échantillons obéissent à la loi de diffusion de Jander (12).

De plus, le  $C_3A$  pur plus réactif, atteint rapidement un degré d'avancement tel qu'il apparaît une diminution de la constante cinétique ; les échantillons dopés ne présentent pas cette particularité

pendant la période d'hydratation étudiée.

D'après Spiering et Breval, la présence de la soude dans le milieu réactionnel favoriserait la formation d'un double hydroxyde aluminocalcique (3) et d'un gel amorphe (13) qui emprisonnerait la solution périphérique dans une enveloppe pseudo-imperméable, dont la consistance croîtrait en fonction de la teneur en soude du milieu.

### 2.3. Cinétique d'hydratation des $C_3A$ en présence de gypse

L'hydratation de l'aluminate tricalcique pur et dopé, en présence de gypse, a été suivie par microcalorimétrie à conduction, à  $25^\circ\text{C}$ , avec un rapport Eau/Solide = 2.

Une étude parallèle de l'hydratation a été réalisée en discontinu, par filtration de la phase liquide après différents temps d'hydratation.

En microcalorimétrie, l'hydratation de  $C_3A$  avec 20 % de gypse a donné le résultat classique qui consiste en deux phénomènes exothermiques dont l'un se situe dans les deux premières minutes et l'autre après 30 heures (14,15,16,17).

Par contre, l'hydratation des phases dopées en présence du gypse subit une importante accélération du déroulement des différentes étapes calorimétriques. En effet, l'intervalle de temps entre les émissions exothermiques se réduit très nettement jusqu'à disparaître pour les fortes teneurs en sodium. Les différentes courbes calorimétriques sont représentées à la figure 4.

Fig. 4 - Microcalorimétrie de  $C_3A$ .

Au tableau III sont consignés les intervalles de temps observés pour chaque hydratation.

Tableau III : Intervalles de temps				
Réactifs	$C_3A$ pur	$C_3A$ dopé I	$C_3A$ dopé II	$C_3A$ dopé III
% $\text{Na}_2\text{O}$	0	1,2	4,6	5,8
Intervalle de temps entre les 2 pics calorim.	30 h.	1h30 min	0	2 h.

Lors des analyses de la phase aqueuse, les hydratations ont été arrêtées après différents temps correspondants aux changements d'allure des courbes calorimétriques.

Les éléments Ca, Na, Al de la phase liquide ont été dosés par absorption atomique, les ions sulfates  $\text{SO}_4^{2-}$  par néphélométrie. Les résultats obtenus sont portés en graphique dans les figures 5, 6, 7 et 8.

Fig. 5 - Analyse de la phase aqueuse.

Fig. 6 - Analyse de la phase aqueuse.

Fig. 7 :

Analyse de la phase aqueuse.

Fig. 8 - Analyse de la phase aqueuse.

Le résidu solide de la filtration, immédiatement lavé à l'acétone et séché, est soumis à l'analyse DRX. Un résultat qualitatif a été obtenu pour l'apparition des hydrates.

Le  $\text{C}_3\text{A}$  qui n'a pas réagi, a été dosé quantitativement. Un degré d'avancement de la réaction par la consommation de  $\text{C}_3\text{A}$  a été calculé à partir d'une courbe d'étalonnage établie sur base de mélange  $\text{C}_3\text{A}$ -Ettringite (figure 9).

Fig. 9 - Cinétique d'hydratation des  $\text{C}_3\text{A}$  + gypse par DRX.

#### Discussion des résultats expérimentaux

L'effet du sodium sur l'hydratation de l'aluminate tricalcique en présence de gypse est bien marqué.

L'hydratation est fortement accélérée dès que la teneur en sodium augmente dans la phase aqueuse ; cependant, lorsque la concentration en  $\text{Na}_2\text{O}$  dans l'aluminate tricalcique atteint environ 5%, on observe une certaine diminution de l'effet du dopant.

Les courbes obtenues par analyse des phases aqueuses ainsi que la cinétique de consommation de l'aluminate tricalcique complètent bien les données microcalorimétriques.

En effet, lors de l'hydratation de l'aluminate tricalcique pur, en présence du gypse, on observe une concentration constante en ions  $\text{SO}_4^{2-}$  (10 mM/l) pendant la formation de l'ettringite ; on remarque

ensuite une diminution rapide de la concentration en ions  $\text{SO}_4^{=}$  accompagnée de l'apparition du monosulfoaluminate après 6 heures d'hydratation (Fig. 5).

La transformation ettringite-monosulfoaluminate se déroule entre la 6<sup>e</sup> et la 24<sup>e</sup> heure d'hydratation. Après ce délai on n'observe plus la présence du gypse par D.R.X. Apparaissent alors le  $\text{C}_3\text{AH}_6$  et les hydrates hexagonaux comme le montrent les spectres RX ainsi que le deuxième pic calorimétrique (Fig. 4).

Dans l'hydratation de l'aluminate tricalcique faiblement dopé (1,2 %  $\text{Na}_2\text{O}$ ) la concentration maximale en ions  $\text{SO}_4^{=}$  est plus élevée (24,5 mM/l) et atteinte plus rapidement (après 1 heure) que dans l'hydratation de l'aluminate tricalcique pur (3 heures). Cette augmentation accélère la formation de l'ettringite.

Parallèlement, la transformation ettringite-monosulfoaluminate s'opère beaucoup plus tôt (entre la 10<sup>e</sup> et la 60<sup>e</sup> minute).

Après l'épuisement du sulfate, on décèle par DRX le  $\text{C}_2\text{AH}_8$ .

L'hydratation du  $\text{C}_3\text{A}$  dopé II (4,6 %  $\text{Na}_2\text{O}$ ) constitue le cas le plus typique d'accélération de la réactivité des aluminates tricalciques dopés ; on observe en effet la consommation quasi instantanée du gypse et la formation simultanée des différents hydrates : le  $\text{C}_3\text{AH}_6$ , le monosulfoaluminate, l'ettringite et le  $\text{C}_2\text{AH}_8$ .

La concordance entre les résultats de microcalorimétrie, de DRX et de l'analyse des phases liquides est très nette. La chute rapide de la concentration en ions  $\text{SO}_4^{=}$  (de 63,5 mM/l à 2 mM/l) indique bien la consommation très rapide du gypse (Fig. 7).

Les deux pics microcalorimétriques se confondent en un seul grand pic exothermique qui apparaît dans les 30 premières minutes.

Les grandes quantités de chaleurs dégagées dans ce processus sont probablement à la base de la formation précoce du  $\text{C}_3\text{AH}_6$  et du monosulfoaluminate.

Pour l'échantillon fortement dopé (5,8 %  $\text{Na}_2\text{O}$ ), on assiste à un changement profond du processus décrit plus haut. Il y a bien une forte concentration en ions  $\text{SO}_4^{=}$  dans la phase aqueuse (120 mM/l) ; la teneur en soude et en aluminate est également très élevée, mais nos analyses de la phase aqueuse révèlent une concentration quasi nulle en ions  $\text{Ca}^{++}$  (due à la présence importante de soude en solution).

Dans ces conditions, on n'observe pas de quantité importante d'ettringite car l'étape limitante devient (exceptionnellement) la concentration en ions  $\text{Ca}^{++}$ . Celle-ci semble être non seulement un paramètre important pour la formation de l'ettringite, mais elle conditionne également la transformation ettringite-monosulfoaluminate ; l'analyse de la phase aqueuse de l'hydratation des différents aluminates tricalciques révèle en fait que la formation du monosulfoaluminate débute lorsque la concentration en ions  $\text{Ca}^{++}$  n'est plus que d'environ 2 mM/l.

## Conclusions générales

Dans ce travail, nous avons étudié l'hydratation de l'aluminate tricalcique pur et dopé au sodium en présence et en absence de gypse.

Dans le système  $\text{C}_3\text{A} + \text{H}_2\text{O}$ , le  $\text{Na}_2\text{O}$  diminue la vitesse de l'hydratation ; on observe, en outre, une stabilisation des hydrates hexagonaux aux dépens de la formation de l'hydrate cubique.

Dans le système  $\text{C}_3\text{A} + \text{Gypse} + \text{H}_2\text{O}$ , on assiste à un phénomène inverse dû aux modifications profondes de la composition de la phase aqueuse.

En effet, le passage de  $\text{Na}_2\text{O}$  dans l'eau entraîne les modifications ci-après :

- (1) Augmentation de la teneur en  $\text{AlO}_2^-$ .
- (2) Augmentation de la teneur en  $\text{SO}_4^{=}$ .
- (3) Diminution de la teneur en  $\text{Ca}^{++}$ .

L'ensemble des résultats montre que pour les échantillons faiblement dopés, la formation de l'ettringite est accélérée, alors que pour l'échantillon fortement dopé, elle est inhibée par manque de  $\text{Ca}^{++}$ .

Ce travail a permis de montrer le rôle primordial de la composition de la phase aqueuse lors de l'hydratation de l'aluminate tricalcique dopé au sodium.

Nos recherches ultérieures devront montrer si l'hydratation de  $\text{C}_3\text{A}$  pur, en présence de soude, est identique à celle des échantillons dopés contenant  $\text{Na}_2\text{O}$  dans leur réseau.

## Remerciements

Nous tenons à exprimer toute notre gratitude à Madame M. Regourd pour la détermination des variétés allotropiques des aluminates tricalciques dopés qu'elle a bien voulu réaliser au laboratoire du CERILH à Paris.

Nous remercions également Madame A.M. Vogel pour sa collaboration scientifique efficace dans l'analyse des phases liquides (Service de Chimie Industrielle - Chimie des Ciments à l'Université Libre de Bruxelles).

## SHORT COMMUNICATION

### « Some considerations on the present state and future trends of knowledge on calcium aluminates, as a possible basis for discussing the future work in this field. »

J. CALLEJA, Instituto Eduardo Torroja (Madrid), Spain.

1. A part of the Principal Paper on DURABILITY presented to the Theme VII, and most of the 27 communications presented to the Seminar A of this 7th International Congress on the Chemistry of Cement deal with :
  - i) The structure and crystalline forms of aluminates and their solid solutions, mainly of  $C_3A$ .
  - ii) The hydration of aluminates and their solid solutions, as influenced by different retarders, admixtures and mediums, or by other clinker components, mainly of  $C_3A$ , either synthetic or as a component of portland cements.
  - iii) The formation, structure, stability and chemical resistance of more or less complex calcium aluminate hydrates, mainly the expansion and sulfate attack of some of them.
2. The principal starting point determining hydration mechanisms of aluminates, and the structure, properties and behaviour of their hydrates is point i).
3. Much research work has been carried out in the last time on anhydrous calcium aluminates and more particularly on  $C_3A$ , which is the most important aluminous component of ordinary portland cement clinker.
4. A part of this work has been directed to synthesize different crystalline forms of  $C_3A$  and to identify them in clinker.  
Another part of the work has been devoted to study the properties and behaviour of those forms of  $C_3A$ , particularly as far as their susceptibility to sulfates is concerned.
5. No doubt that both parts of this work have been attempted and developed mainly as a (scientific) research basic in nature. The interest of it is obvious, as a good mean -and perhaps the better way- to gain and cumulate new solid knowledge on the theme of the chemistry of calcium aluminates.
6. But no doubt as well that the final interest of this necessary and more basic research is to form the support and the starting point for an applied research, more technical in nature, able to give practical results.
7. It is worth while not to forget that for cement makers and cement users calcium aluminates are more interesting as "natural" components of industrial portland cement clinker than considered as isolated "artificial" laboratory synthetic products.
8. In this view, once established -if so- that different forms of  $C_3A$  have different nature, properties and behaviour in different technical aspects, two lines of study and action may arise immediately.
9. The one is analytical in nature : to develop reliable, practical easy and rapid methods to detect qualitatively the presence and if possible to determine quantitatively the content of the different forms of  $C_3A$  -occasionally of other calcium aluminates- in portland cement clinker.
10. The other line is technical in nature : to develop procedures and techniques to create preferently in industrial portland cement clinker those forms of  $C_3A$  -and occasionally of other calcium aluminates- whose behaviour may be better in all or part of the aspects involved in the use and applications of portland cement, i.e., in concrete science and technology.
11. It is thought that so, and only so, the whole chain beginning with the more pure, basic, scientific, fundamental, theoretical or academic research, and finishing with the more applied, technical, practical or industrial research in the field of calcium aluminates may be continuous and complete.
12. This may permit the development and the innovation of the world cement industry. Otherwise the chain is broken and the knowledge gained may be sterile, at least during a long time, for practical purposes.
13. Probably this second type of research -or this second way to direct the single and unique research for those who prefer to consider it so-, is more difficult than the first type or way to focus and project research in the field of calcium aluminates.
14. But, anyway there is no doubt that it is a tempting challenge for those who like and wish to make progress the cement industry and subsidiarily the concrete technology, i.e., the building and construction industry.

Conclusion du séminaire par le Président.

## INTRODUCTION DU PRESIDENT

Chaque année, l'industrie produit de grandes quantités de boues contenant des corps nocifs, essentiellement des ions métalliques. Ces boues proviennent de l'épuration des eaux résiduaires et des effluents gazeux et concentrent un grand nombre d'éléments dangereux pour l'environnement. Parmi ces éléments, les métaux lourds se trouvent être initialement dans la nature sous forme de minerais insolubles. L'homme a extrait ces minerais et a solubilisé les métaux afin de pouvoir les utiliser dans les divers circuits de l'activité humaine. Ces éléments, lorsqu'ils ont rempli leurs fonctions, sont en général recyclés mais ce recyclage s'accompagne toujours de pertes qui se traduisent par des rejets dans le milieu naturel. La présence de ces éléments dans la nature est en général éphémère si l'on se réfère à l'échelle géologique car, tôt ou tard, ils sont fixés à nouveau sous la forme d'un minerai insoluble en rencontrant des sites minéralogiques réactifs. Mais en attendant, ils transitent dans les circuits des eaux de surface et souterraines en concentration parfois importante, ce qui constitue une menace pour la qualité des eaux.

Le rejet de ces éléments en milieu naturel, s'il constitue la seule issue possible, doit donc se faire dans des conditions bien déterminées. Deux solutions peuvent être envisagées. D'abord, le stockage des boues dans des sites réputés étanches à toute infiltration d'eau. Les boues resteront en attente pendant un temps plus ou moins long, mais continueront à présenter un danger potentiel important. L'autre solution est d'accélérer le cycle naturel en mettant les boues en contact avec un minéral réactif afin de les retransformer immédiatement en un minerai insoluble. Le minerai réactif le plus couramment utilisé dans l'industrie et le plus facilement disponible est le ciment ou, plus généralement, les produits appartenant à la famille des liants hydrauliques.

Le ciment permet de reconstituer des pierres dont la durabilité est équivalente et même supérieure à celle des pierres naturelles. Les premiers ciments confectionnés il y a plus de 2000 ans par les romains n'ont rien perdu de leurs qualités avec le temps et ont atteint un équilibre géologique. Lorsque l'on traite des boues industrielles contenant des métaux lourds avec des liants hydrauliques, on vise ce même équilibre géologique pour obtenir une pierre inattaquable et insoluble qui constituera un piège idéal pour les éléments à fixer.

L'action des liants hydrauliques sur les boues est multiple ; elle est d'abord chimique, physique et enfin mécanique, c'est-à-dire qu'il se produit des liaisons au niveau des molécules, que ces molécules s'organisent en réseaux cristallins et que ces réseaux cristallins s'enchevêtrent pour donner des structures résistantes.

L'objectif de ce Séminaire est d'étudier ces liaisons et mécanismes de solidification dans la perspective de prévoir l'évolution à long terme des produits solidifiés. Il est en effet nécessaire de bien comprendre le processus de solidification afin d'évaluer le degré de confiance que l'on peut accorder à ces procédés pour la sauvegarde de notre patrimoine écologique.

# Chimie des ciments et traitement des boues minérales

## *Cement chemistry and mineral sludge processing*

P. LONGUET - G. BELLINA, Département « Chimie des Ciments » - C.E.R.I.L.H. - Paris, France.

### RESUME

Après avoir situé le sujet vis-à-vis des conséquences écologiques du rejet inconsidéré de déchets minéraux plus ou moins toxiques, on développe les caractéristiques particulières des composés de la chimie du ciment considérés comme réactifs chimiques. Les réactions de neutralisation, de précipitation et de complexation sont particulièrement étudiées soit dans leurs principes, soit sous l'angle de l'application. On précise ensuite les manières d'apprécier l'efficacité d'un traitement principalement vis-à-vis des caractéristiques de l'eau potable.

### SUMMARY

After we have set the subject beside ecological consequences of rash rejection of mineral wastes highly poisonous or not, we develop the specific characteristics of cement chemistry compounds regarded as chemical reagents. Neutralization reactions, precipitation and complexation reactions are studied with carefulness and looked at from whether their principles or their applications. Then we clarify the ways to estimate the effectiveness of some processings mainly beside drinkable water characteristics.

## I - PRESENTATION

En l'an 2000 la population du globe atteindra six milliards d'êtres humains. L'homme devient donc selon l'expression du professeur Vlado VERNADSKY, spécialiste des sciences de la terre, une puissante force géologique.

Compte tenu de l'intensité des activités humaines actuelles cette force peut provoquer en quelques décades des changements qui auraient demandé des millions d'années pour s'accomplir naturellement.

Indépendamment d'une gestion optimale des ressources terrestres cette rapidité d'évolution pose le problème du traitement des déchets plus ou moins toxiques qui en résultent. Le but de cet exposé est de montrer comment, dans le domaine particulier et limité des boues minérales toxiques, peut intervenir la chimie du ciment pour éviter particulièrement la pollution de l'eau potable et la dispersion des matières premières minérales.

## II - LIMITES DE L'EXPOSE ET RAPPEL DE QUELQUES DEFINITIONS

L'exposé concerne essentiellement le traitement des boues compatibles avec les composés de la chimie des ciments c'est-à-dire le plus souvent des déchets d'origine minérale. Il suppose que la nature et la composition de ces déchets s'opposent à leur rejet direct dans le milieu naturel (toxicité certaine) et qu'ils se présentent dans leur état final c'est-à-dire qu'ils ne peuvent plus pour des raisons techniques, économiques ou toxicologiques subir d'opérations de concentration et que le traitement doit être définitif et durable. Le terme de traitement ultime est souvent utilisé pour définir cette opération.

## III - BUTS DU TRAITEMENT

Le traitement cherche d'abord à assurer la solidification du milieu afin de le rendre manipulable et transportable.

Le second point concerne la fixation des substances toxiques présentes afin d'éviter au maximum leur rejet dans le milieu naturel environnant compte tenu des conditions de stockage ou d'utilisation.

Enfin le traitement doit assurer le mieux possible une stabilisation dans le temps, l'idéal étant le retour vers des formes thermodynamiquement stables comparables à des espèces minéralogiques.

L'efficacité du traitement se définit à partir de ces trois paramètres: solidification, fixation, stabilisation.

Il est évident que l'on recherchera une efficacité d'autant plus grande que la toxicité de la boue à traiter sera plus grande. Parallèlement le coût du traitement croît le plus souvent avec l'efficacité.

## IV - POSSIBILITES APORTEES PAR LES COMPOSES DE LA CHIMIE DU CIMENT

Citons d'abord les propriétés classiques bien connues des liants hydrauliques. Gâché en pâte avec l'eau un ciment fait prise et durcit en consommant de l'eau pour former des hydrates de très grande surface spécifique (100 fois environ la surface du solide initial) et générer finalement un solide mécaniquement très résistant et pratiquement inattaquable par les agents naturels habituels. Ces caractéristiques conduisent déjà à proposer les liants hydrauliques

pour le traitement des boues minérales aqueuses. Mais l'examen plus approfondi des propriétés des composés de la chimie du ciment met en évidence bien d'autres propriétés intéressantes permettant de réaliser toute une série de réactions bien plus générales que celles rappelées précédemment et qui amènent à considérer le ciment comme un réactif chimique.

### - Réactions de neutralisation

Si nous considérons, pour simplifier, que pour notre sujet les deux constituants essentiels du ciment sont le silicate tricalcique ( $C_3S$ ) et l'aluminate tricalcique ( $C_3A$ ), nous avons affaire dans les deux cas à des sels d'acides faibles (silice et alumine) et de base forte (chaux).  $C_3S$  et  $C_3A$  mis en contact avec des acides forts vont se comporter sensiblement comme une base forte en libérant les acides faibles correspondants sous des formes hydroxylées très réactives (cf. exposé de PETIT et ROUXHET). L'effet tampon propre à ce type de neutralisation sera par ailleurs très favorable pour assurer une faible solubilité aux hydroxydes pouvant exister dans la boue à traiter (cf. exposé de BLANCHARD).

Le ciment apparaît donc comme un réactif de choix pour la neutralisation des effluents acides qui représentent d'après les statistiques la plus grande partie des rejets aqueux industriels.

### - Réactions de précipitation

Le milieu apporté par le ciment est fortement calcique. Les sels de calcium étant pour la plupart peu ou très peu solubles un grand nombre d'anions susceptibles d'être présents dans la boue à traiter vont précipiter et venir s'insérer dans la texture du ciment hydraté. Citons les fluorures, les zincates, les borates, les arsénates, les phosphates, les plombates, les tungstates, les chromates,....

Cette possibilité de précipitation de sels de calcium confirme l'intérêt de la neutralisation d'un effluent acide par un ciment à la place de  $Na_2CO_3$  ou  $NaOH$  qui augmentent obligatoirement la teneur du milieu neutralisé en sels solubles (bases alcalines).

### - Réactions de complexation

Ces réactions sont propres aux phases aluminiques du ciment ( $C_3A$ , phases aluminoferritiques). La grande réactivité du  $C_3A$  intervient très souvent dans la chimie du ciment (cf. Séminaire A).

Dans le cadre de notre sujet nous nous intéressons aux complexes prenant naissance en milieu fortement alcalin et calcique. Le plus connu est le trisulfoaluminate de calcium hydraté ( $Al_2O_3 \cdot 3CaO \cdot 3SO_4Ca \cdot 31H_2O$ ) que l'on forme volontairement d'une manière tout à fait générale pour régulariser la prise du ciment (gypsage des clinkers). Mais de nombreux anions peuvent aussi former des aluminates de calcium complexes dont les sels de calcium sont peu ou très peu solubles. Citons les ions suivants: sulfate, chromate, séléniate, carbonate, chlorure, bromure, iodure, nitrate, nitrite, permanganate, iodate, formiate, acétate, propionate....(A).

D'autre part les ions aluminium peuvent être partiellement substitués dans ces aluminates complexes par les ions  $Cr^{3+}$ ,  $Ti^{4+}$ ,  $Ti^{2+}$ .... La phase aluminatée, et aussi la phase aluminoferritique qui donne en première approximation des réactions analogues, sont les composés du ciment qui apportent des

possibilités de fixation très diverses pour de nombreux ions toxiques.

Nous n'entrerons pas ici dans les détails des réactions pour lesquels nous renvoyons à la bibliographie commentée de cet exposé. En résumé les composés de la chimie du ciment présents dans les liants hydrauliques sont à considérer comme de véritables réactifs chimiques susceptibles de consommer de l'eau (déshydratation), de neutraliser les milieux acides, de précipiter des sels de calcium, de complexer de nombreux ions toxiques, d'adsorber (adsorption et chimisorption) et de solidifier les suspensions aqueuses minérales (prise et durcissement).

Bien entendu il peut y avoir, et il y a le plus souvent, compétition entre les diverses réactions possibles. Cette compétition soulève, lors du traitement, des problèmes très différents des problèmes classiques de la chimie des ciments et dont l'étude fort intéressante n'a été entreprise que depuis quelques années seulement. Nous avons essayé malgré tout d'indiquer les lignes directrices actuellement suivies pour conduire un traitement.

## V - MODALITES D'APPLICATION

### - Connaissance du milieu à traiter

Bien qu'essentiel ce point est quelquefois négligé à cause des difficultés analytiques posées par un milieu dont il est souvent très difficile d'établir l'histoire complète (mélange de plusieurs effluents, traitements de produits inconnus, mise en lagune ancienne... et qui dans la plupart des cas présente une hétérogénéité importante). De toute manière il faudra s'efforcer d'obtenir un échantillon aussi représentatif que possible et déterminer sa composition élémentaire complète (anions et cations) et préciser les espèces chimiques présentes: effluents directs plus ou moins acides, effluents déjà traités (décyanuration, réduction de  $\text{Cr}^{6+}$ , neutralisation avec précipitation d'hydroxydes...). C'est à partir de ces données qu'il convient ensuite de conduire le plus efficacement possible les réactions de base mentionnées. Citons quelques incidences pratiques à considérer:

### - Sur les réactions de neutralisation

Une acidité élevée du milieu entraîne une consommation importante de ciment pour sa neutralisation avec la formation éventuelle trop importante d'hydroxydes. (Un ciment portland artificiel précipite environ la moitié de son poids en hydroxydes). Dans ce cas une neutralisation partielle préalable avec du carbonate de calcium ou de la chaux ( $\text{CaO}$  ou  $\text{Ca(OH)}_2$ ) permettra une opération convenable.

### - Sur les réactions de précipitation

La difficulté provient ici de la compétition entre les propriétés d'enrobage et de colmatage des sels insolubles de calcium formés qui inhibent plus ou moins totalement la poursuite de l'hydratation du ciment. Il faut alors jouer soit sur des facteurs physiques qui changent les vitesses de réaction (température, dilution...) soit sur des facteurs chimiques (accélérateurs ou retardateurs...) soit sur des facteurs mécaniques (agitation, dispersion ou même traitement en broyeur pour renouveler les surfaces de contact...).

### - Sur les réactions de complexation

C'est la teneur en alumine du liant et l'alcalinité du milieu qui interviennent le plus dans ces réactions indépendamment de la formation de composés insolubles traitée au paragraphe précédent. Dans bien des cas le taux de fixation peut être augmenté par addition de laitier granulé de haut fourneau ou quelquefois de cendres volantes de centrale thermique. Il conviendra cependant de bien connaître la teneur du milieu en alcalis libres ( $\text{NaOH}$  ou  $\text{KOH}$ ) qui peuvent limiter la solubilité de  $\text{Ca(OH)}_2$  et s'opposer ainsi à la formation des complexes calciques dont le produit de solubilité ne peut ainsi être atteint.

Inversement d'ailleurs la boue à traiter peut avoir une teneur élevée en alumine, il convient alors d'ajouter un anion complexant, sulfate par exemple.

### - Sur les réactions de dispersion et d'adsorption

Nous avons déjà signalé l'intérêt du développement important de surface spécifique lié à l'hydratation du ciment. Quelquefois on recherche uniquement l'action dispersante du phénomène c'est ainsi que certaines chaux vives activées seules ou en mélange avec un support minéral, sont utilisées pour disperser des résidus organo-minéraux. Dans ce cas le matériau pulvérulent obtenu doit être compacté et protégé de l'action dissolvante des agents atmosphériques ou réinséré dans une matrice insoluble. Signalons encore l'utilisation des propriétés des échangeurs d'ions (cf. exposés de SUZUKI et Coll. et de FORMANEK).

Ces quelques commentaires sur les modalités de réalisation du traitement des boues montrent la complexité du problème et confirment la nécessité d'une étude préalable avec des essais de vérification pratique dans chaque cas (cf. exposés de SUGI et Coll. de RAU et de LEROY).

Sur un autre plan, il est certain que cette nouvelle application des liants hydrauliques aura des conséquences bénéfiques sur notre connaissance de la chimie des ciments.

## VI - APPRECIATION DE L'EFFICACITE DU TRAITEMENT REALISE

Lorsque l'étude préalable indique que le traitement est possible il convient de vérifier ses qualités potentielles et d'essayer de prévoir son évolution dans le temps compte tenu du mode de conservation envisagé (fig. B texture d'une boue traitée).

De très nombreux essais ont été décrits. Nous en mentionnerons trois qui correspondent chacun à une préoccupation différente:

- Connaissance de l'état d'équilibre ionique de la solution interne de la boue traitée: on utilise la technique déjà proposée pour le ciment hydraté.

- Connaissance de l'état d'équilibre de la surface externe de la boue traitée avec une eau stagnante: c'est l'adaptation de la méthode préconisée par l'agence nucléaire internationale.

Cet essai correspond à l'effet le plus faible de l'action dissolvante de l'eau.

- Connaissance de l'action d'une eau de ruissellement.

La simulation est obtenue au laboratoire dans un extracteur type Soxhlet perfectionné.

La capsule d'extraction dans laquelle est disposé l'échantillon, conditionné de manière à présenter une surface connue à l'action de l'eau, est maintenue isotherme (C et D).

Cette particularité permet une mesure conductimétrique continue sur la solution d'extraction et permet d'établir un diagramme de solubilité ( E ).

Cet essai dynamique représente l'action la plus agressive d'une eau.

L'analyse élémentaire des solutions extraites permet au moins un classement des traitements réalisés. Les valeurs obtenues ne sont évidemment qu'indicatives et la transposition au cas réel est souvent difficile. En effet la conservation en site naturel fait intervenir un très grand nombre de facteurs tantôt favorables (importance des masses traitées, qui diminue l'effet de surface, action colmatante due à la formation du carbonate de calcium...) tantôt défavorables (acidité des eaux naturelles, mouvements de terrain, alternances climatiques....). Cependant il est toujours intéressant de comparer les valeurs fournies par les essais de laboratoire à celles des tables fixant les limites des teneurs en ions toxiques de l'eau potable.

Ici encore indépendamment des conclusions tirées des essais de laboratoire, ce sera la toxicité initiale de la boue traitée qui pourra orienter les précautions à prendre a priori pour l'utilisation ou le stockage des produits traités. On pourra aller ainsi de l'addition à un béton de préfabrication dans le cas d'une nocivité négligeable jusqu'au stockage sur une aire imperméable permettant le contrôle permanent des eaux de ruissellement ayant été en contact avec la boue traitée (cas des résidus nucléaires par exemple).

#### CONCLUSION

Suivant la toxicité de l'effluent initial le traitement ultime des boues par les liants hydrauliques apporte, chaque fois qu'il est réalisable, des solutions intéressantes pour la protection de l'environnement:

- Amélioration de la manutention.
- Facilités de mise en décharge.
- Utilisations diverses : charges routières ou autres, béton manufacturé...
- Stockage sans pollution des eaux potables permettant d'éviter la dispersion d'éléments importants dont le retraitement sera possible dans l'avenir....

# La solidification des déchets : motivations, acquis, perspectives

## *Solidification techniques, motivations, state of the technology, developments*

Philippe J. PICHAT, CdF Chimie-A.P.C., Paris-La Défense, France.

**Resumé :** Le devenir des déchets toxiques est un sujet qui n'intéresse plus seulement les milieux spécialistes de l'environnement et de la protection des ressources en eau. En effet, plus particulièrement aux Etats Unis, ce sujet, par le biais d'incidents concernant parfois des centaines de personnes, a atteint une dimension nationale, puis a eu une audience internationale. La grande presse a consacré des articles à ce thème techniquement et médicalement délicat en présentant parfois des hypothèses comme des faits.

Cet intérêt des élus, du public est compréhensible, compte tenu de l'importance fondamentale maintes fois soulignée par l'O.M.S. (l'Organisation Mondiale de la Santé) de l'eau pour la santé des humains.

Cet exposé résume les relations entre l'eau et les déchets, une nouvelle filière technologique qui élargit la gamme d'outils dont disposent les spécialistes de l'anti-pollution. La solidification-fixation des déchets a déjà obtenu des résultats appréciables. De meilleures performances à un rapport efficacité-coût intéressant peuvent être escomptées à condition d'intensifier et d'infléchir les premiers efforts.

**Summary :** Toxic wastes no more concern the alone specialists of pollution control. Problems which took place for example in the U.S.A. and in the Netherlands gave an international size to the topic. The mass media feel concerned. The importance of water to the public health explains these reactions.

This article reminds links between drinkable water and wastes, describes briefly the solidification techniques which are a useful new tool of the pollution control. Results have been obtained. Better performances would be reached along efforts of Research-Development.

## 1 - L'eau et la protection des ressources en eau

### 1.1. La biosphère et le cycle de l'eau

La biosphère qui abrite les êtres vivants peut être comparée à une mince enveloppe recouvrant notre globe.

La biomasse (masse totale d'organismes vivants) varie selon les régions de la biosphère dans de fortes proportions (forte dans une prairie normande, faible en haute montagne,...).

Figure 1

La biosphère n'est pas peuplée de façon désordonnée par les êtres vivants mais par des communautés, associations de microorganismes - végétaux - animaux, installées dans un milieu déterminé et que l'on dénomme "biocoénose". Ce milieu déterminé (un "biotope") de dimensions variables, est caractérisé par des dominantes homogènes (t°, humidité, type de sol...)

On a pu écrire :

$$\text{Ecosystème} = \text{biotope} + \text{biocoénose}$$

A la surface des terres émergées, la biomasse est sensiblement proportionnelle au volume des précipitations

Cette eau de pluie, arrivée au sol, peut :

a/ ruisseler jusque dans les océans, en empruntant ruisseaux, rivières, fleuves. Le ruissèlement est important sur les terrains imperméables, par exemple granitiques.

Dans ce cas, l'eau de pluie alimente essentiellement les eaux de surface. Il n'y a pas de ressources en eau souterraine notables (Bretagne, Massif Central). Il en découle que les cours d'eau ont un débit irrégulier, fonction des précipitations.

b/ percoler, s'infiltrer et alimenter les gisements aquifères souterrains.

Il se forme une nappe lorsque l'eau d'infiltration rencontre une assise pratiquement imperméable : argile, roche. Il peut exister dans la même région plusieurs nappes (ou niveaux d'eau) superposées. C'est ainsi que l'on trouve des nappes stampiennes, sauroisiennes, bartoniennes, de la craie sénonienne, de la craie turonienne, cenovonienne, albienne dans la région parisienne...

c/ s'évaporer, transpirer (ces deux processus sont groupés sous le nom d'évapotranspiration) par l'intermédiaire du système foliaire. Les racines contribuent fortement à ces mouvements ascendants d'eau sol-atmosphère.

On a représenté ci-dessous le schéma simplifié du cycle de l'eau.

Figure 2

### 1.2. La vitesse de circulation de l'eau et ses implications

Le processus général de circulation des eaux dans le sol est gravitationnel, freiné par les phénomènes de capillarité. Il se développe des courants analogues à ceux des rivières et des fleuves. Indiquons, pour donner une idée de l'échelle de ces phénomènes, que la vitesse varie entre quelques centaines de mètres et quelques centaines de kilomètres par an.

La circulation diachronique donne lieu à de nombreuses variations de vitesse. Par contre, en milieu suffisamment homogène et isotrope, la circulation en milieu poreux peut être représentée par la loi de Darcy :  $I = \frac{\Delta V}{V}$  I étant la perte de charge unitaire et V la vitesse de circulation. Ces vitesses sont en général très faibles, de quelques mètres par an à un mètre par jour, alors que pour un cours d'eau, elles sont de l'ordre du mètre par seconde.

Lorsqu'un déchet liquide (fosse septique, lixiviation de pesticides, agent antigel d'autoroute...) sera déversé au-dessus d'une nappe, la pollution n'apparaîtra que lentement : la contamination peut demander des années, voire des décades à se manifester. Dans le passé, on a supposé que si un site acceptait des sous-produits ou des déchets sans dommage immédiat, on avait réalisé un stockage ultime. Cette façon de voir explique des incidents du genre de LOVE CANAL qui se sont passés aux Etats Unis (1).

Au contraire, dans le cas d'un cours d'eau, la pollution pourra être détectée rapidement au moyen de méthodes physico-chimiques (absorption atomique, chromatographie) ou biologiques (utilisation de poissons sensibles à la pollution, de crustacés du type Daphnies). Les nappes sont alimentées par les eaux de surface. Lorsque ces dernières sont polluées, leur infiltration dans le sol souille les couches aquifères.

### 1.3. Pollution, "formation" des déchets

La pollution, stricto sensu, est la destruction d'un cycle biologique dans un écosystème, exemple la mort de tonnes de poissons dans la Saône en 1974 par suite des déversements en amont de Lyon.

Chaque utilisateur d'eau, qu'il soit un particulier,

un industriel ou un cultivateur, a tendance à rejeter celle-ci sans trop se soucier des utilisateurs suivants situés en aval, en pensant que la nature s'accommodera de cette eau additionnée de diverses substances.

Les cours d'eau jouent un rôle de convoyeurs de déchets vers la mer. Le résultat est que l'eau est dans certains cas, très polluée.

Cette pollution est soit d'origine :

- organique (égouts urbains, abattoirs, sucreries, laiteries... usines de pâte à papier, hydrocarbures, phénols, détergents, pesticides...)
- inorganique : métaux lourds, plomb, acides, silico-aluminates provenant de dragages, etc... ;
- bactérienne et virale.

La nature ne peut "assimiler" les déchets qu'en quantité limitée et très variable (selon leurs propriétés physico-chimiques et biologiques) en un point donné. Ce principe essentiel a été trop longtemps oublié alors que l'on assiste à une "concentration" des rejets par suite des phénomènes d'urbanisation et d'industrialisation massifs.

Il y a confusion entre besoins en eau et besoins d'écoulement d'eau. La plus large part du besoin en eau vient de l'habitude d'utiliser l'eau en mouvement comme "vecteur" de transfert de déchets.

Dans ces conditions, il n'y a rien d'étonnant à ce que les déchets contiennent une forte proportion d'eau même dans le cas des boues ou de pseudo-solides pelletables qui peuvent encore atteindre des teneurs de l'ordre de 60 % d'eau libre.

#### Déchets Primaires

## 2 - Principe de la solidification des déchets

Lorsque la valorisation, toujours souhaitable, n'est pas possible, il s'agit de transformer un déchet liquide ou une boue en un véritable solide afin de supprimer les dangers (et les coûts d'un point de vue économique) liés au stockage de liquides ou de boues liquides.

D'autre part, le solide ainsi constitué doit relarguer peu d'ions ou de molécules vers le milieu naturel.

Les déchets, par exemple d'un atelier de chromage sont détoxiqués, neutralisés et on obtient une boue "déchets des déchets".

Souvent sous l'action des intempéries, les constituants des boues peuvent être entraînés dans les eaux souterraines ou de surface (Photo P.J. PICHAT)

Les boues si celles-ci ne sont pas judicieusement stockées, sous l'action des intempéries, pourront peu à peu être entraînées dans les eaux de surface ou les eaux souterraines. Une parade est le dépôt des boues dans des sites étanches au point de vue hydrogéologique. (Une conférence patronnée par l'ANRED aura lieu à l'INSA de Lyon (FRANCE) en février 81). Un tel site peut ne pas exister à proximité. Une autre parade qui peut d'ailleurs être complémentaire est de transformer de l'eau libre en eau liée.

L'eau contenue dans le déchet réagira avec le liant hydraulique, mélange constitué principalement de silicates et d'aluminates de calcium anhydres qui vont être transformés en silicates et aluminates de calcium hydratés. (On rappelle, pour mémoire, que d'autres filières technologiques existent : bitumes, thermodurcissables, céramiques, verres).

Ces effets ont lieu soit à l'échelle microscopique, soit à l'échelle macroscopique.

## 3 - L'acquis, Sommaire de l'état de la technique

Les méthodes de solidification-fixation sont récentes (3, 4). Elles datent d'une dizaine d'années et elles ont été consacrées principalement aux boues de désulfuration des fumées et aux boues toxiques (le cas des déchets radioactifs n'étant pas abordé ici).

En mars 1979, a été organisé par l'A.C.S. (American Chemical Society) et la C.S.J. (Chemical Society of Japan) à Hawaï le premier séminaire consacré exclusivement aux méthodes de solidification-fixation. A peu près simultanément paraissait aux U.S.A. le premier livre consacré à ces techniques (2) qui depuis a été suivi de 2 autres volumes : en quelques années, ces techniques se sont bien développées et un certain nombre d'entreprises, par exemple :

- aux U.S.A. (I.U., DRAVO, CHEMTIX, COTTRELL...)
- en France (SARP Industries, GEREP, PEC-ENGINEERING)

les utilisait

### 3.1. Phases du traitement

Le tableau ci-dessous rappelle succinctement les phases d'un traitement industriel :

#### a/ CHOIX D'UNE FORMULATION

Homogénéisation du déchet brut	Echantillonnage (Opération délicate comme le rappellerait Monsieur BLANCHARD)	Analyse	Choix d'une formulation
--------------------------------	--	---------	-------------------------

#### b/ MISE EN OEUVRE

qui induisent des réactions de : neutralisation, précipitation, adsorption, complexation, substitution, enrobage.

Mise en place appropriée.

#### c/ CONTROLE

- Propriétés mécaniques Rp (la résistance à la compression doit être compatible avec le passage d'engins et le stockage sur de fortes épaisseurs sans fluage.
- Propriétés écologiques - essai statique de lixiviation
  - essai dynamique
  - perméabilité

### 3.2. Principaux paramètres

#### 3.2.1. Influence du traitement primaire - Intégration du traitement ultime dans le processus global de traitement

Les déchets bruts, primaires pour utiliser une autre terminologie sont souvent acides. Ils sont ensuite neutralisés. Le type de neutralisation n'est pas sans répercussion sur la qualité de la solidification ultérieure du déchet. On doit préférer à l'utilisation d'un hydroxyde dont le métal sous forme ionique est très soluble, l'utilisation de l'hydroxyde de calcium. Ce thème sera développé par Monsieur LONGUET.

Il est nécessaire dès le traitement primaire (et à plus forte raison, secondaire) que la production de déchets ait le souci du traitement ultime du déchet, c'est-à-dire du devenir du déchet, ceci dans l'esprit de la loi française des déchets de 1975. On ne peut pas demander au traitement de solidification de "gommer" toutes les erreurs qui ont été faites précédemment.

#### 3.2.2. Type de déchets traités - Flexibilité des procédés - Ambiguïté des objectifs

L'incinération des déchets ayant un PEI convenable est pratiquée. Des déchets biodégradables sont traités par les méthodes d'aspersion, d'épandage, voire de landfarming lorsque les caractéristiques du sol et le climat le permettent.

Par contre, les méthodes de solidification semblent particulièrement appropriées avec des produits inorganiques pouvant contenir une certaine proportion de produits organiques, ou biologiques ou organo-métalliques variables selon le procédé et ses conditions d'exploitation.

Il y a probablement un effort à faire dans le sens d'une plus grande adaptation du dosage (avec un procédé donné) au type de déchet considéré (5).

On peut dire qu'il y a eu souvent une tendance à sous-doser en liants hydrauliques pour des raisons économiques bien compréhensibles.

Cette attitude a amené des exploitants à ne pas solidifier des déchets qui, en fait, auraient pu être traités convenablement en abaissant le rapport eau/liant.

Dans ce domaine, il existe d'ailleurs une certaine confusion sur l'objectif à atteindre :

- S'agit-il de solidifier pour stocker à un prix attractif des boues ou des déchets liquides en abaissant par voie de conséquence la lixiviation

- ou s'agit-il de fixer les éléments polluants avec des préoccupations de coût moindres.

Des représentants des pouvoirs publics ont pu être parfois être un peu déçus des performances d'un procédé parce que, pour des raisons commerciales, la première attitude avait dû être adaptée, compte tenu de ce que la détenteur du déchet ne proposait pas un budget suffisant.

#### 3.2.3. Conditions de mise en place et de stockage

Il est important que la mise en place du déchet soit définitive avant sa solidification, c'est-à-dire, en d'autres termes, sans reprise. Une reprise n'est possible, comme en techniques routières, qu'avec un liant à prise lente du genre grave-cendres, et l'expérience montre que dans le domaine de la solidification des déchets, on se trouve en général assez loin de ces conditions.

Les précautions usuelles vis-à-vis du grand froid, du soleil, du vent, lors de coulées de béton sont aussi recommandées lors d'une opération de solidification.

Le résidu doit être placé en couches compactes continues présentant un rapport surface/masse faible de façon à minimiser la lixiviation (du genre tumulus).

### 3.2.4. Evaluation des résultats

On peut distinguer non sans quelque arbitraire, l'eau stagnante et l'eau de ruissèlement et les essais de lixiviation peuvent être classés dans ces deux catégories.

Souvent ont été utilisés, dans le passé, des tests qui n'ont que des liens trop éloignés avec les réalités industrielles et qui consistaient à faire des essais de solubilité sur des échantillons qui, après avoir été solidifiés étaient broyés ou concassés ou avec des solutions à caractère artificiel au lieu d'eau de pluie. Un béton classique soumis à ce genre de test peut se révéler un matériau toxique !

Le plâtre se révélerait un matériau inutilisable alors que les maisons parisiennes (XVII<sup>e</sup>) ont souvent défié les années.

Il existe un besoin de définir avec précision des tests simples (utilisables par les exploitants) qui prennent bien en compte les conditions de stockage du déchet solidifié à l'échelle industrielle.

La Société IU CONVERSION SYSTEMS (Dr RAU) présentera une expérience dans ce domaine (6).

On trouvera ci-dessous à titre d'information les résultats obtenus par un déchet traité par un procédé de solidification "intégrée" ayant les caractéristiques suivantes (en g/l) avec le test statique.

pH	Cu	Fe	Zn	Cr	Cd	Ni	Mn
0	9,4	8,1	7,6	1,6	0,038	0,65	0,65

On obtient une eau de lixiviation ayant les concentrations ci-dessous : (expression en 10<sup>-3</sup> g/litre)

0,1	0,1	1,2	0,1	0,1	0,1	0,1
-----	-----	-----	-----	-----	-----	-----

L'échantillon avait un an. La durée de contact échantillon - eau a été d'une semaine.

Il y a longtemps que les agronomes utilisent des "lysimètres" pour étudier par exemple l'effet d'un épandage d'engrais, de lisier sur un sol et sa flore.

## 4 - Evolution des procédés

Un certain nombre de facteurs concourent à une évolution rapide des procédés : d'une part les nouvelles conditions économiques (augmentation du prix de l'énergie, ralentissement de la croissance), d'autre part la constitution d'une masse critique, d'un capital technologique de Recherche-Développement

De nombreux travaux ont été effectués. On ne compte pas moins de quatre cents publications et brevets. Ces travaux sont récents et restent encore à l'état de Recherche-Développement mais dans les années qui viennent, ils devraient donner naissance à de nouveaux procédés

industriels exploités. Rappelons que ce domaine très complexe touche à la physico-chimie de l'eau, des liants hydrauliques, la physico-chimie des surfaces. On peut écrire les schémas suivants :

Eau (pure) + liant hydraulique + agrégat → mortier

Dans le cas de la solidification des déchets (Eau + Agrégat) est remplacé par une variété considérable d'espèces physico-chimiques. Incidemment pour cette raison on peut escompter des retombées sur la connaissance de l'hydratation des ciments hydrauliques et leur utilisation dans des milieux difficiles (eaux usées, mer...).

Ce domaine intéresse de nombreux scientifiques et techniciens dont les travaux devraient contribuer à l'évolution des techniques.

Les méthodes de solidification/fixation contribuent à protéger l'Environnement (Photo Ph. PICHAT)

## CONCLUSIONS

Les techniques de solidification-fixation élargissent la gamme des traitements. Cette filière technologique est d'ailleurs pratiquée depuis des années dans le traitement des déchets dits faiblement radio-actifs.

Seule une élite des entreprises de construction possède les moyens scientifiques et techniques nécessaires pour fabriquer des bétons à hautes performances. Compte tenu de la très grande complexité des méthodes de solidification des déchets, ces techniques ne peuvent actuellement être exploitées avec une fiabilité acceptable que par les quelques entreprises ayant acquis le bagage scientifique et technique indispen-

sable à leur exploitation convenable.

Par ailleurs, la jeunesse de cette technologie fait appel à des efforts importants de Recherche-Développement.

# Incorporation d'ions métalliques dans la silice

## *Incorporation of metallic ions in silica*

L. PETIT et P.G. ROUXHET, Groupe de Physico-Chimie Minérale et de Catalyse, Université Catholique de Louvain, 1, place Croix du Sud 1, B-1348 Louvain-la-Neuve, Belgique (\*).

RESUME : L'incorporation d'ions métalliques dans la silice entraîne une perturbation du squelette silicique qui se marque dans le spectre infrarouge (glissement de la bande de vibration de valence SiO vers les faibles fréquences) et dans le diagramme de diffraction des rayons X (étalement vers les valeurs  $2\theta$  élevées de la bosse caractéristique de la silice). Ces méthodes permettent d'observer l'incorporation, par coprécipitation avec un sol silicique acide, de l'aluminium à un pH égal ou supérieur à 4 et du calcium à pH égal ou supérieur à 9 en milieu concentré. L'action du calcium sur l'organisation du squelette silicique se manifeste même lorsque l'on procède à une coprécipitation de silice et d'aluminium à pH 9, en partant d'un sol silicique; ceci est confirmé si l'on extrait le calcium et l'aluminium du squelette silicique par carbonatation et titrage acide, respectivement.

Les mêmes méthodes instrumentales confirment l'incorporation de métaux de transition ( $\text{Fe}^{3+}$ ,  $\text{Ni}^{2+}$ ,  $\text{Cu}^{2+}$ ) dans la silice par coprécipitation à pH 7 et 9 avec un sol silicique. Des dosages chimiques montrent que l'incorporation de  $\text{Cu}^{2+}$  et  $\text{Ni}^{2+}$  est favorisée par la présence de  $\text{Al}^{3+}$  et  $\text{Fe}^{3+}$  et par un passage rapide du pH initial du sol silicique au pH de coprécipitation.

SUMMARY : The incorporation of metallic ions in silica produces a perturbation of the siliceous skeleton, which is revealed by the infrared spectrum (shift towards lower wavenumbers of SiO stretching) and the X-ray diffraction diagram (flattening towards high  $2\theta$  values of the hump characteristic of silica). These methods show incorporation of aluminium at pH equal to or higher than 4 and of calcium at pH equal to or higher than 9 in a concentrated medium, by coprecipitation with an acidic silica sol. The influence of calcium on the organization of the siliceous skeleton is even marked when silica and aluminium are coprecipitated at pH 9, starting from a silica sol; this is confirmed if calcium and aluminium are extracted by carbonation and acid titration, respectively.

These instrumental methods confirm incorporation of transition metals ( $\text{Fe}^{3+}$ ,  $\text{Ni}^{2+}$ ,  $\text{Cu}^{2+}$ ) by coprecipitation with silica sol at pH 7-9. Chemical analyses show that incorporation of  $\text{Cu}^{2+}$  and  $\text{Ni}^{2+}$  is favored by the presence of  $\text{Al}^{3+}$  and  $\text{Fe}^{3+}$  and by a quick rise from the pH of silicic sol to the pH chosen for coprecipitation.

## INTRODUCTION

Beaucoup de chimistes ne reconnaissent la formation d'un solide comme produit de réaction entre certains réactifs que lorsque la phase formée est cristalline. Il est vrai que la diffraction des rayons X est une méthode particulièrement concluante pour identifier une phase solide et mettre en évidence la formation d'une liaison chimique entre des éléments présents dans celle-ci; cependant c'est également une méthode extrêmement restrictive.

Cette communication vise à illustrer l'incorporation de certains ions (Al, Ca, métaux de transition) dans une matrice silicique et la formation de liaisons entre ces ions et la silice par simple coprécipitation.

La possibilité d'incorporer l'aluminium dans une matrice silicique par coprécipitation ne fait plus de doute. Si le mode d'organisation du solide est mal connu, s'il peut être hétérogène, on admet généralement l'existence d'une phase mixte silice-alumine, qui possède notamment des caractéristiques particulières d'acidité et possède de l'aluminium en substitution du silicium (1-6). Les silicates de calcium anhydres ou hydratés offrent un exemple intéressant d'un autre mode d'association chimique entre un ion et la silice. Si la formation de phases cristallines est possible, les produits de réaction fréquemment obtenus sont mal cristallisés ou amorphes (7,8).

Nous allons montrer comment des méthodes très simples comme la spectroscopie infrarouge et l'observation de la large bande de diffraction des rayons X des produits amorphes silicatés permettent de mettre en évidence l'incorporation d'ions métalliques tels que l'aluminium et le calcium dans un squelette silicique. Nous examinerons ensuite le comportement d'ions de métaux de transition vis-à-vis d'une silice en voie de polymérisation. La formation d'oxydes mixtes silice-oxyde ferrique a été moins étudiée que la formation de silico-alumine; la substitution isomorphique du silicium par le fer, moins favorisée que la substitution du silicium par l'aluminium en raison de la dimension de l'ion ferrique, est suggérée par certains auteurs (9) mais rejetée par d'autres (10,11). L'obtention de silicates basiques contenant du nickel ou du cuivre est délicate et nécessite des températures élevées et des temps de réaction longs (12).

## METHODES EXPERIMENTALES

Les produits étudiés ont été préparés par une coprécipitation conduite à un pH donné et à température ambiante, en milieu aqueux fortement agité, d'un sol silicique et de l'ion métallique introduit par un sel soluble ( $\text{Al}(\text{NO}_3)_3$ , U.C.B. p.a.;  $\text{NiCl}_2$ ,  $\text{CuCl}_2$ ,  $\text{FeCl}_3$ , Merck p.a.); ils sont recueillis par filtration sur buchner, sans lavage, et séchés à 120°C.

Le sol silicique est obtenu par passage d'une solution de silicate de sodium (Merck) 1.2 M sur une résine échangeuse d'ions (Amberlite IR-120, BDH) saturée en protons. La base utilisée est un lait de chaux à 10%  $\text{Ca}(\text{OH})_2$  en poids (Merck p.a.)

Les spectres infrarouge ont été enregistrés à l'aide d'un spectrographe Beckman IR-12; la poudre était dispersée dans une pastille KBr de manière à obtenir une épaisseur effective de l'ordre de 0.4  $\text{mg}/\text{cm}^2$ . Les diagrammes de diffraction des rayons X ont été obtenus en utilisant un diffractomètre Philips ( $\text{CuK}\alpha$ , 34 kV ou  $\text{CoK}\alpha$ , 28 kV); les réglages de l'appareil sont

rigoureusement identiques pour tous les échantillons. Le dosage des ions métalliques a été réalisé par absorption atomique

## SYSTEME SILICE-ALUMINIUM-CALCIUM

Les figures 1 et 2 se rapportent à des produits préparés à pH 4 et 9, avec une concentration globale  $\text{Si} + \text{Al} = 0.6 \text{ M}$  et pour des rapports atomiques  $\text{Si}/\text{Al}$  valant respectivement 100/0, 80/20, 60/40, 40/60.

Fig. 1. - Spectres infrarouge de produits obtenus par coprécipitation de silice et d'aluminium à pH 4 (A) et 9 (B); milieu de concentration  $\text{Si} + \text{Al} = 0.6 \text{ M}$ ; rapports  $\text{Si}/\text{Al} =$  (a) 100/0, (b) 80/20, (c) 60/40, (d) 40/60.

Fig. 2. - Diagrammes de diffraction des rayons X de produits obtenus par coprécipitation de silice et d'aluminium à pH 4 (A) et 9 (B); milieu de concentration  $\text{Si} + \text{Al} = 0.6 \text{ M}$ ; rapports  $\text{Si}/\text{Al} =$  (a) 100/0, (b) 80/20, (c) 60/40, (d) 40/60.

Les spectres infrarouge des produits préparés à pH 4 sont présentés à la figure 1A. La bande donnant deux composantes à 1100 et 1200  $\text{cm}^{-1}$  dans la silice pure (spectre a) est due à des vibrations de valence

antisymétriques Si-O-Si; les bandes à 950, 800 et 485  $\text{cm}^{-1}$  sont dues respectivement à la vibration de valence Si-O du groupe SiOH, à une vibration de valence symétrique Si-O-Si et à la déformation O-Si-O (13).

Lorsque la précipitation a lieu en présence d'une grande quantité d'aluminium (spectre d) on observe une bande importante à 600  $\text{cm}^{-1}$  ainsi qu'une absorption marquée vers 980  $\text{cm}^{-1}$ , qui sont probablement dues à une phase libre d'alumine hydratée (13,14). Pour des teneurs intermédiaires en aluminium, on observe un élargissement vers les basses fréquences de la bande à 1100  $\text{cm}^{-1}$ . Ce glissement pourrait être dû à une modification des vibrations du squelette silicique (6,13,15) résultant de la substitution de Si par Al; cependant il pourrait également résulter de la présence en quantité croissante d'une phase alumine libre.

Les diagrammes de diffraction des rayons X des mêmes échantillons, présentés à la figure 2A, indiquent un net déplacement vers les valeurs  $2\theta$  élevées de la bande de diffusion des rayons X de la silice, qui reflète une perturbation du squelette silicique par l'aluminium et indique donc une incorporation de cet ion. Les fins pics présents sur le diagramme d sont dus au nitrate de calcium.

Le spectre de la silice pure précipitée à pH 9 en présence de calcium (figure 1B, spectre a) présente une bande de valence SiO qui est élargie vers les basses fréquences, en comparaison de la silice précipitée à pH 4. Cet élargissement indique une perturbation du squelette silicique par le calcium; en effet il ne se manifeste pas si le calcium est remplacé par le sodium. La perturbation est confirmée par la comparaison des diagrammes de diffraction de la silice précipitée à pH 4 et 9 (figures 2A et B, diagramme a). Il convient de signaler que cette incorporation de calcium au squelette silicique ne se produit pas si la précipitation a lieu en mettant en œuvre des réactifs 10 fois plus dilués.

L'évolution de la bande de valence Si-O des produits précipités à pH 9 indique une perturbation très nette du squelette silicique par l'aluminium (figure 1B, spectres b,c,d); cette perturbation est confirmée par l'évolution des diagrammes de diffraction des rayons X (figure 2B). Les pics observés à  $2\theta = 29.5^\circ$  à la figure 2B et à 875  $\text{cm}^{-1}$  à la figure 1B sont dus à la présence de  $\text{CaCO}_3$  résultant de l'exposition des échantillons à l'air.

Le traitement d'un coprecipité silice-alumine par HCl donne lieu à une extraction progressive de l'aluminium et à la restauration d'une bande à 1100-1200  $\text{cm}^{-1}$  typique de la silice pure. Il est connu que la carbonatation du ciment donne lieu à la production de silice et de carbonate de calcium à partir des silicates de calcium hydratés (16). La figure 3A présente le spectre d'un produit obtenu par précipitation d'un sol silicique à pH 13, de concentration  $\text{Si}=0.4\text{M}$ , avec un rapport molaire  $\text{CaO/SiO}_2 = 3/1$ ; la bande de valence SiO indique que le squelette silicique est nettement plus perturbé que lors de la précipitation à pH 9 (figure 1B, spectre a). Une carbonatation de ce produit a été réalisée en faisant barboter du  $\text{CO}_2$  dans la suspension obtenue immédiatement après précipitation, jusqu'à obtention de différentes valeurs du pH. Les spectres infrarouge de ces produits carbonatés (figure 3A) illustrent la restauration d'un squelette silicique non perturbé; le produit obtenu après carbonatation complète donne des bandes de la silice

identiques à celles obtenues après attaque acide.

Fig. 3. - Spectres infrarouge :  
A - Silice précipitée par la chaux en milieu de concentration  $\text{Si} = 0.4\text{ M}$  et de rapport  $\text{CaO/SiO}_2 = 3$  (a); silice précipitée puis soumise à une carbonatation jusqu'à pH 10 (b), 8 (c), 6 (d); silice précipitée, séchée puis traitée par HCl (e).  
B - Silico-alumine précipitée à la chaux ( $\text{Al/Si}=0.45$ ,  $\text{Si+Al}=0.5\text{ M}$ ,  $\text{CaO/SiO}_2=3$ ) obtenue comme telle (a), soumise à une carbonatation après précipitation (b), traitée à l'acide (c).

La figure 3B permet de bien distinguer la formation de liaisons silice-calculum et silice-aluminium. Le produit de départ a été précipité à pH 13 à partir de réactifs donnant les proportions suivantes  $\text{Ca/Si} = 3$ ,  $\text{Si/Al}=2.2$  et une concentration globale  $\text{Si+Al}=0.5\text{ M}$ . Une carbonatation intense de la suspension donne lieu à l'extraction du calcium et à une réorganisation partielle du squelette silicique (spectre b) dont la bande SiO est typique d'une silico-alumine (voir figure 1B, spectres b et c). Une attaque acide complète la réorganisation du squelette silicique (spectre c).

#### REACTION DE METAUX DE TRANSITION AVEC LA SILICE

Les produits se rapportant aux figures 4 et 5 ont été obtenus à partir d'une concentration  $\text{Si} = 0.07\text{ M}$  dans le milieu réactionnel.

La figure 4A présente les spectres infrarouge de la silice pure, du produit de coprecipitation de la silice avec  $\text{Fe}^{3+}$  dans un rapport  $\text{Si/Fe} = 3/1$  et d'un produit similaire contenant du cuivre et du nickel dans un rapport atomique  $\text{Si/Ni} = \text{Si/Cu} = 10/1$ . La forme de la bande Si-O indique une perturbation du squelette silicique par les métaux de transition, cette perturbation est confirmée par les diagrammes de diffraction des rayons X (figure 5A), qui montrent un élargissement marqué de la bande de la silice.

La figure 4B présente les spectres de la silice pure précipitée à pH 9; l'interaction de la silice avec le calcium est très faible en raison de la dilution du milieu. Les autres spectres se rapportent aux produits de coprecipitation correspondant aux rapports atomiques  $\text{Si/Ni} = 10/1$ ,  $\text{Si/Cu} = 10/1$  et

Si/(Cu + Ni) = 10/1. Dans tous ces cas on observe un élargissement vers les basses fréquences de la bande SiO<sub>2</sub>, qui reflète une interaction entre la silice et les métaux de transition. Il faut souligner que la perturbation du squelette silicique par Cu et Ni est observée pour un faible rapport ion métallique/Si, de l'ordre de 1/10. Les diagrammes de diffraction des rayons X présentés à la figure 5B montrent que l'incorporation de Ni et Cu est plus marquée à pH 9 qu'à pH 7.

Fig. 4. - Spectres infrarouge de produits précipités en milieu de concentration Si=0.07 M.

A - à pH 7: (a) silice pure; (b) Si/Fe=3/1; (c) Si/(Cu+Ni)=10/1.  
B - à pH 9: (a) silice pure; (b) Si/Cu=10/1; (c) Si/Ni=10/1; (d) Si/(Cu+Ni)=10/1.

Fig. 5. - Diagrammes de diffraction des rayons X : A - (CoK<sub>α</sub>): (a) silice pure, pH 7; (b) Si/Fe=3/1, pH 7; (c) Si/Fe=3, Si/(Cu+Ni)=10, pH 7. B - (CuK<sub>α</sub>): (a) silice pure pH 7, (b) Si/(Cu+Ni)=10, pH 7; (c) Si/(Cu+Ni)=10, pH 9.

Ces résultats montrent que la rétention de métaux de transition par une silice peut se faire par des

liaisons chimiques et n'est pas limitée à une simple adsorption à la surface de particules siliciques (17,18).

Nous avons examiné l'influence du pH de coprécipitation sur le taux de fixation du cuivre et du nickel. A cet effet nous avons mesuré la quantité de ces métaux soustraite à la solution aqueuse lors de la précipitation de silice, de silice en présence d'aluminium avec un rapport Si/Al = 3/1, de silice en présence de fer avec un rapport Si/Fe = 1/1; la concentration initiale du milieu réactionnel était de 10 ppm en Ni et Cu; la quantité de silice mise en oeuvre correspondait à un rapport Si/Ni = Si/Cu = 200.

La figure 6 montre l'évolution du degré d'élimination du nickel et du cuivre en fonction du pH de précipitation. La case A donne, à titre de référence, les résultats attendus sur base d'une simple précipitation des hydroxydes, calculés à partir du produit de solubilité. Ces résultats indiquent que la coprécipitation avec la silice permet l'élimination du nickel et du cuivre à des pH bien inférieurs au pH de précipitation. Il apparaît en outre que la présence d'aluminium ou de fer est favorable à une fixation à plus bas pH.

Fig. 6. - Degré d'élimination du nickel et du cuivre à différents pH (10 ppm en Ni et Cu; rapport Ni/Si = Cu/Si = 1/200):

A - résultats attendus sur base d'une simple précipitation;

B - résultats obtenus par précipitation de silice; C - résultats obtenus par coprécipitation de silice et d'aluminium (Si/Al = 3);

D - résultats obtenus par coprécipitation de silice et de fer (Fe/Si = 1/1).

Traits pleins : Cu, traits discontinus : Ni.

Il ne nous est pas possible de discuter ici les explications de cet effet d'entraînement par l'aluminium et le fer. Il peut être lié aux phénomènes transitoires qui se produisent lorsque le sol silicique est porté au pH imposé pour la coprécipitation; on peut notamment imaginer que, grâce à leur affinité pour la silice à bas pH, ces ions bloquent la polymérisation de la silice et préservent une réactivité qui se manifeste à pH plus élevé.

L'importance de la concurrence entre la polymérisation de la silice et l'incorporation d'autres ions est illustrée par un examen de l'influence des conditions opératoires. Nous avons étudié la précipitation de silice en présence d'aluminium (Si/Al = 3/1)

et de nickel et cuivre ( $Si/Ni = Si/Cu = 20$ ); la concentration du milieu réactionnel en Ni et Cu était de 100 ppm. Outre une coprécipitation à pH 7, nous avons réalisé une neutralisation du sol silicique additionné des métaux par addition d'un lait de chaux à différentes vitesses jusqu'à montée du pH à 7.

Les taux d'élimination du nickel et du cuivre de la solution sont comparés pour différentes conditions opératoires à la figure 7. L'influence sur le cuivre n'est pas marquée en raison de sa faible solubilité à pH 7; par contre il apparaît clairement que l'élimination du nickel est favorisée par une élévation rapide du pH.

Fig. 7. - Influence du mode de précipitation du système sol silicique-métaux sur le taux de fixation de ces derniers par la silice ( $Si/Al = 3/1$ ;  $Si/Ni = Si/Cu = 20$ ): montée jusqu'à pH 7 en 4 jours (A), en 2 jours (B), en 2 minutes (C); coprécipitation à pH 7 (D).

Traits continus : Cu; traits discontinus : Ni.

Nous avons déjà souligné qu'une simple adsorption des métaux lourds sur la surface des particules de gel ne peut rendre compte des caractéristiques structurales des produits obtenus. En raison de ces derniers résultats on ne peut attribuer une part importante de l'élimination des métaux de transition à une induction par la surface silicique de la précipitation des hydroxydes. L'influence du mode opératoire peut s'expliquer par le fait qu'une polymérisation relativement lente, à des pH où les ions  $Cu^{2+}$  et  $Ni^{2+}$  sont très solubles, produit une silice qui incorpore peu de nickel et de cuivre et est incapable d'en incorporer par la suite. Au contraire une réaction rapide, se produisant d'emblée dans des conditions où les ions  $Cu^{2+}$  et  $Ni^{2+}$  ne sont pas trop solubles permet à la

silice en voie de polymérisation d'incorporer ces derniers.

## CONCLUSION

Notre étude montre que la simple précipitation d'une silice en présence d'ions métalliques donne lieu à leur élimination de la solution. Les spectres infrarouge et les diagrammes de "diffraction" des rayons X des solides obtenus montrent qu'il y a une perturbation réelle du squelette silicique par les ions et donc formation de liaisons chimiques entre la silice et les ions; il ne s'agit pas d'une simple adsorption d'ions par la silice ou de l'induction par celle-ci de la formation d'hydroxydes métalliques. Cette incorporation peut se faire à un pH légèrement plus bas que le pH de précipitation des hydroxydes; elle implique que la polymérisation de la silice ne soit pas trop poussée avant que l'on atteigne ce pH.

# Caractérisation des boues d'hydroxydes

## *Characterization of hydroxide sludges*

J.M. BLANCHARD, Maître-Assistant, Laboratoire de Chimie Physique Appliquée et d'Environnement, I.N.S.A., 20, avenue Albert-Einstein, 69621 Villeurbanne, France.

RESUME : Préalablement à toute opération de prétraitement visant à solidifier ou à atténuer le potentiel polluant d'un résidu industriel ayant la consistance d'une boue, il est nécessaire de disposer d'une démarche analytique comparative permettant d'apprécier l'impact du déchet initial et du produit résultant du traitement de solidification de ce même déchet.

Cette démarche, que nous avons appliquée aux boues d'hydroxydes, s'inscrit dans une approche scientifique de l'impact de la mise en décharge des résidus industriels.

SUMMARY : Previously to every processing action aimed at solidifying an industrial waste which has a sludge consistence or weakening its polluting potential, it is necessary to have at its disposal a comparative analytical procedure allowing to estimate the impact of the initial waste and that of the product obtained through the solidifying process of this waste.

This procedure that we applied to hydroxide sludges is inscribed in a scientific approach of the impact of the landfill of industrial wastes.

## 1.- Aspect théorique - Solubilité des hydroxydes en fonction du pH.

La préparation de surfaces métalliques à base de fer ou d'alliages de métaux de la même famille nécessite souvent une attaque en milieu acide à l'aide de réactifs en solution aqueuse tels que HCl, H<sub>2</sub>SO<sub>4</sub>, HNO<sub>3</sub>, HF, H<sub>3</sub>PO<sub>4</sub> pris individuellement ou à l'état de mélange.

Cette attaque des métaux conduit à la formation de sels. Leur dissolution en milieu suffisamment acide donne une solution des ions constitutifs, donc en particulier du cation plus ou moins hydraté.

Si nous ajoutons une solution de base forte, soude, potasse ou comme on le fait souvent dans l'industrie de la chaux, nous allons rendre le milieu progressivement plus basique, et nous constaterons souvent la précipitation d'une espèce nouvelle dont la solubilité est faible, dans les conditions de pH atteintes.

Ce précipité peut ensuite se maintenir ou se dissoudre lorsque nous augmenterons le pH. Il s'agit donc d'un phénomène de solubilité lié au pH qui peut se traduire par les réactions équilibrées suivantes :

$$(n'' < n')$$

Nous avons alors les relations suivantes :

$$K_{S1} = [M^{n+}][OH^{-}]^n \quad \text{soit} \quad [M^{n+}] = \frac{K_{S1}}{[OH^{-}]^n} = K [H_3O^{+}]^n$$

$$\text{avec } K = \frac{K_{S1}}{[OH^{-}] \cdot [H_3O^{+}]} = \frac{K_{S1}}{K_a}$$

$$\text{puis } K_{S2} = \frac{\left[ MO_{\frac{n+n''}{2}}^{n'-\frac{n+n''}{2}} \right]}{[OH^{-}]^{n'}} \quad \text{soit :}$$

$$\left[ MO_{\frac{n+n''}{2}}^{n'-\frac{n+n''}{2}} \right] = \frac{K'}{[H_3O^{+}]^{n'}} \quad \text{avec :}$$

$$K' = K_{S2} [OH^{-}]^{n'} [H_3O^{+}]^{n'} = K_{S2} \cdot K_a^{n'}$$

La solubilité de l'espèce métallique considérée s'écrit :

$$S = [M^{n+}] + \left[ MO_{\frac{n+n''}{2}}^{n'-\frac{n+n''}{2}} \right]$$

ce qui permet d'écrire :

$$S = K [H_3O^{+}]^n + \frac{K'}{[H_3O^{+}]^{n'}}$$

Ce calcul n'est valable bien sûr que lorsque la solution est saturée puisque nous avons établi cette équation à partir des relations données par le produit de solubilité.

S varie en fonction du pH suivant la courbe (1). Les deux branches sont des fonctions exponentielles. La branche de gauche varie surtout comme  $K [H_3O^{+}]^n$  ou  $K \times 10^{-npH}$ , celle de droite comme  $K'/[H_3O^{+}]^{n'}$  ou  $K' \times 10^{n'pH}$ .

Ainsi, nous avons traité dans son ensemble le problème des hydroxydes amphotères. Les hydroxydes insolubles en milieu plus basique auraient seulement la branche de gauche comme courbe de solubilité.

Enfin, il est intéressant de noter l'effet tampon des hydroxydes ; en considérant la forme de la courbe de solubilité des hydroxydes en fonction du pH, nous voyons que, si nous sommes en présence d'un excès de précipité, le pH de la solution se maintient fixé à une valeur presque constante, tant que l'hydroxyde précipité n'est pas complètement dissous.

Considérons à titre d'exemple 1000 g d'hydroxyde de manganèse Mn(OH)<sub>2</sub> qui sont lessivés par 1 l d'eau de pluie renfermant 49 mg d'acide sulfurique par litre (eau de pluie polluée), soit 10<sup>-3</sup> mole de proton H<sup>+</sup>. Que va-t'il se passer ?

$$\text{Dans l'eau pure on a } [Mn^{++}] = \frac{[OH^{-}]}{2}$$

$$K_S = 4 \times 10^{-14} (\text{mole.l}^{-1})^3 \text{ à } 18^{\circ}\text{C}$$

$$\text{et donc } \frac{[OH^{-}]^3}{2} = 4 \times 10^{-14} \quad [OH^{-}]^3 = 8 \times 10^{-14}$$

$$[\text{OH}^-] = \sqrt[3]{8 \times 10^{-14}} = 4,31 \times 10^{-5}$$

$$[\text{H}^+] = 2,32 \times 10^{-10}$$

$$\text{pH} = 9,63_4$$

Dans l'eau acidulée préalablement  $0,5 \cdot 10^{-3}$  mole de  $\text{Mn}(\text{OH})_2$  est attaquée selon :

Donc il reste un excès de  $\text{Mn}(\text{OH})_2$  et le nouveau pH peut être calculé d'après la réaction de solubilité.

$$4 \times 10^{-14} = [0,5 \times 10^{-3} + \frac{x}{2}] [x]^2$$

$\frac{x}{2}$  étant la fraction de  $\text{Mn}(\text{OH})_2$  provenant de l'équilibre de solubilité. Il vient :

$$x^3 + 1 \times 10^{-3} x^2 - 8 \cdot 10^{-14} = 0$$

On trouve alors :

$$x = 8,9 \times 10^{-6} \text{ mole.l}^{-1}$$

$$\text{pH} = 8,95$$

Il est clair que si le pH a varié de façon relativement importante, cela est dû à la faiblesse des concentrations en  $\text{Mn}^{++}$  ; mais malgré cela, il va y avoir un apport de 27,5 mg/l de  $\text{Mn}^{++}$  dans le lessivât.

Ce qui vient d'être dit pour le manganèse est tout aussi valable pour les autres ions métalliques et surtout pour les métaux lourds.

Tout apport d'acide faible ou fort a pour conséquence de libérer des ions métalliques toxiques, même si la quantité libérée est négligeable vis-à-vis de la masse d'hydroxydes. Cette seule considération justifie pleinement la solidification de ces composés dans une matrice minérale présentant des propriétés basiques et difficilement lixiviable dans le milieu naturel.

## 2.- Aspect pratique. Neutralisation des solutions acides industrielles par la chaux.

### a - Cas "idéal"

Il semble a priori relativement simple de neutraliser correctement à la chaux une solution acide contenant seulement plusieurs sels métalliques ; apparemment, il suffirait de maintenir un pH dans la solution tel que la solubilité de tous les différents hydroxydes concernés tende vers une valeur nulle.

En fait la précipité obtenu, une fois décanté et convenablement déshydraté (filtre presse par exemple), s'il est placé tel quel et sans précautions dans le milieu naturel risque sous l'influence des acides humiques, d'acides faibles organiques provenant de fermentation, des eaux de pluies, ou même de réactions d'oxydo-réduction en son sein, de se redissoudre et d'introduire des ions métalliques dans le circuit des eaux naturelles.

L'intérêt d'utilisation de la chaux se trouve à la fois dans son faible coût, mais aussi parce qu'elle permet d'éliminer à l'état de sels de calcium les

anions de certains acides (sulfates et fluorures) selon :

Mais à nouveau si le pH redevient acide ( $\text{pH} < 5$ ) la solubilité de ces sels augmente et les ions fluorures sulfates et phosphores repassent en solution, ce qui est extrêmement gênant.

### b - La "dure réalité"

En fait, les solutions acides industrielles sont des mélanges extrêmement complexes. Elles renferment généralement :

- des cations métalliques "simples" -  $\text{Cu}^{++}$ ,  $\text{Ni}^{++}$ ,  $\text{Mn}^{++}$ ,  $\text{Co}^{++}$ ,  $\text{Fe}^{++}$ ,  $\text{Fe}^{+++}$ ,  $\text{Cr}^{+++}$ , qui peuvent déjà poser des problèmes d'oxydo-réduction ;
- des ions minéraux complexes non précipitables à la chaux qu'il faudra préalablement traiter -  $\text{Cr}_2\text{O}_7^{--}$ , ( $\text{Cr}^{6+}$ ),  $\text{NH}_4^+$ ,  $\text{CN}^-$ , ...
- des agents complexants minéraux ( $\text{NH}_4^+$  par exemple) ou organiques (pyridine, E.D.T.A. ...) qui entravent la précipitation ;
- des composés organiques plus ou moins toxiques, huiles, hydrocarbures, solvants, des phénols, des détergents.

Il est inutile de préciser que le produit résultant du traitement à la chaux de telles solutions est fort loin des hydroxydes dont nous avons parlé dans le paragraphe 1.

### 3.- Le problème analytique

La complexité des mélanges obtenus rend illusoire, coûteuse et absurde une analyse physico-chimique complète.

Les seules propriétés intéressant l'élimination d'un tel résidu sont celles qui concernent les interactions de ce dernier et des eaux météorites que l'on peut trouver sur un site de décharge.

Il faut donc disposer d'un test facile à mettre en œuvre, répétable et peu coûteux pour comparer les potentiels polluants d'un résidu seul et d'un même résidu préalablement solidifié,

C'est en tenant compte de telles constatations que nous avons mis au point une démarche analytique [\*\*] permettant de comparer des échantillons de boues hydroxydes entre eux. Nous avons testé au laboratoire dans le cadre de cette démarche une centaine d'échantillons de boues d'hydroxydes.

[\*\*] Contrat I.N.S.A.-M.E.C.V.- Mise au point d'un protocole d'extraction à l'eau des substances solubles ou entraînables contenues dans un déchet solide ou pâteux - Décembre 1979.

Le protocole expérimental que nous avons mis au point consiste à réaliser à l'aide d'une agitation mécanique l'extraction des composés solubles ou entraînables jusqu'à obtention de paramètres physico-chimiques constants (résistivité, pH, mesure d'oxydabilité : C.D.T., D.T.O. ou D.C.O.).

Nous vérifions par une seconde extraction le niveau de solubilité ou d'entraînement des substances extractibles.

L'étude d'un déchet s'effectue alors selon l'organigramme ci-dessous :

- |                               |  |
|-------------------------------|--|
| 1/ IDENTIFICATION préalable   | { Enquête sur place. Renseignements généraux.<br>Filiation du déchet. Toxiques présumés.   |
| 2/ ANALYSES AU LABORATOIRE    | { Evaluation massique et volumique des phases (eau, boue, huile, émulsion ...).<br>Recherche qualitative des éléments ou combinaisons.<br>EVALUATION DES PARAMETRES CHIMIQUES LIES A LA MISE EN DECHARGE.<br>Test de lixiviation. ANALYSES EAUX USEES. |
| 3/ EXPLOITATION DES RESULTATS | { Bilan total des toxiques.<br>Orientation éventuelle des prétraitements.<br>Essais particuliers.  |

#### 4.- Conclusions pratiques.

Tout d'abord, il faut noter que sous la même appellation plus ou moins précise, se trouve une palette extrêmement étendue de résidus.

Sous l'appellation de boues ferritiques se trouvent toutes sortes de produits de décapage de tôles ou de fûts qui peuvent contenir en plus du fer sous forme  $Fe(OH)_2$ , des traces de métaux lourds (Pb, Cd, Mo ...), mais aussi parfois jusqu'à 10% d'huile (sur la boue brute), voire même d'autres dérivés organiques (phénols, détergents, agents complexants ...) qui peuvent poser de graves problèmes pour leur mise en décharge.

En plus, si ces boues dites ferritiques contiennent des quantités notables de  $Fe(OH)_2$  elles s'oxydent à l'air en  $Fe(OH)_3$ , ce qui a pour conséquence de faire chuter le pH par production de protons et donc de permettre la mise en solution de métaux lourds par exemple.

Enfin, pouvant être considérées en général comme bien traitées, les boues dites de  $Cr^{3+}$  qui présentent en général une teneur faible en éléments solubles ou lessivables.

Les problèmes les plus graves sont posés par les boues de centres de détoxification dont la composition varie d'un jour à l'autre et au sein desquelles se trouvent parfois à côté de quantités importantes d'ion ammonium, des complexants organiques (Pyridine, E.D.T.A.) engendrant des fuites chroniques de métaux complexés (Cu, Ni, Cd, ...).

La pollution saline engendrée par les boues hydroxydes est souvent négligeable, sauf accident (cyanures ou  $Cr^{6+}$  non éliminés par les traitements préalables à la précipitation des hydroxydes) eu égard à la toxicité potentielle des métaux lourds sous forme ionique.

Ces remarques engendrent deux conclusions précises au niveau des traitements de ces boues :

- 1/ La nécessité de toujours travailler avec un notable excès de chaux, même si les eaux résultant du traitement ont un pH supérieur à 9 ("fuites" de chaux), car ainsi les boues obtenues ne risquent pas de relarguer rapidement des ions des métaux constituant des hydroxydes.
- 2/ La solidification d'une boue est une opération difficile car la complexité des mélanges traités conduit à ne considérer que des cas d'espèces.

# Importance de l'absorption des ions métalliques sur les surfaces minérales dans le procédé de flottation

## *Importance of metallic ions absorption on the mineral surfaces in the floating process*

V. FORMANEK, Ingénieur E.N.S.C.T., Conseiller Technique de Minemet Recherche (Groupe « IMETAL »), France.

### R E S U M E.-

La modulation de la solubilité des ions métalliques est à la base du procédé de valorisation des minerais par flottation.

Les ions métalliques libérés au cours des différentes phases du processus sont neutralisés par l'utilisation de toutes les forces d'origine chimique ou physico-chimique qui se développent à l'interface solide-liquide et par l'addition de réactifs tels que la chaux, les silicates, etc.....

L'importance de l'hydratation et des structures minérales environnantes sur la précipitation des ions métalliques est soulignée.

-:-:-

## 1.- INTRODUCTION.-

L'absorption sélective d'ions minéraux et organiques sur la surface de particules minérales en suspension dans l'eau est à la base du procédé de flottation.

Pour séparer les minéraux de valeur, préalablement libérés de leur gangue par le broyage, l'industrie utilise à grande échelle le procédé de flottation qui fait appel aux différences des propriétés physico-chimiques des surfaces. On utilise des réactifs, qui se fixent spécifiquement sur les minéraux de valeur à récupérer, qui rendent leur surface hydrophobe afin de permettre l'accrochage de bulles d'air.

Ce sont les bulles d'air, finement dispersées dans la pulpe, qui effectuent le tri entre les grains hydrophobes et les grains hydrophiles circulant dans les cuves de traitement.

La plupart des réactifs organiques utilisés pour hydrophobiser la surface forment un composé insoluble avec l'ion du métal à récupérer.

On utilise par exemple des xanthates pour former des composés insolubles avec le plomb, le cuivre, l'argent, etc....., ou encore des acides gras pour former des composés insolubles avec les ions calcium, fer, tungstène etc... de la surface du minéral.

Ce sont les ions actifs de la surface du minéral qui interviennent directement dans le procédé de flottation.

Mais le minéral de valeur à récupérer par insolubilisation et hydrophobisation de sa surface est environné d'autres minéraux qui libèrent des ions métalliques et non métalliques qui peuvent perturber complètement le procédé de flottation.

La flottation est un système à trois phases : solide - eau - air.

Or, lorsqu'un solide est immergé dans l'eau, il y a interaction avec les molécules polaires de l'eau et les ions de la surface du solide. Les énergies de liaison hydrogène de l'eau avec les sites non électriquement saturés de la surface du solide conduisent à la formation d'une atmosphère de molécules d'eau dipole fortement orientées ; cette surface est alors hydrophyle.

Plus la surface du solide a une charge électrostatique élevée, plus la surface est hydratée.

La plupart des minéraux immergés dans l'eau possèdent une charge superficielle due :

- soit à des remplacements isomorphiques dans le réseau,
- soit à un déficit ou un excès superficiel d'ions constitutifs du réseau,

- soit à la formation sur la surface d'acides faibles par suite de l'hydratation de groupements superficiels. (Cas des oxydes, des silicates, des carbonates, des phosphates, etc...).

Les solides ont alors un comportement d'échangeurs d'ions. Ainsi dans une eau pure, à la température ambiante, il se dissout :

- 2,4 mg/litre de sulfate de baryum
- 14,3 mg/litre de carbonate de calcium
- 16 mg/litre de fluorure de calcium

Enfin, l'hydratation d'une surface solide peut aboutir à une réaction chimique comme la décomposition de sulfures, formation d'hydroxydes, etc...

Il en résulte qu'un certain nombre d'ions sont mis en solution dans l'eau. Ces ions vont réagir avec les zones des surfaces de minéraux à haut potentiel d'énergie pour tendre vers le point de charge nulle (PCN).

Lorsque la liaison normale est d'origine électrostatique, l'absorption est contrôlée par le pH de la solution.

Selon la nature des charges (électrostatique, chimique ou physique), l'absorption des ions sera réversible ou irréversible.

Les paramètres qui déterminent le degré d'absorption des ions de la pulpe sont principalement la stabilité de la surface (importance et nombre de sites à énergie libre), la surface spécifique, la concentration dans la pulpe de l'absorbant et de l'absorbat, la valeur du pH, les conditions d'agitation.

La quantification des interactions qui se produisent à l'interface eau-minéral peut être faite par les méthodes électro-cinétiques, par la détermination de la solubilité des composés qui se forment en fonction du pH et de la réaction du réactif collecteur avec le minéral. On utilise de plus en plus les diagrammes de potentiel des systèmes Métal-ion-eau, proposés par Du RIETZ et de POURBAIX, et qui maintenant sont établis sur ordinateur. (1)

D'autres moyens d'investigation électro-niques sont en cours de développement pour avoir une meilleure connaissance du mécanisme de l'absorption et du chimisme de l'interface. (2)

- (2) J.L. Cécile et G. BARBERY "Techniques nouvelles de l'étude des interfaces" Congrès de la Sté de l'Industrie Minérale - Perpignan - 1979.

Il est de première importance dans le procédé de flottation de pouvoir maîtriser à tous les stades du traitement la solubilité des différents ions présents dans l'eau et à l'interface solide-eau.

## 2.- MODULATION DES IONS METALLIQUES DE LA PULPE AU STADE DU BROyage.-

L'importance de la mobilité des ions métalliques apparaît dès la première phase du traitement qu'est le broyage et dont la fonction est de libérer les minéraux de valeur plus ou moins finement imbriqués dans la gangue stérile. En fonction de ses caractéristiques et de son schéma de traitement, le minerai subit un broyage plus ou moins fin, en un ou plusieurs étages.

Le schéma de broyage, les types d'appareils et de corps broyants, les additifs de broyage, auront une influence sur le nombre de sites à énergie libre des particules créées et sur les ions métalliques solubilisés ou précipités.

Le broyeur est un réacteur, où par suite de la formation de surfaces nouvelles, par suite de la transformation de l'énergie en chaleur, par suite des conditions intenses de mélange, par suite de l'aération, se produisent des interactions importantes à l'interface solide-eau.

Un certain nombre d'ions des substances minérales passent en solution pour être immédiatement plus ou moins réabsorbés sur les surfaces fraîches.

Les sulfures de plomb, de cuivre, de zinc, de fer, sont soumis, sous l'action combinée de l'oxygène et de l'élévation de la température de la pulpe au cours du broyage, à des réactions d'oxydation avec libération d'ions métalliques qui se refixent sur les sites des surfaces à haute énergie libre des surfaces. Ces phénomènes sont accentués lorsque la gangue est basique.

IL en résulte pour le procédé de flottation une diminution importante de la sélectivité et des rendements métalliques.

Les remèdes connus jusqu'à présent consistent à neutraliser in situ les ions métalliques par insolubilisation soit par addition d'un réactif collecteur organique (xanthate, di-thio-phosphate), soit par précipitation à la chaux, au carbonate de soude, au silicate de soude, soit par cémentation sur de la poudre de fer métallique ajoutée au broyeur. "Quelques facteurs influençant la sélectivité dans la flottation différentielle des minerais plomb-zinc, particulièrement en présence des minéraux oxydés du plomb".  
Congrès de Préparations des Minerais -  
Londres 1960.

Ces moyens d'insolubilisation des ions métalliques ne sont pas cependant d'une efficacité absolue comme le montrent les essais comparatifs avec des broyages à sec ou en broyeurs auto-gènes, dans lesquels les ions métalliques ne sont pas autant libérés.

Indépendamment de la modification des niveaux d'énergie, un broyage très poussé, en augmentant considérablement la valeur de la surface spécifique du minéral broyé, peut accroître sa solubilité. Des micro-particules de calcite, d'anglésite, de malachite, etc..., se dissolvent et viennent accroître la quantité de sels solubles qui ont un effet nocif en flottation.

Un autre phénomène prend également plus d'importance dans les broyages fins, c'est le "slime coating". Certaines fines particules se fixent aux particules plus grossières, probablement surtout par des forces d'origine chimique.

La calcite, l'hématite, par exemple, sont fréquemment responsables, par suite du phénomène de slime coating, de mauvais rendements. Nous verrons plus loin que ce "slime coating" peut, par contre, être bénéfique pour le piégeage des ions des métaux lourds dans les boues de décantation, lors des séparations solide-liquide.

Dans certaines conditions de broyage (broyage ultra-fin, broyage dans des systèmes à forte dissipation d'énergie sous forme de chaleur) des surfaces minérales verront leur niveau énergétique homogénéisé vers le niveau le plus bas ; il y aura amorphisation. On aura une insolubilisation des ions métalliques. (\*)

L'amorphisation des surfaces n'est pas recherchée ici puisqu'elle détruit les différences de propriétés de surface qui sont précisément utilisées dans les procédés de séparation par flottation.

### 3.- MODULATION DES IONS METALLIQUES DE LA PULPE AU STADE DE LA FLOTTATION.-

Dans la phase de flottation proprement dite, les minéraux, sous forme d'une suspension aqueuse entre 20 et 50 % de solide, fortement aérée, reçoivent des réactifs modulateurs de l'hydrophilie des différentes espèces de particules : régulateurs de pH, sequestrants ou précipitants des ions métalliques, collecteurs, moussants.

Toutes les surfaces de sulfures métalliques mises en contact avec de l'eau aérée s'oxydent. L'oxydabilité des sulfures métalliques dépend de l'environnement et du type de sulfure ; elle croît dans l'ordre : galène, pyrite, blende, chalcopryrite, pyrrhotine, mispickel.

Dans les pulpes, il y a de nombreux consommateurs d'oxygène : certains sels dissous comme les sels ferreux et cuivreux, le fer d'abrasion des boulets et des revêtements métalliques des appareils, la présence de minéraux fortement oxydables.

Aussi, étant donnée la complexité des phénomènes intervenant simultanément dans la pulpe de la flottation des minerais polymétalliques, la mise au point des conditions opératoires ne peut qu'être facilitée par le suivi du potentiel redox, la teneur en oxygène dissous, et le pH.

Dans toutes ces opérations, il s'agit d'insolubiliser sélectivement les ions des métaux lourds et des alcalino-terreux. On dispose de tout un arsenal de réactifs minéraux et organiques. (Thiosels, acides carboxyliques, alkylsulfates, alkylphosphates, amines, chélatants, cyanure, polyphosphates, silicates, tannins, charbon actif, colloïdes, etc....).

### 4.- MODULATION DES IONS METALLIQUES DE LA PULPE AU STADE DE LA SEPARATION SOLIDE-LIQUIDE.-

Dans la phase finale, décantation, séparation solide-liquide, l'insolubilisation des métaux lourds doit être alors non-sélective et aussi totale que possible. En effet, le plus généralement les eaux, après décantation, sont renvoyées par pompage au bassin de stockage des eaux industrielles avant d'être de nouveau recyclées dans l'usine de traitement.

Les réactifs utilisés en cours de traitement sont absorbés tout au long du circuit par le minerai, ou neutralisés.

Des analyses chimiques, biochimiques et toxicologiques montrent qu'on ne les retrouve sous aucune forme dangereuse dans les eaux résiduaires de l'usine.

Les résidus solides sont déversés dans des zones d'épandage spécifiquement aménagées pour éliminer tout risque de pollution mécanique

et pour répondre aux normes actuelles relatives à la protection du site et de son environnement.

A titre d'exemple, indiquons que l'usine de Largentière, dans l'Ardèche, avec une production journalière de 2.700 tonnes de minerai brut, sort environ 2.500 tonnes de rejets sous forme de pulpe que l'aire de stockage doit être en mesure d'emmagasiner et de décanter chaque jour ; ceci représente le traitement de près de 200 m<sup>3</sup>/heure d'eaux chargées de particules solides très fines. Depuis le démarrage de l'exploitation, plus de 5 millions de tonnes de solides furent ainsi déversés dans la zone d'épandage.

En ce qui concerne la qualité des eaux résiduaires, le tableau ci-dessous, extrait d'une publication récente sur la mine de St SALVY, indique que les teneurs en métaux lourds sont inférieures aux normes actuelles.

Tableau

Qualité des eaux résiduaires de l'usine de traitement de minerais de St SALVY.

Contrôle mensuel des effluents

Août 1978 - Quantités exprimées en mg/l

	Normes SSB	Normes Complément.	Teneurs SSB
pH	5,5 - 8		7,6
MeS	50		4,3

Fer		2	0,1
Plomb		1	0,0004
Zinc		6	0,4
Aluminium		2	0
Cobalt		3	-
Cr total		2,2	0
Etain		2	-
Mercure		0,1	0,0006
Total métaux lourds	15		0,505

Ce tableau est extrait de la "Monographie de la

laverie de Noailhac - SAINT SALVY" (de H. GISTAU et A. MILHAU - publiée dans la revue de l'Industrie Minérale de février 1980).

La faible quantité d'ions métalliques dans les eaux résiduaires des usines de traitement de minerais par le procédé de flottation s'explique, par le contrôle et l'ajustement du pH qui est réalisé de façon à obtenir la précipitation d'ions métalliques sous forme d'hydroxydes; et par l'exploitation des phénomènes d'absorption propres aux fines particules. (slimes).

En effet, l'action du pH seul, par addition de chaux par exemple, n'est pas suffisant car il y a formation de floccs d'hydroxydes volumineux qui sédimentent difficilement.

En présence de slimes minéraux, la situation est fortement modifiée : la précipitation des ions peut être obtenue à un pH beaucoup plus bas et par suite de l'absorption des floccs par le phénomène de "slime coating", ces ions métalliques sont piégés par les substances minérales.

Ce phénomène de "slime coating" varie naturellement en intensité avec le type de minéral utilisé. Les roches de type basique sont préférables aux roches de type acide.

La fluorine, le calcaire, la pyrite ( $\text{FeS}_2$ ), la pyrrhotine ( $\text{FeS}$ ), le feldspath, le quartz, peuvent être, par le phénomène de "slime coating", de remarquables sequestrants des ions métalliques.

Ainsi une tonne de particules, ayant une surface de  $20.000 \text{ cm}^2$  par  $\text{cm}^3$ , sequestrent entre 1 à 2 kg d'ions  $\text{Mg}^{2+}$ ,  $\text{Cu}^{2+}$ ,  $\text{Pb}^{2+}$ ,  $\text{Zn}^{2+}$ ,  $\text{Cd}^{2+}$ ,  $\text{Fe}^{2+}$ ,  $\text{Fe}^{3+}$ ,  $\text{Cr}^{3+}$ ,  $\text{Mn}^{2+}$ , présents dans les eaux.

Ces propriétés absorbantes des particules minérales, sous forme de slimes, sont précisément utilisées pour purifier des eaux industrielles ou des eaux urbaines. (\*).

En SUEDE, l'eau d'un lac au nord-ouest de Stockholm, polluée par des ions mercure provenant d'une usine proche, a été complètement assainie par addition de particules fines de fluorine et de calcaire. Ces substances minérales absorbaient, de façon irréversible, jusqu'à 10 kg de mercure par tonne.

L'absorption du mercure (et de l'arsenic) sur le calcaire ou sur la fluorine est renforcée par la présence de fer, sous forme métallique ou sous forme ionique.

Des essais ont montré que la pyrrhotine, à surface spécifique équivalente, pouvait fixer plus de 350 kg de mercure par tonne.

Le mercure est alors bloqué sous forme de sulfures de mercure particulièrement insoluble (produit de solubilité  $10^{-23}$ ).

Les slimes de calcite et de fluorine sont également utilisés pour abaisser la concentration des phosphates dans les eaux par formation de phosphate de calcium et de fluorophosphate insolubles.

Pour toutes ces opérations de purification des eaux, il faut utiliser des substances minérales fraîchement broyées.

## 5.- CONCLUSIONS.-

Les minéraux, notamment s'ils sont broyés, présentent, une fois immergés dans l'eau, une surface hétérogène avec des charges superficielles qui ont un rôle déterminant dans les mécanismes de l'absorption sélective des ions métalliques et des tensio-actifs. Ces absorptions sélectives sont à la base de la valorisation des minerais par le procédé de flottation.

C'est par la modulation de la solubilité et de l'absorption des ions métalliques à l'interface minéral-eau qu'il est possible de séparer sélectivement les minéraux de valeur de ceux de la gangue, en jouant sur l'hydrophobie et l'hydrophilie induite par l'addition de réactifs.

Les propriétés absorbantes des surfaces minérales peuvent être considérablement modifiées par le broyage, le temps de séjour dans l'eau, les ions environnants, etc....

Des recherches sont encore nécessaires pour mieux connaître les phénomènes d'hydratation des surfaces et le chimisme de l'interface.

Néanmoins, les interactions adsorbant-adsorbant à l'interface eau-substance minérale continuent d'être très largement exploitées à l'échelle industrielle pour la valorisation des minerais et pour la purification des eaux.

# Stabilizing industrial sludge for fill applications

## *Stabilisation des boues industrielles pour comblement d'excavations*

J.J. EMERY, Associate Professor, Department of Civil Engineering and Engineering Mechanics, Ms Master University, Hamilton, Ontario, Canada.

RESUME : Un procédé de stabilisation des boues industrielles a été mis au point récemment. La boue obtenue, qui sert à des fins de comblement d'excavations, répond à la fois aux besoins de la protection de l'environnement et à ceux du génie civil. Des mélanges contenant différentes proportions de boues, de cendres volantes, de poussières de fours, et de ciment, sont utilisés dans un procédé combiné "séchage-pouzzolanique-hydraulique", selon le degré de résistance exigé. Des tests de solidification et de solubilité sont décrits ainsi que les détails des essais faits dans des conditions normales et leurs résultats.

SUMMARY: A stabilization process for industrial sludge has been developed that meets both environmental and engineering requirements for use as fill. Various combinations and proportions of sludge with fly ash, waste kiln dusts, and cements are used in a combined drying/pozzolanic/hydraulic process, depending on the desired strength development. Laboratory solidification and solubility testing is described along with details on field trial procedures and results.

## INTRODUCTION

Expansion of a steel plant in Hamilton requires both the removal of a large quantity of very soft, high water content, industrial sludge from an old disposal area, and replacement with suitable fill to provide a construction site. Some treatment of the sludge to meet landfill disposal requirements would be required (1), and various stabilization methods have been evaluated in the laboratory and small field trials. It has been found that the sludge can actually be satisfactorily stabilized/solidified to meet both environmental (solubility of toxic constituents) and engineering (bearing capacity) requirements for industrial site fill applications. Thus, the disposal area reclamation process will consist of removing the sludge by stone fill displacement below the water surface and dredging (in progress), stabilization, and then return to the site to act as fill above the water table.

The stabilization process involves a number of possible combinations and proportions of sludge with stabilizing agents - fly ash, waste cement kiln dusts, waste lime kiln dusts, steel slag fines, portland cement, and slag cement - to give various strengths and rates of strength gain for the highly variable sludge. Industrial byproducts have been used where possible, with low level cement additions, to minimize stabilization materials costs. A wide range of these byproducts has also been evaluated to ensure supply continuity. Construction soil stabilization concepts have essentially been adopted involving initial drying by high surface area materials (fly ash, dusts) and then pozzolanic and/or hydraulic reactions as required. For disposal to landfill, just some drying and fairly low strengths (shear strength  $\approx 0.01$  to  $0.02$  N/mm<sup>2</sup>, equivalent to soft clay) are desirable, while for fill, initial handling strength and then high strength development (shear strength  $> 0.1$  N/mm<sup>2</sup>, equivalent to very stiff clay) is required.

As the various combinations and proportions of materials used are largely a function of the specific industrial sludge involved, masses of test data will not be given, but rather the methodology, and typical combinations and strengths. For the reader interested in a more complete review of stabilization/solidification technology than can be incorporated here, the volumes edited by Pojasek are excellent (2).

## INDUSTRIAL SLUDGE

The industrial sludge involved (approximately 300,000 m<sup>3</sup>) had been deposited over a number of years under lake level in an old harbour slip area adjacent to the plant. Geotechnical studies indicate the sludge is fairly consistent in appearance along the slip - very loose, oily, black, organic metallic (mainly iron oxide) waste - but highly variable in moisture content (29 to 75%, weight

of water to total weight used throughout), insitu bulk density (1300 to 1650 kg/m<sup>3</sup>), and loss on ignition (7 to 31%). While mainly of industrial origin from rolling mills, at early stages the slip received municipal sewage. In summary, a rather unpleasant and variable industrial sludge is involved.

## LABORATORY STABILIZATION TRIALS

A simple laboratory procedure for preparing and monitoring stabilized sludge was developed so that a wide range of stabilizing agents and addition rates could be considered to provide information for field trials and costing. This involved mixing the sludge with the selected quantities of stabilizing agents in a small Hobart mixer (or by hand) until consistent, placing this mix in 10 cm diameter by 10 cm high cans, sealing the can with both a twist lid and double plastic bags to maintain moisture conditions, and then taking penetrometer\* readings to monitor unconfined compressive strength development with time at 20°C(3). Supplemental tests included pH, moisture content, temperature and bulk density monitoring.

This approach is considered more representative of conditions in a large mass of solidifying sludge than open curing where significant strength development may be due to simple drying, rather than cementitious reactions. Other conditions can be readily simulated in the laboratory such as lowered or elevated temperatures and curing under water.

Some typical laboratory stabilization trials for a 46% moisture content sludge (combinations and proportions by weight, with 1, 7, 14 and 21 day penetrometer strengths in brackets) would include:

80% sludge/15% lime kiln dust (quick)/  
5% portland cement  
(0.29, 0.43,  $> 0.43$  N/mm<sup>2</sup>)  
80% sludge/15% lime kiln dust (quick)/  
5% slag cement  
(0.25, 0.31, 0.41, 0.43 N/mm<sup>2</sup>)  
80% sludge/15% cement kiln dust (bypass)/  
5% portland cement  
(0.04, 0.42, 0.43,  $> 0.43$  N/mm<sup>2</sup>)  
80% sludge/15% lime kiln dust/5% portland cement  
(0.12, 0.20, 0.22, 0.24 N/mm<sup>2</sup>)

\*Soiltest Pocket Penetrometer CL-700 which gives a direct measure of unconfined compressive strengths up to  $0.43$  N/mm<sup>2</sup> (4.5 TSF). For a safety factor of 3, these readings are very close to the safe bearing capacity for a footing at the surface of a cohesive soil. However, care should be taken in extrapolating to the field as correlations have not been checked.

80% sludge/15% fly ash (=8% carbon)/5% lime kiln dust (quick)  
(0.07, 0.12, 0.17, 0.18 N/mm<sup>2</sup>)  
75% sludge/15% lime kiln dust/10% fly ash (=8% carbon)  
(0.16, 0.27, 0.30, 0.34 N/mm<sup>2</sup>)  
75% sludge/20% cement kiln dust/5% portland cement  
(0.02, 0.20, 0.43, >0.43 N/mm<sup>2</sup>)  
75% sludge/15% fly ash (=8% carbon)/5% lime kiln dust/5% portland cement  
(0.12, 0.24, 0.43, >0.43 N/mm<sup>2</sup>)  
75% sludge/15% fly ash (=8% carbon)/5% lime kiln dust/5% slag cement  
(0.04, 0.12, 0.15, 0.31 N/mm<sup>2</sup>)

These results for stabilization trials meeting strength requirements for landfill and/or structural fill indicate that the high organic content is not stopping pozzolanic and hydraulic reactions, but probably inhibiting them to some extent. Quick (i.e. unslaked) lime kiln dust is much more efficient than ordinary calcitic or dolomitic lime kiln dust and slag cements require a fair degree of alkaline activators. The additive costs are in the Can.\$1.50 to \$4.00 range per tonne of final stabilized material. The combinations and proportions for satisfactory stabilization of a wide range of sludge moisture contents have been established.

To check that miniaturization of the laboratory strength gain tests is valid, some large, 90 kg samples were prepared with various stabilizing agents and mixed in an Eirich R-7 mixer using only the drum rotation to simulate a large stabilization plant pug-mill. Both sealed curing and curing under a 0.8 m head of water were considered at a 7 to 13°C temperature range to simulate cooler field conditions. Strength development monitored with a penetrometer and probe rod indicated similar results to parallel small samples. These results, particularly for the submerged curing, supported the laboratory test methodology adopted. While bearing capacity is the major geotechnical factor of concern, it is planned to complete laboratory triaxial, consolidation and permeability testing on specimens recovered from the early full-scale stabilization work (4).

#### SOLUBILITY TESTING

The major environmental concern with any industrial sludge is the potential level of soluble toxic constituents and their significance to the fill design. However, there are a number of solubility testing procedures and acceptable toxic constituent levels to choose from (5-9). The writer has adopted and modified an OECD solubility test procedure (7) as it gives the required solubility rate for each constituent of interest. Selection of the maximum allowable concentrations of toxic constituents is not easy as indicated by the range in Table I for various agencies.

The results for typical solubility tests on the raw and stabilized industrial sludge are

given in Table II. Batch kinetics and desorption isotherms indicated a 1 g sludge to 0.05 x distilled water ratio and 24 hour shaking to be appropriate. Unfortunately, the shaking at 3 Hz is rather aggressive, even on stabilized sludge, so there was continuous turbidity in the shaker flasks. After 24 hours, the shaker flask contents were allowed to settle, the supernatant drawn off and filtered, and the filtrate stored in a refrigerator until chemical analysis. This was repeated four more times although only the first, third and fifth shaking results are given in Table II. While not shown here, it is also possible to draw solubility curves from the data for each constituent as cumulative solubility in mg/g against cumulative filtrate in L/g.

The solubility data summarized in Table II indicate that the stabilization has reduced trace element constituent levels in all cases except copper and lead, but these are still well below the maximum allowable (EPA extract or Ontario industrial effluent in Table I for instance). While the alkalinity that results from the stabilization materials is important and very effective in limiting the solubility of many trace metals, this is probably not the case for copper and lead. Since the stabilized sludge was broken up before testing and then continually reduced during shaking (constant rates of solubility indicate this), the solubility test is far too severe to represent field conditions. This is now being checked by using a much gentler shaking action and column tests (6). Cadmium will also be considered in future solubility testing.

Regardless, it is clear that the stabilized sludge is fully acceptable from an environmental viewpoint.

#### FIELD TRIALS

Field trials to check the possibility of completing the stabilization in-situ (generally under water) without removing the sludge were completed early in the study. This involved the use of a large drag-line to mix waste cement kiln dust into the sludge. Where adequate mixing was achieved there was a noticeable stiffening of the sludge. Unfortunately, this process required too much machine time and there were substantial pockets of unstabilized sludge. It was decided at this stage that the sludge would have to be put through some sort of stabilization plant to produce the desired strength properties, and stabilized material would probably only be used for fill above the water table. A few simple trials using a large grader to mix sludge with waste kiln dusts confirmed that "proper" mixing resulted in the required stabilization. At this stage, the laboratory testing was emphasized to develop a range of suitable combinations and proportions of stabilizing agents.

- Notes: a. Using OECD test procedure adopted in Construction Materials Laboratory (7). Solid (70 g) to distilled water (pH 6.4) ratio of 1 g to 0.05 ℓ. Cr <0.01 mg/ℓ in all cases.  
b. Raw industrial sludge R. R-1, R-3 and R-5 filtrates from first, third and fifth 24 hour shaking respectively.  
c. Stabilized industrial sludge S - 75% wet sludge/15% slag cement/10% lime kiln dust (quick), cured 77 days and crushed. S-1, S-3 and S-5 filtrates from first, third and fifth 24 hour shaking respectively.

Recently, field trials have been completed to prepare for the proposed stabilization process. A rather efficient method has been developed for large field trials that allows a number of batches to be tested each day: a chute has been constructed that allows excavated sludge to be fed into a standard ready-mix truck; then the stabilizing agents are added using a small belt conveyor with the most reactive agent going in last to allow for visual control of initial stiffening; and after mixing, the batch is discharged at a location where strength monitoring can be completed on the stabilized sludge "lump". Samples are also taken for laboratory testing. As the summer weather in Hamilton can be very hot, the stabilized sludge is excavated to below any surface influences before using the penetrometer. In several cases the stiffening has been so rapid that water additions have been necessary to get the stabilized sludge out of the truck. After several days, it is possible to drive vehicles onto the stabilized sludge. This ready-mix truck operation proved so efficient that it has been adopted as an alternative to a large base stabilization plant for the production rates required.

While field evaluations are continuing, some typical results can be given:

72.8% sludge/13.7% fly ash/8.1% lime  
kiln dust/5.4% portland cement  
(0.41 N/mm<sup>2</sup> at 6 days)  
83.6% sludge/12.9% lime kiln dust/3.5%  
portland cement  
(0.28 N/mm<sup>2</sup> at 5 days)  
75.7% sludge/11.5% fly ash/9.9% lime  
kiln dust/2.9% portland cement  
(0.22 N/mm<sup>2</sup> at 5 days)

Based on these types of field results, final process (large ready-mix truck with central additive storage silos) and stabilization agent selection(s) (i.e. economics and availability, with waste lime kiln dust and slag cement favoured) were completed. It is estimated that the total cost for removal, stabilization and placement as fill is about Can. \$5.00 per tonne of stabilized material. This is most favourable compared to sludge disposal and fill material costs.

## CONCLUSIONS

It is hoped that at the time of the congress it will be possible to report on the progress of the full-scale field stabilization process and results. The concept of industrial sludge stabilization using industrial byproducts and low cement contents, and construction stabilization technology, appears most attractive. Hopefully other sludge applications will develop.

## ACKNOWLEDGEMENT

The assistance of D. Matchett with the experimental work is gratefully acknowledged.

# Solidification of sludges with cement-slag- $\text{CaSO}_4$

## *Solidification des boues à l'aide de ciment, de laitier et de gypse*

Tomonitsu SUGI, Koji KATAOKA, Shuzo YAMADA, Yutaka ANDO, Japan.

RESUME : Au Japon, il est devenu nécessaire, pour préserver l'environnement et assurer la sécurité des ouvrages à construire sur ces terrains, de traiter les boues qui se sont accumulées sur les bords des lacs et de la mer pendant des années.

Ce rapport a pour but de trouver un matériau de solidification bon marché, apte à traiter les boues en les solidifiant.

24 sortes de ciments ont été utilisées dans ces essais de solidification des boues, en faisant varier les diverses proportions du ciment portland, du laitier et du gypse.

On a observé que les mélanges de ciment et de laitier, dans des proportions allant de 40/60 à 20/80 pour une teneur en  $\text{CaSO}_4$  de 10 à 20 % avaient la résistance la plus élevée; cette résistance était dix fois plus élevée que celle donnée par le ciment Portland seul. Ces mélanges forment principalement de l'ettringite lors d'hydratation, et on peut penser que celle-ci crée une résistance élevée en se liant efficacement aux hydrates.

Summary: In Japan, it has become necessary to preservation of environment and securing of building lots to deal with the sludge deposited in rivers, lakes and seashores over a long term of years.

In order to find effective and inexpensive solidifying materials for sludge, the authors studied solidifying ability of 24 kinds of mix cements with different mix proportions of portland cement, slag and anhydrite for sludge.

As the result, present cement with mix proportion of cement : slag = 40 : 60 - 20 : 80 and  $\text{CaSO}_4$  content of 10 - 20% showed high strength the highest of which was 10 times as strong as that of portland cement.

It is known that ettringite, a main product of hydration of the cement, gave the high strength by interlocking effectively with other hydrates.

## 1. Introduction

Up to now, quicklime ( $\text{CaO}$ ), Slaked lime ( $\text{Ca(OH)}_2$ ) and ordinary portland cement have been used for solidifying the sludge deposited in rivers, lakes and seashores. However, the use of quicklime involves problem in conservation of environment as it generates intense heat on hydration. The slaked lime is used in expectation of pozzolanic reaction with clay minerals in the sludge, and in many cases gives no sufficient strength. Solidifying strength of ordinary portland cement extremely decreases with increase of organic components in the sludge.

The authors studied a preliminary experiment mixing several materials with the main object of solving such weak points involved in using conventional sludge solidifying materials as intense heat evolution and insufficient solidification of organic sludge. Out of the materials, it was found that solidifying materials of the ternary system of ordinary portland cement - slag - anhydrite showed very good results.

This report describes the experiments conducted on the basis of the preliminary experiment to find out a optimum composition, which is able to give high strength, safe for use and inexpensive from abovementioned ternary system.

## 2. Method of experiments

The sludges prepared in the laboratory were following three kinds: Silty sludge which is inactive with cement; clayish sludge that causes pozzolanic reaction with cement; and organic sludge containing humic acid which is harmful to hydration of cement. Beside three kinds of sludges, silty sludge to which 1.0%, 2.0% and 4.0% of acetic acid were added to lower PH was also used in a part of the experiments. The sludges were prepared with Toyoura standard sand pulverized with a test mill, powderly bentonite, humic acid, and prescribed amount of water. Mix proportions and physical properties of each sludge are shown in Table I. Moisture contents were made approximately equal to those of actually existing sludges. Table I. Mix proportions and physical properties of sludges.

Item	kind	Silty sludge	Clayish sludge	Organic sludge
Mix proportions (%)	sand	100	50	47.5
	bentonite	0	50	47.5
	humic acid	0	0	5
Moisture content (%)		75	300	300
Wet density ( $\text{kg/m}^3$ )		1,562	1,165	1,165
Grain size distribution (%)	$>75 \mu\text{m}$	99	51	48
	$75 \sim 5 \mu\text{m}$	84.3	50.0	47.5
	$< 5 \mu\text{m}$	5.8	44.9	47.7

Solidifying materials of 24 different kinds were prepared by blending ordinary portland cement, granulated glassy blast furnace slag, and anhydrite obtained from the fluorine acid industry. Cement to slag ratios were 100 : 0, 80 : 20, 60 : 40, 40 :

60, 20 : 80, 5 : 95 and  $\text{CaSO}_4$  were 3.4%, 10%, 20%, 30% abovementioned slag - cement mix. Specific gravity, fineness and chemical composition of these materials are given in Table II.

Table II. Chemical composition and physical properties of portland cement, slag and anhydrite.

Item	kind	Portland cement	Blast furnace slag	Anhydrite
Chemical Composition (%)	g. loss	0.3	0.3	0.5
	Insol	0.1	0.4	—
	$\text{SiO}_2$	22.0	33.7	—
	$\text{Al}_2\text{O}_3$	5.0	15.3	—
	$\text{Fe}_2\text{O}_3$	3.2	0.6	—
	$\text{CaO}$	64.3	43.7	40.8
	$\text{MgO}$	1.8	4.0	—
	$\text{MnO}$	—	1.1	—
	$\text{SO}_3$	2.0	—	57.4
	Total	98.7	100.2	98.7
Specific surface ( $\text{cm}^2/\text{g}$ )		3300	4100	8430
Residue on $80 \mu\text{m}$ (%)		1.0	0.5	5.0
Specific gravity		3.15	2.92	2.92

The specimens for solidifying test were prepared by adding 100 kg or 200 kg of solidifying materials to  $1 \text{ m}^3$  of sludge, then mixing for 5 minutes with a mixer and molding in  $45 \times 10 \text{ cm}$  mold followed with curing in moisture at  $20^\circ\text{C}$ . The unconfined compressive strength of the hardened specimen was determined in conformity to JIS method (JIS A 1216). To identify hydration products, the specimen was crushed, washed with ethanol and dried at  $45^\circ\text{C}$ . Identification was made on the sample prepared as above by means of X-ray diffraction, DTA-TGA and SEM. Pore size distribution was also measured on a part of the specimens using a mercury penetrating porosimeter.

## 3. Results of experiments

Unconfined compressive strength of specimens prepared by adding 200 kg each of 24 kinds of solidifying materials to  $1 \text{ m}^3$  of sludge are shown in Fig. 1. For silty sludge, solidifying materials proportioned in cement : slag = 20 : 80 and  $\text{CaSO}_4$  content of 10% and 20% were high in strength, and for clayish sludge, solidifying materials proportioned in cement : slag = 40 : 60 and 20 : 80, and  $\text{CaSO}_4$  content of 10% showed high strength. The results of organic sludge resembled that of clayish sludge.

The strength ratio to portland cement in these optimum compositions was generally 3 - 5 times and in case where  $100 \text{ kg/m}^3$  of solidifying material was added to silty sludge, it was 9 - 10 times at age of more than 3 days.

The hydration products were mainly ettringite according to X-ray diffraction, DTA, TGA and SEM, and its quantity increased with increase of  $\text{CaSO}_4$  content. The relation between the quantity of formation ettringite determined by X-ray diffraction peaks and age is shown in Fig. 2. In the case where  $\text{CaSO}_4$  content was 10%, the quantity of ettringite was nearly constant from one day on, and when the content was 20% and 30%, the quantity increased with the time elapsed. Monosulphate was

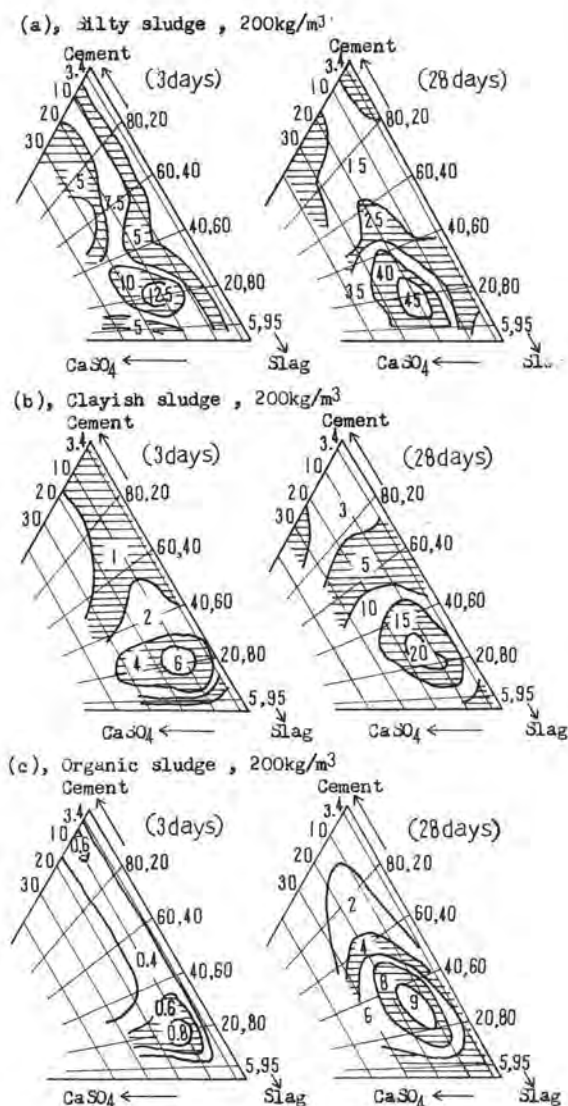

Fig.1. Unconfined compressive strength ( $\text{kgf/cm}^2$ ) of solidified specimens with mix cements blended cement, slag and  $\text{CaSO}_4$ .

formed at  $\text{CaSO}_4$  content 3.4% and 10%, but it was scarcely recognized in case of organic sludge.  $\text{Ca}(\text{OH})_2$  was formed at rich amount of cement.  $\text{CaSO}_4$  remained unreacted at early age in case of 20% and 30%  $\text{CaSO}_4$  content and disappeared from one week on of age (Fig.2).

Fig.3 shows the pore size distribution of hardened specimens at the age of 13 weeks. No interrelation was recognized between total pore volume and strength. However, it was recognized that the specimens of higher slag content showing higher strength had more pores of small pore radii.

Fig.2. Height of X-ray diffraction peaks of  $\text{CaSO}_4$  and ettringite, in case of silty sludge and adding  $200 \text{ kg/m}^3$  of solidifying materials.

Fig.3. Pore size distribution at 13 weeks, in case of silty sludge and adding  $200 \text{ kg/m}^3$  of solidifying materials.

In the case of adding  $100 \text{ kg/m}^3$  of solidifying material to the organic sludge, solidification was not effected by the use of solidifying material blended with 3.4%  $\text{CaSO}_4$  or solidifying material of high slag content. The mix proportion that gave relatively good solidification for the organic sludge was  $\text{CaSO}_4$  content of 10% or more and rich in cement (cement : slag = 100 : 10 - 60 : 40).

The low PH value, as experienced the organic sludge, was thought to be the main cause of the phenomenon. For the purpose of examining influence of lowering of PH value in these type cement upon strength, solidifications of silty sludge of low PH value were experimented using a solidifying material proportioned in cement : slag = 20 : 80 and  $\text{CaSO}_4$  content of 10%. The result is shown in Table III. At PH 10, solidification was not effected up to 3 days of age. As seen in Fig. 4, formation of ettringite was not observed at PH 10.

#### 4. Discussion

It was found that in solidifying sludge of high moisture content, solidifying materials proportioned in cement : slag = 40 : 60 - 20 : 80 and  $\text{CaSO}_4$  content of 10 - 20% were effective. More ettringite was formed with increasing anhydrite and slag. Behavior of the ettringite is considered to be acting to lower pore water and to increase density of hardened specimens and as a interlocking material in the hardened specimens. These are presumed to be one of principal factors to increase the strength.

When solidifying sludge, formation of

Table III, Unconfined compressive strength of specimens lowered PH value, in case of adding  $200\text{kg/m}^3$  of solidifying material proportioned in cement: slag = 20 : 80 and  $\text{CaSO}_4$  content of 10%.

Addition of acetic acid	PH after mixing(lhr)	Strength ( $\text{kgf/cm}^2$ )			
		1 day	3 days	7 days	28 days
1.0 %	11.5	3.1	11.0	11.5	12.9
2.0 %	11.2	2.1	9.9	12.8	16.6
4.0 %	10.2	x	x	7.0	10.0

x-----not solidified

Fig.4, SEM photographs of specimens, at 3 days.

ettringite was greatly influenced by PH of the sludge. In the case where PH after mixing became 10 or thereabout, formation of ettringite was hindered and strength was remarkably lowered. Therefore, when solidifying low PH sludge using these type materials, it is necessary to adjust PH above 11.

A tendency was observed in pore size distribution that the greater the slag content of solidifying materials added to the specimen the greater the number of openings of small pore radii. This can be attributed to the influence of difference in generated hydrates consequent on difference in solidifying material.

As seen in Fig 1 and Fig. 2, interrelation between the strength and the quantity of formation of ettringite cannot be determined distinctly. It is rather considered that in addition to the formation of ettringite, interactions of C-S-H and or C-A-S-H hydrates formed from the slag cement are contributing to the strength.

#### 5. Conclusions

In solidifying sludge of high moisture content with solidifying materials of portland cement - slag - anhydrite system, high strength was obtained throughout every age by mix proportions of cement : slag = 40 : 60 - 20 : 80, and  $\text{CaSO}_4$  content of 10 - 20%. The highest strength obtained was 10 times as strong as that using ordinary portland cement.

As stated above, it is possible to solidify sludge of high moisture content to give strength several times as strong as that of ordinary portland cement by the use of solidifying materials mixed with a large quantity of blast furnace slag and chemical anhydrite which are supplied in quantities as industrial by-products.

# Removal of valuable but toxic ions from waste water by synthetic hydroxyapatites

## *Utilisation des hydroxyapatites de synthèse pour la récupération d'ions métalliques toxiques*

Takashi SUZUKI, Toshiaki HATSUSHIKA and Yasumasa HAYAKAWA,  
Department of Applied Chemistry, Yamanashi University, Takeda-4, Kofu-shi, 400 Japan.

RESUME : La récupération des ions  $\text{Cd}^{2+}$ ,  $\text{Zn}^{2+}$  et  $\text{Ni}^{2+}$  dans diverses solutions aqueuses, au moyen d'hydroxyapatites de synthèse, a fait l'objet d'études approfondies, en utilisant plusieurs méthodes d'analyse, telles que : la titrimétrie ATDE, la sélection des ions aux électrodes et la spectroscopie d'absorption atomique. On a montré ainsi que le comportement de ces ions ne consistait pas en un simple effet d'adsorption, mais en un échange d'ions entre les ions à récupérer et les ions  $\text{Ca}^{2+}$  des apatites. L'importance des échanges est plus grande avec les ions  $\text{Cd}^{2+}$  ou  $\text{Zn}^{2+}$  qu'avec les ions  $\text{Ni}^{2+}$ , mais n'est pas complète pour les premiers, même avec une proportion cent fois plus grande d'ions  $\text{Ca}^{2+}$  ; ces ions sont stabilisés sur les apatites.

Ces résultats suggèrent que les apatites ont le pouvoir de sélectionner les cations métalliques ; aussi peuvent-elles être utilisées comme échangeur de cations inorganiques, pour récupérer ou pour fixer les ions de valeur mais toxiques dans les effluents.

SUMMARY : The removal behaviour of  $\text{Cd}^{2+}$ ,  $\text{Zn}^{2+}$  and  $\text{Ni}^{2+}$  ions from various aqueous solutions by synthetic hydroxyapatites was probed in detail by using analytical methods such as EDTA titrimetry, ion electrode analysis and atomic absorption spectroscopy. It was elucidated that the behaviour is not a mere adsorption effect but such an "ion-exchange reaction" between the ions ( $\text{Cd}^{2+}$  etc ...) in the solutions and  $\text{Ca}^{2+}$  ions on the apatites. The amount of the exchanged  $\text{Cd}^{2+}$  or  $\text{Zn}^{2+}$  was larger than that of the  $\text{Ni}^{2+}$  and the former ions were not eluted with even 100 times  $\text{Ca}^{2+}$ , i.e., the ions were stabilized on the apatites. These results suggest that the apatites have a selectivity for metallic cations and can be employed as an inorganic cation-exchanger for removing and stabilizing the valuable but toxic ions in waste water.

## 1. INTRODUCTION

It is well known that hydroxyapatite is not only a main constituent of phosphate rock, but also the major inorganic constituent of bones and teeth. The authors have been investigating surface characteristics<sup>1-5</sup> of various synthetic apatites and have happened to discover a new and important fact that  $\text{Cd}^{2+}$  ions in the aqueous solution are strongly held on some synthetic hydroxyapatites at room temperature and moreover, the behavior is not a mere adsorption phenomenon but a cation exchange phenomenon between  $\text{Ca}^{2+}$  ions on the apatites and the  $\text{Cd}^{2+}$  ions. Starting from the interesting result, the authors intended to examine the feasibility of employing the apatites as inorganic cation exchangers for treatment of waste water containing valuable but hazardous metallic ions.

## 2. EXPERIMENTALS

### Materials.

Various synthetic hydroxyapatites were prepared in the usual way<sup>6,7</sup> by precipitation from hot water and stored in a desiccator over phosphorus pentoxide. All chemicals were analytical grade commercial materials and used without further purification.

### Specific surface area.

The specific surface areas of the apatites were determined by applying BET method to the nitrogen adsorption data obtained at the liquid nitrogen temperature, assuming the cross-sectional area of a nitrogen molecule to be  $16.2 \text{ \AA}^2$ .

### Crystal structure.

The structural changes of the apatites before and after the uptake phenomena were investigated by X-ray diffraction method.

### Procedures.

Each sample (1.0 g) of the hydroxyapatites was mixed and stirred with 400 ml of 100 PPM  $\text{Cd}^{2+}$ ,  $\text{Zn}^{2+}$  and  $\text{Ni}^{2+}$  aqueous solutions at various temperatures (20-40°C), and released  $\text{Ca}^{2+}$  ions in the solutions and adsorbed ions on the apatites were analyzed by measurements with a cadmium ion meter, EDTA titrator and an atomic absorption spectrometer. In addition to the batch operation, column method was also applied to the case of  $\text{Ni}^{2+}$  and  $\text{Zn}^{2+}$  solutions.

## 3. RESULTS AND DISCUSSION

The specific surface areas and Ca/P molar ratios of the apatites are summarized in Table I. From the table, it was found that each of the apatites had relatively large surface area and the molar ratio values close to the ideal value (1.66) calculated from the molecular formula  $\{\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2\}$ .

Table I. Specific surface areas and Ca/P molar ratios of various synthetic hydroxyapatites.

apatite measured value	S - 1	S - 2	S - 3
Ca/P molar ratio	1.65	1.63	1.63
surface area ( $\text{m}^2/\text{g}$ )	62.8	60.2	45.3

Table II shows the amounts of uptaken  $\text{Cd}^{2+}$  on S-1 or S-2 from 400 ml of 100 PPM  $\text{Cd}^{2+}$  aqueous solutions and those of released  $\text{Ca}^{2+}$  in the solutions at 20°C. Note that the molar ratios ( $\text{Ca}^{2+}/\text{Cd}^{2+}$ ) almost equal to an integer 1.0. This means that the  $\text{Cd}^{2+}$  uptake phenomenon is not a mere adsorption effect but such an ion-exchange reaction between  $\text{Cd}^{2+}$  in the solution and  $\text{Ca}^{2+}$  on the apatite as R-Ca system, where R-Ca is a commercial  $\text{Ca}^{2+}$  form cation exchange resin. The interesting result is very important because the hydroxyapatite has been considered to be an anion exchanger<sup>8</sup> and much attention has not been paid to the divalent cationic characteristics. pH changes of the solutions before and after the addition of the apatites are listed in the table for reference.

Table II. Removal of  $\text{Cd}^{2+}$  ions by S-1 and S-2.

sample measured value	S - 1	S - 2	R - Ca
$\text{Ca}^{2+}$ mg/400 ml ( $\times 10^{-4}$ mol)	11.9 (2.96)	9.76 (2.43)	3.82 (0.95)
$\text{Cd}^{2+}$ mg/400 ml ( $\times 10^{-4}$ mol)	33.2 (2.95)	28.5 (2.54)	11.3 (1.00)
$\text{Ca}^{2+} : \text{Cd}^{2+}$ molar ratio	1 : 1	0.96:1	0.95:1
before addition of the apatites	5.7	5.7	-
after 30 min. pH	6.0	6.1	-
dissolved amount of $\text{Ca}^{2+}$ in water (mg/400 ml water)	1.21	1.10	-

Table III contains the amounts of adsorbed  $\text{Zn}^{2+}$  on the S-1 from 400 ml of 100 or 50 PPM  $\text{Zn}^{2+}$  aqueous solutions, those of the released  $\text{Ca}^{2+}$  in the solutions,  $\text{Ca}^{2+}/\text{Zn}^{2+}$  molar ratios and pH changes of the solutions at various temperatures (20-40°C). As indicated in the table, the  $\text{Ca}^{2+}/\text{Zn}^{2+}$  molar ratios are close to an integer 1.0. The result means that the  $\text{Ca}^{2+}$  ions on the apatites are not peculiarly exchanged with  $\text{Cd}^{2+}$  ions in the solutions.

Table III. Removal of  $Zn^{2+}$  ions by S-1 at various temperatures

system measured value	$Zn^{2+}$ 100 PPM (400 ml)			$Zn^{2+}$ 50 PPM (400 ml)		
	20°C	30°C	40°C	20°C	30°C	40°C
$Ca^{2+}$ mg/400 ml ( $\times 10^{-4}$ mol)	14.56 (3.63)	15.68 (3.91)	20.52 (5.12)	7.36 (1.84)	10.24 (2.55)	12.07 (3.01)
$Zn^{2+}$ mg/400 ml ( $\times 10^{-4}$ mol)	20.04 (3.52)	25.76 (3.94)	30.08 (4.60)	11.36 (1.74)	15.92 (2.43)	18.57 (2.84)
$Ca^{2+} : Zn^{2+}$	1.03 : 1	0.99 : 1	1.11 : 1	1.06 : 1	1.05 : 1	1.06 : 1
before addition of the apatite	5.8	5.8	5.9	6.0	6.1	6.0
after 30 min. pH	6.2	6.2	6.3	6.2	6.2	6.2

Concerning  $Ni^{2+}$  uptake, it was found in Table IV that the molar ratios of  $Ca^{2+}$  and  $Ni^{2+}$  are almost close to 1.0 and the difference of exchanged quantities of  $Ni^{2+}$  between batch method and column operation was small (S-3 sample was treated by column operation. The flow rate of 100 ml of  $Ni^{2+}$  solution with a concentration of 100 PPM is 1 ml/min.).

Table IV. Removal of  $Ni^{2+}$  ions by S-1, S-2 and S-3.

apatite measured value	S - 1	S - 2	S - 3
$Ni^{2+}$ solution	100 PPM 100 ml	100 PPM 100 ml	100 PPM 100 ml
operation	batch	batch	column (1 ml/min.)
$Ca^{2+}$ mg (mol)	4.65 ( $1.16 \times 10^{-4}$ )	4.49 ( $1.12 \times 10^{-4}$ )	3.87 ( $0.97 \times 10^{-4}$ )
$Ni^{2+}$ mg (mol)	6.72 ( $1.14 \times 10^{-4}$ )	6.35 ( $1.08 \times 10^{-4}$ )	5.80 ( $0.99 \times 10^{-4}$ )
$Ca^{2+} : Ni^{2+}$	1.02 : 1	1.04 : 1	0.98 : 1

Table V contains the quantities of exchanged  $Ni^{2+}$  and  $Zn^{2+}$  on 1 g of the S-3 from 400 ml of 100 PPM solutions by column method, those of eluted  $Ni^{2+}$  and  $Zn^{2+}$  from the loaded S-3 with 400 ml of 0.001 N sulfuric acid and so on. From the table, it was found that the amount of the exchanged  $Zn^{2+}$  was larger than that of the  $Ni^{2+}$ . The result also suggest that the apatite have a selectivity for metallic cations. This consideration is also supported by the difference of the amounts of recovery ratios between  $Zn^{2+}$  and  $Ni^{2+}$  (cf.  $Zn^{2+}$  : 50 %,  $Ni^{2+}$  : 65 %). Moreover, the dissolved amounts of P from the S-3 were negligibly small. (cf.  $Ni^{2+}$  system ; 0.21 mg,  $Zn^{2+}$  system ; 0.22 mg).

Table V. Removal and elution of  $Ni^{2+}$  and  $Zn^{2+}$  ions by using column method.

system measured value	S-3 — $Ni^{2+}$	S-3 — $Zn^{2+}$
$Ca^{2+}$ mg (mol)	5.4 ( $1.34 \times 10^{-4}$ )	13.4 ( $3.3 \times 10^{-4}$ )
$Ni^{2+}$ mg and $Zn^{2+}$ (mol)	7.4 ( $1.26 \times 10^{-4}$ )	20.8 ( $3.2 \times 10^{-4}$ )
$Ca^{2+} : Ni^{2+}$ and $Ca^{2+} : Zn^{2+}$	1.06 : 1	1.03 : 1
P mg (mol)	0.21 ( $0.068 \times 10^{-4}$ )	0.22 ( $0.071 \times 10^{-4}$ )
eluted amount of $Ni^{2+}$ and $Zn^{2+}$ (mol)	4.8 ( $0.82 \times 10^{-4}$ )	10.4 ( $1.59 \times 10^{-4}$ )
recovery ratio (%)	65 %	50 %

#### 4. CONCLUSION

In addition to the above results, it was found out that the structural changes of the apatites before and after the uptake phenomena were not detected at least by X-ray diffraction method, the exchanged  $Cd^{2+}$  or  $Zn^{2+}$  ions on the apatites were not eluted with even 100 times  $Ca^{2+}$  ions, i.e., the  $Cd^{2+}$  or  $Zn^{2+}$  ions were stabilized on the apatites and maximum value of the exchanged  $Cd^{2+}$  was 80 mg per 1 g of the S-1. These results suggest that the apatites can be employed as an "inorganic cation-exchanger" for removing and stabilizing the valuable but toxic ions in waste water.

We thank the Ministry of Education of the Japanese Government for financial support

(contract No. 403046) and Mrs. H. Hatsushika for her secretarial help in the preparation of this paper.

# The Poz-O-Tec process for fixation of industrial wastes

## *Le procédé Poz-O-Tec de traitement des cambouis industriels*

Dr. Eric RAU, Director of Research and Development, IU Conversion Systems, Inc. Horsham, Pennsylvania, U.S.A.

RESUME : Le procédé Poz-O-Tec permet de traiter complètement les cambouis qui se déposent dans les conduites de gaz désulfurisé. Ces cambouis contiennent du  $\text{CO}_3\text{Ca}$  et du  $\text{SO}_3\text{Ca}$ ; mais ils contiennent aussi, d'une façon aléatoire, plusieurs éléments lourds, qui peuvent réagir avec les cendres volantes et la chaux, et produire un matériau à faible perméabilité. Cette réaction peut être utilisée, en la menant convenablement, pour éviter toute contamination des eaux souterraines, à partir des écoulements à la surface des sols. Et même, ces eaux peuvent être réutilisées après traitement.

Ce procédé est utilisé aux U.S.A., où vingt installations, déjà réalisées ou en cours de construction, seront capables de traiter annuellement dix huit millions de tonnes de ces cambouis. La présente communication donne des détails sur le processus chimique et sur l'expérience déjà acquise du procédé.

Ce procédé a aussi été utilisé pour traiter des effluents industriels. Ces derniers ont été classés en effluents traitables ou non traitables par ce procédé, d'après leur réaction avec la pouzzolane. Cette classification est exposée en détail.

SUMMARY: The Poz-O-Tec<sup>R</sup> process is a complete waste management system for the disposal of flue gas desulfurization sludges. In this system the  $\text{CaSO}_4/\text{CaSO}_3$  sludges, which contain many heavy elements considered hazardous, are reacted with fly ash and lime to produce a material of low permeability. This composition can be landfilled in a manner that assures virtually no contamination of groundwater by leachates nor contamination of surface water by surface runoff. Further, the ground is suitable for re-use after the landfill is closed. The system is in use in the U.S.A., with 20 plants capable of solidifying over eighteen million tons per year of sludge now in operation or under construction. Details on process chemistry and operational experience are presented.

The method had also been adopted to the processing of industrial wastes. These wastes have been classified into materials that affect the pozzolanic reaction which are beneficial, compatible, or incompatible with the systems. Details of the classification are presented.

The Poz-O-Tec<sup>R</sup> process developed by IU Conversion Systems, Inc. (IUCS), is a system of waste management in which hazardous materials are encapsulated in a pozzolanic matrix formed by the reaction of lime with fly ash. Retention within the matrix may be by chemical as well as physical forces. Chemically bound material is rendered insoluble by the formation of complex calcium silicate alumina compounds. Physically held materials are entrapped in the dense cementitious matrix which is virtually impermeable to water. Thus, the host matrix is able to retain a wide variety of wastes and prevent contact with solvents that might leach the toxics from the matrix.

#### POZZOLAN CHEMISTRY

By definition, pozzolans are materials which are not cementitious in themselves, but which contain constituents that will combine with lime at ordinary temperatures in the presence of water to form cementitious compounds. Natural pozzolans are usually materials of volcanic origin, but include some diatomaceous earths and, in the broadest sense, soils. Artificial pozzolans are mainly products obtained by heating clay or shale. Today, the primary artificial pozzolan is fly ash, a residue from the combustion of pulverized coal at modern electric power plants.

When lime or lime-based additives are mixed with fly ash in the presence of water, a chemical reaction takes place producing materials whose properties are similar to the reaction products of Portland cement. The major cementitious reaction occurs between silica and lime with some alumina contributions. In addition, sulfur-bearing compounds can react with lime and alumina to form calcium sulfo-aluminohydrates. The chemical equations for these reactions are shown below:

The chemical reactions are complex. Initially, the fly ash surface is attached by lime, creating a gel. This gel contains predominantly calcium, aluminum, and silica ions in solution, which combine to form insoluble hydrate complexes. Since the chemical reactions take place on the fly ash surface, the pozzolanic reactivity of the fly ash increases with greater surface area (i.e., smaller particle size).

The pozzolanic reactions described in (2) can be used to chemically fix  $\text{SO}_2$  scrubber sludges from electric utilities. These scrubber sludges contain  $\text{CaSO}_3 \cdot \frac{1}{2}\text{H}_2\text{O}$  and/or  $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$  depending on scrubber conditions.<sup>2</sup>

Other wastes which may contain hazardous components can be rendered innocuous by this same pozzolanic reaction. The liquid phase of the waste is utilized to form the hydration compounds that are cementitious in nature. The hydration reaction progressively seals off the pore structure in the resultant mass. Permeability is typically reduced to  $10^{-6}$  and  $10^{-7}$  cm/sec. Sulfur compounds may be chemically reacted to form insoluble compounds. Other solid wastes are physically entrapped in the rigid matrix which develops. The basic pH of the pozzolanic reaction renders most heavy metals insoluble. In addition, the hydrating gel provides a large surface area for adsorption and ion exchange processes.

The longevity of these reaction products has been amply demonstrated by structures (such as the Apian Way) built centuries ago during the Roman Empire.

#### APPLICATION TO FLUE GAS DESULFURIZATION SYSTEMS

With the resurgence of coal as fuel, it has become necessary for utilities to install and operate a growing number of flue gas desulfurization (FGD) systems for  $\text{SO}_2$  removal. It is estimated that nearly 60,000 MW of FGD capacity will be installed by 1980.

Among the various FGD scrubber systems available, wet-lime/limestone scrubbing and double alkali (indirect-lime/limestone) scrubbing have gained the widest acceptance. These scrubbing operations produce an enormous volume of low-solids-content sludge, which must be properly treated so that groundwater and surface water are not polluted by unacceptable concentrations of heavy metals and dissolved solids.

A solution to this massive sludge disposal problem is the chemical stabilization of scrubber sludge by the Poz-O-Tec<sup>R</sup> process to prevent significant environmental damage and minimize land disposal requirements. The Poz-O-Tec<sup>R</sup> system has received large-scale commercial acceptance on a wide variety of scrubbers. Twenty utilities have contracted to install it.

The Poz-O-Tec<sup>R</sup> process is a complete waste-management system for coal-fired power plants. It blends fly ash, bottom ash (if desired), scrubber sludge, lime, and other wastes. Concentrated streams from the evaporator and cooling tower sludge can also be incorporated. The stabilized material is a cementitious material, and with proper placement and compaction, exhibits low permeability and superior structural properties.

#### PROCESS CONSIDERATIONS

The fixation of power plant wastes involves more than just combining the wastes. Each of the waste materials contributes chemically and physically to the process. Variations in those materials must be considered in developing the specific process design.

##### Fly Ash

Fly ash is utilized in the Poz-O-Tec<sup>R</sup> process for several reasons. It is a waste material which must be disposed of, and is usually available from the same plant as the sludge waste. It is a fine-particle material and provides the alumina and silica which are necessary for the pozzolanic reactions to bind the sulfur compounds of the sludge.

The quantity of fly ash will also contribute to the final solids content of the product and affect its handling characteristics. Generally, ash-to-sludge ratios of 1:1 or higher will result in an immediately placeable material; those below that ratio will usually require interim stockpile conditioning prior to final placement.

Particle size of the ash also contributes to the process chemistry: the extremely fine particles have more surface area and therefore react faster.

##### Scrubber Sludge

The chemical composition of a sludge is one of the most important considerations in designing a stabilization system, because it can vary greatly, even

during standard power plant operation. All FGD sludges can be stabilized, but it is important to understand those characteristics of sludge which have the greatest potential effect on stabilization systems.

Sulfite/sulfate proportions primarily affect dewatering. The larger size of the sulfate particles affords easier dewatering. However, given the same ash to sludge ratio, sulfate based sludges require a numerically higher solids content of the final product to be equally handleable than do sulfite based sludges.

The lime or limestone used in scrubbers also has an effect on process design. Poor quality reagent requires greater quantities in the scrubber to achieve the required  $\text{SO}_2$  removal, and the high proportion of non-lime materials increases loads on the dewatering equipment. When in the form of grit, it causes extensive wear on piping and process equipment.

#### Process Additives

Most stabilization processes require that some additive be used to initiate chemical reactions. Although this activator may already be present in some coal, such as lignite, it must be added separately in most cases.

For pozzolanic stabilization, the additive most used is lime, available as pebble lime (which requires crushing), pulverized quicklime, hydrate, or lime slurry. The important considerations for the lime are  $\text{CaO}$  and  $\text{MgO}$  content and particle size distribution.

#### PLANT DESIGN CONSIDERATIONS

Concurrent with the evaluation of process variables to achieve chemical stabilization, the physical processing systems for the plant must also be planned. A stabilization plant is a materials handling system in which liquids, sludges, damp and dry solids are combined into a reactive mass.

#### Siting

The location of the stabilization facility will depend on land availability, location of the disposal area, and other physical and economic factors. Ideally, the landfill should be located near the power plant to minimize transportation costs for both waste materials and the stabilized product. A 600-800 MW plant producing 1,000,000 tons per year of stabilized material will require about 60 hectares of disposal area 35m high, over a 20-year period.

#### Dewatering

Dewatering of the sludge is important in dry stabilization systems to produce higher final product solids. Most FGD systems, however, only thicken the sludge to 25-30% solids.

Dewatering in the stabilization facility is usually accomplished by vacuum filtration, although centrifuges have been used in some applications. Scrubber sludge can be vacuum-filtered at rates of 250-500  $\text{kg/m}^2/\text{hr.}$  depending on the composition of the sludge, the filter medium, and filter aids. Sulfate sludges usually yield higher filtration rates and solids than do sulfites. Conversely, high concentrations of magnesium often result in lower filtration rates and solids. If these conditions are known at the time

of design, the filtration equipment and operating parameters can be adjusted to maximize sludge dewatering.

A lime base sludge will usually dewater from 30% solids to 40-60% solids, and limestone-based sludge to 55-60% solids. Oxidized sludges are reported to achieve 80-85% solids, which when mixed with fly ash and additive, would result in a high-solids final product. This product may require water addition to achieve optimum placement density.

#### Materials Feeding

Feed systems for fly ash and lime involve more than just adding these materials to the sludge. For situations where there is limited ash available, controlled feed is important to conserve ash. This equipment must not only feed accurately but must control flooding.

As lime constitutes a small percentage of a mix on a dry-weight basis and is the activator of the chemical stabilization reactions, accuracy of measurement and uniform dispersion of the lime in the product is absolutely necessary. Dispersion within the mix depends upon accuracy of feed, location of lime feed into the system, particle size, and uniformity of mixing.

#### Mixing

Mixing is the combining of the waste and additives to permit the fly ash lime to contact all sludge particles so complete chemical action can take place. The mixer must be able to provide the required blending, even though the ratio of wet and dry materials may vary over any given period, and the mixer designed for 200 tons per hour (TPH) may only be operating at 100 TPH due to reduced station load. The specific combination of waste materials to be mixed at a facility must be evaluated for material ratios, solids content, particle size, retention time, type of additive, etc., to ascertain the proper mixing design.

#### FINAL PRODUCT HANDLING

The achievement of a structurally stable and environmentally compatible landfill requires a detailed materials handling and placing program, landfill preparation, and quality control procedures. In many respects, the disposal and placement procedures are as important to the overall stabilization system as the processing facility itself.

Once the processed sludge leaves the facility, it is usually placed in a surge pile. Normally, a drier final product will require less time in the surge pile prior to handling. For example, final product with solids in the range of 50-58% require initial conditioning of several days before movement. Table I gives a range of final product solids and required conditioning times.

TABLE I: Time required for stockpiling a various processed material solid content.

Solids Range (%)	Stockpile Conditioning (days)
50-58	4+
58-63	3-4
63-70	1-3
70-80	0.1

Temperature can also affect the material cure, handling and placement operations. During winter months, with temperatures below 5°C, the chemical reactions in the material are slowed—as in cement chemistry. As a result, greater curing times may be required for the material in the surge pile before placement in the landfill. Adequate storage capacity in the surge pile area must be included in system design for this requirement.

The processed material is usually moved to its final disposal area by front-end loading directly onto trucks or by direct conveyor to the landfill. In all instances, grading, placing and compacting are required for final placement.

Material is usually placed in 30 to 60 cm lifts. The disposal site should be maintained so that a minimum surface area of fresh material is exposed to the elements. The working face should have a slight grade, so that any rainfall will tend to run off rather than collect in pockets. Should rainwater pockets occur, especially on fresh material, the material stabilization will be adversely affected or stopped completely, creating soft spots in the landfill.

In the landfill, the material can be graded to elevations up to 35m and greater. The landfill is developed in approximately 8m lifts and benched at the outer surface to provide haul roads and prevent erosion. Side slopes can be 2:1 horizontal to vertical, with 15m benches. The finished surfaces should have at least an 0.5m layer of topsoil and be revegetated to retard erosion.

At several of IUCS' installations, long-range plans call for material to be built into small mountains in excess of 35m in height, thus minimizing land area requirements.

The biggest potential environmental impact could be water runoff. For this reason, exposed surface area of freshly placed material should be kept to a minimum. Sedimentation ponds should collect the runoff discharge from the landfill area.

A good landfill operation will use monitoring wells to sample groundwater. These should be installed well in advance of the beginning of operations to obtain background data.

#### Resource Recovery

Considerable effort has also been expended on finding applications for re-using processed material. It has been used in road base, parking lots, liners, and aggregate for cement blocks. A novel proposed application has been in synthetic reef material for ocean disposal. Opportunity for Poz-O-Tec utilization depends on the local economics and need for such material.

#### ENVIRONMENTAL CONSIDERATIONS

The major objective of an FGD waste management program is to protect surface and subsurface water quality and resources. This is achieved by minimizing leachate generation potential, providing adequate runoff control measures and placing the processed material in a structural matrix. To protect surface and subsurface water quality, the landfills are designed to promote rapid surface runoff. The low permeability of the placed material ( $10^{-6}$  to  $10^{-7}$  cm/sec) contributes fur-

ther to promoting runoff. All surface runoff is controlled through swales, paved ditches, piping, and sedimentation basins. Discharges from the sedimentation basins are subject to National Pollution Discharge of Effluents Standard (NPDES) or state discharge criteria for pH, alkalinity, suspended solids, total dissolved solids, sulfates and sulfites. Table II presents the combined results of surface runoff quality monitoring at three disposal sites. IUCS also monitors the eight heavy metals specified in Resource Conservation and Recovery Act (RCRA). The monitoring program results show that no heavy metal contamination is expected from a stabilized FGD sludge surface runoff discharge.<sup>1</sup>

TABLE II (mg/l)

#### SURFACE RUNOFF QUALITY

	Stabilized FGD Sludge	Discharge Criteria	EPA IPDWS
pH	6.5 - 10	6 - 10	N/A

\*EPA Interim Primary Drinking Water Standards, effective October 13, 1979.

The chemical characteristics of a waste material, the method of disposal, and the physical integrity of the in-place waste materials directly influence potential leachate quality. Values were obtained by the proposed American Society for Testing Materials (ASTM) Test Procedure, Leaching Test of Waste Material, Method A, a 48-hour shake test procedure.

TABLE III (mg/l)

	Fly Ash	Sulfate Sludge	Sulfite Sludge	Stabilized FGD Sludge	EPA IPDWS	EPA RSDWS
pH	4-6	6-8.5	10-12.5	9.5-11.5	—	6.5-8.5
TDS	4,000-6,000	16-20,000	16-18,000	700-1,800	—	500
SO <sub>4</sub>	800-1,200	7-10,000	7,000-9,000	300-850	—	250
Arsenic	.01-.20	<.02	<.02	.003-.02	.05	—

Silver	<.05	<.05	<.05	<.05	.05	—

Table III shows that leachate from an unstabilized fly ash, sulfate sludge, or sulfite sludge disposal site could be expected to exceed the EPA Interim Primary Drinking Water Standards for arsenic, cadmium, lead and selenium, and the recommended secondary standards for pH, total dissolved solids (TDS), sulfates ( $\text{SO}_4$ ), copper, iron and zinc. The values for the same waste materials stabilized show that all of the primary drinking water standards would be met; however, the values for pH, TDS and  $\text{SO}_4$  would exceed the recommended secondary standards. Groundwater contamination is not seen as a problem since no leachate or permeate is expected.

The unconfined compressive strength of the stabilized FGD waste materials is a function of the filtercake solids, fly-ash-to-sludge ratio, in-place density, and additive content. For a given plant, the above factors, with the exception of additive content, remain relatively constant on a month-to-month basis. The additive content may vary to compensate for the effect of adverse weather conditions, lowered ambient temperatures, and changes in waste material characteristics and ratios. Figure 1 shows the unconfined compressive strength of laboratory-cured samples versus in-place cured samples with typical fly-ash-to-sludge ratios and additive content.

Permeability of the landfilled material was also measured after several periods of time after placement. As shown in Figure 2, the slow pozzolanic reactions are sealing the material with increasing time.

#### APPLICATION TO INDUSTRIAL WASTES

American industry is estimated to generate 57 million tons of hazardous wastes each year. The promulgation of the Resource Conservation and Recovery Act will

have significant impact on the manner in which disposal of this material is carried out. Since disposal of toxics into water is prohibited, wastes will either have to be incinerated or landfilled. Landfilled materials must be buried under safe and secure conditions to assure that no contamination of the environment occurs.

The same fixation technology used for disposal of FGD scrubber sludge can be applied to industrial wastes. Since the type and concentration of hazardous material in these wastes vary widely, IUCS has tested many wastes and classified them into categories so that judgment on treatability could be made. The following kinds of wastes have been examined.

#### Generic Types of:

**Sludges:**  $\text{CaSO}_4/\text{CaSO}_3$  sludges result from neutralization of waste battery acid, lagooning of waste gypsum and lime scrubbing of  $\text{SO}_2$  gases in industrial or utility operations. Metal hydroxide sludges result from neutralization of acid waters containing heavy metals from steel mill and plating operations. **Dust and Slag:** Dust results from the purification of air streams by exhaust devices on the furnaces of ferrous and non-ferrous smelting operations. Cement and lime kiln dusts are also included. Slag is produced in the smelting operations of ferrous and non-ferrous metals industries.

**Solid Wastes:** This category comprises solid wastes that are not dusts or slags but also cannot be described as sludges. Typical wastes in this category are chrome ore residue, mine tailings, and incinerator ash.

**Organic Wastes:** Biological sludges result from bacterial treatment used to destroy certain organic compounds. Heavy ends or still bottoms are the viscous, tarry residue from distillation or purification columns. Solvent waste streams are used solvents that have been contaminated by reactants or products from the processes or reactions for which they were the solvents.

These categories account for a majority of industrial waste streams and are useful for classifying industrial waste management options.

#### Chemical Stabilization of Industrial Waste

It was found convenient to classify the wastes as beneficial, compatible, and excluded, with respect to the stabilization reaction.

#### Beneficial Wastes

Beneficial wastes are defined as wastes which have a synergistic effect on the lime/fly ash reaction or wastes which can be used as a lime or fly ash substitute.

Several waste products were found to be acceptable fly ash substitutes as received. These include, for example, cement kiln dust, electric furnace dust, spent catalyst, and precipitator fines.

In addition, the following waste materials were acceptable replacements for fly ash when ground to a fine particle size: blast furnace slag, bottom ash, smelter fines, and coal mine tailings.

The blast furnace slag and cement kiln dust cannot technically be called pozzolans because they can react with water alone to produce a cementitious product. In this respect, these waste products are true cement-type compounds.

Considerable work has been performed at the IUCS Research and Technical Services laboratories on the use of cement kiln dust (CKD) and electric furnace dust (EFD) in waste stabilization. These dusts may be used for their lime value.

#### Compatible Wastes

Compatible wastes are defined as materials which do not contribute significantly to the pozzolanic reaction, do not inhibit or retard the reaction, do not contribute significantly to environmental pollution through leachate or runoff, and can be economically stabilized. The majority of compatible wastes are  $\text{CaSO}_4/\text{CaSO}_3$  sludges and metal hydroxide sludges.

Heavy metal sludges may contain three readily identifiable potential problems. Hexavalent chromium is a soluble anion which is not rendered insoluble by the lime/fly-ash treatment. Reduction of the hexavalent chromium to the trivalent oxidation state is easily accomplished by the addition of ferrous ion in the form of ferrous sulfate. Cyanide may be destroyed by alkaline chlorination or ozone/ultraviolet treatment. Certain metals, chiefly lead and trivalent/arsenic may be solubilized at the high pH values required for the lime/fly ash reaction.

#### Incompatible Wastes

Incompatible wastes are defined as those materials for which microencapsulation, or microencapsulation alone, is not feasible. Generally, incompatible wastes are soluble salts, organic wastes, biological sludges, low-solids or liquid waste streams, wastes that retard the pozzolanic reaction, or wastes containing hazardous components which are released under high alkalinity.

Organic wastes have not been extensively studied, although several wastes which contain small amounts of organics have been evaluated. Neutral hydrocarbons such as oil, grease, and tars appear to have little effect on the pozzolanic reaction. Up to 8.5% of oil and grease in a lime/fly-ash mix does not decrease the compressive strength, and actually produces slightly greater strength than lime and fly ash alone. Decanter tar from a coke process was stabilized by mixtures of lime or CKD with fly ash or EFD in amounts of up to 20%. Benzene and xylene at 8.5% showed no effect on the pozzolanic reaction, although there is evidence that these organic compounds volatilize from the matrix within a few days after compaction. Polar function groups such as the alcohol or carboxylic acid groups inhibit or retard the pozzolanic reaction. Carboxylic acid groups also neutralize the lime and render it useless for the pozzolanic reaction.

Biological sludges deserve separate comment. Biological or activated-sludge treatment utilized microbial enzymes to anaerobically or aerobically decompose organic substances. Some of the end products of this biological degradation are amino acids, organic acids, alcohols, methane, carbon dioxide, water, ammonia, nitrates, hydrogen sulfide, sulfuric acid, and fatty

acids. In addition, the sludge may contain organic compounds that are wholly or partially resistant to biological degradation, and the microbial enzymes (dead or alive) themselves. Many of the organic compounds in biological sludges are known to retard cement and pozzolanic reactions. Therefore, attempts at pozzolanic stabilization of bio-sludges have to be approached very carefully with special testing after long-term stability.

#### CONCLUSIONS

Pozzolanic stabilization is becoming a major process for the disposal of undesirable waste materials. Among the oldest of stone-forming reactions, the known longevity of the reaction products is adequately demonstrated.

The largest-volume application today is the stabilization of  $\text{SO}_2$  scrubber sludge and fly ash. Some 18 million tons per year capacity has now been built or contracted with continued growth expected. In this system, sludge, fly ash and lime are combined to form a strong, impermeable landfill material. Since the reaction depends on the chemical and physical properties of the reactants, careful characterization of these is necessary. Plant design must reflect these characteristics, or difficulties in operation will be met. Data obtained from the landfill corroborates design predictions from the laboratory. The results indicate that water discharge criteria for pH, alkalinity, and suspended solids are being met. Monitoring shows no contamination can be expected from the eight heavy metals considered hazardous.

Pozzolanic stabilization has also been applied to industrial wastes. Here it has been found that many wastes containing reactive materials are actually beneficial to the pozzolanic process. Many others are encapsulated by the cementitious material and prevented from leaching by the impermeability of the matrix. Incompatible systems have also been identified.

#### ACKNOWLEDGEMENTS

I am pleased to acknowledge many contributions from my co-workers at IU Conversion Systems with particular emphasis on those of Dr. A. A. Metry, L. C. Cleveland, L. Ruggiano, E. Poulson, and C. L. Smith.

# Fixation des boues industrielles avant décharge

## *Consolidation of industrial sludge before disposal*

Jean Bernard LEROY, Ingénieur Principal à la Compagnie Générale des Eaux à Paris, France.

**RESUME :** Pendant longtemps, la mise en décharge des ordures ménagères puis des déchets de l'industrie a été considérée comme une solution définitive. Certes, on entendait plutôt ce terme dans un sens subjectif considérant qu'il n'y avait plus aucune raison de se soucier des résidus mis à l'écart dès qu'ils ne se manifestaient guère, plutôt que dans un sens objectif, supposant résolue la question de leur évolution ultérieure. Il fallut les récents progrès en matière d'analyse, surtout de celle des eaux profondes, pour que l'on décidât d'examiner de plus près les phénomènes de cheminement des matières nocives dans les décharges. Lors du premier symposium "Sol et Déchets" tenu à Angers en Avril dernier, plusieurs communications ont mis l'accent sur les interactions entre les déchets et le sol, même à travers des couches imperméables à l'eau et entre les déchets eux-mêmes. Des études poussées se poursuivent sur cette importante question. Dès lors qu'un déchet peut rester dangereux même placé en décharge, à des titres et à des degrés d'ailleurs très divers, n'y aurait-il pas une méthode, sinon pour le neutraliser, du moins pour en réduire la nocivité à la limite du mesurable?

La fixation des boues, par gélification au moyen de réactifs où les liants hydrauliques prennent une grande part, méthode que nous pratiquons maintenant depuis plus de cinq ans, semble être une des réponses à ce nouvel aspect de la protection de l'eau et de la nature.

Des essais de lixiviation en laboratoire et en vraie grandeur ont montré l'efficacité de cette méthode commercialisée sous le nom de CHEMFIX. Il existe actuellement une installation fixe à LIMAY, près de MANTES et une autre mobile, prête à intervenir sur n'importe quelle lagune même éloignée.

**SUMMARY :** The disposal of domestic, and then industrial, waste effluents has, for a long time, been regarded as a definitive solution. With this removal and disposal of wastes has, come a subjective out of sight out of mind way of thinking rather than one based on objective consideration of what happens to these wastes a little further down the road. Recent improved methods in the field of analyses, especially as applied to groundwater, have made possible a much closer examination of movements of toxic substances in waste effluents. At the first symposium on "Soil and Waste Effluents" held last April in Angers, many statements laid stress to interactions between waste effluents and the soil, even across strata that are impermeable to water, and within the effluents themselves. Thorough studies have been made on this important question. Is there not a method, therefore, whereby the various types and concentrations of toxic materials in the waste effluents, from the time of disposal and throughout the period they remain toxic, could be neutralized or at least reduced in toxicity to measurable maximum limits?

Sludge consolidation by gelification with the application of special chemical reactants along with heavy reliance on hydraulic binding agents is a process we have used for the last 5 years and which appears to respond to this new aspect of protecting water resources and the environment in general.

Lixiviation experiments conducted in the laboratory and in the field have demonstrated the efficacy of this method which has been made available commercially under the name of CHEMFIX. There now is a stationary facility at Limay, close to Mantes and another mobile one ready to intervene no matter what sludge lagoon or distance away.

## -I-ASPECT THEORIQUE

De nombreuses études ont récemment démontré que l'évolution d'une boue pouvait se poursuivre longtemps après sa mise en décharge. Un des dangers les plus sournois étant la libération de métaux lourds à la suite d'une baisse de pH due à une action microbienne. Pour empêcher cela, on peut rassembler les déchets toxiques soigneusement déshydratés dans des fûts qui seront ensuite placés dans des mines désaffectées. On peut aussi opérer une "fixation" dans le but de rendre les boues analogues aux minerais qui ont inclus les éléments les plus toxiques pendant l'étendue des temps géologiques; les plus fréquents de ces minerais étant les silicates à la structure octaédrique particulièrement stable.

### -A- Principes du procédé de fixation

La fixation, objet de la présente communication, consiste en un mélange intime des boues à traiter avec un réactif solide constitué essentiellement de ciment auquel est joint un liquide catalyseur à base de silicates. Le procédé est destiné aux boues dont le jus de pressage ne serait pas acceptable pour un rejet dans le milieu extérieur, soit en raison d'une DCO trop forte, soit en raison des métaux lourds qu'il pourrait contenir.

Avant de parler de la mise en œuvre de ce traitement qui relève surtout de la technologie, il a semblé bon de s'étendre sur les caractéristiques du matériau obtenu et sur les résultats d'essais tant en laboratoire que in situ sur des masses plus importantes de boues fixées soumises à des arrivages d'eau parfois acidulée. Ces derniers essais étaient destinés à étudier une évolution possible à long terme, même dans des conditions inhabituelles.

Bien que les réactions qui ont lieu dans le mélange boues-réactifs soient particulièrement complexes, on peut distinguer plusieurs actions simultanées :

- une neutralisation des boues faiblement acides sous l'action du calcaire contenu dans les réactifs solides. Les silicates réagissent dans le milieu basique ainsi formé pour donner des ions de la forme  $\text{Si}(\text{OH})_6^-$  qui se rassemblent sous la forme octaédrique mentionnée ci-dessus. La silice étant au préalable très divisée, la surface de contact est très grande comme dans le cas de réactifs "activés".

- une précipitation des composés hydratés (hydroxydes), comme toujours en milieu alcalin. Cette précipitation ayant lieu en même temps que la formation des ions d'acides siliciques. Le résultat est la formation de sels complexés et hydratés très insolubles qui incluent les molécules d'eau présentes dans le milieu, la surface de contact est encore accrue au cours de ce processus.

- des réactions d'absorption entre composés ionisés plus ou moins faiblement, les cations étant attirés par les anions du système réticulaire en cours de formation. Cette absorption sera plus importante pour les cations les moins solubles qui sont souvent les plus lourds; c'est un élément favorable. Il est aussi possible qu'il y ait dans la

masse en réaction des échanges d'ions :

- la gélification du réseau ainsi constitué se propage de proche en proche, la solidification totale ayant lieu dans un délai de 1 à 3 jours. Les cations métalliques sont enrobés dans des réseaux extrêmement fins et serrés qui donnent une grande stabilité au produit final désigné souvent sous le nom de "pseudo-minéral".

### -B- Caractéristiques physiques du matériau obtenu

Les essais et mesures faits sur les eaux de lixiviation seront résumés au chapitre suivant qui traitera de l'efficacité du procédé. Du point de vue purement mécanique, si la boue à la sortie du réacteur a encore un aspect liquide, elle le perd assez rapidement pour prendre l'aspect d'une terre argileuse allant en se durcissant. Des mesures ont donné comme résistance à la compression des valeurs de l'ordre de 2,5 à 3 Bars; un chiffre de 5 Bars a été enregistré aux Etats-Unis. De fait, quelques temps après son épandage, il est possible de marcher sur les boues solidifiées, d'y circuler à bicyclette ou même en voiture. La température a une influence certaine sur le temps de séchage : en été, le temps de prise peut être ramené à quelques heures. En hiver, il est beaucoup plus lent en cas de froid prolongé, même si la réaction n'est jamais complètement arrêtée. La couleur du produit final dépend des constituants des boues à fixer, elle peut varier du jaune au gris-vert, voire au bleu. L'odeur est imperceptible sauf cas tout à fait particuliers. Elle reste d'ailleurs toujours très inférieure à celle de la boue primitive.

Une fois mises en décharge, les boues fixées se comportent comme n'importe quel remblai argileux. Elles ont été souvent recouvertes de terre arable, afin d'être le support d'espaces verts ou de terrains de jeux. La végétation s'y est développée tout à fait normalement ce qui est un excellent indice d'efficacité si l'on se rappelle le caractère toxique de la plupart des ions emprisonnés.

Il faut aussi rappeler le caractère tampon des boues fixées, qui a pour cause la présence de calcaire dans les liants hydrauliques utilisés. Ce caractère tampon est particulièrement précieux dans les décharges où sont reçus conjointement des déchets organiques et des déchets comprenant des ions métalliques plus ou moins nocifs. Un abaissement de pH du sol, qui peut être la simple conséquence d'une activité bactérienne, peut avoir pour résultat le dégagement de mauvaises odeurs (non neutralisation des acides organiques dégagés) et la remise en solution d'ions précipités en milieu basique. Dans de tels sites, l'addition de boues fixées a un double rôle bénéfique : elle constitue une couche parfaitement étanche bloquant ou retardant considérablement l'évolution des déchets entreposés et elle maintient le pH à un niveau suffisamment élevé. Bien qu'évoquée assez rarement, il s'agit

d'une propriété particulièrement intéressante. La rétention de l'eau contenue dans les boues et son blocage avec les autres constituants montre bien qu'il s'agit d'un procédé "définitif". Cela implique par contre qu'il n'y a aucune réduction de volume; par rapport à la boue primitive, il y a même une augmentation d'environ 20%, tant en raison des réactifs ajoutés qu'au foisonnement du produit final par rapport à certaines boues.

## II - EFFICACITE DU PROCEDE - ESSAIS DE LIXIVIATION

De nombreux essais ont été effectués, non seulement en FRANCE mais aussi aux ETATS-UNIS, en ANGLETERRE et au JAPON, pour ne citer que les principaux. Avant d'examiner deux cas particuliers, il est intéressant de tracer les grandes lignes des résultats de laboratoire. Les essais de lixiviation ont été menés par immersion dans des colonnes d'eau.

On a considéré que l'évolution au cours d'une année était obtenue par le passage de 800 cm<sup>3</sup> dans une colonne normalisée de manière à ce que le débit corresponde à une année de précipitations en FRANCE (hauteur moyenne de pluie 760mm/m). Ces essais ont été menés en faisant descendre le pH de l'eau de lixiviation jusqu'à 3, ce qui est bien rare pour une eau de pluie. La nature de l'acide utilisé à cette fin n'a eu qu'une influence négligeable sur les résultats (on a employé entre autres les acides acétique, hydroxybenzoïque, nitrique, chlorhydrique, sulfurique). Pour les métaux suivants : fer, zinc, nickel, plomb et cadmium, la teneur de l'eau de lixiviation de boues traitées provenant de l'industrie automobile est restée inférieure à 0,10 g/m<sup>3</sup>. Pour le cuivre et le chrome, elle n'a atteint 0,25 que la première "année", dans le cas d'une eau acidifiée à un pH inférieur à 4 au moyen de l'acide chlorhydrique. Pour le chrome même à un pH de 1, la teneur en chrome total est restée inférieure à 0,5 g/m<sup>3</sup> après trois ans de "précipitations" simulées comme il a été dit ci-dessus.

En régime de précipitations moyennes, la quantité d'ions métalliques relâchée par mètre carré de terrain revêtu d'une couche moyenne de 60 cm de boues fixées est inférieure à 0,4 g pour le chrome, 0,35 pour le cuivre, 0,05 pour le zinc, elle a été indécélable pour le nickel, ce qui s'explique peut-être par une fixation de cet ion au cours de la percolation. Ce sont des quantités bien inférieures à celles des eaux de ruissellement d'une décharge classique.

Il faut enfin remarquer que les ions métalliques sont eux-mêmes assez dilués dans la boue fixée en place, plus dilués que dans la boue d'origine puisqu'il y a ajout de réactif.

"Il est évident que ces premières tentatives de contrôle in situ ne sont pas parfaites et demanderaient à être améliorées, mais telles quelles, elles amènent à des conclusions positives. Elles montrent que, si l'insolubilisation totale des éléments toxiques n'est pas possible (ce que tout chimiste aurait pu affirmer a priori avec une certitude

parfaite), leur facteur de possibilité de passage en solution est ramené à des valeurs parfaitement compatibles avec la politique actuelle de protection de l'environnement." (M. Longuet-Cérilh).

## III - INSTALLATIONS EXISTANTES

### -A- Installation fixe

Contrairement aux solutions anglaise et américaine qui ont choisi de placer l'ensemble des appareils nécessaires au traitement dans une seule remorque de grandes dimensions, la SARP-Industries a choisi à LIMAY de construire une installation fixe et cela pour plusieurs raisons. D'abord parce que ce centre produit lui-même des boues en quantités importantes lors de ses opérations de neutralisation et de détoxification. En particulier les effluents de traitement de surface contenant du chrome hexavalent sont traités par réduction puis précipitation sous forme de chrome trivalent.

Ensuite parce que, la France étant moins étendue mais d'un peuplement plus dense que les Etats-Unis - peut être aussi pour des raisons de tradition industrielle - les lagunes de boues et d'effluents sont rares.

Situé en Région Parisienne, le Centre de LIMAY était destiné à recevoir les effluents de diverses usines, en quantités relativement modestes pour chacune d'elles (une ou deux citernes par mois) mais devant subir un traitement élaboré.

Le Centre de LIMAY possède donc :

- a) Une lagune de stockage d'une capacité de 2000 m<sup>3</sup>, dans laquelle les boues reconnues aptes à ce type de traitement sont déversées. Elle est étanchéifiée par un revêtement plastique. Les boues entreposées sont homogénéisées par une drague automatique qui retarde en même temps la formation d'une couche de dépôt.
  - b) Un groupe de pompage qui reprend les boues pour les diriger dans le réacteur.
  - c) Un ensemble de stockage et d'alimentation du réactif solide pour lequel l'alimentation par fluidisation, trop coûteuse en énergie, a été abandonnée au profit d'une alimentation gravitaire et d'un dosage volumétrique moins précis mais plus fiable que le précédent.
  - d) Un ensemble de stockage et d'alimentation du réactif liquide pompe doseuse asservie aux pompes d'alimentation.
  - e) Un réacteur placé sous le silo de réactif solide dans lequel boues et réactifs sont mélangés énergiquement et aspirés par un groupe d'échange.
  - f) Deux lagunes de solidification de 1000 m<sup>3</sup> chacune dans lesquelles les boues achèvent leur évolution avant d'être reprises par tractochargéur et envoyées en décharge.
  - g) Un bâtiment de régulation et de contrôle.
- Cet ensemble a une capacité nominale de 50 m<sup>3</sup>/h soit, pour 2000 heures de travail, une possibilité de 100.000 m<sup>3</sup>/an, ce qui permet d'abaisser le prix de revient du traitement dans la mesure où le prix du transport reste acceptable.

#### -B-Installation mobile

Une installation fixe ne peut toutefois répondre à toutes les demandes, ne serait-ce qu'en raison du prix de transport du déchet. C'est pourquoi un poste de traitement mobile a été mis à l'étude dès que l'installation fixe a pu être mise en marche industriellement.

On a surtout recherché la souplesse, la facilité de mise en place et la fiabilité. Dans cet esprit, les différentes parties du traitement ont été distinguées, leur assemblage n'étant fait qu'au dernier moment.

La plate-forme de traitement a été éclatée en trois parties :

- stockage et alimentation en réactif solide
- stockage et alimentation en réactif liquide
- mélange et contrôle.

Parties auxquelles se joignent naturellement les dispositifs de pompage, de transit et d'évacuation (tuyaux et pompes).

Le réactif solide est introduit par une alimentation gravitaire avec dosage volumétrique. Le réactif liquide est transporté en citerne, le reste de l'installation (mélange, dosage, régulation etc...) tient dans un camion classique. Le train routier se compose donc de trois véhicules dont aucun ne sort du gabarit légal, ce qui est un avantage incontestable.

Pour chaque matériel choisi, une attention particulière a été apportée à sa simplicité et sa solidité. En effet, le matériel mobile peut être amené à travailler dans des conditions difficiles. Tout ce matériel est vendu sur le marché français, ce qui simplifie les problèmes d'entretien.

#### IV- DOMAINE D'APPLICATION DU PROCÉDE

Comme toutes choses en ce bas monde, ce procédé n'est pas universel, environ 10% des échantillons examinés ne sont pas propres à être traités par ce procédé. Il y a des inhibiteurs connus parmi lesquels

- le sucre : qui exclut que l'on traite les boues de vinasse, les mélasses ...
- le chrome hexavalent, les cyanures, l'arsenic, le phénol qui ne sont pas retenus, ce qui implique qu'un traitement préalable puisse être nécessaire pour des boues chromées afin de réduire l'état d'oxydation de ce cation.
- Les sulfures et le mercure sont parfois bien piégés, parfois non, sans qu'il soit toujours possible d'en discerner les causes.
- L'ion ammonium se conduit comme un "poison" de la réaction à partir d'une concentration de 500 g/m<sup>3</sup>.

Il est donc indispensable avant de traiter une boue de vérifier son aptitude à la fixation. Cette analyse préliminaire consiste en un essai en laboratoire qui permet en outre de déterminer les taux de réactifs. Après 24h d'attente, on procède à des essais de lixiviation par trois percolations de 800 ml chacune, on a donc les résultats correspondants à trois années de précipitations simulées. L'analyse des métaux est faite par spectrographie. Ces exceptions mises à part, le domaine d'appli-

cation du procédé est très étendu. On peut citer pêle-mêle : liqueurs de décapage, huiles et goudrons (en solution), boues de neutralisation, boues de collecteurs de poussière, régénération des acides, liqueurs noires, boues de déchromatation, de neutralisation d'acides ou bases forts, toutes boues contenant des métaux lourds, boues de dépigmentation etc...

Sans prétendre à l'universalité, la fixation des boues a donc de grandes possibilités et tient une place importante dans la lutte actuelle pour la sauvegarde de la nature.

#### V - CONCLUSION

Outre la fixation des boues, le Centre de la SARP-Industries à LIMAY dispose d'installations de neutralisation, de détoxication, de cassage d'émulsions huileuses et de traitement de déchets cuivro-ammoniacaux avec récupération du cuivre. La comparaison des quantités de déchets traités en 1979 est assez instructive (les poids sont exprimés en tonnes) :

Traitement physico-chimique (neutralisation et détoxication)	45.800
Liquides incinérés	17.400
Emulsions huileuses	16.200
Boues fixées	33.150
Déchets de laboratoire et cuivre ammoniacal	850
	-----
TOTAL	113.400

Il est symptomatique qu'aucun procédé n'ait de place véritablement prédominante, cela confirme s'il en était besoin le caractère illusoire de la recherche d'une solution "fourre-tout". La fixation des boues est une solution très intéressante parce que "définitive". Elle complète très bien la panoplie actuelle. Mais elle n'a aucune prétention à l'universalité et le meilleur traitement reste celui qui permet de récupérer ce qui peut l'être.

Le premier exposé relatif au rôle de la chimie des ciments dans la compréhension et la réalisation du traitement optimum d'une boue donnée a surtout suscité des questions sur le rôle des alcalins sur les réactions de fixation des ions toxiques par le ciment. En fait l'hydroxyde de calcium est une base forte peu soluble dans l'eau (environ 0,025M) dont l'équilibre de solubilité dépend de l'activité des OH<sup>-</sup> présents dans la solution:

En présence de fortes quantités de bases alcalines (NaOH, KOH) complètement dissociées, la concentration en Ca<sup>2+</sup> peut s'abaisser au-dessous du produit de solubilité du composé dont on recherche la formation et la précipitation (chloroaluminate de calcium hydraté par exemple, dans ce cas Cl<sup>-</sup> reste en solution). On voit combien la connaissance du milieu à traiter est indispensable. Il est possible de regrouper d'une manière très générale les réactions de traitement en fonction des ions à traiter sur un tableau de classification périodique (figure F de l'exposé de P. LONGUET et G. BELLINA)

Ajoutons que certains fabricants ont proposé l'élaboration de liants spéciaux pour le traitement des boues.

L'exposé de Monsieur PICHAT montre les impératifs qui conduisent au traitement, les problèmes économiques posés par l'application des procédés de traitement (centres de traitement ou unités mobiles), les succès et les difficultés de réalisation avec une vue prospective du développement à venir.

L'exposé de Monsieur PETIT soulève des questions sur la nature des liaisons entre les ions fixés et les gels silicique et aluminique présents dans un milieu acide dont on abaisse progressivement le pH. Le manque d'organisation structurale des composés ainsi générés rend délicate la réponse exacte, mais il est bien établi que géologiquement des minerais actuellement parfaitement cristallisés ont eu une genèse identique.

Monsieur BLANCHARD précise que même si la boue toxique se présente sous une forme très peu soluble (hydroxyde), cette forme n'est pas forcément la mieux adaptée au stockage (action des agents atmosphériques acides). Il montre que l'utilisation de la chaux et des liants hydrauliques assurent une bonne stabilisation pratiquement irréversible.

L'intéressant exposé de M. FORMANEK sur l'incidence des solubilités des différents ions à l'interface liquide solide dans la flottation n'a pu être suivi d'une discussion à cause de l'horaire.

Avec l'exposé de Monsieur EMERY on aborde plus directement le domaine des applications. L'auteur

relate une étude conduite pour le traitement d'une boue donnée avec des mélanges en quantités variables de poussières de four, de cendres volantes et de ciment. La discussion qui suit cet exposé dégage l'importance des aspects économiques pour ce genre de problème.

Monsieur KATAOKA développe une étude du même genre réalisée dans son cas avec des mélanges de ciment portland, de laitier et d'anhydrite. Ces liants à prise essentiellement ettringite développent des résistances mécaniques fort intéressantes. Malheureusement aucune mesure de lixiviation n'est indiquée dans cet exposé.

L'exposé de Monsieur SUZUKI et collaborateurs n'est pas présenté par les auteurs. Sa lecture publique montre une application originale des hydroxyapatites de synthèse pour la séparation sélective de certains ions métalliques. L'impossibilité d'une discussion est regrettée par les participants.

Monsieur RAU présente le procédé POZ.O.TEC utilisant principalement les cendres volantes et la chaux, procédé qui présente l'avantage d'une longue pratique. La discussion concerne surtout les problèmes de lixiviation des produits traités qui dépend évidemment de la boue initiale et des conditions de stockage. L'auteur signale que sur un remblai recouvert par la suite de végétation aucun rejet dangereux n'a été mis en évidence dans des puits de contrôle disposés autour du terrain traité.

Monsieur LEROY nous fait part de son expérience sur un autre procédé industriel utilisé dans un centre de traitement de déchets en France et qui assure le traitement du tiers environ du tonnage des déchets collectés par ce Centre.

L'examen des divers exposés relatifs à des applications met clairement en évidence la nécessité de pouvoir disposer de méthodes d'essais sur terrain pour apprécier l'efficacité réelle d'un procédé. C'est à partir de tels essais qui restent souvent à établir ou à perfectionner que pourra vraiment se dégager une comparaison objective des nombreux procédés proposés et partant apporter la garantie indispensable au développement du traitement des boues par les liants hydrauliques.

Le Président donne ensuite la parole à Madame ALOISI, Chef de Service au Ministère de l'Environnement et du Cadre de Vie qui nous a fait l'honneur de participer à nos travaux. Madame ALOISI exprime tout l'intérêt porté au problème du traitement des déchets par son Ministère et montre le rôle de l'Administration en France dans la lutte contre les déchets toxiques (incitations légales, aides financières, poursuites judiciaires....).

Le Président dégage ensuite les conclusions essentielles de ce séminaire.

## CONCLUSION DU SEMINAIRE PAR LE PRESIDENT

A la lumière des exposés présentés, il apparaît que le traitement des boues industrielles à l'aide de liants hydrauliques permet, au moins en théorie, de fixer définitivement les ions métalliques contenus dans ces boues. De nombreux procédés fondés sur ce principe sont entrés ou sont sur le point d'entrer en application. Ces procédés reposent en général sur des connaissances héritées de la technique des bétons ou de la chimie classique des silicates. Bien que ces procédés soient dans leur ensemble satisfaisants, des progrès peuvent encore être accomplis par des recherches fondamentales sur les réactions d'hydratation en présence d'une concentration importante de molécules étrangères. Ces réactions conduisent à des produits spécifiques dont la durabilité doit être étudiée. Il s'agit là d'un champ de réflexion très vaste pour les chimistes du ciment, mais il n'est pas nécessaire d'attendre qu'il soit entièrement exploré pour mettre en exploitation les procédés de solidification actuels car, tels qu'ils existent, ils constituent déjà une solution infiniment préférable au rejet pur et simple dans le milieu naturel.

Des débats très animés qui ont eu lieu aujourd'hui à l'occasion de ce Séminaire, on peut tirer un ordre de priorité pour les recherches à entreprendre dans l'avenir :

- . D'abord, il faudra définir une procédure de mise en oeuvre de procédés rigoureuse calquée sur celle du béton. En effet, pour garantir la durabilité des ouvrages d'art, on identifie soigneusement les liants utilisés, on analyse l'eau de gâchage, le sable et les granulats afin de déterminer les dosages appropriés. Lorsque l'ouvrage est en cours d'exécution, une surveillance vigilante est exercée. Dans certains cas, des prélèvements conservatoires permettent de retrouver l'origine d'éventuels désordres. Dans le cas de la fixation des boues, cette même procédure pourrait être adoptée pour obtenir une garantie de qualité sur le résultat de l'opération.
- . Ensuite, il est nécessaire de définir un test représentatif des phénomènes qui se déroulent sur le site où les produits traités sont entreposés. Ce qui a été proposé jusqu'ici ne constitue qu'un point de départ ; il semble particulièrement utile de tenir compte de l'acidité du milieu naturel. Cette acidité constitue une agression pour le produit solidifié au même titre que pour les bétons courants.
- . Finalement, il faut aboutir à une meilleure connaissance des réactions de base qui se déroulent entre les composants de la boue et les phases actives du ciment ; cette connaissance permettra d'établir les limites des procédés et de choisir les réactifs les plus appropriés.

Ce Séminaire, qui a été l'occasion d'une rencontre entre les industriels, les physicochimistes et les représentants de l'Administration, aura donc permis aux différents points de vues de s'exprimer et, je l'espère, de se rejoindre pour un objectif commun qui est la protection de l'environnement.

## SEMINAIRE C

### Economies d'énergie Vues prospectives

Président : M. GUY (France)

## La chimie solaire à température élevée

### *High temperature solar chemistry*

Geoges URBAIN, Lab. des Ultra-Réfractaires, CNRS, B.P. 5, 66120 Odeillo, France.

#### Résumé

L'article présente quelques exemples de réactions effectuées avec des réacteurs solaires à température élevée en chimie préparative ou énergétique. Ces études sont financées en France par le C.N.R.S.

#### Abstract

Some examples are given of material research and energetics reactions using high temperature solar reactors. These projects are sponsored by the C.N.R.S. in France.

## 1. INTRODUCTION.

Les avantages du chauffage au moyen du rayonnement solaire concentré sont les suivants :

- un apport d'énergie sans contamination et en absence de champs magnétiques,
- une densité d'énergie élevée,
- la localisation précise de l'impact énergétique,
- la possibilité d'effectuer ce chauffage en atmosphère oxydante (air)

A ces possibilités intéressantes sont associées des difficultés notables en ce qui concerne :

- la mesure des température des cibles,
- la régulation de l'énergie reçue par la cible,
- le confinement de la cible pour travailler sous vide ou sous atmosphère contrôlée.

Ces difficultés technologiques sont actuellement résolues pour les équipements de laboratoire de quelques kW. Les solutions ainsi utilisées ne sont pas toujours transposables aux installations de plus forte puissance. En particulier les parois transparentes utilisables au laboratoire (Pyrex ou silice transparente) ne seront pas économiquement possibles pour les installations pilotes. Le verre Pyrex supporte un flux de  $20 \text{ W cm}^{-2}$  et la silice transparente environ  $500 \text{ W cm}^{-2}$ . A l'occasion de la description de quelques montages précis nous verrons les méthodes utilisées au laboratoire pour résoudre ces difficultés spécifiques.

## 2. LA CHIMIE SOLAIRE PREPARATIVE.

Les premières années du développement des fours solaires correspondent surtout à des essais destinés à présenter leurs possibilités. Les montages démonstratifs ainsi réalisés exploitent de façon judicieuse les avantages du chauffage solaire par rapport aux techniques classiques d'obtention des températures élevées.

De tels essais ont été effectués de 1958 à 1970 à Montlouis avec un four de 50 kW, depuis ils sont réalisés à Odeillo avec le four de 1 MW et différents montages de 1,5 et 2 kW. Les principaux domaines d'application du chauffage solaire sont :

- les fusions ou préparations de produits réfractaires,
- les traitements de minerais,
- la détermination de grandeurs thermochimiques à température élevée.

Pour les traitements à température élevée citons par exemple:

- des fusions de zircon ( $T_f = 2710^\circ\text{C}$ ) en continu (150 à 250 kg par heure, d'alumine ( $T_f = 2054^\circ\text{C}$ ) à 150 kg par heure et de différents mélanges d'oxydes (zircon et oxydes de terres rares, etc...) qui ont été effectués avec le concentrateur de 1 MW en four tournant (lit brassé). La méthode de fusion en tas avec granulation du produit par soufflage du jet liquide est aussi utilisée. Ces fusions, suivies ou non de granulation, conduisent à un produit fondu ou divisé, particulièrement apte aux opérations de frittage ultérieur. Avec ces techniques ont été traités des bauxites (de  $1850$  à  $1950^\circ\text{C}$ ) à 120 kg par heure, des composés alumineux ( $2000$  à  $2100^\circ\text{C}$ ) à 30 kg par heure et des zircons dopées (20 kg par heure), à l'occasion de contrat avec des groupes industriels intéressés.

Avec les montages de faible puissance (2 kW) mais disposant des mêmes densités d'énergie, des essais de fusion de zone sur nacelle refroidie et de croissance de monocristaux ( $\text{TiO}_2$ ) ont aussi été effectués. Comme exemples de traitement de minerais on peut citer :

- l'élimination du fluor par voie thermique de phosphates apatitiques,
- la décarbonatation de minéraux (phosphates contenant 30 à 40 % de carbonates),
- le grillage de minerais sulfurés (molybdénite),

- la fragmentation par choc thermique (basnaésite).

Les objectifs visés sont alors l'application de techniques solaires (de haute température) pour valoriser des ressources minérales des pays à fort ensoleillement.

Ces techniques sont néanmoins suffisamment simples pour être mises en place sur le site des exploitations minières. Les intérêts économiques de ces pré-traitements sont :

- diminuer les inertes à transporter par élimination des carbonates, etc...
- obtenir un produit de pureté technique ( $\text{MoO}_3$  par grillage de la molybdénite),
- économiser une part importante de l'énergie de broyage pour les minerais étonnables thermiquement : basnaésite.

D'autre part les équipements solaires de 2 kW du laboratoire sont utilisés pour des études de thermochimie à température élevée :

- des mesures de pression de vapeur, et de cinétiques d'évaporation de composés réfractaires sous différentes atmosphères sont ainsi réalisées. Les réfractaires (isolants et conducteurs électriques) spéciaux prévus dans les programmes concernant la conversion magnéto-hydro-dynamique (MHD) ont été soumis à des essais de corrosion, d'évaporation, de tenue au choc thermique, sous des atmosphères contrôlées (air, vapeur d'eau, argon + oxygène, etc...).
- l'étude de la dissolution des gaz (oxygène, vapeur d'eau, gaz carbonique) dans des oxydes et des aluminosilicates est aussi menée à bien avec ces fours solaires. La connaissance des équilibres de dissolution (chaleur de dissolution) et des conditions cinétiques du dégazage au cours du refroidissement (influence du chemin de solidification, des solubilités dans les différentes phases et de la viscosité de ces phases) sont très importantes pour les in-

dustries utilisatrices de laitiers, scories et réfractaires fondus : métallurgie, sidérurgie, réfractaires électrofondus, etc... Les mécanismes des remontées magmatiques dépendent aussi des variations de solubilité de phases gazeuses ( $\text{H}_2\text{O}$  et  $\text{CO}_2$ ) dans les familles d'aluminosilicates constituant les magmas suivant la pression et la température.

Des montages utilisant un concentrateur parabolique de 2 kW à axe horizontal permettent le tracé de courbes de refroidissement d'oxydes réfractaires. Le montage en autocreuset, en rotation autour de son axe horizontal, permet d'obtenir la mesure des températures d'équilibre solide-liquide avec une bonne reproductibilité.

Ces applications du chauffage par rayonnement (fours à image et fours solaires) utilisent au mieux leurs caractéristiques : rapidité, non contamination, concentration localisée de l'énergie.

On opère souvent de façon dynamique avec des fluctuations notables de la température à la fois dans le temps et l'espace. L'équilibre thermique du matériau irradié est difficile à obtenir. Par contre un état de régime, proche de l'équilibre thermodynamique est obtenu en lit brassé avec le montage en four tournant. Pour des réactions entre phases condensées (solides et liquides) l'expérience vérifie bien, par des mesures de températures de transition par exemple, la réalité d'un régime stationnaire.

### 3. LA CHIMIE SOLAIRE ENERGETIQUE.

L'objectif est ici de produire un vecteur énergétique à partir du rayonnement solaire. Ce vecteur peut être l'hydrogène, un métal, un oxyde, soit en général le produit d'une réaction réversible. En effet, une condition nécessaire à l'utilisation énergétique du rayonnement solaire est la possibi-

lité de stockage de ce vecteur. L'utilisation différée, grâce au stockage, des produits de la réaction se fera avec restitution d'une partie de l'énergie initiale et production de chaleur en un lieu et au moment voulu par le consommateur. Le "génie chimique solaire" comporte les étapes suivantes :

1°) des études thermodynamiques des réactions réversibles possibles. Ce sont des calculs et des modélisations à partir de données expérimentales. Les grandeurs manquantes doivent être estimées ou mesurées. Le résultat est une optimisation des paramètres réactionnels : température, pression et nature de l'atmosphère gazeuse, etc...

2°) l'étape suivante est le choix d'un réacteur adapté au problème posé suivant la nature des phases en présence, de la température et de la pression. Pour un réacteur donné on doit ensuite mesurer ou calculer les transferts thermiques et les bilans de masse. Ce travail suppose connue la cinétique de la réaction choisie. Ce sont des essais à l'échelle du laboratoire, puis l'établissement de modèles qui permettent une transposition à une échelle pilote. Les trois exemples suivants concernent de tels aspects du génie chimique solaire :

- étude de deux réacteurs (réaction de décarbonatation),
- réaction en phase gazeuse (thermolyse de l'eau),
- réaction entre solide et gaz (grillage).

#### Etude de deux modèles de réacteurs solaires.

En prenant la réaction bien connue :

c'est à dire la décomposition du carbonate de calcium, on étudie deux types de réacteurs au foyer des fours solaires de 2 kW à Odeillo :

- un réacteur à lit fluidisé,
- un réacteur tournant à lit brassé.

Le réacteur cylindrique tournant absorbe presque complètement le rayonnement et ses parois sont à température élevée (500°C). Les gradients thermiques sont élevés (montage en auto-creuset) mais le rendement de la captation de l'énergie rayonnante est bon (40 %). En marche continue, avec une alimentation arrière en produit, avec un temps de passage de 100 secondes, on mesure un taux de décarbonatation de 60 % et un rendement thermochimique global de 15 %.

Le second réacteur testé est un lit fluidisé recevant latéralement le rayonnement au travers d'un tube de silice transparente. La température du lit fluidisé varie entre 800 et 1300°C suivant le coefficient d'absorption du solide divisé. En régime permanent la température en un point du lit fluidisé est bien stable. Une décomposition complète du carbonate est obtenue avec une consommation de l'ordre de 5 kW par kg de carbonate. Le rendement thermochimique est de l'ordre de 20 % en fonctionnement discontinu.

#### Etude d'une réaction en phase gazeuse à température élevée.

La décomposition thermique de l'eau est obtenue dans une tuyère réfractaire (réfractaire à base de zircone) située au foyer d'un concentrateur solaire à 2200°C. Le choc thermique, puis le refroidissement à la vitesse de  $10^6$  degré par seconde permet de tremper les constituants de la réaction dont l'hydrogène.

Un semblable traitement (chauffage éclair et trempe brutale) appliqué à du méthane au foyer d'un concentrateur de 1,5 kW (le gaz est porté à environ 1500°C) donne à peu près 10 % d'acétylène.

#### Etude d'un réacteur solaire pilote pour le grillage de minerais.

Le grillage de minerais sulfurés (molyb-

dénite) en réacteur solaire rotatif à lit brassé devrait permettre :

- d'économiser une fraction importante de la consommation d'énergie pour les broyages,
- d'obtenir directement un oxyde ( $\text{MoO}_3$ ) de pureté technique.

Après l'étude thermodynamique (mesure des enthalpies aux températures élevées) et cinétique de la réaction d'oxydation des produits susceptibles d'être traités en réacteur solaire. Ce travail montre l'intérêt de traiter la molybdénite après un premier enrichissement par flottation (produit à 6 % environ de molybdénite). Le minerai brut à 0,5 % de molybdène entraînerait le chauffage de quantités importantes d'inertes (silice). Le grillage du concentré à 96 % ne présente aucun intérêt économique. C'est le semi-concentré à 6 % qui présente la granulométrie et la concentration les mieux adaptées au traitement solaire. Les problèmes à résoudre et en cours d'étude sont la réalisation d'un réacteur solaire tournant à lit brassé avec récupération du  $\text{SO}_2$  et condensation de l'oxyde de  $\text{MoO}_3$  vaporisé. La taille des cristallites de  $\text{MoO}_3$  est comprise entre 300 et 500 nm. Cette filtration et cette épuration posent de délicats problèmes technologiques.

Ces trois études sont en cours de développement dans le cadre de contrats passés avec le PIRDES. Elles engagent six laboratoires et la somme de trois contrats sont de l'ordre de 480 kF pour deux années.

#### 4. CONCLUSION.

Les orientations prises par les laboratoires engagés dans les études de chimie solaire à température élevée sont cohérentes avec les options exprimées par les responsables nationaux (COMES) : études prospectives de faisabilité (niveau labo-

ratoire et pilote de première génération) pour l'horizon 2000, avec des moyens réduits, mais une certaine continuité.

# Utilisation d'un sous-produit à très haute teneur en soufre comme combustible dans un four de cimenterie, sans transfert de pollution atmosphérique

## *Use of a by-product with very high sulphur content as fuel in a cement kiln, without transferring atmospheric pollution*

P. ETOC, Ingénieur à la Société des Ciments Français, Professeur à l'Ecole Nationale Supérieure Céramique de Sèvres et à l'Ecole de Thermique (I.F.E.), France.

**RESUME** : En prévision d'avoir à brûler dans l'avenir des fuels extra-lourds à haute teneur en soufre, la Société des Ciments Français a effectué des essais d'utilisation d'un goudron de pétro-léochimie non encore commercialisé comme combustible, sur un four à voie humide de 1 000 t/d de clinker.

Ces essais en vraie grandeur comportaient de gros risques car on ne savait pas si le procédé allait accepter un combustible à teneur en soufre nettement plus élevée que celle du fuel lourd ordinaire, 5 % contre 3,5 %; par ailleurs le goudron est nettement plus visqueux que celui-ci au niveau de la température de pompage et, de plus, fuel lourd et goudron ne sont pas miscibles.

Au moyen d'une tuyère-prototype permettant de brûler simultanément le goudron et un fuel à basse teneur en soufre, il a été possible d'augmenter progressivement la teneur en soufre résultante des combustibles injectés. Finalement, les essais ont montré qu'il était possible de fonctionner à 100 % de goudron sans difficultés d'exploitation et sans modification significative de la qualité du clinker. Depuis Mars 1979, l'utilisation de ce produit est devenue routine d'exploitation.

Le four de cimenterie a confirmé ses propriétés de piège à soufre - on devrait dire de piège à polluants. Rien n'interdit à présent d'envisager de brûler dans un four de cimenterie des combustibles encore plus sulfureux, par exemple des bitumes et, également de détruire de nombreux déchets industriels, sans transfert de pollution, mais avec récupération de la valeur énergétique.

**SUMMARY** : As it is anticipated that extra heavy fuel oils with a high sulphur content will have to be used in the future, Société des Ciments Français has carried out field trials with steam cracking residue (tar), which is not yet commercialised as fuel, in a 1000 t/d wet process rotary cement kiln.

These full-sized trials involved great risks, as it was not known whether the process would tolerate a fuel with a percentage of sulphur much higher than that of the ordinary heavy fuel, 5% as against 3.5%; also, the viscosity of the tar is notably higher than that of the heavy fuel at pumping temperature and, in addition, heavy fuel and tar do not mix together.

Using a prototype burner which allows the simultaneous firing of tar and low sulphur content fuel oil, it was possible to increase progressively the sulphur percentage of the injected fuels. Finally, the trials showed that it was possible to work with 100% tar without running into operating problems and without significant modification of the clinker quality. Since March 1979 the use of tar has become routine.

It has been proven that the cement kiln has the characteristics of a sulphur trap - or should we say a pollution trap. It now seems perfectly feasible to consider the firing of a cement kiln with fuels of an even higher sulphur content, such as bitumen, and the burning of industrial waste without transferring pollution, whilst recovering its energy value.

## I - INTRODUCTION

A partir de 1974, l'alourdissement du fuel-oil lourd ordinaire déjà constaté, la perspective de mise en place dans les raffineries d'unités de conversion avec apparition sur le marché français de combustibles "hors normes", extra lourds, à haute teneur en soufre tels que résidus sous vide, sous-produits de pétrochimie, l'éventualité d'avoir à brûler divers résidus industriels, nous ont incité à étudier l'utilisation de tels produits comme combustibles dans nos fours. Nous pouvions légitimement penser que cette utilisation ne devait pas conduire à un transfert de pollution, car nous avions déjà à notre disposition les résultats de nos travaux expérimentaux sur les fours des usines de Ranville et de Guerville, montrant que le four de cimenterie se comportait comme un "piège à soufre efficace" (1). Cette étude allait dans le sens de la recherche de la récupération d'énergie et surtout de la substitution de tout combustible au fuel-oil lourd, à laquelle les Cimentiers Français s'étaient engagés en signant le 22.03.76 le premier Contrat Sectoriel d'Economies d'Energie avec le Ministère de l'Industrie.

Aussi, lorsque vers le milieu de 1975, Esso-Chimie a proposé à la Société des Ciments Français des fournitures assez importantes de goudron de pétrochimie - souvent baptisé "tar" dans les compte-rendus - dont la teneur en soufre pouvait dépasser 5%, il a été décidé de tenter l'expérience.

Les essais ont eu lieu de septembre 1977 à juin 1978 sur le four de 1 000t/d de clinker gris à voie humide, à l'usine de Guerville et, en définitive, la fabrication du clinker n'a pas été affectée par l'utilisation du nouveau combustible. Au cours de ces essais, nous avons contrôlé particulièrement les marches à fuel-oil pur, en mixte goudron 60% - fuel-oil 40% et à goudron pur et, de ce fait, nous avons obtenu un grand nombre de résultats nouveaux à verser au dossier du "four de cimenterie piège à soufre", c'est l'objet du présent mémoire.

Notons que depuis mars 1979, la chauffe au goudron est devenue routine d'exploitation non seulement dans le cas du clinker gris, mais également dans celui du clinker blanc.

## II - LE PROBLEME DU GOUDRON A ESSO-CHIMIE

Ce goudron, qui est un sous-produit de la fabrication d'éthylène à l'usine Esso-Chimie de Port-Jérôme, est considéré par les Douanes françaises non comme un combustible pétrolier, mais comme analogue à un produit de distillation des goudrons de houille. Il est très aromatique, non miscible aux fuel-oils lourds et sa teneur en soufre est supérieure à celle du fuel-oil lourd n°2.

L'usine de Port-Jérôme, dont l'émission totale journalière de soufre est obligatoirement limitée pour raison de lutte contre la pollution atmosphérique, ne pouvait utiliser pour ses besoins propres la totalité du goudron qui pouvait être produit dans des conditions économiques optimales. Plutôt que de ne pas produire le goudron, et par conséquent

de limiter ses exportations pourtant assurées d'éthylène, Esso-Chimie a cherché à commercialiser ce combustible "hors normes".

## III - LA LEGISLATION FRANCAISE CONCERNANT LA TENEUR EN SOUFRE DES COMBUSTIBLES

La législation française n'interdit pas à proprement parler la vente et l'utilisation d'un combustible non classé administrativement comme un fuel-oil lourd, même si sa teneur en soufre dépasse celle de ce dernier, soit 4 %.

En fait, très vite d'autres contraintes peuvent intervenir :

- a) une contrainte technique : l'apparition ou l'augmentation des corrosions à basse température "côté fumées", et l'émission de fumérons acides,
- b) deux contraintes administratives :
  - le respect de la "Circulaire ministérielle sur la hauteur des cheminées" du 24.11.70 (J.O. du 13.12.70) : une augmentation du débit d'anhydride sulfureux implique une surélévation de la cheminée,
  - une décision du Comité Interministériel pour l'Aménagement de la Nature et de l'Environnement prise le 27 janvier 1972 de faire mettre en place et d'exploiter un réseau de contrôle du SO<sub>2</sub> par les Etablissements Industriels émettant plus de 0,5 t/h de SO<sub>2</sub> (cette émission est calculée à partir de la consommation annuelle de combustible, de la teneur en soufre de celui-ci et du nombre d'heures d'utilisation).

En fait, ces contraintes ne concernent pas les fours de cimenterie, car sur le plan technique, nous verrons plus loin que le captage des oxydes de soufre par la matière réduit presque totalement les risques de corrosion et sur le plan réglementaire, l'Administration admet que, dans les divers calculs, on utilise les teneurs d'oxydes de soufre réellement mesurées.

## IV - CHOIX DU SITE DE GUERVILLE

Le four à voie humide de Guerville a été retenu pour les raisons suivantes :

- du fait de sa taille, il peut détruire beaucoup de goudron
- du fait du procédé et de la composition de la matière, il n'est pas exagérément affecté par les anneaux lorsqu'il est chauffé au fuel-oil normal
- il fait partie d'une usine située en bordure de la Seine qui peut être ravitaillée par bateaux de 700 tonnes (capacité retenue dans le cas des livraisons de goudron).

## V - CARACTERISTIQUES DES COMBUSTIBLES UTILISES

### V-1 Objectif : montée progressive de S %

Pour ne pas avoir à surmonter simultanément, dès le début de l'opération, les problèmes de manipulation d'un combustible inhabituel, très visqueux à

froid, non miscible au fuel-oil lourd et les problèmes dus au soufre, il a été décidé de brûler en même temps du goudron et du fuel-oil lourd à basse teneur en soufre, de façon à augmenter progressivement la teneur en soufre résultante et de ne pas dépasser la valeur de 4% - teneur limite dans le fuel-oil lourd utilisé jusqu'ici - qu'après avoir maîtrisé les problèmes de préparation, de transfert et de combustion du goudron - Ceci a été possible grâce à la mise au point d'une tuyère à circuits séparés.

## V-2 Le goudron Esso

Durant les essais, 9 analyses de goudron comprenant les déterminations suivantes : C %, H %, S %, pouvoir calorifique ont été effectuées par des laboratoires extérieurs. Aux résultats rassemblés dans le tableau 1, nous avons ajouté quelques informations complémentaires communiquées par Esso.

Par ailleurs, les mesures de viscosité effectuées par SCF confirment une particularité de la courbe viscosité/température d'un goudron qui avait déjà été mentionnée par Esso. Dans le diagramme log-log habituellement utilisé pour cette représentation graphique, les courbes caractérisant les fuel-oils sont des droites parallèles. Or, la droite relative au goudron a une pente plus élevée et croise celle des fuel-oils. En d'autres termes, le goudron est plus visqueux que les fuel-oils ordinaires au niveau du pompage et du stockage et plus fluide qu'eux au stade de la pulvérisation (figure 1).

## V-3 Les fuel-oils lourds

Composition centésimale et pouvoir calorifique des fuel-oils lourds qui ont été utilisés pendant les contrôles sont donnés dans le tableau 1.

		Goudron Esso	Fuel-oil lourd ordinaire	Fuel-oil lourd B.T.S.
Soufre	%	4,6 à 5,2	3,69	1,13
Hydrogène	%	6,5 à 7,1	11	11,79
Carbone	%	84,7 à 89,0	85	86,6
C/H		12,5 à 13,1	7,7	7,35
Pouvoir calor. (mth/kg)		8 930 à 8 960	9 625	9 778
inférieur (kJ/kg)		37 360 à 37 500	40 285	40 925
Asphaltènes	%	env. 20	N.D.	N.D.
Conradson	%	env. 20	N.D.	N.D.

## VI - DESCRIPTION DE L'INSTALLATION

### VI-1 Ensemble de cuisson

- Four Fives Lille à voie humide à chaînes, 1970, 4,80x4,40x150m
- Capacité maximale : 1 150 t/d de clinker
- Production pendant les essais : 965 à 1 050 t/d
- Consommation thermique : 1 270 à 1 370 th/ck (5 320 à 5 735 MJ/t ck) à l'époque des essais. Au début de 1980, celle-ci est de 1 200 th/t ck (5 025 MJ/t ck)
- Refroidisseur de clinker Fuller, à grille, température d'air secondaire 650°C
- Electrofiltre Elex, émission de poussières : 40 à 50 mg/Nm3.

## VI-2 Pâte

Pâte "lourde" dont la teneur en eau est, en 1980, de l'ordre de 30 à 31%, alors qu'elle était de 32 à 33% pendant les essais et de 43% en 1974. Cette réduction effectuée dans l'optique de la recherche des économies d'énergie, a été obtenue grâce à la mise au point d'un mélange de défloculants et de l'utilisation dans la pâte de cendres de centrale thermique.

## VI-3 Préparation du goudron

Pour définir les installations de dépotage, stockage et réchauffage de pulvérisation et la tuyère, nous avons suivi deux recommandations essentielles : ne pas mélanger le goudron et le fuel-oil lourd, même au niveau du pulvérisateur et prévoir un réchauffage à la pulvérisation de 180°C.

L'ensemble d'alimentation comprend trois circuits de combustibles : goudron, fuel-oil lourd B.T.S. et fuel-oil lourd ordinaire, un circuit de rinçage des canalisations de goudron par un solvant spécial et finalement constitue une installation assez complexe.

En définitive, les températures de réchauffage retenues sont les suivantes :  
 dépotage et stockage 70°C  
 pulvérisation 140°C

## VI-4 Tuyère

La Société Pillard a spécialement conçu pour cet essai une tuyère à trois injecteurs, aux caractéristiques suivantes :

- Le tube central de Ø 220mm est équipé de trois fourreaux de Ø 70 permettant chacun le passage d'une canne terminée par un injecteur (fig. 2).
- Chaque injecteur est du type MY à deux arrivées de combustible, l'une en rotation, l'autre axiale. En réglant la pression différentielle entre les deux circuits, on peut faire varier l'angle du jet.
- Autour du tube central, un tube concentrique et une rosace permettent de distribuer l'air en rotation. Un dernier tube concentrique, sans rosace, permet d'amener l'air axial. En réglant la pression différentielle entre les deux arrivées d'air, on peut ajuster l'angle de la flamme.
- débit air primaire 13 000 Nm3/h, soit environ 15% de l'air total de combustion
- pression air en rotation : 250 mm C.E.
- pression air axial : 400 mm C.E.
- pression amont de pulvérisation : goudron et fuel-oil lourd ordinaire 42 bars, fuel-oil lourd B.T.S. 39 bars
- pression différentielle entre les deux circuits de chaque combustible 1,75 bar (la même pour les trois combustibles).
- température de pulvérisation 140°C pour le goudron et le fuel-oil ordinaire et 130°C pour le B.T.S.

## VII - PROGRAMME EXPERIMENTAL

### VII-1 Recherche de la teneur en soufre résultante optimale

Avant les essais, il était acquis que l'ensemble four/matière pouvait "accepter" un fuel-oil dont la teneur en soufre était comprise entre 3,5 et 4%. En utilisant

la tuyère Pillard à deux combustibles, goudron et fuel-oil lourd B. T. S., le pourcentage de goudron utilisé a été progressivement et rapidement augmenté jusqu'à atteindre 60% du débit thermique, ce qui donnait une teneur en soufre résultante voisine de celle du fuel-oil ordinaire. Une longue période de marche dans ces conditions permit de vérifier que le fonctionnement du four était satisfaisant. Enfin, le débit de goudron a été poussé à 100% et il a été vérifié que l'ensemble four/matière "acceptait" le nouveau combustible. A chaque étape de ce programme, plusieurs séries de contrôles portant sur le soufre ont été effectués.

## VII-2 Contrôles effectués - Techniques utilisées

### VII-21 Généralités

A chacun des trois stades de la montée de la teneur en soufre résultante, il a été effectué un bilan soufre c'est-à-dire un état comptable des entrées et des sorties de soufre :

- entrées : combustible et pâte
- sorties : clinker, poussières captées à l'électrofiltre et fumées.

On considère comme négligeable le soufre contenu dans les poussières s'échappant à la cheminée (rappelons que l'émission est de 50mg/Nm<sup>3</sup>).

Chaque bilan établi sur une durée de 24 heures comporte donc des mesures de débit et des contrôles sur les matières minérales, les combustibles, les fumées.

### VII-22 Mesure sur les matières minérales

En ce qui concerne pâte et clinker, les mesures de débit et les analyses complètes sont des contrôles de routine. On a opéré un prélèvement par poste et analysé le produit aux rayons X. A l'occasion du bilan le même contrôle a porté sur les poussières captées à l'électrofiltre.

### VII-23 Contrôle des combustibles

Les débits sont mesurés au moyen de compteurs. Lors de chaque bilan, une analyse a été opérée.

### VII-24 Contrôle de routine sur les fumées (sortie four)

Le débit de fumées est calculé à partir de l'analyse et du débit de la pâte, de l'analyse et du débit de combustible, et de l'excès d'air. La connaissance de cette dernière caractéristique implique que l'on mesure la teneur en oxygène des fumées et leur teneur en imbrûlés. Le four est équipé normalement d'un analyseur en continu d'oxygène (basé sur les propriétés paramagnétiques de O<sub>2</sub>) et d'oxyde de carbone (absorption de rayonnement infra-rouge).

### VII-25 Contrôles relatifs au soufre dans les fumées (après électrofiltre)

Plusieurs déterminations de point de rosée ont été faites au moyen de l'appareil B. C. U. R. A. (2,3). Cet appareil a été conçu pour permettre des mesures de point "acide" dans la zone 120-160°C. En fait, nous avons déjà vérifié (1) sur un four de cimenterie -

et nous verrons que cela a été encore confirmé ici - que le point de rosée mesuré est égal au point de rosée "de l'eau" qui, au point de mesure, dépasse rarement 70°C et par suite on peut dire que SO<sub>3</sub> = 0 et que le soufre des fumées se trouve sous forme de SO<sub>2</sub> (on sait en effet qu'il suffit de quelques millièmes de SO<sub>3</sub> pour faire croître considérablement le point de rosée des fumées qui dépasse alors rapidement 120°C(5). A notre avis, l'appareil B.C. U. R. A. est l'appareil le plus sensible pour détecter l'absence de SO<sub>3</sub> dans les fumées. En définitive, cette mesure préalable nous permet de simplifier considérablement l'appareil de mesure d'oxydes de soufre, en supprimant le condenseur à SO<sub>3</sub> en fait à H<sub>2</sub>SO<sub>4</sub> (5)(3). Pour chaque analyse, le SO<sub>2</sub> a été capté dans l'eau oxygénée et dosé par acidimétrie. La mesure comprend trois prélèvements au débit de 200 l/h pendant 30 mn.

## VIII - RESULTATS

### VIII-1 Caractéristiques d'exploitation durant les essais

Durant la période considérée octobre 1977-juin 1978, le four a continué à produire du clinker dans les conditions les plus économiques possibles. De ce fait, certains paramètres ne sont pas restés constants, en particulier la composition de la pâte dont la teneur en eau a été réduite de 36,5% en octobre-novembre, à 32-33% en mai-juin, ce qui a eu pour conséquence de faire passer la consommation thermique moyenne de 1 370 th/t à 1 270 th/t de clinker (5 735 MJ/t à 5 320 MJ/t). L'alourdissement de la pâte semble avoir entraîné un plus grand débit de poussières captées à l'électrofiltre et, par conséquent, apporte un certain changement dans la répartition des sorties de soufre. Nous y reviendrons au paragraphe "discussion".

La combustion du goudron a eu lieu sans imbrûlés et il ne semble pas que l'utilisation du nouveau combustible ait entraîné une augmentation de la consommation thermique. La réduction de consommation évoquée au paragraphe VIII-1 correspond bien à la réduction de la teneur en eau de la pâte. Il n'a pas été constaté de formation d'anneaux et la qualité du clinker n'a pas été affectée de façon significative.

### VIII-2 Contrôles relatifs au soufre dans les fumées

Les principaux résultats de mesures de SO<sub>2</sub> et de point de rosée sont résumés dans le tableau 2.

% goudron	date	Soufre résultant du combustible %	teneur en SO <sub>2</sub> sur fumées sèches 10 <sup>-6</sup> (ppm)	teneur en SO <sub>2</sub> sur fumées humides* 10 <sup>-6</sup> (ppm)	Point de rosée °C	O <sub>2</sub> au point de mesure %
0	31.05.78	3,69	554	384	63	8,4
62,5	5.10.77	3,34	70	50	ND	10,2
58,6	2.11.77	3,20	77	53	60	8,6
100	2.05.78	4,64	354		ND	9,2
100	6.06.78	3,86	361		62	9,5

VIII-21 Le calcul de point de rosée de la vapeur d'eau des fumées donne dans chaque cas des valeurs de l'ordre de 70°C, donc assez proches du point de

rosée mesurée. Comme nous l'avons dit au paragraphe VII-25,  $SO_3 = 0$ , ce qui explique pourquoi on rencontre fort peu de cas de corrosion à basse température "côté fumées" dans un four de cimenterie.

VIII-22 Il n'apparaît pas de relation entre la teneur en soufre résultante du combustible et la teneur en  $SO_2$  des fumées. L'incidence de l'augmentation de cette teneur a peut-être été masquée par l'alourdissement progressif de la pâte; les dernières concentrations dans le temps sont plus élevées.

VIII-23 Les teneurs en  $SO_2$  mesurées sont relativement faibles, 354 ppm le 2.05.78 et 554 ppm le 31.05.78. Le calcul montre que les teneurs théoriques en  $SO_2$ , provenant du combustible, dans les mêmes conditions de dilution et sans captage par la matière seraient respectivement de 1 900 et 1 526.

### VIII-3 Les bilans-soufre

Six bilans soufre ont été établis sur une durée de 24 heures. Nous présentons dans le tableau 3, les résultats des trois bilans les plus significatifs.

Tableau 3 BILANS - SOUFRE			
Combustible	Fuel-oil lourd ordinaire	{ B. T. S. 38,5 goudron 62,5 %	Goudron
date	31.05.78	5.10.77	21.03.78
Soufre résultant %	3,69	3,34	4,78
<b>ENTREES SOUFRE</b>			
(t/d			
Pâte %	1,997	0,963	0,755
	29,7	16,3	10,0
Com- (t/d	4,723	4,944	6,788
bustible %	70,3	83,7	90,0
total (t/d	6,720	5,907	7,543
entrées %	100,0	100,0	100,0
<b>SORTIES SOUFRE</b>			
(t/d			
clinker %	1,300	1,426	2,218
	19,8	27,6	35,1
(t/d	3,212	3,410	2,443
poussières %	48,9	65,9	38,6
(t/d	2,051	0,335	1,666
fumées %	31,3	6,5	26,3
total (t/d	6,563	5,171	6,327
sorties %	100,0	100,0	100,0
Indétermination %	- 2,3	- 12,5	- 16,1

On remarque que ces bilans sont déficitaires (moins de sorties que d'entrées de soufre) et que l'indétermination va de 2,3 à 16,1 %. Il est difficile de connaître le ou les postes responsables de l'indétermination quand on connaît les difficultés d'analyse ou de pesée. En particulier, les variations de la teneur en soufre de la pâte sont du même ordre que la teneur en soufre elle-même. Il n'en reste pas moins qu'il est évident que la majeure partie du soufre des sorties se trouve dans le clinker et les poussières.

## IX - DISCUSSION

### IX-1 Remarque générale sur les essais sur four

Nous insistons sur le fait que nous relatons ici des résultats d'essais industriels et non des résultats sur maquette, en laboratoire, il n'existait pas à

Guerville de four à clinker gris disponible, plus petit que le four 7. De ce fait, les essais ont été menés en vraie grandeur sur un four produisant environ 1 000 t/d de clinker et, pendant leur durée, il a fallu continuer à réduire la consommation thermique autant que faire se pouvait par réduction de la teneur en eau de la pâte. Ce manque de rigueur dans le plan de travail a peut-être eu pour conséquence de masquer quelques phénomènes secondaires, mais il a conduit à de substantielles économies.

Notons également que la composition des fumées dans un four n'est pas aussi constante que dans un générateur à fumées séparées du fluide caloporteur par suite des irrégularités de l'écoulement de la matière (formation d'anneaux dans la partie rotative qui se détruisent ensuite, avalanches). Ces retenues de matière font que la composition des fumées ne correspond pas toujours à celle de la matière dans les bilans. Certes, en effectuant un bilan sur une durée de 24 heures, on minimise ce genre d'erreur, mais on n'est pas sûr de la supprimer.

### IX-2 Sur les très faibles émissions d'oxydes de soufre

L'absence de  $SO_3$  dans les fumées ne peut nous surprendre. Il y a en effet 20 ans qu'il a été prouvé expérimentalement que des additifs basiques injectés dans les fumées pouvaient neutraliser le  $SO_3$  (6) (4). La matière crue introduite dans le four, constituée principalement de calcaire, joue parfaitement ce rôle. Par ailleurs, du fait des températures rencontrées dans un four de cimenterie, la majeure partie du  $SO_2$  est fixée par les matières calcaires indépendamment de la teneur en alcalins du cru. Cette propriété a été étudiée entre autres par E. VOGEL (7)

### IX-3 Comparaison des émissions d'oxydes de soufre par différents générateurs

Dans le tableau 4 ont été rassemblés les résultats obtenus dans la présente étude, ceux enregistrés en 1972 sur le four de Ranville et ceux que l'auteur a obtenus jadis sur des générateurs aussi différents que le sont des chaudières domestiques et industrielles et les fours de briqueterie. L'examen de ce tableau confirme l'intérêt exceptionnel du four de cimenterie pour détruire des produits hautement sulfureux.

## X - CONCLUSIONS

X-1 Les problèmes de dépotage, stockage, transfert et préparation du goudron Esso particulièrement visqueux à froid et non miscible au fuel-oil lourd ont été surmontés.

X-2 La chauffe au goudron à près de 5 % de soufre, seul, après mise au point, a lieu sans difficulté de combustion ou d'exploitation, sans augmentation de consommation thermique, sans modification significative de la qualité du clinker et sans problème de pollution atmosphérique. Elle n'a absolument pas été un obstacle à la poursuite de la recherche de réduction de teneur en eau de la pâte. Depuis un an, la chauffe au goudron Esso est devenue routine d'exploitation dans les fours à clinker gris et à clinker blanc. L'usine de Guerville a brûlé 26 000 tonnes de goudron en 1978 et 48 000 tonnes en 1979.

X-3 La tuyère Pillard à deux arrivées indépendantes de combustible, décrite ici et mise au point spécialement pour ces essais, permet, avec deux produits, l'un hautement sulfureux, l'autre moyennement ou peu sulfureux, de constituer un combustible à teneur résultante en soufre prédéterminée, compatible avec le procédé et le degré de pollution admis. Bien que l'emploi de cette tuyère ne soit pas indispensable pour la marche à 100% goudron, elle garde tout son intérêt pour des applications futures où le procédé serait plus exigeant.

X-4 Le four de cimenterie a confirmé ses propriétés de "piège à soufre" - on peut dire de façon plus générale de "piège à polluants" - Les émissions de  $SO_2$  sont au moins cinq fois plus faibles que ce qu'elles seraient si le goudron brûlait dans un foyer, sans réaction de neutralisation. Rien n'interdit, à présent, de brûler dans un four de cimenterie des combustibles encore plus sulfureux, par exemple du résidu "sous vide" ou des bitumes et de détruire des déchets industriels très gênants, tels que des goudrons sulfuriques, sans transfert de pollution. Cette étude ouvre de larges perspectives sur la récupération de sous-produits ou de déchets industriels ayant une précieuse valeur énergétique.

C'est pour cette raison qu'en novembre 1979, la Société Générale a décerné pour cette étude, à l'équipe de la Société des Ciments Français, constituée de MM. Jean Commène, Claude Mayrargue, Marc Dancoisne et de l'auteur de la présente communication, un de ses prix de l'Energie.

# Complex utilization of rotary kiln heat losses

## *Utilisation complexe des pertes de l'énergie thermique par les fours rotatifs*

L. VOROBICHKOV, senior scientific worker, candidate of technical sciences,  
V. SATARIN, professor, doctor of technical sciences, Yuzhghiprotsement, USSR.

SUMMARY: Rotary kilns operate with low heat efficiency: external losses are 10-25%, with clinker and aspiration air 5-10%, with flue gases 15-20%, etc. Equipment for complex heat utilization consists of an installation for using the heat of kiln shells and an air-evaporative cooler. These installations have been built and used, with the aim of heat recovery and use for central heating and technological requirements. The service period of lining is increased due to automatic control of coating formation.

RESUME: Le rendement des fours rotatifs est bas: les pertes du groupe de fours dans le milieu ambiant sont de 10 à 25%, avec le clinker et l'air d'aspiration de 5 à 10%, avec les fumées d'échappement de 15-à 20%, etc. Les installations complexes d'utilisation de la chaleur se composent de: dispositif pour l'utilisation de la chaleur des corps de four, réfrigérant d'évaporation à l'air. On a créé et implanté les installations complexes d'utilisation de la chaleur dans le but d'utilisation et de conservation de l'énergie thermique pour l'alimentation en chaleur et pour les besoins technologiques. Augmentation de la durée de vie du garnissage grâce à la commande automatique de la formation de l'enduit.

Cement industry is a large-scale consumer of thermal energy. Every year more than 100 000 000 tons of conventional fuel is consumed in the whole world.

In cement industry fuel is mainly consumed by clinker burning; it is also consumed by heat supply and some other technological needs which depend on the climatic zone of the country, presence of certain heat consumers, kind of fuel, etc. The heat which is produced in the boiler room is used for the heat supply of the plant, dwelling-houses, production of reinforced concrete and asbestos slate, for mazut heating, for heating greenhouses and for other needs; this heat amounts to 25% of all fuel. In zones with hot climate, heat may be used for mazut heating and for obtaining cold for air conditioning.

Rotary kilns which are the main fuel consumers, have low thermal efficiency. Irrecoverable heat losses in rotary kilns are distributed in the following way: environment losses from the kiln body (10-20%); losses in the cooler (5-10%); with waste fumes (15-20%). These heat losses can be successfully used for covering heat needs. Correspondingly, the kiln thermal efficiency increases. The heat surplus, obtained by using secondary power resources, is preserved in the kiln unit.

Complex heat utilization installations, consisting of a cooling device for kiln bodies and means for coating formation, have been theoretically grounded and installed at a number of cement plants in the Soviet Union. These installations have been patented in the USA, Japan, German Federal Republic, France, England, Spain and other countries.

Such installation is mounted on the body in the burning zone and is intended for recovering the lost heat which in the form of hot water with the temperature up to 373 K is used for the needs of heat supply and technological process. The installation has a system of air supercharging which allows to control the coating thickness and almost double the lining operating period. The kiln has movable insulation due to which fuel consumption for clinker burning is reduced.

The device for cooling recuperator refrigerators consists of heat exchangers sections and a system of suction of hot air for supplying it to the kiln in hot state which is especially important for mazut burning. The control of the kiln bodies state and of the complex installations work is reliably performed by means of the indications of a recorder which moves along the kiln body and by means of visual inspection. For this purpose there is a special window in the protective housing along the kiln axis.

The devices for clinker burning trap and use the heat of the hot clinker in such a

way, that the temperature of the air, supplied for fuel burning, is not reduced. The device for air-evaporative clinker cooling in the grate refrigerator allows to eliminate heat exhaust with suction air and to use the heat of evaporative clinker cooling. In the nearest time scientific work on using the secondary heat of waste fumes will begin.

For the contactless method of heat exchange, which is used in utilization installations, the candidate of technical sciences Vorobeichikov L.T. has elaborated a mathematical model - a system of analytical connections between the parameters of the heat exchanger input and output and the construction parameters. In our case the mathematical model is developed according to the main processes of water heating in heat exchangers of the utilization installation. Here the thermal process for steady-state conditions can be described by the following equation:

$$C \cdot G \frac{dT}{dx} = Q(x) \quad (1)$$

where  $C$  is the heat capacity of the heat exchanger water, J/kg (kcal/kg);  $G$  - water mass flow, kg/h;  $x$  - coordinate, measured from the tube inlet to the studied section, m;  $Q(x)$  - heat flow supplied to the heat carrier per tube length unit of the heat exchanger, J/m h (kcal/m h);  $T$  - average water temperature along the tube length, K/°C).

For calculating the value of  $Q(x)$ , let us examine Fig. 1 where the schematic diagram of the heat exchanger tubes location is given:

$S$  - the distance between the axes of tubes in the bundle, m;  $D$  - heat exchanger tube diameter, m; 1 - the external surface of the kiln body,  $F_1 \cdot m^2$ ; 2 - the external surface of the tube,  $F_2 \cdot m^2$ ; 3 - the surface of the inner walls of isolated flaps,  $F_3 \cdot m^2$ .

For calculating  $Q$  we introduce the following assumptions:

1. The average temperature of the heat exchanger tubes surface is assumed to be equal to the average temperature of the heat carrier (heated water).
2. The complex heat exchange between the surfaces 1,2,3 (mainly by radiation and convection) is generalized in the form of heat transfer coefficients ( $\alpha_1, \alpha_2, \alpha_3$ ).
3. The temperature of the rotary kiln body surface is assumed to be independent on the construction and operating conditions of the cooling system (according to measurements data).

Let us introduce the following indices:  
 $\alpha_{1,2}$  - heat transfer coefficient,  
 J/degree  $m^2 \cdot h$  (kcal/ $m^2 \cdot h \cdot ^\circ C$ ) from the surface with the first index to the surface with the second index. The same indices are used for mutual surfaces of heat exchange.

Now we can write the following equations:

$$Q = \alpha_{1,2} \cdot F_{1,2} (T_1 - T_2) + \alpha_{3,2} \cdot F_{3,2} (T_3 - T_2) \quad (2)$$

It means that the heat flow, which influences the heat exchanger tube, consists of two flows - from the body and from the housing flaps.

For calculating  $T_3$  let us use the following equation:

$$F_{1,3} \cdot \alpha_{1,3} (T_1 - T_3) = \alpha_{3,2} \cdot F_{3,2} (T_3 - T_2) + \alpha_{3,0} (T_3 - T_0) F_{3,0} \quad (3)$$

which represents heat balance of the surface 3, received from the hot body; the heat is consumed by heat transfer to the tube and by losses to the environment.

From eq. (3) we can obtain the value of  $T_3$ :

$$T_3 = \frac{\alpha_{3,2} \cdot F_{3,2} \cdot T_2 + \alpha_{1,3} \cdot F_{1,3} \cdot T_1 + \alpha_{3,0} \cdot F_{3,0} \cdot T_0}{\alpha_{3,0} \cdot F_{3,0} + \alpha_{1,3} \cdot F_{1,3} + \alpha_{3,2} \cdot F_{3,2}} \quad (4)$$

When  $\alpha \rightarrow \infty$ ,  $T_3 = 273 \text{ K } (0^\circ C)$ , eq. (4) can be freely used in the absence of housing flaps.

Representing eq. (4) and (2), and then the result and eq. (1) we obtain:

$$\alpha G \frac{dT}{dx} = A - BT \quad (5)$$

where  $A = \alpha_{1,2} \cdot F_{1,2} \cdot T_1 +$

$$+ \frac{\alpha_{3,2} \cdot F_{3,2} (\alpha_{1,3} \cdot F_{1,3} \cdot T_1 + \alpha_{3,0} \cdot F_{3,0} \cdot T_0)}{\alpha_{1,3} \cdot F_{1,3} + \alpha_{3,2} \cdot F_{3,2} + \alpha_{3,0} \cdot F_{3,0}} \quad (6)$$

$$B = \alpha_{1,2} \cdot F_{1,2} + \frac{\alpha_{3,2} \cdot F_{3,2} (\alpha_{1,3} \cdot F_{1,3} + \alpha_{3,0} \cdot F_{3,0})}{\alpha_{1,3} \cdot F_{1,3} + \alpha_{3,2} \cdot F_{3,2} + \alpha_{3,0} \cdot F_{3,0}} \quad (7)$$

or

$$c \cdot G \frac{dT}{dx} = \alpha_{1,2} \cdot F_{1,2} \cdot T_1 + \frac{\alpha_{3,2} \cdot F_{3,2} (\alpha_{1,3} \cdot F_{1,3} \cdot T_1 + \alpha_{3,0} \cdot F_{3,0} \cdot T_0)}{\alpha_{1,3} \cdot F_{1,3} + \alpha_{3,2} \cdot F_{3,2} + \alpha_{3,0} \cdot F_{3,0}} - (\alpha_{1,2} \cdot F_{1,2} + \frac{\alpha_{3,2} \cdot F_{3,2} (\alpha_{1,3} \cdot F_{1,3} + \alpha_{3,0} \cdot F_{3,0})}{\alpha_{1,3} \cdot F_{1,3} + \alpha_{3,2} \cdot F_{3,2} + \alpha_{3,0} \cdot F_{3,0}}) \quad (8)$$

For obtaining the output value of  $T$ , it is sufficient to solve the eq. (5) - (8) and substitute into the solution, as function "x", the complete length of the tube part.

The calculating formulae will be more convenient, if the temperature reference will be from the conventional zero 273 K, i.e. the temperature in the heat carrier system:

$$T_{x=0} = 0$$

Then eq. (5) will be written as follows:

$$T(x) = \frac{A}{B} \cdot \left[ 1 - \exp\left(-\frac{B}{\alpha G} \cdot x\right) \right], \quad (9)$$

and the water temperature at the outlet:

$$T(1) = \frac{A}{B} \left[ 1 - \exp\left(-\frac{B1}{\alpha G}\right) \right] \quad (10)$$

By means of eq. (6, 7, 10) it is possible to calculate the final temperature of the carrier according to the values:

- 1) kiln body temperature,  $T_1$ ;
- 2) ambient temperature,  $T_0$ ;
- 3) heat carrier consumption,  $G$ .

For this purpose it is necessary to know the heat exchange characteristics  $\alpha$ ,  $F$  and others.

Eq. (10) is one of the possible mathematic models of the analyzed heat exchanger, having six parameters: three of them characterize the dependency of heat exchange on temperature conditions ( $\alpha$ ), and the other three characterize the system geometry ( $F$ ). But it is impossible to estimate these values in a pure theoretical way, therefore additional experiments have been performed. In the result of experimental research we have obtained an equation for defining the amount of heat recovered by the utilization installation.

$$Q = 10 \cdot \psi D_K \cdot K_{\Delta} T_{1-3,0} \cdot F_{3,0} (T_{3,0} - T_{e.a.}) \quad (11)$$

where 10 is an empirical coefficient;  $\psi$  - screening degree;  $D_K$  - kiln body diameter, m;  $K$  - heat transfer coefficient,  $J/m^2 \cdot h \cdot K$ ;  $T$  - thermal head,  $K (^{\circ}C)$ ;  $l$  - length of sections zone (according to the kiln length), m;  $F_{3,0}$  - housing flaps surface,  $m^2$ ;  $T_{3,0}$  - temperature on the housing flap surface,  $K (^{\circ}C)$ ;  $T_{e.a.}$  - external air temperature,  $K (^{\circ}C)$ .

The obtained main experimental dependences allowed to transform the main equation of the mathematical model (eq. (10)) and to reduce it to a form convenient for engineering calculations.

As the parameters  $\alpha_{1,3}$  and  $\alpha_{3,2}$ , due to the low temperatures of housing flaps, exert small influence on the heat exchange, and because of the difficulties of their exact defining, we substitute them conventionally by  $\alpha$  which can be experimentally defined [1,2]

Then eq. (10) can be transformed and written in the following form:

$$T_{(1)} = T_{in.} + (T_k - T_{av.v.}) \left[ 1 - \frac{(-\alpha_{1,2} \cdot Q_k \cdot \alpha_{k,1,2} \cdot Q_k) \varepsilon_k \cdot 255 \cdot D_n}{cG \cdot \psi T} \right] \quad (12)$$

Substituting in the main equation (12) the value of the criterion dependence  $N_u = \psi(Re)$ , we obtain:

$$T_{(1)} = T_{in.} + (T_k - T_{av.v.}) \left[ 1 - \frac{4,8 \cdot \lambda \cdot Re \varepsilon_x \cdot 2,55 \cdot D_n \cdot l_e}{cG \cdot \psi T} \right] \quad (13)$$

The performed theoretical and experimental research allowed to elaborate the method of thermal estimation, control conditions and thermal schemes of heat utilization.

When the contactless method of rotary kilns heat utilization is used, the heat take-off varies in a limited range. The parameters of the heat, taken from kiln bodies, are in the range 323 - 383 K and are conditioned by the necessary operating schedule of the kiln, at which the necessary coating is formed protecting the lining from quick wear.

Optimum conditions of heat takeoff for summer and winter seasons are finally established during the operating process of utilization installations and depend on the quality of burned raw material, on the kiln

diameter, climatic conditions, etc. In the winter heating period the heat carrier parameters and the periods of peak heater boilers joining-up are chosen in dependence of the relation of the quantity of taken-off from the kilns heat  $Q_n$  to the estimated - consumed quantity  $Q_{max}$ , i.e.

$$\psi = \frac{Q_n}{Q_{max}}$$

The annual economical effect from using utilization installations differs with kilns dimensions, climatic conditions and heat supply systems. It is achieved due to fuel economy, reducing of capital and operation expenditures and the increase of lining durability. In most cases the expenses are justified in approximately one year. Technical economic indices are shown in Table 1.

Already nowadays there is a practical possibility to economize up to 15% of thermal energy due to the use of the complex method of heat utilization.

Fig. 1

Table 1

Indices	Unit of measurement	Before introducing heat utilization installations	After introducing heat utilization installations
<u>Kiln 3.6x103.9 m</u>			
Annual take-off of secondary heat	thousands Gcal/year	-	11-12
Conservation of heat of the kiln during clinker burning (due to the kiln body insulation)	thousands t/year	-	1.2-1.8
Increase of lining life	days	320	590
<u>Kiln 5x185 m</u>			
Annual take-off of secondary heat	thousands Gcal/year	-	30-35
Conservation of heat in the kiln during clinker burning (due to the kiln body insulation)	thousands t/year	-	5.0
Increase of lining life	days	200	300

# Opportunities for energy saving in the cement industry

## *Les économies d'énergie dans l'industrie cimentière*

G.R. GOUDA, Ph. D. manager, Cement Technology, Fuller Company, Bethlehem, Pennsylvania, U.S.A.

G.J. LABELLE, B.S. General manager, Cement Industry Group, Fuller Company, Bethlehem, Pennsylvania, U.S.A.

SUMMARY: Opportunities for energy saving in the cement plants is discussed and the following points are covered:

1. Selection of raw materials
2. Process change to improve efficiency
3. Reduction of heat loss from the kiln system
4. Better sintering process and retention time
5. Waste heat recovery
6. Energy conservation through high efficiency fans
7. Improve combustion, control of temperature, oxygen, and turbulence
8. Kiln insulation
9. Automatic process control
10. Use of alternative fuels and energy supply systems
11. Good maintenance
12. Dust use
13. Clinker quality

In a suspension preheater or a flash calciner system about 340 kcal/kg clinker is wasted. This represents the amount of heat used in excess of the theoretical amount of heat required. A great amount of energy can be saved in the existing plants by (a) controlling: the mix design, (b) improving the sintering process, (c) using high efficiency fans, (d) controlling combustion, (e) using automatic process control, (f) good maintenance and (g) the production of a porous clinker.

RESUME: Cet article s'agit d'une discussion sur la conservation d'énergie dans les fabriques de ciment. Les sujets suivants sont compris:

1. Sélection des matières premières.
2. Changement du procédé pour améliorer l'efficacité
3. Réduction des pertes de chaleur du système du four
4. Un meilleur procédé de clinkérisation et temps de rétention
5. Récupération des chaleurs perdues
6. Conservation d'énergie par des ventilateurs d'haute efficacité
7. Amélioration de combustion, régulation de températures, d'oxygène, et de turbulence.
8. Isolation du four
9. Régulation automatique du procédé
10. Emploi des combustibles et systèmes d'alimentation d'énergie alternatifs
11. Bon entretien
12. Emploi de pousse
13. Qualité de clinker

Environ 340 kcal/kg de clinker est perdu dans un système de préchauffeur à suspension ou de précalcination. Celui-ci représente la quantité de chaleur employée au-dessus de la quantité de chaleur théorique exigée. Une grande quantité d'énergie peut être conservée dans les fabriques existantes (a) en régulant le mélange, (b) en améliorant le procédé de clinkérisation (c) en employant les ventilateurs d'haute efficacité (d) en régulant la combustion (e) en employant la régulation automatique du procédé (f) en effectuant le bon entretien et (g) en produisant le clinker poreux.

## INTRODUCTION

Energy conservation is a vital concern of every industrial company throughout the world because everyone is aware of the energy crisis. The steadily rising dependence on imported oil continues to threaten the economic stability everywhere, due to heavy balance of payment deficits. In the U.S.A., for example, industry shares a large portion of responsibility for energy consumption as it uses nearly 40% of the nation's net energy requirement. Steady improvement in energy efficiency by obtaining maximum energy per Btu, and by establishing long-range energy conservation programs, is mandatory for the improvement of the profitability of industrial operations.

There is no doubt that the success achieved over the last twenty years in cement production, by using the preheater system, is considered a major step in energy conservation, in comparison to the wet process. But, even in the dry process there is still wasted heat; the theoretical amount of heat required to form one kg of clinker is equal to 1040 kcal, while the amount of heat which is recuperated is about 600 kcal/kg clinker. This means that the theoretical heat required to form clinker is about 440 kcal/kg clinker. Practically, it is impossible to reach this figure, and the average lowest fuel consumption obtainable by an SP (Suspension Preheater) or SF (Suspension Flash Calciner) system is about 780 kcal/kg clinker. About 340 kcal/kg clinker is wasted through heat loss in the kiln and cooler radiations, by heat transmitted by convection, and by the kiln gases and the dust in the gases.

## ENERGY CONSERVATION IN THE CEMENT INDUSTRY

The cement industry is in a unique position to play a major role in conserving energy, materials, and the environment. Modernization of existing equipment and conversion of the existing wet process plants to dry process using suspension preheater or suspension flash calciner, can save a substantial amount of energy. Application of mixed cement should be widely used. Additionally, there are various operating techniques which can be modified. These are:

1. Selection of raw materials
2. Process change to improve efficiency
3. Reduction of heat loss from the kiln system
4. Better sintering process and retention time
5. Waste heat recovery
6. Energy conservation through high efficiency fans
7. Improvement of combustion, control of temperature, oxygen, and turbulence
8. Kiln insulation
9. Automatic process control
10. Use of alternative fuels and energy supply systems
11. Good maintenance
12. Dust use
13. Clinker quality

### 1. SELECTION OF RAW MATERIALS

Selection of the cement raw materials for better clinkerability and quality offer a good opportunity for fuel consumption in the cement industry. Raw mixes with (a) high free silica, (b) low flux content, (c) high moduli (silica modulus and alumina modulus) are sintered at high temperature com-

pared to raw mixes with low free silica, high flux content and low moduli.

Each cement plant should review the mix design, fineness and the additive characteristics in order to achieve optimum energy conservation throughout the entire cement production process, including the cement mills (1 & 2). Better clinker and cement qualities can also be obtained by this energy conservation effort.

Choice of raw materials with low alkali content eliminates the need of an alkali bypass in a clinker producing system. Hence, the fuel wasted by the alkali bypass system is saved.

Raw materials with quartz are harder to crush, grind, and burn than those without a high percentage of quartz (2).

### 2. PROCESS CHANGE TO IMPROVE EFFICIENCY

Dry process cement manufacturing undoubtedly reduces fuel consumption and provides better utilization of energy, especially when either an SP or SF system is used. But, about 340 kcal/kg clinker is wasted. Now is the time to analyze the cement manufacturing process in order to reduce or eliminate the loss of the 340 kcal/kg clinker. The following are to be considered to minimize wasted heat:

- a. Use of a new and efficient process to produce the clinker.
- b. Improve the clinker cooler heat recuperation efficiency.
- c. Reduce the sintering temperature by using fluxes and/or mineralizers in various ways.
- d. Recover the heat loss through the exit gases and the kiln shell radiation.
- e. Production of porous clinker, which requires less energy to grind (3).
- f. Modify the crushing and the grinding processes, as about 75% of the total power is used for these two processes.
- g. Use a five-stage preheater system.

### 3. REDUCTION OF HEAT LOSS FROM THE KILN SYSTEM

In order to increase the cooler recuperative efficiency, the leaking air should be reduced. It has been found that reducing inleaking or primary air by about 15% of combustion air saves about 25 kcal/kg clinker for a dry SF kiln.

The cooler and the kiln should work with maximum possible efficiency by reducing the inleaking ambient air. This allows a higher volume of hot combustion air to enter the kiln from the cooler and greatly reduces fuel consumption. Priority should be given to reduction of air leaking through the hoods and the combustion chamber and to improvement of the clinker cooler recuperation.

The kiln shell loss, as well as the SP or SF system, greatly influences fuel requirements. Insulation of the kiln, preheater, and cooler reduces, but does not eliminate, the heat loss.

Depending on the capacity of the kiln and the fuel consumption, hood leakage can reach 6% to 15% of the combustion air; this undesirable inleaking air can be reduced by modifying the seal gap and/or hood draft. Density differences of ambient and hot cooler secondary air produces localized pressure differences, which causes a large air exchange. A radiation protection system is required to insure the temperature of the kiln shell remains low despite the high waste gas temperature.

#### 4. BETTER SINTERING PROCESS AND RETENTION TIME

Sintering cement raw materials differ from one plant to another depending on the characteristics of the raw materials. Ideally, each burner should burn the raw materials with the most economic fuel consumption and with the least retention time to obtain a high quality clinker. Overburned clinker is expensive as much fuel is wasted, much energy is required to grind such a clinker, and the cement produced from this clinker is considered poor quality.

Kiln feed should be homogenous and constant. Its chemistry should be adjusted so that it can be burned with a minimum amount of fuel. Evaluation of the clinker microstructure by a scanning electron microscope (4), or by a polarized microscope, is essential to relate raw mix burnability to clinker quality. The most economical burning process can be achieved by continuously examining the clinker microstructure. Thus the optimum in fuel savings, retention time, crystal distribution and size, and cement quality can be determined.

#### 5. WASTE HEAT RECOVERY

The exhaust gases from the kiln and cooler are considered the major components of wasted energy in the cement industry; about 20% of the energy in fuel is wasted in the kiln exhaust gases. The heat from the kiln exhaust gases is recovered, partially or completely in the case of dry grinding raw materials.

Recovery of the kiln and/or cooler exit gases by a heat exchanger serves both as an air pollution function and a method of recovering heat. The heat exchanger helps save capital and conserve fuel. The air-to-air heat exchanger eliminates the need for a baghouse by establishing a closed system of air circulation. Ordinarily, hot dust-laden kiln gases pass through the clinker cooler and a baghouse before being discharged into the atmosphere. In the case of a heat exchanger, the dusty air from the clinker cooler is directed through the heat exchanger and then back to the cooler inlet again without discharge to the atmosphere. The air is cooled in the heat exchanger from 315° to 93° C (600° to 200° F) by atmospheric air flowing over the outside of the tubes carrying the heated air.

A study is required to recover the heat radiated from the kiln shell by a hood system in the form of hot air; this air can be used for space heating in the cement plant or for drying the raw materials.

#### 6. ENERGY CONSERVATION THROUGH HIGH EFFICIENCY FANS

Fans are among industry's largest energy consumers. Evaluation of the compatibility of the fan with its system and analyses of the fan curves should be performed continuously. Any air leakage into (induced draft) and out of (forced draft) the system should be prevented. Every square inch of external ducting must be carefully inspected. Leak air increases the pressure drop and the horsepower which is proportional to the air volume cubed.

Excessive static pressure losses through various components of the air distribution system contribute to needless horsepower consumption. These losses can be caused by pluggage, deterioration of internal components, or absence of turning vanes in critical duct locations.

In the cement plant, the process fans play a very important role as they participate greatly in the chemical and physical modification of the raw material. The fans also have a great influence on the consumption of energy per ton to clinker produced. For example, a kiln with a capacity of 4700 metric ton per day clinker requires a total power of 8810 hp with an overall efficiency of 86% by using a high efficiency fan. In the case of low efficiency fans, 10,400 hp is required, with 73% efficiency. The power saving is 1590 hp. In the U.S.A., the cost of energy is approximately 3.0 cents per kW (0.13 FF). For fans running 7500 hours per year, the savings amounts to \$268,000 U.S. (1,163,000 FF).

Besides, the high efficiency fan blades have a higher resistance to stresses and vibrations than the straight radial blades (5).

#### 7. IMPROVE COMBUSTION, CONTROL OF TEMPERATURE, OXYGEN, AND TURBULENCE

Combustion can be improved by using oxygen-enriched air to increase kiln production and to achieve a reduction in fuel consumption. The oxygen-enriched air creates higher flame temperature and reduces the nitrogen concentrations in the combustion products. The flame emissivity is increased and the shell losses per kg of clinker is decreased.

Most efficient combustion is achieved by a short, high energy release flame which generates the maximum flame temperature.

Trimming the fuel/air ratio can produce savings. It is important to have fuel/air ratio controls and burners that can hold operations close to correct fuel/air ratio throughout their entire firing range. Too little air results in unburned gases going up the stack and too much air wastes heat. Optimum fuel combustion depends on the proper fuel and air mixture. Practically 10% excess air would give a flame temperature of about 200 degrees hotter than the 30% excess air, greatly improving heat transfer efficiency (6). Most efficient burning condition is obtained by controlling the fuel/air ratio until the maximum CO<sub>2</sub> is obtained, which are:

in natural gas: 11-12% CO<sub>2</sub>  
 in light oils: 15-15½% CO<sub>2</sub>  
 in heavy oils: 15½-16% CO<sub>2</sub>  
 in case of coal, the CO<sub>2</sub>% varies from one coal to another according to the percentage of volatile matter, ash and moisture content.

#### 8. KILN INSULATION

A way to reduce kiln shell losses is by using insulating refractories. In this category it is required to:

- a. Improve the kiln installation, by development of new materials to extend the life of the existing lining and/or reducing the heat loss through the kiln shell.
- b. Develop new refractories with low thermal conductivity or refractory combinations to lower the overall sensible heat loss from the kiln shell.

This area needs additional research to develop new kinds of bricks which can lower the heat radiated from the kiln.

#### 9. AUTOMATIC PROCESS CONTROL

Undoubtedly, using an automatic process, controlled by a computer, will have a great affect on energy savings and on production of a homogenous clinker (?).

#### 10. USE OF ALTERNATIVE FUELS AND ENERGY SUPPLY SYSTEMS

It has been shown (8) that 15% of pulverized refuse (with a calorific value of approximately 3000 kcal/kg) is used as an alternative fuel. The ash is absorbed into the clinker without any harmful affects. This application should be widely used, and the application of different kinds of energy supplies in various qualities and percentages should be evaluated.

#### 11. GOOD MAINTENANCE

Good maintenance throughout the cement plant will minimize inleaking air and will increase production. This includes the crushing system, raw materials and clinker grinding, and kiln linings, etc. Use of proper grinding balls (size and amount) will reduce the energy consumption for the grinding process. Using classifying liners increases capacity and reduces the required grinding energy kW per ton.

#### 12. DUST USE

The dust in cement plants is a calcined ground raw mix which is too costly to be disregarded. Unless it contains a high percentage of alkalis and chlorides, it should be reused in the process. Research is needed to investigate the feasibility of using the kiln dust, having a high alkali content, in the process once more.

#### 13. CLINKER QUALITY

Clinker produced should be porous, as such clinker is easier to grind and requires less energy. Very dense, hard-burned clinker consumes more energy in comparison to a porous clinker (3). A great amount of energy can be saved by grinding porous clinker rather than non-porous clinker.

#### CONCLUSIONS

Energy conservation and eliminating energy waste in the cement industry should be considered. Study of the existing technology and development of new processes are recommended in order to produce clinker with the lowest energy consumption. The produced clinker should not be overburned as non-porous clinker consumes more energy in grinding than the porous clinker. An international committee is suggested to coordinate the efforts and the studies required to accomplish energy conservation in the cement industry.

# Industrie et électricité dans un proche avenir

## *Industry and electricity in a near future*

BOUCHET Jacques, Contrôleur Général Adjoint à la Direction Générale d'E.D.F., France.

La France n'a pas de pétrole dans son sous-sol ; elle avait un peu de charbon et de gaz naturel, mais leur production est maintenant en décroissance.

Aussi dès 1974, le Gouvernement a-t-il pris des décisions fermes :

- les économies d'énergie devraient être fortement encouragées ;
- il y aurait accroissement du programme de réalisation des centrales nucléaires.

Les premières de ces centrales sont maintenant proches de la mise en service ; aussi la pénétration de l'électricité dans l'industrie doit-elle être activement poussée pour économiser devises et énergie.

Cette pénétration semble dans beaucoup de cas devoir être intimement liée à une forte baisse du rapport : coût moyen de l'électricité sur coût moyen des combustibles fossiles.

Du fait de la mise en service d'un grand nombre de centrales nucléaires au cours de la prochaine décennie, une telle décroissance surviendra très vraisemblablement.

Mais un peu d'électricité sera encore produite dans des centrales à fuel-oil, surtout dans les périodes chargées d'hiver.

De ce fait, l'électricité pourra à ces moments rester à un niveau de prix relativement élevé, contrastant avec des niveaux plus bas les autres saisons.

Ces changements dans les niveaux relatifs de prix pourront entraîner des changements dans la façon d'exploiter les usines ; et la plupart des fois, il y aura au moins deux façons de minimiser les coûts d'exploitation sans compliquer l'optimisation de la qualité des produits. Toutes les deux pourront être des moyens efficaces d'économiser l'énergie.

France has no oil underground; it had some coal and some natural gas, but their production is by now decreasing.

So, as soon as 1974, Government made up its mind :

- energy conservation was to be strongly promoted ;
- there would be an increase in the development of nuclear power plants.

The first of these plants are now close to commissioning ; so electrification of industry must be actively promoted, in order that foreign currencies and energy might be saved.

Such an electrification seems in many cases to be closely related to a strong decrease in the ratio : mean cost of electricity vs mean cost of fossil fuels.

Due to the commissioning of a large amount of nuclear power plants within the next decade, such a decrease is very likely to occur.

But some electricity will yet be produced in oil-fired plants, mainly during winter peak times.

As a result, price of electricity may then remain at a relatively high level in contrast with lower levels during other seasons.

These changes in relative levels of prices may result in changes in how to run a factory ; and most of the times there will be at least two ways to minimize running costs without adding difficulties to how to optimize quality of products. Both may be very efficient ways to conserve energy.

## CONTEXTE GENERAL

Depuis quelques années, la France s'est trouvée placée dans un contexte énergétique et dans une situation économique qui imposent des choix -mais aussi offrent des possibilités- qui ont encore peu d'équivalents dans le monde.

Certes, le problème "énergie" n'est pas particulier à la France ; il est mondial et point ne sera besoin de rappeler longuement deux faits majeurs :

- les besoins énergétiques s'accroîtront encore fortement, aussi bien du fait de l'accroissement de la population que de celui de l'accroissement de la consommation par habitant, encore à des niveaux très bas dans certains pays ;
- les découvertes d'hydrocarbures ne se font désormais qu'à un rythme inférieur à celui de la consommation ; d'où report obligatoire sur d'autres formes d'énergie, charbon et nucléaire principalement.

La France a été parmi les premières nations à s'industrialiser et l'a fait à partir de ses ressources en charbon et en houille blanche.

Aujourd'hui, ses gisements de charbon économiquement exploitables sont en voie d'extinction et ses sites hydrauliques à peu près tous équipés. Aucun gisement notable d'hydrocarbures -sauf le gaz de Lacq qui arrivera bientôt au terme de son exploitation- n'a été (et ne sera probablement) découvert sur son territoire.

Dans ces conditions, dès le déclenchement en 1973 de la crise pétrolière politico-économique qui nous affectera encore longtemps sans doute, la France s'est trouvée dans l'obligation d'agir vite pour réduire sa dépendance énergétique vis-à-vis de l'étranger. Actuellement, cette dépendance, près de 75 %, porte à la fois sur les hydrocarbures et le charbon -ce dernier étant cependant moins dispendieux en devises.

## CHOIX FONDAMENTAUX

Dès 1974, des choix ont été faits, d'égale importance dans leurs effets prévus pour 1985 :

- promouvoir une politique d'économies d'énergie ;
- intensifier le programme de construction de centrales nucléaires.

Ces centrales, qui nécessitent six à sept ans pour être réalisées, commencent à être mises en service ; désormais, cette formulation des choix doit donc se compléter par :

- reporter les consommations sur l'énergie nucléaire (très peu dispendieuses en devises) aussitôt que le report est techniquement réalisable et économiquement rentable.

Car l'accroissement annuel de production des centrales nucléaires est désormais du même ordre de grandeur que celui des besoins énergétiques globaux, et le restera pendant longtemps. Certains objectent que le recours à l'énergie électrique restera un gaspillage d'énergie et de devises tant que des centrales au fuel-oil resteront en service -et cela du fait du rendement limité de la transformation chaleur-électricité- ; ils en

prennent prétexte pour repousser tout usage thermique de l'électricité.

Cela est doublement erroné car :

- au niveau des appareils d'utilisation, les rendements de l'électricité global production-utilisation est, dans la majorité des cas, meilleur que dans les processus à combustibles fossiles ; ceci est dû à la spécificité des formes sous laquelle elle peut être mise en oeuvre (induction, rayonnement, etc.) et à la facilité de contrôle (régulation, automatisation) ;
- la part du fuel dans la production d'électricité va tomber à 10/12 % dès 1985 et 5/7 % vers 1990. La plus grande partie de la production d'électricité va être en France assurée par ce que l'on a coutume d'appeler l'électricité primaire -l'hydraulique et le nucléaire-. Dès 1985, on peut prévoir 20 % d'hydraulique et 50 % de nucléaire ; en 1990, ces chiffres passeront respectivement à 15 % et 70 %.

## INTERET POUR LES UTILISATEURS

L'accroissement parallèle des besoins énergétiques et des moyens de production d'électricité nucléaire auront plusieurs conséquences attrayantes pour l'utilisateur de cette forme d'énergie.

La première est une assurance contre les risques de rupture d'approvisionnement de longue durée. Plusieurs raisons contribuent à cette assurance :

- le stockage d'uranium-métal peut aisément (faible prix - faible encombrement) couvrir une ou deux années de besoins ;
- le sous-sol français recèle pas mal de minerais d'uranium (100 000 tonnes à des conditions actuellement compétitives) et ces réserves ne sont, par prudence, que faiblement entamées chaque année grâce à une politique de recours à des importations d'Afrique francophone ;
- la répartition du minerai d'uranium sur le globe est très différente de celle du pétrole et présente a priori moins de risques de non-respect de contrats à longue durée ;
- la mise au point des surrégénérateurs divisera par 50 au moins les besoins en minerai.

La deuxième découle du moindre coût de production du kWh nucléaire -de l'ordre de 13 centimes aux bornes d'une centrale nucléaire fonctionnant en base contre plus de 20 pour une centrale analogue au charbon et près de 24 pour une centrale au fuel-oil (y compris frais de lutte contre la pollution sulfurique). La part du combustible est en gros de 4 centimes pour le nucléaire contre 12 pour le charbon et 16 pour le fuel-oil.

Il y aura donc un intérêt économique évident à faire fonctionner aussi régulièrement que possible les centrales nucléaires et à réserver les centrales thermiques au fuel-oil pour la satisfaction des besoins de pointe. Car la part élevée des amortissements dans la formation du coût du kWh nucléaire rend les centrales thermiques classiques intéressantes pour des utilisations annuelles inférieures à 2 000 heures environ.

Cette évolution des prix de revient et des conditions d'exploitation se répercuteront bien évidemment dans les tarifs. En ce domaine, la politique d'EDF est de refléter d'aussi près que possible dans ses tarifs les variations horaires et saisonnières des coûts de production. Non pas d'ailleurs tellement celles que l'on constate aujourd'hui, mais celles que l'on prévoit à échéance de cinq à dix ans.

Une telle politique, qui tient compte des délais de décision et des durées de vie des installations industrielles, a pour objet d'inciter les industriels à des choix conformes à l'intérêt collectif.

D'où une double tendance :

- globalement une baisse du coût moyen du kWh pour des fournitures types à l'Industrie. Cette baisse était prévue pour s'amorcer franchement vers 1981 après une période de stabilité de 1974 à 1980. En fait, les relèvements de tarifs en francs courants autorisés pendant cette période ont été insuffisants pour respecter la stabilité à francs constants. Cela retardera jusque vers 1985/87 l'époque où l'ensemble des tarifs (certains y sont déjà) reviendra, en francs constants, aux niveaux d'août 1973, avant le début de la crise pétrolière ;
- Plus dans le détail, une forte baisse de l'énergie d'été (heures pleines et heures creuses) et un maintien, voire une légère remontée, du prix de l'énergie d'hiver, surtout pendant les périodes de pointe (4 heures par jour ouvrable pendant trois mois). Il en résultera en heures creuses d'hiver (5 mois par an) une énergie électrique plus chère qu'en heures pleines d'été. Cette tendance s'est déjà concrétisée à l'occasion des deux dernières révisions de tarif.

Est-ce à dire que pour suivre ces principes les structures tarifaires seront à modifier profondément ? Certainement pas. Autant que l'on puisse le prévoir aujourd'hui, le "Tarif Vert" pour les fournitures à l'industrie bénéficiera d'une évolution, mais ne subira pas de bouleversements profonds.

Pour les clients les plus importants, il y aura probablement deux ou trois postes horo-saisonniers de plus, afin de mieux suivre les tendances d'évolution des coûts. Mais pour la très grande majorité des clients industriels, il devrait y avoir simplification, d'autant plus sensible que leur puissance souscrite sera faible, et cela aux niveaux des comptages et facturations aussi bien que du raccordement au réseau.

#### INDUSTRIE ET ELECTRICITE

Dans ce cadre général, où il y aura assurance d'approvisionnement en une énergie revenue en moyenne à son niveau de prix de 1973 -à francs constants-, quelle pourra être l'attitude des industriels, accoutumés de longue date à recourir surtout à d'autres énergies, qui verront fortement décroître le coût relatif de l'électricité par rapport à celui des combustibles fossiles ?

Il est difficile de préjuger de leur réaction ; elle sera fonction non seulement de la vitesse

d'évolution -brutale ou lente- du prix des autres énergies, mais aussi des possibilités techniques et financières de se convertir à des matériels utilisant principalement l'électricité. Ce que l'on peut dire, surtout s'ils sont gros consommateurs d'énergie, c'est qu'ils sont dans l'obligation d'envisager, dès maintenant, dans quelles conditions l'électricité pourrait être utilisée dans leur industrie, que la décision finale soit fonction de facteurs économiques évoluant progressivement ou d'une rupture brutale des possibilités d'approvisionnement.

Plusieurs voies sont d'ailleurs ouvertes dans chaque industrie. En gros surtout lorsque le coût de l'énergie est un poste fondamental des prix de revient, elles peuvent se réduire à deux :

- rechercher des procédés techniquement à l'avant-garde du progrès -très performants et économes en énergie- en profitant des multiples formes sous laquelle l'électricité peut être utilisée (rayonnements, plasma, ...) ;
- se limiter à des techniques simples (par exemple basées sur l'effet Joule), mais bien étudiées en profitant au mieux des avantages tarifaires dont le recours de plus en plus marqué à l'énergie nucléaire permettra de bénéficier à certaines heures et à certaines saisons.

Ces deux voies ne sont nullement exclusives l'une de l'autre, bien au contraire et leur combinaison pourra amener à secouer bien des routines et fera fructifier l'innovation.

Dans la recherche de la solution, il pourra notamment être tenu compte de la saisonnalité de la demande en produits fabriqués, des possibilités physiques -ou financières- de stockage temporaire (parfois sous forme de produits non totalement élaborés encore)- et aussi des facilités d'automatisation d'au moins certaines phases des processus. Il y a là un large champ de possibilités, particulièrement dans les industries du ciment.

Ainsi, l'électricité ajoutera-t-elle à ses attraits de disponibilité, de respect de l'environnement d'amélioration du cadre de travail et, ce qui n'est pas négligeable, de qualité des productions, celui de donner matière à imagination dans la recherche de conditions d'exploitation économiquement optimales. Ce qu'il ne faut pas perdre de vue, ce sont les longs délais nécessaires à un changement profond des techniques, surtout dans les industries lourdes. Aussi les choix d'aujourd'hui doivent-ils prendre en compte les possibilités d'approvisionnement -et les coûts- des énergies à échéance d'une dizaine d'années. Et ne perdant pas de vue cette échéance, nul doute que les industriels ne soient dès aujourd'hui tentés par les possibilités immédiates et les perspectives d'avenir qu'apporte l'électricité.

#### PENETRATION DE L'ELECTRICITE ET ECONOMIES D'ENERGIE

Dans un séminaire consacré à des vues prospectives sur les Economies d'énergie, on ne peut éviter de souligner l'effet global que pourra avoir une pénétration profonde de l'électricité dans les processus industriels.

Une substitution rationnelle de l'électricité aux combustibles entraîne généralement de sensibles

réductions des consommations d'énergie primaire. Le "handicap" lié au médiocre rendement de la transformation chaleur-énergie mécanique au niveau de la production de l'électricité est plus que compensé par le rendement élevé au niveau des installations de distribution et d'utilisation de l'énergie. Ainsi un kWh peut remplacer un nombre  $\gamma$  de mégajoules supérieur à celui qui aurait été nécessaire pour le produire dans une centrale thermique. Un certain nombre de réalisations et d'études ont confirmé cette affirmation. A titre d'exemple, l'analyse de 38 projets, de puissance unitaire variant de 50 à 7 000 kW, a donné pour  $\gamma$  les valeurs moyennes ci-après :

- Chimie (12 projets de 620 kW en moyenne):	21	MJ
- Agro-alimentaire (12 projets de 380 kW en moyenne)	: 26	MJ
- Métallurgie, Mécanique (5 projets de 2 120 kW en moyenne)	: 9,5	MJ
- Industries diverses (9 projets de 520 kW en moyenne)	: 20	MJ
<hr/>		
TOTAL (38 projets de 710 kW en moyenne) $\gamma$	= 17,5	MJ

En tenant compte que les projets "électriques" sont peut être comparés à des solutions classiques, susceptibles de perfectionnements sur le plan économie d'énergie (gain de 15 % par exemple), le coefficient moyen apparaît de l'ordre de 15 MJ/kWh; c'est-à-dire en extrapolant, que des besoins actuellement satisfaits par 3,5 Mtep pourraient être satisfaits par 10 TWh, qui ne nécessiteraient pour être produits dans une centrale moderne, brûlant du fuel-oil, que moins de 2,5 Mtep.

La substitution de l'électricité au fuel-oil, surtout dans certaines applications et certains secteurs, peut donc avoir pour premier effet de réduire la demande apparente en énergie primaire exprimée en Mtep.

Point ne sera besoin d'ailleurs de ne recourir qu'à des techniques "de pointe" pour obtenir de tels résultats. La possibilité pour l'électricité d'être utilisée seulement là où il le faut et seulement quand il le faut, l'absence de pertes à la cheminée sur les lieux d'utilisation, permettent dans beaucoup de cas à des procédés basés sur l'emploi judicieux de simples résistances de s'avérer énergétiquement intéressants.

D'autant qu'à l'époque où la substitution pourra être devenue effective de façon appréciable, l'électricité nécessaire ne sera plus, même dans un raisonnement marginaliste, que peu fournie par des centrales au fuel.

Le recours à l'électricité provoquera donc un transfert des consommations primaires vers le charbon, puis de plus en plus, vers le nucléaire.

Ce transfert sera d'autant plus rapide que pour applications visées, les besoins auront de l'importance en heures creuses ou semi-creuses (nuit, week-ends, été, demi-saison).

Et l'automatisation, rendue plus aisée par l'électricité, combinée avec les différenciations des postes horaires tarifaires, aura pour effet de faciliter ces reports en heures "moins chargées", diminuant par là très notablement la charge en devises des consommations énergétiques de l'industrie.

Sauf pénurie brutale en combustibles fossiles, la pénétration de l'électricité semble devoir rencontrer quelques freins à son développement, notamment : difficultés de modifier les habitudes, difficultés de consentir à des renouvellements ou à des transformations de matériel avant leur obsolescence...

On ne peut donc être certain qu'aucun "accident majeur" dans l'approvisionnement en hydrocarbures -liquides ou gazeux- ne pourra survenir avant que la pénétration de l'électricité soit suffisamment profonde pour protéger l'industrie de ses conséquences.

Or, si un tel accident arrivait prématurément, les études et mises au point nécessaires à l'optimisation des processus et des matériels risqueraient de n'avoir pas encore été faites et le matériel adéquat ferait sans doute défaut pour répondre massivement à des besoins immédiats.

Dans ces conditions, des solutions "rustiques" de transfert rapide vers l'électricité ne manqueraient pas de fleurir et il serait hasardeux d'espérer que l'on puisse en espérer des gains en énergie primaire.

Point n'est besoin d'insister sur les répercussions catastrophiques qu'une telle situation entraînerait au niveau de la production industrielle.

Il faut éviter de se trouver dans un tel cas ; et comme on ne peut raisonnablement escompter agir au niveau de "l'accident", il faut pallier ses conséquences par un recours progressif, mais très rapide, à des procédés basés sur un emploi aussi développé que possible de l'électricité : son origine presque exclusivement nucléaire, hydraulique et charbonnière -du moins en France-, sa large disponibilité et son coût modéré seront une bonne protection contre des risques que l'industrie ne peut absolument pas se permettre de courir.

# Corrélations entre la proportion de laitier, le type de ciment et les consommations énergétiques dans la fabrication des ciments mixtes

## *Correlation of slag ratio, cement class and power consumptions in mixed cement production*

I. TEOREANU, Professeur, Faculté d'Ingénierie Chimique, Institut Polytechnique de Bucarest,  
D. DULAMESCU, Ingénieur, ICPIA, Roumanie.

**RESUME :** Dans le présent travail, on a examiné l'obtention des ciments mixtes dans le contexte des corrélations qui existent entre la proportion de laitier, les propriétés des ciments et leurs paramètres dispersionnels, en considérant l'influence de ces derniers sur les consommations énergétiques.

On a eu en vue, en même temps, la corrélation du rapport ciment / laitier - paramètres dispersionnels - consommation d'énergie - propriétés des ciments avec la composition minéralogique des clinkers utilisés.

**SUMMARY :** In the present study were investigated the mixed cement obtained in the context of the correlations of slag ratio, cement properties and their dispersion parameters, taking into account the influence of last mentioned ones upon power consumptions.

It have been taken into consideration, also, the agreement of cement / slag ratio - dispersion parameters - power consumption - cement properties - with mineralogical composition of the used clinkers.

## INTRODUCTION

L'industrie de ciment est, actuellement, un grand consommateur d'énergie. Du point de vue statistique, approximativement 20% de la consommation totale d'énergie (75% de la consommation d'énergie électrique) revient à la préparation des matières premières et au broyage du ciment et plus de 75% au procès de calcination-clinkérisation. Dans ce contexte, la fabrication et l'utilisation des ciments aux additifs cimentoids (laitier de haut fourneau) ou hydrauliquement actifs (cendres volantes par exemple), dans les conditions d'une plus grande proportion de pareils additifs et sans modification essentielle des propriétés de résistance des ciments durcis, représente, à ce moment, l'une des voies d'intérêt exceptionnel, dans l'ensemble des préoccupations pour la restriction des consommations énergétiques (1-4).

Dans le présent travail, l'obtention de tels ciments a été abordée dans le contexte de la détermination, non seulement des corrélations qui existent entre la proportion de cimentoid et les propriétés du ciment, mais aussi en considérant l'influence des paramètres dispersiologiques des ciments sur leurs propriétés physico-mécaniques et sur les consommations énergétiques au broyage. On a considéré, en même temps, la corrélation du rapport ciment/laitier, des paramètres dispersiologiques, de la consommation d'énergie et des propriétés des ciments, avec la composition des clinkers.

## MATERIAUX UTILISES

Les ciments à laitier ont été préparés à partir des clinkers de fabrique (A et D): un clinker à une plus haute teneur en alite (D) et un autre à une moins haute teneur en alite (A). La composition chimique des clinkers utilisés, ainsi que la composition chimique du laitier de haut fourneau (Z), sont présentées dans le Tableau I.

TABLEAU I

Composition chimique (%)	Clinker		Laitier de haut fourneau
	A	D	
P.F.	0,86	0,72	1,14
SiO <sub>2</sub>	21,67	21,37	36,07
Fe <sub>2</sub> O <sub>3</sub>	4,03	2,36	0,35
Al <sub>2</sub> O <sub>3</sub>	5,73	5,95	8,27
CaO	62,71	64,53	54,40
MgO	1,30	0,79	5,20
SO <sub>3</sub>	1,38	1,83	0,70
TiO <sub>2</sub>	0,24	0,19	0,24
Na <sub>2</sub> O	0,44	0,58	0,55
K <sub>2</sub> O	1,15	1,65	0,55

Dans le Tableau II on présente, pour les clinkers, la composition minéralogique potentielle (calculée d'après Bogue), ainsi que celle réelle (déterminée par diffraction des rayons X).

A partir de ces deux clinkers, on a préparé des ciments unitaires (étalon, sans laitier)

TABLEAU II

Minéraux	Teneur (%) :			
	D'après Bogue		Par diffraction des rayons X	
	A	D	A	D
C <sub>3</sub> S	48,6	58,5	40-45	55-60
C <sub>2</sub> S	27,5	16,7	30-35	15-20
C <sub>3</sub> A	8,4	11,5	12	15
C <sub>4</sub> AF	12,2	7,0	7-10	5-7

et mixtes (avec 15%, 30% et 60% laitier); tous les ciments préparés ont été broyés à des surfaces spécifiques Blaine d'approximativement 3000, 4000 et 5000 cm<sup>2</sup>/g.

## LE COMPORTEMENT AU BROYAGE DES CIMENTS ET DE LEURS COMPOSANTS

Les influences négatives, que, parfois, les additions de laitier peuvent induire dans les valeurs de résistance des ciments mixtes obtenus, pourraient être éliminées ou bien atténuées par un broyage plus avancé.

Le développement plus rapide des résistances mécaniques élevées, en même temps que l'augmentation des surfaces spécifiques des ciments portland, sans ou avec additifs (de laitier ou de puzzolane) est unanimement confirmé; ainsi, on accepte le fait que, dans des mêmes conditions chimico-minéralogiques, la résistance mécanique du ciment portland durci augmente avec la finesse de broyage de celui-ci (dans un spectre granulométrique restreint et uniforme), la limite supérieure de la surface spécifique étant d'autant plus grande que le ciment est moins actif; dans cette dernière catégorie on inclue aussi les ciments mixtes.

En tenant compte de ce que nous avons montré plus haut, on peut réaliser - pour les ciments à laitier - des surfaces spécifiques qui conduisent à l'obtention des résistances mécaniques comparables à celles du ciment unitaire étalon. Certainement, on doit tenir compte des éventuelles consommations supplémentaires d'énergie au broyage. C'est pourquoi on est nécessaire d'examiner les clinkers, le laitier et les ciments à laitier du point de vue de l'aptitude au broyage et de corréler les résultats obtenus avec le comportement au durcissement des ciments étalons et mixtes, ayant différentes surfaces spécifiques.

Les informations obtenues concernant la consommation spécifique d'énergie en fonction de la surface spécifique du laitier, des clinkers A et D, ainsi que des ciments mixtes afférents (ciments avec 15%, 30% et, respectivement, 60% laitier) sont présentées dans les figures 1 et 2.

Les données présentées dans les figures 1 et 2 ont été obtenues, en utilisant un broyeur de laboratoire avec les dimensions : Ø 0,5 x 0,5 m, qui fonctionne d'une manière discontinue.

Fig. 1 - Aptitude au broyage

- 1- laitier ; 2- clinker A ;
- 3- clinker A + 15% laitier;
- 4- clinker A + 30% laitier;
- 5- clinker A + 60% laitier;

Pour une surveillance plus facile, les données concernant la corrélation entre la consommation d'énergie électrique et la surface spécifique Blaine des clinkers broyés sont inscrites dans le Tableau III.

TABLEAU III

Surface spécifique Blaine (cm <sup>2</sup> /g)	Consommation spécifique d'énergie au broyage (kwh/t) :	
	Clinker A	Clinker D
2000	31	27
3000	53	53
4000	88	87
4500	117	108
4600	127	115
4800	148	121

Fig. 2 - Aptitude au broyage

- 1- laitier ; 2- clinker D ;
- 3- clinker D + 15% laitier;
- 4- clinker D + 30% laitier;
- 5- clinker D + 60% laitier;

Ces valeurs démontrent que le clinker plus béliétique (A), comme prévu, présente une aptitude au broyage inférieure à celle du clinker plus alitique (D).

Dans le cas du clinker A (à une plus haute teneur en bélite), on constate une importante augmentation de la consommation spécifique d'énergie électrique, correspondant à des surfaces spécifiques, dépassant 4000 cm<sup>2</sup>/g Blaine; en arrivant à plus de 4800 cm<sup>2</sup>/g Blaine, pratiquement, la surface spécifique du ciment n'augmente plus, avec la croissance de la consommation d'énergie électrique. Ce comportement est évidemment atténué dans le cas du clinker plus alitique (D). Le comportement différent au broyage des deux clinkers est en concordance avec les résultats de Beke (5), qui a trouvé que, dans le cas des clinkers très béliétiques, le phénomène d'agglomération se manifeste même

à des surfaces spécifiques supérieures à  $4400 \text{ cm}^2/\text{g}$  Blaine, le phénomène d'agglomération, dans le cas de ce clinker étant plus grand que celui du laitier.

Bien que le laitier comme tel montre des aptitudes au broyage, en général, inférieures aux clinkers dont on a préparé les ciments mixtes examinés, elle met pourtant en évidence un effet légèrement additif, d'amélioration de la broyabilité des clinkers avec lesquels on broie en mélange.

On constate aussi, dans le cas des ciments à laitier, un comportement différentiel au broyage, en fonction de clinker utilisé (A ou D) dans les ciments. Ainsi, à l'utilisation du clinker A, l'addition de 15% laitier ne détermine pas la réduction de l'intensité du phénomène d'agglomération au broyage (intensité caractéristique au clinker A) et, en totalité, le mélange : clinker-15% laitier se broie plus difficilement que le clinker seul; ce comportement est d'autant plus accentué, que la surface spécifique du ciment est plus grande (fig. 2); par la suite, l'augmentation de la proportion de laitier, détermine des diminutions de la consommation spécifique d'énergie, avec la réalisation d'un minimum de celle-ci. Dans le cas des ciments préparés avec le clinker D, l'effet additif se manifeste même à une addition de 15% laitier.

Pour les ciments à partir des clinkers A et D aussi, la proportion optimale de laitier (correspondant à une consommation spécifique minimale d'énergie) se déplace vers des valeurs inférieures à l'augmentation de la surface spécifique (fig. 3 et 4).

Fig. 3 - L'influence de l'addition de laitier sur la consommation spécifique d'énergie (clinker A)

Surface spécifique Blaine :  
1-  $3000 \text{ cm}^2/\text{g}$ ;  
2-  $4000 \text{ cm}^2/\text{g}$ ;  
3-  $5000 \text{ cm}^2/\text{g}$ .

Fig. 4 - L'influence de l'addition de laitier sur la consommation spécifique d'énergie (clinker D)

Surface spécifique Blaine :  
1-  $3000 \text{ cm}^2/\text{g}$ ;  
2-  $4000 \text{ cm}^2/\text{g}$ ;  
3-  $5000 \text{ cm}^2/\text{g}$ .

#### LES PROPRIETES DES CEMENTS EN CORRELATION AVEC LEURS CARACTERISTIQUES COMPOSITIONNELLES ET DISPERSIONNELLES

L'obtention des ciments à laitier ayant des propriétés équivalentes à celles du ciment unitaire étalon, dans les conditions d'une consommation énergétique optimale, suppose la modification simultanée de la proportion du laitier et de la surface spécifique du ciment. En tenant compte de ce qu'on a mentionné, on a examiné, du point de vue des résistances mécaniques, les ciments mixtes à proportions de laitier et des surfaces spécifiques différentes, préparés de la manière plus haut présentée (voir "Les matériaux utilisés"). Les représentations graphiques des informations obtenues sont données dans les figures 5 et 6. Les courbes des figures 5 et 6 illustrent la corrélation simultanée entre les résistances mécaniques, la proportion de laitier et la surface spécifique des ciments; de leur examination il en résulte l'effet négatif de l'addition de laitier sur les résistances mécaniques, dans les conditions de maintien nonmodifié de la surface spécifique du ciment, effet manifesté d'une manière évidente à des périodes courtes de durcissement; pour des termes plus longs de durcissement (28 jours), l'effet mentionné plus haut est atténué, ou bien il cesse même de se manifester dans le cadre de certaines proportions relativement limitées de laitier, ajoutées au broyage des ciments (la proportion limite dépendant de la nature du clinker et de la surface spécifique prise en considération).

Pour éliminer l'effet négatif plus haut mentionné s'impose la modification de la

Fig. 5 - L'influence de l'addition de laitier sur la résistance à la compression (clinker A)

1a, 2a, 3a : ciment à surface spécifique de 3000, 4000 et, respectivement, 5000  $\text{cm}^2/\text{g}$  à l'âge de 2 jours ;  
1b, 2b, 3b : idem à l'âge de 7 jours ;  
1c, 2c, 3c : idem à l'âge de 28 jours .

Fig. 6 - L'influence de l'addition de laitier sur la résistance à la compression (clinker D)

surface spécifique du ciment, en corrélation avec la proportion de laitier utilisé et la marque du ciment qui doit être obtenue; ainsi, en vue de l'obtention d'un ciment d'une certaine marque (Pa 35 en conformité avec les standards roumains), il est nécessaire de réaliser - dans les conditions de l'utilisation des clinkers A et D et de laitier Z - les corrélations inscrites dans les Tableaux IV et V (avec les consommations énergétiques correspondantes au broyage). En partant de ces données, on peut

TABLEAU IV

C l i n k e r A			
Addition laitier (%)	Surface spécifique Blaine ( $\text{cm}^2/\text{g}$ )	Consommation spécifique d'énergie électrique (kwh/t)	
		Laboratoire	Industrie
15	3100	57	42
30	3500	61	46
60	5400	160	109

établir l'influence globale sur l'énergie consommée à la fabrication des ciments à différente teneur en laitier, sans affecter les propriétés de résistance au durcissement; dans le Tableau VI on présente les résultats obtenus pour les ciments à base de clinker D.

TABLEAU V

C l i n k e r D			
Addition laitier (%)	Surface spécifique Blaine ( $\text{cm}^2/\text{g}$ )	Consommation spécifique d'énergie électrique (kwh/t)	
		Laboratoire	Industrie
15	2600	37	32
30	3000	45	35
60	5000	135	93

TABLEAU VI

Destination de l'énergie	L'unité de mesure	Consommation (économie) d'énergie, correspondant à une tonne de ciment à laitier dans la proportion (%):		
		15%	30%	60%
Broyage	kwh	32	35	93
Séchage laitier	kcal	$26,4 \cdot 10^3$	$52,8 \cdot 10^3$	$105 \cdot 10^3$
Clinker économisé	kcal	-	$135,8 \cdot 10^3$	$406 \cdot 10^3$
Economie d'énergie	kcal	-	$106,8 \cdot 10^3$	$274 \cdot 10^3$

(\*) On a considéré comme liant de référence un ciment à 15% laitier, à base de clinker

D. On a gardé la comparabilité, en considérant, pour le laitier, la même humidité et, pour 1 kwh- l'équivalence théorique en kcal.

### CONCLUSIONS

Les résultats des recherches, qui ont fait l'objet du présent travail, soulignent d'une manière évidente la possibilité d'obtenir des ciments à laitier, de relativement bonne qualité, dans des conditions de la corrélation optimale de la proportion de laitier, de la finesse de broyage des ciments et de la nature des clinkers et des laitiers utilisés.

La proportion de laitier dans les ciments mixtes, sans affecter les propriétés de résistance de ceux-ci, est limitée autant par l'activité des clinkers et des laitiers utilisés, que par les difficultés technologiques de l'obtention des ciments à grandes surfaces spécifiques. Même dans les conditions du broyage avancé des ciments, en vue de la conservation d'une qualité correspondante de ceux-ci, il en résulte, indubitablement, une économie globale très importante d'énergie pour la fabrication des ciments à laitier.

# The latest operation performance of the MFC system

## *Les résultats récents d'opération du système « MFC »*

M. KONDO, Vice President, Mitsubishi Mining and Cement Co., Ltd.  
S. FUKUDA, Manager, Research and Development section, Japan.

**RESUME :** Le système de calcination fluidifiée de Mitsubishi ("Mitsubishi Fluidized Calciner" ou MFC) est un nouvel équipement pour la calcination du ciment au clinker appartenant aux systèmes de NSP sus-mentionnés et est mis en opération depuis 1971 après les développements par Mitsubishi Mining and Cement Co., Ltd. pendant plusieurs ans.

Depuis ce temps 16 équipements chauffés au mazout ont été construits au Japon et aux divers pays, se faisant une excellente réputation pour sa performance. De plus le système a été perfectionné continuellement pour répondre aux besoins de l'époque.

Le système de MFC est notamment caractérisé par le fait que la calcination des matières se fait dans une couche fluidifiée montrant une haute efficacité d'échange de chaleur et permettant un long temps de rétention des matières. Par conséquent en comparaison du système SP conventionnel, celui permet une capacité augmentée de calcination du four, une opération continue et stabilisée du four pendant long temps même avec un combustible solide de combustion lente.

Mitsubishi Mining & Cement Co., Ltd., ayant vérifié au moyen des divers essais sur l'équipement industriel que ses opérations peuvent être accomplies d'une manière satisfaisante avec les combustibles solides et que le charbon d'une inférieure qualité de 3,000 - 4,000 kcal peut être seulement utilisé comme le combustible, a établi de fondement de MFC chauffé au charbon. Ici, trois exemples du système MFC sont donnés d'après l'opération récente de performance.

Depuis la crise de pétrole dans 1973, dans l'industrie de ciment qui est un consommateur d'une grande quantité d'énergie, le développement d'une technologies d'utiliser une énergie autre que la de pétrole a été un objectif plus important, à cause de la hausse du prix du mazout.

Dans telle situation, nous croyons que l'importance de la technologie de MFC accroîtra de plus en plus.

**SUMMARY :** Mitsubishi Fluidized Calciner (MFC) system is one of the NSP systems, which has been developed by Mitsubishi Mining & Cement Co., Ltd. (MMCC) after the long efforts and put into practice since 1971.

So far, 16 units of oil/coal fired MFC system have been installed in Japan as well as in foreign countries and have won a reputation for its excellent performance. Furthermore, continuous efforts for the improvement of the MFC system has been done to meet the requirement of the time.

The peculiarity of the MFC system lies in the adoption of fluidized bed which gives high heat exchange efficiency and long retention time of raw meal. Consequently, it makes possible to increase the kiln capacity, to achieve the long stable and continuous kiln operation, and to burn exclusively any kinds of solid fuel having low combustion velocity.

Various kinds of test were performed to apply solid fuel to the MFC system at MMCC's Kuroaki Works. As the results of these test, it has been confirmed that there is no problem for firing in the MFC, even such low grade coals having the calorific value of 3,000 to 4,000 kcal/kg.

In this paper, three examples of the MFC system are described from the latest operation performance.

Since the oil crisis in 1973, the development of energy diversification other than oil has become the most urgent and important subject for cement industries.

At this period, the availability of the MFC technology will be extended further.

## INTRODUCTION

Various precalciner systems which have been developed in both Japan and Europe are currently in use. Among them the MFC system is unique because it uses a fluidized bed as the precalciner. So far 16 units of the MFC system have been installed and have won a high reputation for its excellent performance.

Recent steep price rises and unstable supply of oil have forced cement manufacturers to save on energy consumption and to convert from liquid to solid fuel. The MFC system admirably meets both of these requirements.

## CHARACTERISTICS OF THE MFC SYSTEM

Fig. 1 shows the general arrangement of the MFC system. Detailed descriptions of the principle, structure and equipment of the MFC system have been given in some papers (1) (2) (3).

The distinct peculiarity of the MFC system lies in the adoption of a fluidized bed which gives high efficiency of heat exchange and combustion.

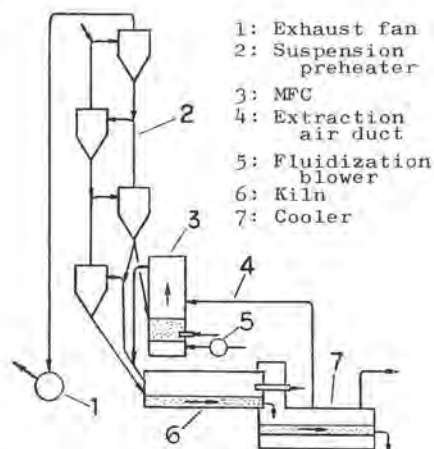

Fig. 1 General arrangement of MFC system

Test operations were carried out to apply solid fuel to the MFC system at Kurosaki Works of MMCC. All of the parameters and criteria necessary for the design of the coal-fired MFC have been obtained through these test operations, and its reliability and stability as a commercial furnace have thereby been confirmed.

Various grades of coal have been burned in the tests and it has been found that there are no difficulties in using pulverized coal to fire the MFC. Very low grade coal, such as that with a value of 3,000 kcal/kg, can be exclusively used for firing.

Using pulverized coal depends mainly on the high mixing effect and the long retention time of several minutes which can be obtained by forming the fluidized bed.

Though there is a slight difference in the

specific gravity between raw meal and pulverized coal, the mixing effect in the fluidized bed is so complete that the behaviour of pulverized coal is almost the same as that of raw meal.

The operating conditions of the MFC and suspension preheater (SP) show no substantial differences, whether oil-fired or coal, if thermally equivalent.

## THE LATEST OPERATION RESULTS OF THE MFC SYSTEM

a) Newly installed MFC system with large capacity

Table I shows the newest kiln of MMCC started in Sep. 1979 at Kanda Works. This system belongs to the so-called doubled capacity type.

With a view to the saving of energy and power, some improvements such as the reduction of the air quantity for fluidization, were made in designing this MFC.

The temperature of the SP exhaust gas is 340 °C or so, which is considered to be the same as that of the conventional 4-stage SP kiln.

Table I Specifications and operating condition of Kiln No. 5, Kanda Works, Mitsubishi Mining & Cement, Japan		
Kiln size	5.4 mφ x 95 mL	
Preheater type	Dopol

Fluidized bed temp.	°C	830
Exhaust gas temp.	°C	870
Specific heat consumption	kcal/kg-cl	740

b) Coal-fired MFC system

Table II shows the Samchock Kiln No. 3 of Tong Yang Cement Mfg., Co., Ltd., in Korea, which was constructed in 1967 and modified to the MFC system in 1978.

The conventional SP system had a burning capacity of 1,300-1,350 t/d. The standard capacity according to the design criteria is 1,290 t/d. By replacing the existing suspension preheater with a large preheater and additional installation of the MFC, burning capacity has been increased to an average of 2,200 t/d and a maximum of 2,300 t/d - a 70 % increase over its standard capacity.

Fuel was changed from oil to coal at the end of 1979. To the kiln is fed a small quantity of oil besides the coal, in order to control the burning zone. But, to the MFC is fed only pulverized coal.

The specific heat consumption is 795 kcal/kg-cl in the case of coal firing and 790 kcal/kg-cl in the case of previous oil firing. The raw materials and the chemical composition, and the fineness of the raw meal are kept the same in both cases.

From these operational results, we have estimated that at present there is no difference in the specific heat consumption between both fuels.

Other operating conditions in coal firing showed the same as those in oil firing.

Table II Specifications and operating conditions of Kiln No. 3, Samchock Plant, Tong Yang Cement Mfg., Korea

Kiln size	4.14 m $\phi$ x 63 mL

Exhaust gas temp.	°C	860
Coal		
Net calorific value	kcal/kg-coal	6800
Specific heat consumption	kcal/kg-cl	795

Table III shows another example of a coal-fired MFC system which was restarted in Dec. 1979 after the modification. The capacity was increased from 600 t/d to 950 t/d. In this MFC system, low grade coal having the calorific value of 4,000 to 4,500 kcal/kg-coal is the only material used for combustion.

The heat consumption was reduced by almost 100 kcal/kg-cl as compared with the previous SP system.

### CONCLUSION

From the above latest operational results, it can be clearly understood that the MFC system is the most advantageous of all precalciner systems. The especial advantage of this system is that solid fuel, even extremely low calorific fuels that cannot be fired in the kiln, can be burned easily in the MFC and the heat contained in these fuels is used in almost the same way as oil.

Since the oil crisis, diversification in the use of fuels has posed serious problems for the cement industry throughout the world. MFC technology will no doubt be used to help solve them.

# CaCl<sub>2</sub> utilization in clinker burning

## *Utilisation de CaCl<sub>2</sub> dans le processus de formation du clinker*

W. KURDOWSKI, Professor, Research Centre of the Industry of Binding Materials,

A. GARBACIK, Engineer, Research Centre of the Industry of Binding Materials, Pologne.

**SUMMARY :** An addition of calcium chloride to the mix of calcium carbonate with silica appears to accelerate considerably the reaction of calcium silicates formation. In this process a series of unstable, intermediate phases are formed.

This effect has been utilized to obtain belite in a rotary kiln. Using an addition of 10% CaCl<sub>2</sub>, belite was burnt at about 1100°C; the chlorine was found to be practically absent in the product, as it passes to the gaseous phase. In similar conditions also high belite content clinkers were burnt. In the case of raw mixes corresponding with Portland cement clinkers the mineralizing action of calcium chloride occurs as well.

The studies on the burnability of raw mixes with various silica- and iron moduli have indicated, that in the mixes with an addition of 5% CaCl<sub>2</sub>, burnt at the temperatures as low as 1300° - 1350°C, no free lime is present. In this case the course of the process is more complicated as in the system CaO-SiO<sub>2</sub>-CaCl<sub>2</sub>, since - as is well known - the calcium chloride forms, apart from chlorosilicate phases, also some transient phases with aluminates. All these phases are unstable and at the temperatures of 1000° - 1250°C they decompose, liberating the chlorine to gaseous phase.

Obtained results, as well as the data from literature, indicate the possibility of utilization of CaCl<sub>2</sub> to obtain the clinkers of various types at relatively low temperatures. The realization of this conception, however, necessitates resolving the problem of the recovery of chlorine from the gaseous phase. The utilization of the kilns with 100% bypass for this purpose seems to be promising.

**RESUME :** L'addition de chlorure de calcium à un mélange de carbonate de calcium et de silice accélère sensiblement la réaction de la formation des silicates de calcium à des basses températures. Dans ce processus une série des phases transitoires est formée. Un mélange contenant 10% de chlorure de calcium a été utilisé pour la préparation de la bélite dans un four rotatif à la température de 1000°C environ. Le produit obtenu ne contenait pas de chlore, ce dernier étant échappé avec les fumées. Dans les conditions analogues les clinkers de ciment Portland à haute teneur en bélite ont été cuits également. En cas de mélanges crus correspondant aux clinkers de ciment Portland l'action minéralisatrice du chlorure de calcium se manifeste aussi nettement.

Les investigations de l'aptitude à clinkérisation des mélanges crus à des modules silicique et aluminé-ferrique variés ont montré, qu'avec l'addition de 5% de CaCl<sub>2</sub> les mélanges cuits à la température allant de 1300° à 1350°C ne contiennent pas de chaux libre. En ce cas le processus est plus complexe que dans le mélange CaO + SiO<sub>2</sub> + CaCl<sub>2</sub>, le chlorure de calcium formant, comme on le sait, non seulement des phases chlorosilicatées, mais aussi des phases aluminochloriques. Tous ces phases sont métastables et se décomposent à des températures entre 1000° et 1250°C avec l'échappement du chlore.

Les résultats obtenus montrent la possibilité d'utilisation de CaCl<sub>2</sub> pour la fabrication des clinkers de différents types, à des températures relativement basses. Cette question nécessite une solution du problème de la récupération du chlore des fumées. Il semble prometteur d'utiliser dans ce but des fours avec un by-pass de 100% des gaz.

## 1. INTRODUCTION

The energetic crisis, accompanied by a growth of fuel prices, results in a continuous increase of the expenses on energy as well as of their part in whole costs of the cement production. This problem obliges to energy saving, among other by reduction of heat consumption in the burning process. At the present moment, for the burning of Portland cement clinker, short kilns with external heat exchangers, for which the specific heat consumption amounts to 3000-3200 kJ per kg of clinker, are more and more widely used.

The energetic efficiency of these installations is close to the limit obtainable in practice by burning a common clinker /1/. In the kiln systems with precalcining, for example of Polysius-Rohrbach process type /2/, the utilization of poor quality fuels with low heating value gives the prospects for reduction of the costs of fuel consumed in the process of clinker burning /3/. Further savings in fuel consumption are possible for example by making hydraulic binders on the basis of materials substituting for the classical Portland clinker or by the use of mineralizers, markedly intensifying the process of sintering of Portland cement clinker.

One obtains substantial energy savings by the replacement of common Portland cements with the slag- or fly ash addition containing cements. The activation of hydraulic properties of these additions allows to increase their part in the process of hardening of blended cements.

Recently, bigger and bigger interest is gained by the problem of manufacturing the hydraulic binders from unconventional clinkers, viz. high belite clinkers or calcium sulphoaluminate clinkers /4/. The clinkering process of the latter takes place at about 1200°C with energy consumption by 25 per cent lower as the energy necessary for the burning of common Portland cement clinker. Similar meaning has the diminishing of clinkering temperature in the process of Portland cement clinker burning, realized through the employment of mineralizers. It was found, that  $F^-$  and  $Cl^-$  simple anions reveal a very efficient action, accelerating this process. In this paper the results of investigations of the course of reaction in the mixtures  $CaO+SiO_2+CaCl_2$  are discussed and the usefulness of calcium chloride as a mineralizer in Portland cement clinker sintering process is considered.

## 2. EFFECT OF $CaCl_2$ ON THE COURSE OF REACTION IN $CaO+SiO_2$ MIXTURES AND IN TYPICAL CEMENT RAW MIXES.

The course of reaction in a mixture of  $2-3CaO+SiO_2$  has been found to be substantially accelerated in the presence of  $CaCl_2$  /5/. The reaction occurs with a high rate already at the temperature ranging from 500° to 600°C, with formation of a series of unstable, intermediate compounds. In the

temperature range given above, well-known, compound chlorosilicate  $Ca_3/SiO_4/Cl_2$  is formed /6/, the presence of which in the mixture  $CaO+SiO_2+CaCl_2$  was stated already by Le Chatelier /7/. The formation of this compound takes place with participation of a liquid phase, which appears at these temperatures, in  $CaO+SiO_2+CaCl_2$  mixture. The reaction advances until the whole quantity of calcium chloride is turned into  $Ca_3/SiO_4/Cl_2$ . Dicalcium silicate, which starts to be formed at the temperature of about 680°C, coexists with  $Ca_3/SiO_4/Cl_2$  up to about 1000°C and above this temperature the decomposition of chlorosilicate takes place into dicalcium silicate and liquid calcium chloride. Heating compounds in atmospheric air leads to a decomposition of the latter with driving off gaseous chlorine,

The decomposition of  $Ca_3/SiO_4/Cl_2$  into  $Ca_2SiO_4$  and  $CaO$  starts at the temperature 900°C. In the case, the free silica is present in the mix, it reacts in the temperature range of 700°-800°C with substantial rate with  $Ca_3/SiO_4/Cl_2$ . The products of this reaction are less basic chlorosilicate phases  $Ca_2/SiO_3/Cl_2$  and  $Ca_4/Si_2O_7/Cl_2$ . The latter compound can be considered to be a chloride analogue of well-known mineral cuspidine  $Ca_4/Si_2O_7/F_2$  /8/. These two calcium chlorosilicates are unstable and they decompose with separation of liquid calcium chloride. The decomposition temperature for  $Ca_2/SiO_3/Cl_2$  is about 850°C and for  $Ca_4/Si_2O_7/Cl_2$  about 995°C.

In carbon dioxide atmosphere in the temperature range of 700°-850°C besides  $Ca_3/SiO_4/Cl_2$  the spurrite  $Ca_5/SiO_4/CO_3$  is formed as a succeeding, intermediate phase.

Mineralizing effect of  $CaCl_2$  on the process of spurrite formation is connected with the formation of liquid phase in the mixture  $Ca_3/SiO_4/Cl_2 + CaCO_3$ . Spurrite can be formed at the expense of chlorosilicate and is more stable as the latter. In these conditions  $Ca_3/SiO_4/Cl_2$  starts to decompose at 910°C and the spurrite at 960°C. Above this temperature  $Ca_2SiO_4$  and  $CaO$  remain in the system and the process of chlorine evaporation is completed at about 1200°C.

An excellent mineralizing activity of  $CaCl_2$  in the process of dicalcium silicate formation has been confirmed by burning the belite in a laboratory rotary kiln 0,39/0,54x7 m /9/.

The burning was realized at 1000°-1200°C employing 10% addition of  $CaCl_2$ . Owing to stabilization with small addition of  $B_2O_3$  the phase  $\beta-Ca_2SiO_4$  was obtained practically without chlorine, which was leaving the rotary kilns with the gases.

Mineralizing action of  $CaCl_2$  appeared again by burning the typical Portland cement raw mixes. An addition of 5%  $CaCl_2$  accelerates notably the clinkering process /Table I/. The course of reaction in this case is more complex as in the mixture of  $CaCO_3+SiO_2+CaCl_2$ .  $CaCl_2$  apart from chlorosilicate phases forms also intermediate phases with alumina /Table II/.

1/ Phases are enumerated in order of quantity estimated to be present						
2/ High-lime calcium chlorosilicate						

This compound decomposes at about  $1000^{\circ}\text{C}$  with separation of liquid calcium chloride. The formation - as a result of this process - of salt melt, accelerates rapidly the process of combination of calcium oxide at the temperatures ranging from  $1050^{\circ}$  to  $1250^{\circ}\text{C}$ . In this reaction an intermediate phase is formed, which constitutes a more basic calcium chlorosilicate /10/.

This phase, as the other chlorosilicates mentioned previously decomposes with evolution of the chlorine, which leaves the kiln with the gases.

In the alite Portland cement clinkers burnt in laboratory rotary kiln with addition of 5%  $\text{CaCl}_2$  at about  $1300^{\circ}\text{C}$  the chlorine content in the product varied within the limits of 0,2 - 0,5 per cent. In principle,

the chlorine is combined entirely in the  $C_{11}A_7 \cdot CaCl_2$  phase /11/.

The microscopic view of a clinker burnt with  $CaCl_2$  admixture shows the phase of alite with irregular habit, with numerous belite inclusions as well as extremely fine-crystalline belite /Fig.1/.

Fig.1 - Reflected light microscopic photograph of normal clinker burnt with  $CaCl_2$  admixture, etched with 1-per cent solution of  $HNO_3$  - alcohol. Shows alite crystals and clusters of belite crystals. Enlarged 800 x.

This effect is connected undoubtedly with low clinkering temperature and it can influence the hydraulic activity of the cement. Intensified hydraulic activity of belite is confirmed also by a substantial increase in the strengths between 7-th and 28-th day of hardening of the mortars made with cements high content of this phase /Table III/. A shortcoming of the clinkers burnt with  $CaCl_2$  addition is the presence of chlorine, the content of which in the cements destined for reinforced concrete constructions is often limited to 0,1%.

### 3. PROSPECTS OF TECHNOLOGICAL UTILIZATION OF THE MINERALIZING ACTION OF CALCIUM CHLORIDE

The utilization of  $CaCl_2$  addition for clinker burning reduces distinctly the clinkering temperature and intensifies this process. As a result of mineralizing action of  $CaCl_2$  it is possible to burn the high belite clinkers at the temperatures ranging from  $1100^\circ$  to  $1200^\circ$  and the normal clinkers at  $1250^\circ$  -  $1300^\circ C$ . In the latter case one acquires a lowering of the clinker burning temperature by  $150^\circ$  -  $200^\circ C$ . It can be assumed, that the clinkering process at so low temperature necessitates an energy consumption lower by about 650 - 850 kJ/kg of clinker as the energy necessary for the production of a mineralizer-free Portland cement clinker. Furthermore, because of low clinker burning temperature, the use of relatively poor coal is possible.

The escape of substantial amounts of chlorine into gaseous phase requires however bypassing of 100 per cent of the gases as well as recovering of the chlorine from gaseous phase.

Complete bypassing of the exit gases causes a marked increase in heat consumption in the process of clinker burning. However, the last reports from various manufactures of cement plant equipment, for example from F.L.Smith Co. /12, 13/, offer the solutions in which complete bypassing of the gases results in heat losses as low as 630 kJ/kg of clinker /Fig. 2/. Such a value of the losses practically cancels the advantages resulting from the reduction of the clinkering temperature.

Acceleration of the clinkering process in presence of the calcium chloride is however so appreciable, that it seems interesting to undertake further works with the aim to verify the possibility of utilization of this mineralizer in unconventional suspension kilns /14/.

TABLE III

Properties of high belite content clinker, burnt with $CaCl_2$ admixture

$C_3S$	$C_2S$	$C_{11A7} \cdot CaCl_2$	$C_4AF$	1	3					7	28		
44	40	7	5	4	3000	26,5	0	1 <sup>40</sup>	2 <sup>10</sup>	8,2	17,3	21,9	36,7
30	50	11	7	4	3000	25,0	0	0 <sup>55</sup>	1 <sup>05</sup>	5,2	9,4	12,7	30,6

Fig.2 - Kiln system with 100 per cent by-passing of the gases for maximum reduction of alkali content in the clinker

Nevertheless, already for the present  $\text{CaCl}_2$  can be employed for the production of high-belite cements or single belite phase. Such possibilities are the more so interesting, as the soda industry yields substantial amounts of by-products with rather high content of calcium chloride.

# Aptitude à la cuisson des crus de cimenterie en fonction de leur finesse de broyage

## *Burning ability of cement raw materials in relation with grinding fineness*

N. MUSIKAS et E. HAAG, Laboratoire Central des Ciments d'Origny,  
J.P. HENIN et P. GARDE, Centre de Recherches de Fives-Cail Babcock, France.

RESUME : Dans la première partie de cet article, on fait une étude comparée de différentes méthodes d'estimation de l'aptitude à la cuisson des crus de cimenterie. Il s'est avéré que le plupart de ces méthodes sont trop qualitatives pour permettre de déboucher sur un critère de prévision du comportement industriel des crus de cimenterie.

Par contre les méthodes adoptées par FCB et par les Ciments d'Origny aboutissent à des résultats directement exploitables, comparables entre eux, et recoupant la réalité industrielle. Dans la deuxième partie, on utilise ces tests de réactivité pour étudier l'influence de la finesse sur la cuisson des crus de cimenterie. Nous avons pu trouver les conditions opératoires permettant d'obtenir des crus de laboratoire de granulométries similaires à celles des crus broyés industriellement et présentant la même aptitude à la cuisson.

A partir de ces travaux, nous sommes à même de définir une finesse optimale de broyage aussi bien pour un projet à partir d'échantillons représentatifs de la carrière que pour affiner les conditions de marche d'une installation existante.

SUMMARY : In the first part of this article, a comparative study is made of the various methods used to evaluate the burning ability of cement raw materials. It has been shown that most of these methods are too qualitative to give a prediction criteria for the industrial behaviour of the raw materials.

On the other hand, the methods adopted by FCB and Ciments d'Origny give results which can be directly employed, they can furthermore be compared between themselves, and they conform to the industrial realities. In the second part of the article, these reactivity tests are used to study the fineness effect on the raw material burning. We could find operative conditions which have given us laboratory raw materials of a grain size identical with that of the ground industrial one and having the same ability to be burned.

As a result of this work, we are able to define a grinding optimal fineness and this for quarry samples as well as for improving the operating conditions of an existing installation.

## I INTRODUCTION

### I - 1) Paramètres conditionnant l'aptitude à la cuisson.

Pour des crus correspondant à un type de clinker donné, les teneurs en constituants principaux :  $\text{SiO}_2$ ,  $\text{CaO}$ ,  $\text{Al}_2\text{O}_3$  et  $\text{Fe}_2\text{O}_3$ , ne peuvent varier que dans des limites relativement étroites ; en outre celles des autres constituants de matières premières :  $\text{MgO}$ ,  $\text{SO}_3$ , alcalins... sont volontairement maintenues à des pourcentages assez bas en raison des difficultés qu'ils peuvent provoquer en cours de fabrication ou de leur "nocivité" dans le ciment.

Aussi, dans la plupart des cas, les faibles variations de composition chimique entre crus de "même famille" ne suffisent pas à expliquer leur comportement parfois nettement différent en cours de cuisson, ni, a fortiori, à prévoir dans le cas d'une nouvelle installation, l'aptitude à la clinkérisation du cru choisi.

De nombreux paramètres interviennent dans le degré de facilité de cuisson des crus. Parmi ceux-ci, outre la composition chimique du mélange, on peut citer :

- La finesse de broyage,
- l'homogénéité chimique et l'homogénéité minéralogique,
- la nature minéralogique des matières premières et leur degré de cristallinité,
- la proportion et la composition des phases liquides successives auxquelles le cru peut donner naissance au cours de sa cuisson.

La mesure quantitative de l'influence de chacun de ces facteurs est extrêmement difficile et n'a pas été entreprise dans cette étude, sauf en ce qui concerne la finesse de broyage ; par contre on peut chercher à déterminer globalement, à partir d'un test de laboratoire sur un échantillon de cru, l'aptitude à la clinkérisation de ce dernier. Le présent compte rendu résume donc les résultats obtenus sur 14 crus industriels en appliquant diverses méthodes de caractérisation relevées dans la bibliographie, en détaillant plus particulièrement les méthodes utilisées par les Ciments d'Origny d'une part et par FCB d'autre part. On commente également les recommandations pratiques sur la finesse de broyage que l'on peut en tirer.

### I - 2) Méthodes d'études

La détermination de l'aptitude à la cuisson des crus peut s'effectuer :

- soit à partir de l'analyse chimique du cru en utilisant des formules empiriques faisant intervenir des grandeurs caractéristiques telles que le module de Kuhl et la teneur en silice libre. (1er groupe de méthodes).
- Soit en pratiquant en laboratoire des cuissons de matières crues suivant un cycle de température déterminé ; le degré de combinaison entre les divers constituants étant estimé par mesure de la teneur en chaux libre du produit calciné (2e groupe de méthodes).

Nous avons plus particulièrement axé notre étude sur ce 2e groupe de méthodes.

## II RESULTATS DES ESSAIS EFFECTUES SUR DES CRUS INDUSTRIELS

Tous les résultats obtenus ont été regroupés dans le tableau ci-après :

Crus indust.	Analyses chimiques en %					Modules calculés		Granulométrie Refus en % à			Indice réfractaire à 1450°C		CaO libre à 1450°C FCB	Aptitude à la cuisson ORIGNY	CaO libre à 1400°C par FUNDAL			CaO libre clinker indust.

Les chiffres ( ) donnent le classement par ordre décroissant, relatif à chaque méthode, de l'aptitude à la clinkérisation des crus industriels.

### III ANALYSES CHIMIQUES ET GRANULOMETRIQUES DES CRUS INDUSTRIELS EXPERIMENTES

Celles-ci sont données dans le tableau ci-avant. Afin de ne pas surcharger ce compte rendu nous n'avons pas reproduit les analyses complètes.

Ces résultats amènent les observations suivantes :

- Les teneurs en éléments principaux,  $\text{SiO}_2$ ,  $\text{Al}_2\text{O}_3$ ,  $\text{Fe}_2\text{O}_3$ ,  $\text{CaO}$  des crus sont comprises dans des fourchettes assez étroites ; on notera toutefois que le cru n° 10, de par la nature minéralogique (calcaire siliceux) de ses matières premières, présente une teneur assez élevée en  $\text{SiO}_2$ .

- Du point de vue analyse granulométrique on notera la granulométrie grossière trouvée sur le cru n° 1, refus cumulé de 6,7 et 25 % respectivement aux tamis de 200 et 90  $\mu$ .

### IV APTITUDE A LA CUISSON

IV - 1) 1er groupe de méthodes : méthodes utilisant les résultats des analyses chimiques.

IV - 1 - 1) Méthodes ne faisant pas intervenir la granulométrie (taux de phases liquides et indices de réfractairité).

- Deux modes de détermination ont été utilisés pour calculer le taux de phases liquides à 1450°C, l'un à partir de l'abaque de Terrier, l'autre à partir de la formule : taux de phase liquide =  $3A + 2,25F + \text{MgO} + \text{alcalins}$ . Les valeurs obtenues n'ont pas été reproduites dans cet article.

- Du point de vue indice de réfractairité, nous avons utilisé la formule :

$$\text{Indice de réfractairité} = \frac{C3S + 0,6C3A - 0,61C4AF}{1,12C3A + 1,45C4AF}$$

Les indices ainsi obtenus (voir tableau du paragraphe II) diffèrent suivant que l'on utilise les valeurs de composition potentielle trouvées à partir des formules de Bogue ou de Glauser.

- On a constaté qu'il n'y avait pas de corrélation précise entre les valeurs obtenues par ces différentes méthodes et l'aptitude à la cuisson des crus de cimenterie. Ces valeurs peuvent toutefois apporter, dans certains cas particuliers, d'utiles renseignements sur d'autres caractéristiques de la matière à cuire.

IV - 1 - 2) Méthodes faisant intervenir la granulométrie (notamment celle du quartz).

La silice présente dans un cru sous forme de quartz se combine difficilement aux autres constituants et rend le cru d'autant moins réactif que le quartz présent est plus grossier. La granulométrie du quartz peut être estimée par examen minéralogique ou mesurée après attaque sélective. Parmi les méthodes faisant intervenir la granulométrie du quartz, nous retiendrons celle développée par FUNDAL.

Fundal a établi une relation empirique :  $X = 0,33 \text{ LSF} + 0,018 \text{ MS} + 0,56 \text{ K} + 0,93 \text{ Q} - 0,349$  qui permet de déterminer le taux de chaux libre (X) du cru après 30 minutes de cuisson à 1400°C.

LSF est le standard de Kuhl,

MS est le module silicique

K est le pourcentage de  $\text{CaCO}_3$  du cru présent dans la fraction granulométrique supérieure à 125  $\mu$ .

Q est le pourcentage de quartz du cru présent dans la fraction supérieure à 44  $\mu$ .

Cette relation a été appliquée sur les crus de Zahana, du Boucau et de Crugéy. Les résultats sont donnés au tableau du paragraphe II.

IV - 1 - 3) Conclusions concernant ce 1er groupe de méthodes

Parmi ces méthodes celle proposée par Fundal nous semble la plus intéressante et elle donne des résultats cohérents avec le 2e groupe de méthode que nous allons étudier dans la suite de ce rapport. Comme elle permet d'analyser l'influence de différents paramètres (en particulier quartz et calcite), elle constitue un complément intéressant aux méthodes du 2e groupe qui fournissent, elles, une mesure directe de la réactivité.

IV - 2) 2e groupe de méthodes : essais de cuisson

Ces méthodes consistent à estimer le degré de combinaison obtenu par cuisson en laboratoire en se basant sur la teneur en chaux libre du produit calciné. Ces essais de laboratoire permettent donc de comparer différents crus quant à leur facilité relative de cuisson. Ils ne permettent toutefois pas de préciser de façon absolue le degré de combinaison des matières dans les clinkers ni la valeur exacte du taux de chaux libre obtenu au four industriel d'une part en raison des conditions différentes de cuisson entre four industriel et four de laboratoire et d'autre part parce que les exploitants règlent la marche de leur four de façon à obtenir un clinker satisfaisant.

#### IV - 2 - 1) Méthode FCB

Les cuissons ont été réalisées sur 5 g de cru industriel placés dans une nacelle de platine qui est introduite progressivement dans un four porté à la température d'essai ; la nacelle est ensuite maintenue 30 minutes dans la zone de chauffage. Après refroidissement rapide, le produit calciné est ensuite broyé à tout passant à 100µ et traité selon la méthode de dosage à l'éthylène glycol EDTA.

Cette méthode ne tient compte que du taux de chaux libre obtenu après cuisson du cru pendant 30 mn à 1450°C.

Les résultats obtenus sont reproduits au tableau du paragraphe II. Plus la valeur obtenue est faible, plus la cuisson du cru est facile.

#### IV - 2 - 2) Méthode Origny

On comprime sous 3 T, 2g de cru de façon à réaliser un cylindre d'environ 1 cm<sup>3</sup>. Sept de ces cylindres sont disposés dans le four à 700°C et vont subir un cycle de température. A chaque étape, on retire un cylindre et on détermine le taux de chaux libre. L'aptitude à la cuisson est définie comme une fonction inverse de l'intégrale de la courbe CaO libre en fonction de la température (1000, 1100, 1200, 1300, 1350, 1400 et 1450°C).

Le tableau du paragraphe II donne les valeurs trouvées par cette méthode pour les différents crus industriels étudiés.

Comme pour la méthode FCB, les valeurs trouvées ne sont que des indices qualitatifs ; plus l'indice est élevé plus la cuisson du cru sera facile.

#### IV - 2 - 3) Conclusions concernant le 2e groupe de méthodes.

On remarquera que les méthodes FCB et Origny aboutissent à deux classements relatifs des différents crus tout à fait comparables. D'autre part, ces classements correspondent aux estimations des exploitants (on rappelle qu'il n'est pas significatif d'établir une relation directe avec la chaux libre du clinker industriel).

- Pour le test FCB, nous estimons que le cru industriel se "cuit" normalement (température maxi clinker  $\approx$  1450°C et taux de chaux libre résiduel dans le clinker  $\leq$  1%) si le calciné obtenu en laboratoire (30' à 1450°C) présente un taux de chaux libre résiduel  $\leq$  2,5 %.

- Pour le test Origny, pour un indice voisin de 1,2 à 1,3, le cru est considéré comme très difficile à cuire ; vers 1,7 à 2,0, il est considéré comme normal ; au delà de 2,5 il entre dans la catégorie des crus faciles à cuire. On peut noter que ces limites sont moins contraignantes que celle déterminée par FCB ce qui est normal car le cimentier a toujours la latitude de modifier les conditions de marche de son four pour obtenir un clinker de qualité correct.

#### V PROBLEMES POSES

Ainsi que nous l'avons vu précédemment, il existe de nombreuses méthodes permettant de caractériser l'aptitude à la cuisson d'un cru industriel, chaque exploitant et chaque engineering constructeur ayant développé la sienne. Nous avons détaillé les méthodes de FCB et des Ciments d'Origny qui donnent des résultats voisins, exploitables industriellement, et qui illustrent deux soucis différents :

- Pour l'exploitant (Ciments d'Origny) il s'agit principalement d'améliorer les qualités des clinkers et les performances des usines existantes utilisant des matières premières données. Les tests de cuisson doivent permettre d'optimiser la composition du cru (ajouts éventuels...) ou la finesse de broyage, et de suivre le comportement de la matière en zone de cuisson par l'observation de la courbe CaO libre en fonction de la température.

- Pour le constructeur responsable des performances d'un four à construire le problème est plus simple (ce qui explique la plus grande simplicité du test FCB), il s'agit, à partir d'échantillons donnés de préconiser une finesse de broyage pour obtenir un clinker de bonne qualité dans des conditions de cuisson normales.

On peut donc dire que dans tous les cas, pour un cru de composition donnée, il s'agit de réduire le broyage au minimum compatible avec une bonne cuisson de façon à diminuer la consommation énergétique de l'usine existante ou projetée. Notons d'autre part qu'un broyage trop poussé d'un cru réactif peut être source d'inconvénients d'exploitation en favorisant les concrétions dans les échangeurs cyclones. Pour bien utiliser le test d'aptitude à la cuisson, il est donc nécessaire de pouvoir broyer au niveau du laboratoire, les mélanges crus à des finesses variables et représentatives de ce que délivrerait un broyeur industriel.

Nous présentons donc ci-après, les moyens mis en oeuvre et les résultats obtenus par FCB et les Ciments d'Origny lorsqu'il s'agit d'étudier l'influence de la granulométrie du cru sur sa réactivité.

#### VI OPTIMISATION DE LA FINESSE DE BROUAGE

##### VI - 1) Préparation des échantillons.

Des essais ont été effectués sur les matières premières en provenance des Cimenteries de Zahana, du Boucau et de Cruguey. Pour chaque cimenterie nous avons reconstitué au laboratoire un mélange, à partir des matières premières préalablement concassées en tout passant à 3,15 mm, ayant une composition chimique

aussi proche que possible de celle du cru industriel.

Les mélanges ainsi préparés ont ensuite été broyés, avec un agent de mouture, au laboratoire : la Société FCB utilise un broyeur Alsing (L = 503 mm,  $\phi$  = 720 mm) chargé de 150 kg de boulets de 30 mm ; les Ciments d'Origny utilisent un broyeur Henry (L = 450,  $\phi$  = 500) chargé de 160 kg de boulets de 25 mm.

Des échantillons ainsi broyés (sur le broyeur Henry et sur le broyeur Alsing) ont été prélevés au cours du broyage.

#### VI - 2) Analyses granulométriques (non reproduites dans ce rapport)

Celles-ci ont été effectuées à l'alpine et à l'élutriateur Bahco. On a constaté une bonne concordance entre les échantillons broyés au laboratoire et les échantillons de cru industriel. Des essais préalables ont d'autre part permis de montrer que l'ajout d'un agent de mouture permettait de reproduire plus fidèlement les granulométries industrielles, notamment pour les finesses poussées, en évitant l'agglomération.

#### VI - 3) Essais de cuisson

Nous avons appliqué sur les échantillons obtenus par broyage en laboratoire, la méthode FCB (cuisson 30 mn à 1450°C) et la méthode Origny (cuisson à plusieurs températures).

Les résultats ont été traduits sous forme de courbes :

- En ordonnées :

pourcentage de chaux libre après cuisson 30 mn à 1450°C (figure 1) ou coefficient d'aptitude à la cuisson déterminé par la méthode Origny (figure 2)

- En abscisse :

pourcentage de refus à 63  $\mu$ .

#### VI - 4) Commentaires sur les essais de broyage.

Ces essais ont montré que l'on pouvait reproduire, sur des broyeurs de laboratoire, un cru ayant une granulométrie et une aptitude à la cuisson tout à fait comparables à celles du cru industriel.

Ces essais ont d'autre part permis de mettre en évidence l'influence de la granulométrie sur l'aptitude à la cuisson d'un cru.

On peut donc à partir d'essais de laboratoire (broyage - essais de cuisson) déterminer la finesse optimum du cru, c'est à dire fixer la finesse de la farine, compatible avec l'obtention d'un clinker de bonne qualité, en évitant le surbroyage.

Les courbes ci-dessus (figures 1 et 2) montrent par exemple que l'on pourrait pour le cru de Zahana se contenter d'un broyage beaucoup plus grossier. Ceci s'est d'ailleurs vérifié lors de la mise en route de cette installation où il a été passé, pendant une période, un cru présentant 20 % de refus à 90 (soit environ 33 % de refus à 63  $\mu$ ) sans que l'on constate d'inconvénients quelconques sur la cuisson et la qualité du clinker obtenu.

## VII CONCLUSIONS

De nombreuses méthodes d'estimation de l'aptitude à la combinaison des crus de cimenterie ont été proposées par divers auteurs. Il s'est avéré que la plupart de ces méthodes sont trop qualitatives pour permettre de déboucher sur un critère de prévision du comportement industriel des crus de cimenterie.

Le choix de la méthode de caractérisation adoptée à FCB s'est porté sur la méthode de cuisson unique à 1450°C. L'adoption de cette méthode se justifie d'une part par la corrélation que l'on a pu faire entre taux de combinaison obtenu en laboratoire et taux de combinaison obtenu industriellement et d'autre part en raison de sa simplicité de mise en oeuvre en laboratoire.

Dans les cas où un cru donné peut être obtenu à partir de différents mélanges de matières premières, la méthode de cuisson unique à 1450°C peut aboutir à des taux de combinaison en laboratoire trop voisins les uns des autres pour justifier le choix de tel ou tel mélange cru. La méthode de cuisson à différentes températures, mise au point par les Ciments d'Origny peut alors permettre de mieux préciser les caractéristiques de chacun des mélanges.

On a d'autre part pu, sur des broyeurs de laboratoire, reconstituer la granulométrie obtenue sur les broyeurs industriels. Ces essais ont ainsi permis de mettre en évidence l'influence de la granulométrie sur l'aptitude à la combinaison d'un cru.

On peut donc à partir d'essais de laboratoire (broyage, essais de cuisson) déterminer la finesse optimum d'un cru, c'est à dire fixer la finesse de la farine compatible avec l'obtention d'un clinker de bonne qualité, en évitant le surbroyage.

# Energy savings through better utilization of waste heat

## *Economie d'énergie par récupération de la chaleur non utilisée*

E.M. GARTNER, Senior Research Chemist, Portland Cement Association, Skokie, Illinois, 60077, U.S.A.

**RESUME:** L'industrie cimentière américaine produit plus de 50% de son ciment par procédé humide. Pour cette raison, ses besoins énergétiques sont élevés comparé à ceux des industries cimentières de l'Europe et du Japon. La conversion des anciens systèmes peu efficaces en systèmes équipés de préchauffeurs et de pré-calcinateurs modernes permettra aux cimenteries américaines de réaliser d'importantes économies d'énergie dans un avenir rapproché. Néanmoins il est déjà possible de réaliser d'importantes économies d'énergie dans les usines actuelles par l'application de méthodes améliorées de récupération de chaleur.

Dans le moment, aux Etats-Unis, on a considérablement intensifié la recherche pour produire de l'électricité à partir de la chaleur perdue, à des températures aussi basse que 260°C. Ces systèmes utilisent généralement un fluide organique plutôt que de la vapeur d'eau. De nouvelles idées telle que l'amélioration des méthodes d'emmagasinement de la chaleur sont à l'étude. D'autres idées plus avant-gardistes présentées ici permettront une meilleure récupération de la chaleur des refroidisseurs à clinker et des gaz d'évacuation des fours à procédé humide.

**SUMMARY:** The U.S. cement industry produces over 50% of its cement by the wet process. For this reason, its specific energy requirements are high compared to the European and Japanese cement industries. Conversion of older, less efficient kiln systems to modern preheater and precalciner kiln systems will probably account for most of the energy savings made by U.S. cement manufacturers in the near future. Nevertheless, there are still opportunities for large energy savings at new and existing plants by means of improved methods of waste heat utilization.

At the present time, a considerable amount of research is being conducted in the U.S.A. in an effort to design high-efficiency electricity generating systems which can use waste heat at temperatures as low as 500°F. These systems generally use organic working fluids instead of steam. Other new ideas include improved methods of heat storage which will permit more efficient use of waste heat. Some more speculative ideas presented here include methods for better recuperation of heat from clinker coolers and also from the exit gases in wet process kilns.

### 1. Background - The U.S. Cement Industry

As of December 31, 1978, there were 162 cement plants, owned by 49 separate companies, operating in the U.S.A. Of the total of 363 kilns, 206 used the wet process and 157 used the dry process, including 41 kilns with some form of preheater. Of the  $73.8 \times 10^6$  short tons ( $67 \times 10^9$  kg) of clinker manufactured in 1978, approximately 55% was produced using the wet process.

In the U.S.A., as elsewhere, the dramatic increases in energy costs over the last six or seven years have led to a decrease in the number of wet plants and an increase in the number of dry plants, especially preheater plants. But we still have a long way to go before all our cement is manufactured by the most energy efficient processes. The North American continent encompasses such a wide range of raw materials and product demand requirements that it is impossible to generalize when considering the design of cement plants for this market. Raw materials with high contents of alkalies, halides, sulfur, and hydrocarbons occur in some areas, and these minor components, combined with frequent specification of low alkali cements, have made U.S. cement manufacturers cautious regarding installation of preheater kilns. The advent of the precalciner kiln, with the capacity for efficient use of high bypass levels, may hasten the conversion to the dry process in the next few decades.

### 2. Waste Heat Generation in the U.S. Cement Industry

In 1978,  $82.9 \times 10^6$  short tons ( $7.52 \times 10^{10}$  kg) of finished cement were produced in the U.S., about 94% being made from U.S.-produced clinker. The total fossil fuel use for the U.S. cement industry was  $421 \times 10^{12}$  Btu ( $444 \times 10^{15}$  J), and total electrical power consumption was  $11.1 \times 10^9$  kWh. The fossil fuel requirement for clinker production averaged about  $5.70 \times 10^6$  Btu/short ton (6,630 kJ/kg). The electrical requirement for finished cement production averaged 134 kWh/short ton (0.148 kWh/kg), including grinding of imported clinker. If we assume that the "theoretical" enthalpy requirement for clinker production from typical raw materials averages about  $1.5 \times 10^6$  Btu/short ton (1,740 kJ/kg), this suggests that about  $4.2 \times 10^6$  Btu/short ton (4,880 kJ/kg) of excess heat is lost during clinker manufacture. This amounts to roughly  $310 \times 10^{12}$  Btu ( $330 \times 10^{15}$  J) annually. To some extent, all of this heat may be regarded as "waste" heat. The better use of this heat is the subject of this paper.

### 3. Current Status of Waste Heat Utilization

The major use of waste heat in U.S. cement plants at present is in raw feed drying. Two minor uses are:

- (1) Space heating in buildings, etc.
- (2) Electricity generation.

Neither of these two account for a very great percentage of the available waste heat. We estimate that about  $4 \times 10^8$  kWh of electricity are generated annually from waste heat at U.S. cement plants. The average conversion efficiency is not known accurately, but is believed to be about 20%. This implies that about  $6.8 \times 10^{12}$  Btu ( $7.2 \times 10^{15}$  J) of waste heat are used annually in electricity generation. The amount of waste heat used for feed drying is also not known to us. Many U.S. cement plants operate separate fuel-fired dryers instead of using waste heat from the kilns, and the fuel for these dryers is included in the total fuel-use figures for cement production given above. Some cement plants also produce steam or hot water for heating of buildings, etc., but, again, this only accounts for a very small fraction of the available waste heat.

There are two large cement plants in the U.S.A. which currently produce significant amounts of electricity from waste heat. There are also one or two small, older plants which have waste heat boilers, but which are near the end of their operational lives. The two large plants both have several dry process kilns, (without preheaters), equipped with steam boilers. Steam from more than one boiler is piped to the turbines for electricity generation. One of the plants has a raw feed, rich in hydrocarbons, which add 0.95 MBtu/short ton (1,105 kJ/kg) to the 4.57 MBtu/short ton (5,314 kJ/kg) of fuel burnt in the kiln. In the past, this was a significant factor in the decision to use waste heat boilers, since this raw feed was unsuitable for use in anything other than a dry-process kiln without preheaters.

One of the major disincentives to the generation of electricity from waste heat in the U.S.A. has been the difficulty in negotiating cogeneration agreements with the local electric power company. Generally, if the cement company sells any power back to the grid, it will only get a small fraction of the price per kWh that it pays when it buys energy. However, this situation is improving slowly, and the Federal government is taking steps to encourage the negotiation of cogeneration agreements which will be fair both to the cogenerator and to the electric company. This is a result of the National Energy Act of 1978.

#### 4. Modern Trends in Electricity Generation from Waste Heat

##### 4.1 Organic Rankine Systems

Currently, there is a resurgence of interest in electricity generation from waste heat. Several North American companies are developing "Organic Rankine Cycle" boilers and generators, which can be used more efficiently than steam-cycle systems, with the low waste heat temperatures typical of the more efficient modern dry-process cement kilns. Most of these units are designed to be "retrofitted" to existing cement plants, without involving drastic changes in the design of the plant. Modern, efficient steam-cycle boiler/generator systems are also being marketed for cement plant installations.

FIGURE 1 - COMPARISON OF ORGANIC AND STEAM SYSTEMS

FIGURE 2 - WASTE-HEAT ELECTRICAL POWER GENERATION CAPACITY vs. KILN FUEL REQUIREMENTS  
NOTE: CALCULATED FOR DRY PROCESS KILNS, ASSUMING A 20% CYCLE EFFICIENCY

An idea of the relative efficiencies of organic rankine and steam cycle power generating plants can be obtained from Figure 1. Organic rankine cycles are potentially up to 50% more efficient than steam cycles for waste heat temperatures in the range 500-1000°F, (260-540°C). This is partly because they have the advantage of a less severe "thermodynamic pinch" due to the lower latent heat of vaporization of the organic fluid. Use of some organic fluids also allows the boiler reject heat temperature to be well below 300°F (150°C), which is impractical for most steam cycles.

The fraction of the electrical energy requirement which can be generated within any given cement plant depends mainly on the thermal efficiency of the kiln system. This is shown graphically in Figure 2; the data have been calculated on the basis of a 20% cycle efficiency.<sup>(1)</sup> The high efficiency of organic rankine cycles at low inlet temperatures means that waste heat boilers can be installed on preheater kilns, where exit-gas temperatures are typically in the range 550-850°F (290-450°C).

##### 4.2 Energy Storage Systems

Together with the use of improved waste heat boilers, there is the possibility of using some form of energy storage to balance power generation against power requirements. This idea has been discussed in a recent report.<sup>(2)</sup> One of the proposed systems uses "draw salt" (a mixture of sodium and potassium nitrates) as the heat storage medium. The salt mixture melts at 430°F (221°C) and has a high thermal capacity. It can also maintain a high thermal density gradient, which allows both hot and cold salt to be stored in a single tank.

Another possible system is "rockbed" energy storage, basically consisting of a simple bed of gravel through which the hot kiln exit gases can be passed. Air can then be used to reclaim the heat. An economic analysis carried out by Martin Marietta Aerospace<sup>(2)</sup> concluded that the ability to store up to 24 hours production of waste heat for use in electricity generation would result in an improved economic return as compared to a simple, direct waste heat to electricity conversion system. However, there is some doubt as to the real economic feasibility of these storage systems; it seems probable that they will be sensitive to erosion and corrosion by dust, etc., in the waste gas streams. Moreover, the density of energy storage is too low to allow storage of more than one or two days' waste-heat production. With the current trend towards cogeneration agreements, such system may be unnecessary.

#### 4.3 Use of Waste Air from Clinker Coolers, and Bypass Gases from Preheater Kilns

Most of the recent studies on the use of modern waste heat electricity generating systems on cement plants in the U.S.A. have tended to rule out the use of clinker-cooler waste air as a useful source of heat for electric power generation, since it is generally at a rather low temperature, i.e., 250-450°F (120-230°C). Nevertheless, since most U.S. cement plants are equipped with grate coolers as opposed to planetary coolers, clinker cooler waste air does represent a considerable source of waste heat. It may frequently amount to well over 0.5 MBtu/short ton of clinker (580 kJ/kg) on preheater kilns. This source of heat could be incorporated into some schemes for waste heat electricity generation from kiln exit gases, especially in cases where the kiln exit gases are excessively hot and must be diluted with cold air. This might be the case if bypass gases from a preheater or precalciner kiln were to be used for electricity generation. The presence of low-melting alkali sulfates and chlorides in bypass gases may make it preferable to cool the gases below about 1350°F (730°C) in order that the alkali salts condense to solid particles before reaching the heat exchanger tubes. Use of clinker-cooler waste air for dilution would be especially advantageous if it were at a temperature above the boiler rejection temperature, as it then would contribute some extra heat to the system.

#### 4.4 Corrosion and Erosion of Heat Exchangers

The problem of sulfuric acid attack on boiler pipes is almost negligible in the case of waste heat boilers on cement kilns, because of the alkalinity of the dust and the low SO<sub>3</sub> content of the kiln exit gases. However, the effects of kiln dust are one of the major considerations when designing waste heat boilers suitable for cement plant use. The boilers themselves are bound to act as a trap for dust particles and must be provided with an efficient system for dust removal, including soot blowers, etc. The dust is not generally very corrosive towards steel but it is abrasive. Another problem is the formation of hard build-ups which frequently result from the recarbonation of calcium oxide particles. These particles apparently stick to the boiler pipes in the presence of small amounts of alkali salts. Recarbonation of CaO gives calcite, with a 120% increase in volume. This can give rise to a very hard, dense layer on the tubes, which cannot easily be removed.

#### 5. Future Developments in Waste Heat Utilization

##### 5.1 More Effective Methods of Raw Feed Drying

Although, currently, much research is being directed towards improving efficiency of electricity generation from waste heat, a simpler use of waste heat is in raw feed drying. Of course, many of the newer preheater plants already have systems for using kiln exit gases for feed drying, especially if roller mills are used for raw feed grinding. Hot gases from the kiln (or clinker cooler) pass directly into the roller mill. However, many plants in the U.S. use separate, fuel-fired dryers when they could well be using waste heat from either the kiln or the clinker cooler. There is sufficient suitable waste heat rejected from the clinker coolers at many dry-process plants to remove upto 6% moisture from the raw feed. In theory, it should be possible to make the system serve two purposes simultaneously, by combining the requirements for a clinker cooler dust-collector with that of a raw feed dryer. This would be especially useful for plants which use ball mills to grind the raw feed. A simple outline of such a system is shown in Figure 3.

It is proposed that hot waste air from the clinker cooler be passed directly through the moist, crushed raw feed, supported on a travelling grate. The bed of raw feed acts effectively as a gravel bed filter which is continually being renewed. At the same time, considerable drying of the feed can be achieved.

Moist air from the bed is blown back through the hot zone of the clinker cooler and thus ultimately ends up as secondary combustion air in the cement kiln. The increased moisture content of this air could be advantageous in that it would have a higher heat capacity than ordinary dry air; this may result in an increased rate of clinker cooling. Water vapor may also help heat transfer in the burning zone, due to increased flame emissivity. Both of these secondary effects should help to improve clinker quality. The overall effect of this system would be to use hot waste air as a drying medium and simultaneously to save on the cost of installing and maintaining clinker dust collectors and a waste air stack. The coarse clinker dust could be removed by cyclones for return to the finish mills, and the fine dust would end up as part of the dried kiln feed, and be returned to the kiln. This system would be most useful for fuel efficient plants, and should free more of the hot kiln exit gases, which would otherwise be required for feed drying, for electricity generation if desired.

## 5.2 Use of Waste Heat from Wet-Process Plants

One area in which few attempts have been made to fully utilize waste heat is in wet process cement plants, which still produce over 50% of the cement clinker manufactured in the U.S.A. The waste heat, which is mainly in the form of the latent heat of vaporization of water, can be used effectively in low temperature heating, mainly at temperatures below 212°F (100°C). There is a limit to the amount of such heat which is required at any cement plant. However, if the plant were located close to a small community or industrial site which did require such heat for space heating, etc., then it should be possible for the plant to install a complete heat exchanger/condenser system, to extract most of the latent heat from the water vapor in the stack gases. If such a system were to be considered, it clearly should include recycle of the condensed water back into the kiln feed slurry. The hot condensate could be cooled via heat exchange with clean water in a closed loop heat transfer system, the clean water be used to transfer heat to nearby homes, factories, etc. A large reservoir for storage of hot water, or for loss of waste heat by evaporation, may also be helpful to level the heating and cooling load between summer and winter. Such systems may be feasible in certain localities.

Figure 4 is a sketch of a possible system for utilizing waste heat from a wet-process kiln. This system is more complex than a simple condenser. It combines heat recuperation devices with a wet scrubber for kiln dust removal and also a special alkali removal cycle, based on kiln dust leaching theories developed at PCA. The wet, dusty gases pass first through a dry cyclone to remove coarse dust particles, which can be returned to the kiln by insufflation, if desired. The gas is then scrubbed with a concentrated solution of the alkali salts normally found in the dust itself, the solution being generated from the dust initially. Heat exchange at this point is such that the gases are cooled to a temperature slightly above 212°F (100°C), where the concentrated alkali solution is close to equilibrium with the vapor. A large fraction of the kiln dust is removed in this stage of the process; the scrubber is specifically designed for dust removal. The dust slurry is thickened and then washed with water from the second stage scrubber, in countercurrent flow, which decreases the alkali content of the slurry before its return to the raw feed mills. A continuous "bleed off" of the alkali-rich solution enables the alkalis to be removed from the system in a concentrated solution which could be a useful byproduct.

The relatively dust-free gases then pass into the second scrubber, where excess cold water is used to aid condensation of water vapor from the gases, as well as removal of the remaining dust. The main heat exchangers heat the cold return water from the external closed-cycle heat transfer system; the water temperature is then increased further in the first stage scrubber. The condensed water and dust form a dilute slurry which may be combined with the slurry from the first scrubber and returned to the raw feed mills. The pH of the dust slurry is lowered by contact with the CO<sub>2</sub> in the kiln exit gases, which tends to carbonate much of the free lime in the dust and make it more suitable for remixing with the feed slurry. Finally, the cool saturated gases leaving the second scrubber pass through a demister, and can then be reheated, using waste air from the clinker cooler if possible, before leaving the stack.

A rough estimate suggests that a wet-process cement plant of average capacity (100 tons/hour) could provide enough heat to heat 4,000-8,000 typical homes during winter.

## 6. Conclusions

Some of the systems suggested in this report may seem far-fetched, and indeed it is doubtful if they would be economically justifiable at present. However, with the ever increasing cost of fuel and electricity, complex systems which combine heat recuperation with other useful processes such as dust removal, etc., will become increasingly attractive. It should be remembered that the best use of waste heat and waste materials can generally be made only by combining and optimizing all the possible uses of the various waste streams from the whole manufacturing process. The major problem with such systems is that they are complex both chemically and physically, and it may take time before industry becomes able to sponsor the extra research required to fully develop them.

# Bilan énergétique de l'incorporation d'ajouts et des moyens d'activation de ces liants

## *Thermal evaluation of binder induction and their induction means*

J.P. BOMBLED, C.E.R.I.L.H. - Paris, France.

### RESUME

L'incorporation de n tonnes de matériaux naturels ou de sous-produits industriels hydrauliques ou pouzzolaniques permet l'économie de n/9 TEP en fabrication.

Outre l'intérêt économique et écologique, l'expérience montre que ces ciments à forte teneur en constituants secondaires ont généralement d'excellentes qualités notamment en ce qui concerne la maniabilité du béton frais et la bonne résistance des bétons durcis en contact avec des milieux agressifs. Néanmoins le principal grief qui leur est reproché est leur moindre vitesse de durcissement pouvant ralentir les cadences de préfabrication ou freiner les chantiers.

L'analyse des séquences de l'hydratation et du durcissement montre que pour les "activer" on peut avoir recours au niveau de la fabrication, au surbroyage ou, au stade de la mise en oeuvre, à des moyens rhéologiques (fluidification et réduction d'eau importante), mécaniques (pressage énergétique), thermiques (étuvages ou autoclavages) ou chimiques (adjuvants accélérateurs).

Les essais effectués sur des CPJ 35 ont permis de comparer l'efficacité de ces différents moyens et aussi les effets de leur association deux à deux, ou trois à trois ...

Hormis le cas d'exigences de résistances mécaniques à très brève échéance (quelques heures) le bilan le plus positif joue en faveur du surbroyage et des adjuvants à l'exclusion des moyens thermiques qui peuvent consommer en énergie beaucoup plus que le bénéfice fait lors de la fabrication de ces liants.

L'avenir sera sans doute dans l'étude de nouveaux procédés d'"activation", dans la recherche d'adjuvants plus efficaces et dans la conjugaison des différents moyens d'action.

### SUMMARY

Using n tons of hydraulic or pozzolanic natural materials and industrial by-products allows the saving of n/9 fuel oil tons.

In addition to economical and ecological interest, experience shows that cements with high content in secondary components generally have excellent qualities, especially concerning the workability of fresh concrete and the strength of hardened concrete in contact with aggressive environments. A low hardening velocity, which is its main defect, can slow down the rate of precast production or slacken the in situ operations.

Hydration and hardening process analysis shows that they can be accelerated during production : by an overgrinding, or during placing : by rheological means (fluidification and high water reducing), by mechanical means (strong pressure), by thermal means (steam curing or autoclaving) or by chemical means (acceleration admixtures).

Compound Portland Cement (CPJ 35) was used in the experiments permitting the comparison of the efficiency of various means and the effects of their association.

Excluding the requirement of a very early strength (some hours), the most positive evaluation is in behalf of overgrinding and admixture. Exception made for thermal means that can have a higher energy consumption than the profit produced by the fabrication of that kind of binders.

New activation processes will be studied in the future to research more effective admixtures and to the conjugation of various means.

## I INTRODUCTION

Les grandes préoccupations de cette fin de siècle et de millénaire sont essentiellement l'amélioration de la qualité de la vie, la sauvegarde de la nature, la diminution de la peine des hommes et les économies aussi bien de matières premières que d'énergie.

Comme la plupart des industries, la cimenterie a été confrontée à toutes ces exigences, qu'il est parfois difficile de concilier.

Le problème prioritaire est sans aucun doute le souci d'économiser les thermies et les kWh nécessaires à la fabrication du ciment et beaucoup d'efforts ont déjà été fournis dans ce sens.

Un des moyens pour économiser le combustible de cuisson du clinker est évidemment de remplacer celui-ci dans toute la mesure du possible par des matériaux naturels ou des sous-produits industriels hydrauliques ou pouzzolaniques. Or il se trouve que la politique de l'ajout de ces constituants secondaires peut aussi être favorable pour certains des autres objectifs qualitatifs cités ci-dessus.

Néanmoins il est indispensable que la qualité de ces ciments composés (CPJ des nouvelles normes, CPM, CHF ...) soit suffisante pour satisfaire aux exigences des cadences des chantiers ou des usines de préfabrication faute de quoi le recours à des procédés thermiques d'accélération du durcissement par exemple, risquerait de compromettre le bénéfice énergétique escompté; c'est par conséquent ce bilan que nous allons essayer d'examiner.

## 2 INTERET DE L'INCORPORATION DES SOUS-PRODUITS

La politique de fabrication des liants contenant des sous-produits industriels a démarré il y a déjà très longtemps en France, avec le développement des ciments de laitier et des ciments à la pouzzolane naturelle (gaize par exemple) ou artificielle (cendres volantes), ceci non seulement pour des raisons économiques lors de périodes difficiles mais aussi souvent à cause des qualités particulières de ces liants.

Si l'on définit les taux d'ajout par :

$$\tau = \frac{\text{tonnage de liant produit}}{\text{tonnage de clinker consommé}} = \frac{L}{K} = 1 + \frac{A}{K} \quad (1)$$

A = tonnage d'ajout incorporé

$$\text{et } \alpha = \frac{A}{L} = 1 - \frac{1}{\tau} \quad (2)$$

pour fixer les idées, le taux  $\alpha$  a oscillé ces dernières années entre 0,20 et 0,25 et  $\tau$  a été très voisin (tous liants réunis) de 1,3.

L'incorporation de sous-produits et de déchets industriels présente des avantages économiques, écologiques et techniques.

### 2.1 Economie d'énergie

La substitution du clinker qu'il n'aura pas été nécessaire de cuire par des matériaux disponibles, procure une économie directe de combustible à laquelle il faut ajouter l'économie de kWh (donc d'équivalent pétrole) faite sur la préparation du cru et en particulier sur le broyage des matières premières qui auraient été nécessaires pour la fabrication du clinker économisé :

$$E = \alpha \left[ \underbrace{C_1}_{\text{cru}} + \underbrace{K \alpha C_2}_{\text{surbroyage du ciment}} \right] - \left[ \underbrace{K C_3}_{\text{transport de l'ajout}} \frac{\Delta S}{1000} + \alpha C_4 d \right] \quad (3)$$

Avec :

E = économie d'équivalent fuel par tonne de ciment.

$\alpha$  = teneur en ajout.

$C_1$  = kg de fuel pour la cuisson d'une tonne de clinker ( $\approx 105$ ).

$C_2$  = kWh par tonne pour le broyage du cru.

$a$  = quantité de cru par tonne de clinker ( $a \approx 1,6$ ).

$C_3$  = consommation spécifique (kWh/t) pour le surbroyage éventuel du clinker.

$\Delta S$  = surbroyage nécessaire.

$C_4$  = consommation de fuel par tonne-km pour le transport des ajouts.

$d$  = distance de transport.

$K$  = consommation moyenne de fuel par kWh à la centrale électrique ( $\approx 0,25$  kg/kWh)

En négligeant la dépense de transport, très variable suivant les conditions, on peut écrire :

$$E = \alpha \left[ 105 + 0,25 (1,6 \times 20) \right] - 0,25 \times 11 \times \frac{\Delta S}{1000}$$

$$= 113 \alpha - \frac{\Delta S}{364} \quad (4)$$

Pour une teneur moyenne  $\alpha$  de 23 % et en remarquant que la part du surbroyage reste généralement faible, on aboutit en moyenne à un gain de 26 kg de fuel par tonne de ciment c'est-à-dire qu'une tonne d'ajout fait gagner plus de 110 kg de fuel et l'emploi en cimenterie de  $n$  tonnes de sous-produits fait économiser environ  $n/9$  tonnes de fuel.

L'incorporation annuelle de sept millions de tonnes de constituants secondaires correspond donc à une économie générale en fabrication, de l'ordre de 750 000 tonnes de fuel soit pratiquement le double de celle estimée lors de l'instauration de l'heure d'été.

### 2.2 Valorisation des déchets et protection de l'environnement

La valorisation de ces sous-produits se situe non seulement dans la lutte contre le gaspillage de matières premières mais représente pour les industries d'amont une économie certaine puisque la commercialisation des déchets évite des dépenses non négligeables pour l'évacuation, l'entassement et la surveillance des décharges et crassiers (outre la difficulté de plus en plus grande de trouver des terrains appropriés).

Par ailleurs au niveau de la cimenterie la substitution du clinker dans les liants fabriqués en France par près de 7 millions de tonnes d'ajouts par an évite d'extraire de l'ordre de 10 millions de tonnes de matières premières annuellement c'est-à-dire, permet de laisser en place chaque année environ 5 millions de  $m^3$  ce qui, outre l'économie d'extraction, n'est pas négligeable pour la sauvegarde de la nature, la conservation des sites et la protection de l'environnement.

Ajoutons que sur le plan purement économique, en dehors des économies déjà indiquées, l'incidence sur les coûts de fabrication de l'emploi des déchets qui n'exige qu'un volume d'investissement de l'ordre de 1/5 de celui qu'il faudrait pour fabriquer le même tonnage de clinker.

### 2.3 Qualités des ciments à constituants secondaires

Ajouté aux considérations ci-dessus et contrairement à l'idée parfois répandue, il convient de souligner sur le plan technique que les liants contenant des constituants secondaires sont d'excellents ciments présentant des propriétés et des qualités spécifiques.

Maintes fois démontrées et bien qu'il sortirait du cadre de ce travail de les développer en détail, nous les résumons rapidement :

- **qualités du béton frais** : dans la plupart des cas la présence de constituants secondaires améliore la maniabilité et la plasticité des bétons frais, toutes choses égales par ailleurs, cela peut se concrétiser par une amélioration de la mise en œuvre et du serrage ou par une diminution de l'exigence en eau à maniabilité égale. Tout cela peut conduire à des gains de compacité, d'étanchéité et de résistance sur le matériau durci.

- **béton durci** : on sait que le point faible des hydrates du ciment portland est la portlandite ; or la teneur en chaux plus faible des ciments à constituants secondaires et la possibilité de son insolubilisation dans les réactions pouzzolaniques rendent les mortiers et les bétons durcis moins sensibles aux actions dissolvantes des eaux pures ou aux attaques des eaux agressives ou chargées.

Par ailleurs un certain nombre d'ajouts à caractère pouzzolanique qui ne sont pas saturés peuvent fixer et insolubiliser une part des alcalins avec les conséquences que cela entraîne : atténuation du retrait hygrométrique à long terme, suppression du risque de réaction alcali-granulats, limitation de la carbonatation.

Outre la bonne maniabilité, facteur de serrage, la masse volumique plus faible de ces ciments conduit, à dosage pondéral égal, à des volumes plus grands de pâte liante ce qui milite en faveur d'une bonne étanchéité donc contribue à la résistance aux attaques, au gel, à la corrosion, bref est favorable à la durabilité.

- **autres qualités** : leur faible chaleur d'hydratation doit diminuer les contractions thermiques ; la plus grande déformabilité de la pâte interstitielle doit atténuer les contraintes dues aux retraits gênés ; certains ajouts peuvent jouer le rôle de stabilisateur dimensionnel à l'égard des éléments expansifs éventuels du clinker utilisé : tout cela conduit à un moindre risque de fissuration dans certains emplois. Ajoutons aussi une bonne aptitude de ces ciments à la plupart des traitements thermiques et généralement une bonne tenue au feu.

En revanche les inconvénients et points faibles habituellement reprochés à ce type de liant, surtout ceux à forte teneur en ajout, sont les vitesses de prise et de durcissement plus faibles que celles de nombreux portland purs. Cette lenteur qui peut freiner la cadence des chantiers ou des usines de préfabrication est nuisible pour les bétonnages à basse température, en hiver, ou dans les pays de climat rigoureux.

Il peut résulter de cette sujétion, non seulement un "surprix" (évalué entre 2 et 8 %) pour le coût du béton mais aussi la possibilité d'une consommation

supplémentaire d'énergie, si l'on a recours à des traitements thermiques par exemple, qui risquent d'annuler une partie du bénéfice réalisé en fabrication. D'où la nécessité d'étudier les moyens d'"activer" ces liants.

## 3 RECENSEMENT ET EVALUATION DES MOYENS D'"ACTIVATION" DES CEMENTS A FORTE TENEUR EN AJOUTS

### 3.1 Généralités

La séquence des phénomènes qui constituent l'hydratation et la prise d'un liant hydraulique est rappelée dans le TABLEAU I avec les moyens théoriques d'action à chaque niveau : mouillage, floculation, pénétration ou non, hydrolyse, dissolution, solvation, diffusion des ions hydratés, sursaturation et précipitation.

On peut noter dans le tableau la fréquence d'apparition de la température, de la surface du contact solide-liquide et d'adjuvants potentiels.

Tableau I

Phase de l'hydratation	Phénomènes physico-chimiques	Action physique ou chimique efficace	Intervention possible en fabrication à l'utilisation	
Mouillage	Tension superficielle de l'eau	Inutile (les ciments sont hydrophiles)	-	-
Floculation (ou défloculation)	Potentiel électrocinétique de l'interface	Adjuvants ioniques	-	Défloculants ou fluidifiants pour réduire les espaces intergranulaires.
Pénétration	Viscosité de l'eau	Température	-	Chauffage
	Surface d'action	Accroissement de la surface ext. Défaits et failles int. des grains.	Broiement Trempe	-
Hydrolyse	Surface d'action	idem	Broiement ou trempe	-
	Affinités chimiques	Ions convenables "catalyseurs"	Teneur en C <sub>3</sub> A	Adjuvants
Dissolution	Forces de séparation des ions	Constante diélectrique	-	-
	Agitation thermique	Température	-	Chauffage
	Surface d'action	Défaut de cristallinité	Broiement, trempe	-
	"Solvants"	Ions convenables	-	Adjuvants
Diffusion	Agitation thermique	Température	-	Chauffage
	Dimensions des ions	Concentration, dosages	-	E/C et serrage
Précipitation et Cristallisation	Gradient de concentration	Concentration, dosages	-	-
	Sursaturation	Ions convenables, température	-	Adjuvants, chauffage
	Germination	Architecture, reticulation (accrétion de cristallisation)	Fillers	Germe, fillers
	Morphologie des cristaux	Concentrations	-	E/C et serrage

Si par ailleurs on essaie de démonter les rouages de l'hydratation et du développement des résistances, on aboutit à une relation schématique telle que celle de la formule (5) qui même si elle n'est pas rigoureuse permet une représentation simple des phénomènes et surtout de mettre en relief les différents facteurs qui peuvent influencer et donc où il faudra agir pour accélérer le processus :

$$R = K S (\theta + a)^n b (1 + \phi) \frac{C}{E + \varepsilon} f_{(t)} \quad (5)$$

R = résistance en cisaillement ou en traction

avec : b et  $\psi$  : teneur en C<sub>3</sub>S et C<sub>3</sub>A

S : aire volumique du ciment

$\theta$  : température du liquide interstitiel

C, E et  $\varepsilon$  : volumes relatifs du ciment, de l'eau et des vides.

Cette relation qui a en définitive la forme de la formule de Feret dont elle explicite le coefficient  $K_t$  montre non seulement l'importance de S et  $\theta$  mais aussi le problème "spatial" représenté par le volume des hydrates (et leur résistance propre évidemment) en rapport avec les espaces à remplir, auparavant occupés par l'eau de gâchage et qu'auront à franchir les liaisons, c'est-à-dire en définitive les problèmes rhéologiques de plasticité, d'exigence en eau et du serrage.

### 3.2 Moyens d'actions pratiques

Il ressort de la relation (5) que l'on devrait pouvoir agir :

- en fabrication : en jouant sur S (surbroyage) et sur b et  $\Psi$  (et le gypage) dans une certaine mesure.
- lors de la mise en oeuvre : en jouant sur C, E et  $\epsilon$  c'est-à-dire les dosages et la rhéologie et sur  $\theta$ .

En pratique on pourra envisager différents moyens:

#### 3.21 Moyens mécaniques

Il s'agit essentiellement du surbroyage et dans des cas très particuliers de broyage sélectif (broyeur à jet) ou de broyage humide d'un coulis de ciment envoyé directement à la Centrale du béton; comme le broyage des CPJ consomme entre 30 et 40 kWh/t, un surbroyage de 1 000 cm<sup>2</sup>/g Blaine pourra coûter un supplément de 50 % soit entre 4 et 5 kg de fuel (à la Centrale électrique).

Le broyage séparé des constituants et leur homogénéisation ultérieure est parfois un moyen efficace pour accroître la réactivité de l'une des phases seulement alors qu'en broyage simultané on broie inégalement en fonction des broyabilités des composants et l'on n'est par conséquent pas maître du résultat.

Les agents de mouture peuvent aussi apporter un gain énergétique d'autant plus marqué que l'on vise des finesses plus élevées et que l'on a des matériaux très "agglomérants".

#### 3.22 Moyens d'actions rhéologiques

Il s'agit de réduire les distances intergranulaires et les vides interstitiels :

- en diminuant la quantité d'eau de gâchage (fluidifiant réducteur d'eau)
- en diminuant la quantité d'air soit en améliorant la maniabilité (plastifiants) soit en augmentant l'énergie de serrage (pressage par exemple).
- éventuellement en augmentant l'énergie de malaxage de la phase eau-ciment (malaxage à haute turbulence) qui désagglomère et "décape" les grains par attrition et augmente la surface réactive.

#### 3.23 Moyens thermiques

La chaleur intervient sur la viscosité de l'eau et sur la diffusion des ions pour accélérer la dissolution et partant l'hydratation et le durcissement. On peut avoir recours à différentes techniques :

- préchauffage du béton lequel peut consommer de 5 à 10 kg de fuel/m<sup>3</sup> pour atteindre 60 °C par exemple
- auto-étuvage par la chaleur d'hydratation ce qui est intéressant mais nécessite des moules parfaitement calorifugés et des ciments à forte chaleur d'hydratation ce qui n'est généralement pas le cas des ciments à forte teneur en ajout.
- étuvage par de nombreux moyens (effet joule, fluides caloporteurs, vapeur perdue, micro-ondes etc) le TABLEAU II montre l'intérêt énergétique évident du chauffage électrique lequel sera encore plus intéressant au niveau national lorsqu'une grande part

des kWh seront d'origine non pétrolière.

- autoclavage lui-même gourmand en énergie et coûteux en investissements.

L'avantage incontestable des traitements thermiques est qu'ils peuvent fournir des résistances suffisantes à très brève échéance, 5 ou 6 heures par exemple, ce que ne peuvent pas donner la plupart des autres moyens.

En revanche ils peuvent englober les économies de fuel faites en fabrication (cf4) et conduisent toujours à un déficit de résistance à longue échéance et parfois à des gonflements ou à des produits plus poreux.

#### 3.24 Moyens chimiques ou physico-chimiques

- adjuvants accélérateurs de durcissement : l'intérêt des adjuvants est de ne pas exiger d'installations et d'investissements coûteux et dans la plupart des cas (mais encore faut-il le vérifier en étudiant les produits de base et leurs procédés de fabrication) ils sont plus économiques que les moyens précédents sur le plan énergétique.
- moyens divers (pour mémoire) : germes, eau magnétisée ... ont été maintes fois proposés mais n'ont jusqu'à présent pu faire les preuves de leur efficacité.

Tableau II

Mode de chauffage		Quantité d'énergie	Coût de ** l'énergie	Investissement
Electricité		60 KWh *	0,15 F x 60 = 9 F	base de 1
Vapeur perdue	Fuel domestique	45 litres	0,75 F x 45 = 33,75 F	environ 1
	Fuel lourd	45 litres	0,40 F x 45 = 18 F	environ 1
Fluides caloporteurs	Fuel domestique	25 litres	0,75 F x 25 = 18,75 F	2 à 4
	Fuel lourd	25 litres	0,40 F x 25 = 10 F	2 à 4

\* Soit 15 litres de fuel lourd à la centrale

( Doc EDF )

\*\* Prix mars 1978

## 4 COMPARAISON ET ASSOCIATION DES DIFFERENTS MOYENS POUR ACCROITRE LES RESISTANCES INITIALES

### 4.1 Comparaison de quelques procédés

Les figures 1, 2, 3 et 4 montrent l'action de quelques-uns des moyens indiqués sur les résistances en compression d'un CPJ 35 en pâte pure et la figure 5 permet de les comparer.

Même si ces résultats donnent une idée sur l'action comparée de ces différents modes d'accélération sur un même ciment il faut bien se garder d'extrapoler à tous les ciments, ceux-ci pouvant réagir différemment selon la composition de leur clinker et la nature des ajouts.

Pour simplifier on a sélectionné seulement les quatre modes d'action suivants :

- A : adjuvant accélérateur sans chlorure
- B : surbroyage
- E : traitement thermique par étuvage (même cycle que figure 3)
- F : abaissement de la teneur en eau par un fluidifiant efficace
- T : témoin sans traitement.

La figure 9 permet la comparaison des résultats obtenus.

#### 4.2 Association de plusieurs moyens

Ces essais ont été effectués sur un autre CPJ 35 ; les résultats sont groupés sur les figures 6, 7 et 8.

#### 4.3 Récapitulation et bilan sommaire

Le TABLEAU III résume les consommations énergétiques correspondant aux quatre modes d'activation

choisis précédemment.

plus efficaces et dans la conjugaison des différents moyens d'action.

Tableau III

	Consommation énergétique				
	B Surbroyage	F Fluidification	E Etuvage	A Accélérateur (CaCl <sub>2</sub> )	
Coût spécifique en énergie	20 KWh par tonne pour ΔS = 1000 cm <sup>2</sup> /g (au voisinage de 4000 cm <sup>2</sup> /g)	33 Kg de fuel et 50 KWh par tonne d'adjuvant naphtalénique **	60 KWh électrique ou 25 à 45 litres de fuel pour chauff. à par chaudière pour 1 m <sup>3</sup> de béton.	136 Kg de fuel et 40 KWh par tonne de CaCl <sub>2</sub> . **	
Kg de fuel (0,25 kg/kWh)	par tonne de ciment	5 Kg	1,1 Kg	37,5 Kg ou 62,5 à 112 Kg	2,9 Kg
	par m <sup>3</sup> de béton *	2 Kg	0,5 Kg	15 Kg ou 25 à 45 Kg	1,2 Kg

\* dose à 400 Kg de ciment m<sup>3</sup>    \*\* 2% d'adjuvant en poids de ciment

\* dose à 400 Kg de ciment m<sup>3</sup> - \*\* 2 % d'adjuvant en poids de ciment

On peut noter l'intérêt évident des adjuvants avec toutefois la réserve faite en 3.23 dans le cas d'exigences à très brève échéance (6 à 8 heures par exemple).

La relation (3) du paragraphe 2.1 peut en définitive s'écrire ;

$$E = \alpha \left[ C_1 + (K \cdot a \cdot C_1) \right] - \left[ KC_1 \frac{\Delta S}{1000} + (u \cdot C_1 \cdot d) + \frac{K(C_1 + C_2)}{\gamma} + \sum \beta_i \cdot C_i \right]$$

Fabrication du ciment
Utilisation

Cuisson Broyage du cru
Surbroyage du ciment
Transport des ajouts
Traitements thermiques du béton
Ajoutants

Economies
Dépenses supplémentaires

(6)

Outre la signification des symboles déjà donnée en 2.1 on a :

γ : dosage en ciment (tonne/m<sup>3</sup> de béton),

β : dosage en adjuvant "i",

C<sub>i</sub> : consommation d'énergie pour élaborer l'adjuvant "i",

C<sub>5</sub> : consommation en kWh/m<sup>3</sup> \* pour chauffer le béton frais.

C<sub>6</sub> : consommation d'énergie pour étuver le béton,

(\* ou en kg de fuel, il faut alors supprimer k)

Un calcul simple montre que l'économie faite par l'incorporation de 25 % de sous-produits est voisine de 24 kg de fuel par tonne de ciment mais le terme négatif pourra atteindre 40 kg de fuel en cas d'étuvage électrique d'un béton dosé à 400 kg/m<sup>3</sup>. Le bilan est donc fortement négatif dans ce cas (le surbroyage ne comptant que pour 2 kg).

## 5 CONCLUSION

Il semble résulter que l'"activation" des liants à ajouts qui économisant l'énergie en fabrication passe par le surbroyage (éventuellement séparé) et par la recherche d'adjuvants de durcissement et de fluidifiants ainsi que par l'association de ces différents moyens entre eux, les procédés thermiques devant être réservés aux cas (à limiter dans la mesure du possible à des besoins très particuliers) où des résistances élevées sont indispensables après quelques heures.

L'avenir sera sans doute dans l'étude de nouveaux procédés d'activation, dans la recherche d'adjuvants

# Fuel oil saving by IHI-SF precalciner-kiln process

## *Economies de combustible pétrolier au moyen du procédé IHI-SF au four de précalcination*

N. NAKAMURA, Manager, Cement Plant Engineering Department, Ishikawamima-Harima Heavy Industries Co, Ltd, Japan.

**SUMMARY :** The application of NSP kilns has seen rapid increase in recent years. Pioneer manufacturer of NSP kilns, IHI has already delivered 50 units of its SF system kilns in eight years since 1971, when the IHI-SF precalciner kiln process was developed by IHI.

Ever since the first installation of a commercial SF plant, IHI has spent much effort in further reducing fuel consumption through a number of improvements brought to the process and component equipment. To meet the needs raised by the spiralling rise in oil prices and the accompanying instability of supply sources, IHI has developed new combustion techniques associated with the SF process, to open the way to the utilization of substitute materials such as spoil from coal mines and oil shale, as well as coal to replace part or all of the petroleum fuel hitherto used as heat source.

The heat required to produce 1 kg of cement clinker is about 800 kcal. This specific heat consumption, hitherto depending almost entirely on petroleum fuel, can be reduced with application of the IHI-SF kilns adapted to burn substitute combustible matter, as evidenced by the following successful examples:

- 1) Use of spoil from coal mines to replace part of the clay, with savings in oil up to 50 kcal/kg clinker.
- 2) The realization of a 3 000 t/d IHI-SF kiln designed to burn 100% coal, which is providing completely stable operation.
- 3) Development of a kiln to utilize oil shale as clay substitute, which promises oil savings amounting to 400 kcal/kg-clinker. An industrial installation incorporating the results of this development, of a capacity of 4 000 t/d, is expected to be completed in October 1980.

**RESUME :** L'application des fours NSP (nouveau système de préchauffage à particules en suspension) a vu une augmentation rapide au cours de ces dernières années. Première à se lancer dans la fabrication des fours NSP, la société IHI a déjà fourni 50 exemplaires de son système SF dans les huit ans depuis 1971, l'année dans laquelle le procédé IHI-SF de four à précalcination a été mis au point.

Depuis la réalisation de la première installation commerciale d'un four SF, la société IHI s'est évertuée à réduire davantage la consommation de combustible, au moyen de maintes améliorations apportées au procédé et à ses éléments constitutifs. Afin de prévenir les besoins suscités par la montée en flèche des prix de pétrole, et l'instabilité concomitante de la disponibilité de cette source d'énergie, l'IHI mit au point de nouvelles techniques alliées au procédé SF, qui ouvrirent la voie à l'utilisation des succédanés tels que déblais de houille, schiste bitumineux, aussi bien que la houille, pour remplacer tout ou partie du pétrole utilisé auparavant en tant que combustible.

La chaleur requise pour produire 1 kg de clinker s'élève à 800 kcal. Cette consommation spécifique, qui dépendait auparavant presque entièrement du pétrole, peut être réduite en appliquant le procédé IHI-SF adapté à brûler ces succédanés, témoin les exemples réussis de:-

- 1) L'utilisation du déblais de mine de houille, pour remplacer une partie de l'argile en tant que matière première, ce qui a réalisé des économies s'élevant jusqu'à 50 kcal par kg de clinker produit.
- 2) La réalisation d'un four de 3 000 t/j conçu pour brûler la houille à 100%, et qui fonctionne avec une stabilité complète.
- 3) Mise au point d'un four utilisant le schiste bitumineux en tant que succédané d'argile, qui promet une économie de pétrole s'élevant à 400 kcal/kg de clinker. Une installation industrielle comportant les résultats de ces études, d'une capacité de 4 000 t/j doit être achevée en octobre 1980.

## 1. INTRODUCTION

Since the commissioning in 1971 of a 2000 t/d SF kiln plant by Ishikawajima-Harima Heavy Industries Co., Ltd. (IHI), the advantages of the SF Process have come to be highly appreciated by the cement industry, and fifty IHI-SF kilns have already been installed within a period of 8 years.

The experience gained with numerous SF kiln plants has served as basis for IHI to develop a new SF Process (NSF), of which the first unit successfully entered service in 1979. The aim held in view in developing the NSF was to further reduce its fuel consumption, and the development has been accompanied by many new features incorporated in the cyclones, clinker coolers and other equipment to become an outstanding energy-saving process.

The present paper covers an outline of the SF and NSF Processes, followed by descriptions of examples in which these Processes have been applied to firing spoil, coal, oil shale and other fuel to substitute heavy oil.

## 2. DESCRIPTION OF PROCESS

### 2.1. Original SF Process

The equipment of the original IHI-SF Process comprises: Suspension preheater such as in the conventional preheater processes, calcining furnace called "Flash Furnace", rotary kiln and clinker cooler (Fig. 1). The raw meal fed to the uppermost (first) stage is gradually heated up to 750°C as it passes through the three preheater stages; the

preheated raw meal is then fed into the Flash Furnace — the main feature of the SF Process.

The Flash Furnace is constituted mainly of a reaction chamber (upper part) and a vortex chamber (lower part). The raw meal inlet is located on the ceiling of the reaction chamber, and multiple burners are arranged horizontally round its lower part. Combustion air for the Flash Furnace is provided by air heated to about 750°C in the clinker cooler. The heated air is introduced into the reaction chamber of the Flash Furnace through the vortex chamber below, where it mixes with the kiln gas.

About 60% of the overall fuel consumption of the clinker burning process is utilized in the Flash Furnace, and the raw meal is calcined to 85 - 90% before proceeding toward the kiln. After leaving the Flash Furnace, the calcined meal passes into the rotary kiln through the last-stage cyclone, where it is separated from the gas.

The remaining 40% of the fuel is fired in the front end of the kiln, where it is mixed with combustion air heated to about 1 050°C in the hot end of the clinker cooler.

The clinker cooler is so arranged to supply the hottest air to the rotary kiln, where the highest temperature is required for the sintering, and to send the next hottest to the Flash Furnace through the air duct.

Fig. 1 Flow sheet of SF Process

## 2.2. Energy Saving Provided by the NSF

### 2.2.1. The new Flash Furnace

The aim held in view in developing the NSF Process was to answer the current needs of energy conservation and conversion from heavy oil to coal and other substitute fuels.

The difference between the original and new Flash Furnaces are as follows (see Fig. 2):

- (1) The hot air from the cooler is introduced through the vortex chamber separately from the

Fig. 2

kiln gas; the kiln gas joins the hot air, rising vertically upward from the riser duct.

- (2) A large part of the raw meal is fed into the flue gas in the riser duct.
- (3) The fuel is injected into the vortex chamber by burners arranged to ensure ignition of the fuel by the swirling hot air.

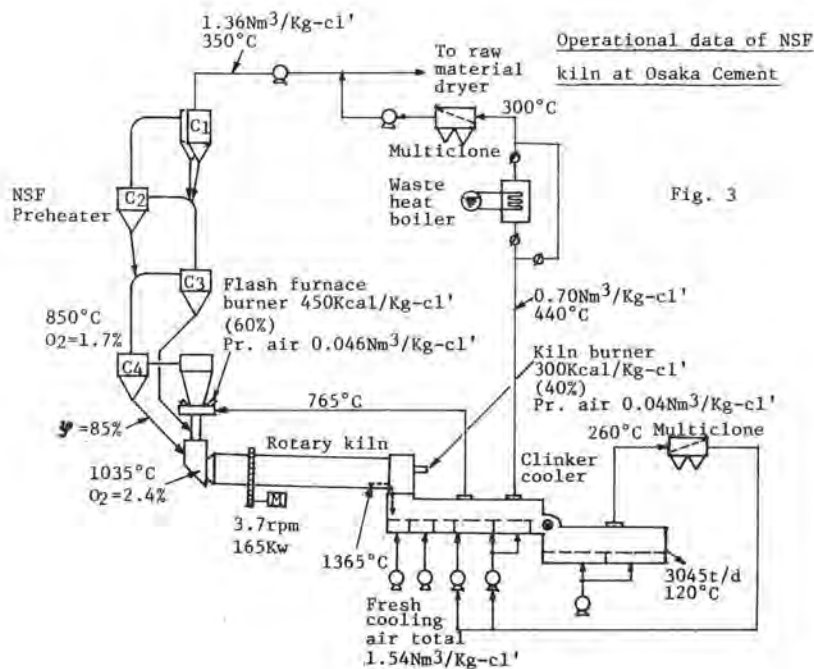

This new arrangement of the Flash Furnace ensures more stable combustion of the fuel, and the enhanced thermal efficiency of the new Flash Furnace provides for reduced fuel consumption; it also opens up possibilities for the firing of coal and other substitute fuels more difficult to burn, without requiring to increase furnace size.

The first industrial NSF unit was installed at the Ibuki Works of the Osaka Cement Company, and entered service in February 1979, since when this 3 000 t/d plant is operating to the owner's full satisfaction.

Figure 3 outlines the NSF production line of this Works. The temperatures indicated in this diagram for the outlets of the four cyclones represent a lowering of 20 - 30°C compared with the corresponding temperatures of the original SF, and the heat consumption has registered a rate as low as 740 - 750 kcal/kg-clinker.

Another notable feature of this plant is -- as shown in Fig. 3 -- the provision of a gas circulating grate cooler, combined with a waste-heat boiler, to ensure energy economy of the Works as a whole.

The grate cooler, of horizontal three-stage type, is equipped with a breaker between its second and third stages. The heated air issuing at about 260°C

from the third stage of this cooler is cycled back into the second grate, to be further heated to about 440°C. The heat acquired by this air is recovered, first in a waste heat boiler, where it cools to about 300°C. The air then joins the exhaust gas from the preheater and is used in the raw meal dryer for secondary heat recovery.

In the present instance, the waste heat boiler serves to supply utility steam, but if the boiler were used for generating power, its capacity should suffice to furnish all the electric power consumed by the cooler and ancillary equipment.

#### 2'2.2. Low pressure loss cyclone

To improve preheater performance, the most straightforward means is to increase the number of cyclones. This however would increase the loss of pressure in the precalcining stages, resulting in increased power consumed by the induced-draught fan. With an orthodox cyclone design, four stages is usually the limit for optimum overall economy.

To increase the number of stages while maintaining overall energy economy, IHI developed the extra low pressure loss cyclones shown in Fig. 4.

Fig. 4 Figure of low pressure loss cyclone

The performance of these cyclones is presented in Fig. 5. The plots reveal that, as compared with conventional cyclones, the new types provide significantly lower values of pressure loss, at a small sacrifice of cyclone efficiency.

In the NSF system, these new low pressure loss cyclones are planned to be adopted for the intermediate stages, while the conventional models will be retained for the top and lowest stages, where the cyclone efficiency is of consequence.

Two actual plants have been trially equipped with the new cyclones in the second stage of a five-stage preheater system. Both plants are operating satisfactorily, and are providing the expected performance, as evidenced by a fuel consumption of 720 kcal/kg-clinker for a throughput of 2 400 t/d.

### 3. FIRING WITH SUBSTITUTE FUELS

#### 3.1. Spoil

Spoil, accompanying mined coal, has a chemical composition that parallels clay, and also contains some coal. It has a heating value of around 1 000 kcal/kg, which could be effectively utilized to economize fuel consumption, if spoil were used to replace part of the clay as raw material.

The spoil is ground together with the other raw materials and charged into the first stage of the preheater. The amount of spoil charged would depend on the composition of the spoil; it is usually limited to about 100 kg/t-clinker, beyond which it is liable to raise the impurity contents in raw meal to the extent of causing clogging trouble in the cyclones and to increase the exhaust gas temperature, with concomitant loss of heat.

The spoil passing through the preheater hardly burns in this stage, on account of the low content of available oxygen, while it burns completely upon entering the Flash Furnace. Some amount of volatile combustible matter contained in the spoil will inevitably be lost from the preheater, but despite this loss, the savings in fuel oil obtained with the use of spoil can amount to 30 - 50 kcal/kg-C1.

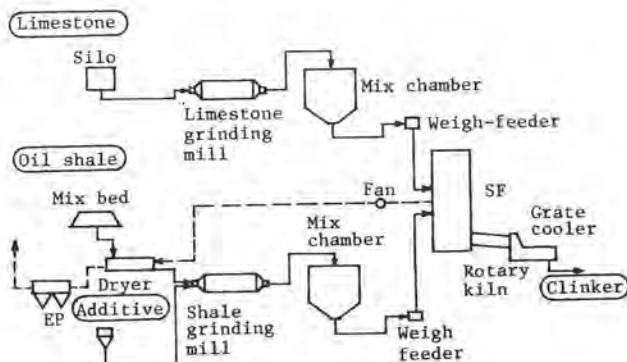

#### 3.2. Coal

In cooperation with the Mitsui Mining Company, IHI has been performing tests on pulverized coal combustion in the Flash Furnace, using the pilot plant in the IHI Research Institute.

These tests proved that with the old type Flash Furnace, coal could not provide combustion performance equal to that of heavy oil, but excellent results were obtained on coal with the NSF Furnace. These results have induced Mitsui Mining to reconstruct their 5.0m dia. x 75m long Repol Kiln of

Operational data of coal fired  
NSF kiln at Mitsui Mining

729

determined according to the quantities and composition of the limestone being treated separately, in order to place within a given range the values of H.M., S.M., I.M. and L.S.D. to produce cement clinker of the required quality.

The previously ground and blended oil shale is further mixed and stored in the mix chamber, before being fed into the preheater via a weigh feeder of high accuracy. The final proportion between limestone and oil shale to be fed into the SF is determined by the chemical composition of the mixture issuing from the mixing chamber. This regulation is automatically ensured by a feed-back circuit incorporating an automatic sampling device and continuous X-ray analyzer connected to a computer.

The foregoing regulation of the feed rate of oil shale would naturally affect the amount of heat generated by this oil shale, but fluctuations in the heat generation in SF are offset by automatic control of the oil burners in the Flash Furnace.

The amounts of oil saving foreseen with the use of oil shale in the plant are as follows:-

- Calorific value of oil shale: 600 - 1 000 kcal/kg-shale
- Total raw meal feed required: 1.6 kg-raw meal/kg-clinker
- Mixing ratio of shale: 25%.

Hence, the calorific value of oil shale burned to obtain 1 kg of clinker is:

$$(600 - 1\ 000) \times 1.6 \times 0.25 = 240 - 400 \text{ kcal/kg-clinker.}$$

Repeated tests with the oil shale in an experimental installation have proved that, with a modified IHI-SF Process, the heat carried by oil shale, as represented by the calorific values cited above, can be utilized to 100%.

The total heat required to produce 1 kg of clinker is about 800 kcal, meaning that economies in fuel oil up to 30 - 50% can be expected with the adoption of the IHI-SF Process arranged for utilizing oil shale.

This 4 000 t/d industrial unit under construction is expected to enter service in October 1980. Its performance, expected to fully meet the design values, will be reported on a future occasion.

#### 3.4. Other substitute fuels

Apart from the various fuels described above, various other substitutes are being actually utilized in SF kilns. Examples include used tyres, waste powdered coke, sludge, bark. Used tyres, in particular, are being utilized by many cement manufacturers in Japan. The oil savings obtained are reported to be 20 - 30 kcal/kg-clinker.

The procedure for feeding kilns with used tyres is to manually feed the material through a gate provided on the kiln inlet chamber between kiln and preheater. From this gate the tyres pass into the kiln. The tyres are raised to the chamber floor by means of a lift available for persons and cargo. The supply of used tyres is ensured by a car scrapping company which offers to deliver the tyres free of charge, as a means of disposal of what to them is unwanted waste.

The current oil situation points toward increasing prices of petroleum combined with continuing instability of supply, so that the range and quantities of petroleum substitutes for fuelling cement kilns would be expected to increase with the years to come. To meet this situation, IHI is continuing its efforts to improve the NSF Process with the view of further enhancing the versatility of this Process.

# L'utilisation des additifs aux différents stades du processus peut apporter une économie importante d'énergie lors de la fabrication du ciment

*The use of additives at different stages of the process can bring in an important economy of energy at the time of cement manufacturing*

F. FIALA, Directeur des Etudes, Travaux et Recherches - S.A. Ciments d'Obourg,  
A. RIVAL, Ingénieur Développement, Belgique.

Les additifs peuvent intervenir à deux stades différents de la fabrication du ciment :

1. Lors de la préparation du cru en voie humide, il est possible de diminuer la teneur en eau de la pâte en moyenne de 25 % en valeur relative, tout en maintenant ses caractéristiques rhéologiques. Cette réduction d'eau s'obtient par addition de produits chimiques à la pâte dans des proportions variant de 0,01 à 0,06 %. L'efficacité du carbonate de soude est connue depuis longtemps, mais, actuellement, on utilise aussi des lignosulfites, des polyphosphates ou d'autres composés mais toujours associés au carbonate de soude. Pour chaque cru, il faut déterminer qualitativement et quantitativement les additifs qui, économiquement, donneront le meilleur résultat. Vu que la composition chimique et minéralogique des matières premières varient dans le temps en fonction de l'avancement de leur extraction, la consigne relative aux additifs devra être revue soit en fonction d'une étude préalable du gisement, soit lorsque des variations significatives de la teneur en eau de la pâte auront été mise en évidence. Il semble que l'action des additifs ait lieu au niveau des micelles et soit liée à la nature minéralogique de la fraction argileuse du constituant principal du cru, la craie ou le calcaire. Une variation des forces électrostatiques au voisinage des particules en suspension déterminerait le mode d'action de ces additifs en réduisant l'épaisseur moyenne du film d'eau entre ces particules.

Pour un four donné, la diminution de la teneur en eau de la pâte dans les proportions ci-dessus modifie le comportement rhéologique de la matière en voie de déshydratation, l'allure de cette dernière et le dégagement de poussières. La conception des échangeurs de chaleur de ce four devra être modifiée en fonction du pourcentage d'eau qui aura été atteint.

L'économie d'énergie réalisée dépendant de plusieurs facteurs, comme de la teneur en eau avant et après l'emploi d'additifs, la température des fumées à la sortie du four, la quantité de poussières dégagées, l'aptitude à la cuisson de la matière crue, il n'est pas possible de la chiffrer d'une manière générale. On peut néanmoins l'estimer, suivant les cas, entre 10 et 15 % de la consommation énergétique totale nécessaire pour la cuisson en voie humide. L'économie ainsi réalisée pourrait varier entre 540 et 800 kJ par kg de clinker.

2. Lors de la mouture du ciment, l'emploi d'adjuvants adaptés à la nature chimique et minéralogique du clin-

ker, conduit à une diminution de la consommation spécifique d'énergie pouvant aller de 10 à 15 %, ce qui représente, pour un ciment ordinaire, 11 à 16 kJ/kg. Ces adjuvants, qui agissent à des dosages sur clinker compris entre 0,01 et 0,1 %, peuvent être des amines ou des sels d'amine, des polyols, des lignosulfites ou des acides organiques faibles. Ils ne sont pas décomposés à la température de broyage et n'ont pas d'action importante sur les résistances des mortiers et bétons. La quantité d'adjuvant nécessaire semble augmenter avec la finesse du ciment.

Leur mode d'action serait le suivant :

Ils évitent le colmatage des boulets et des plaques de blindage. Ils empêchent la formation d'agglomérats contenant à la fois des particules fines et des particules grossières. Il en résulte une augmentation de l'efficacité des séparateurs à air.

Lors de leur emploi, il y aurait réduction des forces électrostatiques sur le blindage, les boulets et les particules de matière broyée.

Les adjuvants améliorent également les propriétés d'écoulement des ciments, ce qui entraîne une diminution de la consommation d'énergie lors de leur soutirage et de leur manutention.

Il faut remarquer que l'air humide est un adjuvant : il facilite l'évacuation des fines particules, diminue le temps de séjour de la matière dans le broyeur et concourt au refroidissement de celle-ci. La vitesse de l'air dans le broyeur ne peut dépasser 1,8 m/sec. Le solde de chaleur sera évacué par l'évaporation de l'eau injectée dans le broyeur.

La solution idéale consiste à combiner, dans un circuit de mouture, l'emploi d'un adjuvant avec une augmentation du débit de ventilation ; l'adjuvant empêche l'agglomération des fines particules et l'air de ventilation les entraîne hors du circuit de broyage.

Une connaissance plus approfondie de leur mécanisme d'action devrait aboutir à une diminution plus importante de la consommation spécifique des installations de mouture.

Pour conclure, on peut dire que les économies d'énergie les plus importantes s'obtiendront, pour la fabrication du ciment en voie humide, par la réduction de la teneur en eau du cru, et, pour la fabrication en voie sèche, par la diminution de la consommation spécifique d'énergie lors de la mouture.

# Intensification of the burning process by using components with high exergy in the raw mix

## *Augmentation du processus de cuisson par utilisation des composés à haute énergie dans les matières premières*

N.P. KOGAN, Candidate of Technical Science,

O.P. MCHEDLOV-PETROSYAN, Doctor of Technical Science, Yuzhgiprotsement, USSR.

**SUMMARY:** The method of exergic analysis is used for technical evaluation of oxides and compounds which are contained in cement raw mix components. This method enables the determination of maximum work of the substance in the process, the final state of which is determined by conditions of thermodynamic equilibrium with the surrounding medium. The normal chemical exergy has been calculated from the phase composition. Increasing of  $Al_2O_3$  - and  $C_2S$ -content in slags causes substantial increase of slag exergy. Iron in the form of  $FeO$  possesses much greater exergy than in that of  $Fe_2O_3$ . Materials with greater exergy, able to melt at lower temperatures and to form silicate melts with low viscosity, can be used in raw mixes as coarse-grained components thus forming an independent physico-chemical system. Slag enthalpy determined by M.A. Pavlov's formula includes heat consumption for heating them to the melting temperature. Calculations have shown that slag admixture to the cement raw mix increases heat capacity and enthalpy of the liquid phase.

Classical method of thermal balances is known to be based on the first thermodynamic law - the law of energy conservation and transformation. According to the second thermodynamic law, the state of chaos and entropy of a closed system, containing a great quantity of individual particles with irregular movement, can be increased or remain unchanged. In such a system there can proceed spontaneously only processes which approach it to the equilibrium state. The exergic method of making out the process balance takes into consideration the second thermodynamic law. While being the measure of potential resources exergy defines the maximum technical ability of the substance to fulfill the work in the process, the final state of which is in thermodynamic equilibrium with the surrounding medium. In the given technological process the normal chemical exergy of compounds (reaction products) is that they must be taken out of the process, as it happens e.g. with blastfurnace slag during cast iron production. However in another process the exergy of such compounds can be still utilized with great technical-and-economical efficiency.

The paper /1/ doesn't give the value of the normal chemical exergy of raw mix components and doesn't take into account devaluation compounds and reactions.

For technical evaluation of oxides and compounds of cement raw mix components we have used the method of normal chemical exergy calculation developed by Ya. Shargut /2/. Devaluation reactions of compounds of reference have been made out on data /2/ for gaseous and solid compounds that may be components and reaction products of clinkering.

While making out devaluation reactions of individual components or clinkering process as a whole it is necessary to take into consideration the phase composition. Carbonate rocks are supposed to contain  $\text{SiO}_2$  admixture represented by quartz,  $\text{MgO}$  represented by carbonate  $\text{MgCO}_3$ . In clayish compounds  $\text{SiO}_2$  is combined into aluminosilicates and can partially be in the form of quartz.

The phase composition of metallurgical slags was defined on the basis of X-ray and petrographic determinations.

For calculation of normal chemical enthalpy of devaluation reaction there has been made out the normalized reaction in which compounds appear at  $T_n = 298.15 \text{ K}$  and  $P_n = 0.101 \text{ N/mm}^2$ .

The following formula was used for calculation of enthalpy of chemical compound devaluation

$$d_n = i_n + \sum_j I_{nj} - \sum_k I_{nk} \quad /1/$$

where:

$d_n$  = devaluation enthalpy in  $\text{kJ/kmol}$ ;

$i_n$  = normal specific (i.e. absolute) enthalpy of the considered compound in  $\text{kJ/kmol}$ ;

$i_n$  = normal enthalpy of the compound of reference (per unit of the considered compound quantity);

$j, k$  = indexes of additional and resulting compounds of reference.

Values of standards enthalpy of compound formation from elements  $H_{298}$  are taken from the monograph /3/.

The entropy of devaluation reaction was determined according to the formula:

$$G_n = a_n + \sum_j a_{nj} - \sum_k a_{nk} \quad /2/$$

where:

$G_n$  = normal devaluation entropy of compound considered in  $\text{kJ/kmol} \cdot \text{K}$ ;

$\sum_j a_{nj}, \sum_k a_{nk}$  = the sum of normal chemical entropies of initial and final compounds in  $\text{kJ/kmol} \cdot \text{K}$ .

When table values of normal entropies of solid compounds are absent  $S_{298}^\circ$  is determined according to the formula /4/:

$$S_{298}^\circ = A \lg M + B, \text{ kJ/kmol} \cdot \text{K} \quad /3/$$

where  $M$  is molecular weight;  $A$  and  $B$  are constants characteristic for each kind of compounds.

Free devaluation entropy is determined as difference between the devaluation entropy and the product of  $(298.15 \times n)$ .

The normal chemical exergy of chemical compounds of initial and final products of clinkering process is determined according to table data /2/. In case of absence of proper data this exergy is determined according to the formula:

$$i_n = d_n - T_n G_n - R_u T_n (\sum_j n_j \ln k_j - \sum_k n_k \ln k_k) \quad /4/$$

The latter member in this equation denotes residual chemical exergy.

Table 1 shows calculation results of normal chemical exergy of materials for cement production according to literature data /2/ and to our own calculations.

On the basis of data indicated it is possible to make out the normalized clinkering reaction in which components content in mols is used as initial compounds; clinker minerals,  $\text{CO}_2$ , and  $\text{H}_2\text{O}$  content in mols is used as final products. On the basis of this equation it is easy to determine the theoretical heat consumption and the normal chemical exergy. The most devaluated initial compounds obviously give the maximum theoretical heat consumption.

The exergy of compounds forming slags composition is greater than that of raw mix natural components. Calcium silicates, calcium aluminosilicates, and magnesium silicates contain the main quantity of slags

exergy. The exergy increases with CaO content. The exergy of FeO is much greater than that of Fe<sub>2</sub>O<sub>3</sub>.

Materials with greater exergy, able to melt at lower temperatures and to form silicate melts with low viscosity, can be used in raw mixes as coarse-grained (unground) components thus forming an independent physico-chemical system /5/. This is accompanied by liquid phase changes in quality and quantity and substantial acceleration of heat-and-mass transfer.

The greater quantity of the liquid phase with increased heat capacity and enthalpy under clinkering conditions in a rotary kiln allows substantial decrease of energy consumption during clinker production. Adding unground slags with great exergy into raw mix results in theoretical heat consumption of less than 880 kJ/kg of clinker.

#### CONCLUSION

Technical evaluation of cement raw materials and of burning process products is made on the basis of exergic analysis. Natural components exergy is shown to be substantially less than that of waste products of pyrometallurgical industry.

Theoretical heat consumption for clinkering mixes containing compounds with increased exergy is substantially lower than that for clinkering mixes composed of natural materials.

Materials with increased exergy can be used in raw mix in unground form permitting the decrease of not only specific heat consumption for clinker burning but also energy consumption for raw mix preparing.

# On reduction of fuel consumption during burning of cement clinker

## *Sur la réduction de consommation de combustible pendant la cuisson du clinker de ciment*

O.I. AVRAMENKO, Candidate of Technical Science,

A.I. ZDOROV, Candidate of Technical Science,

V.M. KOPELIOVICH, Candidate of Technical Science, Yuzhgiprotsement, USSR.

**SUMMARY:** Results of investigations ensuring fuel consumption decrease for cement clinker production through slurry moisture decrease, intensification of slurry drying and dehydration by means of heat-exchanging units, kiln rotation speed increase, proper fuel combustion, and utilization of kiln secondary heat are given.

Kiln rotation speed increase is found to favour heat exchange particularly in processes with great endothermal effect and to increase total heat transferred to the material by 10% on average.

Proper fuel combustion is achieved by gas burners with diffusion flame position and length control what affects clinker size distribution.

Process regularities found are given.

Various methods of fuel saving for clinker burning in rotary kilns have received wide use in the cement industry of the U.S.S.R.

One percent decrease of slurry moisture content ( $W_{sl}$ ) decreases fuel consumption for burning by 28 - 35 kcal per kg of clinker or by 1.7 - 2 % /1/, since in a  $W_{sl}$  range of 36-48 % the heat consumption for water evaporation varies from 550 to 900 kcal/kg.

The decreasing of moisture content is most advantageous at  $W_{cl} > 40$  %, since a relative quantity of evaporating water at this value is higher.

When mechanical methods of dewatering are used, so called partial dewatering seems rational. Average moisture content of thus treated raw mix fed into the kiln is 30-35 %. In this case, a required filtration area substantially decreases and the process gets simplified.

The use of thinning agents is the cheapest way of decreasing  $W$ . Depending on raw materials kind, on account of thinning agents based on human acids,  $W_{sl}$  can decrease by 3-7 %, which saves 6-10 % fuel. Addition of sulcor, oxidized lignine, sodium metasilicate and others can decrease slurry moisture content by 4-9.5 % /2/.

As for intensification of slurry drying and dehydration by installation of rational heat-exchanging units in rotary kilns, our investigations have shown that it is most effective when a system of built-in heat-exchanging units is used. The system includes a drum-type slurry filter-heater, a chain curtain with a developed surface of heat exchange and a metal cellular heat-exchanger installed in succession. The system worked out ensures stable operation of 4.5 x 170 m and 5 x 185 m kilns with an exit gases temperature of 160-180 °C and 210-230 °C, respectively. That saves 2-2.5 % fuel. In addition, the filter-heater decreases total dust losses from the kiln by 10-15 %.

There are used garland chain systems, curtain systems, in which only one end of the individual length is fastened to the shell, and mixed-type chain systems at the cement plants of the U.S.S.R. Though, compared with the curtain systems, the garland chain systems have higher coefficient of heat emission from a unit of chain surface to material ( $\alpha_p$ ), the possibility of chain surface ( $F_{ch}$ ) increase is limited by construction factors (maximum admissible superficial coefficient of suspension density  $K_p$  is 3.8 m<sup>2</sup>/m<sup>2</sup>). As a result, high values of  $F_{ch}$ , of volume coefficient of suspension density  $K_v$  and of steam removal  $p_B$  can not be achieved. These three parameters are very important for intensification of kiln operation, especially when  $W_{sl}$  is high (more than 42 %). As for the free-ended chain systems, the possibility of  $K_p$  and  $K_v$  increase is little limited by construction factors. As a result, it is possible to create a large chain surface in kilns, to

obtain high values of  $\alpha_v$  (the volume coefficient of heat transfer in the chain zone) and  $p_B$ , to lower easily the exit gases temperature to 160-200 °C (depending on type-and-size of a kiln), to decrease the specific consumption of fuel for burning.

The free-ended chain systems are considerably simpler in operation, erection and repair.

In our opinion, the optimum operation conditions of slurry drying in the chain zone are those, under which material leaves the zone with 2-5 % moisture content and a temperature of not higher than 120-130 °C /1/. A material moisture content after the chains of 8 %, and according to the offer of some researchers that of 15-20 %, is not desirable, as already at the material moisture content of 8 % the relative quantity of water not evaporated from the slurry will be 13 % and at that of 15-20 % it will be 27-38 %, respectively. Under such operation conditions the degree of material preparation is artificially limited, the evaporating capacity of the chain curtain is not fully used, while the process of material drying in the hollow kiln is 3-5 times less intensive.

The metal cellular heat-exchanger with reliability protects the discharge part of the chain curtain from burning out and prolongs its service life and at the same time successfully ensures fuller utilization of the kiln inner volume. As the investigations have shown, in the 4.5 x 170 m kilns with a heat-exchanger length of 11.5 m the passing along material heats by 350-400 °C; whereas in the hollow kiln the temperature increases only by 70-100 °C.

Increase of the kiln rotation speed influences both geometry of the material layer and the very process of thermal treatment. As a result of theoretic analysis the heat rate of the material layer in the kiln has been determined:

$$m = 3s \left( \frac{4\mu^2}{B_1 - C_1 n} + \frac{4\mu^2}{B_2 - C_2 n} + \frac{4\mu^2}{L^2} \right) \quad (I)$$

where:  $B_1, B_2, C_1, C_2$  = coefficients,  
 $n$  = rotation speed, s<sup>-1</sup>,

$a$  = coefficient of temperature conductivity, m<sup>2</sup>/s,

$L$  = material layer length, m

$\mu$  = radicals of the following characteristic equation:

$$\operatorname{ctg} \mu = \frac{L}{B_1} \cdot \mu$$

$B_1$  = Bio criterion.

The equation shows that the heat rate of a body increases with  $n$ .

The heat-engineering calculations of  $n$  influence on heat transfer and the material

layer thickness in 2.4 to 5 m dia. kilns over the material temperatures range of 115-1300°C have shown that the charge ratio ( $\rho$ ) decreases and the heat quantity transferred to the material ( $q_m$ ) increases with increase of  $n$ . In this case, the minimum increase of  $q_m$  is 8-10 % when  $n$  increases by 1.5-2 times.

At present, increase of  $n$  of various type-and-size kilns with a length from 100 to 185 m is widely spread in the U.S.S.R. That ensures 1-3.5 tph output increase and simultaneous decrease of specific fuel consumption by 2-5 kg per 1 t of clinker.

Improvement of fuel combustion conditions is a practicable way of fuel saving and improvement of kiln operation conditions.

During last 10-15 years in the fuel balance of the U.S.S.R. cement industry the use of fuel oil increased. In this connection, a set of measures has been developed which allows considerable increase of efficiency of fuel preparation and fuel combustion in furnaces:

- development and commissioning of efficient burner units - two-channel fuel-oil burners - in various type-and-size kilns; these burners ensure fine dispersion of fuel oil and its combustion with small  $\alpha = 1.05-1.1$  without chemical underburning. They have a wide control range of flame length and volume;
- rise of temperature of fuel oil heating before combustion to 120-140°C and use of the system for control and stabilization of fuel oil viscosity at a set level (2-3° relative viscosity);
- development of a method for combustion of water-containing fuel oil by making fine-dispersed water-fuel-oil emulsions; the use of these emulsions in rotary kilns gives not only a uniform water distribution in fuel oil, but also almost instantaneous evaporation of dispersed water drops ("microbursts") which considerably intensifies fuel oil dispersion;
- supply of hot aspiring air from coolers into burners as primary air;
- installation of continuously operating fuel oil flow-meters and erection of special stands for their calibration.

Execution of above-mentioned measures will allow saving of 4-5 kg of fuel oil per a ton of clinker.

The "YGC" type gas burner [3] developed by the Institute "Yuzhgiprotsement" ensures efficient combustion of gaseous fuel. This burner forms the minimum flame divergence angle due to absence of gas flow swirls and due to the new curvilinear shape of the nozzle and the core. The carried out investigations of flame length influence on clinker burning with a constant consumption of natural gas in various type-and-size kilns confirm the possibility of localization of material inadequate preparation by changing the length and position of the dif-

fusion flame and production zones in the rotary kiln without output decrease and fuel consumption increase.

Flame length control with a minimum divergence angle does not cause coating deterioration what promotes lining service life increase and heat losses decrease from the kiln shell into surroundings. Double air passage and increased bed thickness of clinker in the grate cooler ensure heat losses decrease during clinker cooling.

Experimental investigations of clinker cooling in a bed resulted in the equation of heat exchange intensity which is characterized by heat transfer coefficient value ( $\alpha_F$ ) dependent on cooling air velocity ( $w$ ), its temperature ( $T$ ), and equivalent diameter of clinker particles ( $d$ ):

$$\alpha_F = 4240 \frac{w^{1.29}}{d^{1.59} T^{0.94}} \cdot \frac{\lambda \cdot \gamma^{0.59}}{c^{0.54}} \quad (2)$$

where:

$\lambda$  = heat conduction,  
 $\gamma$  = kinematic viscosity,  
 $c$  = heat capacity of air.

Rational cooling of clinker in a bed of 0.5-0.6 m thickness in "Volga-CA" type grate coolers is found to reduce heat losses by 20-30 kcal/kg of clinker.

Complex utilization of kilns secondary heat lost by the kiln shell (10-25 % of total heat consumption), in waste gases (20-25%), in aspiring air from coolers and in clinker (5-10%) can result in substantial decrease of total heat consumption for clinker burning. Installations for recovery of heat radiated from rotary kilns shells operate in the U.S.S.R. providing for annual 15 000-20 000 Gcal heat removal by each installation depending on kiln type-and-size. The characteristic feature of such installations is the possibility for coating formation control and thus for increase of lining durability and of calendar time of kiln operation as a whole.

Above-mentioned methods of fuel saving are recommended for wide use in the future.

# Economie d'énergie lors de la cuisson du ciment par utilisation intégrale de déchets et de combustibles de moindre qualité

Helmuth RECHMEIER, Diplom-Chemiker,  
Portlandzementwerk Dotternhausen, Rudolf Rohrbach KG, RFA.

## Resume:

Les procédés modernes de cuisson du ciment permettent d'atteindre des rendements thermiques de l'ordre de 50 %.

Des rendements thermiques plus élevés nécessitent une amélioration considérable du rendement du radiateur. De telles améliorations ne sont pas projetées à l'heure actuelle.

Trois alternatives s'offrent pour une production plus économique du ciment, particulièrement au niveau de ce facteur de coûts qu'est le combustible:

1. L'utilisation de combustibles pauvres permettant un déroulement très rapide de la combustion dans la mesure où l'on respecte les particularités touchant au mélange du combustible avec les gaz d'échappement du four rotatif, à l'échauffement du combustible et au processus de combustion un peu modifié. Ici, l'impulsion de la farine chargée (farine brute, comme combustible) joue un rôle particulier.
2. L'utilisation de combustibles plus riches, tels que les pneus de véhicules, les déchets plastiques, les solvants, etc.. Afin de pouvoir les utiliser et les exploiter de façon optimale, ces combustibles doivent être amenés à une forme aptes à la combustion, ce qui peut avoir lieu par traitement dans la couche fluidisée. L'utilisation de telles matières permet de lier dans le clinker des substances nocives qui, autrement, sont difficiles à éliminer.
3. La production d'additifs hydrauliques au ciment par réaction à l'état solide en dessous de la température de frittage et sans grande consommation de chaleur. Les procédés ayant recours à des matières comportant déjà leur combustible, comme c'est le cas du schiste bitumineux, du calcaire bitumineux ou des schistes de lavage, sont particulièrement avantageux ici.

Les conditions définies de température et de temps de séjour nécessaires à la production de telles matières peuvent être établies de façon optimale dans une couche fluidisée, laquelle permet également l'utilisation de combustibles à très faible capacité calorifique.

Dans ce procédé, la chaleur excédentaire provenant du lit fluidisé peut servir à la production d'énergie électrique, ce qui favorise l'économie, selon le prix de l'électricité devant être achetée et le pouvoir calorifique des combustibles à utiliser.

Ces trois alternatives sont actuellement utilisées à l'échelle industrielle, ou du moins partiellement, dans les usines de ciment portland, Rudolf Rohrbach KG de Dotternhausen.

La fabrication du clinker est un processus nécessitant beaucoup d'énergie. Les procédés les plus économiques requièrent des quantités de chaleur allant de 3140 à 3350 J par kg de clinker, ce qui correspond approximativement à 75 ou 80 kg de fuel-oil par tonne de clinker.

Le rendement thermique des fours à dispositif de préchauffage par mise en suspension dans les gaz se situe aux environs de 50 %. La chaleur de récupération est le rayonnement des différentes parties du four, la chaleur perdue du clinker et le gaz perdu à température relativement faible (350 à 360°C) provenant de l'air d'échappement du radiateur et du four. Le rendement calorifique pourrait être amélioré par un système de radiateur exploitant mieux la chaleur dégagée par le clinker puisque les gaz d'échappement du four sont déjà utilisés en grande partie pour le séchage du matériau brut.

Jusqu'à présent, tous les efforts entrepris pour améliorer le rendement des systèmes de radiateur sont restés vains. Il est vraisemblable qu'aucune amélioration sensible ne puisse être actuellement apportée au rendement thermique du système de cuisson du clinker.

Une meilleure rentabilité du procédé de cuisson peut être obtenue par utilisation de combustibles bon marché, tels que les combustibles naturels comme le schiste bitumineux, le calcaire bitumineux et autres ainsi que de combustibles de récupération de haute qualité. Cependant, le pouvoir calorifique d'un combustible n'est pas le seul facteur déterminant pour le processus, encore faut-il que ce combustible permette d'atteindre la température de flammes nécessaire.

Afin de réduire suffisamment le temps de formation du clinker lors de sa cuisson, il fut que la température de flamme calculée des brûleurs doit dépasser 2000°C.

Une température inférieure à cette valeur peut entraîner des coefficients de transmission thermique si faibles qu'il devienne impossible de cuire du clinker dans le four considéré.

Pour cette raison, les combustibles à très faible pouvoir calorifique ne peuvent donc pas être utilisés dans la zone de frittage car leur faible valeur calorifique ne permettrait pas d'obtenir la température de flamme indispensable.

Afin de tirer malgré tout parti de ces combustibles, ils doivent être utilisés là où une forte énergie thermique est certes exigée mais où la température de flamme requise n'est pas très élevée. Dans la cuisson du clinker, il s'agit ici de la zone de désacidification. La température nécessaire ici est relativement faible, à savoir de l'ordre de 900°C au maximum.

Il est donc judicieux d'introduire les combustibles de moindre qualité dans l'échangeur de chaleur et de les y brûler. La zone la plus appropriée ici est celle avec la température la plus élevée, à savoir celle qui va de l'admission du four tubulaire rotatif au premier cyclone d'échangeur de chaleur. Dans cette zone, le combustible doit être chauffé, mélangé à l'oxygène contenu dans le gaz résiduel du four tubulaire rotatif (env. 10 %/vol.) et brûlé.

Les combustibles médiocres ne peuvent brûler dans la zone de réaction pendant leur temps de séjour relativement court (env. 2 s) et libérer leur énergie que s'ils sont intensément mélangés aux gaz, chauffés suffisamment vite et s'ils peuvent entrer rapidement en réaction avec l'oxygène disponible.

Au cas où l'une de ces conditions ne serait pas remplie, l'énergie potentielle serait dilapidée dans l'échangeur de chaleur, ce qui conduirait en fin de compte à une consommation de chaleur exagérée.

Afin d'obtenir un mélange homogène du combustible d'alimentation avec les gaz chauds et visqueux, impulsion nécessaire au mélange doit être procurée au combustible lors de son chargement.

L'impulsion nécessaire ne pouvant pas être transmise au combustible comme dans une flamme au moyen du gaz porteur, il doit être enfourné à une vitesse aussi grande que possible générée par une hauteur de chute importante avant son arrivée dans la zone de combustion et par concentration en un seul chargement.

L'impulsion contenue dans la farine brute de l'étage cyclone suivant à l'entrée dans le réacteur peut être exploitée pour le mélange par une disposition adéquate des deux zones d'admission. La combustion du combustible pauvre ne doit avoir lieu que là où l'énergie calorifique peut être absorbée par désacidification de  $\text{CaCO}_3$ .

Abstraction faite des processus de combustion, la vitesse d'échauffement est étroitement liée au transfert de chaleur entre la gaz et les particules. La plus grande partie du transfert de chaleur consistant, pour les températures en question, en une chaleur rayonnante, la vitesse d'échauffement dépend de la différence de température existant entre le gaz et les corps solides s'élevant environ à  $(T)^4$  et peut être calculée selon la formule suivante:

$$Q = C \cdot F \cdot \left[ \left( \frac{T_1}{100} \right)^4 - \left( \frac{T_2}{100} \right)^4 \right] \text{ J/h}$$

L'échauffement des particules est donc extrêmement rapide (une fraction de seconde).

La quantité de chaleur nécessaire à l'échauffement est tout d'abord prélevée sur la capacité calorifique des gaz d'échappement du four.

Si l'on admet que les gaz d'échappement quittent le four à une température de  $1100^\circ \text{C}$ , leur capacité calorifique est donc de  $335 \text{ J/Nm}^3$  environ entre  $1100$  et  $960^\circ \text{C}$ , ce qui équivaut à environ  $307 \text{ J}$  par kg de clinker. La proportion de poussières contenue dans les gaz d'échappement du four n'est pas prise en considération dans ce calcul. Environ  $200 \text{ J}$  sont nécessaires à l'échauffement de  $200 \text{ g}$  de combustible pauvre de  $0$  à  $900^\circ$ . La capacité calorifique des gaz d'échappement du four suffit donc amplement pour amener le combustible à la température de désacidification sans que cela nécessite une combustion.

Dans les zones de réaction, les processus de combustion tels qu'ils ont lieu entre le four tubulaire rotatif et le premier cyclone sont vraisemblablement quelque peu différents et un peu plus compliqués que ceux normalement observés dans les fours tubulaires rotatifs. En général, la combustion du carbone se déroule de la façon suivante:

une couche mince appelée couche limite hydrodynamique est toujours en repos à la surface du grain du combustible, même lorsque le grain est soumis à des turbulences dans de l'air.

La vitesse de diffusion des gaz participant à la combustion détermine la vitesse de combustion. Ici, la réaction primaire à la surface du grain est la réaction du  $\text{CO}_2$  avec du carbone par rapport à  $\text{CO}$ , alors que la combustion proprement dite, à savoir la réaction de  $\text{CO}$  avec  $\text{O}_2$  a lieu dans la couche limite hydrodynamique.

Sans s'étendre sur les vitesses des différentes réaction, il est possible d'admettre que la vitesse de combustion se déroule, à température constante de la surface du grain, de façon proportionnelle à la concentration de  $\text{CO}_2$  à la surface du grain. A son tour, cette concentration est proportionnelle à la vitesse de diffusion de l'oxygène, ce qui fait que la vitesse diminue donc en fonction de la diminution de la concentration d'oxygène.

Partant de ces considérations, la combustion d'un combustible pauvre dans le réchauffeur devrait ralentir dès que la teneur en oxygène diminue.

Pourtant, comme nous l'avons vu, la vitesse de combustion est parallèle à la pression partielle du  $\text{CO}_2$  à la surface du combustible. Il existe donc un autre processus pouvant devenir primordial pour la vitesse de combustion, à savoir la pression partielle du  $\text{CO}_2$  dans le grain désacidifié, lequel est en même temps support de combustible. A  $900^\circ \text{C}$  environ, cette pression partielle est de l'ordre de  $760 \text{ mm Hg}$ . Pour comparaison: lors de la combustion du carbone, la pression partielle du  $\text{CO}_2$  régnant dans le compartiment des gaz en présence d'air comme gaz combustible est de l'ordre de  $160 \text{ mm Hg}$ , ce qui équivaut à  $21 \%$  seulement de la pression ci-dessus.

Ceci signifie que, lorsque la température de désacidification est atteinte et maintenue, la réaction primaire doit se dérouler à une vitesse 5 fois plus grande que lors d'une combustion normale sans  $\text{CO}_2$ .

La pression partielle du  $\text{CO}_2$  sur le grain étant fonction de la température du grain, le temps d'échauffement est, en fin de compte, décisif pour la vitesse de combustion. La pression partielle intégrale du  $\text{CO}_2$  est pratiquement disponible dans le compartiment à gaz immédiatement après le chargement des composants et la conversion avec le carbone peut avoir lieu à une vitesse très élevée.

Les considérations ci-dessus sont valables pour un combustible pauvre dont les cendres comportent du  $\text{CaCO}_3$  en proportion importante.

Si cela n'est pas le cas, la combustion ne sera, certes, pas aussi rapide qu'en présence d'une grande proportion de  $\text{CaCO}_3$ ; pourtant, la proportion de  $\text{CO}_2$  contenue dans les gaz d'échappement du four et provenant de la désacidification de la farine brute est si élevée qu'une pression de diffusion considérable est générée à la surface du grain, ce qui fait que la conversion se déroule plus vite que ne le permettrait la basse pression d'oxygène partielle.

La seconde alternative s'offrant pour économiser une énergie chère et précieuse réside dans l'exploitation d'une énergie de haute qualité tirée de déchets tels que: huile usée, pneus de véhicules, déchets de papier, bois et plastiques, vernis, peintures, solvants, restes de cuir, écorces d'arbres éventuellement, bagasse résultant du traitement de la canne à sucre.

Alors que les déchets liquides, pour autant qu'ils puissent être amenés à une forme atomisable, comme l'huile lourde, peuvent être diffusés et brûlés avec elle, les déchets pâteux et solides doivent être amenés à une forme combustible. Certains matériaux comme les pneus se désagrègent très vite sous l'effet de la chaleur. Ils peuvent alors être ensuite grossièrement broyés et brûlés dans le réchauffeur; les armatures en acier des pneus peuvent être également brûlées dans le four tubulaire rotatif et se retrouvent ensuite dans le clinker sous forme de  $Fe_2O_3$ .

Si non, elles doivent être thermiquement décomposées dans des installations à couche fluidisée puis enfournées.

Une telle installation à couche fluidisée permet une conversion rapide de la plupart des déchets combustibles en des combustibles aptes à la combustion. Il est important de noter ici que, suite aux températures de combustion élevées régnant dans le four tubulaire rotatif, l'environnement n'est pas soumis à des nuisances olfactives. La gazéification se déroule selon la réaction de Boudouard ou encore du gaz à l'eau. Par fonctionnement en dessous du point de Curie du fer, des particules de fer peuvent être magnétiquement retirées de la couche.

Les composants anorganiques, principalement le  $ZnO$  et le soufre, sont entièrement liés au clinker. Le soufre sous forme d'alcali ou de sulfate alcalino-terreux et le  $ZnO$  sous une forme n'influençant pas négativement la résistance du ciment.

Dans l'échangeur de chaleur, seule la moitié environ du combustible nécessaire peut, au maximum, être utilisée.

La troisième possibilité d'économiser de l'énergie consiste dans le production d'adjuvants hydrauliques au ciment par traitement thermique de marnes ou d'argiles dans la couche fluidisée selon la température et le temps de séjour. En présence de composants marneux, des aluminates et des silicates calcaires à activité très élevée peuvent être obtenus ici à l'état solide.

Certaines argiles peuvent également être activées par de tels procédés. De tels procédés sont surtout intéressants à partir du moment où le combustible nécessaire est déjà contenu dans les composants comme le schiste bitumineux par exemple. La chaleur perdue résultant de tels procédés peut alors être utilisée pour la production de courant électrique. Il est pratiquement possible de prétendre que les coûts d'investissements nécessaires à la fabrication d'une tonne d'additifs hydrauliques activés, production de courant y comprise, ne sont pas plus élevés que pour la production d'une tonne de clinker.

L'unité habituelle est le KJ.

# Saving energy during cement burning by complete utilization of waste material and low-grade fuels

Helmuth RECHMEIR, Diplom-Chemiker,  
Portlandzementwerk Dotternhausen, Rudolf Rohrbach KG, RFA.

## Summary:

Today, with a modern process of cement burning, it is possible to reach a thermal efficiency of about 50 %. Higher thermal efficiencies require essential improvements of the cooler efficiency. Such improvements are not yet available.

For more economical production of cement there are three possibilities, concerning the costs of combustibles:

1. The use of poor graded combustibles is possible, if the special conditions concerning the mixing with kiln exhaust gases, the heating of the combustibles and the different conditions of combustion are taken into consideration. The combustion takes place in a short time. It is important to pay attention to the impulse of the feeded meal.
2. Relatively high graded waste combustibles, tires, plastics, liquid solvents can be used. They must be converted into a suitable state for combustion. This is made by upgrading in a fluidized bed. During combustion of such materials there may arise air polluting problems which are difficult to overcome. In cement production, many air polluting substances can be combined to the cement clinker in a harmless way.
3. The production of artificial pozzolanes, by reaction in solid state, below the sintering temperature with a low heat requirement. Especial advantage is gained with processes where substances are used, containing fuel, like oil shale, bituminous limestone or washery slates.

The conditions which are needed for the production of such substances, referring to temperature and treating time can be favorably maintained in a fluidized bed system. The use of very low grade fuels is possible.

In this process it is possible to use the surplus heat for production of electric energy. According to the price of the electric energy, which is to buy, and the calorific value of the used combustibles it is possible to cut down expenses.

At the Portlandzementwerk Dotternhausen, Rudolf Rohrbach KG, these possibilities are technically used in full scale or will be also used in full scale in the near future.

Manufacturing cement clinker is a process that entails a great deal of energy. In the case of those processes which are the most economical with respect to energy consumption, amounts of heat energy of between 3,140 and 3,350 J/kg of clinker are necessary. This corresponds to approximately 75 - 80 kg of heavy fuel oil per ton of clinker.

The thermal efficiency of furnaces incorporating suspension-type heat exchangers is approximately 50 %. The heat loss consists of radiation from the various furnace sections, heat loss through the clinker and exhaust gas at a relatively low temperature (350° to 360° C) from the cooler - and furnace exhaust.

Improving the thermal efficiency could be achieved by using a cooling system making better use of the waste heat from the clinker as the furnace exhaust gases are, for the most part, already used for drying the raw materials.

Up until the present, all attempts to develop a cooler system operating at an improved level of thermal efficiency, have failed. Proceeding from this, we may assume that no essential improvements leading to increased thermal efficiency of the system when burning cement clinker can be expected at the present time.

An improvement in the burning process efficiency may be achieved by using more price-worthy fuels. Fuels in this class include low-grade natural fuels such as oil shales, bituminous limestone, and the like, as well as high-grade waste fuels.

However, it is not only the calorific value of the fuel but also the flame temperature achievable when using the fuel which is the crucial factor in the process.

In the case of cement clinker burning especially, a computed flame temperature of over 2,000° C in the burner flame must be achieved in order to be able to carry out the process of clinker formation in a sufficiently short time.

If the temperature is lower than this, the heat transfer coefficients may be so small that it is impossible to burn clinker in the furnace in question. For this reason, fuels with a very low calorific value cannot be used in the sintering zone. This is because an insufficiently high flame temperature is reached owing to the low calorific value.

In order to be able to use such fuels despite this fact, they must be used where there is, admittedly, a high thermal requirement but, however, where there is no need for a high flame temperature. In the case of clinker burning, this is the decarbonating zone.

In this zone a relatively low temperature is required, i.e. a maximum of 900° C.

This therefore provides an opportunity to supply the heat exchanger with low-grade fuels and, thereby, combust them. For this purpose, the highest temperature zone, i.e. the section extending between the inlet to the rotary kiln and the first heat exchanger cyclone is the most suitable section.

It is in this section that the fuel supplied has to be heated and both mixed and combusted with the oxygen present in the residual gas from the rotary kiln (approximately 10 % of the volume).

Low-grade fuels are only able to burn and make available their energy during the relatively short dwell period in the reaction zone (approximately 2 sec), if they are intensively mixed with the gases and heated sufficiently rapidly and also only if they are able to react rapidly with the available oxygen.

If any one of these conditions is not satisfied, the available energy is dragged through the heat exchanger, thereby leading to increased heat consumption in the long run.

To bring about thorough mixing of the fuel to be supplied and of the hot viscous gases, the energy required for mixing must be supplied to the fuel in the form of an impulse during charging.

In order to do this, the fuel must be supplied from as high a vertical position as possible before entering the combustion section and must be supplied at as high a speed as possible by concentrating the fuel in one charge since the fuel, unlike a flame, is unable to receive momentum by means of the carrier gas.

The impulse possessed by the raw meal from the next higher cyclone stage when entering the heat exchanger can be made available for the mixing process if a correct arrangement of both input locations is provided. The low-grade fuels must not be combusted until the heat energy can be absorbed by the decarbonating process of  $\text{CaCO}_3$ .

If we temporarily disregard the processes of combustion, the rate of heating is a matter of heat transfer between gas and particles. Since radiant heat constitutes the major proportion of heat transfer in the case of the temperatures in question, using the formula:

$$Q = C \cdot F \cdot \left[ \left( \frac{T_1}{100} \right)^4 - \left( \frac{T_2}{100} \right)^4 \right] \text{ J/h}$$

the rate of heating is dependent upon the temperature difference between gas and solids at approximately  $(\Delta T)^4$ .

For this reason, the particles are heated extremely rapidly (within a fraction of a second).

The quantity of heat required for heating is, firstly, absorbed from the heat content of the kiln exhaust gases.

Assuming that the kiln exhaust gases leave the kiln at a temperature of  $1.100^{\circ}\text{C}$ , their heat content between  $1.100^{\circ}\text{C}$  and  $960^{\circ}\text{C}$  will be approximately  $335\text{ J/Nm}^3$ , i.e. approximately  $307\text{ J/kg}$  of clinker. This does not take into account the dust content of the kiln exhaust gases.

In order to heat up  $200\text{ g}$  of low-grade fuel from  $0^{\circ}$  to  $900^{\circ}$ , approximately  $200\text{ J}$  are required. The heat content of the kiln exhaust gases is, therefore, more than sufficient to heat the fuel to decarbonating temperature without combustion being required.

The combustion processes in reaction sections such as those between the rotary kiln and the first cyclone are probably somewhat different and somewhat more complicated than can normally be observed in rotary kilns. Carbon combustion normally proceeds in the following manner:

Even if the particles are in turbulent motion in the air, there will be a thin quiescent layer on the surface of the fuel particles, the so-called hydrodynamic interface. The diffusion rate of the gases involved in combustion determines the rate of combustion.

In this process, the primary reaction on the surface of the particles is the reaction of  $\text{CO}_2$  with carbon to form  $\text{CO}$ , whilst "actual" combustion, i.e. the reaction of  $\text{CO}$  with  $\text{O}_2$  takes place in the hydrodynamic interface.

Without examining the rates at which the individual reactions take place, we may assume that at constant temperature of the surface of the particles, the combustion rate will proceed proportionally to the concentration of  $\text{CO}_2$  on the particle surface, which in turn, will be proportional to the oxygen diffusion rate. This therefore means that with a decrease in oxygen concentration, the rate of combustion will also decrease.

Using this approach, the combustion rate of low-grade fuels in the pre-heater would have to decrease with decreasing oxygen content.

However, as we have seen, the combustion rate runs parallel to the  $\text{CO}_2$  partial pressure at the fuel surface.

So there is another process which is decisive, and indeed crucial, to the rate of combustion, i.e. the  $\text{CO}_2$  partial pressure of the decarbonating particles, which are, at the same time, the fuel carrier. At a temperature of approximately  $900^{\circ}\text{C}$ , this partial pressure is approximately  $760\text{ mm Hg}$ . By way of comparison: during carbon combustion, the  $\text{CO}_2$  partial pressure in the gas chamber using air as the fuel gas is approximately  $160\text{ mm Hg}$ , i.e. only approximately  $21\%$  of the above pressure.

This means that, if the decarbonating is reached and maintained, the primary reaction must proceed at five times the rate for normal combustion without carbonate  $\text{CO}_2$ .

As the  $\text{CO}_2$  partial pressure in the particles is a function of the particle temperature, in the final analysis, the heating rate will be the decisive factor determining the combustion rate. The complete  $\text{CO}_2$  partial pressure is available practically straight away after the components have been supplied to the gas chamber and reaction with the carbon may, for this reason, proceed at a very high rate.

The above considerations apply to low-grade fuels whose ashes contain considerable proportions of  $\text{CaCO}_3$ .

In other cases, combustion will, admittedly, not proceed at quite as rapid a rate as in the case of a high  $\text{CaCO}_3$  content, but, however, the  $\text{CO}_2$  content of the kiln exhaust gases is so high, owing to the decarbonization of raw meal that a considerable diffusion pressure occurs at the particle surface. This therefore means that the reaction proceeds more rapidly than would be expected in view of the low oxygen partial pressure.

The second possible method of saving expensive, high-grade energy is by using high-grade waste energy. The relevant energy sources in question for this purpose include:

Oil recovered from waste oils and fats, car tires, plastic-, wood- and paper waste, lacquers and varnishes, solvents, waste leather and even, possibly, tree bark and residue bagasse from sugar cane processing.

Whilst the liquid waste products, providing they are able to be converted into a form useable in an atomizer, like fuel oil, are able to be atomized together with the fuel oil and combusted, the pasty and solid waste must be converted to a combustible form.

Amongst them are materials, such as tires, which very rapidly disintegrate under the influence of heat. They may accordingly either be combusted in coarsely comminuted form in the preheater, whereby the steel linings of the tires are combusted along with the rest of the tire in the rotary kiln, appearing again as  $\text{Fe}_2\text{O}_3$  in the clinker or, they must be thermally decomposed e.g. using fluidized bed systems and then fed to the kiln.

In fluidized bed plants, the majority of combustible waste materials are able to be converted in rapidly combustible fuels. One important point to bear in mind, is that owing to the high combustion temperatures in rotary kilns no odorous substances can reach the atmosphere.

Gasification proceeds following the Boudouard or watergas reaction process. By allowing the iron to drop to its Curie point, iron sections may be removed magnetically from the charge.

The inorganic constituents, chiefly  $\text{ZnO}$  and sulphur, are completely bonded into the clinker. Sulphur as alkaline or alkaline earth sulphates and  $\text{ZnO}$  in a form which is not detrimental to the development of cement strength.

No more than approximately half of the necessary fuel is able to be used in the heat exchanger.

The third way of saving energy is by producing hydraulic material to be admixed to the cement by heat treatment of marls or clays in the fluidized bed, the heat treatment process being matched to the temperature and dwell. Using this process, calcium aluminates and calcium silicates of very high activity are achieved in the presence of marly constituents by reaction in a solid state.

Certain clays may also be activated using this process. Such processes are particularly attractive if the required fuel is already contained in the components, such as, e.g. oil shales amongst others. This means that the heat given off by such processes may be used to produce electrical power.

We may start from the fact that the investment costs for the manufacture of one ton of hydraulically activated aggregates including power generation are no higher than the costs of producing one ton of cement clinker.

---

NB. The dimensions of energy requirements are given in J. Correctly dimension must be in KJ .

# Utilization of combustible wastes in cement manufacture

## *Utilisation des déchets combustibles dans la fabrication du ciment*

T.M. LOWES, B.Sc., PhD, Deputy Manager, Engineering R and D, B.C.I.,  
B. TETTMAR, B.Sc., PhD, Manager, Engineering R and D, B.C.I., Grande-Bretagne.

RESUME : Des grandes quantités de déchets combustibles tels que des ordures municipales se trouvent fréquemment disponibles tout près des cimenteries. L'utilisation de ces déchets dans la fabrication de ciment permet d'économiser des combustibles primaires aussi bien que fournir une méthode peu coûteuse d'élimination qui n'augmente pas la pollution atmosphérique. Les expériences de B.C.I. de l'utilisation directe de déchets combustibles sont examinées et on fait allusion particulière aux ordures combustibles municipales et aux effets de déchets matériau sur l'ensemble des opérations d'une usine. On recommande des limites d'utilisation pratiques en ce qui concerne la substitution de déchets combustibles qu combustible primaire et on propose un schème pour la production totale de ciment de l'énergie des déchets combustibles.

SUMMARY : Large quantities of combustible waste materials such as domestic refuse are frequently available near a cement works. The utilisation of these wastes in cement manufacture can save prime fuel as well as providing a relatively cheap method of disposal, which does not increase the pollutant emission. B.C.I.'s experience in the direct use of waste fuels, is reviewed with special reference to municipal refuse and the effect of a waste fuel on overall works operation. Practical limitations to the prime fuel replacement by the direct use of waste fuels are recommended. A scheme to produce cement totally from the energy from waste fuels is suggested.

## 1.0 INTRODUCTION

In recent years the rising costs and decreasing resources of prime fossil fuels, have caused National Government and Private Industry to re-examine their energy usage and look for alternative sources of energy. Governments have had to become involved with long term strategic planning of energy usage, in order to develop energy policies which would take account of the finite reserves of the various prime fuels. Meanwhile, industry is directing its efforts to a shorter time scale; to reduce energy consumption so that production costs can be reduced or maintained at a reasonable level when other costs are rising.

Cement manufacture is an energy intensive process; the cost of energy is the largest single item in running a cement works. In 1978 the fuel and electrical costs associated with the production of OPC by Blue Circle Cement (BCC), was almost half the production costs. While many industries are now looking actively at the reduction of their energy consumption, the fact that it represents such a high proportion of the costs of cement production, has encouraged cement manufacturers to pursue actively this area long before the energy crisis of the mid-70's. Figure 1 shows the reduction in fuel consumption in BCC since 1965. This reduction has generally been achieved via good housekeeping (e.g. low back-end oxygen, reduction of inleaking air) and the application of improved technology (e.g. reduction of slurry moisture and kiln chain design). The above principles have generally been applied fully to BCC and therefore with the exception of the conversion of wet to semi-wet or dry process, the only significant changes in energy consumption in the manufacture of OPC that are left to BCC are generally associated with the implementation of innovative research.

Figure 1 - Reduction in fuel usage by B.C.C. in the making of OPC.

Unfortunately, the cost of replacing a wet process with a semi-wet or dry process is high. An even higher rate of increase in relative energy costs than has occurred in recent years is required to make it a reasonable commercial investment.

Therefore, the cost effective reduction of energy consumption via innovative research is required. Current research work is aimed at reducing fuel consumption by up to approximately 75 kcal/kg via an optimum firing system design for low primary air operation, and the electrical consumption by up to 30 kWh/ton via flame and mill optimisation and external electricity generation from waste heat. These reductions are representative of most of the feasible improvements in energy consumption for the dry process. This statement also applies to the wet process once the slurry moisture has been reduced to its lowest practical value. However, even with reductions in energy consumption via innovative research, associated investment costs must be considered as the work progresses, as these often make the energy saving uneconomic from a commercial viewpoint.

An alternative method of reducing the energy costs associated with cement manufacture is to use a less expensive fuel. BCC already produce all of their OPC using a medium ash pulverised coal as a fuel, therefore, savings arising from the cost of the fuel can only come from the use of higher ash coals or low grade fuels. Techniques are being developed for firing higher ash coals (e.g. 35-45% ash) while maintaining product quality. These techniques are also being extended to low grade fuels, into which category can be included a large number of combustible wastes. This paper is based on BCI's experience and indicates how waste fuels could be used currently and in the future, to reduce energy costs in cement manufacture. Specific reference is made to Blue Circle Industries (BCI) use of municipal refuse as an auxiliary fuel.

## 2.0 WASTE MATERIALS AS ENERGY SOURCES

As a general rule the use of waste as a fuel cannot compete commercially with dumping. However, as the availability of viable dumping areas decreases and alternative methods of disposal are considered, the use of waste as a fuel becomes a possibility. Generally, there is between 5 and 8% (1) of a Nation's annual energy consumption available in the form of combustible waste. As this amount of energy is significant in terms of the cement industry, and the process of cement manufacture is one of the few industrial processes that could utilise the energy in combustible wastes in its different forms, consideration of this area of energy cost reduction can be fruitful to the cement manufacturer.

The energy in wastes can, in theory, be utilised in a process in 4 ways, i.e.:-

- Directly, via pretreatment and injecting in a similar manner to a prime fuel.
- Semi-directly, via a gasification/pyrolysis and then using as a prime fuel.

- the large and high temperature combustion chamber is capable of completely destroying odoriferous and toxic organic compounds.
- the raw materials act as a natural calcium carbonate scrubbing system to remove acid gases.
- the kiln is already fitted with an efficient waste gas de-dusting device.

Despite all these advantages it is not possible to supply shovel in waste and forget about it. The waste must be subjected to similar types of storage, blending, comminution, feeding and firing operations as a prime fuel. It is important that the pretreatment plant supplies the firing plant with an "adequately" prepared waste fuel, which is then supplied to the kiln at a "uniform" calorific value and chemical composition, where it has no "significant" detrimental effect on production or product quality. The exact definitions of and difficulties in achieving "adequately", "uniform" and "significant" depend on the fuel and the cement making process. It is important that product quality and production capacity is maintained, dangers must be avoided, costs and general inconveniences assessed to make sure that they do not outweigh the benefits derived from payments for taking the waste and from prime fuel saving. Generally, a waste without substantial beneficiation has insufficient combustion and heat transfer intensity, to be able to supply the energy requirements of a process via its direct use. Therefore, as these beneficiation processes are not yet viable commercially, wastes are normally used as auxiliary fuels.

### 3.1 THERMODYNAMIC RELATIONSHIPS

Simulation programmes have been developed, based on plant trials, which predict changes in output and the fuel consumption together with "effective" calorific value, when wastes are used as auxiliary fuels in wet, dry and semi-dry processes.

### 3.2 PRODUCT QUALITY

While the waste material must be adequately prepared to give a similar combustion pattern to the prime fuel being used and then injected into

the cement kiln with a constant thermal input in order to maximise its thermal value; further constraints are introduced by the requirement to maintain product quality. It is important that a constant thermal input and combustion stoichiometry are maintained to ensure that the cement clinker is burnt at a consistent temperature to a specific free lime. Additionally, both chemical and thermal reducing conditions have to be avoided in order to minimise the effect of the waste fuel on strength/growth characteristics, grindability and workability of the cement. Special care has to be taken to avoid reducing conditions in the burning zone when the clinker has a high  $C_3A$ . The constant thermal input and combustion stoichiometry is maintained via the appropriate design of the pretreatment plant and feeding part of the firing plant. The combustion intensity can be achieved via adequate material preparation and injecting the waste via a specially designed burner system, which has the momentum flux that is calculated to produce the gas recirculation ratio, which is required to minimise the chemical reducing conditions in the burning zone. Additionally, the combustion intensity of the waste material should be maximised via its injection along the axis of the kiln through the centre of the flame formed from the prime fuel, preferably through a swirl induced reverse flow zone. The burner configuration and the gas recirculation pattern is shown in figure 3.

Figure 3 - Gas flow pattern in the burning zone of a cement kiln.

Waste materials which have significant ash contents must be prepared so that the incombustible material is reduced to an appropriately small particle size after it has passed through the flame region, and the injection system designed so that the ash is homogeneously incorporated into the kiln feed. A burner system which maximises the combustion intensity of the waste, by injecting it along the axis is usually optimum for incorporating the ash homogeneously into the kiln feed, as it eliminates interaction with the externally recirculating gases. Failure to produce an adequately small particle size of the ash or to homogeneously incorporate it into

the kiln feed, gives rise to the necessity to burn the clinker at a higher temperature in order to achieve combination, which can result in thermally reduced and over burnt clinker. In addition to being homogeneously incorporated into the feed, the ash must be of relatively constant chemical analysis, in order that the cement raw material mix may be adjusted to maintain clinker quality. Fortunately, the chemical analyses of the ash from most wastes do not vary significantly in the short term. A variation in terms of percentage ash is more usual. Such a variation can be allowed for via the design of an adequate blending system.

In addition to product quality problems due to: combustion intensity, variable thermal input, ash variability and heterogeneity, significant product quality problems can occur due to relatively minor constituents. The inputs of volatile compounds such as alkalis, chlorides and sulphates have to be assessed in the light of similar inputs from the normal kiln fuel and raw materials to anticipate their possible effects on kiln operation and product quality. The level of volatile compounds which can be tolerated is known technology and depends on the type of cement making process used. Other minor, but potentially harmful constituents have to be considered. Special laboratory work has to be undertaken and related to full scale trials, to anticipate their behaviour and eventual destination when introduced into the kiln system, in order to determine possible effects on production quality and kiln operation. With minor constituents, common problems are that their range of variation in waste materials are not known. Furthermore, it is not easy to get representative samples of the waste.

### 3.3 ATMOSPHERIC POLLUTION

The raw material calcium carbonate scrubbing system associated with each Works usually means that there will be little problem with exhaust emissions when waste is successfully used as a fuel. However, each waste needs to be considered carefully.

### 3.4 WORKS' OPERATION

The pretreatment and firing plant must be suitably designed to prevent inconvenience to Works' personnel, to meet statutory requirements and to maintain acceptable working conditions. At the same time these plants must be capable of providing the kiln with uniform quality of waste fuel at a cost effective rate. In commercial considerations the real effect on Works' operation of running the waste fuel plant has to be carefully identified.

### 4.0 PRACTICAL APPLICATION OF DIRECT FIRING OF WASTE

While it is possible to completely replace a prime fuel with a waste in firing a cement kiln, this

can only be achieved for a good quality OPC at a reasonable fuel consumption and output if the waste is in fact a high grade fuel (e.g. refinery tail gas) or it has been highly beneficiated. Generally, however, there is either insufficient supply of the waste to supply completely the fuel requirements of the kiln or the beneficiation process is not commercially attractive. Many combustible wastes which are available in sufficient quantities have a significant ash content, e.g. colliery minestone, municipal refuse. The ash content is usually the limiting factor in their replacement of the prime fuel, once adequate pretreatment has taken place and an appropriate firing plant is available. In order to maintain an acceptable clinker quality the maximum ash on clinker that could normally be considered for introduction via the flame is approximately 10%, providing the ash's particle size distribution after combustion is similar to that which occurs with pulverised coal. Depending on the waste and cement making process used, prime fuel replacements of 10-25% can be achieved.

BCI has evaluated, carried out trials, and in some cases brought into operational fruition, the use of wastes as an auxiliary fuel in a cement kiln. Typical examples are: charcoal fines, power station grit, rice husks, colliery minestone, wood-waste, coconut shells, Fullers Earth, battery cases, rubber tyres/chars, municipal refuse, waste oils, acid tar and solvent recovery residues. The scope of the paper does not allow detailed description of each evaluation. Generally, however, if they are not currently being successfully applied, the overall "cost" of using the waste is too high compared to the prime fuel saving. This can be due to many reasons; however, the investment and operating costs of the pretreatment plant required to maintain cement quality and output, combined with the potential disposal fee often predominate. More details of the evaluation procedure, which is based on R & D analysis that should be applied to assessing the commercial viability of a waste as an auxiliary fuel is given in reference (4).

A typical successful example of the use of a waste as an auxiliary fuel in BCI, is that of municipal refuse. Initial trials were carried out in 1971(5) on a 4.5 t.p.h. experimental cement kiln and involved repulverising refuse from a nearby municipal pulveriser plant and mixing with the normal coal before firing into the kiln. The trial showed that the method of disposal was practical but that the method of addition was difficult to control. Trials were carried out to develop adequate pretreatment and firing plants on 20 and 40 t.p.h. wet process kilns. The process developed is currently in commercial operation at a minimum of 60,000 t.p.a. of refuse on a coal fired wet process Works. Figure 4 shows a schematic diagram of the installation which passes the refuse on an as-received basis through a two stage milling process. The primary stage reduces the refuse to 80% < 50mm and the second stage to essentially all minus 50mm. It is particularly important that few "streamers" and little ferrous metal penetrates

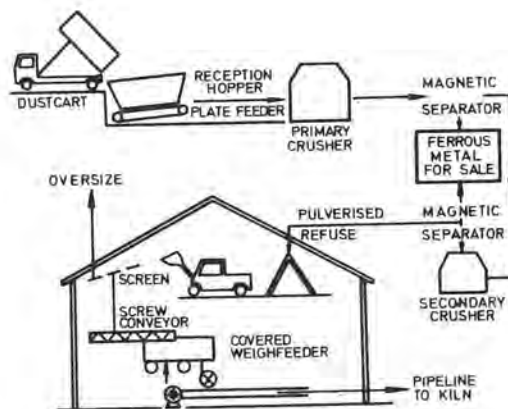

Figure 4 - Typical flow sheet for a pretreatment and firing plant for municipal refuse.

into the firing plant. The pulverisers and process line were chosen accordingly. The streamers are avoided by using a Hazemag Universa 16/20 as a primary pulveriser and a Hazemag EM 1000/1500 or a Gondard "Civic" as secondary pulverisers. Over-band magnets after each pulverisation remove approximately 90% of the ferrous metal. The pretreated refuse is then fed to the firing plant, where it is injected into the kiln via a screw feeder, weight belt, rotary valve and burner. Provisions exist to increase the refuse input providing the cement quality can be maintained. It should, however, be noted that the maximum coal ash that one would normally consider incorporating into the raw material via the flame is 10% of the clinker output. At 60,000 t.p.a. refuse, it's ash plus the ash in the coal gives an ash on clinker level is approximately 6%.

There is an increasing preponderance throughout the world of dry process kilns, including many firing with fuel oil. Therefore, the most recent commercial trials have been carried out in such a kiln in the UK. A mobile pretreatment plant was used to supply nominally 100% < 50mm refuse to a firing plant which comprised of an elevator, screen, weigher, screw, rotary valve and a double concentric, swirling oil/refuse burner. Appropriate adjustments were made to the cement chemistry to accommodate the ash from the refuse. The trials showed that:-

- the use of refuse as an auxiliary fuel in the dry process can be compatible with the manufacture of good quality cement.
- the amount of refuse which may be insufflated depends on its chloride content.
- the amount of refuse which can be used as an auxiliary fuel when not restricted by chlorine level, is largely dictated by its fineness.

- with the appropriate chloride levels and fineness significant replacements (6) of fuel oil can be achieved.

Unfortunately the major drawback in the use of refuse as an auxiliary fuel is the capital and operating costs of the pretreatment plant. The fuel equivalent of the refuse on its own is not an attractive investment, therefore it is important that a realistic price be paid by the local Waste Disposal Authority (W.D.A.) for its disposal. This process is less costly to the W.D.A. than incineration and makes maximum use of its fuel value without any significant increase pollutant emission (6).

The major limitations governing the increased use of refuse as an auxiliary kiln fuel, are associated with its combustion intensity, ash and chloride levels. Future work will concentrate initially on increasing the combustion intensity and decreasing the ash on clinker level, via a simple beneficiation process which takes out the heavier fraction. For the longer term, process developments which would facilitate the use of refuse for cement manufacture (or indeed any other waste) in other than the direct form of energy will be followed, with specific attention being given to the semi-direct method. This latter development could give rise to cement kilns being fired entirely by a waste fuel. As there is usually sufficient municipal refuse in a country to supply all the necessary energy for cement making, the fact that its disposal via cement making competes favourably with incineration and has reduced overall pollutant emission, could make the disposal method part of a countries strategic plan to reduce their consumption of prime fuel at the same time as reducing their overall pollutant emission.

## 5.0 CONCLUSIONS

1) Wastes having a significant calorific value can be used as an auxiliary fuel to provide energy directly to the cement making process, provided they are subjected to the appropriate pretreatment and introduced into the process via a suitably designed firing plant.

2) Even with an appropriate pretreatment and firing plant, the direct firing of waste is normally limited to an auxiliary fuel rôle due to product quality and process operation considerations.

3) The fuel savings arising from using solid waste as a fuel does not normally made the investment/development costs of the pretreatment plant commercially viable. A disposal charge for the waste has normally to be made.

4) The limitations imposed by the use of waste as a direct source of energy, may be overcome by the development of suitable gasifiers or combustors. However, development and operating costs could be a problem.

# SEMINAIRE D

## Influence des caractéristiques du ciment sur les propriétés du béton

Président : M. MCHEDLOV PETROSSYAN, URSS

Correspondant français : M. BARON

### INTRODUCTION AU SEMINAIRE D

Le ciment, en réagissant avec l'eau, forme la colle du béton. On doit donc s'attendre à ce qu'il y ait une relation entre les propriétés du béton et les caractéristiques du ciment. Les communications qui suivent montrent que cette relation est souvent loin d'être claire ; parfois, elle semble ne pas exister ; parfois encore, d'un auteur à l'autre, elle est contradictoire.

#### Exemple 1

Pour un béton riche en ciment, le dosage en eau nécessaire pour obtenir une consistance donnée, peut être décomposé en deux parties, l'une attribuable au ciment, l'autre au granulat inerte :

$$e = A_c + D_g$$

A et D caractérisent le ciment et le granulat inerte ; c et g sont les volumes de ciment et de granulat dans le mélange,

Toutes choses égales par ailleurs (c, D et g), il existe alors une relation entre e et A, donc entre une propriété du béton et une caractéristique du ciment. En particulier si le ciment est plus fin, A est plus grand et le dosage en eau du béton, nécessaire pour avoir une consistance donnée, est plus grand.

Pour les dosages en ciment usuels, la relation ci-dessus n'est plus valable ; le dosage en eau dépend toujours de la finesse du ciment mais il dépend aussi de la porosité du granulat inerte, c'est-à-dire de la répartition granulométrique de l'ensemble des grains. Augmenter la finesse du ciment peut alors, suivant le cas, augmenter ou diminuer, ou encore ne pas changer le dosage en eau nécessaire pour avoir un béton de consistance donnée.

#### Exemple 2

Influence du moment de mise en place sur la résistance à 28 j. Le moment optimal de mise en place dépend du ciment et de la température interne. Le choix d'un moment arbitraire peut fausser la comparaison entre les ciments adjuvantés ou non.

#### Exemple 3

Il n'existe pas un rapport fixe entre le retrait au jeune âge du béton et celui de sa pâte (le granulat étant toujours le même par ailleurs). Suivant les ciments, ce rapport varie entre 0,1 et 0,25. Cela est probablement dû, en partie, aux microfissures qui se forment dans le béton au jeune âge entre la pâte et les granulats. Quoi qu'il en soit, la valeur de ce rapport dépend de la cinétique de durcissement de la pâte de ciment, de la répartition granulométrique des grains du granulat et du ciment, des caractéristiques élastiques du granulat ainsi que des conditions mécaniques imposées aux limites de l'éprouvette. Compte tenu de tout cela, une pâte de ciment au retrait supérieur peut donner un béton au retrait plus faible.

On pourrait multiplier ainsi les exemples. Mais cela n'est pas nécessaire pour être convaincu que la relation entre les propriétés des bétons et les caractéristiques des ciments ne peut être étudiée qu'au travers de modèles physiques schématisant le fonctionnement global.

En Union Soviétique, on a vu ces dernières années le développement de modèles semi-empiriques, prenant en compte l'influence de très nombreux paramètres (caractéristiques du ciment, des granulats, des proportions du mélange, des conditions de mise en oeuvre, des conditions atmosphériques). Le développement de ces modèles est possible grâce aux progrès des moyens de calcul.

D'un point de vue pratique, ces modèles permettent une optimisation globale du béton qui peut être une source de progrès et d'économies importantes.

Le Séminaire a été organisé selon 5 thèmes, organisé chacun par un rapporteur :

- 1 - Influence de la composition chimico-minéralogique et de la finesse du ciment - M. J.P. BOMBLED
- 2 - Influence des constituants secondaires (cendres volantes, laitiers, pouzzolanes, etc ...) - M. LUDWIG
- 3 - Influence des traitements thermiques - M. L.J. PARROT
- 4 - Influence des adjuvants - M. O. HENNING
- 5 - Influence des effets extérieurs et de leur association - M. O.P. MCHEDLOV PETROSSYAN

# Thème 1 - Influence de la composition minéralogique et de la finesse du ciment sur les propriétés du béton

par J.P. BOMBLED, C.E.R.I.H.L, Paris, France.

## 1 Introduction

Dans un béton hydraulique le ciment représente pratiquement la fraction la plus fine donc, par unité de volume, de béton l'élément solide présentant le plus grand nombre de points de contact et la plus grande surface d'échange avec ce qui l'entoure c'est-à-dire au début, l'eau de gâchage ; par ailleurs, le ciment forme avec cette eau l'élément actif de cet ensemble et aussi, à l'état frais, l'élément déformable.

Il est par conséquent assez logique de penser que les caractéristiques du ciment influenceront en grande partie les propriétés du béton frais ou durci.

Toutefois il ne faut pas aller trop loin dans ce raisonnement et attribuer au ciment toutes les qualités et pourquoi pas aussi tous les défauts d'un béton : ne perdons pas de vue qu'une réalisation en béton et sa bonne tenue c'est aussi le résultat :

- du soin dans la conception de l'ouvrage,
- du choix d'une composition du béton,
- de la présence d'autres composants y compris des adjuvants,
- de la qualité de la mise en oeuvre,
- du déroulement des traitements éventuels,
- des conditions de travail ou d'environnement immédiates ou ultérieures.

Certains de ces points font d'ailleurs l'objet d'autres thèmes de ce séminaire.

Le thème I concerne "L'influence de la composition minéralogique du clinker et de la finesse du ciment sur les propriétés du béton",

Auparavant pour essayer d'avoir une vue globale de l'état de nos connaissances il est bon de se reporter au Tableau I formant une matrice dont les colonnes correspondent aux propriétés du béton que j'ai divisées en cinq groupes :

- les propriétés à l'état frais,
- l'évolution depuis l'état initial pendant les premières heures de la vie du matériau (prise, raidissements...),
- les performances mécaniques à plus longue échéance,
- les variations dimensionnelles et les risques de fissuration qui leur sont souvent associés,
- la durabilité.

Les lignes correspondent à des caractéristiques ou des facteurs liés au ciment :

- La composition minéralogique du clinker [et chimique en ce qui concerne des éléments dits "mineurs"] .
- La composition du ciment en tenant compte des constituants en dehors du clinker : laitier, pouzzolanes naturelles ou artificielles ... et le gypse.
- La finesse de mouture soit par son aspect synthétique de l'aire massique soit par son aspect analytique de la granulométrie.
- Et, bien que ce ne soit pas une propriété intrinsèque du liant, son dosage dans le béton.

Dans ce tableau j'ai essayé de faire le point de nos connaissances en les estimant en trois niveaux :

- 1 Celui que j'ai symbolisé par un ou plusieurs points d'interrogation pour signifier qu'il reste encore dans ce domaine beaucoup de questions à élucider par les chercheurs.
- 2 Dans quelques cas le symbole ondulé veut dire que nous disposons déjà d'un certain acquit mais qu'il reste des zones d'ombre à éclaircir et sans doute des synthèses à effectuer.
- 3 Enfin dans le troisième niveau indiqué par la lettre B ce sont les domaines où j'ai estimé notre connaissance satisfaisante.

Les appréciations portées dans ce tableau sont évidemment très subjectives et peuvent donner lieu à des discussions, on peut ne pas être d'accord et je laisse à chacun le soin de les modifier à son gré.

Néanmoins on peut penser que cette forme de présentation a le mérite de nous mettre sous les yeux un panorama de nos connaissances et de nos lacunes. Evidemment chaque colonne et chaque ligne peuvent elles-mêmes se subdiviser en plusieurs facteurs ou éléments.

Les différentes colonnes du tableau formeront les têtes de chapitre, de cette courte présentation du Thème I. Mais pour ce thème I qui est mon sujet, il faut faire abstraction des lignes 2 et 4 qui ressortissent des autres sujets qui seront abordés par les autres rapporteurs.

		"Propriétés" du Béton				
		Etat frais : maniabilité	Evolution : prise et raidissements	Performances mécaniques	Variations dimensionnelles, fissuration	Durabilité
"Caractéristiques" du ciment	Composition minéralogique et chimique du clinker (y compris éléments mineurs)	??	≈	≈	??	???
	Composition du ciment (en tenant compte des divers composants : laitier, pouzz., etc.)	?	~	~	?	???
	Finesse de mouture	B	B	B	B	≈
	Dosage en ciment dans le béton	B	~	B	B	B

? domaine du il reste des questions plus ou moins nombreuses à résoudre.

~ domaine du il existe un sujet important mais encore des zones d'ombre à éclaircir.

B domaine du on peut admettre avoir une bonne connaissance de l'essentiel pour comprendre et agir pratiquement.

## II Caractéristiques du ciment et propriétés du béton frais

Les recherches sur le comportement rhéologique du béton frais et les composants de l'ouvrabilité (cohésion, viscosité, frottement interne) ainsi que sur les facteurs qui les influencent, commencent à nous permettre d'entrevoir les mécanismes.

On connaît en particulier assez bien l'influence soit sur la cohésion, soit sur l'effet lubrifiant de la pâte interstitielle, soit sur la lutte contre les risques de ségrégation etc, l'influence de la proportion d'éléments fins et, par conséquent, de la finesse de mouture du ciment d'une part et du dosage de celui-ci dans le béton d'autre part.

Dans ce domaine de la finesse on s'est aperçu par ailleurs que le mode de broyage n'était pas sans répercussions rhéologiques et c'est un problème à l'étude actuellement.

En ce qui concerne l'influence de la composition du clinker, on est beaucoup moins fort mais des études sont en cours sur la floculation, sur la thixotropie, sur le potentiel zeta en relation avec la constitution du clinker et les ions présents dans la phase aqueuse.

On sait néanmoins que la teneur en  $C_3A$  dont la vitesse de dissolution est grande, doit jouer un rôle prédominant puisque si son hydratation rapide et les liaisons précoces qui peuvent en résulter ne sont pas correctement ralenties, on risque de voir augmenter rapidement la résistance au cisaillement du béton frais et de voir ainsi la prise empiéter sur la période de mise en oeuvre.

On a commencé aussi à mieux comprendre le rôle des sulfates de calcium et du gypse en particulier, floculants, réducteurs de solubilité des aluminates, comme sulfo-aluminate, colmateurs de certaines plages des grains, accélérateurs des silicates ; selon la teneur en  $C_3A$  du clinker l'incorporation du gypse pourra soit produire un effet pseudo-fluidifiant soit au contraire pour une teneur en  $C_3A$  faible, conduire à une diminution de maniabilité ou à une exigence en eau plus grande à caractéristique rhéologique égale.

L'action des alcalins dépend non seulement du cation mais aussi de l'anion toutefois ils présentent généralement deux effets contradictoires l'un fluidifiant l'autre accélérateur de prise, et dans ce cas peuvent contribuer à diminuer rapidement l'ouvrabilité ; si les alcalins sont en trop grande proportion c'est ce dernier effet qui risque de prédominer.

Tout ceci commence à être mieux connu et il faut remercier Monsieur GEBAUER de son étude très intéressante et très instructive fondée sur une grande quantité d'observations et un grand nombre de ciments.

Cette communication propose une relation qui permet de calculer l'exigence en eau à consistance normale, en fonction de trois facteurs qui sont parmi ceux que nous venons de mentionner.

Nous l'avons vérifiée avec quelques ciments et elle nous a donné de bons résultats. Toutefois on peut s'étonner de deux choses : l'absence du terme sulfate et le fait que la finesse est caractérisée par la fraction 10/30  $\mu m$ . Remarquons que pour le sulfate, comme la teneur optimale en gypse est fonction de la teneur en  $C_3A$ , en alcalin et de la finesse, on conçoit que l'influence du gypse soit difficile à

dissocier des autres facteurs pour les ciments commerciaux.

Un autre enseignement du travail de Monsieur GEBAUER est de montrer combien les variations rhéologiques liées au facteur ciment sont assez faiblement répercutées et fort atténuées sur la maniabilité du béton ; c'est un avantage mais aussi un inconvénient :

- Ceci devrait d'abord nous conduire à une certaine modestie et décourager ceux qui proposent de mesurer une maniabilité intrinsèque du ciment alors que c'est toujours de maniabilité du béton qu'il s'agit.
- En revanche ceci nous interdit de transposer sans précaution les résultats des essais rhéologiques obtenus sur pâte ou sur mortier à des bétons, et pour les laboratoires c'est toujours une charge très lourde et une difficulté que d'effectuer toutes ces mesures sur béton d'autant plus qu'il n'existe pas de béton normalisé.

## III Evolution initiales et caractéristiques du ciment

Il s'agit de la deuxième colonne du tableau ; cette évolution peut se manifester de trois manières :

- par une prise habituelle après une période dormante ou d'induction plus ou moins longue
- par une perte d'ouvrabilité progressive mais quelquefois assez rapide (et qui peut être parfois fort gênante).
- par des raidissements prématurés qui sont rédhibitoires pour une bonne mise en oeuvre.

Il va de soi que ce sont les éléments rapidement solubles qui interviennent à ce stade ; on sait bien aussi comment la finesse de mouture influe sur la vitesse de prise.

En ce qui concerne la composition du clinker ce sont essentiellement  $C_3A$  et les éléments alcalins qui agissent soit comme, constituants à prise rapide soit pour les alcalins généralement comme accélérateurs, la conjonction des deux pouvant évidemment entraîner des temps de prise très courts ou des raidissements prématurés.

L'action modératrice des sulfates de calcium (gypse, anhydrite, semi-hydrate) dépend de la vitesse de dissolution de ceux-ci et de celle des différents éléments en présence, laquelle conditionne cette compétition qui régit la cinétique d'hydratation dans les premiers instants laquelle sera influencée :

- par la concentration des éléments en présence,
- par la nature et la mobilité des ions qui apparaissent,
- par l'état d'hydratation et de solvation des éléments dissous,
- par la température qui agira entre autres sur la diffusion etc.

Nous commençons à comprendre certains de ces mécanismes ce qui ne veut pas dire qu'il ne reste pas encore des points à préciser ; il reste en particulier à mieux élucider l'influence d'un certain nombre d'éléments dits "mineurs" dont la cinétique de dissolution et dont les effets que j'appellerai faute de mieux "catalytiques" peuvent déplacer notablement les équilibres ioniques qui régissent tous ces systèmes.

Un point important sur lequel nous sommes beaucoup moins forts et qui pourtant nous pose des problèmes fréquemment, est celui des raidissements prématurés ; on a pu leur trouver un certain nombre de causes mais il reste beaucoup à faire pour démontrer tous les mécanismes : il est d'ailleurs surprenant qu'aucune communication ne se soit intéressée à cette question ; peut-être a-t-on quelque pudeur à reconnaître notre ignorance.

Dans le domaine de la prise nous trouvons la très intéressante étude de Monsieur le Professeur TAM de Thaïlande qui étudie en particulier l'influence des éléments alcalins notamment dans le cas où l'on incorpore des adjuvants dont le but est justement de modifier la vitesse de prise.

On peut toutefois s'interroger sur la validité de conclusions tirées de l'addition d'hydroxyde de sodium aux alcalins déjà présents dans le clinker, dont le passage en solution est sans doute plus lent (l'ordre d'incorporation des additions peut d'ailleurs généralement intervenir) mais aussi parce que l'anion  $\text{as}$  sans doute aussi son mot à dire et joue un rôle non négligeable dans les états d'équilibre dont j'ai parlé.

Néanmoins la recherche de l'influence des éléments alcalins sur la solubilité et sur la cinétique de dissolution des autres constituants, est très intéressante et peut aider à comprendre les répercussions éventuelles dans le cas d'incorporation de certains adjuvants.

#### IV Caractéristiques du ciment et résistances

Je serai relativement bref sur ce point pourtant important car beaucoup est déjà connu et a été fait.

La relation entre la finesse de mouture et en particulier la granularité et la cinétique de durcissement a fait l'objet de fort nombreux travaux. On sait que la résistance entre 0 et 24 h est directement proportionnelle à la surface spécifique, on sait aussi quelles sont les tranches granulaires qui donnent les premières résistances et l'intérêt d'un spectre granulométrique resserré.

Mais la corrélation entre finesse et résistance n'est pas sans dépendre elle aussi de la composition car la constitution des différentes fractions granulaires est liée à la broyabilité de chaque minéral : par exemple plus un clinker est dur à broyer, plus les fines seront riches en  $\text{C}_3\text{S}$ .

Pour ce qui est de l'influence de la composition minéralogique le  $\text{C}_3\text{S}$  est l'élément essentiel des résistances finales. Par ailleurs n'oublions pas les possibilités d'interaction, des effets de synergie, entre différents constituants,  $\text{C}_3\text{A}$  et  $\text{C}_3\text{S}$  par exemple, et il ne faut pas se borner à additionner les propriétés séparées de chacun.

Mais dans ce domaine la composition n'est pas tout et on commence à entrevoir que la morphologie des cristaux peut influencer notablement ; ainsi on a pu entendre dire ça et là que des alites en cristaux hexagonaux ou prismatiques, des bélites en cristaux arrondis donneraient les meilleurs résultats.

En outre la dimension des cristaux a aussi son importance : des petits cristaux de quelques dizaines de microns, peu différents de la grosseur des grains qui résultent du broyage, donnent généralement de très bons résultats du fait qu'à ces dimensions le broyage entraînerait des contraintes plutôt génératrices de défauts et de failles ce qui est favorable à l'hydratation en augmentant la vitesse de pénétration de l'eau. Notons ici que les

conditions de refroidissement et de trempe du clinker ne sont pas non plus sans importance.

Pour les éléments mineurs, en schématisant, un ciment riche en alcalins donnera des résistances initiales plutôt plus élevées (effet accélérateur de durcissement) ce qui ne sera plus le cas des résistances finales ; par ailleurs l'insertion et l'inclusion de certains éléments mineurs peuvent être bénéfiques.

N'oublions pas que la résistance mécanique d'un béton outre la résistance propre de la pâte interstitielle de ciment hydraté fait intervenir l'adhérence de celle-ci aux granulats et cette adhérence mécanique par les multiples queues d'aronde qui réalisent une infinité d'ancrages est liée d'une part à des problèmes rhéologiques, la pénétration dans ces anfractuosités, et d'autre part à l'état de surface des grains : la communication de Monsieur AYAPOV nous montre des tentatives de traitement de granulats notamment des laitiers par des actions chimiques.

Par ailleurs il faut dire que la plupart des propriétés des pâtes de ciment durcies sont en relation avec leur porosité et plusieurs communications (qui ne relèvent pas essentiellement du Thème I d'ailleurs) sont consacrées à ce point.

Enfin, bien que cette communication relève de bétons spéciaux (refractaires) il faut citer l'intéressant travail de Monsieur TOREANU et collaborateurs qui trouve quelques liens avec ce que nous avons dit plus haut.

#### V Propriétés du ciment et variations dimensionnelles

Je serai très bref, ici aussi, car il n'y a pas eu de communication traitant de ce sujet, ce qui pourrait laisser penser que tout est connu alors que beaucoup de recherches s'effectuent encore dans ce domaine et celui de la fissuration.

On a trop souvent tendance à relier retrait entravé du ciment et fissuration du béton alors que l'on sait très bien que les causes de fissuration des ouvrages sont multiples et que la plupart du temps le retrait hygrométrique à long terme du ciment, celui que l'on mesure habituellement, n'y a qu'une très faible part. Si le retrait hydraulique d'une pâte de ciment est une grandeur facilement mesurable, en revanche, la fissurabilité qui dépend de très nombreux facteurs intrinsèques ou extrinsèques au béton n'a qu'un caractère aléatoire et ne peut être en aucune manière une caractéristique propre des ciments.

Pour les facteurs qui interviennent sur le retrait d'une pâte de ciment on connaît bien l'influence de la finesse de mouture mais moins bien celle de la composition du clinker : il est certain que les alcalins solubles sont connus comme facteurs de retrait, il semble que l'influence de la teneur en  $\text{C}_3\text{A}$ , négligeable jusqu'à 7 ou 8 %, joue au-delà dans le sens d'un accroissement de retrait hydraulique.

Quant aux causes d'expansion elles ont donné lieu à de nombreux travaux et, outre les facteurs extérieurs font intervenir les constituants du ciment tels que chaux ou magnésie libre (périclase), excès de sulfate, réaction avec les granulats ; mais on aborde ici les problèmes de la 5ème colonne du Tableau I c'est-à-dire ceux de la durabilité.

## VI Composition du ciment et durabilité du béton

Pour ce qui concerne la composition du clinker de base du ciment, il existe une littérature abondante qui confirme que les bétons sont d'autant plus vulnérables à la plupart des milieux agressifs, que la teneur en  $C_3A$  du ciment augmente.

On admet souvent qu'au dessous de 7 à 8 % de  $C_3A$  il y a fort peu à craindre et en revanche beaucoup au dessus de 10 %, la zone frontière pouvant donner lieu à des discussions.

N'oublions pas toutefois trois remarques qui peuvent être fort importantes :

- Qu'il peut exister des différences relativement notables selon les moyens de chiffrer ou de doser les constituants minéralogiques du clinker et donc le  $C_3A$ .
- Qu'ici aussi la forme cristallographique des minéraux peut intervenir au moins autant que leur teneur.
- Qu'enfin ce n'est pas le  $C_3A$  anhydre qui est attaqué mais les hydrates parfois fort complexes où l'insertion d'éléments "mineurs" n'est pas sans jouer un rôle.

On peut ajouter deux choses importantes sur lesquelles tout le monde est d'accord :

- Une bonne résistance à la carbonatation et une bonne protection des armatures exigent une forte teneur en chaux et pour les aciers un enrobage suffisant d'un matériau imperméable.
- Deuxièmement l'unanimité est faite sur l'importance de la perméabilité dans les problèmes de durabilité des bétons : il faut donc avant tout réaliser des pièces en bétons compacts et étanches donc des bétons maniabiles, non ségrégeables, richement dosés en ciment et bien serrés, si cela est réalisé le plus important est fait le reste apparaît secondaire.

L'importance de ces divers points de la perméabilité est bien rappelée par la communication de Monsieur MATOUSCHEK.

## VII Conclusions

Les résumés que nous avons reçus des travaux de Monsieur SZEKELY de Hongrie et de Monsieur SHESTOPYROV et collaborateurs confirment combien on cherche actuellement

- D'une part à bien mettre en relief le rôle du ciment dans le béton,
- D'autre part combien on souhaite et on recherche des moyens et des critères de prévision des qualités du béton,
- Enfin de la nécessité de connaître parfaitement les relations entre les nombreux facteurs en jeu.

Nous avons vu que si l'on connaît généralement assez bien l'influence de la finesse de mouture il reste beaucoup à faire pour bien connaître d'une façon certaine l'influence de la composition : sur le Tableau II j'ai essayé de regrouper ce que l'on croit savoir aujourd'hui ; ici aussi ce sont surtout des tendances et vous êtes libres de ne pas être d'accord avec ce qui est indiqué.

		"PROPRIETES DES BETONS"				
		rhéologie du béton frais - maniabilité	vitesse de prise	performances mécaniques	retrait	durabilité
CARACTERISTIQUES DES CEMENTS	$C_3A$			[âge / finales]		
	$C_3S$ (Alite)					
	Sulfates	selon $C_3A$				
	Alcalins			[âge / finales]		
	Finesse					

relation contradictoire    évolution dans le même sens    présence d'un optimum    action peu marquée ou sujette à caution  
 Nota : il s'agit surtout de tendances car il ne faut pas oublier l'interdépendance de nombreux facteurs.

On a beaucoup parlé des alcalins, des sulfates et surtout de  $C_3A$  mais on est maintenant sûr que ce n'est pas seulement la teneur de ce composant qui joue mais bien d'autres choses dont les polymorphismes les inclusions, le mode de formation etc ...

En réalité les variables liées à la composition du clinker ne sont pas indépendantes et il y a une telle interdépendance qui commence déjà à partir de la clinkérisation et va bien entendu jusqu'à l'hydratation qu'il est pratiquement impossible de ne faire varier qu'un seul facteur à la fois et surtout on risque d'observer des corrélations qui n'en sont pas ou qui sont hasardeuses sur le plan des mécanismes physico-chimiques.

Néanmoins même s'il reste encore beaucoup de points à éclaircir et de synthèses à effectuer, je pense que l'on peut être optimiste devant le développement de nos connaissances dans ce domaine ces dernières années.

# Influence of cement on the properties of fresh concrete

## *Influence du ciment sur les propriétés du béton frais*

Dr. J. GEBAUER, Chimiste, Chef du Groupe « Application du Ciment » du Département Matériaux de la « Holderbank » Gestion et Conseils S.A., 5113 Holderbank, Suisse.

**RESUME :** L'effet de la composition et de la finesse du ciment sur la consistance, la perte de consistance et le raidissement du béton est discuté à partir d'une investigation compréhensive effectuée sur un grand nombre de ciments industriels et différentes proportions de mélanges de béton.

Au cours de l'investigation, on a utilisé des méthodes d'essai standardisées telles que : besoin en eau pour pâte normale, temps de prise selon Vicat et en plus la résistance à la pénétration à l'aide du pénétromètre Francardi. Les mesures de consistance effectuées sur béton sont : affaissement, degré de compactibilité DIN, étalement DIN, ainsi que la perte de consistance à différents intervalles dès le malaxage et mesure continue de la vitesse de la propagation de l'ultrason durant les premières 24 heures.

Les caractéristiques du ciment influencent significativement les propriétés des pâtes fraîches de ciment. Les facteurs principaux d'influence sont : les teneurs en aluminat, en alcalis et en sulfate du clinker, l'ajout de sulfate de calcium et la granularité du ciment. Les effets du ciment, qui sont facilement mesurables sur pâte, sont fortement affaiblis dans le béton. Par conséquent, on a trouvé, en général, une relation faible entre les propriétés de la pâte et du béton. Certaines relations ont été observées entre l'évolution de la résistance de la pâte à la pénétration, mesurée par pénétromètre, et le raidissement du béton.

**SUMMARY :** The effect of cement composition and fineness on the consistency, loss of consistency and stiffening of concrete is discussed on the grounds of a comprehensive investigation carried out on a large number of industrial cements and various mix proportions of concrete.

In the investigation standardized test methods on paste were used : water requirement of the standard consistency, Vicat setting time and penetration with the Francardi penetrometer. The tests performed on concrete were: consistency, namely Slump, compacting factor DIN, flow test DIN, as well as loss on consistency at various time intervals after mixing and continuous measurement of ultrasonic pulse velocity during the first 24 hours.

The cement characteristics significantly influence the properties of fresh cement paste. The main influencing factors are : the aluminate - alkali - and sulfate-content of clinker, the calcium sulfate admixture and the particle size distribution of cement. The effects of cement, which can easily be measured on paste, are greatly diminished in concrete. Consequently, the relation between the properties of paste and concrete was generally found to be poor. Some relations were observed between the penetration of paste, as measured by means of the penetrometer, and the stiffening of concrete.

## 1. INTRODUCTION

The influence of cement upon the properties of fresh concrete is frequently examined on cement paste by means of standard methods on the assumption that there is a close relationship between the properties of cement paste and those of fresh concrete: the water requirement of cement paste is related to the water requirement or workability of concrete, the stiffening rate of cement paste to the loss of workability and stiffening rate of concrete.

The testing methods using cement paste offer the advantage of allowing a better differentiation and thus better comparison between the different cement qualities. A disadvantage consists in the fact that the relationships between the properties of cement paste and those of fresh concrete are sometimes doubtful.

Our investigation was concerned with the influence of the cement upon the properties of both cement paste and fresh concrete. It is based on the comprehensive testing of 48 ordinary portland cement samples from 48 different cement plants. Each cement sample complied with the requirements of the ASTM and DIN standards for type I and type 2 35 F, respectively.

## 2. INFLUENCE OF CEMENT UPON THE PROPERTIES OF CEMENT PASTE

The water requirement of cement paste of normal consistency depends mainly upon the aluminate and alkali content of clinker and upon the fineness of cement. The following relation was derived from a multiple regression analysis carried out on the 48 portland cements:

$$\text{Water requirement (\%)} = 17.4 + 0.15 A + 0.26 B + 0.52 C$$

A = particle size fraction 10 - 30  $\mu\text{m}$  in weight percent

B =  $\text{C}_3\text{A}$ -content in weight percent

C = total alkali content in weight percent

The correlation coefficient was 0.829.

The stiffening rate of cement paste is influenced by both the composition and fineness of cement; the sulphates and phosphates of clinker generally retard while the aluminate of clinker and the increased fineness of cement accelerate it. The gypsum, if dehydrated during grinding or storage of cement, may cause false set. A calcium sulphate deficiency leads to fast stiffening

of the paste which is called flash set.

The stiffening of the cement paste was measured by means of the Francardi penetrometer. The penetrometer continuously measures the stiffening rate of the cement paste, starting immediately after mixing. The false set, as well as other unfavourable types of setting, can easily be recognized by the penetration measurement (see Fig. 1).

The regression analysis of the 48 cement samples did not reveal a satisfactory correlation between the composition of cement and the stiffening rate of cement paste, thus making a reliable prediction of the stiffening rate of paste based on the composition of cement impossible.

## 3. INFLUENCE OF CEMENT UPON THE PROPERTIES OF FRESH CONCRETE

The correlation between the properties of cement paste and those of concrete was found to be rather poor. Let me illustrate this by a few results of our investigation.

Figure 2 shows the correlation between the water requirement of cement paste and that of concrete, expressed as W/C ratio of concrete of specified consistency. For this testing 13 cements with distinct composition, each being representative for a specific group of cements, were selected from the 48 cements under investigation. A standardized concrete of plastic consistency (slump 7.5) containing 300 kg of cement per  $\text{m}^3$  and natural aggregate graded according to Fuller was used for all the concrete tests. The different cement qualities, with a water requirement of the cement paste varying between 24.5 and 28.5%, showed a deviation of the water/cement ratio of concrete of only 0.03.

A comparison between the influence of cement and that of other factors on the water requirement or workability of concrete shows that the impact of cement is rather insignificant. The results of another comparative study on the quality of ready mixed concrete indicated that a substantially greater influence upon the water requirement of concrete is exerted by the aggregate in particular by the sand. In many ready mix plants variations in the water/cement ratio being due to variable batching accuracy have an influence which may not be neglected.

In Figure 3 the possible influences of cement, aggregate, admixture and batching on the water/cement ratio of concrete with specified consistency are compared.

Figure 4 shows the relation between the stiffening rate of cement paste and the loss of workability of concrete. The loss of workability was measured by means of the slump loss after 45 minutes. Again we failed to find a significant correlation between the stiffening rate of paste and the slump loss of concrete. Although it seems obvious that cement with a fast stiffening rate would also have a faster slump loss, the contrary may be true: a cement with false set properties on cement paste showed the lowest slump loss in concrete under our particular testing conditions, i.e. vigorous mixing of concrete in a laboratory pan mixer during three minutes.

As suspected, the attempt to find a correlation between the composition and the properties of fresh concrete - in particular workability and loss of workability - was unsuccessful.

The only distinct correlation between cement paste and fresh concrete was observed between the stiffening rate of paste and that of concrete after placing, measured by means of ultrasonic pulse velocity. The measurement of the ultrasonic pulse velocity in fresh concrete showed a sharp rise in the sound velocity between 2 and 5 hours after mixing (see Fig. 5). The time of this sudden increase in the sound velocity in concrete closely corresponds to the setting time of cement paste

## CONCLUSION

The composition and fineness of cement, provided that it complies with the specifications for portland cement, exert only a limited influence upon the properties of fresh concrete, particularly upon the workability and loss of workability.

The pure cement paste reflects the effect of the influence of the cement quality to a much greater degree than concrete. The influence of cement upon the properties of fresh concrete is weakened by "other" factors and by the interaction of these factors. These "other" factors include fine and coarse aggregates, chemical admixtures, fine fillers or active additives, proportioning of concrete, particularly the W/C ratio, temperature of concrete, mixing, transport and placing.

The introduction of special testing methods on cement paste in order to achieve a more differentiated classification of the cement quality with respect to the properties of fresh concrete is hardly advantageous and should be discouraged.

# Influence des caractéristiques du ciment sur les propriétés du béton et de sa résistance à la corrosion atmosphérique

## *The influence of cement properties on the concrete behaviour and its resistance to the atmospheric corrosion*

M. MATOUSEK, Chargé de cours, Docteur ès Sciences Techniques, Institut de Technologie des matériaux, Université Technique de Brno, Tchécoslovaquie.

RESUME : La corrosion du béton par suite des gaz nocifs présents dans l'atmosphère est régie par les lois de perméabilité. La résistance du béton à la corrosion peut être jugée le mieux d'après son coefficient de résistance à la perméabilité.

La profondeur de la corrosion du béton après un certain temps dans des conditions égales en reste dépend indirectement même de la teneur en CaO réactif dans le béton.

Selon cette réalité il faut donc faire le choix du ciment pour les constructions qui, plus que les autres, sont soumises à la corrosion atmosphérique.

SUMMARY : The concrete corrosion through deturious gases from the atmosphere is governed by the laws of permeation. The concrete resistance to the corrosion can be appreciated the best by the coefficient of permeation resistance.

The depth of concrete corrosion after certain period of time under the same conditions depends also indirectly on the contents of reactionable CaO in the concrete.

Therefore it is necessary to chose the cement for building structures, which are particularly loaded by the atmospheric corrosion.

Les influences atmosphériques agissant sur les matériaux de construction, surtout les bétons, sont assez différents. Il y prédomine cependant l'influence de l'humidité de l'air ainsi que celle de gaz carbonique et de l'anhydride sulfurique. La résistance du béton à ces deux derniers est réglée par d'autres lois qu'il n'en est au cas de la corrosion du béton par suite des solutions aqueuses, et dans un milieu liquide en général. Les travaux exécutés à l'Institut de technologie de la fabrication des matériaux de bâtiment à l'Université Technique de Brno ont prouvé que la corrosion du béton produite par les gaz nocifs à réaction acide dans les conditions réelles des constructions des bâtiments est réglée surtout par l'état de la structure poreuse capillaire du béton.

Au cas de la corrosion du béton produite par les influences atmosphériques, les gaz se propagent en forme de perméabilité. Pour ce phénomène on peut alors appliquer avec une grande précision la loi de Fourier et la première loi de Fick. En examinant plus exactement ces lois d'une façon semblable à celle qui est usuelle dans la technique thermique on peut constater que la pénétration des gaz nocifs dans le béton dépend indirectement de la valeur du coefficient de résistance à la perméabilité du béton, évent. du mortier.

Le coefficient de résistance à la perméabilité nous indique combien de fois la résistance à la perméabilité du béton est supérieure à la résistance à la perméabilité de l'air à la même épaisseur et la même température. Au laboratoire on peut le mesurer assez facilement, p.ex. à l'aide des soi-disant méthodes de coupe. De nos expériences il résulte que l'appréciation de la résistance du béton à la corrosion d'après son coefficient de résistance à la perméabilité est tant de fois plus sensible et sûre qu'il n'en était jusqu'à présent d'après sa densité, son poids volumétrique etc.

D'après ce qu'on vient de dire, les lois de la perméabilité sont les meilleures à caractériser la résistance du béton à différents gaz atmosphériques. Ce sont donc des lois physiques. On peut cependant démontrer qu'en même temps on peut y découvrir même des caractéristiques chimiques du ciment employé et de la composition du béton frais, surtout la teneur en anhydride de calcium réactif du ciment. A savoir que si l'on exprime la soi-disant profondeur de carbonatation du béton d'après la loi de Fick comme

$$d = K \cdot \sqrt{\tau} \quad [m],$$

le coefficient K accompagnant la racine carrée du temps  $\tau$  [s] sera égal à :

$$K = \sqrt{\frac{2 \cdot D \cdot p}{b \cdot \mu \cdot R \cdot T}} \quad [m \cdot s^{-\frac{1}{2}}],$$

où D = coefficient de la diffusion du gaz nocif dans l'air [m<sup>2</sup>.s],  
p = pression du gaz nocif dans l'atmosphère [Pa],  
b = quantité du gaz pouvant se lier

dans 1 m<sup>3</sup> de béton [kg.m<sup>-3</sup>],  
 $\mu$  = coefficient de la résistance à la perméabilité du béton [-],  
R = constante de gaz de la vapeur d'eau par rapport à 1 kg de vapeur [J . kg<sup>-1</sup>. K<sup>-1</sup>],  
T = température absolue [°K].

Le coefficient K sera donc inversement proportionnel non seulement à la racine carrée du coefficient de la résistance à la perméabilité du béton, mais encore à la racine carrée de la quantité du gaz nocif donné, p.ex. du gaz carbonique nécessaire pour la carbonatation d'un mètre cube de béton. Cette quantité peut être déterminée, par la méthode stœchiométrique, de la concentration de l'anhydride de calcium qui est contenu dans le béton et qui provient du ciment employé.

Le résultat principal de l'analyse effectuée consiste dans le fait, que le ciment Portland à la teneur supérieure en CaO, fournira avec le même dosage et le même serrage des bétons plus résistants à l'influence des anhydrides carbonique et sulfurique, et d'autres gaz nocifs faisant partie de l'air que les bétons fabriqués avec des ciments à une moindre teneur en CaO, p.ex. avec des ciments contenant du laitier de haut fourneau, de la cendre volante etc.

Un mesurage de longue durée des vieilles constructions en béton réalisé à notre Université Technique a pleinement attesté cette dépendance, c'est à dire que la résistance du béton à la corrosion atmosphérique dépend de la composition du ciment utilisé. L'expérience a plutôt démontré que ce cas là, dans les conditions réelles des constructions des bâtiments, l'influence de la teneur en CaO dans le ciment et, par suite de cela, même l'influence du choix de la sorte de ciment est plus considérable, parce que l'anhydride de calcium se formant grâce à l'hydratation du ciment et présent dans la solution intercellulaire dans les pores capillaires du béton en plus grande profondeur sous sa surface passe peu à peu vers la surface du béton carbonatant ce qui est dû à la chute de concentration. C'est ici qu'il se lie avec le CO<sub>2</sub> en diffusion tout en formant des cristaux de CO<sub>3</sub>Ca appartiennent surtout en modification de calcite. Les néoplasmes cristallins réduisent le diamètre des capillaires ce qui produit une ultérieure retardation, évent. même l'arrêt d'une ultérieure influence nocive des gaz sur le béton.

Ce fait atteste donc, lui aussi, que les ciments qui, grâce à leur composition ou à la présence des ingrédients, ne font pas de solutions intercellulaires dans les pores du mortier en ciment présentant une assez grande et durable concentration de hydroxyde de calcium pourront servir à préparer seulement des bétons lesquels, dans des conditions en reste égales, auront toujours une moindre résistance à la corrosion produite par les gaz contenus dans l'atmosphère.

# Influence of chemical interaction of cement and aggregates on the properties of concrete

## *Influence de l'interaction chimique et des agrégats sur les propriétés du béton*

U. AYAPOV, U.R.S.S.

Positive effect of accelerated chemical interaction of aggregates made from blast-furnace and phosphoric slag with cement on concrete properties was shown. This interaction was accelerated by pre-activation of grains surface of aggregates with water solutions of  $H_2SO_4$ .

Quantity of the studies on surface grain activation of aggregates and fine-grained additives to concrete and mortars is not so large though the actuality of this problem is not disputed.

It is shown in the study of Yurkul/I/ that during treatment of aggregates by polyhydroxiloxane emulsion [K]K-94 /GKZh-94/ new growth in the contact zone of aggregates with cement paste in the form of polyorganocalciumsiloxane appears which expands adhesion.

Ljubimova/2/ has suggested to treat the sand from quartzite by 10 % HCl and distilled water and following activation of it by the saturated solution of

calcium oxide. Such treatment in the author's opinion makes far better crystallization of calcium hydrosilicates on the more large particles of quartz sand which increases the strength of mortars. It was shown in /3/ that surface treatment of large aggregates with phthalic acid was enlarging the adhesion strength of mortars to 20-40 %.

According to USA Patent No. 395222/4/ the treatment of fly ash by water solutions of inorganic acids for example by 10% HCl concrete strength in the age of 72 hours has been increased almost 2 times. But it is necessary to point out that ash after acid treatment was not washed with water. Therefore the increase of the concrete strength in the earlier dates of hardening is possible to relate with acceleration of concrete hydration and hardening.

The treatment of aggregates from blast-furnace slags with HCl solution du-

ring 24-48 hours before the concrete preparation has also increased the bending strength of concrete to 15 %/5/.

The effect of increasing of adhesion strength of mortars with the surface of lining ceramic tiles was also found during treatment of surface of these tiles with the 5 % solution of HCl.

According to [7] freshly crushed materials are having increased adhesion strength with mortar which is explained by increased chemical activity of their surface.

Application of clinker from Portland cement as aggregates is increasing concrete strength to one order because of appearing of chemical bonding between aggregates and cement paste [8].

Taking into consideration that GKZh-94 and phthalic acid are expensive and scarce materials we have studied the influence of aggregates activation with water solutions of HCl which was comparatively cheap and not scarce product. Aggregates were prepared by the crushing of crystallized phosphoric and blast-furnace slags.

Blast-furnace slags consisted as a rule from melilite and gehlenite and phosphoric slags - from pseudo-wallastonite.  $P_2O_5$  content in it was ~ 2 % and F-content ~ 2,5 %.

In order to obtain optimal parameters of slag activation the kinetics of their destruction by water solutions of HCl was studied and phase composition of new growths was defined. In all cases the quantity of HCl solution was taken equal to 2h / T = 0,5 by volume.

For the preparation of concrete samples Portland cement -400 and sand from slag and natural sand with standardized grain composition were used.

Standard methods of preparation, hardening and testing of concrete samples were used.

Slag destruction rate was measured by the temporal pH values of water solution of  $H_2SO_4$  in comparison with the results of  $SO_4^{2-}$ -ions content determination in solution by chemical analysis.

Adhesion strength of grains of slag aggregates with cement paste was determined by testing of samples made in the form of number 8 in the middle of which prisms from aggregates with the dimensions corresponding to minimal cross-section of number 8 were placed.

Reaction kinetics between slags and water solutions of  $H_2SO_4$  is satisfactorily described by the first order equation:

$$k = -\frac{1}{\tau} \ln \frac{c}{c_0}$$

where  $c_0$  = initial concentration of

c = concentration at the moment  $\tau$

Limiting stage of the reaction possibly is  $H_2SO_4$  diffusion through the layer of hard-dissoluble new growth /gips and silica-gel/ formed on the grains surface.

Dependence of reaction rate constant from temperature in the Figure 1 shows that at the temperature 20-80°C this factor has insignificant meaning. Con-

sequently process of aggregates activation is possible to carry at usual temperatures without special lowering of its intensity.

It was found out by X-ray, petrographic and thermographic analyses that products of slag destruction by  $H_2SO_4$  are basically silica gel and gips which preferably are precipitated on the surface of grain aggregates.

Values of adhesion strength of activated aggregates from phosphoric and blast-furnace slags are given on the Figures 2 and 3. It is seen from them that there are optimal concentrations and period of preparation of aggregates. For example, for the aggregates from slags the best adhesion strength with cement paste is seen for the water solution of  $H_2SO_4$  with concentration 0,1 M and with the maintaining of aggregates in this solution during 12-48 hours.

During these periods of time difference between adhesion strength of aggregates with cement is not significant.

Adhesion strength of activated aggregates with cement is increasing more than 2 times after 7 days of concrete hardening and to 85 % after 28 days in comparison with the values for the non-activated aggregates. The effect of adhesion strength increase with cement for aggregates made from blast-furnace slags was on the average 10 % lower than for the aggregates from phosphoric slags.

When the concentration of  $H_2SO_4$  0,5-

-1,0 M/ solution increases adhesion strength of aggregates with cement paste lowers and the thickness of contacting layer increases. Thickness of zone in contact equal to 60-200  $\mu m$  corresponds to maximum positive effect. At the bigger concentrations of reagent stratification within contacting zone is taken place/Figure 4/. It is possible that at the bigger thicknesses of contacting zone its adhesion is determined exclusively by cohesion of new growths in solid state appearing during treatment of aggregates by the reagent. At optimal thicknesses of contacting zone its strength is conditioned by adhesion of low-based hydro-silicates with aggregates; these hydro-silicates are appearing as a result of interaction of hydrolyzed calcium oxide of cement with silica gel which is near the grains' surface of preactivated aggregates; therefore they in its turn are having more strong ion bond with original matter of aggregates.

It is necessary to consider paper of reference /9/ where it is shown that strength of adhesion coupling between aggregates and cement paste lowers as thickness of contacting layer increases.

Study of phase composition of new growths in contact zone of preactivated aggregates with cement paste has shown that they were as a rule gypsum, silica gel and gel-like calcium hydrosilicate C-S-H. Portlandite and calcium hydrosul-

foaluminate are also present. Contents of gypsum, silica gel, and C-S-H increases with the increase of  $H_2SO_4$  solution concentration and treatment time and contents of portlandite lower what is seen from thermographical and radiographical data/Figures 5 and 6/. Analogous data

were received during study of contacting zone between preactivated aggregates from blast-furnace slags and cement paste.

Data concerning water demands of concrete mixtures on the basis of activated phosphoric-slag aggregates are given in Table I.

It is possible to conclude from the data in Table I that aggregates activation considerably lowers water-demand of concrete mixtures. Concrete mixtures with concentration 0,1-0,5 M have the lowest water demand during seasoning equal to 1-3 hours.

Further increase of solution concentration and elongation of treatment lowers positive effect.

Data concerning stability of concrete made with activated aggregates from phosphoric slags are given on Figure 7.

It follows from these data that concretes with activated aggregates have strength which is 1,4-1,6 times/ by 100-200 kg/cm<sup>2</sup> / more than concretes made with non-activated aggregates.

For the preparation of steamed concretes positive effect of aggregates activation is higher when cement expenditures are higher. Optimal parameters of activation process of slag aggregates are:  $H_2SO_4$  solution concentration- 0,1-0,5 M; period of seasoning of aggregates- 1-3 hours. Solution quantity is 0,5 ton/m<sup>3</sup>.

Positive effect of slag aggregates activation may be used both for the obtaining of high-strength concretes of grades 500-600 using common cement of grade 400 by widely used technology of vibroformation and for the lowering of cement expenditures for concretes to 20-30 %.

Determination of strength and deformation properties of concretes with activated aggregates has shown that they at equal indications of strength are the same that the properties of concretes with usual aggregates. Special interest has various increase of adhesion strength of concretes on activated aggregates with steel framework/Table 2/, which allows to use activated aggregates for the preparation of pre-stressed concretes and constructions with steel framework.

Concrete mixture on the basis of activated phosphoric slag aggregates is recognized as the invention/IO/.

### Conclusions

It is shown that activation of surface grains of aggregates from blast-

furnace and phosphoric slags by maintaining them in weak water solutions of  $H_2SO_4$  considerably increases adhesion strength of them with cement paste, lowers water-demand of concrete mixtures or increases packability and causes increase of adhesion strength of concretes 1,4-1,6 times or allows to lower cement expenditures to 20-30 %.

Optimal parameters of activation of slag aggregates were elaborated. It was shown that new growth in the form of silica gel on grain surface of activated aggregates quickly reacted with hydrolysed calcium oxide of cement forming C-S-H- gel. Silica gel layer of 200.  $\mu m$  on the surface of aggregates grains was causing increased adhesion strength of it with cement paste and with original aggregates grains providing ion bond in contact zone.

It is possible to make chemical activation of concrete aggregates and solutions of every chemico- mineralogical composition using special methods and reagents which makes this branch rich in perspectives.

# The development of porosity in hydrated pastes and water-cement ratio

## *Evolution de la porosité dans les pâtes hydratées et rapport eau-ciment*

V. LACH, Professor Department of Building Material Technology, Technical University, Brno

M. ROSOVA, Assistant Department of Building Material Technology, Technical University Brno, Tchécoslovaquie.

**SUMMARY :** The development of porosity was studied on the pastes prepared from various cement samples and from cement clinker. The variables were: the water-cement ratio  $w$  (0.30, 0.35, 0.40 and 0.50) and the time of curing (7, 14, 28 and 56 days).

The microstructure of hardened pastes was determined by means of mercury porosimetry, X-rays diffractometry, thermography and observed by scanning electron microscope as well.

The various water-cement ratio  $w$  were manifested as follows:

- the porosity increases with water-cement ratio and decreases with the time of curing. The correlation could be expressed mathematically;
- the chemical and mineralogical composition and the fineness of cement influences the initial porosity more than the time of curing;
- with high water-cement ratio the hydrated components form coarser crystals as the product of "outer" hydration and
- the contact between the hydration products are not so frequent; this was found out by the scanning electron microscope.

**RESUME :** L'évolution de la porosité a été étudiée sur les pâtes préparées de ciments différents et de pure clinker de ciment. Les variables ont été: le rapport eau - ciment (0.30, 0.35, 0.40 et 0.50) et la période retenue (7, 14, 28 et 56 jours).

La microstructure des pâtes durcies ont été déterminées par la porosimétrie de mercure, diffraction X, l'analyse thermique et aussi observées dans le microscope électronique à balayage.

Les rapport différents eau-ciment ont manifestés comme suivit:

- la porosité s'agrandit avec le rapport eau-ciment et diminue pendant le temps de la conservation. La corrélation peut être exprimée mathématiquement;
- la composition chimique et minéralogique et la granulométrie influencent la porosité plus que le temps de la conservation;
- avec grand rapport eau-ciment les composants hydratés forment les grands cristaux comme les produits de la hydratation "extérieure" et
- les contacts entre les produits de la hydratation ne sont pas si fréquents, ce qui était trouvé par le microscope à balayage.

## INTRODUCTION

The properties of hardened Portland cement pastes depend not only on the amount and character of the solid phase, but also on the volume, diameter and shape of the pores (1). During the hydration and formation of the cement stone, a part of the water is more or less firmly bound into the solid phase and a part remains in the capillaries of the hardening paste. This water exerts a decisive influence onto the changes of the porous system in the microstructure of the cement paste during the hardening and influences the ratio between the solid and "zero" phase which together with the diameter and the shape of the pores determine eg. the strength characteristics of the cement stone, as has been shown by numerous authors, eg. Powers (2), Grudemo (3), Kondo and Daimon (4), etc.

The kinetics of pore system formation in the cement stone, dependent on its hardening time and conditions, on the mineralogical composition and the fineness of the cement, was studied eg. by Diamond (5), Chekhovsky and Berlin (6), etc. So far, however, it has not been sufficiently clarified.

The volume and the pore size distribution in hardened pastes can be determined by two methods: a) by calculation from either adsorption or desorption isotherms, or b) by calculation from the relationship between the pressure and volume of mercury intruded into the hardened paste. The results of these two methods differ and are limited by the diameter of the determinable pores, i.e. below 300 Å in the first case and in the range of 0.0075 to 7.5 µm in the mercury method. It is assumed that the total pore volume as measured by mercury intrusion is more nearly equal to the volume of evaporable water in saturated pastes (1).

In the cement stone microstructure can be found pores of various sizes. They are named in different ways according to their location and sizes. So far no unified classification has been worked out, so that the marking and division of pores differ from author to author (4).

On the basis of the previous as well as our own findings we divided the pores in a simplified manner according to their location in the microstructure into a) internal pores which appear in the gel and in the crystallites of the hydration products, and b) external pores formed between the gel and crystallite grains. With the division is also connected the diameter of the pores and the method of its determination (7).

Internal pores are determined by adsorption methods (small  $d < 12$  Å, large  $d > 12$  Å), external pores by mercury porosimetry (small  $d < 0.2$  µm, medium  $d = 0.2 - 1.0$  µm, large  $d = 1.0 - 15$  µm). With regard to the fact that in this way can be determined pores up to a size of  $d = 75$  Å, it is possible to classify according to the method employed the pores in the above manner.

In this study we are not dealing with inter-

nal pores that represent only a part of the total pore volume and are limited to the formed C-S-H phases, but with external pores. These pores are in the course of the cement stone formation subjected to considerable changes that are connected with the hydration of clinker minerals and their volume is also influenced by the employed water-cement ratio.

It follows from the above that with the aid of mercury porosimetry we are determining the volume and distribution of external pores, limited up to a diameter of  $d = 15$  µm, and we thus obtain knowledge about the formation and strengthening of the microstructure in the course of the hardening of the cement paste on the basis of changes of the pore system, in this case also with special reference to the effect of the water-cement ratio (w).

## EXPERIMENTAL

The samples chosen for the present studies were various Portland cements, slag-Portland cements and cement clinker. The properties of the samples are given in Table 1.

Pastes of a water-cement ratios  $w = 0.30, 0.35, 0.40$ , and  $0.50$  were prepared in the form of prismatic rods with the dimensions  $10 \times 10 \times 30$  mm. After 24 hours the prismatic rods were removed from the mould and conditioned under water. At the time of testing (7, 14, 28 and 56 days), the samples were dried for a period of 24 hours at  $105^\circ\text{C}$  and analyzed.

The development of pores in the microstructure of the hardened pastes was determined by mercury porosimetry. Apart from that, the samples were studied by means of thermal analysis, X-ray diffractometry and observed in the scanning electron microscope.

### Mercury porosimetry

The total pore volume TPV and the individual pore distribution IPD were determined in all samples. The minimum TPV were always obtained for a water-cement ratios of  $w = 0.5$  after 56 days of conditioning, the maximum TPV with ratios of  $w = 0.5$  after 7 days of conditioning. The clinker sample exhibited in both cases the smallest TPV, the slag-Portland cement samples M and H SPC 250 the highest TPV values.

Analysing the results it follows that the greatest influence onto the external pore volume is exerted by the water-cement ratio, as can be seen from a comparison of TPV values at  $w = 0.30$  and  $w = 0.50$  for a conditioning period of 7 and 56 days, respectively (Table 2).

The microstructure of the samples with  $w = 0.30$  exhibited roughly half the TPV value than for  $w = 0.50$ . It should be noted that the M PC 400 sample appeared as anomalous and approached the behaviour of slag-Portland cement.

If we compare the investigated range of the water-cement ratio  $w = 0.30$  and  $0.50$ , we find that already a small change in  $w$  causes

a large change of TPV. When the water-cement ratio is reduced e.g. by 0.01, TPV drops by 2.5 to 2.75%, i.e. absolutely 6 - 9 mm<sup>3</sup>/g after 7 days and 3 - 6 mm<sup>3</sup>/g after 56 days of conditioning. This fact confirms a considerable sensitivity of the water-cement system onto the amount of added water and the

favourable effect of additives that reduce this water amount.

Not only the total pore volume TPV, but also the individual pore distribution exhibits for various water-cement ratios w considera-

ble differences. The greatest changes occur for pores with a diameter of  $d = 0.20 \mu\text{m}$  through  $15 \mu\text{m}$ , as can readily be seen from Table 3.

The pores with the size  $d = 0.2 \mu\text{m}$  represent for  $w = 0.50$  after 7 days conditioning practically half of all the measured pores (43 to 55 %). This proportion of pores drops for  $w = 0.30$  to 7 - 15 % for Portland cements, with the exception of the anomalies observed in M PC 400. For slag-Portland cements it is different (54 and 16 %).

The proportion of pores  $d = 0.20 \mu\text{m}$  can decrease markedly for  $w = 0.50$  after 56 days (11 to 21 %) and approached the values for  $w = 0.30$ .

The reduction of the total pore volume TPV is caused by the filling of the pores with hydration products and partly also by the overall shrinkage of the hardened paste. The hydration products are readily formed in the region of water filled pores, so that the large pores are reduced and the small ones even filled up. Since for  $w = 0.50$  has occurred in contrast with  $w = 0.30$  a considerable decrease of the  $d > 0.20 \mu\text{m}$  pore volume, it can be assumed that the hydration products are crystallically better developed due to the influence of the present liquid phase. In other words, in this case prevails the "outer" hydration over the "inner" hydration which leads rather to gel and imperfectly developed products (8).

As is generally known, a reduction of the water-cement ratio  $w$  leads to the growths of strengths. With regard to the previous findings, this is caused on one hand by a smaller total pore volume TPV and thus by a denser microstructure, on the other hand also by a greater tendency for the formation of gel and imperfectly developed hydration products. Cohesion and adhesion are caused by surface forces, especially by the influence of the huge surface of the C-S-H gel, whose proportion in the microstructure also increases the strengths of the hardened paste. The crystalline products exhibit on the other hand a smaller specific surface and thus also a smaller number of contacts, so that the mechanical properties show a decrease.

The total pore volume TPV was influenced also by the type of cement. The group of Portland cements forms microstructures which have smaller TPVs than slag-Portland cements. As long as differences exist among Portland cements, this can be attributed to the influence of the fineness of grinding. An exception is represented by the Portland cement M PC 400.

Both slag-Portland cements have TPVs in comparison with Portland cements larger by 21 and 45 % ( $w = 0.50$ ) and by 58 and 32 % ( $w = 0.30$ ), respectively, after 56 days of conditioning. The filling of pores with hydration products occurs more slowly also for  $w = 0.50$ . That means that slag-Portland cements do not exhibit such a tendency for the formation of hydration products that grow into the pores, and that hydration takes place more slowly

even for a higher  $w$ . The larger porosity of the microstructure of slag-Portland cements is caused by the presence of slag and its slow hydration. This is the reason why the formed gel and sparsely crystalline hydration products, despite their favourable binding properties, are not able to compensate the low compactness of the microstructure of the hardened paste. This explains the worse mechanical properties of the slag-Portland cements and also the phenomenon that only after a very long period of conditioning they approach with their porosity the Portland cements. The differences in the volume and distribution of pores between the two slag-Portland cements are caused by a different "activity" of the slag and their fineness of the cement.

The total pore volume TPV for the M clinker attained the smallest values. The microstructure of the hardened paste was in all cases the most compact.

The influence of the conditioning period was the same in all the samples. The total pore volume TPV gradually dropped, until it reached the smallest values after 56 days. The water-cement ratio exhibited no substantial influence onto the course of TPV reduction, as can readily be seen from Table 4.

From this follows the important conclusion that TPV depends even after a long conditioning period on the starting TPV, and that the porosity dependent properties of the hardened paste can by conditioning be improved only to a certain extent, as the pores are gradually depleted.

We have tried to express the development of

pore mathematically. By plotting TPV against time, the curves of an exponential character were obtained (Fig. 1), for which holds true

$$TPV = a \cdot e^{-\alpha \tau} + b \quad (1)$$

where TPV is the total pore volume,  $\tau$  the conditioning period and  $\alpha$ ,  $a$ ,  $b$  are constants.

Figure 1

It can be assumed that the total pore volume TPV will not practically change any more with time after 56 days and it can therefore be used as the orientational value  $b$ . By introducing the water-cement ratio into the calculation and from the known values of TPV,  $\tau$  and the orientational value  $b$  were determined the values  $a$ ,  $b$  and  $\alpha$  for each water-cement ratio and shown graphically (Fig. 2).

Figure 2

The plots  $a = f(w)$  and  $b = f(w)$  can be taken as straight lines and expressed by the relationships

$$a = (Aw + B) \quad (2)$$

$$b = (Cw + D) \quad (3)$$

The relationship  $\alpha = f(w)$  was expressed by a parabola according to the relationship

$$\alpha = (p_2 w^2 + p_1 w + p_0) \quad (4)$$

This dependence can also be expressed expo-

nentially by the relationship

$$\alpha = (p + q^{-rw}) \quad (5)$$

By substituting the constants  $a$ ,  $b$  and  $\alpha$  into equation (1) are obtained the following TPV depletion equations against time  $\tau$  and the water-cement ratio  $w$ :

$$TPV = (Aw+B) \cdot e^{-(p_2 w^2 + p_1 w + p_0) \cdot \tau} + (Cw+D) \quad (6)$$

$$TPV = (Aw+B) \cdot e^{-(p+q^{-rw}) \cdot \tau} + (Cw+D) \quad (7)$$

The above equations were verified on the actual case of the H PC 400 sample and the following parameters were calculated:

$$a = -219.46 + 945.75 w \quad (2')$$

$$b = -26.73 + 350.35 w \quad (3')$$

$$\alpha = -0.3364 + 1.1506 w - 1.2743 w^2 \quad (4')$$

By substituting into equation (6), we obtained for this sample the equation

$$TPV = (945.75w - 219.46) \cdot e^{-(0.3364 - 1.1506w + 1.273w^2) \cdot \tau} + (350.35w - 26.73) \quad (6')$$

The calculated and determined TPV values

shown in Table 5 indicate a good agreement of the two values and confirm the significance of the water-cement ratio  $w$  and the starting pore volume TPV.

#### Thermal analysis

The thermal analysis was suitable for the determination of  $\text{Ca(OH)}_2$  and  $\text{CaCO}_3$ . The amount of  $\text{Ca(OH)}_2$  increased with the water-cement ratio and with the conditioning period  $\tau$  up to 28 days. After that they do not change any more. With slag-portland cement the amount of  $\text{Ca(OH)}_2$  did not change

practically after 14 days and grew slightly with a larger water-cement ratio  $w$ . It was possible to ascertain that the quantity of bound water has grown with the conditioning period  $\tau$  and the water-cement ratios  $w$  in all the samples on the average by 30 to 45%.

#### X-ray diffractometry

By X-ray diffractometry the presence of C-S-H phases, portlandite and calcite, apart from non-hydrated clinker minerals, especially  $\beta$ -C<sub>2</sub>S, was identified. Also weak lines belonging to ettringite and C<sub>4</sub>AH<sub>13</sub> were found. In certain Portland cement samples were also determined weak lines  $d_{hkl} = 11 \text{ \AA}$ .

#### Scanning electron microscopy

The examination of fracture surfaces on selected samples showed that differences exist in the morphology of the microstructure, in the arrangement and appearance of the hydration products. These differences were caused mainly by the type of cement and the water cement ratio  $w$ . Samples with  $w = 0.50$  contained a larger quantity of crystalline phases that formed a maize of rods and similar aggregations as a result of the "outer" hydration. The contacts between these hydration products were not as frequent as in the "inner" hydration products. Great differences in the microstructure were found between Portland and slag-portland cement. In all the samples could be seen a heterogeneity of the microstructure and changes in the micro-regions given by the mineralogical composition of the cement and the presence of the water in the above region.

#### CONCLUSIONS

The studies of external pores in the hardened cement pastes have shown that their volume and distribution depend on

- water-cement ratio  $w$
- curing time  $\tau$
- type and fineness of cement

The water-cement ratio  $w$  influences the total starting external pore volume TPV which is reduced exponentially with the conditioning period  $\tau$ , as has been shown mathematically. Hardened pastes with a higher water-cement ratio  $w$  have after the same time  $\tau$  higher TPV's than pastes with a smaller water-cement ratio. The above holds true for  $w = 0.30$  to  $0.50$ .

The total pore volume TPV depends also on the mineralogical composition and the fineness of the cement. With the same  $w$ , various types of cement have a different initial total pore volume TPV which though uniformly reduced with the conditioning period  $\tau$ , still leads again to differences in the final TPV values. Greater differences were found between Portland cement on one hand and slag-portland cement on the other hand. With a high water cement ratio ( $w = 0.50$ ) the better cristallized hydration products in the form of rods and similar aggregates were formed in the microstructure of hardened cement pastes. The portlandite crystals were in the larger form. But the contacts among these products were not as frequent as in the "inner" hydration products.

Because the mechanical properties of hardened pastes depend to a considerable extent on the porosity, the results about the development of pores during hardening very important. In this case have been investigated only external pores in the range of  $d=0.015$  to  $15 \text{ \mu m}$  by means of mercury porosimetry. The results have confirmed that in this range a significant proportion of pores lies in the hardened paste so that though them can be characterized the development of porosity. The knowledge about microstructure with respect to the total volume, diameter, shape and orientation of the pores contributes to the understanding of the behaviour and properties of the hardened cement during the hydration and represents a valuable contribution to the application of the cement in the practice.

# Pore structure of cement stone and its influence on the mechanical properties of concrete

## *Structure poreuse du ciment durci et son influence sur les propriétés mécaniques du béton*

G. BOZHINOV, Senior Res. Associate, M. Sc., C.E.,  
N. BAROVSKY, Junior Res. Associate, C.E., Bulgaria.

**RESUME :** En vue de programmer des expériences et d'élaborer un modèle mathématique, on a cherché à déterminer l'influence de facteurs technologiques généraux sur la porosité du ciment durci. On a aussi recherché la relation entre la résistance à la compression du béton et le volume total de ses pores.

Les facteurs technologiques pris en compte sont : le rapport E/C - la teneur en gypse ajouté - la finesse de mouture du ciment - et la durée de l'hydratation à la vapeur. La porosité est représentée par le volume total des pores et par les volumes des pores dont les rayons sont inférieurs à cent et à mille Å. Ces volumes sont rapportés aux facteurs ci-dessus. On a cherché à déterminer l'influence de chacun de ces facteurs, pris isolément, ou considérés ensemble, sur ces volumes de pores.

On a constaté l'influence dominante du rapport E/C sur la porosité du ciment durci. L'augmentation de la finesse de mouture du ciment diminue le volume total des pores, et surtout diminue fortement les deux autres volumes partiels. L'influence combinée du rapport E/C et de la finesse de mouture est beaucoup plus compliquée et varie avec le temps.

La relation entre la résistance à la compression et la porosité du béton a été représentée graphiquement. Elle a été examinée, en tenant compte du mode de formation des pores, de la composition du béton et des caractéristiques superficielles du granulat.

**SUMMARY :** On the basis of the method of experimental design and mathematical modelling an attempt is made to evaluate the influence of the main technological factors on the porosity of cement stone. The relation between total pore volume and compressive strength of concrete is established as well.

The factors involved are: water/cement ratio, gypsum additive, dispersity of cement and duration of steam curing. The porosity of cement stone is presented by the total pore volume and partial pore volumes of pores with radii up to  $10^2$  Å and  $10^3$  Å respectively. This pore volumes are considered as functions of observable responses being affected by the factors mentioned above. Their individual and joint effects on the pore structure of cement stone are evaluated.

It is shown that the W/C ratio plays a dominant role in the process of pore structure formation. Dispersity of cement causes some reduction of the porous space. Its effect is strong exceptionally on the partial pore volumes. The joint effect of W/C ratio and fineness of cement is more completely and should be regarded in time.

The strength/porosity relation of concrete is discussed in terms of the pore structure formation, composition of concrete and features of contact zone.

## INTRODUCTION

The mechanical properties of cement stone and concrete are strongly dependent on the structure of their porous space (1,2,3). It is also shown, that the mechanical behaviour of cement stone is influenced both by the total pore volume and pore size distribution (4). The latter is defined by means of the volumes of pores with radii up to  $10^2 \text{ \AA}$  ( $V_p^x$ ) and  $10^3 \text{ \AA}$  ( $V_p^{xx}$ ).

In this paper some results are presented and discussed to estimate the complex influence of the main technological factors on the pore structure formation of cement stone. For that purpose the method of experimental design and mathematical modelling is used (5,6). The relation between total pore volume and compressive strength of concrete is given as well.

## EXPERIMENTAL PROCEDURE

A pure clinker cement ( ZP - 78 ) is used with following mineral composition (%):  $C_3S = 60,24$ ;  $C_2S = 18,30$ ;  $C_3A = 6,63$  and  $C_4AF = 8,78$ . The factors involved in experiments are as follows: water/cement ratio (W/C); gypsum additive ( $SO_3$ ); Blaine fineness ( $S_B$ ) and duration of steam curing at  $358 \pm 5^\circ \text{ K}$  ( $\tau$ ). Their levels are presented in Table 1.

TABLE 1				
$X_i$	Factors and dimensions	Levels		
		$X_{i,min}$	$X_{i,o}$	$X_{i,max}$
$X_1$	W/C ratio	0,30	0,40	0,50
$X_2$	$SO_3$ (%)	2,50	3,00	3,50
$X_3$	$S_B$ ( $m^2/g$ )	0,22	0,36	0,50
$X_4$	$\tau$ (hours)	6	8	10

A parallel experimental block of specimens including the factors  $X_1$ ,  $X_2$  and  $X_3$  is cured under water ( $T = 293 \pm 2^\circ \text{ K}$ ). These specimens are tested at 1,3 and 28 days.

The factors  $X_i$  mentioned above are coded into nondimensional co-ordinates  $x_i$  by the formula:

$$(1) \quad x_i = \frac{X_i - X_{i,o}}{\Delta X_i}$$

where:

$$(2) \quad \Delta X_i = 0,5(X_{i,max} - X_{i,min}).$$

The function of observable responses  $Y_p$  is searched as polynomial of second order in the form:

$$(3) \quad Y_p = b_0 + \sum_{i=1}^n b_i x_i + \sum_{i=1}^n b_{ii} x_i^2 + \sum_{i < j} b_{ij} x_i x_j$$

where:  $Y_p$  is characteristic of the porosity ( $\ln V_p$  and  $\ln V_p^{xx}$  - for water cured specimens;  $\ln V_p$  and  $\ln V_p^x$  for steam cured specimens);

$n = 3$  for water curing;

$n = 4$  for steam curing.

The total pore volume ( $V_p$ ) of cement stone is determined by using both the mercury pressure porosimetry and a physico-chemical method according to the relation:

$$(4) \quad V_p = \left[ 1 - \frac{C_0(1 + n_t)}{\rho_{c,s}} \right] \cdot 100 \quad (\%)$$

where:  $C_0$  is quantity of the cement in  $1 \text{ cm}^3$  cement paste ( $\text{g/cm}^3$ );

$n_t$  - chemical bound water ( $\text{g/g}$ );

$\rho_{c,s}$  - specific gravity of cement stone ( $\text{g/cm}^3$ ).

The partial pore volumes ( $V_p^x$  and  $V_p^{xx}$ ) are calculated from the integral curves of porosity obtained by means of the mercury porosimeter "CARLO ERBA", mod.1540. The concrete specimens (cubes sized  $10 \times 10 \times 10 \text{ cm}$ ) are prepared using the same cement with  $S_B = 0,5 \text{ m}^2/\text{g}$  and  $SO_3 = 3,5 \%$ , and with different water/cement ratios  $0,45 - 0,65$ , sand/cement ratios by weight  $K = 1 - 3$  and gravel/cement ratios  $L = 3 - 4$ . Pure quartz sand with fineness modulus  $2,86$  and river gravel with  $D_{max} = 20 \text{ mm}$  are used

The total volume of pores in concrete  $V_p^c$  is calculated from the following relation:

$$(5) \quad V_p^c = \frac{V_p(1-V_a)}{1 + \frac{C_o K}{S_s} + \frac{C_o L}{S_g}} + V_a \quad (\%)$$

where:  $V_a$  is air content (%);  
 $S_s$  and  $S_g$  are specific gravity of the sand and gravel respectively.

The evaluation for the individual and joint influences of the factors investigated on the total and partial pore volumes of cement stone is made on the basis of the values and signs of coefficients of regression equations.

The relation between the total pore volume and compressive strength of concrete is presented grafically. The curves are drawn on the basis of the Chebishev's polynomial of second order.

## RESULTS AND DISCUSSION

The change of the coefficients of regression equations during the time for water cured specimens is shown in Fig. 1.

It can be seen that the total porosity of cement stone decreases during the time, while the partial pore volume  $V_p^{xx}$  increases. In the centre of experimental block ( $W/C = 0,40$ ;  $SO_3 = 3,0\%$ ;  $S_B = 0,36 \text{ m}^2/\text{g}$ ) their values are very close ( $b_0 \approx b_0^{xx}$ ).

The total porosity increases with increasing of  $W/C$  ratio and the influence of this factor is intensified during the time. This is likely due to the larger free space in which new hydrate products arise. The effect of the same factor is demonstrated more clearly on the partial pore volume (see curve  $b_1^{xx}$ ).

The smaller the  $W/C$  ratio in the earlier stage of hardening the bigger is the partial pore volume. This effect is also intensified during the time, remaining smaller than it is on the total porosity.

Fig. 1 - Coefficients of regression equations vrs. the time. Compact curves -  $V_p$ , dotted curves -  $V_p^{xx}$ .

In general the influence of water/cement ratio on the pore structure formation is dominant.

The increase of dispersity of cement causes some reduction of the porous space, which is due to the larger reactive surface of cement grains. The effect of this factor at earlier ages is exceptionally strong on the partial pore volume  $V_p^{xx}$ . It remains as a dominant factor up to 5 - 6 days (cross - point of lines  $b_3$  and  $b_3^{xx}$ ).

The joint influence of  $W/C$  ratio and fineness of cement on the partial pore volume is illustrated by the coefficient  $b_{13}^{xx}$ . It can be seen that this effect changes its direction during the time. It means that the positive joint effect of these two factors on  $V_p^{xx}$  could be obtained either by combination of lower  $W/C$  and higher dispersity of cement at 1 day, or higher values

of W/C ratio and Blaine fineness of cement at 28 days.

During the first 3 days of hardening gypsum additive does not effect observably the porosity of cement stone. The higher values of this factor lead to some increasing of total porosity at 28 days, which is probably due to the ettringite destruction under conditions considered.

The regression equations for the steam cured specimens are as follows:

$$(6) \ln V_p = 3,429 + 0,251 x_1 - 0,030 x_3 - 0,038 x_4 ;$$

$$(7) \ln V_p^x = 1,881 + 0,286 x_3 + 0,290 x_4 + 0,112 x_3^2 - 0,191 x_4^2 + 0,104 x_2 x_3.$$

The total pore volume  $V_p$  is dependent mainly on the W/C ratio, while the influence of dispersity and duration of steam curing is quite feeble (eq.6).

More complicated is the influence of the factors considered on the partial volume of pores with radii up to  $10^2 \text{ \AA}$  ( $V_p^x$ ) (eq.7). Positive individual effects on  $V_p^x$  are demonstrated by the dispersity ( $x_3$ ) and duration of steam curing ( $x_4$ ). The presence of quadratic effects, however, deform essentially the influence of these factors: in the first case ( $x_3$ ) the effect is reinforced, while in the second case ( $x_4$ ) the effect is strongly reduced. The prolonged steam curing leads to some decrease of dispersity of hydration products, which reflects into decreasing of partial volume  $V_p^x$ .

The effect of gypsum additive is only manifested jointly with the dispersity of cement. It is shown that the simultaneous increase of the factors causes increasing of  $V_p^x$ .

The relation between the total porosity and compressive strength of concrete is presented in Fig.2 and Fig.3.

The experimental points relate to concretes with different compositions (varied ratios: W/C; K and L) and corresponding pore volumes after formula (5). In general the re-

sults presented confirm the well-known character of strength/porosity relation.

Fig.2 - Strength/porosity relation for concrete cured under water

Fig.3 - Strength/porosity relation for concrete at steam curing

It should be pointed out that such a relation is not only determined by the total porosity, but is also necessary to take into account the pore size distribution and the thickness and properties of contact zone. It means that the relation between strength and total porosity is also affected by the quantity and surface of the aggregates, adsorbed water, etc. The total pore volume decreases with increasing the ratios K and L, and the contact surfaces increase too. Both they stimulate the increa-

sing of the strength of concrete. During the time total porosity of cement matrix decreases, a redistribution of pore size takes place and this also leads to the increasing of compressive strength (Fig.2). In addition the contact zone in the steam cured specimens is weakened to a greater extent and this affects adversely the strength of concrete (Fig.3). A comparison of the results presented in Fig.2 and Fig.3 shows that the relation "strength/porosity" for steam cured specimens is very close to the same relation for water cured specimens at 3 days.

#### CONCLUSION

The individual and joint effects of the main technological factors on the total and partial pore volumes of cement stone are evaluated. It is shown that the W/C ratio plays a dominant role in the process of formation of pore structure of cement stone. Dispersity of cement causes some reduction of the porous space. Its effect is strong exceptionally on the partial pore volume  $V_p^x$ .

The joint effect of W/C ratio and fineness of cement is more completely and should be regarded in time.

Gypsum additive demonstrates its effect at the later ages of hardening (28 days).

The influence of the factors considered on the total porosity of steam cured cement stone is analogous to that concerning the water cured specimens. In this case, however the effect of dispersity is quite feeble.

The partial pore volume here is presented by the volume of pores with radii up to  $10^2 \text{ \AA}$  ( $V_p^x$ ). It is shown, that the presence of quadratic effects deform essentially the effect of dispersity of cement and duration of steam curing.

The effect of gypsum additive is only manifested jointly with the fineness of cement.

The relation between the compressive

strength of concrete and its porosity is presented grafically and discussed in terms of the pore structure formation, composition of concrete and features of contact zone.

# Behaviour of reinforced concrete under the action of flue gases as a function of the cement composition

## *Comportement du béton armé sous l'action des gaz de fumée en fonction de la composition du ciment*

W. TISCHER, Dr. rer. nat., University-Lecturer, Technische Hochschule Leipzig, DDR.

SUMMARY : Chemical changes by the action of flue gas on reinforced concrete take place first of all by the reactivity of the sulphur oxides with the components of the hydrated cement. Their damaging influence consists first of all in the formation of crystalline phases in the structure of the hydrated cement caused by the sulphite and sulphate formation, above all of the calcium. Analogous to the term of the carbonatisation the change of the cement concrete caused by the action of gaseous sulphur oxides is designated with sulphatisation. Contrary to the carbonisation it is no process happening naturally at the concrete because the sulphur oxides do not belong to the normal components of the air, but come in the flue gas only by combustion processes of sulphurous compounds of the fuels or arise by chemical conversions in other large-scale processes, so that the air in industrial areas contains, in general, increasingly sulphur oxides. In an accumulated form these sulphur oxides are contained as components of the flue gases of lignite furnaces which are particularly discussed in this paper.

## 1. Sulphatisation

As to the course of the sulphatisation there is an extreme parallelism with the carbonisation. In the same way as in the carbonisation it happens a neutralisation of the basic environment and thus a reduction of the pH value in the hydrated cement up to in ranges, in which a natural protection of the reinforcing steel does not exist. But owing to the stronger acid properties of the sulphur oxides as compared with the carbon dioxide some deviating modes of behaviour must be observed.

The oxides of the sulphur and their acids do not only convert with the strongly basic calcium hydroxide, but also with the less basically reacting salts of the hydrated cement subjected to the hydrolysis as well as with the product of the carbonisation, the calcium carbonate. The oxides of the sulphur with an acid reaction disturb the hydrolysis equilibria of the hydrated cement and owing to the low solubilities of the

hydrolysis products a slow structural change takes place:  
e.g.

As a result of the water being available only to a limited extent and the temperatures exceeding 50 °C there is a fundamental difference between the action of sulphur oxides and the concrete corrosion caused by sulphate ions in aqueous solution and arising because the formation of ettringite. The observation that at the penetration of the concrete with moisture a carbonatisation is excluded seems not to hold in the same strict measure with regard to the sulphatisation as the oxides of the sulphur possess a very good solubility in the water and the acids arising react already in the dilute state with the basic substances. That became obvious from the material change of concrete cubes hung in the chimney mouth and frequently penetrated with moisture, at which an outer layer of some millimetres of thickness with a high content of calcium was arisen. The sulphatisation is always the change of the hydrated cement structure occurring after the carbonatisation and then passing together with it. As to the sulphation velocity there are analogous considerations as with the carbonatisation. The concrete possesses by the arising calcium sulphate a greater diffusion resistance to penetrating gases than in the carbonatisation because the final product of the conversion possesses a volume being enlarged by 124 % as compared with the solid starting material and thereby may lead to the bursting corrosion.

For the reactivity of the gas with the solid matter the presence or the absence of water is decisive. If no water is present, also not in the gaseous phase, no chemical conversion, e.g. between  $\text{CaCO}_3$  and  $\text{SO}_2$ , is virtually detected in the temperature range up to 150 °C / 1 /. The sulphur dioxide is only physically adsorbed on the solid matter surface. In the presence of water and sulphur dioxides it happens a mixed adsorption on the solid matter surface. In this case the sulphur dioxide reacts with calcium sulphide or calcium hydrogen sulphide and an oxidation to the sulphate may secondarily happen. Ettringite which arises in the presence of sulphateous solutions in the concrete was not detected after flue gas action at temperatures up to 200 °C. From this behaviour it is derived that the corrosion of the cement concrete in the flue gas cannot be equated with the process in solutions containing sulphate ions. That has consequences as to the cement selection with regard to the  $\text{C}_3\text{A}$  content at such aggressive stresses. Indeed, the sulphur trioxide is contained in the flue gas in a considerably smaller concentration than the sulphur dioxide, yet in particular because of the strong and stable sulphuric acid arising from it as well as of the raise of the acid dew point resulting from the presence of the sulphur trioxide it is a highly important component to the concrete corrosion in the flue gas atmosphere.

## 2. Action of Sulphur Oxides on Pure, Hydratised Cement Clinker Minerals

Owing to the very versatile composition of the cements and the hydrated cement resulting from them it is very difficult to determine on which its chemical resistance is dependent. In order to detect more exactly with which components the sulphur oxides do mainly react, their reactivity to the pure, hydrated main clinker materials is investigated / 2 /. In laboratory tests hydrated  $\text{C}_3\text{S}$ ,  $\text{C}_2\text{S}$ ,  $\text{C}_3\text{A}$  and  $\text{C}_4\text{AF}$  were exposed in the presence of water at a temperature from 125 to 130 °C in closed glass flasks to the action of gaseous sulphur dioxide and after a longer period their sulphate content determined.

**Table 1:** Change of the concrete properties by sulphatisation

Concrete Properties	Influence by Sulphatisation
Corrosion protection of the reinforcement	Decomposition of the passive layer on the steel owing to the reduction of the pH value and action of sulphate ions
Compressive strength	Increase of strength in the initial stage by incorporated $\text{CaSO}_4$ , bursting corrosion is possible in the later stage, above all at subsequent moisture action, formation of cracks
Permeability	In the initial stage reduction by incorporation of calcium sulphate, in the later stage increase by developing micro-flaws
pH value	Decrease by conversion of the basic components of the concrete with sulphur oxides with acid reaction
Efflorescences	Reduction, easily soluble, surface-near calcium hydroxide is converted into sulphite or sulphate being more hardly soluble
Bond of protective layers	Improvement of the bond with alkali-sensitive protective layers such as polyester or polyurethanes by neutralisation

**Table 2:** Sulphate content in hydrated cement clinker minerals (approximate values)

Cement Clinker Mineral	Sulphate Content in Weight Percentage	
	after 12 months of period of action	after 36 months of period of action
$\text{C}_3\text{SH}_x$	29	57
$\text{C}_2\text{SH}_x$	15	59
$\text{C}_3\text{AH}_x$	9	46
$\text{C}_4\text{AFH}_x$	14	50

During the twelve months of period of action of the sulphur dioxide a reaction takes preferably place with the hydrated cement clinker minerals which split off the strongly basic calcium hydroxide. The hydrated  $\text{C}_2\text{A}$  reacts at the temperatures up to  $130^\circ\text{C}$  first only on a small scale with the sulphur oxides. If the period of action goes on, indeed, the sulphur absorption increases considerably, but in the final result  $\text{C}_3\text{AH}_x$  contains after 36 months of period of action of the sulphur oxides the smallest part of combined sulphur of the four main clinker minerals.

### 3. Conclusions from the Investigations

From the results of investigation it can be concluded that the action of gaseous sulphur oxides on cement concrete cannot be equated with the action of solutions containing sulphate ions. That is due to their reaction in the presence of only a small quantity of water and the temperatures as high as about 200 °C. Under these conditions the hydrous calcium sulphate aluminate hydrate (ettringite) being instable at temperatures above 50 °C cannot arise and is instable. If concrete is used under these conditions, the C<sub>3</sub>A content may have the values of a normal portland cement and a C<sub>3</sub>A-poor cement must not be used.

# Influence du dosage et de la nature du liant sur les propriétés de certains bétons réfractaires

## *Influence of dosage and binder type on the properties of some refractory concretes*

I. TEOREANU, Professor, Faculty of Chemical Technology, Bucharest Polytechnical Institute,  
N. CIOCEA, Scientific researcher, Bucharest Polytechnical Institute, Roumanie.

**RESUME:** On présente les propriétés de certains bétons réfractaires, à teneur élevée en  $Al_2O_3$ , lorsque la proportion de liant hydraulique varie entre 15 et 25 %. On met en évidence surtout, le rôle de la finesse de broyage et de la composition chimico-minéralogique du ciment sur les propriétés des bétons.

Les propriétés de ces bétons ont été déterminées par les échantillons gardés à l'air, ainsi qu'après leur cuisson à de diverses températures.

**SUMMARY:** The properties of some refractory concretes of high alumina content, if the hydraulic binder ratio there is in the range 15 - 25 % are shown. The effect of grinding fineness and cement chemical - mineralogical composition upon concrete properties is presented. The properties of these concretes were determined both on unfired samples kept in air and on samples fired at different temperatures.

Dans de diverses applications industrielles, on sollicite des bétons réfractaires à résistance satisfaisante à l'attaque chimique ou bien à l'érosion de certaines poudres, dans des conditions des températures élevées qu'intermédiaires (1-5). Conformément à de pareilles exigences on peut utiliser des bétons réfractaires à base de ciment alumineux; avec des agrégats, dont la granulation maximale est de moins de 3 mm (2, 6). En vue de la réalisation de pareils bétons, dans le travail ci-présent, on a examiné l'influence, sur leurs caractéristiques, de la composition chimico-minéralogiques, de la finesse de broyage et du dosage du ciment employé.

La caractérisation des ciments utilisés.  
Pour la préparation des bétons qui ont constitué l'objet des investigations de ce travail, on a utilisé 5 types de ciments alumineux, dont les compositions minéralogiques, ainsi que les caractéristiques initiales de dispersion, l'eau de consistance normale et le temps de prise sont présentés dans le Tableau I

avec les calculs des compositions minéralogiques (dont les résultats sont inscrits dans le Tableau I).

Fig. 2- Roentgénogramme du Ciment 2

TABLEAU I

Symbole du ciment	Al <sub>2</sub> O <sub>3</sub> %	Composition minéralogique (déterminée par calcul) <sup>x</sup>	Finesse de broyage, refus sur le tamis de 0,06 mm %	L'eau de consistance normale, %	Le temps de prise, heures-minutes	
					Commencement	Fin

P <sub>2</sub>	40 % CA <sub>2</sub>	60,0	0,00	0,00	100,00	4220

élevée, qui a été observée, dans le cas de l'utilisation des mélanges de bétons réalisée avec le ciment 4, dont la surface spécifique est d'approximativement  $4700 \text{ cm}^2/\text{g}$

#### Bétons réfractaires à haute teneur en $\text{Al}_2\text{O}_3$

Dans les bétons réfractaires, formés à la base des types de ciments plus haut mentionnés, ont été utilisés des agrégats d'alumine tabulaire avec les granulations suivantes : 8-14 mesh, 28-48 mesh, - 100 mesh et - 325 mesh.

Pour suivre l'influence du dosage de ciment sur les propriétés des bétons, on a utilisé 3 variantes de recettes, qui sont présentées dans le Tableau III.

TABLEAU III

La dénomination des composants solides des bétons	Dosage, %		
	Variante		
	I	II	III
L'alumine tabulaire	75	80	85
Ciment alumineux	25	20	15

Avec les ciments obtenus après le premier broyage, ayant les granulations présentées dans le Tableau II (et notées symboliquement : 1, 2, 3, 4 et P), on a réalisé les 3 variantes de recettes. Leurs caractéristiques sont présentées dans le Tableau IV

plus grand de ciment en béton, la quantité d'eau est plus grande elle-aussi, tandis que le rapport eau/ciment est plus petit. La masse volumique des échantillons noncuits augmente, généralement, en rapport avec le baissement de la proportion de ciment (l'augmentation de la proportion de  $\text{Al}_2\text{O}_3$  du béton) et de l'eau de mise en oeuvre.

La résistance mécanique des bétons (appréciée par la résistance à la traction et à la compression) après un jour et trois jours de conservation dans une atmosphère humide varie en rapport avec la proportion de ciment.

Les plus grandes variations sont enregistrées, surtout, dans le cas des ciments faiblement broyés.

De même, les bétons exécutés avec des ciments faiblement broyés ont aussi des résistances mécaniques plus basses. Pour cela, pour suivre l'influence de la finesse de broyage du ciment sur la résistance mécanique des bétons durcis, après la conservation à l'air et après le séchage et leur cuisson, on a préparé aussi des bétons avec les types de ciment broyés à une plus grande finesse.

Dans le Tableau V on peut observer l'influence simultanée de la nature du ciment, de sa finesse et son dosage sur les résistances à la compression des bétons obtenus des ciments 1-4 et P (on garde les mêmes dosages de ciments que plus haut : I-25 % ; II - 20 % et III - 15 %, mais on utilise tous les ciments, broyés à de diverses fines- ses, qui sont données dans le Tableau II :

TABLEAU IV

Symbole du béton	La proportion de ciment, %	L'eau de mise en oeuvre, %	Le rapport eau/ciment	La masse volumique du béton durci, $\text{kg}/\text{dm}^3$	La résistance à la traction, $\text{daN}/\text{cm}^2$		La résistance à la compression, $\text{daN}/\text{cm}^2$	
					1 jour	3 jours	1 jour	3 jours
I - 1	25	9,6	0,39	2,92	93,5	101,0	180	400

à un traitement de chauffage ( avec une conservation à la température respective de séchage et de chauffage de 5 heures) ont eu une période de 3 jours de conservation dans l'atmosphère humide, avant d'être introduits au chauffage.

De l'analyse du Tableau V, il en résulte que les résistances mécaniques à la compression sont fortement influencées par la finesse de broyage du ciment.

L'influence de la surface spécifique est corrélée avec la composition minéralogique et le dosage de ciment, elle étant plus accentuée dans le cas des ciments plus alumineux (à une teneur plus élevée en  $Ca_2$ , dont la vitesse d'interaction avec l'eau est plus petite que celle des aluminates de calcium plus basiques) et des dosages plus petits de ciment. Comme suite, l'influence positive de l'augmentation du dosage de ciment, dans les limites examinées devient elle-aussi plus importante dans le cas de l'utilisation de certains ciments à surfaces spécifiques élevées. De même, les ciments plus alumineux (à teneur en  $Ca_2$ )(7)

développent des résistances mécaniques plus élevées que les ciments plus basiques, dans des conditions équivalentes de surface spécifique mais à des valeurs plus élevées de celle-ci.

Les résistances mécaniques de tous les bétons cuits atteignent un minimum dans le domaine de température 950-1100°C, après quoi elle connaissent une nouvelle augmentation, comme suite du commencement de la syntérification et de la réalisation de la liaison céramique. Des déterminations présentées dans le Tableau V, il paraît que les plus grands baissements de résistance, qui sont enregistrés à 950°C, sont possédés, dans la majorité des cas, par les bétons à une teneur plus élevée en ciment (si on compare la résistance à la compression, déterminée sur des échantillons conservés trois jours, dans l'atmosphère humide, avec celle déterminée, sur des échantillons cuits à 950°C).

Les additifs de syntérification ( frittage), en corrélation avec la nature, la finesse et le dosage du ciment, peuvent améliorer le

Comportement des températures intermédiaires des bétons réfractaires à la base de ciment alumineux.

Les éclats de verre finement broyés sont souvent utilisés. Dans ce présent travail, l'influence des additifs de syntérification, on a suivi sur les recettes avec 25 % et, respectivement 15 % ciment  $S_2$ . Dans le Tableau VI, on a inscrit les résistances mécaniques des échantillons des béton à additif de verre finement broyé.

TABLEAU VI

Symbole d'échantillon	Proportion de ciment %	Proportion de verre %	Résistance à la compression ( $\text{daN/cm}^2$ ), après la cuisson à :				
			la conservation		cuisson à :		
			1 jour	3 jours	800 °C	950 °C	1100 °C
I- N1	25	1,0	200	230	250	160	240
I- N2	25	3,0	220	350	274	200	300
I- N3	25	5,0	200	200	250	180	250
III-N1	15	1,0	350	400	300	200	280
III-N2	15	3,0	300	350	300	235	380
III-N3	15	5,0	300	320	290	260	430

Des données présentées, il en résulte que l'addition de verre finement broyé n'exerce pas une influence favorable sur les résistances des bétons à 25 % ciment; en échange introduit dans les bétons à dosage plus faible de ciment (15 %), elle détermine une amélioration des valeurs des résistances.

## CONCLUSIONS

L'analyse de l'influence du dosage et du type de liant sur les propriétés de certains bétons réfractaires à haute teneur en  $\text{Al}_2\text{O}_3$  a démontré que l'amélioration des résistances mécaniques de ceux-là peut être réalisée par de diverses voies. Dans ce sens on doit prendre en considération, premièrement, la composition chimico-minéralogique du ciment utilisé; les plus grandes résistances sont obtenues ainsi dans le cas des ciments contenant  $\text{CA}$  et  $\text{CA}_2$ .

On peut obtenir l'augmentation des résistances mécaniques aussi par l'augmentation de la finesse de broyage des ciments. Cette augmentation de la finesse de broyage est plus importante, surtout, dans le cas des bétons à la base des ciments plus alumineux et préparés avec un dosage plus réduit de ciment.

L'influence des additifs de syntérification se trouve dans une évidente corrélation avec la nature, la finesse ou le dosage du ciment.

### RESUME :

L'assortiment des ciments portland est très varié. L'ingénieur-bétonier ne peut pas s'y orienter facilement. Les paramètres de départ de ciments, très importants pour le longévité, la résistance au froid, etc., sont souvent cachés derrière les difficultés liées à leur apolyminéralité, polydispersité et polyagrégation, à la composition minéralogique agissante lors du durcissement des minéraux. Les ciments de diverses usines bien que pareils par leur minéralogie, sont au fond sensiblement différents. Et vice versa. Il convient de chercher des procédés faciles à l'aide desquels on peut pronostiquer, en fonction des propriétés des ciments, la qualité durable des bâtiments. Les conditions de la formation des structures de la pierre de ciment doivent se combiner manière organique avec les possibilités potentielles du ciment. Le cataloguement doit se baser sur les propriétés du ciment à durcir au maximum lors de la technologie chimique progressive pour l'obtention du béton.

Le catalogage de tous les ciments fabriqués dans le pays non d'après leurs propriétés isolées dans le béton mais d'après un groupe de propriétés, i.e. d'après le type complexe, est un problème important d'actualité.

Pour réaliser les travaux de bétonnage dans diverses conditions d'utilisation des constructions il ne suffit pas de prendre en considération seulement la résistance standard du ciment, car ceci conduit à son utilisation irrationnelle, ne révèle pas de liaisons du type de ciment avec toutes les complexités des processus de formation de structure dans le ciment durci qui doit être stable à l'action des conditions extérieures spécifiques dans chaque cas concret.

Pour résoudre le problème de catalogage des ciments, exigeant beaucoup de temps et de travail, sur la base de l'étude de leurs propriétés techniques on ne peut pas se limiter au problème de détermination des propriétés isolées des ciments fabriqués par n'importe quelle cimenterie. Le problème principal est l'étude des causes déterminant ces propriétés, la recherche des lois régissant la liaison de ces propriétés avec la qualité des matières premières et la technologie de la production, ce qui rend possible le changement essentiel de tout le complexe de propriétés.

L'analyse de nombreux résultats des expériences conduit à la conclusion principale que sur la base des divers procédés courants d'évaluations standards de la résistance et d'autres indices on ne peut pas obtenir une information complexe si nécessaire pour la construction.

En procédant à de nombreuses expériences on a établi que les ciments de différentes cimenteries fabriqués à partir de matières premières différentes et d'après la technologie différente avec la composition minéralogique à peu près identique déterminée par les méthodes conventionnelles existantes, confèrent aux bétons une combinaison essentiellement différente de propriétés techniques. Il est difficile de choisir des exemples où les différents ciments de même composition donneraient les bétons analogues d'après toutes les propriétés. Les différences commencent à se manifester dès le stade de préparation du paté de béton, lorsqu'on observe les désaccords de la plasticité et de la séparation de l'eau. À mesure que les processus de durcissement deviennent plus profonds les particularités d'abord peu sensibles deviennent de plus en plus profondes. Ceci entraîne une perte de possibilités du contrôle le plus complet de la qualité du produit fini (le béton), de la prévision de son comportement lors de son utilisation dans les différentes conditions variables du milieu ambiant.

Il est également connu que certains ciments portlands livrés par des cimenteries différentes, qui se distinguent par la minéralogie et la dispersité, montrent, lors des essais dans les bétons, des résultats assez

proches en ce qui concerne certaines propriétés mécaniques. Il est évident que l'étude de ce problème sur les causes de la similitude des propriétés de ciments à première vue différents est liée aux particularités individuelles du déroulement des processus d'hydrolyse et d'hydratation suivis d'une formation de structure dans la pierre de ciment, ce qui est lié également à la composition minéralogique agissante du ciment. C'est justement dans cette direction de l'étude de structures fines qu'il faut chercher des bases physico-chimiques profondes pour résoudre le problème de catalogage des ciments.

Pour cinq ciments étudiés proches d'après l'activité, la composition chimico-minéralogique, la consistance normale et certaines autres caractéristiques standards, on a obtenu une série d'indices nettement différents de propriétés importantes du béton. Ceci témoigne que les données initiales utilisées ne traduisent pas complètement les propriétés essentielles des ciments déterminant la qualité du béton. Ainsi, en particulier, l'étude de la résistance du béton durcissant dans des conditions différentes a montré que la différence de manque de résistance des bétons préparés avec des ciments différents lors du durcissement à l'air sec en comparaison du durcissement à l'air humide (conditions normales) peut varier dans de larges limites (de 20 à 50 %).

Dans quelques cas, à une étape déterminée les différentes parties constitutives de la structure dans les échantillons à base de ciments différents peuvent être formées identiquement et également ; c'est justement ce fait qui déterminera certaines propriétés du béton. Dans ce cas la cinétique tant des processus physico-chimiques que des processus mécaniques peut varier fortement pour des ciments différents, autrement dit, les propriétés techniques de ces bétons ne peuvent pas au fond être identiques.

Le problème d'économie du ciment et de diminution du contenu des matériaux dans le béton et le béton armé dans la construction est directement lié à l'utilisation de l'activité du ciment dans des délais différents de son durcissement. C'est pourquoi il est nécessaire de savoir évaluer la résistance d'après la courbe de son accroissement et non seulement d'après un seul indice de résistance standard.

Evidemment on peut être certain que dans la formation de la résistance mécanique et d'autres propriétés du ciment c'est la structure silicique qui joue le rôle décisif. Toutefois la présence dans le ciment des phases de substance intermédiaire corrige la formation des structures à partir de minéraux siliciques. En envisageant le rôle de  $C_3A$  il faut noter que jusqu'à présent l'on ne prête pas assez d'attention à l'étude du rôle de la substance intermédiaire, ce qui concerne en

premier lieu le verre faisant partie de la composition de la substance intermédiaire et ayant une capacité de rétention d'eau élevée.

En fonction du rapport entre le minéral  $C_2A$  et l'addition de gypse dihydraté il se forme dans la pierre de ciment de l'ettringite ainsi que, grâce à ce processus, il y a formation de la structure de coagulation en  $C_2A$  hydraté, qui diffère par ses propriétés et qui se forme en plus grandes ou plus petites quantités à un rythme accéléré ou ralenti.

Il faut également tenir compte de l'action sur la vitesse de formation de l'ettringite de la morphologie du clinker, de la répartition près de la surface des particules du ciment des substances minérales mères séparées et de leur cristallochimie.

Les facteurs succinctement énumérés déterminent tant la quantité de l'ettringite formée que ses particularités dans la structure du ciment durci. Il est évident que l'ettringite formée de façons si différentes différera par ses propriétés fonctionnelles et influera sur les propriétés du ciment durci de manière tout à fait différente. Notons que ce n'est pas l'ettringite, constituant instable et peu résistant du ciment durci, qui importe mais le fait de destruction des structures de coagulation fixé par la formation de l'ettringite.

Les aluminates de calcium hydratés qui existent sous forme de structures de coagulation et qui se forment principalement vu le manque du gypse dihydraté respectivement pour la teneur élevée du ciment en aluminates et les finesse de broyage correspondantes du clinker, empirent notablement les propriétés techniques du béton. Notons que ce résultat identique peut être obtenu par suite de causes premières tout à fait différentes.

L'étude de la composition du ciment durci aux différentes étapes de son hydratation à l'aide de la dérivatographie montre que sur les courbes DTG on peut déceler la présence d'effets des aluminates de calcium hydratés  $C_4AH_{13}$  dans les intervalles de température de 155 à 185 °C et au-dessus. Dans d'autres intervalles de température on enregistre la fixation du gypse et l'augmentation simultanée de la quantité d'ettringite. L'apparition dans le ciment durci des hydrates est décelée également d'après un autre indice. Simultanément avec l'hydratation de  $C_2A$  on voit apparaître de la chaux hydrolytiquement détachée qui sature la solution et augmente le pH du milieu. Mais  $Ca(OH)_2$  change également la basicité des aluminates de calcium hydratés qui se forment en apportant des changements dans les structures de coagulation, ce qui se répercute inévitablement sur les propriétés du béton à partir du moment de gâchage et de formation du mélange, bien que le cas où les ciments contiennent la même quantité de minéral  $C_2A$  et le gypse dihydraté est introduit en proportion nécessaire, soit également possible.

D'autres particularités, par exemple l'éventement du ciment conduisant à la corrosion de la surface de ses particules, en particulier du constituant alitique, diminue le pH du milieu et la possibilité de la formation de l'aluminate tétracalcique hydraté, ce qui entraîne des écarts correspondants dans les structures de coagulation et les propriétés du béton.

L'introduction d'additions hydrauliques actives exerce une influence sur la composition de la phase liquide au cours de l'hydratation du ciment. Dans ce cas la chaux hydrolytiquement détachée est activement absorbée, la séparation de l'eau du mélange est réglée. Par suite les structures de coagulation instables subissent des changements morphologiques, ce qui se répercute directement sur les propriétés du béton des ciments initialement similaires.

L'élaboration du problème des liaisons des propriétés du béton pour la comparaison de ciments différents tant d'après les indices techniques que d'après les caractéristiques des structures fines et des particularités des compositions du ciment durci, est possible dans la direction indiquée ou dans d'autres directions. Les comparaisons données sont possibles à condition que les mélanges choisis soient tels qu'une grande distinction dans la répartition de l'eau, sa coupure, la sédimentation du ciment d'après la grosseur des grains, n'aura pas lieu, car ceci influe considérablement sur la formation de la structure des pores (y compris les pores de contraction remplis d'air ou les pores inondés par l'eau) et finalement, sur toute une série de propriétés techniques.

En développant ce qui était dit plus haut sur les structures en phases de la substance intermédiaire il faut établir d'une manière certaine les types des structures qui se forment en leur présence et les hydrates qui améliorent certaines propriétés des bétons. Des essais mécaniques standards habituels ne permettent pas d'obtenir une telle information nécessaire. Il importe de savoir en quelle relation se trouvent entre elles certaines propriétés du béton et comment les particularités spécifiques de la structure des constituants de clinker modifient le déroulement des processus de durcissement. Notons que sous forme existante le ciment portland n'est pas un liant universel. On peut le voir en particulier en comparant les résistances des échantillons durcissant dans les conditions normales et à l'air sec.

La mise en évidence des mécanismes des relations indiquées au niveau des structures d'hydrates ouvrent de bases scientifiques profondes pour le catalogage des ciments.

Pendant de nombreuses années de travail on n'a pas trouvé de procédés sûrs d'évaluation d'une série de propriétés impor-

tantes du ciment. L'analyse du phénomène de contraction et de son liaison avec une série de propriétés importantes du béton est insuffisante. Quant aux problèmes de formation des structures du ciment durci en pâte de ciment (suspension concentrée) on leur accorde injustement peu temps. Cependant l'étude des processus d'hydrolyse et d'hydratation à toutes les étapes de la formation de structure doit être précédée par l'étude de la propriété du ciment de séparer une quantité d'eau différente dans les compositions du béton variées. Une étude plus détaillée montre que la propriété du ciment de séparer l'eau est liée à la présence de surfactifs (SDB), les processus de séparation de l'eau étant influencés par les additions minérales contenues, le dosage du gypse et sa relation avec la quantité de  $C_2A$ , la granulométrie du ciment, son "éventement" (pertes de calcination) et par un nombre d'autres facteurs. Généralement on ne prend pas en considération l'évaluation des particularités de l'"agglutination" de ciments différents et des causes de la différence d'hydratation des ciments lors de l'introduction dans le paté de béton d'électrolytes différents, accélérateurs du durcissement. Les causes d'une plastification différente des ciments séparés par les modifications de surfactifs, des particularités de leur action sur les propriétés des ciments, de l'autoplastification de la pâte de ciment, de l'entraînement de l'air sont peu étudiées. Il convient d'élargir les renseignements disponibles sur le fluage, le retrait et la résistance au gel des bétons. On n'utilise pas les possibilités de la vibration réitérative multiple du paté de béton ainsi que son maintien jusqu'au début du compactage et le rôle de ces procédés dans les processus de durcissement des bétons. Un large développement de la production du béton armé préfabriqué inscrite à l'ordre du jour le problème d'étude des causes de la différence de résistance, de déformabilité et de résistance au gel des bétons après leur traitement à la vapeur humide.

Pour résoudre ces problèmes et bien d'autres on doit mettre en jeu tant les méthodes actuelles de l'analyse physico-chimique que les procédés simples de l'analyse rapide, faciles à réaliser dans les conditions de laboratoire et argumentés du point de vue scientifique et méthodique, dont l'utilisation complexe assurerait l'obtention de l'information nécessaire, ce qui est très important pour la prise en compte approfondie des propriétés des bétons lors du catalogage des ciments (voir le schéma du catalogue des ciments).

La pratique de plusieurs années montre que l'utilisation correctement élaborée du ciment d'après le type complexe du béton détermine la longévité des constructions et l'utilisation rationnelle du ciment. Dans ce cas il est possible d'obtenir une diminution de contenu des matériaux dans les structures en béton d'après la masse du ciment jusqu'à 10 %.

L'argumentation scientifique et technique du catalogage des ciments se fait sur la base de la vérification des résultats obtenus, des recommandations de différents chantiers et usines de structures en béton armé et de la révision des normes.

#### SCHEMA DU CATALOGUE DES CIMENTS (Variante possible)

n°s	Propriétés du ciment déterminant le type complexe du béton	Directions de l'utilisation d'après leurs changements possibles
1	Cinétique du durcissement	D'après le type de la dépendance analytique $R = f(t)$
2	Attitude envers le durcissement pour différentes humidités de l'air	Différences de cinétique du durcissement à l'air humide et à l'air sec
3	Efficacité du durcissement en cas du traitement à la chaleur humide	D'après les écarts dans la cinétique du durcissement après le traitement à la chaleur humide en régimes différents
4	Efficacité de l'utilisation de différentes additions (surfactifs, électrolytes, etc.)	Détermination du groupe de plastification du ciment et du domaine d'application, choix des additions nécessaires et de la technologie de leur introduction
5	Déformabilité (retrait, module d'élasticité, fluage) et résistance au gel	Prévision des valeurs attendues d'après la composition minéralogique agissante du ciment et les processus initiaux de formation de la structure
6	Correspondance du ciment à la technologie de la préparation du paté de béton et à l'équipement utilisé, aux procédés et actions	Établissement du domaine d'application optimal, variation des paramètres technologiques ou particularités lors de la réalisation des travaux

# Dependence of high-strength and rapid-hardening cements optimum granulometry from W/C and hardening conditions

## *Rapport entre le E/C et les conditions de durcissement et granulométrie optimale de ciments à haute résistance et de nouveaux ciments à prise rapide*

I. KRAVCHENKO, prof., doc. of tech. sciences,

M. VLASOVA, cand. of tech. sciences,

B. YUDOVICH, cand. of tech. sciences, NIITSiment - Moscow, U.S.S.R.

**SUMMARY:** On the basis of precondition of strength reduction as a result of local disturbances of hydration products medium density analytical dependencies according to an optimal strength criterion of "x" small and medium fraction of cement (less than 5 and 5-30  $\mu$ k) have been plotted against a starting w/c ratio and hydration degree of these fractions considering their composition and quantity of larger fraction. There also shown that "x" should be increased with gain in w/c ration and strengthening requirements to cement early strength values. With w/c = 0.4 and medium fraction hydration degree of 0.9 (28 days) the experimental values of  $x = 0.195 - 0.21$  are close to the calculated of 0.208 - 0.218. Analytical calculation of rational granulometry is thus possible according to the data on a starting w/c ratio and its hydration degree by a given age of hardening.

**RESUME:** Partant des conditions de la chute de résistance due aux perturbations locaux de la densité moyenne des produits d'hydratation, on a établi des dépendances analytiques de la proportion "x", optimale quant au critère de résistance, entre les fractions fine et moyenne dans le ciment (moins de 5 et 5-30  $\mu$ k) par rapport au E/C initial et au degré d'hydratation de ces fractions compte tenue de leur composition et de la quantité de fraction plus grosse. On a montré qu'un accroissement du E/C et/ou celui de la résistance précoce du ciment doivent être suivis d'une augmentation de "x". Avec un "E/C"=0,4 et un degré d'hydratation de la fraction moyenne 0,9 (28 jours), les données expérimentales "x"=0,195-0,21 sont proches des calculs théoriques 0,208-0,218. On en conclut sur la possibilité du calcul analytique d'une granulométrie rationnelle pour le ciment portland à partir des données sur le E/C initial et le degré de son hydratation à un délai de durcissement voulu.

The attempts have been repeatedly made to calculate an optimal granulometric composition of portland cement on the basis of hydration rate of its individual fractions. It has been thus found that cement fraction dispersed by the air with moisture content of more than 40% and with cement specific consumption of more than 0.3 m<sup>3</sup>/kg considerably changes its hydration activity.

In addition, an optimal granulometric composition of cement must depend on concrete density first of all and on a starting w/c ratio. The report presents a method of calculation of cement granulometric composition with the given amendments; the task does not coincide with the seminar theme but is also urgent.

**Starting items.** Strength of cement (concrete) reaches a maximum on filling of capillary pores by hydration products. 2. As this takes place, suitable average density also reaches a maximum. 3. Local disturbances of average density will develop if absolute volume of hydration products considering contraction exceeds capillary pore volume. 4. Cement is considered as a composition of three fractions: small - not less than 5  $\mu$ k, average fraction - 5-30  $\mu$ k and large - more than 30  $\mu$ k. 5. In the case of random placing of cement particles in a process of forming and compaction of cement paste (concrete) the small fraction fills voids in placing of average fraction and the large is speckled in the placing of the others. It has been experimentally proved on the basis of the fact that an efficient diameter of two modes of capillary pore volume size distribution in early age (up to one day) cement stone (about 1 and 8  $\mu$ k) is less than weighted mean diameters of particles of the small and average fractions of cement (about 1.2-1.8  $\mu$ k and 11-13  $\mu$ k, correspondingly).

**Legend.** Let  $\theta$  and  $V$  be density and volume of particle layer,  $\gamma$  and  $v$  - density and specific volume of particles themselves,  $m$  - fraction content in cement in parts per unit,  $G$  - hydration degree, indices "sm., av., l., lf, mf, c" relate to small, average and large fractions, layer, fraction mixture and cement, correspondingly,  $x$  - ration of small and average fraction in weight,  $\varepsilon$  - porosity in parts per unit,  $W_n$  - weight content of water bound on hydration of cement,  $W_{n, \max}$  - the same on  $G = 1$ ,  $W_t$  - the same by a given moment of hydration  $t$ .

**Calculation of  $x$  without hydration.** Let us consider a mixture of the small and average fractions. Then, following T. Powers and starting density analysis from the compositions of its placing which are rich with average fraction we have:

$$\theta_c = \theta_{av} + \Delta\theta,$$

where  $\Delta\theta$  - density increment as a result of the small particles disposition among the average, according to equation  $\Delta\theta =$

$= m_{sm}/(\gamma_{sm} \cdot v_{sm})$ . If all the voids of the average fraction placing are filled with the small then according to:  $v_{sm} = m_{av}/(\gamma_{av} \cdot v_{av})$  and substituting (1) this in (1) we shall obtain:

$$\theta_c = \theta_{av} + \frac{m_{sm} \cdot \gamma_{av} \cdot \theta_{av}}{m_{av} \cdot \gamma_{sm}} \quad (2)$$

Starting analysis from the compositions riched with the small fraction we shall similarly obtain for layer volume:

$$V_c = \frac{m_{sm}}{\gamma_{sm} \cdot \theta_{sm}} + m_{av}/\gamma_{av},$$

and particle volume in a layer:  $V_p = m_{sm}/\gamma_{sm} + m_{av}/\gamma_{av}$ , where from, by definition,

$$\theta_c = V_p/V_c = \frac{m_{sm}/\gamma_{sm} + m_{av}/\gamma_{av}}{m_{sm}/\gamma_{sm} \theta_{sm} + m_{av}/\gamma_{av}} \quad (3)$$

when  $\gamma_{sm} = \gamma_{av}$  and  $x = m_{sm}/m_{av}$  the equations (2) and (3) are transformed into:

$$\theta_c = \theta_{av}(1 + x), \quad (4)$$

$$\theta_c = \frac{x + 1}{x + \theta_{sm}} \theta_{sm}. \quad (5)$$

The equations (4,5) characterize increase in density of placing of the average fraction - on filling voids by the small fraction and of the small fraction - in changing conglomerate of its particles spaces between them by the particles of average fraction. It is evident that the equations (4, 5) are hyperbolas (Fig. 1), correspondingly, referring to the arguments  $m_{sm}$  and  $m_{av}$  considering that  $\theta_{sm}$  and  $\theta_{av}$  - constant.

Ratio of  $x_{\text{optimal}}$  for maximum density of the mixture of the small and average fractions will be the following, determining an intersection point of hyperbolas in Fig. 1, i.e. equating (4) to (5):

$$x_{\text{optimal}} = \theta_{sm}/\theta_{av} - \theta_{sm}. \quad (6)$$

In ideal case of spherical particles  $\theta_{sm}$  equals to  $\theta_{av}$ , then

$$x_{\text{optimal}} = 1 - \theta_{sm} = \varepsilon,$$

i.e. an optimal ratio of the small and average fractions numerically equals to placing porosity. With the increase of the later due, for example, to the growth of w/c ratio, the optimal content of the small fraction in

Fig. 1. Placing density of mixtures of cement small and average fractions.

- 1 - curve according to equations (3,5);
- 2 - curve according to equations (2,4);
- bold curve - calculated placing density;
- 3 - experimental placing density;
- MN - area of optimum (shaded);
- B - calculated optimum.

cement should increase and it has been experimentally proved. In particular, in the USSR when passing from the cement tests in rigid consistency samples to the tests in plastic consistency samples and changing w/c ratio of the standard mortars from 0.25-0.28 to 0.4, correspondingly, the average data on cement strength growth with increase in specific surface area from 3000 to 4000 cm<sup>2</sup>/g constitute about 110 kgF/cm<sup>2</sup> with w/c ratio = 0.4 against 70 kgF/cm<sup>2</sup> with w/c ratio = 0.28, correspondingly, i.e. "contribution" of cement dispersity into its strength is increasing with the growth of w/c ratio. For the case of  $\gamma_{sm} = \gamma_{av}$  we can obtain:

$$x_{optimal} = (\theta_{sm}/\theta_{av} - \theta_{sm}) \gamma_{sm}/\gamma_{av}. \quad (7)$$

Large fraction effect. Volume of layer of mixture of all fractions equals:

$$V_{mf} = \frac{m_{sm} + m_{av}}{\gamma_{sm} \theta_{mf}} + m_1/\gamma_1,$$

while in the particle volume:  
 $V_p = m_{sm}/\gamma_{sm} + m_{av}/\gamma_{av} + m_1/\gamma_1$ , then

$$\theta_c = \theta_{mf} / [1 - m_1(1 - \theta_{mf})]. \quad (8)$$

This suggests that in placing of the large particles with the method - "particle after particle", as in mosaic where space is available for every large particle the closer  $x$  to  $x_{optimal}$  and the lower  $\xi$ , the less its positive effect on layer density. Really, there are no voids corresponding to the large particles and when placed on random they have to move apart available voids; A. Weymouth was the first to establish this fact. The moving apart process can be estimated with the Gerts equation for middistance between particles in random placing:

$$D = 0.55 n^{-1/3},$$

where  $n$  - coordination number  $\approx \gamma_1/\gamma d^3$ ,  
 $d$  - particle diameter. Having introduced the coefficients  $B = k_1 d_1^{-1.5}$  and  $A = k_2 d_{mf}^{-1.5}$  we shall obtain after conversion:

$$\theta_{mf} = B [(0.2 + 0.8 m_1^{1.5}) \cdot (1 + A m_1^{-0.5} - m_1)^{-1}].$$

The equation proves the fact that density decreases in random placing of the average and small fractions when the large fraction is introduced into it, the larger size of its particles and lesser total porosity the greater decrease in density. It should be noted that a positive effect of the large fractions on cement technical properties found in a number of the previous experiments, such as the experiments of H. K hl, Ch. Bruer or G. Burrows, was likely conditioned by the far from optimal ratio of the small and average fraction (lack of the average fraction) used in cements and high values of w/c ratio.

Calculation of placing density considering hydration. By definition,  $\theta = 1 - \xi$ , therefore available calculation methods for estimating content of different group pores in cement stone are suitable for calculation of  $\theta$  and, thus, - for granulometry of cement.

If on the basis of the experiments we assume  $W_{n,max} = 0.5$ ,  $v = 0.32$ , gel pore volume in cm<sup>3</sup>/g of cement  $q = 0.2$  and volume of contraction  $j = 0.09$  cm<sup>3</sup>/g then a summary of the calculated equations given in the Table will be obtained.

In the Table the values of  $W_n$ ,  $W_{n,max}$ ,  $q$  and  $j$  are selected according to the experimental data;  $a$  is a correction for deviation

of a coordinating number in a layer from a mean value. According to the experiment  $a_{sm} = 1.2$ .

Projecting of cement granulometric composition. On the basis of the equation (7) and considering the aforesaid the following system of the three equations is sufficient to projecting of cement granulometry:

$$m_{sm}/m_{av} = (\theta_{sm}/\theta_{av} - \theta_{sm})\gamma_{sm}/\gamma_{av};$$

$$m_{sm}/m_1 = (\theta_{sm}/\theta_1 - \theta_{sm})\gamma_{sm}/\gamma_1;$$

$$m_{sm} + m_{av} + m_1 = 1.$$

Solutions to this system with the following symbols:

$$E = \theta_{sm} \gamma_{sm} (1 - \theta_{av}) (1 - \theta_1) + \theta_{av} \gamma_{av} (1 - \theta_1) + \theta_1 \gamma_1 (1 - \theta_{av}) \text{ are:}$$

$$\left. \begin{aligned} m_{sm} &= \theta_{sm} (1 - \theta_{av}) (1 - \theta_1) \gamma_{sm} \cdot E^{-1}; \\ m_{av} &= \theta_{av} (1 - \theta_1) \gamma_{av} \cdot E^{-1}; \\ m_1 &= \theta_1 (1 - \theta_{av}) \gamma_1 \cdot E^{-1}; \end{aligned} \right\} (10)$$

$m_1$  considering the above estimation from (9).

Here specific mass of fractions and density of placing should be calculated considering values of hydration degree of individual fractions which can be calculated according to the data on values of hydration degree of a combination of not less than 3 cements having known but different grain composition at various ages of hardening and using a diffusion equation and an additivity law assuming  $G = 1$  and  $t \geq 1$  day.

The values of  $G_{sm} < 1$  when  $t > 1$  day commonly met in calculations testify the reality of non-evaporated water extract from hydration products of the small fraction for hydration of the average and large fractions of cement.

Table 5  
Equations for calculation of cement stone placing density

Porosity	Small fraction	Average and large fraction
Capillary	$D_{I sm} = \frac{a_{sm}(w/c) - W_{t,sm} \cdot G_{sm}}{a_{sm}(w/c) + V_{sm}};$ $D_{I sm} = \frac{1.2(w/c) - 0.65 G_{sm}}{1.2(w/c) + 0.34};$	$D_{I av,1} = \frac{a_{av,1}(w/c) - W_{t,av,1} \cdot G_{sm,1}}{a_{av,1}(w/c) + V_{av,1}}$ $D_{I av,1} = \frac{0.97(w/c) - 0.5 G_{av,1}}{0.97(w/c) + 0.32}$
Contraction	$D_{2 sm} = \frac{q_{sm} \cdot G_{sm}}{a_{sm}(w/c) + V_{sm}};$ $D_{2 sm} = \frac{0.08 G_{sm}}{1.2(w/c) + 0.34};$	$D_{2 av,1} = \frac{q_{av,1} \cdot G_{av,1}}{a_{av,1} \cdot (w/c) + Y_{av,1}}$ $D_{2 av,1} = \frac{0.09 G_{av,1}}{0.97(w/c) + 0.32}$
Gel	$D_{3 sm} = \frac{j_{sm} \cdot G_{sm}}{a_{sm}(w/c) + V_{sm}};$ $D_{3 sm} = \frac{0.19 G_{sm}}{1.2(w/c) + 0.34};$	$D_{3 av,1} = \frac{j_{av,1} \cdot G_{av,1}}{a_{av,1}(w/c) + Y_{av,1}}$ $D_{3 av,1} = \frac{0.2 G_{av,1}}{0.97(w/c) + 0.32}$

Porosity	Small fraction	Average and large fraction
Common	$D_{\text{common,sm,l}} = \frac{a_{\text{sm,av,l}}(w/c) - (W_{\text{t,sm,av,l}} - q_{\text{sm,av,l}} - j_{\text{sm,av,l}})G_{\text{sm,av,l}}}{a_{\text{sm,av,l}}(w/c) + V_{\text{sm,av,l}}}$	
	$D_{\text{common,sm}} = \frac{1.2(w/c) + 0.38 G_{\text{sm}}}{1.2(w/c) + 0.34} ;$	$D_{\text{common,av,l}} = \frac{0.97(w/c) - 0.21 G_{\text{av,l}}}{0.97(w/c) + 0.32}$
Placing density	$\Theta_{\text{sm}} = 1 - D_{\text{common}} = \frac{V_{\text{sm}} + (W_{\text{t,sm}} - q_{\text{sm}} - j_{\text{sm}})G_{\text{sm}}}{a_{\text{sm}}(w/c) + V_{\text{sm}}} ;$ $\Theta_{\text{sm}} = \frac{0.34 + 0.38 G_{\text{sm}}}{1.2(w/c) + 0.34} = \frac{1.1 G_{\text{sm}} + 1}{3.5(w/c) + 1}$	$\Theta_{\text{av,l}} = 1 - D_{\text{common,av,l}} = \frac{V_{\text{av,l}} + (W_{\text{t,av,l}} - q_{\text{av,l}} - j_{\text{av,l}})G_{\text{av,l}}}{a_{\text{av,l}}(w/c) + V_{\text{av,l}}}$ $\Theta_{\text{av,l}} = \frac{0.32 + 0.21 G_{\text{av,l}}}{0.97(w/c) + 0.32} = \frac{0.65 G_{\text{av,l}} + 1}{3(w/c) + 1}$

The possibility of the extract has been firstly postulated by H. K hl but it turned out that opposite to his opinion expressed in the papers of 1928-32 the greater efficiency of this extract, the slower growth of cement strength. This enables the destruction role to be ascribed to the extract process and many investigators believed this starting from T. Powers (1949).

The equations (10) show that small fraction content must be higher with the decrease of placing density of the rest fractions whether it is conditioned by

short ages of hardening required for concrete to reach necessary strength (this suggests high dispersity of the new particularly rapid-hardening cements), increased value of w/c ration, or delayed clinker hydration due to its undesired composition and structure.

Example. When w/c ratio = 0.4 and  $G_{\text{av}} = 0.9$  (28 days) the experimental values of  $x_{\text{optimal}} = 0.195-0.21$  for clinker characterized in the stand report of B. Yudovich et al., are close to the calculated values of 0.208-0.218.

## Theme 2 - Influence of secondary components

by M. CORRADI, Mac Mediterranea, Treviso, Italy.

### INTRODUCTION

The interest in fly ashes, pozzolanas and slags has greatly increased in the last few years because of the potential economical and energetic saving they allow.

The shortage of oil has not emphasized only the problem of energy saving, but also urged many countries to a diversification of energy sources. So many thermoelectric power plants are being changed to the use of coal instead of oil. The production of hundreds of tons of fly-ashes all over the world has induced researchers to deepen the study of the possible use of this combustion residual product. The use of fly ashes together with cement in the concrete production is a good combination which, besides solving the problems of waste disposal, enables a substantial energy saving per cubic metre of concrete produced.

### POZZOLANAS AND POZZOLANIC CEMENT

Composite binders containing Portland cement and natural or artificial pozzolana are widely manufactured in many countries and are mostly standardized as Portland pozzolanic cements.

Fly ash is an artificial pozzolana, the combustion process residue of power plants using coal.

While the quality of pozzolana is generally constant, at least for the one coming from the same source, fly ash quality differs according to quality, fineness, method of burning pulverized coal, collecting facilities etc.

The standardization of fly ash characteristics and the development of the technique of its addition to concrete on one hand and the standardization of pozzolanic cement characteristics on the other, give a good guarantee of constant quality of composite binder.

### The Influence of Fly Ashes on Concrete Properties

It is well-known that fly ashes and pozzolana influence among the other properties of concrete the following :

- Workability, which is generally improved when a good quality fly-ash is used, while is generally reduced with the use of most of natural pozzolana. On the other hand natural pozzolanas will reduce bleeding rate.
- Strength, which generally lowers at early ages and improves at longer ages, the effect being related to the percentage of cement replaced by pozzolana or fly ashes.
- Heat of hydration, which lowers when a portion of cement is replaced by fly ashes or pozzolana.
- Durability against sulphates, which increases when part of the cement is replaced by fly ashes or pozzolana.

### POZZOLANIC REACTION

Pozzolanic activity is the ability to react with calcium hydroxide in presence of water and to form hydrated products with binding properties. In the case of addition of pozzolana or fly ashes to Portland cement, the hydroxide necessary for the pozzolanic reaction comes from the hydration of cement and/or free lime.

The reaction products of the lime/pozzolana/water combination are substantially analogous to the hydration products of Portland cement. But some free lime consuming during the pozzolanic reaction, the final product contains a lower amount of  $\text{Ca(OH)}_2$  and a higher amount of hydrated silicates.

This partly explains the lower strength of pozzolanic cement at early ages compared to Portland cement, and its higher strengths at longer ages. In fact, at early ages at ambient temperature the contribution of the pozzolanic reaction is practically nil; therefore strengths are affected by the lower quantity of the silicates  $\text{C}_3\text{S}$  and  $\text{C}_2\text{S}$  present because of the substitution of pozzolana in place of clinker. At longer ages the hydrated silicates from the pozzolanic reaction add to the silicates of the clinker reaction, strengths being then equal to those of pure Portland cement.

The paper presented by P.L. Owens and F.G. Buttler, called "The Reaction of Fly-ash and Portland Cement with Relation to the Strength of Concrete as a Function of Time and Temperature", investigates the influence of concrete temperature rise, due to cement hydration, on strength. Owens points out the difference in strengths between a concrete poured into small standard specimens, cured at 20°C in laboratory, and large volume pours of the same concrete where temperatures higher than 60°C are reached because of the heat of hydration.

Mortar specimens, based on a 1:3 cement/sand ratio, with sufficient water to attain an ASTM flow consistency of 100-110 % were prepared by replacing the cement content by fly-ashes up to 75 %. The proportion of mix water required was then reduced from 0.495 to 0.39. The specimens have been cured at different curing cycles, ranging between 20 and 80°C, thus simulating typical temperature/time profiles of mass concrete pours.

The author notices that at 20°C the early strength of mortars, cured for 11 days, is reduced by increasing the amount of fly ashes. The calcium hydroxide, produced by calcium silicates hydration, is reduced too by increasing the amount of fly ashes. The reduction in both strength and calcium hydroxide is proportional to the reduction of cement thus indicating there is a little pozzolanic reaction between  $\text{Ca}(\text{OH})_2$  and fly ashes. However, at 28 days the reduction in strength is lower than one could expect from those reductions in cement. This agrees with a pozzolanic reaction of  $\text{Ca}(\text{OH})_2$  and fly ashes found at 28 days.

Some specimens have been early cured at high temperature and then normally cured at 20°C. For mortars which do not contain fly ashes the 28-day strength after the early curing at 80°C is 32 % lower than the strength of the same mortar constantly cured at 20°C. It is well-known that this reduction is mainly due to the heat developed by cement hydration. Because of the different thermal expansion of air, water, cement paste and aggregates in the mix, cracks occur in mortar or concrete. When the cement is replaced by fly ashes the pozzolanic reaction speed at high temperatures is higher than at ambient temperature. The 28-day strength after an early curing at high temperatures is greater than the corresponding strength at 20°C. In particular, with 75 % of fly ashes the 28-day strength after an early curing at 80°C is more than doubled compared to the 28-day strength at 20°C. The pozzolanic reaction together with the water/cement + fly ash ratio reduction, which occurs when fly ash is used, are responsible for the strength improvement found by the authors.

In mortar tests (cement/sand 1:3) the water/cement plus fly ashes ratio varies from a maximum of 0.495, when pure cement is used, to a minimum of 0.390 when

75 % of the cement is substituted by fly ashes. But calculating the water/cement ratio it follows that it is 0.495 when pure cement is used, up to 1.56 when 75 % of the cement is substituted by fly ashes. This means that till the reaction of fly ashes with lime does not start, the substitution of cement with fly ashes causes a remarkable increase of the water/binder ratio because fly ashes behave as an inert. This furtherly explains the low strengths at early ages when cement is substituted by fly ash.

At longer ages when the reaction between fly ashes and lime starts both hydration products and a reduction of the water/binder ratio make strengths increase.

The more the fly ashes will react with lime the higher the reduction of the water/binder ratio will be. The water/binder ratio, then, is a variable ratio whose influence is the more beneficial, the quicker and the more fly ashes react with lime.

Nevertheless, notwithstanding the evident pozzolanic reaction, the residual amount of lime in the cement paste is sufficient to maintain a pH high enough to prevent corrosion to embedded reinforcement. Some problems could rise if carbonation occurs.

The authors' results indicate, in conclusion, that by adding fly-ash to the mortar subjected to curing temperatures, similar to those that can occur in practice in mass concretes, the adverse effect of high curing temperatures on the strength of Portland cement mortars is counteracted by a pozzolanic reaction acceleration. The optimum strength improvement is to replace 35 % of cement with fly ashes.

Mr. M. Matousek's paper entitled "The Influence of Cement Properties on Concrete Behaviour and its Resistance to the Atmospheric Corrosion" investigates the corrosive effect of atmospheric acid gases on concrete. The corrosive action of these gases is generally ruled by the concrete capillary pore structure. Therefore Fourier's Law and Fick's first law can be used for the diffusion of gases in the concrete. According to these laws, the penetration of aggressive gases into the concrete is inversely proportional to the coefficient of concrete permeability resistance. The author defines this coefficient as the permeability resistance of aggressive gases compared to the permeability resistance of the air diffusing through the same thickness of concrete and at the same temperature.

If aggressive gases react with the basic component of the concrete (lime), as carbon dioxide does, the thickness of carbonated concrete, according to Fick's law, is expressed by :

$$D = K \sqrt{t}$$

where D is the thickness of carbonated concrete (meter), t is the time (seconds), and K is inversely proportional not only to the square root of permeability resistance coefficient of concrete but also to the square

root of the quantity of aggressive gas fixed by the unit volume of concrete. For example the quantity of  $\text{CO}_2$  required for the carbonation of one cubic meter of concrete.

The author's conclusion is that Portland cement concretes with high content of  $\text{Ca}(\text{OH})_2$  provide a better resistance to aggressive  $\text{CO}_2$  attack.

In this respect composite cements, containing fly-ash or pozzolana which through a pozzolanic reaction reduce the content of  $\text{Ca}(\text{OH})_2$  cause a lower resistance of the concrete to acid gas corrosion.

#### SLAGS AND SLAG CEMENTS

Granulated blast furnace slags are mainly composed of glassy materials with a composition which varies according to the parameters of the production process. Unlike pozzolana they possess latent hydraulic properties which are promoted by alkaline activators. Combining the slag with Portland cement, the calcium hydroxide, produced by silicate hydration, activates the reaction of slag with water.

The alkaline activators are thought to increase the permeability of silica and alumina gels, formed as initial products by the reaction of slag with water, allowing the reaction to proceed furtherly.

All slag-Portland cements can be grouped into two classes. The cements of the first group contain slags in the proportion of 20 to 40 % and are usually used alternatively to Portland cement. The cements of the second group contain higher amounts (up to 80 %) of slag. These cements are generally used for hydrothermal curing, works in hot climates or where good sulphate resistance properties are required. Slag cement hydration heat, in fact, is lower than Portland cement's, the reduction depending on the relative proportion of cement and slag. The durability of a concrete, prepared with slag cement, to aggressive sulphate is also improved especially if cements containing high quantities of  $\text{C}_3\text{A}$  are used. On the other hand, if the slag, which generally contains  $\text{CaO}$ ,  $\text{SiO}_2$ ,  $\text{Al}_2\text{O}_3$  and  $\text{MgO}$  as main components, has a very high content of alumina, the sulphate resistance generally lowers. The sulphate resistance of slag cement pastes is thought to be mainly related to the lower  $\text{Ca}(\text{OH})_2$  content, and to the lower content of  $\text{C}_3\text{A}$  available to react with  $\text{CaSO}_4$  and to form solfoaluminate.

#### PAPER RECEIVED

Mr. U. Ayapov's paper, entitled "Influence of Chemical Interaction of Cement and Aggregate on the Properties of Concrete" investigates the properties of concretes when slag is used as aggregate instead of binder with hydraulic properties.

The slag aggregates are pretreated before being used in concrete in order to improve the properties of concrete. Previous studies on aggregate surface treatment reported that concrete strength is improved when normal aggregates are treated. For example, with polyhydrosiloxane, diluted hydrochloric acid or phthalic acid. This improvement is generally explained by the increase in the aggregate/cement paste surface of contact or by a better crystallization of calcium hydrosilicates of the cement paste on the aggregate surface.

Crystallized phosphoric slags or blast furnace slags have been crushed and then activated by an acid treatment. The author investigates the optimum parameters of slag activation through the kinetic of dissolution of the slag aggregate in an acid solution. Using diluted  $\text{H}_2\text{SO}_4$  as slag aggregate activator, the author shows that the rate of dissolution is very slightly dependent on temperature, in the range of 20-80°C, while it is influenced by the time of treatment and by the acid concentration. Measures of adhesion strength between slag aggregates and cement paste are determined after treatments at different activation conditions.

An optimum adhesion strength was found in the slag-aggregate treatment with 0.1 M sulphuric acid for periods of over 12 hours. After seven days of curing the adhesive strength of activated aggregate with cement paste was doubled and slightly less than doubled after 28 days of curing, compared with non-activated aggregates. Activated blast furnace aggregates showed 10 % lower adhesive strength than phosphoric slag aggregates. By increasing the sulphuric acid concentration over 0.5 - 1 M the adhesive strength of aggregates with cement paste decreases. This is probably related to an excessive thickness of the treated aggregate layer. The optimum thickness of the treated aggregate layer has been found in the range of 60 - 200  $\mu\text{m}$ . By an X-ray petrographic and thermal analysis the author found that the treated aggregate layers are mainly constituted of silica gel and gypsum precipitated on aggregate surface. The products formed on the treated layer in contact with the cement paste are mainly composed of gypsum, silica gel and calcium hydrosilicate gel.

Concrete mixes, whose composition is not given, prepared with Portland cement PZ 400, slag sand and natural sand also showed an approximately 26 % lower water demand, when slag aggregates were activated for 1 - 3 hours with 0.1 - 0.5 M sulphuric acid solution.

The same concrete also showed a much higher strength (1.4  $\pm$  1.6 times) than concretes prepared with non-activated aggregates. Beneficial effect of activated aggregates was found by the author also in the adhesion of concrete to steel.

In conclusion, by activating slag aggregates at the optimum conditions of 0.1 - 0.5 M sulphuric acid water solution, for 1 - 3 hours, it is possible to improve considerably concrete mechanical properties or, at constant performances, to obtain a cement saving.

#### CONCLUSIONS

The chemistry of cement secondary components and the interactions they have with cement hydration products have been long studied in the last decade. Many aspects of the development of the binding function of these secondary components have been clarified even if one of the main problems is still the slower development of strengths at early ages when the cement is partially substituted by pozzolana, fly ash or slag. A deep investigation on thermic parame-

ters - both endogenous and exogenous - as reported by Owens and Butler's paper, could optimize the use of composite binders.

One of the problems that faces us on this subject is the possibility of effectively reducing the water/binder ratio so that at early ages - when the secondary component has not yet started reacting - an effective reduction in the water/cement ratio could be obtained. Another aspect of the problem which should be investigated is the study of the possibility of accelerating - catalytically or thermically - the pozzolanic reaction or slag hydration, so that secondary components can develop their binding action since very early ages.

The economical and energy saving needs will certainly stimulate some research on this subject in the next years.

# The reactions of fly ash and portland cement with relation to the strength of concrete as a function of time and temperature

## *Les réactions de la cendre volante et du ciment portland en rapport avec la solidité du béton en fonction du temps et de la température*

P.L. OWENS, Technical Manager, Pozzolanac Limited, Chester,  
F.G. BUTTLER, Chemistry Department, Teeside Polytechnic, Middlesbrough, UK.

**RESUME :** Quand le béton de portland subit des élévations de température occasionnées par la chaleur de l'hydratation du ciment, la solidité et la durabilité prolongées sont ordinairement mal affectées. En outre quand le béton de portland subit les grandes élévations de température, i.e. plus que 60°C, aux phases premières, le produit est un béton d'une solidité restreinte qui est formé avant biens des jours, par contraste avec le produit qu'on attend si le béton est submergé dans l'eau à 20°C pendant longtemps.

Par la simulation d'un nombre de traitements vieillissants typiques des traitements que le béton peut subir, on peut rapporter la solidité de l'hydrate des divers âges et des portions différentes du portland et de la cendre volante de qualité réglée à la quantité de la chaux, présente comme  $\text{Ca(OH)}_2$ , qui est trouvée dans la structure de l'hydrate. On trouve aussi que tant que la portion de la cendre volante grandit, il y a non seulement un perfectionnement de la solidité qui s'agrandit avec la température du vieillissement, mais aussi une réduction de la quantité de la chaux.

De l'examen des systèmes où 0% à 75% du ciment est remplacé par la cendre volante, on trouve la solidité la plus grande après un vieillissement de 28 jours à une température de 80°C quand presque 30% du ciment est remplacé. Cela coïncide avec une réduction de presque 50% de la chaux dans l'hydrate. Cette quantité de la chaux est, pourtant, plus qu'il n'en faut pour donner la protection suffisante aux renforcements enfouis d'acier.

**SUMMARY :** Where Portland cement concrete is subjected to rises in temperature, due to the effect of the heat of hydration of the cement, the long term strength and durability of that concrete is usually adversely affected. Further when Portland cement concrete is subjected at early ages, to excessively large temperature rises i.e. exceeding 60°C, the result is a concrete of restricted and limited strength reached within days, in contrast to that which is expected from the long term storage of concrete in water at 20°C.

By simulating different typical curing regimes to which concrete can be subjected the strength of the hydrate at different ages, with various combinations of Portland cement and controlled quality fly ash, can be related to the quantity of lime, as  $\text{Ca(OH)}_2$ , found in the structure of the hydrate. It was also found that as the proportion of fly ash increased not only was there an improvement in strength, which increased with temperature of curing, but that in the hydrate there was an incidental reduction in the quantity of lime.

Within the range from nil to 75% fly ash as a proportion of the cement content, at about 30% fly ash, a maximum strength was attained at 28 days from curing at 80°C, this coincided with a reduction of about 50% in lime content of the hydrate. However, this amount of lime is more than sufficient to provide adequate protection to embedded steel reinforcement.

## 1.0 INTRODUCTION

1.1 When concrete made with Portland cement undergoes an early age temperature rise, such as that caused by the heat of hydration of the cement, the strength at 28 days is reduced in proportion to the size of the temperature change (1).

1.2 This reduction of strength can be partly explained by the combination of the impaired bond at the interface of paste and aggregate, known as micro-cracking (2) and by the macro-fracture of the gel structure by the expansion of air and water (3). However, if these phenomenon normally occur in concrete, how can the significant increase of strength be explained that occurs to concrete by the use of a composite cement, such as made of Portland cement and fly ash.

1.3 Research has shown that under comparable high temperature curing conditions, the 28 day strength of Portland cement concrete can be 60% or less of that made with a composite cement (4). This indicates, that whilst concretes made with different types of cement can undergo similar orders of temperature change, during hydration, there could be a significant difference in the chemical structure of the hardened paste.

## 2.0 EXPERIMENTAL

2.1 For this research to have practical application the test specimens required conditions of curing typical of that known to occur in concrete at early ages (5). The profiles of temperature and time known to be caused as a result of cement hydration are mainly dependant on the quality of cement and the dimensions of the element. Thus both the greater the cement content and/or size of the element, the greater will be the profile of temperature with time.

2.2 Figure 1 illustrates four profiles of temperature and time that are typical for a range of different conditions. Profile A represents for instance the standard curing of test specimens at 20°C, and profile D which could be typical of that within an element that has dimensions exceeding 2.5m x 2.5m x 2.5m, cast with concrete made with 450 kg/m<sup>3</sup> Portland cement.

Fig. 1 - Typical temperature/time profiles for concrete.

2.3 The technique for inducing the temperature rise in the test specimens, similar to that of the profiles in Figure 1 was to match by simulation the different curing regimes. This was done by having a series of 7 water baths each held at a constant temperature of 20, 30, 40, 50, 60, 70 & 80°C. Then by the transfer of sealed test specimens at various predetermined times the heating and cooling cycles of each profile of temperature could be simulated to those shown in Figure 2.

Fig. 2 - Curing cycles simulated to typical temperature/time profiles.

2.4 The authors have also observed from other research

i) Other than under adiabatic conditions the peak temperature experienced in most concrete elements usually occurs within 50 hours after casting.

ii) At 20°C the pozzolanic reaction between Portland cement and fly ash commences usually at about 11 days.

2.5 The means of correlating the effects of the different temperature profiles with both the maturity and the test results of the specimens, was to assume the equivalent period at 20°C was to the base temperature of -10°C (6). Thus the relative maturity of specimens cured by different regimes of temperature could be assessed to approximately 11 days or 8000°C hours (266.67 hours at 20°C.) Then by making the curing regimes conform with convenient factors of maturity i.e. 1.0, 1.125, 1.5 & 2.0, the test results could be correlated to 8000°C.

2.6 In conjunction with the primary test age at 11 days, the test times at 50 hours and 28 days were included so that crushing strength, the more conventional method of assessment, could be related to the different levels of maturity.

## 3.0 DETAILS of materials, mixes and tests

3.1 The criteria for the Portland cement selected was that it should be from a source with characteristics as close to the mean of that for all UK produced Ordinary Portland cements. Details of the cement used together with the mean and range of variability of 25 UK sources (excluding N. Ireland) are shown in Table 1.

See Table 1 at the end of the communication.

3.2 The fly ash conformed with UK Agreement Board Certificate ABC 75/283 ( 7 ). The results are compared in Table 1 with

- i) the typical chemical composition of UK fly ash, calculated to 3.0% loss on ignition, after ( 8 ) and
- ii) the mean quality of fly ash to ABC 75/283 produced during the period July, 1978 to June, 1979.

3.3 The mix was mortar, based on 1:3; cement:sand, to BS 4550 Part 6 quality. The mortar was machine mixed by a standard procedure, with sufficient water to attain a measured ASTM flow consistency of 100 - 110%. In each mix the fly ash substituted a proportion of the Portland cement in increments from nil to 15, 30, 45, 60 & 75%. In consequence the proportion of gauging water required was reduced relative to the amount of fly ash used from 0.495 for the control mix with no fly ash to 0.465, 0.445, 0.415, 0.40 & 0.39 respectively

3.4 From each mix 18 No. 50 mm cube specimens were made, compacted by vibration in 2 layers, then sealed and stored immediately, still in the mould, in water at 20°C. All specimens were removed from the moulds at 22 hours, sealed in polythene air evacuated envelopes and returned to the respective curing regime. At the appropriate time 3 specimens from each mix were tested for the determination of crushing strength and  $\text{Ca(OH)}_2$  content.

3.5 The technique used for the determination of  $\text{Ca(OH)}_2$  content was by the carbonation method of thermal analysis ( 9 ). This was effected by drilling to the centre of each of 3 cubes and immediately testing each of the drillings.

#### 4.0 TEST results

4.1 The results of the crushing tests at 50 hours, 11 days and 28 days are shown diagrammatically in Figures 3, 4, & 5.

Fig. 4 - Effect of fly ash on the 11 day strength as affected by maturity.

Fig. 5 - Effect of fly ash on the 28 day strength as affected by maximum curing temperature

4.2 The results for the amount of  $\text{Ca(OH)}_2$  present at 11 days are shown diagrammatically in Figures 6, 7, & 8.

Fig. 3 - Effect of fly ash on the 50 hour strength as affected by maturity.

Fig. 6 - Calcium Hydroxide in mortar at 11 days

Fig. 7 - Percent Calcium Hydroxide removed in mortar at 11 days.

## 5.0 DISCUSSION of the results

5.1 The crushing strength of the mortar with no fly ash cured at 20°C at 50 hours, 11 and 28 days was 19.1, 36.3 & 41.8 N/mm<sup>2</sup> respectively. Although the mortar was different in every respect i.e. mix proportions, size of aggregate and water/cement ratio, very close agreement was obtained to the

respective concrete crushing strength shown in Table 1.

5.2 The reduction of 32 percent in 28 day crushing strength of the mortar, with no fly ash, cured at more than 60°C is similar in magnitude to that found by other research (1).

5.3 For comparable curing conditions, at and exceeding 60°C, the 28 day crushing strength of the mortar with no fly ash was less than 70% of that made with 30% fly ash, this follows the effects found in (4).

5.4 Figure 3 shows that

- i) The strength at 20°C decreases proportionally with the percentage fly ash.
- ii) The increase in strength with maturity of the mortar with no fly ash is not maintained above 2750°C hours, where increased maturity reduces the strength.
- iii) Corresponding with increases in both fly ash content and maturity, the strength of the mortar increases. The optimum strength occurs with about 35% fly ash at a maturity of 3470°C hours. This approximates with a 2.64 factorial increase in strength for 2.33 factorial increase in maturity.

5.5 As Figure 4 shows at 11 days the trend is similar to that at 50 hours, in that:

- i) The crushing strength at 20°C proportionally decreases with the amount of fly ash, indicating little or no pozzolanic reaction.
- ii) The reduction in strength with increasing maturity for the mortar containing no fly ash is in agreement with other research (1).
- iii) By doubling the maturity and increasing the fly ash to 50%, twice the strength is obtained. However, the maximum strength obtained corresponds with about 30% fly ash.

5.6 Figure 5 shows the effect of fly ash on the 28 day crushing strength as affected by the early curing regimes and that:

- i) The crushing strength at 20°C is no longer proportional to the increase in fly ash, and there is indications of a strong pozzolanic reaction at all percentages of fly ash.
- ii) The strength, as affected by the early age curing regime of mortar without fly ash, is decreased, but increased at all percentages of fly ash, particularly at 75% where the 20°C strength is doubled by curing at 80°C.

5.7 Figure 6 shows the percentage Ca(OH)<sub>2</sub> plotted with respect to both the percentage fly ash and the maturity in °C hours. The Ca(OH)<sub>2</sub> is expressed as a percentage of the anhydrous weight of the sample, as the total loss on ignition of each sample was known from the thermogravimetric analysis.

The surface denoted by the solid lines in Figure 6 shows the amount of Ca(OH)<sub>2</sub> found to be present, and the surface denoted by the dashed lines the amount of Ca(OH)<sub>2</sub> that would have been present, from the cement, if there had been no reaction with the fly ash.

with each of the curing regimes the amount of  $\text{Ca(OH)}_2$  present, is proportional to the amount of Portland cement used and, therefore the amount of  $\text{Ca(OH)}_2$  formed for each concentration of Portland cement was calculated from the results obtained with no fly ash.

5.8 It is apparent from Figure 6 that:

- i) For samples cured at  $20^\circ\text{C}$  for 11 days there is a straight line relationship between the percent  $\text{Ca(OH)}_2$  and the percentage fly ash, indicating no pozzolanic reaction, which confirms the strength observations in 5.5.1.
- ii) For all other samples, in which both the maximum temperature attained and the period the samples experienced temperatures in excess of  $20^\circ\text{C}$ , the linear relationship ceases to exist between the percent  $\text{Ca(OH)}_2$  and the percentage of fly ash. In every case the fly ash reduced the amount of  $\text{Ca(OH)}_2$  present when compared with similar samples cured at  $20^\circ\text{C}$ .
- iii) Where no fly ash was used there was an increase in the percentage of  $\text{Ca(OH)}_2$  when the curing temperature exceeded  $20^\circ\text{C}$ .

5.9 The difference between the two surfaces illustrated in Figure 6, corresponds with the amount of  $\text{Ca(OH)}_2$  which has been removed by reaction with the amount of fly ash present. This difference is shown in Figure 7 where the percentage  $\text{Ca(OH)}_2$  removed is plotted with respect to both the amount of fly ash and the maturity at 11 days. Figure 7 also shows that the greatest amount of  $\text{Ca(OH)}_2$  was removed from specimens containing about 30% fly ash. Since the amount of  $\text{Ca(OH)}_2$  removed must have reacted with the fly ash, and if it is assumed that such a reaction increases the strength of the mortar, then this result implies that the greatest increase in strength with the curing regimes used, should occur with this amount of fly ash. This conclusion is seen from Figure 4 to be in very good agreement with the strength of the mortars at 11 days.

5.10 Figure 8 shows the amount of  $\text{Ca(OH)}_2$  that has been removed expressed as a percentage of that available from the cement. It is evident that the quantity removed increases with the percentage of fly ash. With the greatest percentage of fly ash very little free  $\text{Ca(OH)}_2$  remained in the hydrate. Such evidence is important when considering the necessity of having sufficient  $\text{Ca(OH)}_2$  present from the cement for good corrosion protection to the steel reinforcement of structural concrete. However, it should be noted that although some 50% percent of the available  $\text{Ca(OH)}_2$  has been removed when using about 35% fly ash, the amount of  $\text{Ca(OH)}_2$  remaining is more than sufficient to maintain a pH of about 12.5 with good corrosion protection.

## 5.0 CONCLUSIONS

6.1 By subjecting mortars to curing temperatures similar to those that can occur in practice the effects on concrete strength can be simulated.

6.2 The adverse effects of high curing temperatures on the strength of Portland cement mortars can be related to the amount of lime in the hydrate.

6.3 If high temperatures are likely to be experienced in practice, gains in strength are likely to occur with cements composed of Portland cement and fly ash.

6.4 The amount of residual lime in the hydrate, even when 75% fly ash was used, is sufficient to afford inhibition of corrosion to embedded steel reinforcement.

# Theme 3 - The influence of thermal treatment upon the creep of cement systems

by Leslie J. PARROTT, Cement and Concrete Association, England.

## INTRODUCTION

The use of concrete in building components and in-situ structures that are subjected to elevated temperatures has increased in recent years. Thermal stresses can arise if potential thermal movements are restrained and such stresses are of concern in nuclear pressure vessels, crude oil storage vessels and bridges subjected to solar radiation. Calculation of stresses requires a general model for the deformation of concrete. Since no reliable model is available concrete properties are normally obtained by experiments in which the concrete mix and the test environment simulate the expected conditions as closely as possible. The results of direct simulation tests are of limited use in developing a general model of thermal creep so basic studies were initiated recently which had the short-term objectives of improving the prediction of thermal creep and assisting the planning of simulation tests. A longer-term aim is to improve general models of creep in concrete. The following sections of this paper indicate recent progress towards these objectives.

## IRRECOVERABLE THERMAL CREEP

In many applications concrete is subjected to rises and falls of temperature and the reversibility of deformation under these conditions is an important factor in controlling long-term stresses. In an elastic material the time-dependence of thermal stresses are controlled by the rate of temperature equilibration and removal of a temperature profile returns the material to its original stress. A viscoelastic material would develop stresses at a rate dependent upon the rate of temperature equilibration and the rate of creep but removal of a temperature profile would again return the material to its original stress. However, in a material that develops irrecoverable creep, stresses develop at rates dependent upon the rates of temperature equilibration and creep but removal of the temperature profile would induce a residual stress. This effect of irrecoverable creep can be a serious problem with cyclic temperature changes and can lead to stresses that are opposite in sign to those calculated from an elastic analysis.

## LITERATURE ON THERMAL CREEP COMPONENTS

Recent work by Illston and Sanders (1,2) showed that thermal creep was a function of the time between the start of heating and the start of stressing. An increase in the period of preheating reduced the thermal creep that was subsequently

measured. Unfortunately this fact had not been appreciated in many studies of thermal creep and in consequence the results are of limited use. Illston and Sanders conducted their creep tests on cement mortar loaded in torsion. This approach simplified a number of testing problems but it was not clear if the results obtained would prove valid in the more practical case of concrete loaded in compression. The torsion results were analyzed, as illustrated in Figure 1, by dividing the load-induced strains into the following components:

- a) Elastic Strain. This was proportional to stress and increased with temperature. A secondary effect of elevated temperature was that it increased cement hydration.

Figure 1. Components of load-induced strain.

This caused some moderation of the increase in elastic strain with increasing temperature. The overall effect of temperature in the range 20 to 80°C upon elasticity was not large.

- b) Recoverable Creep. This was similar in many ways to elastic strain but it took a few weeks for its development to stabilize.
- c) Flow (Irrecoverable). Flow developed over a prolonged period and was proportional to stress. Its rate of development was dependent upon the current temperature and did not depend upon temperature history apart from a small indirect effect upon the development of the cement paste microstructure.
- d) Transitional Thermal Creep (Irrecoverable) This component dominated creep if the mortar had not been heated previously. It developed fairly rapidly after heating (i.e., within one month) and there were no subsequent increases in creep with a reduction in temperature or a second increase.

Deformation results from concrete loaded in compression under various temperature regimes could also be divided into the four components given above (3). The components of compressive creep were incorporated into the analysis of a flexurally-restrained concrete wall that was periodically subjected to a temperature gradient. The analysis successfully predicted experimental results from a full scale wall element and this suggested that a better understanding of the components of thermal creep would be of practical benefit. For example if the effects of mix proportions, aggregate type, cement type or age of heating upon thermal creep were known to be significant some control would be possible. As a preliminary step towards understanding the components of thermal creep we will now consider the effects of elevated temperature upon the microstructure of concrete and its cement paste phase.

#### POSSIBLE EFFECTS OF HEATING UPON MICROSTRUCTURE

It is appropriate for many practical applications to consider moist concrete subjected to temperatures up to 80°C but even with these limitations a number of microstructural changes are possible. Although most aggregates are not altered by heating some thermal stress and cracking could develop at the aggregate/cement paste interface as a result of thermal expansion coefficient differences. Furthermore the cement paste matrix can be modified chemically and physically. The main chemical effects are an acceleration of cement hydration and an increase in the level of silicate polymerization within the cement hydrates. There is also a possibility that some cement hydrates may dehydrate at elevated temperature. Physical changes can arise from what may be regarded as coagulation of hydrate particles. This would cause a change in the pore size distribution. The porosity would diminish if any additional cement hydration occurred.

#### CAUSES OF IRRECOVERABLE THERMAL CREEP

A preliminary stage in understanding thermal creep is to clarify the role of aggregate/cement paste thermal incompatibility. The simplest approach was to compare the thermal creep of cement paste and concrete or mortar. The results of such a comparison (4) suggested that the thermal creep of concrete was dominated by the response of the cement paste matrix. Each of the strain components mentioned earlier in Section 3 were present in the cement paste results. Measurements of physical and chemical structure indicated that the irrecoverable thermal creep correlated with an increase in polysilicate formation in the cement hydrates (5,6). Some experimental results are illustrated in Figure 2a and they suggest that acceleration of the molecular rearrangement that is associated with silicate polymerization greatly enhances creep. The similarity between the results for 20 and 60°C in Figure 2a suggests that there is no difference in mechanism between "flow" and "transitional thermal creep." Increases in creep can be found in other materials if they undergo a phase change whilst loaded.

Although the results in Figure 2a were encouraging it was possible that some unmeasured change in the complex microstructure of the cement paste was responsible for the increase in creep. The effect of silicate structure upon creep was therefore studied using a very simple cement; hydrated

Figure 2. Thermal creep versus polysilicate formation as indicated by  $S_{300}$  (7)

calcium silicate. The primary components in this system are calcium silicate hydrates and calcium hydroxide. The results obtained so far (Figure 2b) again show that thermal creep development is associated with changes in polysilicate formation. Indeed if allowance is made for the slight difference in stress level used in the cement and tricalcium silicate tests the slopes of the lines in Figures 2a and 2b are virtually the same. This similarity indicates that thermal creep in cement paste (and in structural concrete) is caused by the response of the calcium silicate hydrates.

It should be emphasized that heating concrete, hardened cement paste or hydrated calcium silicate before stressing will reduce thermal creep because the potential for microstructural changes in a subsequent thermal creep test will thereby be reduced (1,2,3,4,6). The reduction in thermal creep will depend upon the duration of preheating since the changes in microstructure take a few weeks to develop. Published results for cement paste (4) and current results for hydrated calcium silicate show that prolonged rest periods at 20°C can cause some regeneration of thermal creep potential.

#### RESPONSE OF HYDRATED TRICALCIUM SILICATE TO HEATING

In addition to the gross changes in polysilicate formation indicated by S300 (7) a more detailed analysis of silicate structure was undertaken together with studies of nitrogen adsorption, x-ray diffraction, thermogravimetric analysis and water sorption. The detailed silicate structure analysis (7) demonstrated that the proportion of polysilicate and its degree of condensation increased with the duration of heating as shown in Figure 3. The increase in polysilicate content was accompanied by reductions in the amounts of monomeric and dimeric silica. The reaction curves in Figure 3b were computed by subtracting the monosilicate and disilicate contributions from the total silica complexed and normalizing the residual polysilicate contribution to unity (7). The decrease in slope of the reaction curves in Figure 3b is indicative of an increasing degree of condensation with duration of heating.

Nitrogen adsorption measurements showed that heating caused minor surface area changes that did not correlate with the thermal creep results. The x-ray diffraction results indicated that heating at 60°C at an age of 42 days accelerated hydration but the changes were small during the period that the main part of thermal creep developed. Furthermore first heating at an age of 175 days caused substantial thermal creep but had no significant effect upon hydration. Calculated values of lime/silica ratio in the calcium silicate hydrates were in the normal range of 1.6 to 1.9 for heated and non-heated samples. Thermogravimetric analysis indicated that there were no major changes in the shape of the weight loss/temperature curves with heating at 60°C. This implies that there were no major changes in the products of hydration. However a slight increase of weight loss was noted in the thermogravimetric temperature range 200 to 440°C for samples treated at 60°C. A similar increase was noted in previous work with hardened cement paste (8).

Figure 3. Polysilicate development in hydrated tricalcium silicate paste heated to 60°C at an age of 42 days a) proportion of polysilicate and b) molybdate complexing curves.

Figure 4. Effect of heating hydrated calcium silicate paste to 60°C at an age of 42 days upon subsequent desorption behavior.

Water sorption studies included first desorption and first adsorption measurements of the type obtained earlier for cement paste (8). The first desorption results for hydrated calcium silicate (Figure 4) suggested, like those for hardened cement paste, that the volume of larger pores increased and the volume of smaller pores decreased with an increase in the duration of heating. The kinetics of these changes in water desorption characteristics were similar to those for thermal creep and silicate polymerization. The first adsorption results suggested, like those for hardened cement paste, that there was no major effect of heating. This difference in sensitivity to heating between first desorption and first adsorption characteristics presumably arose because heating and drying had similar effects upon pore structure.

### CONCLUSIONS

Some conclusions from the data presented in this report are listed below:

- i. Irrecoverable thermal creep in concrete is a consequence of the basic constituent of the cement binder - the calcium silicate hydrate. Thus thermal creep is not likely to be greatly altered by normal variations of aggregate type, cement type or mix proportions.
- ii. One obvious way of controlling thermal creep is to heat prior to stressing, although this may be of limited use because of the possible regeneration of some thermal creep potential with prolonged rest periods at 20°C.
- iii. Modelling of thermal creep is likely to be more successful if it reflects the observed changes in microstructure.
- iv. Thermal creep is associated with changes in silicate polymerization and pore structure.

## Theme 4 - Influence of admixtures

by O. HENNING - HAB - Weimar, DDR,  
V.B. RATINOV - MAI - Moscow, USSR.

### I Introduction

Starting-point of development and application of chemicals for the use in the production of concrete is the fact that the improvement of cements is limited not only by raw materials but also by technology of cement production.

Moreover there is an actual demand to economize energy, which can be accomplished either by reducing specific cement contents of concrete, i.e. to produce more concrete by using the same quantity of energy intensive cement, or by omitting heat treatment of concrete.

After it was empirically established that many natural and synthetic compounds affect the setting process, at present the mechanism of the processes are being investigated in order to systematically develop more effective admixtures.

In recent years many investigations have been performed in several countries in the field of concrete admixtures. The aim of these investigations was to improve some properties of concrete, to reduce costs of production of concrete, and to avoid secondary effects which impair concrete.

Because during hydration concrete is a continually changing system of many compounds the results of all efforts have been small so far. Nevertheless some exact relationships and regularities have been found.

### II Classification of admixtures

It has to be considered that each admixture has several effects but only one effect is most distinctive. For instance, the accelerator calcium chloride also acts as an antifreezing admixture for winter concreting. The plasticizer lignosulfonate also acts as a retarder.

Admixtures for concrete can be classified into two main groups:

- admixtures affecting hydration behaviour
- admixtures affecting flowability behaviour

Beside the two main groups there is a third group of admixtures with special effects. To this group belong antifreezing agents, corrosion inhibitors for reinforcing steel etc.

To the group of admixtures affecting hydration behaviour belong accelerators and retarders. Accelerators shall either shorten the time until setting starts to a few minutes (e.g. sodium fluoride, iron(III) chloride, sodium aluminate / potassium carbonate / sodium sulfate) or increase the initial development of strength or make the heat treatment of concrete more effective resp., by reducing the starting period, lowering the maximum temperature, and reducing stopping time (e.g. calcium chloride, calcium nitrate / calcium nitrite).

Retarders were used in order to extend the setting time or to reduce the hydration, resp. Compounds such as sodium phosphates and borates result in the possibility of washing out the concrete at the surface of concrete elements, which leads to good surface effects of exposed concrete.

To the group of admixtures affecting flowability behaviour of fresh concrete belong plasticizers and superplasticizers. These additives are mainly used to improve the following concrete properties:

- improved workability without increasing water content (dispersing effect)
- decreased water content at the same workability (increased strengths)
- improved penetration and pumpability
- reduced unit costs of concrete

It has been shown that both short-chain and long-chain surfactants can be used as cement dispersing agents. They can be made synthetically or be obtained from natural products. It seems to be essential that not the length of chains but the presence of hydrophylic and hydrophobic groups in definite distribution is most important. These compounds are adsorbed at the cement surface and cause a reduction of the attractive forces between cement particles. The maximum effect is obtained with monomolecular covering. Higher concentrations lead to a considerable retardation of hydration rate causing an obstruction of the water diffusion to the cement surface.

### III Papers received

In the following it will be given a short survey of the presented papers which belong to the sub-theme 'Influence of admixtures'. These papers are:

- The combining of sodium chloride and calcium chloride by hardened portland cement compounds  $C_3S$ ,  $C_2S$ ,  $C_3A$  and  $C_4AF$ , by E.M. THEISSING, T. MEBIUS-VAN DE LAAR and C. DE WIND
- Influence of sulfonated naphtalene on the fluidity of cement pastes, by M. COLLEPARDI, M. CORRADI, G. BALDINI and M. PAURI
- Influence of cement composition on setting time of concrete containing a set-retarding admixture, by C.T. TAM
- Effect of surfactants on the hydration properties of cements, by O. HENNING and L. GORETZKI

The contribution by THEISSING et al. informs about an interesting non-destructive method which allows the experimental measurement of the amount of chloride ions dissolved in the pore solution of hardened cement compounds setting in the presence of sodium chloride and calcium chloride. The equilibrium between the pore solution and the equilibrating solution is considered to be a liquid/liquid equilibrium. That means that the equilibrium concentrations in the equilibrating solution and the pore solution are equal. That it is possible to calculate the dependence of the amount of chloride combined by the compound on the total amount added to the compound. Knowledge of the amount of free chloride in the pore water is necessary to predict corrosion of steel reinforcement.

The paper presented by COLLEPARDI et al. concerning the effect of sulfonated naphtalene in monomeric and polymeric form on cement pastes confirms the theory suggested above. It has been shown that with a dry polymeric addition of 0,25 - 0,50 % by weight of cement the dispersing effect is good enough without any significant retarding effect in the hydration rate. With higher quantities of 1,0 - 1,5 % the retarding effect is significantly increased whereas the flowability is not substantially improved.

The paper by TAM deals with the effect of a retarder of unknown composition depending on the alkali content of cements. The results indicate that tricalcium aluminate and alkali content influence both the absolute setting time and the delay in setting. A change in equivalent alkali content in excess of 0,25 % alters the delay in setting significantly.

The paper of HENNING et al. gives a summarizing survey of cement dispersing agents and shows the development of an effective plasticizer on the basis of

succinic acid. The plasticizers used were synthesized from anhydride of maleic acid, sodium hydrogensulfite, aliphatic alcohols ( $C_{16}$  -  $C_{18}$ ), and ethylene oxide (5 - 40 mole). Using the WASHBURN equation for the flow of liquid through a capillary it was possible to calculate from the rate of penetration the magnitude of the advancing contact angle (fig. 1) and the energy of adhesion between the liquid and the cement powder (fig. 2). With increasing concentration of optimum plasticizer the contact angle decreases and within a definite range of concentration it becomes zero. At higher concentration the angle rises again. The calculated energy of adhesion is at its maximum using a medium concentration.

Finally it should be added that a comprehensive paper concerning the present theories of the mechanism of cement hydration and its interaction by admixtures is presented by SKALNY and YOUNG as report to the sub-theme II-1 of this congress.

# The combining of sodium chloride and calcium chloride by the hardened portland cement compounds $C_3S$ , $C_2S$ , $C_3A$ and $C_4AF$

## *Les propriétés combinatoires des constituants du ciment portland par rapport à $NaCl$ et $CaCl_2$*

E.M. THEISSING, T. MEBIUS-VAN DE LAAR, G. DE WIND,  
DELFT University of Technology, Dept. of Civil Engineering, Materials Science Group, Stevin Lab.,  
Delft, The Netherlands.

SUMMARY : A non-destructive method is presented to study the combining properties of hardened  $C_3S$ ,  $C_2S$ ,  $C_3A$  and  $C_4AF$  for  $NaCl$  and  $CaCl_2$ . The compounds hardened with solutions of  $NaCl$  and of  $CaCl_2$  are equilibrated in solutions of these electrolytes in a special way. To interpret the results the equilibrium between the pore solution and the hardened compound is taken as a general solid/solution equilibrium. The equilibrium between the pore solution and the equilibrating solution is considered to be a liquid/liquid equilibrium. That means that the equilibrium concentrations in the equilibrating solution and the pore solution are equal. Thus it is possible to calculate the dependence of the amount of chloride combined by the compound on the total amount added to the compound.

RESUME : On décrit une méthode non-destructive pour déterminer les propriétés combinatoires par rapport à  $NaCl$  et  $CaCl_2$  des constituants durcis du ciment portland  $C_3S$ ,  $C_2S$ ,  $C_3A$  et  $C_4AF$ . Les constituants durcis avec des additions de  $NaCl$  et  $CaCl_2$  sont équilibrés dans des solutions de ces sels d'une manière spéciale. Dans le but d'interpréter les résultats expérimentaux on considère l'équilibre entre le constituant durci et le liquide interstitiel comme un équilibre général entre une matière solide et une solution. L'équilibre entre la solution interstitielle et la solution équilibrante est considéré comme un équilibre liquide/liquide. Cela signifie que les concentrations des électrolytes dans ces solutions sont les mêmes en l'état d'équilibre. Cela rend possible de calculer la relation entre la quantité de chlorure, combinée par le constituant et la quantité totale de chlorure dans le constituant.

## INTRODUCTION

The behaviour of chlorides in concrete has aroused much interest throughout the years especially because of their special properties as to the hardening acceleration of cement and the corrosion of steel reinforcement. It is therefore that one is interested in the amount of free chloride in the pore water and in the amount of chloride combined by the cement when chlorides have been added to the mixing water.

It has been known for many years that both NaCl and CaCl<sub>2</sub> can be combined by cements. A number of authors investigated the combining properties of hardened cement (mostly portland cement). They determined the amount of combined chloride by extraction of free chloride in the pore water of the hardened cement by means of water or an organic liquid. For a review of the literature we refer to Theissing, van Hest-Wardenier and de Wind (1).

All these extraction methods are in fact destructive methods with all their drawbacks as disturbance of sorption and chemical equilibria between the pore water solution and the pore surfaces in the hardened cement. We consider these methods to be unsuitable for the said purpose. Moreover, the solubilities of some compounds present in the pore water are only slightly soluble in organic liquids. They may precipitate, thus disturbing the precipitation.

Theissing, van Hest-Wardenier and de Wind (1) reported on a non-destructive method to determine the combining properties of hardened cement paste. That method does not have the drawbacks of the extraction methods.

We applied this non-destructive method to the main portland cement compounds C<sub>3</sub>S, C<sub>2</sub>S, C<sub>3</sub>A and C<sub>4</sub>AF aiming at determining the relative contribution of these compounds to the overall combining properties of portland cement.

In the following sections we will describe the method used and report on the results.

## METHOD

When hardened cement compound has been equilibrated with a chloride solution, there are two overall-equilibria in the case. First, there is the equilibrium between the free chloride in the pore water and the solids in the cement and second, that between the chloride in the pore water and in the equilibrium solution.

This can schematically be depicted as:

In this equation no other ions are being taken into account.

The first equilibrium (I) consists of a chemical, a sorption, a solid solution/liquid equilibrium or a combination of these three. The overall-equilibrium is generally represented by a curved equilibrium isotherm.

The second equilibrium (II) we consider to be a water/water partition equilibrium. That means that the equilibrium concentrations in the pore water and in the chloride solution are equal, assuming that pore water generally spoken has bulk water properties. Thus its equilibrium isotherm is a straight line bisecting the right angle between the axes.

To be able to calculate the amount of chloride, combined by the compound hydrates, one has to measure three quantities. These are the total chloride content of the compound Cl<sub>t</sub>, the amount of its pore water w<sub>p</sub>, and the concentration of the equilibrium solution Cl<sub>e</sub>. The quantity of combined chloride Cl<sub>c</sub> can then be calculated by subtracting w<sub>p</sub>Cl<sub>e</sub> from Cl<sub>t</sub> i.e. Cl<sub>c</sub> = Cl<sub>t</sub> - w<sub>p</sub>Cl<sub>e</sub>.

The described method may produce somewhat uncertain results in the lower concentration range, whenever the cement is prone to react as an ion exchanging material i.e. when ion exchanging groups are fixed on the pore walls. This phenomenon generally is of influence, as far as the concentration in the equilibrium solution is comparable to the concentration of these groups, calculated on the quantity of pore water. In that case a Donnan equilibrium is established. For details on this phenomenon we refer to textbooks on physical chemistry, as for instance Moelwyn-Hughes's treatise (2).

## EXPERIMENTAL METHODS AND RESULTS

### MATERIALS

Analytical grades of NaCl, CaCl<sub>2</sub> and Ca(OH)<sub>2</sub> have been used throughout the investigations. All cement compounds have been supplied by the Portland Cement Ass., Skokie, Ill., (USA).

The analyses as far as available are presented in Table I.

### METHODS and results

The cement compounds are thoroughly mixed with salt solutions of known concentrations. The water/compound ratios (w.c.r.) are 0.35 for C<sub>3</sub>S and C<sub>2</sub>S, 0.5 for C<sub>4</sub>AF and 0.7 for C<sub>3</sub>A.

The following hydration is carried out in test tubes, tightly closed with rubber stoppers. After a period of 28 days the hardened paste is broken into small lumps. A few of these lumps are weighed and then placed in solutions of either NaCl or CaCl<sub>2</sub> of known concentrations. In order to prevent extraction of Ca(OH)<sub>2</sub> from the cement during equilibration the salt solutions have been saturated with this compound. The solution/compound ratio is 5. After an equilibration time of 10-14 days, the supernatant solution is titrated for chloride. The system has not been thermostatted. The ambient temperature is 21 ± 2°C.

TABLE I					
	CaO	SiO <sub>2</sub>	Free CaO	Al <sub>2</sub> O <sub>3</sub>	Fe <sub>2</sub> O <sub>3</sub>
C <sub>3</sub> S	72.60	26.06	0.57		
C <sub>2</sub> S					
C <sub>3</sub> A	61.48	0.83		37.07	
C <sub>4</sub> AF	45.82			20.43	32.65

Analysis of the portland cement compounds (wt.%)

Whenever the solution concentration after that time interval is equal to be initial concentration, it is considered to be the equilibrium concentration. New lumps are placed in solutions of higher or lower concentrations, whenever the concentration of the supernatant solution, determined after the specified time interval, has decreased or increased resp. This procedure is repeated, until the concentration of the equilibrating solution has not changed after 10-14 days of contact with the compound.

Pore water content is determined on separate samples after the 28 days hardening period, by heating them in a stove at 105°C to constant weight. The whole of the compound is considered to be in equilibrium with the pore solution, including the surfaces of its cracks and pores containing air. This means that, when solution of equilibrium concentration penetrates these voids, chloride is neither taken up nor liberated by the cement. The accuracy of the results is estimated to be ca. 5%.

The results for the compounds are recorded in Tables II-V.

Total content of  $\text{NaCl}$ ,  $\text{Cl}_t$  (in % by wt. of compound), equilibrium solution concentration,  $\text{Cl}_e$  (in % by volume of solution) and combined  $\text{NaCl}$  (in % by wt. of compound) for a hardened  $\text{C}_3\text{A}$  and b hardened  $\text{C}_4\text{AF}$ .

In figs. 1 and 2 total  $\text{CaCl}_2$  and  $\text{NaCl}$  contents of the compounds  $\text{C}_3\text{S}$ ,  $\text{C}_2\text{S}$ ,  $\text{C}_3\text{A}$  and  $\text{C}_4\text{AF}$  are plotted against solution equilibrium concentrations of these salts. It has to be noted that the solution equilibrium concentration of the salt is considered to be equal to the equilibrium salt concentration in the pore water.

In figs. 3 and 4 combined amounts of  $\text{CaCl}_2$  and  $\text{NaCl}$  are plotted against equilibrium solution concentrations.

## DISCUSSION

As to the question whether by our method equilibrium is attained, we refer to ref. 1. We reported there that the differences between  $\text{Cl}_e$  values after one year and short term equilibrations (as applied in our experiments) for a number of cement samples were all smaller than 0.5%, calculated on the short term values. We therefore assume that in our cement compound experiments equilibrium has been attained.

We will discuss the results for a  $\text{C}_3\text{S}$  and  $\text{C}_2\text{S}$  b  $\text{C}_2\text{A}$  and c  $\text{C}_4\text{AF}$  separately.

a  $\text{C}_3\text{S}$  and  $\text{C}_2\text{S}$ .

The mechanisms by which the electrolytes can be combined are chemical reactions, solid solution formation

Fig. 1 - Dependence of total  $CaCl_2$  content of hardened  $C_3S$ ,  $C_2S$ ,  $C_3A$  and  $C_4AF$  on equilibrium concentration of  $CaCl_2$ .

Fig. 2 - Dependence of total  $NaCl$  content of hardened  $C_3S$ ,  $C_2S$ ,  $C_3A$  and  $C_4AF$  on equilibrium concentration of  $NaCl$ .

Fig. 3 - Dependence of calculated combined  $\text{CaCl}_2$  by hardened  $C_3S$ ,  $C_2S$ ,  $C_3A$  and  $C_4AF$  on equilibrium concentration of  $\text{CaCl}_2$ .

Fig. 4 - Dependence of calculated combined  $\text{NaCl}$  by hardened  $C_3S$ ,  $C_2S$ ,  $C_3A$  and  $C_4AF$  on equilibrium concentration of  $\text{NaCl}$ .

and sorption on the pore walls. The method reported here does not enable us to differentiate between these mechanisms.

The electrolyte concentrations in our experiments are too low to allow forming complex compounds of  $\text{Ca}(\text{OH})_2$  and  $\text{CaCl}_2$ . Compare also the literature review in ref. 1. Using Richartz's results (3), however, it is possible to roughly calculate the amount of  $\text{CaCl}_2$  sorbed on the pore walls of hardened  $\text{C}_3\text{S}$ . This investigator completely hardened  $\text{C}_3\text{S}$  in solutions of  $\text{CaCl}_2$  (w.c.r. 5). To determine the amount taken up into the hydrate lattice, the samples were next thoroughly extracted with water. At a concentration level of the mixing water of 1.33%  $\text{CaCl}_2$  the  $\text{CaCl}_2$  content of the hardened  $\text{C}_3\text{S}$  sample turned out to be 0.47% (by wt. of  $\text{C}_3\text{S}$ ). Considering the final solutions of Richartz's hydration experiments to be equivalent to our equilibrium solutions one can calculate the equilibrium concentration in Richartz's final hydration solution. It is 1.34%  $\text{CaCl}_2$  (by wt. of vol.). Interpolation in Table II leads to a total amount of  $\text{CaCl}_2$  i.e. electrolyte taken up into the hydrate lattice and electrolyte sorbed on the hydrate surface,  $\text{Cl}_t$ , of 1.45% (by wt. of compound). That means that about 1%  $\text{CaCl}_2$  is sorbed on the hydrate surface. It has to be noted, however, that Richartz's samples had been completely hydrated. The extent of hydration of our samples was not determined.

Comparing  $\text{C}_3\text{S}$  to  $\text{C}_2\text{S}$  we found the equilibrium concentrations i.e. the pore water concentrations, to be higher for  $\text{C}_3\text{S}$  than for  $\text{C}_2\text{S}$ . The pore water contents of the  $\text{C}_3\text{S}$  samples are lower than those of the  $\text{C}_2\text{S}$  samples. We assume that that means that the extent of hydration of the latter samples is lower. Hydration water figures are not available, however.

We compared the  $\text{C}_3\text{S}$  and  $\text{C}_2\text{S}$  results to the results for portland cement (PC) (ref. 1) for the lower range of  $\text{CaCl}_2$  additions. We suppose the PC to consist of 60%  $\text{C}_3\text{S}$ , 15%  $\text{C}_2\text{S}$ , 10%  $\text{C}_3\text{A}$  and 10%  $\text{C}_4\text{AF}$  ("synthetic PC"). Moreover, we suppose that the silicates react independently of the other compounds in the cement. In Table VI the figures are recorded for  $\text{C}_3\text{S}$  and  $\text{C}_2\text{S}$ . For the "synthetic PC" they were obtained by interpolation in Table III in ref. 1.

The figures in Table VI show that more  $\text{CaCl}_2$  is combined by PC than is calculated for a "synthetic PC". We suppose that the rest is combined by  $\text{C}_3\text{A}$  and  $\text{C}_4\text{AF}$  (compare b and c).

As to the difference between  $\text{NaCl}$  and  $\text{CaCl}_2$ ,  $\text{CaCl}_2$  is generally somewhat stronger combined than  $\text{NaCl}$  on a weight basis.

#### b $\text{C}_3\text{A}$ .

The experiments show that chlorides very strongly combine with hydrated  $\text{C}_3\text{A}$ ,  $\text{CaCl}_2$  even more strongly than  $\text{NaCl}$ . We therefore assume that in any case part of the discrepancy between PC and "synthetic PC" is caused by free  $\text{C}_3\text{A}$  and  $\text{C}_4\text{AF}$  hydrates. The chlorides are only combined by the cement when all the sulphate has been combined by the hydrates of  $\text{C}_3\text{A}$  and  $\text{C}_4\text{AF}$  as investigations by e.g. Schwiete, Ludwig and Albeck (4) showed when cement is hardened with solutions of  $\text{CaCl}_2$ .

A w.c.r. of 0.70 has been taken for the hydration of  $\text{C}_3\text{A}$ . Mixtures with lower w.c.r. could not be handled because of their very high rate of hardening.

$\text{CaCl}_2$  is more strongly combined than  $\text{NaCl}$ , especially at the higher concentration levels. The combining capacity of  $\text{C}_3\text{A}$  hydrate for both  $\text{CaCl}_2$  and  $\text{NaCl}$  is much higher than that of  $\text{C}_3\text{S}$  and  $\text{C}_2\text{S}$ .

#### c $\text{C}_4\text{AF}$ .

The combining properties of the hydrate of this compound are equal to those of  $\text{C}_3\text{A}$  to within the accuracy of the measurements. The w.c.r. has been taken as 0.5. A value of 0.70 would have been preferable. Mixtures of that composition were too wet to handle, however.

### CONCLUSIONS

$\text{NaCl}$  and  $\text{CaCl}_2$  are combined by both hardened  $\text{C}_3\text{S}$  and  $\text{C}_2\text{S}$ . The greater part of the combined amount of electrolyte is very probably bound by sorption on the pore walls in the hardened compound.

The calculated amount of  $\text{CaCl}_2$  combined by a mixture consisting of quantities of  $\text{C}_3\text{S}$  and  $\text{C}_2\text{S}$  as present in an average portland cement is smaller than the measured amount of  $\text{CaCl}_2$  combined with a portland cement. That is probably caused by those parts of the hydrated  $\text{C}_3\text{A}$  and  $\text{C}_4\text{AF}$  not having reacted with the sulphate present in the cement.

Hydrated  $\text{C}_3\text{A}$  and  $\text{C}_4\text{AF}$  combine much more strongly with both  $\text{NaCl}$  and  $\text{CaCl}_2$  than do hydrated  $\text{C}_3\text{S}$  and  $\text{C}_2\text{S}$ .

$\text{CaCl}_2$  is somewhat more strongly combined than  $\text{NaCl}$  by both hydrated  $\text{C}_3\text{A}$  and  $\text{C}_4\text{AF}$ .

# Influence of cement composition on setting time of concrete containing a set-retarding admixture

## *L'influence de la composition du ciment sur la durée d'affermissement d'un béton qui renferme un mélange retardant la prise*

C.T. TAM, Singapour.

RESUME : Le temps de prise d'un béton, défini par l'essai de pénétration sur le mortier obtenu par tamisage de ce béton, est l'un des critères de choix des additifs chimiques. La durée absolue du temps de prise et le retard provoqué par l'additif retardateur ont été tous deux étudiés en utilisant une méthode modifiée, dans laquelle le mortier est malaxé séparément. Quatre sortes de ciments, contenant des proportions fixes d'additifs, ont été étudiés dans la série A.

Dans la série B, l'effet d'une augmentation de l'alcalinité par addition d'hydrate de soude pur a été étudié. Dans ces deux séries, on a comparé les résultats des essais avec et sans additif. Les résultats montrent que les teneurs en aluminat tricalcique et en alcali influencent le temps de prise et le retard de prise. Une variation de la teneur en alcalis de 0,25 % modifie beaucoup le temps de prise.

SUMMARY : Setting time of concrete as determined from penetration resistance of mortar wet-sieved from a concrete mix is one of the acceptance criteria for chemical admixtures. Both the absolute setting time and the delay in setting due to the addition of a set-retarding admixture were investigated using a modified approach in which the mortar was directly mixed. Four different brands of cement at constant mix proportions were studied in Series A.

In Series B, the effect of increasing alkali content of a cement was observed by adding sodium hydroxide of reagent grade. For each series, plain and admixture treated mixes were compared. The results indicate that tricalcium aluminate and alkali content influence both the absolute setting time and the delay in setting. A change in equivalent alkali content in excess of 0.25 percent alters significantly the delay in setting.

## INTRODUCTION

The setting of Portland cement is a complex process. In practice, the setting time is defined as the time taken for a cement paste of standard consistency to reach an arbitrary degree of stiffness, for example by the Vicat apparatus. Similarly, the setting time of concrete is defined as the time from the completion of mixing for the wet-sieved mortar from the concrete mix to reach a chosen penetration resistance. The main purpose of the test is for measuring the change in setting time due to the presence of a chemical admixture. The effect of cement composition on the ability of a retarder to delay setting is the main theme of this paper.

## SETTING TIME TEST

The development of the setting time test for concrete was based on the work by TUTHILL and CORDON (1) using the Proctor Penetrometer. This has been incorporated in ASTM C 403, (2) Test for Time of Setting of Concrete Mixtures by Penetration Resistance. The penetration resistance is not measured directly on the concrete mix but on the mortar fraction wet-sieved from the mix. Two setting times are defined. The initial set is taken to be at a penetration resistance of  $3.5 \text{ N/mm}^2$  (500 p.s.i.) which according to TUTHILL and CORDON (1) corresponds to the vibration limit of concrete, i.e. the mix cannot be made plastic by re-vibration. The final set is at the penetration resistance of  $27.6 \text{ N/mm}^2$  (4,000 p.s.i.). At this stage the concrete starts to harden, having a compressive strength of about  $0.7 \text{ N/mm}^2$  (100 p.s.i.).

The test method prescribed in BS 5075: 1974 (3) is basically similar to that of ASTM C 403 (2). It specifies two stages of the setting process, one at  $3.5 \text{ N/mm}^2$  which corresponds to the initial set in ASTM C 403 (2), and the other at a much lower penetration resistance value of  $0.5 \text{ N/mm}^2$  (73 p.s.i.). According to FLETCHER and ROBERTS (4), this earlier stage corresponds to the extreme limit of workability for placing and compacting the concrete. There are other differences in the details of conducting the setting time test between the methods of ASTM C 403 (2) and BS 5075: 1974 (3). A comparison of these two methods of testing and comments on their relative merits are in the course of preparation (5).

## EXPERIMENTAL PROGRAMME

The programme of study was divided into two series of mixes to investigate the different parameters as follows:-

Series A - four different brands of ordinary Portland cement at constant mix proportions (sand-cement ratio = 2.0 and water-cement ratio = 0.40).

Series B - increase in alkali content by the addition of reagent grade sodium hydroxide at 0.25, 0.50 and 0.75 percent by weight of cement with constant mix proportions as those in Series A.

For each series plain mixes and corresponding mixes with the addition of a water-reducing set-retarding admixture at the recommended dosage were investigated.

## Materials

The materials for the two series were not always identical. However, within each series all materials were kept constant except for Series A where the cement brand forms the variable parameter. The sands used were always in the oven dry condition. One brand of water-reducing set-retarding admixture was used in Series A and a different brand of admixture, but of the same class, was employed for Series B. In all cases the admixture was added at the recommended dosage. Details of the various cements, sands and admixture for the programme are listed in Appendix A. The combinations of materials used are indicated in the respective table of results.

## Testing method

For the setting time test, both ASTM C 403 (2) and BS 5075: 1974 (3) call for the mortar sample to be wet-sieved from the concrete mix. However, in this programme all mortar mixes were batched directly in their chosen proportions. OKABE, NAKAJIMA and YOSHIHARA (6) have found that similar results may be produced for either method of obtaining the mortar sample by suitable adjustment to the method of mixing the mortar directly. This was not attempted in the present study. However, for a particular case where data for both methods of preparation are available, it is observed that although the absolute values of setting time are different, the resultant delay in setting is similar. Appendix B shows a summary of the data for this case.

The method employed in mixing the mortar directly was standardised as follows:

- 90 percent of the total mixing water was thoroughly mixed with the sand in a mechanical mixer of the epicyclic type.
- the balance of the water, with the admixture thoroughly mixed into it if used, was then added while the mixer was still running.
- cement was added within the next minute while the mixer was kept running for  $2\frac{1}{2}$  minutes at low speed.
- the mixer was stopped and materials on the side of the bowl was scrapped down.
- the mixer was then restarted at medium speed and allowed to run for  $\frac{1}{2}$  minute to complete the mixing.

In order to compromise between different detailed requirements of ASTM C 403 (2) and BS 5075 (3) the conduct of the penetration resistance test was in accordance with BS 5075 (3) up to a penetration resistance just beyond  $3.5 \text{ N/mm}^2$  (500 p.s.i.), and after this, in accordance with ASTM C 403 (2). For Series A only single runs were conducted. For Series B two duplicate batches were tested. The average of the two runs is reported in the results. This is in agreement with BS 5075 (3) but ASTM C 403 (2) calls for the average of three duplicates. Since by mixing the mortar directly the degree of control is much better than by wet-sieving, this is considered satisfactory. CHEW and CHOOI (7) reported achieving a standard deviation of 15 minutes for plain mixes and 20 minutes for mixes containing a water-reducing set-retarding admixture. The range for four duplicate batches was within 45 minutes in both cases. These compare favourably against the corresponding values of 25 minutes and 84 minutes respectively as permitted

by ASTM C 403 (2) for three duplicates.

Full details on the conduct of the penetration resistance test are described in both standards and will not be repeated here. The apparatus used in the later part of this study differs from those described in the standards only in the load indicating device. A sensitive proving ring mounted on a drill press records accurately the applied force to improve the precision of the results.

## RESULTS AND DISCUSSIONS

In reporting the setting time both ASTM C 403 (2) and BS 5075 (3) specified a common penetration resistance of 3.5 N/mm<sup>2</sup> (500 p.s.i.). However, the time to reach this value has to be estimated from readings taken below and above this exact value. The two standards employ slightly different technique to arrive at this time. In general, the difference has been found to be negligible as discussed in Reference (5). Hence only one value is reported for the time to reach this penetration resistance, and referred to as initial set as in ASTM C 403 (2). Similarly the time to reach 27.6 N/mm<sup>2</sup> (4,000 p.s.i.) is referred to as final set as in ASTM C 403 (2). The time to reach the much lower penetration resistance of 0.5 N/mm<sup>2</sup> (73 p.s.i.) specified in BS 5075 (3) is tentatively called the "workability limit" in view of the statement by FLETCHER and ROBERTS (4) regarding the behaviour of the concrete corresponding to this stage of stiffness. Besides the absolute setting times, the delay time, i.e. the increase in setting time due to set-retarders is reported for checking against compliance with specification, e.g. BS 5075 (3) and ASTM C 494 (8).

### Series A - cement composition

In this series of experiment four brands of ordinary Portland cements of varying composition were used with the same admixture. The mix proportions were kept constant at water-cement ratio of 0.40 and sand-cement ratio of 2.0.

Table I shows the results for this series together with the tricalcium aluminate and equivalent sodium hydroxide contents of each cement. These two components have been reported by POLIVKA and KLEIN (9), NEWLON (10) and TAM (11) as the major components in cement which affect the effectiveness of a water-reducing and set-retarding admixture. It can be seen that the results in Table I reflect the importance of these parameters similar to that reported in the references quoted above. An increase in either or both components will reduce the effectiveness of the admixture to delay set. However, it is difficult to correlate these parameters with the setting times quantitatively because of several factors. Firstly, the calculated tricalcium aluminate content by Bogue's method does not allow for the effect of the actual cooling rate of the clinker, nor the formation of solid solutions and the influence of minor compounds. The total alkali content as obtained from chemical analysis does not indicate the soluble alkali content. It is this portion that is effective in influencing the behaviour of the fresh cement paste. The lack of correlation between soluble and total alkali contents has been studied by MCCOY and ESHENOUR (12).

In spite of the above, the results in Table I follow the trend dictated by the tricalcium and alkali

contents. However, it should be noted that although all four brands of cement meet the requirement of BS 5075 (3) with respect to setting time, all except Cement C, show excessive delay time. ASTM C 494 (8) limits this to less than 3½ hours. This situation poses a rather interesting question in acceptance testing as discussed in Reference (5).

TABLE I  
EFFECT OF CEMENT COMPOSITION ON SETTING TIMES

Cement	A	B	C	D
C <sub>3</sub> A content - %	11.5	10.9	12.3	9.8
Equivalent Na <sub>2</sub> O - %	0.20	1.04	0.68	0.39

Final set	4.7	4.4	2.9	6.4

Mining sand used in all mixes with water-cement ratio of 0.40 and sand-cement ratio of 2.0 and admixture Y added when used.

### Series B - alkali content

In order to study the effect of alkali content alone, reagent grade sodium hydroxide was introduced to increase the alkali content of Cement E. Only fractional percentages were added thus there is little change in the relative percentage of the rest of the oxide composition of the cement. Since the original equivalent sodium hydroxide content of the cement is 0.53 percent, a maximum of 0.75 percent was added to keep the total alkali content below 1.30 percent, the upper end of the normal range in Portland cements. The results of this series are presented in Table II. The increase in alkali content has very little effect on the setting times for the plain mixes, showing but a slight reduction in the final set. However, its effect on mixes treated with the admixture is severe. Hence there is similarly a serious reduction in the delay time. Fig. 1 shows a plot of the delay time for various percentages of added alkali content. It can be seen that an increase in excess of 0.25 percent leads to a significant reduction in delay time.

The influence of alkali content on the concentration of the various ions in the liquid phase of cement paste was studied by FORSEN (13). A high alkali content in cement tends to increase the solubility of the aluminates thus promoting faster rate of reaction. LERCH (14) attributes this to the neutralizing action of the alkali on gypsum thereby reducing its retarding influence on the aluminates. LEA (15) suggests that a certain minimum concentrations of lime and calcium sulphate in solution are necessary for the proper retardation of the alumi-

nates. The presence of the chemical retarder reduces the rate of hydration of the silicates. This slows down the release of calcium hydroxide into solution thereby allowing the direct hydration of the aluminates and resulting in abnormally quick setting.

TABLE II  
EFFECT OF ALKALI CONTENT ON SETTING TIMES

Added alkali content - %	0.0	0.25	0.50	0.75
Workability limit-hr				
Plain	0.9	1.0	0.9	0.7
With admixture	1.7	2.0	1.3	0.3

Workability limit	0.8	1.0	0.4	-0.4
Initial set	1.6	1.3	0.8	-0.5
Final set	1.5	1.4	1.0	0.0

Cement E and mining sand used in all mixes with water-cement ratio of 0.40 and sand-cement ratio of 2.0 and admixture X added when used. Equivalent Na<sub>2</sub>O content of Cement E is 0.53 percent.

(Original equivalent sodium hydroxide content is 0.53%)

FIG. 1 EFFECT OF ALKALI CONTENT ON DELAY IN SETTING

Cements from different sources and even between batches from the same manufacturer may possess variations in alkali content equal to those investigated in this study. Table III summarises the computed potential compounds and equivalent alkali content of four brands of cement, some with several batches, supplied to the Department of Civil Engineering University of Malaya over a period of five years. It can be observed that cement from different works may have a difference in alkali content of nearly 1.0 percent. Even cement from the same manufacturer may have a variation up to 0.5 percent. In practice, suitable dosage of admixture is obtained from past performance or trial mixes. Subsequent changes in alkali content in the cement delivery may cause erratic setting behaviour in admixture treated mixes. Quality control at cement works involves only the behaviour of plain mixes. Thus the variation in alkali content does not manifest its effect in routine quality control at cement works but only affect the concrete producer employing a set-retarder, e.g. the ready-mixed concrete industry.

TABLE III  
COMPOUND COMPOSITION OF CEMENTS

Cement brand	Sample number	Computed potential compounds				Equivalent Na <sub>2</sub> O
		C <sub>3</sub> S	C <sub>2</sub> S	C <sub>3</sub> A	C <sub>4</sub> AF

Equivalent Na<sub>2</sub>O content = %Na<sub>2</sub>O + 0.658 x %K<sub>2</sub>O

#### SUMMARY AND CONCLUSIONS

The effect of cement composition on setting times and their influence on the effectiveness of a water-reducing set-retarding admixture are discussed. This is by no means the only factor influencing setting times. Other significant parameters include different types of cement, fineness of cement, gypsum content, temperature of the mix, ambient environment, different types of chemical admixtures as well as dosages for a given admixture. Many of these have been investigated and documented in publications such as ASTM STP 266, Symposium on Effect of Water-reducing Admixtures and Set-retarding Admixtures on Properties of Concrete,

1959 and RILEM International Symposium on Admixtures for Mortar and Concrete, 1967. The present study draws attention to factors not previously reported. Cement composition is subject to variations even under good practice of quality control in cement and concrete production. An understanding of the factors influencing the absolute setting times and the delay time is important to ensure suitable quality of the mix exists during the process of transporting, placing, compacting and finishing of the concrete.

In conclusion, this study has indicated that:-

1. An increase in alkali content of cement reduces to a small extent only the absolute setting times of plain mixes.
2. The corresponding increase in alkali content of cement may produce a much more severe reduction in absolute setting times of admixture treated mixes, thereby shortening seriously the delay time. For the cement studied, an increase in excess of 0.25 percent changes significantly the delay in setting.

#### ACKNOWLEDGEMENTS

The author wishes to acknowledge the contribution by Mr. Chew, T.P., Mr. Chooi, H.L., Mr. Chew, S.Y., Mr. Yip, C.Y., Mr. Ng, B.C. and Miss Yap, A.C. from whose project reports the bulk of the data for this paper has been extracted. The permission of the University of Malaya, at which the author formerly worked, to publish this paper is also gratefully acknowledged.

# Effect of surfactants on the hydration behaviour of cement pastes

## *Effet des substances qui sont actives sur la surface à la réaction d'hydratation des pâtes de ciment*

O. HENNING, Prof. Dr. rer. nat. habil. et L. GORETZKI, Dipl.-Chem.,  
Hochschule für Architektur und Bauwesen Weimar, DDR.

### SUMMARY

Surfactants, which are used as water reducing agents or cement dispersing agents, influence also the hydration mechanism of cements. A systematic review about the known cement dispersing surfactants is given. Particularly the chemical structure, the molecular size, and the origin of surfactants were taken into consideration.

One group of short-chain surfactants investigated by us are composed of sulphonated dicarboxylic acids esterified by several aliphatic alcohols. In addition the chain length of ester groups was systematically increased by ethoxylation.

The results show dependences of the effect of agents on the hydration and the structure of agents. Rheological properties such as workability and apparent viscosity show the effect of plastification of cement pastes depending on the degree of ethoxylation and the chain length of alcohols. The wettability of cement powder, depending on the contact angles determined by capillary tests, is largest on medium ethoxylation degrees. Strengths after 1 day and 28 days are highest if 5 to 10 molecules of ethylene oxide were incorporated into the alcohol rest of the ester group.

### RESUME

Combinaisons, qui sont actives sur la surface, qui sont utilisées en qualité des agents pour réduire l'eau ou agents qui dispersent le ciment, influence sur le mécanisme d'hydratation des ciments. Une discussion systématique sur les combinaisons qui sont actives sur la surface, qui nous connaissons, est donnée. Spécialement la structure chimique, la grosseur des molécules et l'origine des agents qui sont actives sur la surface, on prit en considération.

Un groupe des agents qui sont actives sur la surface, que nous avons exploré, est composé des acides sulfamides dicarboxyliques qui sont esterifié par divers alcools aliphatiques. La longueur de chaîne des groupes des esters était augmenté systématique par l'éthoxylation.

Les résultats montrent les dépendances de l'effet des agents sur la hydratation et la structure des agents. Les propriétés rhéologiques comme la maniabilité et la viscosité apparente montrent l'effet de la liquification des pâtes du ciment qui dépendent du degré d'éthoxylation et de la longueur de chaîne des alcools. La mouillabilité de la poudre du ciment, qui est déterminé fermée en dépendance de l'angle de contact par des expériences capillaires, est le plus large médium en degrés d'éthoxylation. La résistance après 1 jour et après 28 jours est la plus haute si 5 molécules de l'oxyde d'éthylène ont été absorbé dans le reste d'alcool du groupe d'ester. Plus ou moins de 5 - 10 molécules mènent à une résistance diminuée.

## INTRODUCTION

In recent years many investigations have been performed in several countries in the field of concrete admixtures. The aim of these investigations was to improve some properties of concrete and to reduce the costs of production of concrete (1 - 8).

Concrete additives are mainly used to improve the following properties:

1. Improved workability without increasing water content (dispersing effect)
2. Decreased water content at the same workability (increased strength)
3. Improved penetration and pumpability
4. Reduced unit cost of concrete (9)

## CEMENT DISPERSING AGENTS

It has been shown that both short-chain and long-chain surfactants can be used as cement dispersing agents. They can be made synthetically or obtained from natural products. A general review including an indication on the most important groups is shown in fig. 1.

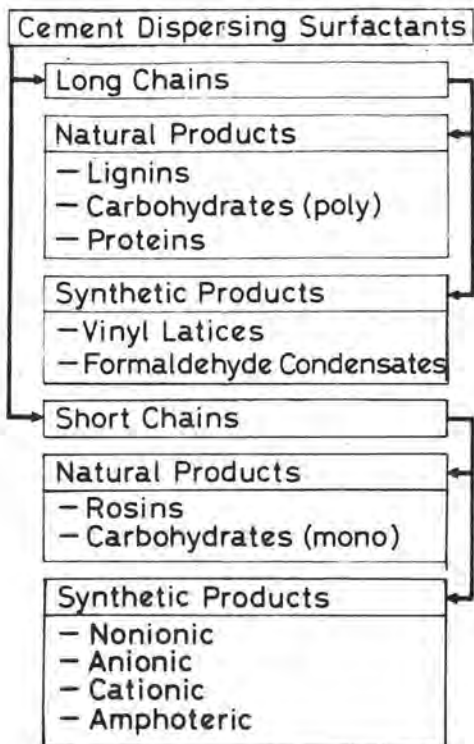

Fig. 1 - Cement dispersing surfactants

Fig. 2 - Natural long-chain surfactants with cement dispersing properties

Fig. 3 - Natural short-chain surfactants with cement dispersing properties

Fig. 4 - Synthetic long-chain surfactants with cement dispersing properties

A closer investigation into individual examples of long-chain and short-chain surfactants (figs. 2 - 5) indicates that a specific molecular structure is required for a dispersing action on water/cement systems.

It seems to be essential that not the length of chains but the presence of hydrophilic and hydrophobic groups in definite distribution is most important.

For the characterization of the dispersing action the degree of plastification  $\alpha_v$  was used which is defined as

$$\alpha_v = \frac{AM_w - AM_o}{AM_w}$$

$AM_o$  slump without admixture

$AM_w$  slump with admixture using the same mortar

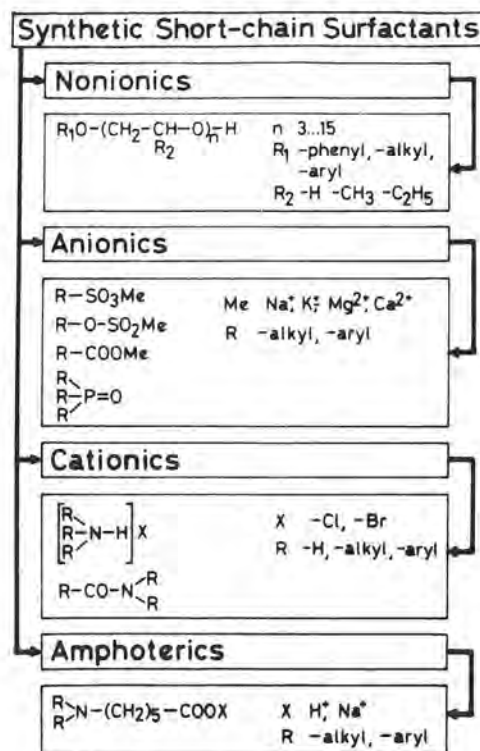

Fig. 5 - Synthetic short-chain surfactants with cement dispersing properties

TABLE I

SBM-10	0,42	this paper

Table I shows optimum degrees of plastification of some surfactants. A vigorous plastificating action is effected by long-chain organic molecules of large molecular weight having a high portion of hydrophilic groups distributed over the whole molecule.

At decreasing molecular weight, decreasing degree of cross-linking, and only a few hydrophilic groups placed at the ends of molecule, the action of plastification of long-chain molecules decreases.

Moreover the formation of pores had to be considered when surfactants are used. Resulting micropores have an unfavorable effect on the strength of concrete. Stable micropores have a plastifying effect (ball bearing model). Surfactants having such an effect are mainly short-chained substances.

The effect of long-chain surfactants can only depend on another mechanism because in this case a good plastification occurs when only a few pores are present. As an explanation a different model has to be taken using the adsorption behavior.

There are some surfactants which are based on both kinds of mechanism (dispersing and air-entraining agents).

#### EXPERIMENTAL

The aim of our investigation was to find and prepare cement dispersing surfactants which are expected to must have a particularly good effect. Compounds of the following structure were prepared:

These compounds were synthesized from the anhydride of maleic acid, sodium hydrogen-sulfite, aliphatic alcohols and ethylene oxide. Twelve different compounds were prepared (Table II).

TABLE II		
Name	R	n

SBM-10	"	10
SBM-11	"	20
SBM-12	"	40

For testing the efficiency, the wetting behavior, the rheological properties, and the behavior of strength were examined.

The wetting behavior was determined by means of a method based on the unopposed penetration of the liquid into a plug of cement powder in a glass tube. Using the WASHBURN equation for the flow of liquid through a capillary (10) it was possible to calculate from the rate of penetration the magnitude of the advancing contact angle and the energy of adhesion between the liquid and the cement powder (fig. 6).

Fig. 6 - Contact angle of SBM solutions on cement powder as a function of concentration

Fig. 7 - Adhesion energy of SBM-3 solutions as a function of concentration

With increasing concentration of SBM the contact angle decreases and within a definite range of concentration it becomes zero. At higher concentration the angle rises again. This behavior is typical of all SBM admixtures. The calculated energy of adhesion is at its maximum using medium concentration (fig. 7).

The influence of admixtures on the flow behavior can be measured by suitable rheological methods (11). In this paper

the slump was used to obtain the degree of plastification. The slump increases at constant water/cement ratio as it occurs with all plasticizers. Reducing the water/cement ratio at constant concentration of the admixture the slump decreases and at a definite w/c ratio the same slump is reached as with a system without admixture at a w/c ratio of 0,5 (fig. 8).

Fig. 8 - Principal connection between w/c ratio and slump on the addition of plasticizers

There is a non-linear function between the slump and the concentration (fig. 9) within a range of concentrations at which the slump changes only slightly.

Fig. 9 - Slump of mortars as a function of the concentration of SBM additives

At an increasing degree of ethoxylation the effect of plastification becomes more effective as shown in fig. 10. The shearing stress was determined by means of a special shearing device. An optimum effect of plastification occurs at the inserting of 5 - 10 molecules of  $C_2H_4O$  (Table III).

The slump at w/c ratios smaller than 0,5 (to 0,3) is still greater than without admixtures (see fig. 8). But compressive strengths show the expected increase at reduced water/cement ratios as is shown in fig. 11.

In addition an increase of the initial strength at constant w/c ratios caused by the action of the admixtures was found to occur.

## CONCLUSIONS

Based on a summarizing survey of the cement dispersing agents used, some general aspects of the structure of cement dispersing substances were deduced. Starting from this, corresponding compounds were synthetically prepared, which are expected to have a good efficiency.

Starting point was a basic molecule containing carboxylic and sulphonic groups, which was systematically modified. By means of rheological and strength investigations the expected efficiency was confirmed. Moreover a relationship between the plastifying effect and the wetting behavior of the cement was found.

This paper deals with problems which are part of the research programme at the VEB Fettchemie Karl-Marx-Stadt DDR.

# Air entrained pores in concrete

## *Air occlus dans le béton*

Dr. Hans MARTIN, 4400 Steyr, Autriche.

### RESUME

C'est un fait bien connu que la résistance au gel et au sel antigel du béton peut être atteinte seulement par l'introduction artificielle d'air sous forme de bulles fines. La quantité d'air entraînée sous forme de bulles fines est déterminée aujourd'hui par des procédés macroscopiques assez bien perfectionnés, en général par 200 essais de gels et de dégels successifs dans une machine frigorifique. Quant aux petits chantiers, pour lesquels telle dépense serait trop élevée, il y a assez de règles pour une détermination empirique.

L'Autriche est située dans la zone limite variable entre le climat atlantique et le climat continental et c'est la raison pour laquelle il faut tenir compte d'une sollicitation alternée gel-dégel très fréquente pour les ouvrages. Durant des mois le point de congélation est dépassé environ deux fois par jour. Pour les barrages dans la haute-montagne les fluctuations de température quotidiennes peuvent atteindre 60°C/140°F. C'est là surtout que la question de l'air entraîné est brûlante. L'influence du gel permanent sur le béton est moins importante.

La formation de bulles d'air peut avoir lieu seulement dans la portion du ciment. En Autriche on utilise pour la plupart du ciment Portland seulement, avec des additifs à savoir laitier, cendres volantes et trass. Il est à présumer que le procédé de la prise est un fait bien connu. Il a lieu d'après les lois de la physique des corps solides. Les travaux y relatifs ont été recherchés par un microscope électronique à transmission et publiés il y a bien longtemps.

Quant à l'introduction d'air dans le ciment durci, on n'en sait rien. Pour cette raison le ministère de la construction d'Autriche a passé commande pour une recherche scientifique au "Zentrum für Elektronenmikroskopie" Graz. Cet institut est engagé d'une part à l'université et d'autre part à l'industrie. Chef de l'institut est le professeur Grasenick. Les recherches ont pour but la détermination de la forme des bulles d'air, leur comportement par rapport à leur milieu - le béton de ciment - ensuite les modes d'introduction possibles à savoir les types aptes à former des bulles d'air. En outre, le comportement de l'air occlus sous l'influence du dégel et de gel sera à l'étude. Ces recherches ne sont pas encore terminées étant donné qu'il s'agit de problèmes techniques et expérimentaux très difficiles. De plus, il aura lieu de déterminer l'aspect des bulles d'air au bout de plusieurs années et de constater si elles se ferment ou si elles restent préservées. On a fait des essais dans le microscope électronique à balayage sur des éprouvettes de béton âgées de plus de 20 ans et prélevées à des centrales d'énergie et des autoroutes. Les problèmes seront commentés en s'appuyant sur les essais effectués et on présentera des photos y relatives du microscope électronique à balayage sur l'affiche.

### SUMMARY

It is well known that resistance against freezing and against thawing salts in concrete can only be obtained by means of introducing air pores. The amount of air pores to be entrained is today already determined with well-defined methods, in general by 200 freezing - thawing cycles in a freezing machine. For smaller building sites for which this method would be uneconomical there exist sufficient empirical rules for determining the required amount.

Austria is situated at the flowing boundary of atlantic (oceanic) and continental climate, thus a very frequent change between freezing and thawing has to be taken into account. For months the freezing point is crossed at least twice daily. At dams across valleys in the high mountains (Alps) daily temperature fluctuations may amount to 60 centigrade (140°F). There the problem of air pores is especially important. Long-lasting frost, however, is of less influence upon concrete.

Air pores can only be formed in the cement portion of the concrete. In Austria nearly exclusively Portland cement mostly with addition of slags, flue dust, and optionally trass is used. The setting process of concrete is well known. It runs off according to the laws of solid-body physics. Papers on this item have been worked out in the TEM and have been published some time ago.

There is practically nothing known, however, about the incorporation of air pores into hardened cement. Therefore, the Research Centre for Electron Microscopy in Graz, Austria, obtained a research order by the Austrian Ministry for Structures (Buildings). That Institute is shared in equal parts by the University and by the industry, respectively. Head of the Institute is Prof. Grasenick. According to the Research Order the shape of the air pores, their behaviour with respect to their environment i.e. the cement stone, and also the possible ways to introduce them (possibilities of forming air pores) should be determined and studied, respectively. In addition, the behaviour of the air pores under the influence of thawing salts and at the ice formation is studied. The last-named studies are not yet terminated because of the difficult technical-preparative problems involved. Also, it should be determined how the air pores look like after periods of years, whether they grow together or remain unaltered. Over 20 year old concrete samples from high-way-roads and power stations have already been examined in the scanning electron microscope. The problems mentioned shall be discussed by aid of the conducted experiments and relating scanning-electron-microscopic pictures will be shown in posters.

In principle, the conglomerate concrete is a ternary compound. Due to external conditions, air may be added, however, as a fourth component to the components PC, aggregate and water. This does not mean air being present in the mixture because of insufficient compaction or an excess of water in the mixture, but air that is introduced artificially over various media. These air bubbles always have an approximately spherical form.

The enthalpy of formation is high, due to the high temperatures used in the burning of PC, and correspondingly also the inner potential plateau in PC is high. The generally known basic components  $C_3S$  etc. are unstable compounds.

Water is a very mobile combination, perhaps the most mobil at all. The transitions from molecule to ion are achieved in periods from  $10^{-11}$  to  $10^{-13}$  seconds. This also explains the high ability for solution with many substances. Now, if water is mixed with PC, the marginal layers of the cement grain are released from the bond as ion or molecule. Tests with isotopes of Ca, Si and Fe have shown that these particles are able to overcome large distances in short periods of time. It should be mentioned, however, that during the tests 2 cm had been considered as a very large distance, while under practical conditions the distance will be only about 100 to 1000 nm.

The solution is first saturated, then oversaturated and by recrystallisation new formations of growing up crystals are produced. Since the matrix is cognate, on the etched surfaces of the cement grains most of the new crystals will be of epitaxial kind, the rest topotaxial. In accordance with the laws of solid-state physics, the new formations should have a geometrical system of growing up crystals, but here they cannot have this kind of growth since the space is restricted. Therefore, they must grow statistically and this is also confirmed by pictures of the electron microscope.

Previously formation of gel in the marginal zone of the cement grain had been assumed as a working hypothesis. This certainly originates from the evaluation of the light-optical microscope which, however, by no means is in a position to supply the magnifications required to clarify the marginal conditions of the cement grain. The formation of gel is impossible at the transition from the cement grain to cement stone, for this would be in contradiction to the laws of solid-state physics. In order to obtain a maximum energy gain the elementary crystal must form itself in accordance with certain rules. Any further monocrystals are added in such a way that more and more energy is won. This is also the reason for the high strenght values of new formations.

Cement is burned from products which due to their geological compositions contain a large number of different minerals. This causes dislocations in new formations which, as a consequence, lead to a differing formation of the crystallization forms. An exact mineralogical definition is possible in a few cases only.

Crystallization leads to an interlocking of the cement grains and after a short time the crystal system shows higher strenghts than the cement grain itself. In the case of a break, the cement grain and not the crystal system will be torn apart.

There are no capillaries in the cement grain; this is clearly proved by great magnifications. The linkage is exclusively achieved by new formations. Le Chatelier's assumption has proved to be absolutely correct.

According to pictures made in the TEM the distance between the cement grains is approximately 100 nm after hardening. However, the release of marginal particles of the cement grain in water continues, the crystal system solidifies and this explains the increasing strenght caused by aging. Interlacement in the cement stone is so dense that the latter may be considered as watertight. On the other hand, the system is permeable formed by the constant transformation of water. They may pass and thus settle on all parts of the cement stone. Movement is then provided by temperature differences on the outside layers.

The bonding of cement stone to the aggregate is likewise achieved by recrystallization. Since, conditioned by the aggregate, the matrix differs greatly, the growth may be of epitaxial nature, but in most cases it will be topotaxial. In both cases the grown up product must have a statistical structure, since there is not enough space for geometrical systems. The cement-water solution in many respects is the outstanding bonding agent. It can form itself to a solid body, it can bind to aggregate, it penetrates through the oxide layers of steel and builds up a rigid connection on the metalically bound iron. In spite of its high strenght it has a weakness: it can resist to crystallization pressures in its interior only to a limited extent. In many regions this is of no significance, for instance when there is no frost or when there is only permanent frost. However, if concrete is exposed to many changes of frost to thawing weather and vice-versa efforts must be made to protect him.

Somewhere about the year 1938 it had been found in the USA that, when using certain types of cement in road construction, freeze-proof concrete could be produced, with others not.

During that time we had lost contact with international science and thus we learned about works of this type only about 1950.

Austria is a country which is subject to a large number of changes in the zero-centigrade border due to the transition from the atlantic to the continental climate and the Alpine meteorological devide.

Every power station, every bridge, every patch of motorway concrete has to be adapted to winter conditions. Moreover, Austria is a transit country, therefore motorway concrete has to be treated, in addition, with thawing salt in order to keep the roads open for traffic.

Both freezing water and thawing salt produce high crystallization pressures in the interior of cement stone. As already mentioned above, the crystal system which generally provides the connections in the cement stone and in concrete, is permeable for water ionic form. Then it can-and it does in fact again change to the molecular conditions also. In every case it may freeze. Only ice I is involved, either as  $I_C$  or  $I_h$ . Ice  $I_C$  may be considered as metastable. For economic reasons, almost exclusively NaCl is used as

thawing salt, only at very low temperatures  $\text{CaCl}_2$ . Ionically dissolved both compounds penetrate into concrete up to a certain depth, then they recrystallize. As chemical compounds, they are without influence on concrete, but the crystallization pressure is to mention.

Crystallization pressure above ice formation and recrystallization of thawing salts are very high, they may be absorbed by concrete (most prominent component: cement stone) only to a limited extent.

By artificially introduced air bubbles it is possible to absorb these crystallization pressures. As a matter of fact, it was by mere chance that they discovered in the USA that by using Vinsol, concrete for road construction can be made freeze-proof.

Somewhere about the year 1950, they started also in Austria to introduce air bubbles into concrete which is endangered by frost. Initially tensides such as for instance spent sulfite liquor or Vinsol had been used. Over the long run spent sulfite liquor did not perform very well since its quality is too production-dependent. Depending on the type of wood used and the type of processing, mixtures of hexoses and pentoses will result which may have a detrimental effect since sometimes sugar has a good, in most cases, however, an unfavourable effect on concrete. It is difficult to control it anyway. Although as a natural product subjected to certain fluctuations, Vinsol is the most customary tenside and also the most used one. A prerequisite is that it must be basified: it should have a  $p_H$  value of more than 10.

Many tensides are obtained in the chemical industry as by-products which could gain importance, but among thousands of possibilities marginal conditions are given.

A tenside that should be introduced as an air-bubble-carrying material into concrete must ensure a certain bubble diameter, the bubbles must not be destroyed during the transport from the mixer to the site, and they also have to resist to compaction. In such a case also the price is of significance, for in an order of many millions of cubic metres of concrete the use of air-bubble entraining agents is also an element which has to be taken into account also from a financial point of view.

The economic researches and the use and the required amount of additives will be determined macroscopically in the Test Institute or by the sitelab.. However, the combined effect of air bubbles and cement stone cannot be solved in such a way, for high magnifications are necessary in such a case. Here it is of importance to recognize the interrelationships in order to classify the various possibilities for the entraining of air bubbles.

These considerations prompted the Federal Ministry of Works in Austria to give to the Centre for Electron Microscopy in Graz a research assignment for exploring the behaviour of air bubbles in concrete. The director of that institute is F. Grasenick, the preparation, the direction of picture-shooting and the supervision of the microscopes used was in the hands of Mrs. J. Blaha.

From approximately 2000 pictures made of cement, aggregate, steel, and air bubbles it resulted that

for pictures on which cement should be perceived a magnification below the 20,000-fold does not supply any definite information, but only - at most - a general idea. Useful are magnifications between the 60,000- and the 100,000-fold. Such pictures can be taken in the TEM only, preparation requires special experience.

This is different when taking pictures of artificially introduced air bubbles. In order to perceive the bubble at all, you must operate within a range of 1,000- to 7,000-fold magnification. For this purpose the REM is most suitable. It works very fast, an instantaneous shot may be made, and, moreover, a microanalysis which may be evaluated immediately. After having obtained a general idea, it is useful to make a picture of the interior zones of the air bubbles with the maximum magnification to be achieved with the REM. However, an identification of the marginal zones of the air bubble requires much higher magnifications which can only be obtained in the TEM. For their evaluation great practical knowledge is needed.

Perfect investigations on cement stone can be made on fractured surfaces only. Cuts and subsequent grinding destroy the marginal zones, leave a heap of rubble on the bottom of the air bubble, the field of observation will be soiled to such an extent that neither pictures taken with the REM or the TEM nor a microanalysis will supply any conclusive evidence.

The preparation of fractured surfaces for TEM and REM is difficult and requires great care. For the REM, gold-sputtering was chosen for the samples to be tested. Difficulties arise from the height and depth differences caused by the fracture.

In the TEM these differences of height and depth become still more apparent. By the fracture the air bubble suffers a sharp break, for its irradiation a Carbon-layer has to be applied which in many cases is torn off at the edge of the air bubble, even if gold-reinforced.

But this is of no importance if only the marginal zone remains undamaged. Thus, pictures could be taken which with a 600,000-fold magnification supplied information about the state of this marginal zone.

There are many possibilities to introduce artificial air bubbles into concrete. In general, this is achieved by means of tensides corresponding to the previously mentioned conditions. However, it is also possible to use prefabricated hollow bodies with a shell consisting of thermoplast or polyurethanes.

In the subject tests the behaviour of air bubbles introduced via Vinsol, then via a tenside produced by Hüls-Marl, a thermoplast hollow body from AKZO and a PU hollow body from Bayer have been investigated. Although all of these products show different structures it was a great surprise that under load they all behave in the same manner. In tensides the molecules turn with their hydrophilous part towards the outside, the hydrophobe part keeps away water so that a waterfree space is created which indicates the air bubble. Yet this molecularly formed "hedgehog" could not endure permanently, it needs support. As usual, cement stones are formed on the outside according to its

crystalline structure and keeps at first its shape. Simultaneously on the inside of the air bubble margin a tiny, but very dense support structure is formed which fixes the air bubble. There is no doubt that the tenside layer allows ions to pass, and the same is surely true also for the support structure. Whether or not these two layers allow also molecules to pass cannot be said as yet, however, this problem is of minor importance because almost all components of cement, thawing salt and, of course, also water may be figuring ionically. Likewise it cannot be clarified as yet whether or not tensides are persisting after their use, here magnifications of at least 1, nm will be required. The microscopes certainly can do the job, but the problem of preparation is still unsolved. But this is not an important question, what matters is only that the air bubble fulfils its function. The permeability of the tenside layer and of the support structure means that ionically solved water and thawing salt may penetrate into the air bubble.

Crystallization pressures are very high, but the enlargement of volume caused by them is relatively insignificant. Only little hollow space is required to allow well prepared cement stone to absorb the rest of the crystallization pressure. This task is performed by the artificially introduced air bubble.

This is proved by pictures taken from samples of more than 20 years old concrete. Water may penetrate into the air bubbles and freeze without doing damage to cement-stone, just like thawing salt simmers down in the pore. The process must be reversible for it is repeated often.

After thawing water is withdrawn from the air bubble to such an extent that only the rest (corresponding to the steam pressure) is left. As shown by pictures, thawing salt forms topotaxies on the inside of the air bubble which, however, remain within certain limits.

To investigate old air entrained concrete, samples had been drilled out of the concrete used in the power station of Ybbs an der Donau (200 MW, 1250 GWh) built from 1954 to 1957, and from two patches on the motor highway A 1 where the concrete had been laid during the same period. In order to avoid any damaging, the samples had been removed by diamond bits. It was intended to find out whether or not the air bubbles are still efficient after such a long time.

Every river is moving finest particles in its boulder drifts. The Danube - within the Upper Austrian territory might be classified as a torrent - produces a lot of small material due to turbulences. Concrete samples had been drawn from the sluice wall, the pier wall and a weir pillar.

The pictures taken in the REM have shown for the sluice wall that the air bubbles are provided with a thick interior lining of fine mud up to a depth of approximately 2 cm. This proves that the air bubble - at least after some time - is also permeable for material beyond the molecule range. Perhaps in this case also the outside stress is decisive, the strain by the numerous lock lifts is high. In a depth of more than 3 cm the air bubbles were free of any fine particles, the natural interior grown up crystals were clearly discernible, the reduction of the volume

of the air bubble is affected only very little.

The examined weir pillar is subject to different outside effects. By the continuous flow of water around the pillar there is no fine mud, the air bubbles are free from it. Also here, within the area of rapid fluctuations of the water level, only the usual subsequent crystals will be found in the interior of the pore, they affect the volume of the air bubble only slightly.

On the above mentioned places of the motor highway A 1 - they are located within the section Enns-Linz-Sattledt, in a zone which is heavily affected by a change of frost and thawing - it was intended to determine the long-term stresses of ice pressure and simultaneously the effects of thawing salt. The combination of crystallization pressures from ice and thawing salt causes a lot of changes of the interior pressure so that surprises had to be expected. Then it was surprising that in spite of ice, recrystallization of thawing salt and the usual calcium oxide hydrates the volume of the air bubbles was reduced only up to a maximum of 30 %.

Due to the high processing speed of the concreting machine units, the air bubbles are smashed in the uppermost concrete layer and the laitance is drawn upwards. This uppermost layer is then also the weakest part of the roadway-platform concrete which, however, is quickly removed by the braking and acceleration manoeuvres of heavy motor vehicles. This unfortunately results in track grooves. After the removal of this thin upper layer a perfect, freeze-resistant and thawing-salt-proof road top layer will be left.

We are able to prove these facts clearly in the REM and the TEM.

# Essai d'action d'addition polyfonctionnelle sur les bétons

## *Study of action of multi-purpose admixture upon concretes*

BAGENOV Y., professeur, docteur d'état, chef de chaire,

### Résumé

Les additions complexes qui se composent de deux et plus matières organiques et minérales permettent renforcer entraînement de l'air, augmenter la plasticité de bétons frais, la compacité et la résistance au gel des bétons. Combinaison de deux additions hydrophobes (abietat de sodium et brai de goudron de bois saponifiable) renforce entraînement de l'air. La valeur d'entraînement de l'air est additif.

Les additions complexes se composent de matières homonènes augmentant la plasticité de bétons frais conformément à principe d'additivité.

L'effet de renforcement réciproque existe en cas d'utilisation d'additions de composants dont le mécanisme de plastification est différent.

Les additions complexes qui se composent de matières organiques ralentissent la prise du béton.

L'utilisation d'additions qui se compose de matière organique et électrolyte permet de diriger le prix du béton en utilisant la propriété d'électrolyte d'accélérer la prise du béton.

Les additions qui se composent d'électrolytes et d'adjuvants entraîneurs d'air augmentent la compacité du béton. Les additions qui se composent d'électrolytes, nitrites - nitrates - chlorures de calcium (NNHK) abietat de sodium (SNB) augmentent la résistance au gel du béton.

En examinant l'action d'additions sur les liants minéraux on considère le schéma cristallin pour le durcissement de celles-ci. Selon ce schéma les phases métastables se dissolvent avec formation de solutions sursaturées par rapport de composées hydratées qui cristallisent sous les phases finales et intermédiaires.

Par conséquent les processus d'hydratation de liants minéraux on peut considérer comme un ensemble de processus dont la vitesse est limitée par solubilisation des phases initiales.

La résistance de pierre de ciment de la dispersité est facilitée de produits d'hydratation et aussi de liaisons entre eux.

L'espèce de contacts essentiels est coagulant jusqu'à la formation de structure capillaire et poreuse. Par la suite sur le fond se forment les contacts cristallins "atomiques" et contacts cristallins "de phase", qui assure la formation au début la carcasse cristalline et par la suite sa consolidation. Les contacts d'assemblage direct prédominent dans les liants monominéraux.

La structure de liants polyminéraux se forme en résultat d'engrenage et d'enchèvement des cristaux.

L'espèce poreux se forme en même temps que la phase solide. Celui-ci et les forces d'adhésion entre la pierre de ciment et de granulats ont une grande influence sur la propriété des bétons.

Essai d'action d'additions différents sur les processus de durcissement de liants minéraux permet choisir la composition d'additions multicomposants. Cidessous on fait l'analyse de l'influence d'additions multicomposants sur l'entraînement de l'air, la plasticité, la durée de prise et la structure de pierre de ciment ce que détermine la résistance à la compression et la résistance au gel des bétons.

### 1. L'entraînement de l'air

Les additions qui s'adsorbent sur les liants et ensuite sur les cristaux de nouvelles phases possèdent la propriété d'entraînement de l'air. Ce phénomène dépend de tension superficielle à la frontière liquide - air -  $\sigma_{12}$ .

Moins grande est la valeur de tension superficielle plus grand est la valeur d'entraînement de l'air.

La plus grande valeur d'entraînement de l'air donne l'addition hydrophobe qui participe dans les réactions chimiques avec les produits d'hydratation de liants minéraux.

L'introduction des deux additions hydrophobes comme par exemple abietat de sodium et brai de goudron de bois saponifiable peut provoquer l'entraînement de l'air dont la valeur est additive en présence de petite quantité d'additions ou moins d'après le principe d'additivité en présence de grand quantité d'additions. Cet effet s'explique par présence dans le deuxième cas de "concurrence" entre les additions. (tabl.1).

Ceci s'explique de ce que dans le dernier cas l'addition dont les propriétés tensioactifs sont plus grands détermine la valeur d'entraînement de l'air.

L'addition hydrophile donne le même résultat.

L'utilisation de mélange d'additions, celle hydrophile (SDB) et hydrophobe dont la valeur est additive provoque l'entraînement de l'air.

La combinaison d'additions hydrophiles et hydrophobes nous permet obtenir l'entraînement de l'air stable dont la valeur et dimensions de bulles d'air ne dépendent de consommation du ciment.

Les additions-"superplastifiants" (des produits de condensation acide naphthalène - sulfonique ou acide mélamine - sulfonique avec formaldéhyde) ne changent pas la valeur de  $\sigma_{12}$ .

Ils n'ont pas d'influence sur la valeur d'entraînement de l'air ou bien le diminuent dans le cas d'utilisation acide sulfonique mélamine - formaldéhyde.

L'utilisation des "superplastifiants" avec d'adjuvants entraîneurs d'air nous permet conserver des propriétés de chaque composant.

### 2. L'effet plastifiant d'addition complexe

Les additions plastifiants, ce sont en général les matières organiques qui absorbent sur la frontière des phases et qui diminuent la valeur  $\sigma_{12}$  ou l'énergie sur la frontière solide-liquide  $\sigma_{32}$ .

Les additions "superplastifiants" possèdent des propriétés analogues. Ils provoquent l'effet de désagrégation des particules de ciment et de graissage hydrodynamique.

Mais aussi il y a des additions (poudre d'aluminium) qui provoquent l'effet de plastification en résultat de formation des bulles d'air qui jouent un rôle de graissage. Il existe aussi l'effet de plastification d'électrolytes, par exemple chlorures de calcium etc.

En étudiant l'effet de plastification d'addition complexe on a établi des régularités suivantes.

a) Si les additions complexes se composent de même classe elles provoquent l'effet de plastification additive ou en tout cas plus grand que ceci de chaque composant (tabl.2).

Premièrement, par conséquent, l'utilisation en qualité d'addition des fractions de produits chimiques dont les capacités de plastification sont considérables peut augmenter leur activité spécifique, mais elle a une limite d'après ce signe et ne peut pas donner augmentation importante de plasticité de béton frais.

Deuxièmement, le mélange de plusieurs additions plastifiants de même type ne donne pas la possibilité d'obtenir un addition "superplastifiant" par l'effet de renforcement d'action de chaque composant d'addition complexe.

L'utilisation de cet espèce de mélange est raisonnable au cas que soit la possibilité de diminuer le prix.

b) On peut renforcer l'effet de plastification au cas que l'addition complexe se compose de constituants dont les mécanismes de plastification sont différents, par exemple électrolyte et plastifiant naphthalène formaldéhyde (NF) (tabl.3).

On a utilisé dans cette recherche comme additions électrolytes chlorures de calcium et nitrites - nitrates de calcium en rapport de 1:1, nitrites - nitrates - chlorures de calcium en rapport de 1:1:2, acétate et sulfates sodium en rapport de 1:1.

### 3. La durée de prise de béton avec les additions complexes

Les agents tensio-actifs augmentent la durée de prise de ciment en ralentissant la solution /1/.

Le facteur compensateur est désagrégation des particules du ciment /5/ ce qui a une grande valeur avec utilisation de "superplastifiants" mélamine - naphthalène - formaldéhyde.

La désagrégation augmente la surface de réaction ciment - eau et la vitesse de solution des particules du ciment.

Le facteur compensateur est aussi la formation de particules dispersionnelles avec la dimension critique d'après l'équation Kelvine

$$r_{cr} = \frac{2V_c}{RT} \ln \frac{\sigma_{32}}{C} \quad (1)$$

$V_c$  - volume moléculaire

$R$  - constante des gaz

$T$  - température absolue

$\frac{C}{C_{\infty}}$  - sursaturation

L'action positive sur la cinétique d'hydratation peut avoir augmentation de vitesse de cristallisation dont la possibilité montre l'équation Gibbs - Folmar

$$\alpha = A \cdot \exp \frac{\Delta Z_{\max}}{RT} \quad /2/$$

$\alpha$  - valeur proportionnelle de vitesse de formation de germe cristallin

$A$  - multiplicateur préexponentiel

$$\Delta Z = \frac{4}{3} \pi \frac{r_{kp}^2}{RT} - \text{énergie libre}$$

$R$ ,  $T$  et  $Z_{kp}$  - les mêmes que dans l'équation /1/

Les certaines additions organiques peuvent augmenter la vitesse d'hydratation en résultat de réaction d'échange des ions ou coordination (acides carboniques, certaines amines etc.).

L'effet de freinage de processus d'hydratation qui augmentent avec la concentration d'addition prédomine pour la plupart d'additions organiques à l'exception d'additions "superplastifiants".

Cela permet augmenter la dose de celles-ci sans appréhension de ralentir la durée de prise de béton.

Deux additions organiques ou plus ralentissent la durée de prise du béton plus qu'une addition. Mais l'effet de synergie est absent dans ce cas. Si la concentration d'une des additions (p.ex. addition hydrophobe) est moins que de l'autre (p.ex. addition hydrophile) cette dernière addition détermine la durée de prise.

La combinaison d'additions organiques et d'électrolyte nous permet de changer considérablement la durée de prise de béton (Fig.1).

Fig.1. Cinétique d'augmentation de résistance plastique de mortier en présence d'additions.

1. Echantillons sans additions

2. 0,15 SDB : 3-0,7% NF

3. 0,7% NF + 2% NNHK

4. 2% NNHK, 5.0,15%SDB+0,7NF+2%NNHK

Cela nous donne la possibilité de diriger la cinétique d'hydratation.

#### 4. La formation de structure de pierre de ciment avec l'introduction d'additions complexes

Les additions-électrolytes augmentent la compacité de pierre de ciment en grandissant la quantité de micropores et de pores de gel dans le volume de pores de pierre de ciment (tabl.4, fig.2).

Fig.2. Résistance au gel de béton étuvé en dépendant de continue volumique de gel.

1. Béton sans additions
2. 2% $\text{H}^+\text{XK} + 0,15\%$  SDB; 2% $\text{H}^+\text{XK} + 0,02\%$  CHB.

Les additions qui composent sulfates, chlorures ou nitrates + ions (p.ex. nitrite - nitrate - chlorure de calcium) renforcement par des cristaux de sels de hydrates (hydrosulfo, hydrochlorures et hydroaluminates de calcium). Ces cristaux forment la structure primaire de pierre de ciment avec son renforcement par hydroclicates et hydroaluminates de calcium. Tout cela agrandit la compacité et l'imperméabilité à l'eau de pierre de ciment. L'amélioration de la structure de pierre de ciment par la compacité avec l'introduction d'additions plastifiants et d'électrolytes ainsi que l'abaissement de la température de congélation de glaces en présence de ces additions augmente la résistance au gel du béton.

L'action d'adjuvants entraîneurs d'air ou d'additions génératrices de gaz se distingue de l'action d'électrolytes et additions plastifiants. La combinaison d'adjuvants entraîneurs d'air et d'électrolytes permet utiliser l'avantage de celles-ci et des autres et obtenir les parois de pores plus denses et résistants avec la conservation de caractère de leur distribution par rayons et dimensions moyennes obtenues à l'aide d'adjuvants entraîneurs d'air.

Les recherches ont montré que l'utilisation d'additions complexes d'électrolyte et de matières tensio-actives (p.ex. abietat de natrium CHB, lignosulfonat de calcium CDB) augmentent considérablement résistance au gel du béton que l'introduction d'une addition ou l'utilisation des bétons sans additions. (Fig.3)

M.S. BARVINOK, Leningrad, U.R.S.S.

RESUME: Dans la communication on a envisagé l'influence des activateurs-plastificateurs inorganiques sur le durcissement des mélanges de béton. On a montré que l'introduction des chromates et des thiosulfates et de leur mélanges conduit à l'accroissement de la résistance précoce et standard du ciment durci, à la diminution du rapport E/C, à l'augmentation de l'imperméabilité à l'eau, à la diminution des déformations de retrait, à l'accroissement de la résistance à la corrosion des béton. L'action des compositions combinées élève les propriétés techniques grâce à la formation du soufre à l'état amorphe, très fin.

SUMMARY: The effect of inorganic activator-plastifiers on hardening of concrete mixtures is studied. It is shown that introduction of chromates and thiosulphates and of their mixtures results in increase of early and grade strength of concrete stone and of water impermeability and corrosion resistance of concretes and in decrease of W/C ratio and shrinkage strains. Combined compositions also increase technical properties due to formation of sulphur in amorphous highly dispersed state.

Pour augmenter la résistance lors de l'étuvage et dans les conditions de durcissement normal, abaisser le rapport e/c et améliorer d'autres propriétés techniques des bétons on peut utiliser les activateurs inorganiques d'action polyfonctionnelle qu'on choisit en partant des faits suivants. Pour l'intensification du durcissement l'oxydation des composés introduits en tant qu'activateurs est indésirable (1 à 3). Au contraire, l'introduction dans le système durcissant de corps simples et composés contenant des éléments à hauts degrés d'oxydation (permanganates, chromates, bichromates) conduit à la plastification du mélange de béton et à l'accroissement de la résistance précoce (à l'âge de 1 ou 2 jours) et standard.

Les données du Tableau I montrent que le chromate de potassium et le thiosulfate de sodium servent d'activateurs du durcissement; notons que, la plasticité du mélange de béton restant la même, on peut observer la diminution du rapport eau/ciment, ce qui conduit à un plus fort accroissement de la résistance.

Le Tableau II pour les bétons et les Tableaux III et IV pour les mortiers montrent que l'introduction du chromate de potassium peut éliminer l'étuvage du béton en abaissant la perméabilité à l'eau et les déformations par retrait. Ainsi le béton sans addition se caractérise par la perméabilité à l'eau de 2 atm ( $B = 2$ ). Le béton avec addition de l'activateur de durcissement en quantité de 2 % de la masse du ciment a supporté la pression de 10 atm ( $B = 10$ ).

Les déformations par retrait des bétons étaient déterminées sur trois échantillons-jumeaux de dimension de  $10 \times 10 \times 30$  cm. La base de mesure du retrait était de 300 mm. Les essais étaient effectués dans une chambre spéciale (avec le régime de réglage automatique) à la température de  $30^\circ \text{C} \pm 2^\circ \text{C}$  et à l'humidité de  $55\% \pm 3\%$ . Les déformations par retrait étaient mesurées par l'indicateur à cadran dont la valeur de la division était de 0,01 mm. Parallèlement à la mesure des déformations on a contrôlé la perte en poids des échantillons de béton. Les résultats concernant la cinétique de variation des déformations par retrait et de la perte en poids du béton ont montré que l'introduction de  $\text{K}_2\text{CrO}_4$  (2 % de la masse du ciment) diminuait sensiblement la valeur des déformations par retrait. Ainsi le béton sans addition à l'âge de 60 jours avait le retrait de  $80 \cdot 10^{-5}$  et le béton avec addition, de  $45 \cdot 10^{-5}$ , i.e. pour le béton avec addition le retrait diminue presque de 2 fois. L'addition dans le béton stabilise le développement du retrait vers 28 jours de durcissement. Pour le béton sans addition la stabilisation du retrait s'observe vers 50 jours. Les données concernant la perte en poids des échantillons de béton sont en bon accord avec le développement des déformations par retrait.

Les données relatives à la résistance au gel des échantillons (Tableau V) témoignent qu'avec l'introduction du chromate la résistance au gel ne s'empire pas et pour certains ciments elle augmente sensiblement. L'efficacité de l'utilisation des additions contenant le chrome peut être augmentée en partant de l'idée de la réalisation du processus d'oxydo-réduction dans le système avec l'introduction simultanée de composés contenant le chrome et de thiocomposés (4). Dans ce cas, à côté d'une diminution encore plus importante du rapport eau/ciment on peut assister à la séparation du soufre à l'état amorphe très fin :

Les données du Tableau VI montrent que cette voie assure un grand effet plastifiant, l'accroissement de la résistance et l'amélioration d'autres propriétés techniques liées à l'augmentation de la densité du béton grâce au colmatage des pores par le soufre et à la diminution du rapport eau/ciment. Les compositions des bétons avec addition de sulfures n° 8, Tableau VI, montrent une prise rapide, ce qui rend possible leur utilisation en tant que compositions Torkret de résistance élevée.

Les études physico-chimiques ont montré que l'accroissement de la résistance s'accompagnait d'une augmentation de l'eau chimiquement liée et des changements dans la composition des phases des échantillons.

#### CONCLUSIONS

Afin de diminuer le rapport eau/ciment, d'augmenter la résistance précoce et standard du béton dans les conditions de stockage normales, de diminuer les déformations par retrait et d'accroître l'imperméabilité à l'eau il est recommandé d'utiliser les activateurs-plastificateurs inorganiques : chromates, thiosulfates et leurs mélanges. Les compositions à base des chromates sont en même temps des inhibiteurs de corrosion de l'armature en acier.
