in which B and b are parameters determined from the data. This relation applies for values of C less than the transition from dilatant to pseudoplastic behavior. In this case b depends upon the rate of shear strain, nature of the material and shape of the particles, as well as being independent of the specific surface area and particle size distribution. The value of b approached a maximum of about 26 at a strain rate of  $40 \text{ s}^{-1}$ . The value of B also increased with the rate of shear strain and the specific surface area, reaching values of several hundred Pa for powders of cement fineness.

The formulation of experimental results represented by Eqs. 3 and 4 is useful because it permits the identification of certain factors affecting the flow behavior in simpler systems; Eq. 4 was also verified for portland cement pastes while vibrated. Data for portland cement pastes without vibration have also been examined in attempts to determine the true functional dependencies and to better understand the factors controlling the flow. Viscometer data was given in Fig. 3 which showed the decreasing yield values and viscosities with increasing water content. A set of data covering a wider range of water-cement ratios for pastes made with an ordinary portland cement of Blaine fineness  $447 \text{ m}^2/\text{kg}$  is given in Table I.

TABLE I		
Water-Cement Ratio g/g	Yield Value Pa	Plastic Viscosity mPa·s
0.4	81	39
0.45	39	22
0.5	25	16
0.6	9	12
0.7	6.4	8.5
0.8	1.6	5.8

Values at lower water-cement ratios are given in Table II, which must include both viscometer and rheograph data (2). Although different cements and mixing procedures were used, these two sets of data show similar variations of the yield values with water contents.

TABLE II	
Water-Cement Ratio g/g	Yield Value Pa
0.24	1900
0.32	130
0.36	65
0.40	30
0.50	8.5

The data in Fig. 2 show the effect of variation of the specific surface area of a cement on the initial yield values in pastes of 0.25 water-cement ratio and how these values vary with time through setting. The effect of cement fineness is also shown in Table III for pastes at water-cement ratios of 0.4, and also for another set of pastes made at the water-cement ratio required to give equal yield values (2). As might be expected from

TABLE III			
Specific Surface $\text{m}^2/\text{kg}$	Yield Value at w/c = 0.4 Pa	w/c for $f = 30 \text{ Pa}$ g/g	Inter- particle Distance* $\mu\text{m}$
235	14.0	0.35	2.0
278	26.5	0.44	2.3
329	75.0	0.475	2.2
442	165.5	0.55	1.9
560	>250.0	0.58	1.6

\*Calculated from Eq. 5 using indicated Specific Surface.

consideration of the water film thicknesses and interparticle distances, increasing the specific surface area progressively increases the yield value at constant water

content. Also, the water content required to obtain a yield value of 30 Pa increases systematically with the specific surface area. Bombled suggested that the interparticle distances remain approximately constant as the water content increases with the surface area to maintain the constant yield value (2). The interparticle distance ( $2 \times$  the water-film thickness in  $\mu\text{m}$ ) was calculated from:

$$d = 2 \times 10^3 \frac{w/c - 0.12}{S} \quad (5)$$

in which  $w/c$  is the water-cement ratio,  $S$  is the specific surface area of the cement, and 0.12 is an estimate of the amount of interstitial water which does not contribute to the water-film thicknesses or interparticle spacings as indicated in Fig. 1. The values of  $d$  in Table III are seen to be approximately constant.

In addition to the functional forms of Eqs. 3 and 4, numerous other exponential and power law equations have been used to describe the dependence of flow properties on water content and cement fineness. The data of Table II at constant  $S$  was used to obtain:

$$f_o = \frac{0.124}{(w/c - 0.15)^{3.97}} \quad (6)$$

by the method of least squares. To do this the value of the water content not contributing to flow was varied to obtain the value 0.15 for the best fit. The data in Table III was fitted simply by determination of the slope and intercept of the logarithmic plot to obtain:

$$f_o = 4.47 \times 10^{-9} S^{4.01} \quad (7)$$

The fact that the exponents in both Eq. 7 and 8 are nearly equal again indicates that the yield value is closely related to the ratio of the surface area to part of the water content. However, the data seem to yield equally good fits for various exponential and power law relationships because of the limited range and accuracy of the data.

The functional dependence of the apparent or plastic viscosity on water content and specific surface becomes even more complex. In one study (9) the apparent viscosity,  $\eta$ , was found to be given by:

$$\eta = 13(d')^{-0.6} - 1 \quad (8)$$

where the quantity  $d'$  used as a measure of the interparticle spacing in  $\mu\text{m}$  was calculated from:

$$d' = \frac{(w - w_a)^2}{S} \times 10^3 \quad (9)$$

in which the water contents,  $w$  and  $w_a$ , and the surface area,  $S$ , are expressed per unit weight of cement. The value of  $w_a$ , the water requirement by a standard test, was about 0.3. This suggests that the functional dependence of the viscosity on the water content may differ considerably from that for the yield values for portland cements.

**WATER REDUCING ADMIXTURES.** Microscopic observations have repeatedly confirmed that the cement particles are dispersed by water-reducing admixtures (2). It has long been believed that this dispersion is the result of neutralization of surface charges and the reduction of attractive forces between particles. The relatively new "super" water-reducing admixtures, such as the sulfonated melamine formaldehyde (M-type) and sulfonated naphthalene formaldehyde (N-type) condensates do not strongly retard cement hydration. They can, therefore, be used at concentrations considerably higher (over 1% by weight of cement) than normally practical with lignosulfonate type admixtures. The latter type usually causes significant retardation at concentrations somewhat higher than 0.1%, whether they are sugar-free or not (27).

Daimon and Roy (28) measured the adsorption of a sulfonated naphthalene formaldehyde condensate by cement particles in water and found that the data yielded a Langmuir isotherm. It was also shown that with the cement used ( $393 \text{ m}^2/\text{kg}$ ) and with additions of the admixture up to about 1.5%, nearly all of the active component was adsorbed (about 20% was not adsorbable), but when larger amounts were added the amount in solution increased rapidly. Measurements of the zeta potential of the finer cement particles showed variation with the amount added similar to the Langmuir adsorption isotherm, reaching values of about -50 mV at maximum adsorption (29). Mortar flow values also showed a similar increase with admixture content. Rotational viscometer measurements on cement pastes gave initial yield stress values which decreased from 40 - 100 Pa (depending on mixing intensity) for the plain paste at 0.4 water-cement ratio to zero at 1% addition. The apparent viscosity was also reduced from about 500 to about 200 mPa.s if the paste was mixed at low intensity (ASTM), but only very slightly if mixed at high intensity (API), as indicated in the discussion of Fig. 4.

The adsorption of two N-type admixtures and two high molecular weight styrene polymers in cements was determined (30) at additions up to 0.5% of the weight of cement. For the N-type admixture the adsorption isotherms were of the Langmuir type; for the styrene polymer they were of H (high affinity) type. Sedimentation rate measurements with the N-type admixture in dilute cement-water suspensions (3 g in

28.5 ml) indicated dispersion of the particles by a progressive decrease from the sedimentation rate with no admixture to very low values at additions of 0.4% by weight of cement.

Petri (14) measured the apparent viscosities of cement pastes with a Brookfield rotational viscometer with and without several admixtures. Additions up to 1.6% by weight of cement were used. With increasing amounts of an N-type admixture he showed the progressive decrease of yield value, viscosity, and the area of the hysteresis loops at increasing and decreasing shear strain rates until Newtonian behavior was obtained with 1.2% of the admixture. Another admixture tested by Petri, sodium hexametaphosphate, produced its maximum effect at about 0.5% addition.

Petri also attempted to determine the functional dependence of the apparent viscosity,  $\eta$ , of cement pastes on the solid volume concentration,  $C$ . Data for cement pastes without admixtures did not fit any of several theoretical equations from electroviscosity. This is not surprising since the theory used has given only equations of Newtonian form. However, Petri did find that his data for pastes containing 1% of the N-type admixture indicated that the suspensions behaved remarkably like a theoretical model for nonattracting spheres of equal size at high concentrations, for which:

$$\eta = \eta_0 (1 - 1.35 C)^{-2.5} \quad (10)$$

There is continuing research on the use of lignosulfonate water-reducing admixtures, especially in low water-cement ratio systems. Soluble carbonate additions are used to overcome excessive retardation. Odler et al (17) studied the rheological properties of portland cement (6% gypsum) pastes with and without sodium lignosulfonate and sodium carbonate additions, and ground clinker pastes with the same additions. Additions of up to 1.25% of each were used, but only when both additives were present was a fluidizing and set-regulating effect obtained. Finenesses ranged from 340 to 850  $m^2/kg$ . When gypsum was present the setting time became much shorter, but without gypsum these additives produced normal setting behavior and rapid strength development. Water-cement ratios as low as 0.225 were fluid enough to be tested in a rotational viscometer. As noted earlier, these pastes showed shear thickening behavior. In another study (31) using calcium lignosulfonate and potassium carbonate, difficulties in testing 0.25 water-cement ratio pastes in a rotational viscometer were reported. The pastes were described as having a rubbery consistency. Other workers have used sulfonated lignins with  $NaHCO_3$  to produce pastes of 0.22 to

0.24 water-cement ratios which are self-leveling but of complex rheological character; they seem to have elastic-plastic properties not readily characterized in normal terms (20).

**CEMENT COMPOSITION AND HYDRATION.** For cements in which the early hydration reactions are properly controlled, the flow properties during the early dormant period do not depend very strongly on the compositions of the cements. One study of 12 cements of different types concluded that, except for a regulated set cement, the chemical and mineralogical composition seemed to be of little importance for flow compared to water content and cement fineness (25). However, the water requirement for flow has been shown to increase significantly with the  $C_3A$  and alkali contents, as well as depending on the particle size distribution (32). In addition, the calcium sulfate must be in a form suitable for control of the early aluminate reactions and the prevention of false set (24,33). However, if viscometer measurements are continued for longer hydration times, the effect of the  $C_3A$  content becomes increasingly important. Measurements using cement of  $C_3A$  contents ranging from 0 to 14% showed little variation of the yield stress, plastic viscosity or the area of the hysteresis loop during the first 45 minutes after mixing (23). However, after 2 hours the thixotropy indicated by the area of the hysteresis loop increased strongly with  $C_3A$  content above 2%. The yield stress also began to increase with  $C_3A$  content at 2 hours. The plastic viscosity, however, did not show this same strong effect until 3 hours.

Wittmann (34) examined the effect of additions of an M-type admixture on the apparent viscosities of cement pastes at a water-cement ratio of 0.6 at ages up to 7 hours. For pastes without the admixture the viscosity versus time curves for different viscometer rotor speeds showed increases with hydration time rather like the rheograph curves in Fig. 2. At a rotor speed of 80 rpm, the apparent viscosity increased from about 2,000 initially to over 20,000  $mPa \cdot s$  after about 4 hours. These reported values seem extraordinarily high. With 1.5% of the admixture added, the initial viscosity dropped to a value about 50  $mPa \cdot s$ , and exhibited nearly ideal Newtonian behavior for 1 to 2 hours. After about 3 hours the viscosity became non-Newtonian and shear rate dependent as it increased to nearly 20,000  $mPa \cdot s$  at 80 rpm at about 7 hours. Studies with several different cements yielded similar results except for a PZ 550 type, which required higher percentages of admixture to retard the increase in viscosity. These and many other results, such as those in Fig. 2, show that the stiffening of the paste through setting is normally a progressive process. This process is a result of the early hydration reactions and is affected

by any factors which accelerate or retard the hydration reactions.

#### CONCLUDING DISCUSSION

It is apparent from the available literature that there are still substantial gaps in our knowledge of the rheology of fresh cement pastes. It has proven difficult to quantify the results in terms of material properties and their functional dependencies on the cement properties and concentrations. This is at least partially a result of the fact that the procedures used to mix cement pastes and to test the flow properties affect the properties to be measured. It appears that it would be desirable to study the rheology of cement pastes in a state of dispersion of the particles in water that is comparable to the state of the paste as it is normally used in concrete. For this reason T. C. Powers advocated the use of high speed blenders because the shear rates in the paste in concrete during mixing were believed to be at least as high as in the most vigorous laboratory mixer. We have seen recent results that show substantial differences between such mixing techniques and other common test methods. It would appear prudent to definitely establish what mixing intensity is required, if that has not already been done, and then to concentrate research efforts on adequately mixed pastes. Similar considerations apply to the use of rotational viscometers of various designs. Much otherwise careful work has been done with equipment that may by its design preclude quantitative determination of the material properties because of non-uniform flow, or by the failure to take non-uniform flow properly into account. It appears that the problem is well appreciated in some quarters and that several equally valid test methods will emerge that can be used to obtain reproducible results. Perhaps some kind of standard test sample of cement, or an inert material of similar rheological properties, should be made available to permit comparison of rheological test methods.

The situation with respect to theoretical interpretation could also be substantially improved. Petri (14) reviewed the theory of flow of suspensions of charged particles in an electrolyte, i.e., electroviscosity. The complex equations for the viscosities of such suspensions contain the electric double layer parameters as well as the volume concentration,  $C$ , of the solids, and the viscosity of the liquid,  $\eta_0$ . When reduced to its simplest terms the general equation becomes:

$$\eta = \eta_0 (1 + kC) \quad (11)$$

which is the well known Einstein equation when  $k$  is 2.5. This reveals an obvious shortcoming of the theory as presently developed for systems like cement pastes

in which interparticle forces cause flocculent structure formation, finite yield values, shear rate dependence, and thixotropy, i.e., non-Newtonian behavior.

Nevertheless, research has given us a good qualitative or even semi-quantitative understanding of the complex behavior of fresh cement pastes. Several apparently satisfactory empirical equations have been established which relate certain rheological properties of the fresh pastes to the specific surface area of the cement and concentration of the cement in water. This matter appears to deserve further study with the objective of being able to predict with confidence the rheological properties of fresh cement pastes from the cement composition and physical properties.

The increasing use of organic water-reducing and other admixtures in concrete and the development of new admixtures have stimulated many studies of their effects on the rheological properties of cement pastes. Such studies are usually aimed at assessing the effectiveness of individual admixtures in concrete. However, since the rheological behavior of cement pastes containing certain admixtures is simpler than that of plain pastes, it may be possible to determine the true functional dependencies for the dispersed state, and then attack the problem of pastes in various degrees of flocculation.

**RESUME :** Cette communication étudie le processus de formation de gel de tobermorite et de composés de silico-hydrato-aluminate et de silico-sulfo-aluminate, lors de l'hydratation des ciments portland, en présence de gypse et pour diverses valeurs du rapport eau sur ciment. De nouveaux résultats expérimentaux sur l'évolution de ces composés sont exposés, ainsi que sur les phases de transition qui apparaissent lors de l'attaque des constituants du ciment par les sulfates.

Un modèle schématisant le mécanisme de l'hydratation et du durcissement du ciment est présenté, dans lequel les constituants hydratés ne sont plus considérés isolément, mais dans l'ensemble complexe de tous les composés. Les résultats expérimentaux exposés permettent de mieux comprendre les processus dans les systèmes hétérogènes de ciments portland durcis. Ceci pourrait servir de base à une nouvelle conception du durcissement du ciment.

**SUMMARY :** Formation processes of tobermorite gel, silicohydroaluminate and silicosulpho-aluminate compounds are discussed and new data on development of these compounds in hydrated cement are given in this paper. Phase transitions occurring during the destruction of Portland cement compounds by sulphate attack in the cement-water system of different composition in the presence of gypsum are studied.

A hardening mechanism (hydration) scheme of Portland cement in water is given, in which the reaction products are shown not as separate hydrated compounds, but as complexes of these compounds. The obtained data provide a better understanding of processes occurring in heterogeneous systems of hardening Portland cements, what in its turn may serve as a base for new conception about processes occurring during cement hydration.

## INTRODUCTION

Up to now different opinions exist on hydrated compound formation mechanism and phase composition of hardening Portland cement.

According to recent theoretical views and experimental data on hydration and hydrolysis of the main minerals of Portland cement in aqueous medium saturated with lime (at initial hardening periods also with  $\text{SO}_4^{2-}$  ions) at room temperature may be expressed by the following chemical equations:

$\left\{ \begin{array}{l} \text{T - gel} \\ m = 0,8-2,0 \end{array} \right.$

However, the results obtained by us in the investigation of phase composition of different Portland cements curing many years in water at room temperature [1,2], enable us to give the another interpretation of cement hardening mechanism and changes in its phase composition, which was partly published in the materials for the Sixth Congress on Chemistry of Cement [1].

## DISCUSSION OF THE RESULTS

Earlier results obtained by us [1] about the existence of complex compound  $\text{C}_3\text{A} \cdot \text{CaSiO}_3 \cdot \text{aq}$  in hardening cements and its formation through liquid phase and decomposition under the action of gypsum present in the system etc. were supported by other authors, who carried out experiments with the help of modern apparatus [3]. However, literature dealing with these questions is quite scarce.

It is known, that at the end of setting period, the duration of which depends on mineralogical composition of Portland cement, its dispersion, crystalline structure of particles, temperature of surrounding atmosphere and etc. all elements composing Portland cement are always observed in different amounts in liquid phase. In this case the liquid phase is a non equilibrium system of dissolved components of C-A-F-S-SO<sub>4</sub>-H order. Immediately upon contact with water, Portland cement minerals interact with it and ettringite is precipi-

tated topochemically in the form of small crystals of irregular shape. In alkali solutions, with/without traces of  $\text{SO}_4^{2-}$  ions, compounds possessing the structure of ettringite are unstable. More stable crystals are formed as a result of recrystallization of ettringite through the liquid phase. After a few days of interaction between Portland cement and water separation of ettringite begins and is usually accompanied by the separation of monosulphate at the same time. This phenomenon results from the presence of  $[\text{Al}(\text{OH})_6]^{3-}$  ions in solution and depends on Portland cement mineralogical composition and hardening conditions. Interaction of ortho- and pyro- ions of silicic acid and  $\text{Ca}^{2+}$  and  $\text{OH}^-$  ions results in formation of microcrystalline precipitates of  $2\text{CaO} \cdot \text{SiO}_2 \cdot \text{aq}$  and  $3\text{CaO} \cdot 2\text{SiO}_2 \cdot \text{aq}$  types of almost colloidal sizes combined to precipitates formed topochemically earlier and of an analogical composition. T-gel formed only from calcium salts of ortho- and pyro silicic acid is of such a nature. Simultaneously with the appearance of T-gel (after a period of 6-12 h, when water is added to Portland cement) formation of silicates of higher degree of polycondensation begins through liquid phase and calcium silicate hydrates of more complex composition than T-gel are formed.

Investigations carried out by us show, that silicic acid in liquid phase of hardening Portland cement is present as

$(\text{SiO}_4)^{4-}$ ,  $(\text{Si}_2\text{O}_7)^{6-}$  and  $(\text{Si}_3\text{O}_9)^{6-}$  ions (higher degrees of polycondensation are possible) or in the form of a coagulated sol. It is known, that in hardening Portland cement paste of normal composition uncombined gypsum disappears during the period of 10-20 h, when water is added and in Portland cements without iron compounds (white cement) after 2-3h, while the concentration of  $[\text{Al}(\text{OH})_6]^{3-}$  ions in the liquid phase increases with time.

The presence of silicic acid ions of different polycondensation degrees and also

$[\text{Al}(\text{OH})_6]^{3-}$  ions in solution determine composition and structure of compounds formed through the liquid phase. Ettringite and monosulfate in liquid phase interact with silicic acid ions of higher polycondensation degree forming large complexes  $\text{C}_3\text{A} \cdot \text{Ca/SiO}_3$ ,  $\text{SO}_4$ ,  $(\text{OH})_2/\text{aq}$  and  $\text{C}_3\text{A} \cdot 3\text{Ca/SiO}_3$ ,  $\text{SO}_4$ ,  $(\text{OH})_2/\text{aq}$  the composition of which corresponds to solid solutions  $\text{C}_3\text{A} \cdot \text{CaSiO}_3 \cdot \text{H}_{12}$  -  $\text{C}_3\text{A} \cdot \text{CaSO}_4 \cdot \text{H}_{12}$  -  $\text{C}_3\text{A} \cdot \text{Ca}(\text{OH})_2 \cdot \text{H}_{12}$

and  $\text{C}_3\text{A} \cdot 3\text{CaSiO}_3 \cdot \text{H}_{31}$  -  $\text{C}_3\text{A} \cdot 3\text{CaSO}_4 \cdot \text{H}_{31}$  -  $\text{C}_3\text{A} \cdot 3\text{Ca}(\text{OH})_2 \cdot \text{H}_{31}$  /1, 3, 5/. Compound

$\text{C}_3\text{A} \cdot n\text{CaSiO}_3$ , /1/ serves as nucleus for such complexes.

X-ray diffraction pattern of these complex compounds corresponds to that of ettringite or monosulfate aluminate /3, 5/. The above mentioned complexes are formed either through the liquid phase in hydration process of initial aluminate phases or as a result of further conversion in liquid

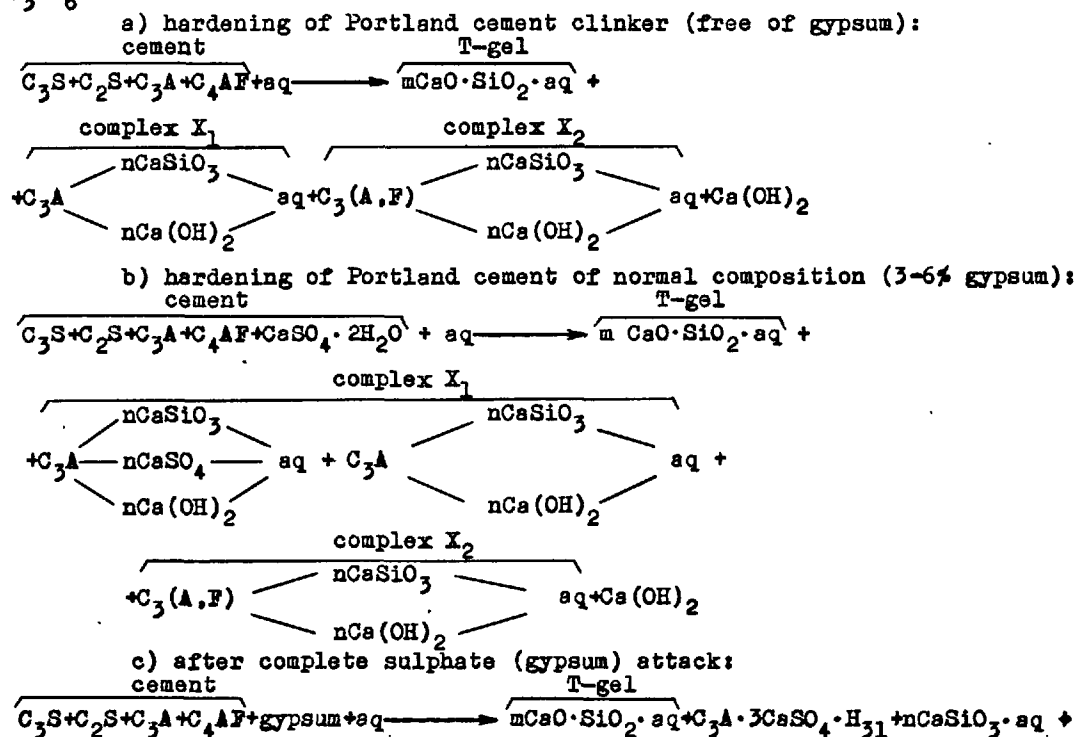

phase of new formations originally formed by the hydration of  $C_3A$ . In hardened Portland cement paste of normal composition (with limited amount of gypsum) above mentioned complexes are in equilibrium and retain stability until a disturbance of this equilibrium occurs as a result of the appearance or an increase in gypsum content in the system, e.g. as in the case of sulphate-gypsum attack. The presence of significant number of  $SO_4^{2-}$  ions in the system leads to the decomposition of silicate complexes with separation of inert  $CaO \cdot SiO_2 \cdot aq$  and ettringite crystals stable under the given conditions -  $C_3A \cdot 3CaSO_4 \cdot H_{31}$  and also to transformation of  $C_3AH_6$  compound to ettringite through liquid phase. Ettringite decomposes cement stone due to an increase in its volume.

A new equilibrium among the components of the system is achieved after gypsum attack. As it is known, hydration process of  $C_3AF$  mineral and mechanism of formation of hydrated compounds during Portland cement hardening is similar to that occurring during  $C_3A$  mineral hydration, however, it has its specific peculiarities. At the relationship of  $A/F = 1$  in initial phase  $C_3AF$  reaction products are equimolar quantities of  $C_3A$  and  $C_3F$  in solid solution, composition of which may be expressed by general formula  $C_3AFH_x$  /6/. Crystalline structure of this compound is similar to that of cubic minerals  $C_3AH_6$  and  $C_3FH_6$ .

Compound  $C_3FH_6$  was not identified by X-ray diffraction in hydrated Portland cement of normal composition. Not in all the investigated specimens was the presence of mixed crystals (solid solutions) of  $C_3(4)(A,F)$  composition identified. In our research chemical phase analysis has shown the formation of complex  $X_2$  of  $C_3(4)(A \cdot nCaSiO_3, F)$  aq composition/1/. This shows the appearance of mixed crystals of  $C_3(4)(A,F)H_x$  composition through liquid phase, aluminate component of which forms the above mentioned complex with calcium salt of metasilicic acid in solution. Formula of complex  $X_2$  may be written as follows:

Such is in general features, the hypothesis suggested by us about structure the formation mechanism and the formation of new compounds in hardening Portland cements. The hydration of minerals in hardening Portland cement is not isolated, but surrounded with compounds interacting with one another, then the hydration process in Portland cement of a normal composition may be expressed by the following equations:

The data obtained in the investigations carried out by the authors of this paper show that in normal hydrated Portland cements (with 3-6% of gypsum) ettringite  $\text{C}_3\text{A} \cdot 3\text{CaSO}_4 \cdot \text{H}_{11}$  in pure form is absent but it is included  $n_{11}$  in the composition of complex  $\text{C}_3\text{A} \cdot 3\text{Ca}/\text{SiO}_3 \cdot \text{SO}_4 \cdot (\text{OH})_2 \cdot \text{aq}$ .

Sulphate (gypsum) attack develops gradually only with the increasing of gypsum concentration in the system followed by the decomposition of complex  $X_1$  [1,2] and cement stone. At the end of attack nearly all the  $X_1$  decomposes into separate  $\text{CaSiO}_3 \cdot \text{aq}$  compounds and ettringite. This process may be observed by the gradual increasing of  $\text{CaSiO}_3 \cdot \text{aq}$  in boiling  $\text{H}_2\text{BO}_3$  solution with a rise in gypsum concentration in the system. Apparently the complex  $X_1$  contains ettringite in amount which does not decompose the complex itself. The increase of ettringite amount for some reason (e.g. in the case of sulphate-gypsum attack) results in decomposition not only that part of complex  $X_1$  where ettringite entered earlier and  $X_1$  also that part, which had not contained it, e.g. compounds  $\text{C}_3\text{A} \cdot n\text{CaSiO}_3 \cdot \text{aq}$  and  $\text{C}_3\text{AH}_3$ . As a result of this separate inert components possessing no binding properties are formed which convert Portland cement stone into a formless mass.

Portland cement hydration process analysis data show, that the end of these processes - strength of Portland cement stone - is the result of total mineralogical composition of cement stone, space distribution of hydration products, crystalline structure of hydrated compounds, their crystal forms and degree of dispersion. Portland cement stone taken as a whole should be looked upon as a texture containing all necessary elements of strength. The main framework of the texture consists of interlocked rigid crystals of  $\text{Ca}(\text{OH})_2$  and calcium hydro-sulfoaluminates entering complex  $X_1$ . Inter-spaces in this bearing framework are filled densely with T-gel and remaining part by complex  $X_1$  of fine crystalline structure. The remaining interframework is filled with mostly colloidal substance of T-gel and with complex  $X_2$  -  $\text{C}_3(\text{A} \cdot n\text{CaSiO}_3 \cdot \text{F}) \cdot \text{aq}$  formed on the base of ferrite phase.

#### CONCLUSIONS

1. It was found, that solid phase of completely hydrated Portland cement of common composition consists of: 25-40% T-gel, 35-50% complex X and 15-20%  $\text{Ca}(\text{OH})_2$ .

2. T-gel contains only 50-60%  $\text{SiO}_2$  of the amount present in hardened Portland cement paste in the form of salts of calcium

ortho- and pyro- silicic acid. The remaining  $\text{SiO}_2$  amount in the form of calcium salts of metasilicic acid (may be of the highest degree of polycondensation) enters the more larger silicohydroaluminate complexes (complex X), the nucleus of which is made up of compound  $\text{C}_3\text{A} \cdot n\text{CaSiO}_3 \cdot \text{aq}$  ( $n=1$  or 3).

Thus, not all the  $\text{SiO}_2$  present in the system enters T-gel in hardened Portland cement as is claimed by the generally accepted conception. The latter conception is based on the data obtained in the investigations, in which specimens of the material (hardened Portland cement paste) during their preparation for phase analysis by the molybdenum method are extracted by HCl solution.

However immersion of hardened Portland cement specimens in HCl solution even of low concentration completely decomposes the above mentioned complex X. Thus silicic ions of higher degree of polycondensation belonging to the complex X pass into solution and then they are estimated as a part of T-gel. Further research work must be carried out in this field.

# Estimation of Chemical Bonding in Hardened Cement Paste and Its Implications

## *Les liaisons chimiques dans les pâtes de ciment durcies et leurs conséquences*

S. CHATTERJI, M.Sc., D.Phil., Research Scientist, H + H-INDUSTRI A/S, Lundtoftevej 1A, DK 2800 Lyngby, Denmark.

**SUMMARY:** The existence of chemical bonding between the cement hydration products has been postulated by different workers to explain some properties of cement pastes. To form a stable three dimensional body the chemically bonded particles must form a fairly dense three dimensional net work. No attempts seem to have been made to quantify the preponderance of chemical bonding in a cement paste from its fundamental requirements. Most fundamental of these requirements is the juxtaposition of appropriate atoms or ions. Basing on this requirement only, the maximum probability of formation of a single chemical bond between two particles can be calculated. Other requirements reduce this maximum. From the above maximum probability it is possible to estimate the extent of three dimensional net work of particles bonded by single chemical bonds. For a water cured paste it is extremely low i.e. chemical bonding plays a negligible role in the structure of a cement paste. Implications of this result as regards the properties of pastes and the aggregate-paste bonding are discussed.

**RÉSUMÉ:** Plusieurs chercheurs ont formulé l'hypothèse que l'existence de liaisons chimiques entre les produits d'hydratation des ciments pouvaient apporter une explication à certaines propriétés des pâtes de ciment. Pour former un corps à trois dimensions stable, les particules liées chimiquement doivent former un réseau à trois dimensions suffisamment dense. Il n'a été fait aucune étude quantitative sur la prépondérance des liaisons chimiques dans une pâte de ciment à partir de ses exigences fondamentales. L'exigence fondamentale prédominante est la juxtaposition des atomes ou des ions appropriés. A partir de cette seule exigence, on peut calculer la probabilité maximale de formation d'une liaison chimique unique entre deux particules. D'autres exigences réduisent ce maximum. A partir de cette probabilité maximale ci-dessus, il est possible d'évaluer l'étendue du réseau à trois dimensions des particules liées par des liaisons chimiques uniques. Pour les pâtes conservées dans l'eau, le résultat est extrêmement faible, c.à.d. que les liaisons chimiques jouent un rôle négligeable dans la structure des pâtes de ciment. Un débat est ouvert actuellement sur les implications de ces résultats en ce qui concerne les propriétés des pâtes et les liaisons chimiques des pâtes-agrégats.

Formation of chemical bonds among cement hydration products has been postulated by different workers to explain some of the properties of cement paste e.g. limited swelling capacity, wet strength etc. (1,2,3). No attempt has been made to estimate the probability of its formation from the pre-requisites of bond formation. These requisites are (i) right types of bond forming atoms or ions have to be juxtaposed within the bond forming distance of about 3Å; (ii) the nearest neighbours of either of the bond forming atoms should not interfere with the bond formation; (iii) after the bond formation the spatial disposition of the bonded atoms should satisfy the required bond angle e.g. Si-O-Si, Ca-O-Si etc. In this paper an attempt will be made to estimate the probability of bond formation from the pre-requisites. Of these requisites the first is the least restrictive and yields the maximum probability. The other two requisites reduce the probability of bond formation sharply and as such their application will be deferred. It is to be noted that the application of the first requisite only is equivalent to an assumption that the material is composed of a random collection of atoms or ions.

After mixing cement with water it takes some time before the paste is capable of carrying any load; though the anhydrous cement grains start to hydrate from the time water is added. The initial hydration products form at isolated places round the anhydrous grains and the water-filled intergranular spaces get filled up by hydration products formed subsequently (4,5,6). When the hydration products from different sources approach each other due to growth or nucleation they do so in random orientation. To perform the functions for which it has been postulated the chemical bonding among these randomly oriented hydration products have to be fairly extensive.

Of the total hydration products of cement only a small part is crystalline and well characterized e.g.  $\text{Ca}(\text{OH})_2$ , ettringite, but the characteristics of the major constituent namely calcium silicate hydrate (CSH) are disputed except that it is composed mainly of positive and negative ions. Various morphologies have been reported for CSH (7); however, analyses of the reports indicated that all these are derived from needle-shaped CSH (8,9) except for the product which form very early (10). The diameter of CSH needles have been reported from 500 to 2000Å (11,7); the latter value refers to needles coated with metal films of unknown thickness. The needles are generally reported to be about a micrometer long. The chemical bond formation among these CSH needles is what has been postulated in 1,2,3.

If a cement paste is kept saturated from the beginning, as is the normal practice in cement testing or some application, the space between the hydration products will be filled by water. Experiments with contacting silica glass surfaces in atmospheres of different relative humidities (rh) showed that upto about 50% rh the surfaces remain in contact. Above this rh the surfaces are disjoined by a water film whose thickness increases with rh and can be as high as 500Å at 100% rh i.e. each surface can have an absorbed water film of about 250Å thickness (2). In a saturated cement paste the CSH needles will also have absorbed water films and will be subjected to a similar disjoining force (1,2). To form chemical bonds between two CSH needles their respective water films have to be thinned down, against the disjoining force, to that in equilibrium with 50% rh; thereafter van der Waals forces will bring the needles still closer (2). This thinning down can only occur when the movements of the needles are restricted whilst the needles are approaching each other due to growth.

Consider two CSH needles which, by chance, have come within the bond forming distance. If they can form a bond at the point of their nearest approach, which can withstand the disjoining force, then further bond formation may occur by accretion of solids round the bond. The first bond formation can occur if oppositely charged ions face each other. The probability of that occurring is given by

$$P_1 = (0.x)(0.y) \text{ ----- [1]}$$

where 0.x and 0.y are the fractional volumes occupied by the positive and negative ions in the needles. When the needles are of similar composition then  $P_1$  will approach its maximum value of 0.25. The probability of forming two bonds at the first instance is  $P_1^2$  and so on.

It now remains to find the strength of a chemical bond and that of the disjoining force. In a silicate structure the Si-O bond is generally considered to be the strongest bond at room temperature. In quartz a single Si-O bond has a strength of  $5.98 \times 10^{-4}$  dyne-Å (12). From the properties of quartz it can be calculated that the average cross-sectional area of a Si-O bond is  $5.23 \text{Å}^2$ . These values will be taken as the average values for bonds in CSH needles.

properties are not dependent on chemical bond formation.

From the above it can be inferred that (a) chemical bonding among the cement hydration products plays very little, if any, part in determining the properties of cements.

(b) in a moist paste the hydration products are separated by films of water. This physical picture of a paste is identical to that proposed by Chatterji and Jeffery (11). From the above picture it follows that

(i) the tensile strength of a paste will be determined by the intervening liquid films and for a given paste will have a maximum (15). Moreover, the tensile strength of the liquid phase will set an ultimate upper limit to the tensile strength.

(ii) compressive strength will have no such limit and be determined by the shear strength of the needles (16).

(iii) during the first drying of a paste, the particles which are separated from each other by thinner water films will be brought nearer to each other from those separated by thicker water films i.e. fine cracks will form (17). These cracks are responsible for the irreversible shrinkage on first drying.

(iv) the potential points of crack formation during drying will also be points at which hydration products will be able to slide over each other or rearrange easily i.e. they will act as sites of creep (18).

Chemical bond formation between CSH and concrete aggregates has been postulated by different workers to explain differences in properties of concrete made with different aggregates. Most natural aggregates are polycrystalline and are often polyminerale. Due to the crystalline nature of aggregates all the three pre-requisites have to be taken into account even for a single bond formation and as a result its probability will be very low. In other words in a concrete the nature of bond between CSH and aggregates is the same as that between CSH particles (19).

# On main formulae of cement stone and concrete strength

## *Formules fondamentales de la résistance des mortiers et bétons*

I.P. VYRODOV, G.P. PADALKINA, U.R.S.S.

RESUME : La présente communication étudie le durcissement en fonction du rapport eau sur ciment  $\frac{E}{C}$ .

Une formule générale en a été déduite, permettant de calculer la résistance des mortiers et bétons; elle dérive (sous certaines restrictions) des formules déjà connues, mais elle est plus simple et plus pratique.

Deux termes antagonistes de cette formule révèlent une analogie avec l'action réciproque des forces moléculaires. L'analyse des données théoriques et expérimentales permet de comprendre le sens physique des paramètres utilisés, et d'aboutir à des calculs numériques.

De nombreuses expériences, et notamment des expériences sur du béton lourd, ont montré la bonne concordance entre les valeurs calculées selon la formule proposée et les résultats expérimentaux. Cette formule permet donc, en fonction du paramètre  $\frac{E}{C}$  de calculer à l'avance les résistances.

SUMMARY : Relationship between strength and watercement ratio ( $\frac{W}{C}$ ) has been under investigation in this study. Generalized formula of cement stone and concrete strength has been deduced. It contains (under certain restrictions) formerly known and more simple formulae used in practice. There have been specified two antagonistic addenda what allowed to establish the identity with intermolecular forces developed in the system. Analysis of theoretical and experimental data resulted in revealing the physical significance of strength parameters and estimating their numerical values. Using the extensive experimental material, in particular taking as an example heavy concrete, the proper correspondence of the experimental and theoretical strength estimated according to the generalized formular has been shown. The formular reflects variations of the main factor ( $\frac{W}{C}$ ) and strength parameters while approaching the value of the predicted strength.

The watercement ratio is one of the most significant factors that determines not only conditions of hydration and new formation recrystallization, but also processes including formation of physicomachanical properties of the binding systems to be solidified. This strength factor was first formalized by Bolomeo to estimate the concrete strength:  $\frac{W}{C} = X^{-1}$

$$R = AR_4^b (Z-b), \quad (1)$$

where

A and b - certain coefficients,

$R_4$  - cement activity.

However this formular can be the proper approximation only in the restricted interval  $Z$  Fig.1 (Typical experimental relationships  $R(Z)$  taken from a series of trials are given in this figure). This fact is taken as a principle of the approximation curve using either a series of straight segments (a broken curve) or a single averaging straight line in some not exact technological calculations. Such an approximation as a consequence of experience conceals the true behaviour of strength relative to the watercement ratio as well as the fundamental properties  $R(Z)$  which can be used by specialists. To clear up a general nature of  $Z$  effect on formation of strength, there has been used a Stochastic approach in the works / 1-3 / what resulted in better approximation

$$R = Az (\alpha + z) \quad (2)$$

as compared with (1). Further generalization / 4-7 / allowed to establish the strength formula

$$R = \eta_1 z (\alpha + z) (\eta_2 + z)^{-2} \quad (3)$$

wherein

$\alpha$  - autohesive-cohesive factor

$\eta_1, \eta_2$  - factors which meaning will be revealed later on.

For theoretical interpretation ratios (3) are given as

$$\begin{aligned} R &= \eta_1 \eta_2 (\eta_2 - \alpha) y^{-2} + \eta_1 [1 + (\alpha - 2\eta_2) y^{-1}] = \\ &= R_I + R_{II} = R_{III} \end{aligned} \quad (4)$$

where

$$y = z + \eta_2$$

Let  $R(z) = R_I + R_{II} = R_{III}$  (Fig.2)

Singling out addenda  $R_I$  and  $R_{II}$  from the summary strength  $R = R_{III}$  reflects the fact that cement stone and concrete are both resistant to the mechanical compression and tension as well. It means that there exist mutual interaction forces  $R_I$  (autohesive-cohesive interaction: adhesion) and repulsion forces  $R_{II}$  between there particles. It is evident that the system is also exposed to overmolecular forces of mechanical tensions of strengthening and weakening together with the interaction  $F_I$  and repulsion forces  $F_2$  of intermolecular interaction.

Fig. 1

Fig. 2

In this connection data of Fig. 1, 2 are compared with the known curves of intermolecular forces of interaction  $F_1$  which are dependent upon a spacing between molecules  $\underline{r}$ , and the result is that there is similarity in behaviour of the summary forces of interaction  $F(r) = F_1(r) + F_2(r)$ , and the summary compression strength  $R_{\text{compr.}}(z^{-1}) = R_1(z^{-1}) + R_2(z^{-1})$ . The antibate character of these curves determines the choice of the strength factor: while comparing tension strength  $R_{\text{tension}}(z^{-1})$  with  $F(r)$  the symbate character of the curves mentioned above as well as curves  $R_1$ ,  $R_2$ , and  $F_1, F_2$  has been established. It is the second peculiarity that proves availability of interparticle interaction forces. As to the third peculiarity of values  $R_1(z^{-1})$  and  $R_2(z^{-1})$  it exhibits itself in diminishing these values up to zero while  $\underline{r}$  increases. Decreasing of strength  $R(z^{-1})$  with growth can be explained by analogy with the behaviour  $F(r)$ : distance increase between the interacting particles. The more complex system is however characterized by other effects, which can be traced in

the formula (4).

The more comprehensive analysis reveals an influence of different strength factors taking into account links that exist between the phenomenological factors and  $\gamma_2$  and cement activity  $P_{cem}$ , cement consumption  $U^x$ :  $\gamma_1 = \alpha R_4$ ,  $\gamma_2 = V_4^*$ , where

$\alpha$  - transition factor between cement strength and concrete strength

$\gamma$  - factor that reflects the water excess value relative to stoichiometry

Evaluation of data on building cement and concrete as well as experimental studies carried out by us made it possible to establish numerical values of factors  $\alpha$ ,  $\gamma_1$ ,  $\gamma_2$ .

Analyses showed that value  $\alpha$  in all cases studied above for concretes having the same base (portlandcement) can be taken for constant  $\alpha = -1.054$ ;  $\alpha$  means from 0.9 to 1.7 depending upon a type of inert (concrete) aggregate, setting conditions, way of testing;  $\gamma$  - a value of water excess and equals to  $-2.8 \cdot 10^{-4}$ , it is the same for cements with identical solidifications (setting) base. Formula (3) with these factors can be used to evaluate ordinary and high-strength concrete having standard setting rate and age of 28 days on portlandcements and inert (concrete) aggregates that meet the requirements of standards. The following concrete aggregates have been used: gravel with grain size  $\max = 80$  mm, granite broken (crushed) stone, pumice, lightweight aggregate, any-iskaya pumice.

Results of actual and estimated factors on heavy concrete compression strength having a 28-day age have been compared in Table. Gravel with grain size up to 80 mm and building quartz sand with module of coarseness 2.56-2.59 mm are taken as inert aggregates. In accordance with the evaluations carried out  $W/C$ -ratio has been varied in the range of 0.38-0.74, and cement consumption - in the range of 200-350 kg/m<sup>3</sup>. Cement activity has been changed in the range of 39.2-55.8.

Comparison of heavy concrete strength with the estimated one

3.50	300	55.52	51.60	54.83	-5.8	96.37	-46.4
4.00	320	55.52	57.78	57.78	0.0	112.64	-48.7
4.50	350	55.52	63.86	60.15	+6.1	129.03	-50.5

It is clear from the table that with change of cement activity formula ( ) shows the higher precision rate as compared with the widely used Bolomea formula.

In conclusion we can assume that the generalized formula (3) offered by us for estimation of concrete and cement stone strength, and which carries in its base the quadratic dependence  $R(z)$ , allows to predict strength  $R$  by way of selecting parameters  $\alpha$ ,  $\eta_1$ ,  $\eta_2$  and the main strength factor  $z$  as well.

# Accroissement de la résistance du ciment portland par introduction des constituants de cristallisation (germes)

## *Increase of portland cement strength at introduction of crystallizing components (crents)*

RESUME : On a étudié le problème d'accroissement de la résistance du ciment portland et de ses constituants par l'introduction d'un constituant complémentaire, dit constituant de cristallisation, car il cumule les fonctions de réactif de démarrage et d'amorce de la formation de deux porteurs de résistance principaux : hydrosilicates de calcium et ettringite. Ce constituant est étudié sur l'exemple du mélange  $Al_2(SO_4)_3$ ,  $Al_2(SO_4)_3 \cdot (OH)_3$ ,  $Al(OH)_3$  et  $SiO_2$  (coll.) introduit dans la composition du ciment. L'accroissement de la résistance initiale de ce dernier est dû à la formation d'une quantité complémentaire d'ettringite et de sa meilleure répartition autour des granulats. L'augmentation de la résistance à long terme est due à l'accélération de l'hydratation de l'alite et à l'élévation du degré d'homogénéité de la structure submicroscopique des hydrosilicates de calcium, produisant une diminution des microtensions internes au niveau du granulat. On a commencé la production de ces ciments aux constituants de cristallisation (germes).

SUMMARY : Increase of strength of portland cements and its components by introduction of an additional component has been studied. The additional component has been called "crystallizing" since it combines the functions of the initial reagent and of seed for formation of two main carriers of strength, calcium hydrosilicates and ettringite. An  $Al_2(SO_4)_3$ ,  $Al_2(SO_4)_3 \cdot (OH)_3$ ,  $Al(OH)_3$  and  $SiO_2$  (col.) mixture introduced into the cement composition was studied. The cement early strength increase of the latter stems from formation of additional amounts of ettringite with increasing the fraction of its regular concretions, whereas the late hardening strength increase stems from accelerated hydration of alite and increase of homogeneity of calcium hydrosilicate submicrostructure which indicates decrease of the natural microstresses level in their aggregates. Industrial production of cements with crystallizing components (crents) has been started.

**INTRODUCTION.** La voie principale d'accroissement de la résistance du ciment passe actuellement par une optimisation successive des paramètres technologiques de sa production à chaque opération entrant dans le cycle technologique, à commencer par le choix de la composition et de la dispersité des matériaux bruts jusqu'au choix de la granulométrie optimale des ciments (1 à 3), les améliorations dues aux modifications technologiques isolées de la production et apportées au résultat final - activité hydraulique du ciment - n'étant pas de simples termes additifs, l'accroissement total de la résistance est toujours inférieur à la somme des contributions isolées. C'est pourquoi les technologues ont conclu qu'il existe une limite de résistance du ciment, impossible à dépasser par les procédés technologiques traditionnels. Il est donc nécessaire d'étudier ses causes microstructurales et sur cette base tracer les voies à suivre pour augmenter la résistance.

**PARTICULARITES DE LA STRUCTURE SUBMICROSCOPIQUE DES CEMENTS DURCIS A HAUTE RESISTANCE ET DU MICROMECHANISME DE DESTRUCTION.** Les études de la structure submicroscopique d'hydratation des ciments à haute résistance, obtenus à l'aide de la technologie classique (3, 4), montrèrent que la résistance de la structure d'hydratation du ciment portland à l'âge de 1 à 3 jours (20 à 40 MPa) est conditionnée par le réseau cristallin biphasé tridimensionnel en fibres rigides inflexibles d'ettringite et d'hydrosilicates de calcium C - S - H (II). Ce réseau recouvre les pores entre les particules de départ du ciment entourées d'hydrates. Après 4 à 6 h de durcissement, les mailles du réseau sont remplies successivement par la "matrice" (autres produits d'hydratation) - en premier lieu par C - S - H (II) - en commençant par les particules de départ, tandis que les mailles "inachevées" continuent à se construire et se fixent au réseau et à l'agrégat à l'aide des zones de portlandite et C - S - H (II). La particularité principale de la structure d'hydratation des ciments à haute résistance consiste en moindres dimensions des mailles de son réseau, des zones d'ettringite, de portlandite et C - S - H (II). La deuxième particularité due à l'hydratation rapide est le volume plus petit des pores capillaires, leurs dimensions plus faibles et la densité plus grande (3). Une résistance élevée liée à ces particularités microstructurales rapproche le ciment hydraté des autres matériaux de construction dont la résistance croît également avec la diminution des dimensions des éléments structuraux (5).

Le micromécanisme de destruction de la structure d'hydratation est envisagé en détail dans le rapport de stand de Y.I. Papiachvili et de certains d'entre nous au Congrès actuel. La conclusion tirée des observations se ramène au fait que la fissure principale de destruction dans la matrice armée par le réseau se propage par sauts. L'extension des zones de fissura-

tion spontanée est liée de façon antibatique, tout comme dans les autres matériaux (5, 6), à la dimension moyenne des éléments structuraux. Ceci conditionne justement l'existence de la limite de la résistance pratique des ciments, qu'on augmente par des méthodes technologiques classiques. Lors de l'essai des échantillons à haute résistance l'accroissement des zones de fissuration sous charge s'accompagne d'effets acoustiques fort caractéristiques, comparables à une détonation.

**JUSTIFICATION DE L'INTRODUCTION DES CONSTITUANTS DE CRISTALLISATION (CRENTS) DANS LE CIMENT.** Nous partons de la nécessité, pour l'accroissement ultérieur de la résistance, d'arrêter ou de prévenir la fissuration de la matrice - "gel" des hydrosilicates. Une des idées maîtresses, à savoir la diminution de la concentration des contraintes près des sommets de microfissures dans les plans normaux à leurs trajectoires (?), n'est discutée en détail que pour les bétons (8). Vu que, pour le mécanisme existant de destruction, les contraintes normales dans la matrice sont celles de traction, les travaux pour la réalisation de cette idée doivent en premier lieu être orientés sur la création des zones de compression perpendiculaires au plan de la fissure, i.e. disposées le long des axes du réseau de fibres de renforcement. Ceci est technologiquement réalisable seulement par l'introduction dans la structure d'hydratation du ciment de la phase fibreuse expansive immergée dans le gel préalablement comprimé par cette dernière. Par conséquent, ce gel doit être présent, si c'est possible, dès le début de la cristallisation de la phase expansive. A cette fin le gel et la phase expansive immergée dans ce dernier doivent être spécialement "amorçés" par introduction dans la composition du ciment du constituant complémentaire dit constituant de cristallisation (crents) (3). Dans ce cas nous nous sommes attendus à l'accroissement équivalent de la résistance et de la résistance à la fissuration. Les lignes qui suivent traitent de l'argumentation chimico-technologique du procédé en question. Il existe également d'autres orientations et lignes directrices dans ce domaine, mais leur examen sort du cadre de cette communication.

**MODE OPERATOIRE. MATERIAUX DE DEPART.** Par cuisson répétée d'après la technique habituelle on a synthétisé les principaux minéraux de clinker  $C_2S(M)$ ,  $C_2S(\beta)$ ,  $C_3A(T)$ ,  $C_4AF$ , tous de pureté de 95 à 98%; le clinker comprenant (%)  $C_2S(R)$ -63,  $C_2S(\beta)$ -18,  $C_3A(T)$ -7,  $C_4AF$ -11,  $R_2O$ -0,25 % était cuit dans un four industriel de 127 mètres. Comme additions on a utilisé : silicagel récemment précipité cuit à 750 °C (2 h) et broyé jusqu'à son passage complet à travers le tamis n° 008 (coll.  $SiO_2$ );  $Al_2(SO_4)_3$  recristallisé incluant les impuretés d' $Al(OH)_3$ ,  $Al_2(SO_4)_3 \cdot (OH)_2$  (jusqu'à 30 %); métakaolinite obtenue par cuisson (620 °C, 1,5 h) du concentré de kaolinite de 90 % et broyée jusqu'à son passage par le tamis

n° 008 ainsi que  $\text{CaSO}_4$  dihydraté recristallisé et séché à  $60^\circ\text{C}$  (1 jour). En outre, on a utilisé le constituant de cristallisation industriel synthétisé pour nous à l'un des combinats chimiques par traitement thermoacide de l'argile.

**METHODOLOGIE DES ESSAIS.** Les constituants de clinker étaient broyés jusqu'à obtenir 0,1-0,3 % du résidu sur le tamis n° 008, et le clinker - jusqu'à obtenir la surface spécifique de  $3440\text{ cm}^2/\text{g}$  avec des résidus sur les tamis n° 02 - 0,3 % et n° 008 - 4,3 % ; à partir d'eux et de leurs mélanges avec additions on a préparé des échantillons de  $1,4 \times 1,4 \times 1,4\text{ cm}$ ,  $2 \times 2 \times 2\text{ cm}$  ainsi que de  $4 \times 4 \times 16\text{ cm}$  avec du sable (1:3) d'après les normes en vigueur en U.R.S.S. (GOST 310-76). Les échantillons fabriqués étaient laissés à l'air pendant 24 h à  $22 \pm 1^\circ\text{C}$  et à l'humidité de 100 % et ensuite mis dans l'eau à la même température. Après l'essai de résistance les échantillons étaient soumis à l'analyse thermique différentielle et à l'analyse aux rayons X. Des portions de la phase liquide étaient prises pendant 3 h par méthode d'extrusion à la presse.

**RÉSULTATS DES EXPÉRIENCES.** Les indices de résistance des échantillons et les résultats de détermination du degré d'hydratation aux rayons X sont donnés dans les tableaux I, II, III. Les résultats des expériences permettent de faire les conclusions suivantes :

1. L'introduction du constituant de cristallisation (crent) augmente considérablement la résistance de  $\text{C}_2\text{S}$  pur à l'âge de 28 jours. Un gain de résistance notable était observé en présence de  $\text{C}_2\text{A}$  et du gypse. La présence de la bélite dans le mélange de minéraux abaisse ces effets utiles. Lors de l'introduction complémentaire dans le mélange de  $\text{C}_4\text{AF}$ , la résistance de la structure d'hydratation baisse brusquement pendant 7 jours de durcissement.

2. Indépendamment de la composition du mélange de minéraux, l'introduction du constituant de cristallisation (crent) aboutit à l'augmentation de sa résistance. Le gain de résistance minimal est observé dans le mélange  $\text{C}_2\text{S} + \text{C}_2\text{A}$  (90 + 10), le gain maximal - pour  $\text{C}_2\text{S}$  pur hydraté.

3. Parmi les additions utilisées en qualité de réactifs de départ et de germes pour la synthèse du gel et de la phase expansive plongée dans le gel, c'est  $\text{SiO}_2$  (coll.) et son mélange avec  $\text{Al}_2(\text{SO}_4)_3$  qui se sont avérés les plus efficaces pour la résistance des échantillons de 28 jours. La métakaolinite et ses mélanges avec d'autres additions sont moins efficaces, mais ils assurent tous le gain de résistance en comparaison du ciment témoin (tableau II).

Toutes les additions réduisent quelque peu les durées de prise.

4. L'étude de la composition de la phase liquide, les données de l'analyse thermique différentielle et de l'analyse aux rayons X montrent qu'en présence de  $\text{SiO}_2$  (coll.), de  $\text{Al}_2(\text{SO}_4)_3$ , de métakaolinite et de consti-

tuant de cristallisation industriel, en raison de l'abaissement initial de la concentration de  $\text{SiO}_2$  et  $\text{Al}_2\text{O}_3$  dans la phase liquide et de la diminution de la concentration de  $\text{CaO}$ , après 1 jour de durcissement il se forme des quantités complémentaires d'ettringite et d'hydrosilicates de calcium dont la basicité n'est pas encore déterminée. Ceci confirme le rôle des additions en tant que réactifs pour leur formation. Le degré d'hydratation du ciment diminue d'abord (après 1 jour) pour augmenter ensuite (après 3 jours et plus), bien que la résistance augmente déjà après 6 h de durcissement.

5. Selon les données présentées partiellement dans le rapport de stand cité, la microstructure des nouvelles formations varie vers une ettringite facettée plus nettement et vers un arrangement plus fin et plus régulier des hydrosilicates dans la masse totale des nouvelles formations.

Les résultats des essais des propriétés du ciment additionné de constituant de cristallisation (crent) industriel (tableau III), dont la majeure partie n'est pas donnée ici vu la place insuffisante, témoignent de l'absence d'écarts notables par rapport aux indices de référence, à

l'exclusion de la résistance élevée et du fluage légèrement augmenté.

DISCUSSION DES RESULTATS. Une amélioration relative de la cristallisation de l'ettringite, y compris l'accroissement de la part de ses agrégats réguliers, surtout de la part des cristaux croissant radialement à partir des grains du ciment, ainsi que l'augmentation du degré d'homogénéité de la structure submicroscopique des hydrosilicates de Ca, plus notable dans les échantillons d'âge avancé, prouvent que les quantités complémentaires de ces phases,

qui se forment au stade précoce, servent en réalité de germes cristallins, au moins en ce qui concerne le caractère de leur influence. Puisque les ciments et les minéraux aux additions considérées ne démontrent pas de proportionnalité directe (qui a lieu dans la situation habituelle jusqu'à 24 heures) entre la surface spécifique, le degré d'hydratation et la résistance et, de plus, la durée de la période inductive d'hydratation devient plus courte, on peut tirer la conclusion que la vitesse d'hydratation est limitée, au stade de la période d'induction, par la germination. Par la suite, les germes apparus à ce stade créent des difficultés pour le stade suivant (cinétique) d'hydratation, qui n'influent pas sur la résistance. Par contre, le troisième stade d'hydratation contrôlé par diffusion (après 24 heures de durcissement) est de nouveau accéléré par ces germes.

Pour expliquer ce phénomène, notons que les produits d'hydratation du ciment préparés à l'avance ne sont pas efficaces pour la réduction de la période d'induction à la température normale du milieu. Ceci n'est pas lié à leur surface spécifique insuffisante ou, au contraire, à une mauvaise taille des cristaux, mais à la perte, lors du vieillissement, de la capacité initiatrice, ce qui est dû semble-t-il à la compensation des charges des centres actifs sur leur surface à cause du réarrangement, par vacances et par trous, de la structure qui a lieu sous cette surface et/ou à l'addition des adatoms de l'atmosphère. Dans les germes actifs la compensation des charges a lieu au stade cinétique du processus et une partie des radicaux libres est utilisée pour cela.

C'est pourquoi ces germes ralentissent quelque peu le déroulement du processus justement à ce stade. Mais ce ralentissement influe de façon favorable sur la taille et la distribution dans le volume du système des produits du stade cinétique, abaisse leur hétérogénéité de concentration et les niveaux de contraintes internes, car l'interaction des germes actifs formés et des radicaux libres a lieu d'abord là où ces derniers dominent quantitativement, ce qui a pour résultat leur distribution plus régulière. De plus, autour des sources de radicaux libres (grains du ciment) leur absorption limite les possibilités d'aggrégation prématurée des nouvelles formations. Ceci conditionne un déroulement plus libre du stade suivant de diffusion du processus et explique également le fluage élevé de ces structures d'hydratation.

Le gain de résistance des ciments à l'âge de 1 à 3 jours n'est conditionné que par l'optimisation de la microstructure et de plus par l'accroissement du degré d'hydratation et, par conséquent, une quantité moindre de pores.

Les germes actifs introduits par les constituants de cristallisation se distinguent

de ceux formés dans les systèmes ordinaires par la quantité, la distribution et le temps de formation - durant la période d'induction - tandis que normalement les germes apparaissent vers sa fin. On sait que les germes actifs jouent en général un rôle principal dans la cohésion et l'adhésion des systèmes de ciment (9), mais ce qui compte surtout c'est la courte durée du stade de leur activité élevée, passée jusqu'à présent presque inaperçue, sans parler des processus conditionnant la suppression de leur activité. Mais c'est justement ces processus qui sont responsables d'une brusque diminution de l'adhésion des systèmes de ciment aux agrégats et substrats dès l'achèvement de la prise, et de l'absence de cohésion après la dispersion de la matière durcie. Nous pensons également que les résultats positifs obtenus avec le traitement aux ultra-sons ou avec une vibration répétée des systèmes de ciment, proposée par S.V. Chestoperov, peuvent être expliqués par le blocage des processus de suppression de l'activité des germes. La même explication est également possible en ce qui concerne l'influence positive de l'atmosphère sans  $\text{CO}_2$ , découverte par Y.S. Malinine et son équipe et décrite dans leur communication à ce Congrès.

**CONCLUSION.** Les résultats exposés partiellement plus haut et les travaux similaires effectués par I.F. Ponomarev, I.A. Kryzhanovskaja, I.M. Syrkine avec collaborateurs et figurant aussi au Congrès ont servi de fondement scientifique pour commencer la production industrielle à l'une des cimenteries de l'U.R.S.S. du ciment à haute résistance additionné de constituants de cristallisation (crents).

# Influence of sulfonated naphtalene on the fluidity of cement pastes

## *Influence de la naphthaline sulfonée sur la fluidité des pâtes de ciment*

M. COLLEPARDI, Professor of Materials Technology and Applied Chemistry,

Research and Development Laboratory, MAC Mediterranea Additivi Cementi, Treviso, Italy.

RESUME : On a examiné, grâce à un test de mini-slump, l'influence de la naphthaline sulfonée (monomère) et de la naphthaline-sulfonée-condensée (polymère) sur les propriétés rhéologiques des pâtes de ciment. L'influence du moment de l'addition de ces produits sur la fluidité des pâtes de ciment a également été étudiée.

Les mesures d'adsorption, de potentiel Zéta, de calorimétrie, de diffraction de rayons X et d'analyse thermique ont été effectuées sur les pâtes de ciment/

En ajoutant une dose inférieure à 0.5 % en poids du ciment de polymère en poudre, on augmente notablement la fluidité de la pâte, alors que l'hydratation du ciment reste pratiquement la même. Des dosages supérieurs en polymère (1 - 1,5 %) augmentent la fluidité de façon négligeable et provoquent un retard de l'hydratation du ciment durant la période d'induction. Par contre, l'addition du monomère ne provoque aucune modification significative de la fluidité ou de l'hydratation.

Le moment de l'addition du polymère influence également la fluidité des pâtes de ciment et la vitesse d'hydratation durant la période d'induction. On a observé d'intéressantes relations entre l'adsorption du polymère, le potentiel Zéta et la fluidité de la pâte de ciment.

### SUMMARY :

The influence of sulfonated naphtalene (monomer) and sulfonated naphtalene condensate (polymer) on the rheological properties of cement pastes determined by mini-slump test was examined. The influence of time of addition of these products on the fluidity of the pastes was also studied.

Adsorption, zeta potential, calorimetry, XRD and thermal analysis (DTG) were also carried out on the cement pastes.

With dry polymer additions lower than 0.5 % by weight of cement, fluidity of the paste is remarkably increased, whereas the cement early hydration is substantially the same. Higher dosages of dry polymer (1 - 1.5 %) increase fluidity to a lower extent and cause stronger retardation in the cement hydration during the induction period. Conversely, no substantial change neither in the fluidity nor in the early hydration rate was caused by the addition of the monomer.

The time of addition of the polymer also affects the fluidity of cement pastes, and the cement hydration rate during the induction period, increasing fluidity and retarding the cement hydration. Some interesting relationships between polymer adsorption, zeta potential, and paste fluidity were found.

## INTRODUCTION

All the properties of the hardened concrete proportionally improve by reducing the water/cement (w/c) ratio of the fresh mix. However, the w/c ratio cannot be decreased under certain limits because of the reduction in the workability of the fresh concrete. The so-called super-water-reducers or superplasticizers can be used as additives that permit a concrete to have about 25 % of the mixing water removed without reduction in workability or a strong increase in workability (for example : from 20 mm to 220 mm in slump) without a significant change in all the properties of the hardened concrete. Combination of the two effects can also be obtained.

A large number of works has been devoted to study the properties of fresh and hardened concrete containing commercial superplasticizers (1). However, relatively few papers have been published to explain the effect of the superplasticizers on the water-cement system. In particular, few data (2-6) have appeared about the effect of pure chemical products used as superplasticizers on the physical-chemical changes of the cement pastes.

Superplasticizers are substantially based on sulfonated naphthalene-formaldehyde polymers or sulfonated melamine-formaldehyde polymers (7). The purpose of the present paper is to examine the influence of sulfonated naphthalene as a monomer and sulfonated naphthalene formaldehyde condensed polymer on the physical-chemical properties of a cement paste. Moreover the effect of the time of addition of the additives on the same properties were also studied.

## EXPERIMENTAL

Materials

Ordinary portland cement was used and Table 1. shows its chemical analysis. Pure sodium salt of naphthalene sulfonic acid (monomer) and sodium sulfonated naphthalene formaldehyde condensate (polymer) both produced as dry powders by MAC Spa were utilized. An aqueous solution of the sulfate-free polymer (wt % solid = 40) shows a viscosity of 40 cp and a specific gravity of 1.224 g/cm<sup>3</sup> at 20°C. Tap water with a specific conductance of 480 mho . cm<sup>-1</sup> was used.

Cement pastes were prepared at 20°C by mixing for 5 min 50 g of cement and enough water to obtain w/c ratio of 0.3 or 2. In a first series of experiments the monomer or the polymer were added to cement with mixing water. In a second series of experiments the solid additives were added 2.5 min after mixing and then the pastes were mixed again for other 2.5 min. Both polymer and monomer additions are expressed as percent by weight of cement. It must be taken into account that commercial superplasticizers are aqueous solutions generally containing from 20 to 40 % of the dry polymer used in the present work.

Techniques

The following experiments were performed : Minislump tests, polymer adsorption on cement, zeta-potential, isothermal calorimetry, X-ray diffraction analysis (XRD), differential thermal gravimetry (DTG). All the measurements were carried out at 20°C with polymer or monomer addition with mixing water or after 2.5 min the mixing had begun.

In the minislump tests (8) the pastes were prepared only with w/c ratio of 0.3, adding each time a different dosage rate of polymer or monomer, and the pat areas (in cm<sup>2</sup>) were measured after five minutes of mixing.

The magnitude of surface adsorption of the monomer or the polymer upon the cement particles was determined by U.V. absorption spectroscopy in the 220-230 nm absorption band due to a sulfonated naphthalene group present in both the polymer and the monomer. Fifty grams of cement and 15 ml (w/c = 0.3) or 100 ml (w/c = 2) of polymer or monomer solution of known concentration were mixed continuously for 5 minutes. In the delayed addition tests the dry polymer or the monomer was added after 2.5 min of mixing with tap water and then the paste was mixed again for other 2.5 min.

The liquid phase was then separated by filtration under vacuum. Each solution was diluted to the optimum concentration and brought to pH 6.5 before spectroscopic measurement. The quantities adsorbed were calculated by differences in concentration of polymer or monomer of the liquid phase before and after adsorption.

The zeta potential measurements were performed using a Laser Zee Meter by Pen Kem Inc. which is based on electrophoretic technique (9) and gives the results directly in millivolt. Zeta potential of colloidal particles is measured by determining the rate at which these particles move in a known electric field.

Zeta potential measurements were performed only with w/c ratio of 2. The samples for the measurements were prepared by mixing continuously 50 g of cement, 100 ml of water and a certain amount of additive for 5 minutes, then separating the liquid phase by vacuum filtration. Small portion of original paste was added to the filtered liquid phase and a suspension (0.5 g of solid/liter) was obtained with the same ionic

strength of the original paste and diluted enough to be observed to the microscope of the Laser Zee Meter.

Heat evolution as a function of time was determined according a method previously described (10) by using an isothermal conduction calorimeter. In the delayed addition tests, the polymer or the monomer was added after 2.5 min by injecting a saturated water solution so that the resulting final w/c ratio was 0.3, and then mechanically vibrating for 2.5 min.

XRD and DTG analysis were also performed on the hydrated cement pastes with a w/c ratio of 0.3.

#### DISCUSSION OF RESULTS

In fig. 1 the influence of monomer and polymer additions on the flowability of cement pastes measured by the minislump test is shown. No substantial change in the flowability is recorded by adding the monomer both in mixing water and after 2.5 min of mixing, whereas very drastic increase in the minislump is caused by the polymer. However, the influence of the polymer is quite affected by the time of addition.

Fig. 1 - Influence of polymer or monomer addition on flowability (minislump) of cement pastes (w/c = 0.3).

A delayed addition of the polymer seems to be more effective particularly in the lower dosage range. For example, 0.25 % of polymer raises the minislump from 15 cm² to 95 cm², when the admixture is added to the cement paste after 2.5 min after mixing had begun, while a negligible increase (from 15 cm² to 20 cm²)

is observed if the same amount of polymer is added with the mixing water. With a delayed addition of 0.5 % of polymer, the minislump rises to 200 cm², while no significant further increase is recorded with higher amounts of additive. On the other hand, the minislump arrives at 160 cm² if about 0.75% of polymer is added with the mixing water, with only minor changes in flowability for higher percentages of addition.

In Fig. 2 the amount of polymer or monomer adsorption by cement as a function of the percentage of admixture added to cement paste is shown. The polymer is much more adsorbed than the monomer. Moreover, the adsorption of the polymer depends on the w/c ratio of the paste and on the time of addition, whereas these parameters do not substantially affect the adsorption of the monomer.

Fig. 2 - Polymer or monomer adsorption on cement as a function of addition.

Polymer adsorption appears to be higher with a higher w/c ratio whereas one would expect the contrary due to the greater polymer concentration in the aqueous phase of the paste with a lower w/c ratio (0.3). Three mechanisms, all related to the larger amount of mixing water, could possibly explain the higher adsorption in the paste with a higher w/c ratio: a) a larger amount of hydrated cement; b) a better dispersion of cement

particles; c) a lower concentration of ions coming from cement phases that could interfere with the polymer adsorption.

Adsorption seems to be greater when the polymer is immediately added with the mixing water. It is possible to think that the polymer adsorbed by cement particles in the early stage of hydration is coated by initial hydration products such as ettringite, and in this way it becomes unaffactive in terms of electrical surfaces properties. By this way the nominal adsorption, calculated by difference between the polymer concentration in water before and after mixing with cement, really includes a certain part of polymer incorporated in the hydrated products of cement. Moreover, when the polymer addition is delayed, there is a much higher concentration of ions coming from cement and these could interfere with the polymer adsorption to a greater extent.

Fig. 3 shows the ratio between the concentration of admixture in the liquid phase after and before the

Fig. 3 - Relationship between the admixture concentration in the liquid before and after adsorption ( $w/c = 2$ ).

adsorption experiments (after/before) as a function of the initial concentration (before) for both polymer and monomer. The after/before concentration ratio is substantially constant for the monomer indicating that

about 85 % of the product always remains in the liquid phase. On the other hand, the after/before concentration for the polymer decreases by decreasing the polymer initial concentration in the liquid phase. However this ratio tends to about 0.15 by extrapolating the initial concentration to zero. Daimon and Roy (5) found 0.20 for the extrapolated value of the after/before concentration ratio and concluded that 20 % of their original admixture (sulfonated naphthalene formaldehyde condensate) was to be considered unadsorbable. By assuming that the monomer is the only unadsorbable impurity present in the "polymer", one could conclude that the percentage of monomer is about 23.5 % ( $= 20/0.85$ ) in the sulfonated naphthalene formaldehyde condensate used by Daimon and Roy and about 17.6 % ( $= 15/0.85$ ) in the polymer of the present work.

In Fig. 4, the zeta potential as a function of the polymer or monomer addition is shown. No substantial change in the zeta potential is caused by the monomer independently of the time of addition, whereas a remarkable increase in the zeta potential is recorded in the presence of polymer. So a certain relationship exists between flowability, adsorption on the cement surface and zeta potential. In fact the monomer does not modify flowability of the cement paste (Fig. 1) and at the same time it is adsorbed to a negligible extent on the cement surface (Fig. 2) and causes only insignificant changes in zeta potential (Fig. 4). On the other hand, polymer addition increases flowability

Fig. 4 - Zeta potential as a function of polymer or monomer addition.

(Fig. 1) and zeta potential (Fig. 4) and it is remarkably adsorbed on the cement surface (Fig. 2). This would confirm (6) that the dispersing effect of the superplasticizer is caused mainly by the change in

Fig. 5 - Heat evolution rate of cement pastes with different dosage rates of polymer as a function of time.

zeta potential as a function of polymer adsorption on the cement particles. However, some other effect must be taken into account to explain that a delayed polymer addition causes larger increases in flowability and zeta potential, whereas the amount of adsorbed polymer is lower than the one for immediate addition of admixture with mixing water. This would confirm the above mentioned hypothesis that a certain part of the polymer is incorporated within the hydrated product formed during the initial mixing time (2.5 min), so that the effective amount of polymer adsorbed on the hydrated cement surface would be larger in the delayed polymer addition. This seems to be confirmed by the results concerning the polymer addition on the hydration rate, as it is seen further on.

Fig. 5 shows heat evolution rate of the cement in the presence of different amount of polymer added with the mixing water. No substantial change in the heat evolution curve is recorded with a polymer addition of 0.25 %. In the presence of higher amounts of polymer the induction period is proportionally delayed, whereas the hydration rate in the acceleratory period is not substantially changed, so that the time of the heat evolution peak is increased by some hour. With a delayed polymer addition the retarding effect is slightly increased particularly when larger amounts of polymer (0.5 - 1.5 %) are used.

In Fig. 6 the X-ray line at 2.18 Å ( $C_3S + C_2S$ ) is reported as a function of the time for immediate polymer addition. Free calcium hydroxide analysis by DTG confirms that higher dosages of additive (0.5 - 1.5 %) and particularly delayed addition cause a more remarkable retardation in the  $C_3S$  and  $C_2S$  hydration.

Isothermal calorimetry, XRD and DTG show that the monomer (0.25 - 1.5 % by weight of cement) does not change the hydration rate independently of the time of addition.

Fig. 6 - X-Ray intensity of cement pastes with immediate addition of different dosage rates of polymer as a function of time.

According Kondo (2) type I anionic surfactants having an hydrophilic group ( $-\text{SO}_3\text{Na}$ ) at the end of the molecule, when present more than a critical amount, are closely adsorbed on cement particle (Fig. 7a). On the other hand, for type II anionic surfactants, having hydrophilic groups in the molecule, a "flat" adsorption occurs instead of "close" adsorption (Fig. 7b). Kondo found that the hydration of cement was strongly retarded when more type I surfactants were added than a critical amount, while in the case of type II the retarding effect became gradually larger with increasing amount of surfactants. Kondo found that the sulfonated naphthalene monomer is a type I anionic surfactant and its critical amount is about 0.3 - 0.4 % by weight of cement, whereas the sulfonated naphthalene formaldehyde condensed polymer is a type II anionic

Fig. 7 - Schematic illustration of "close" (a) and "flat" adsorption (b) of anionic surfactants on cement (2).

surfactant. The results of the present paper do not confirm the data of Kondo concerning the behaviour of the monomer, since the cement hydration rate was not changed by monomer addition of 0.25 - 1.50 %. On the other hand no significant adsorption (Fig. 2) or change in the zeta potential (Fig. 4) were recorded. However the authors of the present paper found that the flat polymer adsorption suggested by Kondo is at moment the most convincing mechanism to explain the influence of the polymer on the flowability of fresh mixes.

## CONCLUSIONS

It seems that there is a certain relationship between the dispersing effect of the admixture and the retarding effect on the cement hydration. Monomer addition neither affects the cement hydration rate nor influences the flowability of the cement paste, while the product is adsorbed on the cement surface to a negligible extent and the zeta potential does not significantly change. On the other hand, polymer addi-

tion increases the flowability of the cement paste and retards the cement hydration rate. It is significantly adsorbed on the cement surface and does change the zeta potential. The effect of the polymer increases by increasing the dosage rate and delaying the addition time. With a dry polymer addition of 0.25 - 0.50% by weight of cement corresponding to that of liquid commercial superplasticizer the dispersing effect is good enough without any significant retarding effect in the hydration rate. With higher dosage rate (1 - 1.5 % of dry polymer by weight of cement), corresponding to three-four times the normal dosage of a liquid commercial superplasticizer, the retarding effect is significantly increased whereas the flowability is not substantially improved.

The results of the present paper would suggest that a certain number of sulfonic groups all linked to a naphthalenic-methylenic polymer chain is essential to a flat adsorption (2) and then to an increased dispersing effect.

RESUME : Des mesures du retrait des pâtes de  $C_3S$ , de  $\beta-C_2S$  et de ciments portland ont été faites et analysées en fonction de deux composantes de la porosité :

l'eau contenue dans les capillaires (CD) et celle retenue par les gels de C.S.H. (GD)  
 Ces deux composantes ont été déduites des pertes de poids au séchage.

Le premier composant (CD) est en corrélation avec la macro-porosité (diamètre des pores compris entre 25 et 300 Å); le second (GD) avec la microporosité (diamètre des pores < 25 Å). Le retrait total est en corrélation avec la somme de ces deux porosités, bien mieux qu'avec le volume total des pores. Une meilleure corrélation a été observée entre le retrait total et un certain facteur structural  $Z$ , calculé à partir de la distribution des pores, caractérisée par la surface spécifique mesurée par l'adsorption d'azote, et celle mesurée par adsorption de vapeur d'eau et par le degré de polymérisation des silicates. Le fluage dépend aussi de la micro-structure, mais plus spécialement du degré de polymérisation des silicates.

ABSTRACT: Shrinkage data for  $C_3S$ ,  $\beta-C_2S$  and ordinary portland cement pastes are analyzed in terms of contribution from the "pore components" (capillary drying, ["CD"] shrinkage) and the "C-S-H component" (gel drying, ["GD"] shrinkage). These two contributions are determined from shrinkage-weight loss curves obtained during drying. CD shrinkage correlated reasonably well with total mesoporosity (pores  $\geq 25-300$  Å diameter) and GD shrinkage with microporosity (pores < 25 Å diameter) as determined by mercury porosimetry. Thus, total shrinkage shows a correlation with the sum of the volumes of mesopores and micropores, rather than with the total pore volume. A better correlation with total shrinkage is obtained using a structure factor ( $Z$ ), which is calculated from the pore size distribution using nitrogen adsorption, surface area from water vapor adsorption, and the degree of silicate polymerization. It is thought that problems in determining the degree of silicate polymerization in substituted C-S-H may affect the value of  $Z$  for portland cement pastes. Creep also depends on microstructural factors, particularly the degree of silicate polymerization.

## INTRODUCTION

The drying shrinkage and creep of cement paste and concretes have been the subject of numerous investigations which have resulted in many conflicting models. Creep and shrinkage are often regarded either as the result of a single mechanism, or the result of several mechanisms which each control deformations in a limited relative humidity range. However, it has recently been pointed out (1,2) that time dependent deformations may be the result of the superposition of several mechanisms, effective over the same relative humidity range. This may in part be the reason for the conflicting results and theories which can be found in the literature.

In previous work (2-6) the microstructural and chemical changes occurring during creep and shrinkage of calcium silicate pastes were studied. It was concluded that shrinkage is the result of two types of mechanisms:

**Mechanism CD (Capillary drying)** - Capillary effects which take place in the "pore component," which represents the pores larger than 25 Å diameter. Significant capillary stresses can only develop in the mesopores (25-300 Å) and therefore this pore fraction is mainly responsible for the CD mechanism.

**Mechanism GD (Gel drying)** - Loss of water from the "C-S-H component," which includes the pores smaller than 25 Å diameter (micropores). In these pores, no capillary effects can take place.

A detailed discussion of these mechanisms is given elsewhere (2) and is only briefly reviewed here. Mechanism CD is considered more influential, but not dominant, in low degree of hydration ( $\alpha$ ) pastes. Capillary stresses cause an irreversible

collapse of pores in the diameter range of 40 to 100 Å which is accompanied by a reduction in the nitrogen surface area [ $S(N_2)$ ]. The GD mechanism has a contribution at all degrees of hydration, but becomes more important at high degrees of hydration. The reduction in spaces between the C-S-H surfaces is accompanied by an increase in the formation of Si-O bonds which can be detected by silicate structure analysis. Condensation of the C-S-H structure also leads to irreversible shrinkage.

This interpretation suggests that shrinkage strains and shrinkage-weight loss curves should be sensitive to the microstructure and chemical composition of the hydrated pastes. The driving force for CD shrinkage is expected to be related to the volume and size distribution of the mesopores while the driving force for GD shrinkage is related to the volume and size distribution of the micropores. The internal stresses induced by movement of water out of these pores will result in shrinkage. The magnitude of this shrinkage will depend not only on these stresses, but also on the rigidity of the paste structure which resists them. For example, the presence of stable crystalline phases like CH and a more stable silicate skeleton of the C-S-H (as exhibited by higher degree of silicate polymerization) are expected to result in reduced shrinkage.

Such aspects of shrinkage can be clarified if changes in time dependent deformations are studied in parallel with changes in microstructure and chemical composition of hydrated pastes. This paper describes the results of such an investigation, in which pastes of  $C_3S$ ,  $\beta$ - $C_2S$ , and ordinary portland cement (OPC) cured at 4°, 25°, and 65°C were studied. Correlations between total shrinkage, CD and GD shrinkage and various structural parameters such as pore size distribution, surface area and degree of

Fig. 1. Shrinkage-weight loss curves determined during drying of pastes of  $C_3S$ ,  $\beta$ - $C_2S$  and ordinary portland cement (%  $\alpha$  indicates degree of hydration).

silicate polymerization were established. A brief discussion of microstructural influence on creep is also given.

### EXPERIMENTAL

The  $C_3S$  and  $\beta$ - $C_2S$  used in this study are described elsewhere (3); a commercial Type I cement was also used. Details of specimen preparation and testing are to be found in previous papers (2,4,6).

### RESULTS AND DISCUSSION

#### Porosity-Shrinkage Relationships

Some typical shrinkage-weight loss curves are shown in Figs. 1 and 2.

Fig. 2. Effect of curing temperature on the shrinkage-weight loss curves of  $C_3S$  pastes.

It can be seen that the shape of the curves is very sensitive to the chemical composition of the hydrating compound (Fig. 1) and to the curing temperature (Fig. 2). An increase in curing temperature is associated with a reduction in the shrinkage values and slopes of the shrinkage-weight loss curves (Fig. 2).

In Fig. 3 typical mercury intrusion porosimetry (MIP) curves for well hydrated  $C_3S$  pastes cured at 25°C and 65°C, and OPC and  $\beta$ - $C_2S$  pastes cured at 25°C are presented. It can be seen that these pastes have different pore structures and these differences may be correlated with the changes in the shrinkage characteristics of these pastes. For example, the coarser pore structure in  $\beta$ - $C_2S$  pastes is associated with the higher weight loss for these pastes (Fig. 1) and is consistent with SEM observations (7). On the other hand OPC pastes have less pore volume below 250 Å than  $C_3S$  pastes and this may account for its lower shrinkage values. A similar qualitative explanation can be given in the case of  $C_3S$  cured at 25°C and 65°C; the high temperature pastes have much less porosity in the range of diameters lower than 250 Å which can explain their smaller shrinkage values.

It was suggested in the introduction that CD shrinkage is related to the volume and structure of the mesopores and that GD shrinkage is related to the volume of the micropores. The information contained in shrinkage-weight loss curves and pore size distribution curves may be used to test the validity of the statement by determining whether such correlations can be found. The mesopore volume was determined from the MIP curves and the micropore volume from the difference between total porosity and the MIP cumulative pore volume, down to pores of 25 Å diameter. In order to analyze the shrinkage curves in terms of the two mechanisms, the observed shrinkage strains must be separated into the contributions of mechanism CD and mechanism GD. This was previously done (2) by dividing shrinkage-weight loss curve into two stages, A and B, as shown in Fig. 2. Stage A is believed to represent the CD shrinkage, while stage B is attributed to the GD shrinkage; the significance and limitation of this simplified approach have been discussed in detail (2).

In Fig. 4, the CD and GD shrinkage values as determined from the shrinkage weight-loss curves are plotted against mesoporosity and microporosity. In both cases, shrinkage increases with porosity, as would be expected. It should be pointed out that the data include systems which are different in many aspects - chemical composition, curing conditions and  $\alpha$  - and yet, they all seem to fit a reasonable linear relationship. Combining the two curves will yield a relation between total shrinkage and the volume of pores smaller than 300 Å (Fig. 5b). It is interesting to compare this plot with that of shrinkage versus total porosity where no distinct correlation can be observed (Fig. 5a).

#### Shrinkage-Microstructure Relationships

The data presented in Figs. 4 and 5 indicate that differences in shrinkage behavior can be accounted for by differences in pore structure. However, it should be noted that there is still considerable scatter in the data which suggests that, although pore structure parameters have considerable influence on shrinkage, other parameters must be taken into account. For example, the size distribution of the micropores and mesopores and the degree of silicate polymerization of the C-S-H component are thought to be important. In view of the complexity of the cement paste structure and the uncertainty with regards to its detailed chemical composition and microstructure, it is extremely difficult to develop a quantitative model taking all these factors into account. However, in a separate set of experiments (6) an attempt was made to define some of these parameters and derive an empirical relation which would correlate with shrinkage better than the simple relations discussed above. Three parameters are considered in this analysis.

(1) The pore volume and pore size distribution of the mesopores are considered. The cumulative pore volume was best expressed using a weighted function which considers the relative importance of the pores in the size distribution with regard to their induced stress that will be generated during drying:

$$V^* = \sum V_i(D_i) \cdot F(D_i) \quad (1)$$

Fig. 3. Mercury porosimetry curves of pastes of  $C_3S$ ,  $\beta$ - $C_2S$  and ordinary portland cement.

Fig. 4. (a) GD shrinkage vs. microporosity of hardened pastes. (b) CD shrinkage vs. mesoporosity of hardened pastes. (Best-fit straight line shown in each case.)

Fig. 5. (a) Total drying shrinkage vs. total pore volume. and microporosity. (Best-fit straight line shown.) (b) Total drying shrinkage vs. total mesoporosity.

where:  $V^*$  is the effective cumulative pore volume;  $V_i$  is the pore volume at the corresponding pore diameter  $D_i$ ;  $F(D_i)$  is the weighted function, which was taken as  $300/D_i$ ; 300 Å being taken as the upper size limit of the mesopores. A better fit of the experimental data was obtained if  $V^*$  is calculated using  $N_2$  adsorption data rather than MIP data.

(2) Water measured surface area,  $S(H_2O)$  was chosen as a parameter representing the effect of microporosity.

(3) The nonvolatile content ( $N$ ) was used as an estimate for the degree of silicate polymerization of the C-S-H (4) and it represents its staleness and ability to resist the shrinkage stresses.

On the basis of an empirical approach it was found that a good linear relationship (correlation factor of 0.97) could be obtained (Fig. 6) between shrinkage and an effective structure factor ( $Z$ ) as defined in Eq. 2.

$$Z = \frac{V^* \cdot S(H_2O)}{N} \quad (2)$$

This empirical relationship indicates that if various physical and chemical parameters are considered at the same time it is possible to account for differences in shrinkage in a wide variety of microstructures. For example a high degree of silicate polymerization [ $C_3S$  cured at 65°C (5)] is associated with a reduction in shrinkage, while an increase in mesoporosity [ $C_3S + CaCl_2$  (5,8)] or  $S(H_2O)$  tends to enhance shrinkage.  $Z$  depends only on the properties of the C-S-H component and the pore component. Thus, as a first estimate it can be assumed that the "CH component", or the residual unhydrated material has little ability to resist shrinkage stresses.

Fig. 6. Total drying shrinkage of  $C_3S$  and  $\beta$ - $C_2S$  pastes vs. the effective structure factor,  $Z$  (Best fit straight line shown.)

It should be noted that the quantities used to calculate  $Z$  are determined on reference pastes. Since it has been observed (4) that changes in pore distribution and silicate polymerization occur during shrinkage experiments,  $Z$  will change with the history of the paste. A reduction in  $V^*$  and an increase in  $N$  are observed on drying, resulting in a lower  $Z$  and hence lower shrinkage on second drying. Such behavior is well documented in the literature (9,10).

It should also be noted that three of the points calculated for OPC show considerable deviation from the best-fit line (which was determined from data for pastes of the calcium silicate pastes only). As can be seen in Table I, OPC pastes have much lower values of  $N$  than  $C_3S$  pastes of comparable degrees of hydration. It is likely that in the case of OPC the  $N$  values may not provide a good assessment of silicate polymerization, because it is well known that C-S-H can undergo isomorphous replacement of  $Si^{4+}$  by  $Al^{3+}$  or  $S^{6+}$ , and that a substituted C-S-H will be formed in OPC pastes. Lentz (11) has shown that Al-O-Si bonds are readily cleaved by TMS derivatization and that the silicate network in aluminosilicates is disrupted where aluminum is substituted. For example, sodalite derivatizes as an orthosilicate and natrolite as a linear trisilicate, which correspond to the arrangements of silica tetrahedra as determined by x-ray diffraction. Also, Rio (12) observed that C-S-H formed from  $C_3S$  in the presence of gypsum had a lower degree of silicate polymerization than C-S-H formed in the absence of sulfate ions. It is noteworthy that whereas monomeric silicate ( $SiO_4^{4-}$ ) in hydrated  $C_3S$  pastes can be wholly attributable to unhydrated  $C_3S$  (13,14) considerable  $SiO_4^{4-}$  is observed in OPC pastes that are completely hydrated (15-17).

Nominal $\alpha$	$C_3S$	OPC
40%	14* (42)	4 (37)
50%	24 (55)	4 (48)
60%	-	6 (60)
70%	20 (68)	-
80%	22 (78)	9 (80)
85%	23 (88)	12 (85)

\*Wt percent of total silicate in hydrated fraction.

#### Creep-Microstructure Relationships

The influence of microstructure on creep strains has not been studied in the same detail as shrinkage. Initial results indicate (1) that creep and shrinkage arise from different structural changes and that the two processes are fundamentally different. For example, the pore component does not influence basic creep, which is to be expected since moisture loss does not occur. However, as in the case of shrinkage, the degree of silicate polymerization is an important parameter in determining creep behavior. Both creep and shrinkage are reduced when the C-S-H component has a higher polysilicate ( $N$ ) content; (determined at 96% rh) as has been observed also by Parrott (18-20).

An interesting observation in the present studies was the increase in  $S(N_2)$  (Table 2) that was observed in several different systems, e.g.,  $C_3S$ ,  $C_2S$  and OPC, but occurs only in well-hydrated systems.

TABLE II

N<sub>2</sub> Surface Area of Well-Hydrated C<sub>3</sub>S and OPC Pastes Treated for Basic Creep and Shrinkage.

	C <sub>3</sub> S*	OPC#
Control	18.1	13.6
Shrinkage	16.3	13.3
Basic Creep	32.5	39.1

\*Hydrated for 90 days. #Hydrated for 150 days

What is the cause of this increase cannot be determined with certainty but it has been suggested (1) that it is the result of an internal dilation in the C-S-H component. This dilation will oppose the bulk creep strain and hence reduce its value. It appears that internal dilation can only occur in a stable C-S-H component with a high polysilicate content; in the less stable C-S-H component of young pastes, internal dilation is reduced or may even become negative due to the large differential movement that can take place between C-S-H particles and which contribute to the measured creep of the bulk specimen. The precise response of the C-S-H component to stress influences the extent to which further polymerization can occur on subsequent, or concomitant, drying.

#### ACKNOWLEDGMENTS

This work was supported by National Science Foundation Grant ENG-75-00422. We thank Prof. S. Diamond for helpful discussion and for the use of the mercury porosimeter.

# Rhéologie et hydratation du ciment sous l'influence des facteurs extérieurs

## *Rheology and hydration of cement at outer influence*

I.B. ZACEDATELEV, Docteur ès Sciences, chef de laboratoire, Teploproekte,

B.D. TRINKER, candidat ès sciences, chef de laboratoire, Teploproekte, et

Yu.S. TCHERKINSKY, docteur ès sciences, chef de laboratoire NIL PCMMTP, Moscou, U.R.S.S.

**RESUME :** Les processus réels d'hydratation du ciment et de formation de la structure de la pierre de ciment se caractérisent par leur dépendance des facteurs extérieurs, ces processus pouvant suivre leur cours dans des conditions non-stationnaires de température, déshydratation partielle et humidification répétées du système durcissant.

On a étudié, pour la première fois, la viscosité des suspensions de ciment à l'aide de la rhéocinétique. La construction des courbes rhéocinétiques pour les températures 293-353°K et la détermination des constantes de vitesse ont permis d'obtenir des équations d'Arrhénius. Ces équations permettent de caractériser la nature du processus de changement de viscosité selon l'énergie d'activation, ainsi que l'intensité de l'effet thermique sur ce processus.

Les propriétés rhéologiques de la pâte de ciment durcissante du début de la prise jusqu'à la fin de la prise ont été déterminées à l'aide d'un plastomètre selon la valeur de contrainte limite de cisaillement. Il est montré que l'emploi du plastomètre conique permet d'évaluer les temps de prise bien fondés physiquement, contrairement à ce qu'on obtient à l'aide de l'aiguille de Vicat. A l'aide des courbes plastométriques on peut juger du processus de formation de structure, y compris des phénomènes anormaux, tels que la fausse prise.

L'utilisation d'une famille de plastogrammes obtenues expérimentalement dans des conditions isothermes permet de construire des courbes plastométriques pour des régimes thermiques non-stationnaires.

On a proposé, en vue de prédire les caractéristiques cinétiques du processus d'hydratation du ciment sous l'influence des facteurs extérieurs, une méthode de recherche et une construction de dispositif pour déterminer la cinétique de dégagement calorifique dans des conditions d'échange extérieur de chaleur et de masse.

**SUMMARY:** Distinctive feature of real processes of cement hydration and cement stone structure formation is dependence of these factors on outer influence. At this time cement hydration and structure formation process may proceed at conditions of nonstationary temperature regime, partial dewatering and repeated moistening of setting system. Rheokinetic method was used for the first time at investigation of viscosity of cement suspensions. Plotting of rheokinetic curves at temperature 293-353°K and determination of velocity constants permitted to obtain equations for description of rheokinetic processes including Arrhenius' equations. Such equations give possibility to characterize nature of process of change of viscosity depending on value, of activation power and also intensity of thermal influence on this process.

Rheological properties of hardening paste up to complete setting are determined by plastometric method depending on value of limit shear stress. It is showed that usage of conical plastometer for determination of setting time permits to obtain physically well-founded values as distinct from applied test method by Vicat device. Plastometric curves permit to evaluate course of structure formation process including anomalous phenomena such as false setting.

Usage of system of plastograms obtained experimentally for isothermal conditions permits to plot by graphic method the plastometrical curves for nonstationary temperature regimes.

Method and construction of device for determination of kinetics of heat liberation at conditions of outer heat and mass change is suggested for prediction of kinetic characteristics of cement hydration process at conditions of outer influence.

Selon le principe de la méthode rhéocinétique (1), si le système est soumis aux processus chimiques ou physico-chimiques, on peut, pour la description de la cinétique de ces processus, employer les équations cinétiques de dépendance de la viscosité spécifique ( $\eta_{sp}$ ) du temps ( $\tau$ ). Dans le plus simple cas on peut comparer l'équation de viscosité d'Einstein avec l'équation formelle de la cinétique chimique et obtenir l'équation rhéocinétique, par exemple, de premier ordre, sous forme différentielle:

$$\frac{d\eta_{sp}}{d\tau} = K\eta_{sp} \quad (1)$$

où  $K$  est la constante de vitesse d'accroissement de viscosité.

Par construction, d'après les données expérimentelles, des équations cinétiques

$$\eta_{sp} = f(\tau)$$

en coordonnées normales ( $\eta_{sp}-\tau$ ), semi-logarithmiques ( $\lg \eta_{sp}-\tau$ ) ou fractionnaires ( $\frac{1}{\eta_{sp}}-\tau$ ), il est possible de déterminer l'ordre du processus (nul, premier ou second, respectivement) et de calculer la rhéocinétique de vitesse d'accroissement de viscosité. La détermination des valeurs des constantes rhéocinétiques ( $K_r$ ) pour températures différentes permet d'employer l'équation d'Arrhénius pour le processus rhéocinétique sous forme

$$K_r = A_0 \exp(E_r/RT) \quad (2)$$

où  $A_0$  est le facteur pré-exponentiel,  $E_r$  est l'énergie d'activation du processus rhéocinétique,  $R$  est la constante des gaz,  $T$  est la température.

Bien entendu, on ne peut étudier à l'aide de rhéométrie que le processus de formation de structure à l'étape initiale, quand l'accroissement de viscosité n'est dû pratiquement qu'à la formation de structure par coagulation. Mais cette étape, très importante du point de vue technologique, peut être décrite avec des équations physiques assez correctes.

Il est à noter que l'équation (1) contient la viscosité spécifique. Pour déterminer l'énergie d'activation du processus rhéocinétique des suspensions des ciments on peut employer la viscosité.

Et, enfin, quand à la concentration de la suspension de ciment, les essais ont démontré que des dépendances satisfaisantes peuvent être obtenues quand le rapport eau-ciment est de 0,4 à 0,6.

Des courbes rhéocinétiques ont été obtenues pour les températures 303, 313, 323, 333, 353°K, et l'on a calculé les valeurs de  $K_r$  correspondantes. L'équation expérimentale d'Arrhénius pour les suspensions de ciment a la forme suivante:

$$K_r = 5,16 \cdot 10^3 \exp\left(-\frac{1000}{RT}\right) \quad (3)$$

L'équation (3) permet de calculer le processus de formation de structure du système simulé ciment-eau, y compris avec des constituants secondaires, pour des différentes températures. Elle est d'intérêt, puisque l'énergie d'activation relativement basse indique que l'interaction des particules de la suspension de ciment conduisant à l'accroissement de viscosité est bien faible, ce qui caractérise notamment la formation de structure par coagulation.

L'évaluation des propriétés du ciment à base des caractéristiques rhéologiques, c'est à dire méchanico-structurales, permet de déterminer les valeurs des périodes de formation et de durcissement de la structure, donc, des temps de prise de la pâte de ciment (2,3).

On a étudié les caractéristiques rhéologiques de la pâte de ciment en comparaison avec les caractéristiques standards.

Pour mesurer la contrainte limite de cisaillement on a adopté la méthode de plastomètre conique. Parallèlement on a déterminé les temps de prise avec l'aiguille de Vicat à l'aide de l'instrument APSS (GOST 310-60). La cinétique d'accroissement de la résistance plastique ( $P_m$ ) de la pâte de ciment est représentée sur fig. 1.

Fig. 1. Variations de résistance plastique de la pâte de ciment à consistance ordinaire: 1 - sans adjuvants; 2 - 0,2% CD; 3 - 0,2% CD + 1% NaNO<sub>2</sub>; 4 - 0,1% CD + 2% CaCl<sub>2</sub>; 5 - sans adjuvants; 6 - 0,2% CD; 7 - 0,2% CD + 1% NaNO<sub>2</sub>; 8 - effet de prise "fausse"; 1,2,3,4,8 - 298°K; 5,6,7 - 333°K

La première période (3-4h) continue du début de gâchage jusqu'à la première inflexion de la courbe et se caractérise par formation d'une structure coagulante réversible. La résistance plastique de la pâte accroît très lentement et atteint à la fin de cette période 0,025-0,2 MPa.

La deuxième période se trouve dans l'intervalle entre la première et la deuxième inflexions des courbes (élévation des courbes sur la plastogramme). La transition de structure coagulante à structure coagulante-cristalline au cours de la deuxième période se produit dans 3-5h après gâchage. La résistance plastique de pâte atteint à la fin de cette période 0,1-0,5 MPa.

Le début de la troisième période se caractérise par formation de structure cristalline-coagulante. Dans cette période la résistance du système "ciment-eau" accroît en avalanche, les courbes étant presque parallèles à l'axe d'ordonnées. La vitesse d'accroissement de résistance est de 0,6-0,8 MPa/h.

Comme il a été démontré par les expériences, en général les courbes plastométriques sont d'un caractère hyperbolique et peuvent être décrites par l'équation générale suivante:

$$P_m = e^{\tau-A} - \frac{\tau^2(\tau-B)}{C} \quad (4)$$

où  $P_m$  est la résistance plastique;  $\tau$  est le temps; A, B, C sont des coefficients dépendants du type de ciment et des constituants secondaires.

L'élévation de température de durcissement de la pâte de ciment ou l'introduction des constituants secondaires conduisent à la diminution de durée de la première et de la deuxième périodes, et, dans des cas particuliers, à la disparition de toutes les deux périodes ou seulement de la deuxième période. La cinétique de formation de structure du ciment portland à prise "fausse" est caractérisée par la courbe 8 (fig. 1).

Les temps de début et de fin de durcissement de la pâte de ciment obtenus avec l'aiguille de Vicat coïncident, dans l'essentiel, avec les caractéristiques obtenues à l'aide du plastomètre conique. La première inflexion des courbes correspond au moment initial de la prise de la pâte de ciment, la deuxième correspond à la fin de la prise (ou elles diffèrent d'eux à 10-20 min). Le remplacement de l'aiguille de Vicat par le plastomètre conique et la construction des courbes plastométriques permettent d'effectuer le contrôle permanent du processus de formation de structure de la pâte de ciment, ce qui est de grande importance, surtout dans des conditions d'actions extérieures thermiques, chimiques et mécaniques sur le système "ciment-eau" durcissant.

La prédiction du processus de formation de structure dans des conditions non-stationnaires de température peut être effec-

tuée sur la base des résultats d'étude de la résistance plastique effectuée pour de différents régimes isothermes. Une famille de plastogrammes isothermes pour un certain type de système durcissant (pâte de ciment, mortier de ciment) peut être défini comme champ plastométrique isotherme. Il a été possible d'employer la méthode de construction graphique, sur ce champ, de variation successive de  $P_m$  en fonction de température.

Les valeurs de  $P_m$  obtenues par expériences, ainsi que celles calculées, dans des conditions d'élévation uniforme de température sont représentées sur fig. 2.

Fig. 2. Variations de résistance plastique du mortier au stade d'élévation de température à vitesse suivante: 1 - 30°C/h; 2 - 15°C/h; 3 - 10°C/h; ●, ▲, ■ - données expérimentales; ○, △, □ - données calculées

En vue de déterminer le caractère de cinétique d'hydratation et de formation de structure du ciment dans des systèmes réels sous l'influence de divers facteurs extérieurs, on a adopté la méthode expérimentale de mesurage de chaleur d'hydratation dans le calorimètre différentiel. Contrairement aux méthodes bien connues, le matériau à étudier a été soumis au chauffage et refroidissement supplémentaires programmés, ce qui a permis d'effectuer des recherches aussi dans les régimes thermiques non-stationnaires (4). Pour étudier la cinétique d'hydratation dans les conditions d'échange

de masse avec le milieu ambiant, on a mis au point de spéciales méthodes et constructions de vases calorimétriques (5).

Il est démontré par les résultats d'expériences que l'influence sur le taux d'hydratation du ciment et sur la résistance de la pierre de ciment de l'eau évaporée est assez faible quand sa quantité ne dépasse pas 10% de l'eau de gâchage. Quand l'évaporation atteint 20 et 30% de l'eau de gâchage le dégagement calorifique abaisse les premiers trois jours à 18 et 25% et la résistance relative abaisse en même temps à 59 et 61% respectivement.

Les résultats d'étude de l'influence de conservation préalable ont montré que, si l'évaporation atteint, par exemple, 20% d'eau de gâchage immédiatement après gâchage, ainsi qu'après conservation pendant 8 et 16h avant l'évaporation, les courbes de cinétique de dégagement calorifique coïncident.

Les résultats de recherche de structure de pierre de ciment durcissante dans les conditions d'évaporation de 10 à 30% d'eau de gâchage ont montré une teneur élevée en pores intermédiaires à rayon  $10^3 \dots 10^4 \text{ \AA}$  en comparaison aux conditions standards de durcissement.

Pour prédire la chaleur d'hydratation du ciment à la déshydratation partielle ( $\Delta B$ ) on peut poser le dégagement calorifique ( $Q_{AB}$ ) au moment  $\tau$  égal au dégagement calorifique spécifique sans pertes d'humidité ( $Q_0$ ) au moment

$$\tau_0 = \frac{\tau_0}{\tau_{AB}} \cdot \tau \quad (5)$$

où, selon S.A. Chifrine,

$$\frac{\tau_0}{\tau_{AB}} = 1 - 0,01 \Delta B, \quad (6)$$

$$\text{alors } Q_{AB} = Q_0 \left( \frac{\tau_0}{\tau_{AB}} \cdot \tau \right) \quad (7)$$

Les processus d'hydratation dans les conditions réelles peuvent contenir pas seulement la déshydratation partielle du système durcissant, mais aussi l'humidification répétée. La singularité du processus d'hydratation dans ces régimes est illustrée par l'intensité de dégagement calorifique (fig. 3). Le régime d'humidification du ciment durcissant après la déshydratation partielle emmène à l'intensification du dégagement calorifique au moment initial, mais ensuite l'intensité du processus d'hydratation s'abaisse par comparaison avec des échantillons ayant durci dans les conditions standards.

L'humidification répétée emmène à l'accroissement de résistance de la pierre de ciment, pourtant cet effet est en rapport inverse avec la durée des processus d'échange de masse. Ainsi, quand la durée de conservation préalable est 6h, l'humidi-

Fig. 3. Intensité de dégagement calorifique dans des conditions non-stationnaires d'humidité: 1 - conservation normale; 2 -  $\tau_{\text{pre} \Delta B} = 16\text{h}$ ,  $\Delta B = 20\%$ , début d'humidification = 2h après l'évaporation; 3 - comme 2, mais début = 6h après l'évaporation; 4 - comme 2, mais sans humidification; 5 -  $\tau_{\text{pre} \Delta B} = 6\text{h}$ ,  $\Delta B = 30\%$ ; début d'humidification = 2h après l'évaporation; 6 - comme 5, mais sans humidification.

fication répétée après l'évaporation emmène à l'accroissement de résistance à 50% en comparaison au régime sans humidification, tandis qu'après 16h de conservation cet effet n'a atteint que 8%.

L'efficacité d'humidification répétée pour l'évaluation des caractéristiques cinétiques d'échange de chaleur abaisse aussi au fur et à mesure qu'augmente la période entre la fin d'évaporation et le début d'humidification répétée.

### Conclusions

L'étude de viscosité des suspensions de ciment à l'aide de la méthode rhéocinétique permet d'obtenir des caractéristiques rhéologiques fondamentales et de comprendre la nature des interactions délicates qui sont au fond de la formation de structure à différentes températures.

Pour contrôler la qualité du ciment, il est avantageux de remplacer l'évaluation des temps de prise avec l'instrument de Vicat par la détermination de résistance plastique avec le plastomètre conique.

Les résultats d'études des processus d'hydratation du ciment quand il y a l'échange de masse avec le milieu ambiant permettent d'approcher le phénomène de la résistance "critique" du ciment durcissant (la résistance critique est la valeur de la résistance initiale après l'obtention de

laquelle l'évaporation de l'eau libre ne produit aucun effet sur la résistance du ciment).

# Le retrait autogène de la pâte de ciment durcissante

## *Autogenous shrinkage of the hardening cement paste*

M. BUIL, Docteur-Ingénieur, L.C.P.C. \*,

J. BARON, Docteur ès Sciences Physiques, L.C.P.C. \*\*, France

\* depuis juillet 1979 à LAFARGE S.A.

**RESUME :** Cet article traite du retrait autogène de la pâte de ciment Portland durcissante, en liaison avec les phénomènes de fissuration précoce du béton. Il existe deux méthodes de mesure de la déformation spontanée d'une pâte de ciment. La méthode unidimensionnelle (= mesure de la distance entre deux plots ancrés dans l'éprouvette) semble en pratique mieux adaptée que la méthode volumétrique (= mesure d'un volume de liquide déplacé par l'éprouvette).

La déformation spontanée d'une pâte de ciment Portland, mesurée dans l'essai unidimensionnel, fait apparaître trois phases successives : un premier retrait, un gonflement et un second retrait ou retrait de durcissement.

Il existe une corrélation expérimentale entre la fissuration précoce des bétons et la vitesse maximale de second retrait ; ceci justifie une étude approfondie du mécanisme du retrait de durcissement.

Le retrait de durcissement est proportionnel à la chaleur d'hydratation, à partir d'un certain temps d'hydratation. On considère que cette relation est perturbée au début du durcissement par la superposition du phénomène de gonflement. On a également constaté la proportionnalité entre la contraction Le Chatelier (= variation du volume absolu de l'eau et du ciment) et le dégagement de chaleur, à partir de quelques heures d'hydratation. Le phénomène de contraction Le Chatelier intervient dans le mécanisme du retrait de durcissement. En effet, il provoque une autodessiccation de la pâte de ciment, et donc un retrait semblable au retrait de dessiccation, l'eau partant non plus vers l'extérieur, mais "vers l'intérieur" de l'éprouvette. On a constaté, sur un ciment donné, que l'ordre de grandeur du retrait d'autodessiccation est semblable à celui du retrait de durcissement. Dans l'état actuel de nos connaissances, l'hypothèse de l'autodessiccation est jugée suffisante pour expliquer le phénomène du retrait de durcissement.

**SUMMARY :** This paper deals with the autogenous shrinkage of the hydrating Portland cement paste, in connection with the phenomenon of the early cracking of concrete. There are two measurement methods of the cement paste autogenous straining. The unidimensional method (= measurement of the distance between two studs sunk into the test-bar) proves better, in practice, than the volumetric method (= measurement of the volume of liquid displaced by the cement paste sample).

The autogenous strain of a Portland cement paste, recorded in the unidimensional test, is splitted into three stages = a first shrinkage, a swelling and a second shrinkage or hardening shrinkage.

The hardening shrinkage maximum rate is experimentally correlated to the early cracking of concrete ; for this reason, an extensive research on the hardening shrinkage is needed.

The hardening shrinkage is proportional to the hydration heat, from a certain hydration time onwards. It is thought that this proportionality is disturbed in the beginning of hardening by the superposition of the swelling phenomenon. The chemical shrinkage (Le Chatelier shrinkage) (= absolute volume change of water plus cement) is also proportional to the heat evolution, from a few hydration hours onwards. The chemical shrinkage operates in the hardening shrinkage mechanism. As a matter of fact, it induces an autodessiccation of the cement paste, and consequently a shrinkage similar to the dessiccation shrinkage, the water evolving "inwards" the sample instead of outwards. It was noticed, with a given cement, that the autodessiccation shrinkage reaches the same magnitude as the hardening shrinkage. In the present state of knowledge, it is found that the autodessiccation hypothesis is adequate to explain the hardening shrinkage phenomenon.

L'étude du retrait autogène de la pâte de ciment durcissante a une importance certaine pour la compréhension des phénomènes de fissuration précoce des bétons. Des recherches sur le retrait autogène sont menées au Laboratoire Central des Ponts & Chaussées depuis 1964. Nous présentons ici une synthèse rapide de ces recherches, avec les résultats les plus récents.

### I - Le retrait de durcissement et sa mesure simplifiée

#### 1- La mesure de la déformation autogène

Il existe deux méthodes de mesure. La première, souvent utilisée, consiste à mesurer un volume de liquide déplacé (1, 2, 3, 4, 5, 6). L'éprouvette est isolée du liquide par une membrane souple. La deuxième méthode consiste à faire des mesures unidimensionnelles = on suit le déplacement d'un capteur ancré dans l'échantillon (7, 8, 9). Ces deux méthodes sont peu sûres dans les premières heures d'hydratation. Dans la méthode volumétrique, des phénomènes de ressuage et de compression de l'éprouvette par la membrane peuvent changer la nature de la mesure (10). Dans la méthode unidimensionnelle, les frottements perturbent l'essai jusqu'au moment de la prise.

D'après la forme typique des courbes de déformation de pâtes de ciment Portland dans l'essai unidimensionnel (fig. 1), on distingue trois phases successives de déformation que l'on peut appeler a) premier retrait, b) gonflement, c) second retrait ou retrait de durcissement.

- X : valeur maximale du premier retrait  
Y : valeur maximale du gonflement  
Z : valeur maximale du second retrait  
P : vitesse maximale de second retrait

[fig.] Déformation d'une pâte de ciment dans l'essai unidimensionnel

a) le premier retrait commence 1 à 3 heures après le malaxage et dure 2 à 4 heures, il coïncide donc approximativement avec la prise et constitue une part importante du retrait plastique. Le premier retrait reste assez faible par rapport au retrait plastique d'une éprouvette exposée à une atmosphère non saturée, c'est pourquoi l'étude du premier retrait autogène ne paraît pas revêtir une grande importance pratique.

b) le gonflement n'apparaît généralement pas dans l'essai volumétrique. Mais il est probable que dans un tel essai, il est masqué par des phénomènes de réabsorption d'eau de ressuage et de compression par la membrane de la pâte encore faiblement cohérente (10). C'est pourquoi nous pensons que l'essai unidimensionnel est seul représentatif des déformations dans les heures qui suivent la prise.

La durée et l'amplitude du gonflement varient beaucoup suivant les ciments, même à l'intérieur d'une même classe de résistance. Pour certain ciment riche en C<sub>3</sub>A et sous-dosé en gypse, il peut n'y avoir aucun gonflement, à peine un ralentissement momentané du retrait. Pour un dosage en gypse un peu plus élevé, le gonflement ne dure qu'une heure ou deux et peut échapper à l'observation tant que les déformations ne sont pas enregistrées. Cependant, pour de nombreux ciments, la période de gonflement dure entre 10 et 20 heures et le gonflement maximal est de l'ordre de  $4 \cdot 10^{-4}$  (pour E/C = 0,27). Le gonflement dépend de la quantité de chaux libre restant non hydratée à la fin de prise : il augmente fortement avec la température (11). L'influence du dosage en eau reste à préciser.

c) second retrait : Il se manifeste après la fin de prise : à déformations égales, les contraintes en jeu sont donc beaucoup plus fortes pour le second retrait que pour le premier. La valeur maximale de second retrait peut atteindre  $1,5 \cdot 10^{-3}$  (en  $\frac{\Delta L}{L}$ ), ceci dans des conditions isothermes et, évidemment, en l'absence d'évaporation. Il faut plusieurs jours, parfois 7 et plus, pour atteindre cette valeur maximale. Le second retrait dépend du rapport E/C. Il diminue lorsque E/C augmente, pour s'annuler pratiquement à E/C > 0,35. Lorsque les essais sont faits sans précautions particulières, une déformation d'origine thermique (résultant de l'échauffement de l'éprouvette en cours d'hydratation) se superpose aux déformations précédentes. Cette déformation dépend beaucoup, évidemment, des conditions d'essais et, notamment, de la taille des éprouvettes. Souvent, sur des éprouvettes prismatiques de 7.7.28 cm, un retrait thermique se superpose pendant quelques heures au second retrait ; la vitesse de refroidissement de l'éprouvette est alors de 0,5 à 1°C par heure en sorte que les vitesses de retrait thermique et de second retrait peuvent être du même ordre. Comme il a été dit plus haut, il est préférable de séparer les deux effets ; pour maintenir constante au degré près la température interne de l'éprouvette, on peut :

- réduire la taille de l'éprouvette (exemple : cylindre de 2 cm de diamètre, 16 cm de hauteur, moule en laiton),
- noyer un circuit de refroidissement par air dans l'éprouvette au moment du coulage (9).

### 2 - Fissuration et retrait de durcissement

La vitesse maximale de second retrait varie considérablement suivant les ciments, même à l'intérieur d'une même classe de résistance (fig. 2). Pour E/C = 0,27, les valeurs s'étalent de 0,2 à  $7 \cdot 10^{-5}$  par heure ; il semble que, en gros, plus le gonflement dure longtemps, plus la vitesse maximale de second retrait est faible ; cette vitesse augmente quand le rapport eau/ciment diminue (12). Il a été avancé que (9) le risque de fissuration précoce après prise était d'autant plus grand que la vitesse maximale de second retrait était plus élevée. Cette hypothèse a été émise après constatation d'une corrélation expérimentale entre les deux phénomènes. Cette fissuration de second retrait se superpose à la fissuration par retrait thermique, dont le mécanisme, proposé par Springenschmidt (13), est le suivant : au cours de la montée en température, sous l'effet de la chaleur d'hydratation, le béton est mis en compression et subit une déformation plastique. Lors de la descente en température, les contraintes de compression s'annulent pour une température  $t_1$  supérieure à la température ambiante  $t_0$ , car du fait du vieillissement du matériau, il y a eu diminution de la longueur d'équilibre de l'éprouvette (longueur pour laquelle les contraintes appliquées sont nulles). La température diminuant encore, le béton est mis en traction. La fissu-

ration est d'autant plus importante que la différence  $t_1 - t_0$  est plus élevée.

fig.2 Déformation de la pâte de ciment au premier âge pour différents ciments.

### 3 - Mesure simplifiée du retrait de durcissement

Etant donné l'intérêt de la mesure de la vitesse maximale de second retrait pour la détermination du risque de fissuration, un essai simplifié de second retrait a été mis au point au L.C.P.C. afin de disposer d'une mesure de routine (12). Dans cet essai, la mesure de déformation est faite verticalement sur des éprouvettes cylindriques ( $L = 160$  mm,  $\phi = 20$  mm) contenues dans des moules en laiton (figure 3)

fig.3 Mesure simplifiée du second retrait

Les essais de répétabilité dans un même laboratoire et de reproductibilité inter-laboratoires font apparaître des coefficients de variation respectivement de 8 % (sur 15 essais) et 13 % (sur 6 laboratoires). On obtient le même résultat dans l'essai simplifié (fig.3) et l'essai de recherche (fig. 1) à partir du maximum

de gonflement (l'enfoncement du plot sous l'effet de la pression du capteur perturbe l'essai simplifié jusqu'à cet instant).

## II - Le retrait de durcissement et la cinétique de l'hydratation

### 1 - Déformation isotherme après prise et dégagement de chaleur

On a étudié la déformation en fonction du dégagement de chaleur pour divers ciments et des rapports E/C de l'ordre de 0,25. Les ciments utilisés étaient des mélanges de clinker et de gypse à différents dosages (3 clinkers et 4 dosages par clinker). On constate que les courbes deviennent linéaires et parallèles entre elles à partir d'un certain temps (48 heures par exemple) pour deux des clinkers utilisés et quel que soit le dosage en gypse (9).

Lorsque le gonflement est inexistant, la courbe est linéaire sur toute son étendue. A partir de cette observation, on a proposé une méthode graphique pour séparer les phénomènes de gonflement et de retrait (9). Le gonflement et le retrait sont supposés être deux phénomènes indépendants qui se superposent, le gonflement prédominant en début d'hydratation, le retrait l'emportant ensuite. On propose de considérer le retrait comme caractérisé par une relation linéaire entre chaleur et déformation, le gonflement s'obtient alors par différence (figure 4).

fig.4 Séparation graphique du retrait R et du gonflement G

### 2 - Contraction Le Chatelier et dégagement de chaleur

La contraction Le Chatelier, qui est la diminution du volume total (volume de l'eau + volume du ciment) au cours de l'hydratation, est un phénomène différent du retrait de durcissement. Le retrait de durcissement est une variation de volume apparent, inférieure de plus d'un ordre de grandeur à la contraction Le Chatelier, qui est une variation de volume absolu. Nous verrons (au § III) que la contraction Le Chatelier joue un rôle important dans le mécanisme du retrait de durcissement.

Powers a montré (14) l'existence d'une relation linéaire entre la contraction Le Chatelier et le dégagement de chaleur. Cette relation était établie à partir de 7 jours d'hydratation. Nous avons pu vérifier que cette relation reste valable à partir de quelques heures à l'aide d'un appareil permettant l'enregistrement automatique de la contraction Le Chatelier (15). Nous avons trouvé le coefficient de proportionnalité suivant (voir aussi figure 5), valable pour différents CPA :

$$\frac{dQ}{dt} \approx 2,0 \frac{dE_i}{dt}$$

Q : dégagement de chaleur en cal/g ciment anhydre initial  
E<sub>i</sub> : contraction L.C. en mm<sup>3</sup>/g " " "

les expériences de Powers donnent en accord avec nos résultats :

$$1,7 \frac{dE_i}{dt} < \frac{dQ}{dt} < 2,0 \frac{dE_i}{dt}$$

fig.5 Exemples de comparaison des courbes de dégagement de chaleur et de contraction Le Chatelier.

Nous avons constaté une divergence dans les premières heures d'hydratation, où la contraction Le Chatelier est proportionnellement beaucoup plus importante que le dégagement de chaleur. Cette différence pourrait provenir de la contraction du volume du liquide interstitiel de la pâte lors du passage en solution d'ions électropositifs comme  $Ca^{++}$  (il y a électrostriction de l'eau au voisinage de l'ion, l'ordre de grandeur de la contraction qui en résulte peut être assez important = la dissolution de 0,5 cm<sup>3</sup> de  $Ca(OH)_2$  dans 1000 cm<sup>3</sup> d'eau donne environ 999,5 cm<sup>3</sup> de solution, soit une contraction d'environ 1‰ (15)).

3 - Contraction Le Chatelier et autodessiccation  
La contraction Le Chatelier, lorsqu'elle se produit dans une éprouvette de pâte de ciment conservée en empêchant tout échange d'eau avec le milieu, se traduit par l'apparition de vides gazeux à l'intérieur de l'éprouvette. Il en résulte une diminution de la pression partielle de vapeur d'eau en équilibre avec la pâte de ciment, c'est-à-dire une autodessiccation. Si l'isotherme de l'éprouvette était une courbe unique, la diminution de la pression partielle  $P/P_0$  serait donnée par cette courbe en y reportant la perte de poids équivalente en volume à la contraction Le Chatelier. En réalité, on a un phénomène d'hystérésis dans les courbes de désorption-adsorption (16) et tous les points compris entre les deux courbes extrêmes sont des points "d'équilibre".

Dans le cas de l'autodessiccation, on se situe à une pression de vapeur comprise entre les limites établies par ces 2 courbes. L'autodessiccation peut être observée directement par mesure de l'hygrométrie dans une enceinte fermée contenant une pâte de ciment durcissante (17, 18). On constate que l'hygrométrie d'équilibre peut descendre jusqu'à environ 75 % lorsque le rapport E/C est suffisamment bas (de l'ordre de 0,25).

### III - Retrait autogène par autodessiccation

Une explication du mécanisme de retrait de durcissement a été proposée depuis longtemps (19, 20). Elle consiste en ceci : l'hydratation engendre une autodessiccation et donc un retrait analogue au retrait de dessiccation, l'eau partant non plus vers l'extérieur mais "vers l'intérieur" de l'éprouvette. Nous allons étudier ici le problème de la vérification quantitative de cette hypothèse.

#### 1 - Les méthodes de mesure du retrait d'autodessiccation

L'Hermite et coll. (21) ont procédé à une estimation quantitative du retrait d'autodessiccation et l'ont comparé au retrait de durcissement. Leur méthode était la suivante : des pâtes de ciment ( $E/C = 0,25$ ) étaient conservées sous eau puis exposées à 50 % d'humidité relative à diverses échéances (2 j, 8 j, 30 j, 90 j, 180 j) avec mesures de la déformation, du poids et de la quantité d'eau non évaporable. Des éprouvettes étaient aussi conservées dans le mercure, ce qui constitue un mode de conservation du type protégé. La courbe de retrait dans le mercure a été portée en fonction de la quantité d'eau absorbée intérieurement (= quantité d'eau correspondant en volume à la contraction Le Chatelier). Les auteurs ont trouvé que cette courbe appartenait à la famille des courbes de retrait de dessiccation (retrait - quantité d'eau évaporée) à différents âges (elles sont toutes à peu près semblables). Ils en ont déduit que le retrait de durcissement résultait bien de l'autodessiccation.

La méthode de L'Hermite présente des inconvénients : la structure d'une pâte de ciment n'évolue pas de la même façon selon le mode de conservation, il n'est pas certain que le retrait d'évaporation soit le même pour une éprouvette conservée sous eau ou protégée. Il est aussi difficile de raisonner sur une courbe globale de retrait sous mercure, puisque le phénomène de gonflement se superpose au retrait de durcissement en début d'hydratation.

Nous avons utilisé une méthode différente pour l'estimation du retrait d'autodessiccation : nous avons mesuré des pentes, ou plutôt des petites variations à partir d'un instant  $t$  considéré. On peut ainsi travailler sur des éprouvettes de retrait de dessiccation et de durcissement qui ont la même structure à l'instant  $t$  et qui n'évoluent pratiquement pas en cours d'essai. Nous avons évalué sur des éprouvettes de pâte de ciment de mêmes rapports E/C et à un instant donné :

- la vitesse de contraction Le Chatelier  $P_1 = \frac{d(\Delta P)}{dt}$ ,

la contraction  $\frac{\Delta P}{P}$  étant exprimée en perte en poids équivalente au volume de la contraction Le Chatelier. (On a utilisé un appareil enregistrant en continu la contraction sur des éprouvettes d'environ 1 cm<sup>3</sup> avec une précision d'environ 1‰).

- le taux de retrait de dessiccation  $p_2 = \frac{d(\frac{P}{P_0})}{d(\frac{\Delta P}{P})}$ .

Il s'agit de la pente à l'origine de la courbe retrait-perte en poids mesurée sur une éprouvette

conservée en empêchant tout échange d'eau avec le milieu jusqu'au moment de l'essai et de forme cylindrique  $\phi = 3,5 \text{ cm}$  -  $L = 10 \text{ cm}$ . La précision de cet essai est mauvaise, elle est estimée à 30 %.

- la vitesse du retrait de durcissement  $p_3 = \frac{d(\frac{\Delta L}{L})}{dt}$  mesurée à l'aide de l'essai simplifié de second retrait.

En faisant l'hypothèse très simplificatrice (voir discussion sur l'isotherme, § II -3) que la contraction Le Chatelier provoque une diminution de la pression partielle d'équilibre égale à la diminution provoquée par l'évaporation d'une masse d'eau équivalente sur une éprouvette de même structure, nous obtenons la vitesse du retrait d'autodessiccation  $p_4$  à l'instant considéré

$$p_4 = \frac{d(\frac{\Delta L}{L})_{\text{auto}}}{dt} = p_1 \times p_2$$

Si  $p_3$  et  $p_4$  sont du même ordre de grandeur, nous pourrions en déduire que l'autodessiccation explique une part importante du retrait de durcissement.

## 2 - Résultats

Nous avons procédé aux essais décrits plus haut sur un ciment du type CPA (analyse chimique, tableau 1) et pour un rapport E/C = 0,25

tableau 1

SiO <sub>2</sub>	Al <sub>2</sub> O <sub>3</sub>	Fe <sub>2</sub> O <sub>3</sub>	CaO	MgO	SO <sub>2</sub>	TiO <sub>2</sub>	Na <sub>2</sub> O	K <sub>2</sub> O
21,02	5,40	2,20	63,24	0,89	3,15	0,32	0,10	0,38 %

insoluble

2,27 %

pour  $t = 48 \text{ h}$ , moyenne 6 essais:  $p_1 = 0,16 \cdot 10^{-3} \text{ h}^{-1}$

moyenne 4 essais:  $p_2 = 1,7 \cdot 10^{-2}$

moyenne 4 essais:  $p_3 = 0,24 \cdot 10^{-5} \text{ h}^{-1}$

$p_4 = p_1 \times p_2 = 0,27 \cdot 10^{-5} \text{ h}^{-1}$

Nous constatons que  $p_3$  et  $p_4$  sont du même ordre de grandeur: Nous avons vérifié ce résultat pour des temps supérieurs à 48 h, mais avec une précision de plus en plus mauvaise, les vitesses  $p_1$  et  $p_3$  devenant de plus en plus faibles.

Ce résultat confirme, pour le ciment choisi, que l'hypothèse du retrait par autodessiccation semble suffisante pour expliquer le retrait de durcissement. Mais cette conclusion devra être vérifiée pour d'autres types de ciment. On ne peut également exclure l'hypothèse que d'autres mécanismes, d'un ordre de grandeur inférieur ou égal, puissent se superposer au retrait d'autodessiccation, étant donnée la mauvaise précision des essais. Le retrait de carbonatation nous fournit un exemple d'un tel mécanisme (le retrait provient d'une dissolution de l'hydroxyde de calcium sous l'effet des contraintes de retrait de dessiccation, avec précipitation du carbonate de calcium dans les zones de faibles contraintes (22)).

## CONCLUSION :

Les principaux éléments auxquels nous sommes parvenus sont les suivants :

- 1) la fissuration précoce des bétons est en relation avec le retrait de durcissement (ou retrait autogène après prise). Il existe un appareil simple

permettant de mesurer la vitesse maximale de ce retrait de durcissement et donc d'évaluer le risque de fissuration précoce.

- 2) le retrait autogène après prise, comme la contraction Le Chatelier, est proportionnel au dégagement de chaleur.

- 3) la contraction Le Chatelier avant prise paraît liée à des phénomènes de dissolution.

- 4) l'autodessiccation résultant de la contraction Le Chatelier semble expliquer une part importante du retrait de durcissement.

# Influence of Phase Composition of Portland Cements on the Resultant Properties of their Pastes Processed by Steam Curing

## *Influence de la composition du ciment sur les caractéristiques des pâtes durcies et chauffées*

Z. SAUMAN, Professor, Research Institute of Building Materials, Brno

F. VAVRIN, Professor, Technical University, Brno, and

J. CERNA, RNDr, Research Institute of Building Materials, Brno, Tchécoslovaquie.

RESUME : Des pâtes ont été préparées avec dix sortes de ciment portland et chauffées à la vapeur à 80°. Ces ciments avaient des surfaces spécifiques très voisines, et des courbes granulométriques semblables.

On a constaté que les caractéristiques physiques et mécaniques des pâtes durcies dépendaient principalement de la teneur en alite, tandis que la bélite et le  $C_3A$  n'avaient qu'une influence secondaire.

Les différences de résistance de ces pâtes, de composition de phases et de granulométrie analogues peuvent être imputées à des solutions solides différentes dans l'alite et à des structures internes différentes de celle-ci, bien qu'aucune différence significative n'ait pu être décelée dans les dimensions des cristaux du clinker.

La microstructure de ces pâtes diffère peu de celles traitées à la température normale (25°); la différence provient essentiellement de la formation, dans les premières, de cristaux de tobermorite en forme d'aiguilles, mais dont la cristallisation est imparfaite.

SUMMARY : The pastes prepared from 10 types of portland cements were subjected to steam curing at 80°C. The cements were characterized by very close specific surface values and not too different granulometries.

It was found that the main influence onto the physical and mechanical properties of the hardened pastes is exerted by the alite contents, whereas belite and  $C_3A$ , respectively are characterized by practically secondary effect.

Differences in the strengths of cement pastes showing similar phase and granulometric composition can be attributed to the character of solid solutions in the alite and to the internal structure of the latter, since no significant differences have been found in the dimensions of the crystals of this main clinker component.

The microstructure of the pastes is somewhat different from the samples that have been treated at normal temperatures (25°C), mainly due to the formation of rod-shaped particles of "crystallically imperfectly developed tobermorite".

## INTRODUCTION

In the course of previous experimental work (1,2) carried out at the Research Institute of Building Materials in Brno there were found certain differences in the microstructure of cement pastes treated at normal room temperature and by steam curing. It appeared expedient to study this phenomenon in greater detail and above all to determine the relationship between the phase composition of the cements and the physical and chemical properties of the pastes prepared from them. For actual work there were employed 10 types of commercial clinkers ground in a programmable manner with 5% gypsum rock in such a way that their specific surface approached the value of  $3500 \text{ cm}^2 \cdot \text{g}^{-1}$  (Blaine). The pastes prepared from these cements ( $W/C = 0,32$ ) were processed after 1 hour rest by steam curing at  $80^\circ\text{C}$  with an isothermal holding period of 2, 4, 8 and 24 hours, 3 and 7 days.

After density and strength determination the phase composition of the pastes, including porosity was ascertained, and their microstructure was studied. As can readily be seen from the results of this work as well as from recent papers (3-8), the hydration mechanism as well as the mutual relations between the degree of hydration and the properties of the cement pastes have not yet been clarified in a satisfactory manner and are therefore the subject of studies in quite a number of research establishments.

## ANALYSIS OF RESULTS OBTAINED

The enclosed table I shows the phase composition of the clinkers studied with the aid of the light microscopic analysis.

TABLE I

Clinker designation	Contents of determined component (%)					
	$C_3S$	$C_2S$	$C_3A$	$C_4A \cdot F_y$	free CaO	$\Sigma$
AR	59,2	23,1	11,9	5,8	traces	100,0
BB	69,1	13,2	6,2	6,9	3,6	99,0
CI	57,5	26,5	14,3	1,1	0,4	99,8
HR	73,5	9,8	8,8	6,2	1,7	100,0
HS	59,9	22,2	10,3	6,1	1,5	100,0
KD	60,6	16,8	10,0	6,7	5,1	99,2
MA	65,0	15,2	4,4	15,3	traces	99,9
ME	74,0	9,1	8,6	8,1	0,2	100,0
ML <sup>+/</sup>	72,2	12,4	4,5	7,8	2,1	99,0
MO <sup>+/</sup>	69,6	8,6	14,8	4,5	1,2	98,7

<sup>+/</sup> In the clinker there was also identified a certain quantity of  $\alpha\text{-C}_2\text{S}$  which could not, however, be expressed in per cents as the differentiation from the belite mass was rather difficult.

On the prepared cements there was carried out a granulometric analysis with the aid

of a Coulter Counter instrument; the results are summarized in Table II.

TABLE II

Design. of cement	Measured interval in $\mu\text{m}$ (%)					
	<4,5	4,6-11,5	11,6-23,0	23,1-36,5	36,6-58,0	>58,0
AR	8,1	22,5	24,1	19,7	21,1	95,5
BB	3,3	22,8	29,8	19,1	16,5	91,5
CI	9,7	21,2	23,5	16,9	22,0	93,3
HR	2,5	23,8	30,0	22,3	18,1	96,7
HS	9,2	25,2	24,8	20,0	18,9	98,1
KD	6,1	24,4	26,9	19,3	17,4	94,1
MA	7,9	24,0	22,1	18,0	20,7	92,7
ME	4,3	17,0	20,5	15,8	22,6	80,2
ML	8,1	20,1	19,1	17,3	23,3	87,9
MO	8,3	21,1	22,6	20,2	22,7	94,9

The highest quantity of the finest fraction ( $<11,5 \mu\text{m}$ ) is exhibited by the HS cement, whereas the sample ME is characterized by the lowest contents of this fraction.

The contents of alite, belite and  $C_3A$  in the treated pastes were determined by X-ray diffraction methods. It was found that after a 7 day hydration more than one third of the alite remains in its original unhydrated state. An exception are the cements ML and MO, where the residual contents represent less than one third of the original quantity. In all the samples after a 7 day treatment there was identified more than one half of still unreacted belite contents. With the exception of MO sample, 1-3%  $C_3A$  could be identified even after the longest treatment.

The resultant compression strength values are given in Table III.

TABLE III

Compress. strength values $\sigma_2$ (N.mm <sup>-2</sup> )	2 h	4 h	8 h	24 h	3 d	7 d

MA	24,1	41,0	66,4	72,9	100,4	101,1
ME	27,9	60,1	71,7	83,5	95,5	101,0
ML	24,8	52,4	80,5	99,1	111,7	113,6
MO	20,2	57,2	75,8	95,1	102,3	105,3

In order to give more instructive information the early (2 h) and final strength (7 d) values are plotted in Figs. 1 and 2,

together with the indication of cements phase composition.

Fig. 1 - Compression strength of cement pastes after 2 hour treatment.

It follows explicitly from the above data that the major influence onto the attained strengths is exerted by alite. The relatively low early strength value (2 h) for the ME paste ( $27.9 \text{ N/mm}^2$ ) is caused by almost 20% the  $>58.0 \mu\text{m}$  fraction amounting almost to 20%. In the case of ML and MO samples, which are also characterized by a marked alite content, the relatively low early strengths are caused by a higher total porosity in comparison with the remaining pastes during the first hydration stages. Only the sample KD is characterized by a relatively pronounced early strength ( $43.1 \text{ N/mm}^2$ ) which is out of proportion with regard to the present alite quantity (60.6 %).

Cement pastes samples CI, AR and HS which contain the highest quantities of belite (26.5 - 22.2 %) exhibit the lowest compression strength values after 7 days of treatment.

Also the increased  $\text{C}_3\text{A}$  content did not positively influence the attained early strengths, as could perhaps have been assumed.

As has been shown experimentally, the differences in the size of the alite particles have not been substantial enough to influence the strength differences of the tested pastes in apparently principal manner.

Thus the main cause seems to be in the character of the contained solid solutions and in the internal structure of the alite itself.

The microstructure of the steam cured pastes ( $80^\circ\text{C}$ ) differs from those treated at room temperature ( $25^\circ\text{C}$ ) mainly by the fact that there is also formed the C-S-H-gel in the form of isometric particles which are mutually linked with the formation of the rod-shaped "crystallically imperfectly developed tobermoritic phase", in which in some cases there can be seen the indication of

Fig. 2 - Compression strength of cement pastes after 7 day treatment.

zoning original formations (Fig.3).

Fig. 3 - Paste of MA cement (7 days,  $80^\circ\text{C}$ ).

Typical portlandite crystals are often mutually intergrown, as a consequence of their formation in different periods of time or growth at different rate which can positively influence the strength of the cement paste (Fig. 4).

The "Type I" C-S-H-gel according to Diamond (4) which forms a fibrous structure, could be identified only sporadically, and the same applies to crystals which should, in accordance with their morphology, correspond to  $\text{C}_4\text{ASH}_{12}$ , but belong to portlandite.

A very frequent case of microstructure is the phenomenon when needle-shaped C-S-H-gel particles of very small dimensions intergrow the tabular portlandite crystals (Fig. 5).

Fig. 4 - Paste of MO cement (24 h, 80°C).

Fig. 5 - Paste of HS cement (24 h, 80°C).

#### CONCLUSION

Pastes from 10 cement types of approximately same specific surface were treated for the various periods of time at 80°C and it was found that the major influence onto the physical and mechanical properties is exerted by alite contents whereas belite and C<sub>3</sub>A, respectively exhibit only an unpronounced effect. The resultant differences in the strengths of samples having a close phase composition and a not too different granulometry are not caused by the difference in the dimensions of alite crystals, but are apparently related to the character of the contained solid solutions as well as the actual structural arrangement of this major clinker component.

# Calculations of Strength Development from the Compound Composition of Portland Cement

## *Calcul du développement de la résistance des ciments portland à partir de leur composition*

Sandor POPOVICS, Department of Civil Engineering, Drexel University, Philadelphia, Pennsylvania 19104,  
U.S.A.

RESUME : On a comparé quatre méthodes de calcul de la résistance des ciments portland, en fonction de leur âge, de leur finesse de broyage et de leur composition chimique :

le modèle linéaire  
le modèle exponentiel  
le modèle du second degré complet  
le modèle du second degré partiel

Un exemple numérique illustre l'application de ces méthodes. Les équations 4, 10 et 11, ainsi que les formules dérivées de l'équation 12, dans le modèle exponentiel, constituent des nouveautés.

Le modèle exponentiel fournit une preuve indirecte de l'action du  $C_3A$  comme catalyseur de l'hydratation des silicates de chaux.

SUMMARY : The paper compares methods of calculation for the strength development of portland cement in terms of age, fineness and compound composition. The following four methods are investigated :

the linear methods  
the exponential formulas  
the complete formula of second degree  
the truncated formula of second degree.

A numerical example illustrates the application of the methods. Eqs. 4, 10 and 11 and the derivation of Eq. 12 from the exponential cement model are new.

The exponential cement model also provides indirect evidence that the  $C_3A$  acts as a catalyst in the hydration of the calcium silicates.

The paper compares several old and new methods of calculation for the strength development of portland cements in standard mortars of ASTM C 109 type. The independent variables are: compound composition, age at testing, and fineness. Equations 4), 10) and 11) and the derivation of Eq. 12) from the exponential cement model have not been published before.

This paper is the continuation of the papers the writer presented at the IV. and V. International Symposia on the Chemistry of Cement.

#### The Linear Cement Models

The mathematical form of the first such model is, as follows:

$$f = \text{Strength} = a(C_3S) + b(C_2S) + c(C_3A) + d(C_4AF) \quad (1)$$

where the symbols in parentheses represent the calculated (Bogue) percentages by weight of the compounds, and a, b, c, and d are empirical coefficients (parameters). A set of the coefficients for Eq. 1) are presented in Table 1. These are valid for standard Ottawa-sand mortars of ASTM C 109 and C 190 types.

Strengths calculated by Eq. 1) and the pertinent parameters of Table 1 for Cement No. 24 of Gonnerman's (1) are shown in Figure 1 along with the experimental values. The composition of this cement is:

$$C_3S = 41\%; C_2S = 37\%; C_3A = 7\%; C_4AF = 12\%.$$

Several attempts have been made to improve the linear model. Blaine and his co-workers introduced a large number of additional variables. (2) Their formulas for portland cements in Ottawa-sand mortars of ASTM C 109 type are as follows:

$$f_1 = -2029 + 18.19C_3S + 224.7S_{O_3} + 349.1 K_2O - 168.8 \text{ Loss} - 228.2 \text{ Insol} + 0.5509S_s - 16.82 \text{ Air} \quad (2a)$$

$$f_3 = -2950 + 41.51C_3S + 22.05C_3A + 432.5 S_{O_3} + 327.3 K_2O - 249.9 \text{ Loss} + 0.7573S_s - 49.55 \text{ Air} \quad (2b)$$

$$f_7 = -4131 + 56.16C_3S + 90.45C_3A + 378.1S_{O_3} + 592.8 K_2O - 39.24 MgO - 68.66 \text{ Loss} + 1.07 S_s - 59.99 \text{ Air} \quad (2c)$$

$$f_{28} = 1075 + 42.08C_3S + 53.03C_3A + 23.60C_4AF + 0.5729S_s - 95.61 \text{ Air} \quad (2d)$$

$$f_{365} = 6518 - 103.4C_3A - 687.7 Na_2O + 0.4345S_s - 100.2 \text{ Air} \quad (2e)$$

$$f_{1825} = 5331 + 16.25C_2S - 85.22C_3A - 1091Na_2O - 107.9MgO + 0.5375S_s - 507.8 \text{ Insol} - 106.5 \text{ Air} \quad (2f)$$

$$f_{3650} = 7833 + 18.77 C_2S - 161.5 C_3A - 71.0C_4AF - 1578Na_2O - 723 \text{ Insol} + 0.2496 S_s - 122.2 \text{ Air} \quad (2g)$$

where

TABLE I - Coefficients for Eq. 1) (1)

Curing of specimens: in moist room at normal temperature up to 28 days, then in water.

Age	Coefficients, psi						
	1 d	3 d	7 d	28 d	3 m	1 y	2 y
Compound	2-in. Plastic Mortar Cubes, 1:2.75 Mix by Weight for Compressive Strength						
C <sub>3</sub> S	8.5	27.4	40.0	48.8	55.7	61.8	70.7
C <sub>2</sub> S	0.3	-1.1	-5.1	19.1	62.9	80.6	82.2
C <sub>3</sub> A	11.3	24.1	58.4	100.1	56.4	5.6	-12.5
C <sub>4</sub> AF	-6.5	-9.8	-0.2	30.8	39.7	39.6	27.2
Age	1:3 Standard Ottawa Sand Briquets for Tensile Strength						
	1 d	3 d	7 d	28 d	3 m	1 y	2 y
C <sub>3</sub> S	2.1	3.6	4.6	5.0	4.7	4.6	4.9
C <sub>2</sub> S	0.3	0.8	1.3	3.8	6.1	6.4	6.1
C <sub>3</sub> A	4.6	6.3	7.1	7.1	4.4	2.1	0.9
C <sub>4</sub> AF	0.4	3.7	3.5	4.0	4.0	2.6	2.2

The conversion factor from psi to MPa is 0.0069.

$f_t$  = standard compressive strength of mortar at the age of  $t$  days, psi,

$C_3S$ ,  $C_2S$ ,  $C_3A$  and  $C_4AF$  = calculated (Bogue) amounts of the four cement compounds, percent by weight,

$SO_3$ ,  $K_2O$ ,  $Na_2O$ , and  $MgO$  = sulfate, potassium, sodium and magnesium contents, respectively, percent by weight,

Loss = loss on ignition, percent by weight,

$S_s$  = fineness of cement by the air-permeability (Blaine) method,  $cm^2/g$ ,

Air = air content of the fresh mortar, percent.

The conversion factor from psi to MPa is 0.0069.

Using again Cement No. 24 from Gonnerman's investigation with the estimated values of Air = 1%,  $SO_3$  = 1.8%,  $K_2O$  = 0.4%,  $Na_2O$  = 0.6%,  $MgO$  = 2.8%, Loss = 0%, Insol = 0.2%, and  $S_s$  = 2700  $cm^2/g$ , the strength values calculated by Eqs. 2a) through 2f) are presented in Figure 1.

In another effort, Alexander presented a simplified two-component linear model (3) for the cube strengths of 2.75 standard Ottawa-sand mortars under wet curing:

$$f_3 = -1477 + 24.64 C_3S + 40.43 C_3A + 0.484 S_s \quad 3a)$$

$$f_7 = -1245 + 41.16 C_3S + 78.84 C_3A + 0.355 S_s \quad 3b)$$

$$f_{28} = 286 + 27.25 C_3S + 146.96 C_3A + 0.384 S_s \quad 3c)$$

where the symbols are identical with the symbols of Eqs. 2a) through 2g).

The conversion factor from psi to MPa is again 0.0069. Strength values calculated by Eqs. 3a) through 3c) for Cement No. 24 are presented in Figure 1.

#### The Direct Exponential Model

Another approach is the following formula for the calculation of compressive and tensile strengths of standard, non-air-entrained mortars of ASTM C 109 and C 190 types:

$$f_t = f_{90} \frac{1 - pe^{-b_1 t} - (1-p)e^{-b_2 t}}{1 - pe^{-90b_1} - (1-p)e^{-90b_2}} \quad 4)$$

where

$f_t$  = estimated mortar strength at the age of  $t$  days, psi

$f_{90}$  = strength parameter representing the mortar at the age of 90 days.

For the standard compressive strength of non-air entraining cements in Ottawa-sand mortars:

$$f_{90} = 5500 S_s / S_o \quad (\text{psi}) \quad 5)$$

Figure 1. Comparison of compressive strengths estimated for the same cement. The specimens were 2-in. (5-cm) cubes of 1 : 2.75 Ottawa-sand mortar made with Cement No. 24 from the series of Gonnerman's. (1) Lines represent values calculated by formulas as marked; points represent experimental values by Gonnerman. The cement composition is:  $C_3S$  = 41%;  $C_2S$  = 37%;  $C_3A$  = 7%; and  $C_4AF$  = 12%

For the compressive strength of the same cements and mortars as above but when the curing takes place in moist air instead of water:

$$f_{90} = 5900 S_s / S_o \quad (\text{psi}) \quad 6)$$

For the tensile strength of standard briquette but with moist-air curing:

$$f_{90} = 580 \quad (\text{psi}) \quad 7)$$

$t$  = age of the specimen at testing, days,

$p$  = computed  $C_3S$  content of the portland cement, percent/100,

$b_1$  and  $b_2$  = rate parameters which are independent of the strength, age, and  $C_3S$  and  $C_2S$  contents, but may be a function of the temperature,  $C_3A$  content, fineness and any other factor that influences the course of hydration (minor constituents, gypsum content, admixtures, water-cement ratio, curing and testing methods, etc.), 1/day.

For the compressive strengths of Ottawa-sand mortar cubes made, cured and tested according to ASTM C 109, the following  $b$  parameters are valid:

$$b_1 = 0.2 S_s / S_o \quad (1 \text{ day}) \quad 8)$$

$$b_2 = 0.005 C_3A S_s / S_o \quad (1 \text{ day}) \quad 9)$$

For the tensile strength of Ottawa-sand briquettes according to ASTM

C 190, the following b parameters are valid:

$$b_1 = 0.80S_s/S_o \quad (1 \text{ day})$$

$$b_2 = 0.02C_3A S_s/S_o \quad (1 \text{ day})$$

$S_s$  and  $S_o$  = Specific surface of the cement in question, and that of a typical Type I cement, respectively. In the case of Kliegar's LTS cements (4)  $S_s$  was usually taken for Type III cements as 2600 cm<sup>2</sup>/g (Wagner), and for the other cement types as 1800 cm<sup>2</sup>/g (Wagner).  $S_o$  was usually taken as 1800 cm<sup>2</sup>/g (Wagner).

The conversion factor from psi to MPa is 0.0069. Strength values calculated by Eq. 4) with Eqs. 6), 8) and 9) for cement No. 24 are shown again in Figure 1.

Eq. 4) is an advanced form of the earlier exponential cement model for relative strengths. (5)

Eq. 4) can also be used to estimate the strength at any age from the experimentally obtained strength of the mortar in question at a given age. For instance, the strength at any age can be estimated from the measured 3-day strength if  $t = 3$  is substituted for 90 in the formula:

$$f_t = f_3 \frac{1 - pe^{-b_1 t} - (1 - p)e^{-b_2 t}}{1 - pe^{-3b_1} - (1 - p)e^{-3b_2}} \quad (10)$$

where the symbol are the same as the symbols for Eq. 4).

Values calculated by Eq. 10) with Eqs. 8) and 9) from the 3-day compressive strength of the Ottawa-sand mortar cubes made with Gonnerman's Cement No. 24 are also shown in Figure 1.

A considerable amount of evidence has been published to show that the exponential cement model is well supported by experimental data. (6) - (9) It is highly unlikely that such a good fit could have been obtained without a fundamental similarity between the hardening process represented by this model, and the actual process. Therefore, it seems safe to say that the  $C_3A$  acts as a catalyst on the hydration of the calcium silicates, as indicated by the structure of the model. (10)

Note that both Eq. 4) and Eq. 10) are also suitable for the estimation of concrete strengths. This, however, is the topic of another paper.

#### Quadratic Models

If one expands the exponential terms in Eq. 4) into the well-known series, and omits the terms of higher degrees, the following formula of second degree is obtained:

$$f_t = g + hC_3S + iC_3S \times C_3A + jC_3A + kS_s \quad (11)$$

where  $g$ ,  $h$ ,  $i$ ,  $j$  and  $k$  are experimental parameters that are independent of the compound composition of the cement but may be affected by any factor that

influences the strength development. Reliable best-fit values for these parameters are not available at this time.

If one assumes that the term of  $jC_3A$  is negligible, then Eq. 11) provides the formulas recommended by Alexander (3):

$$f_3 = -1248 + 22.32 C_3S(1 + 0.030 C_3A) + 0.468S_s \quad (12a)$$

$$f_7 = -772 + 34.20 C_3S(1 + 0.043 C_3A) + 0.329S_s \quad (12b)$$

$$f_{28} = 1129 + 15.36 C_3S(1 + 0.181 C_3A) + 0.325S_s \quad (12c)$$

where the symbols and the limits of validity are the same as those for Eqs. 2a) through 2g). The conversion factor from psi to MPa is 0.0069.

Using again Cement No. 24 from Gonnerman's investigation, the strength values calculated by Eqs. 12a) through 12c) are practically the same for this cement as those by Eqs. 3a) through 3c) shown in Figure 1.

#### Conclusion

All the presented formulas are suitable for the estimation of the strength developing capacity of portland cements, although none of them is completely satisfactory. The reason for this is that none of the formulas includes all the factors that affect the strength development of a cement. Nevertheless, it appears that the exponential model, that is Eq. 4), is perhaps the most promising partly because it is more in accordance with accepted concepts of cement chemistry than the other models, and partly because it contains only two parameters.

# The Distribution of Evaporable water in hardened cement paste (h.c.p)

## *La distribution de l'eau évaporable dans les pâtes durcies de ciment*

S. SABRI and

J. M. ILLSTON, Division of Civil Engineering. The Hatfield Polytechnic, Hatfield, Herts, U.K.

RESUME : Nous avons étudié la répartition de l'eau évaporable dans les pâtes de ciment durcies, en utilisant une méthode thermogravimétrique semi-isotherme et une méthode dérivée de la thermogravimétrie.

Ces mesures permettent de distinguer deux sortes d'eau évaporable. Les variations des quantités d'eau de chaque sorte ont été déterminées expérimentalement, en fonction des durées d'hydratation, de l'humidité relative ambiante, de la température et du rapport eau/ciment. Nous en avons conclu que l'eau évaporable dans les pâtes de ciment durcies n'est pas due uniquement à l'eau physiquement adsorbée, mais aussi à l'eau de combinaison de certains hydrates, instables quand la teneur en eau interne de la pâte varie.

SUMMARY: The distribution of evaporable water in h.c.p. was studied using a simultaneous semi-isothermal method of thermogravimetry and derivative thermogravimetry.

The measurements allow quantitative differentiation between two different types of evaporable water in h.c.p. The variations in the amount of each type in response to changes in curing period, relative humidity, temperature and water-cement ratio were determined experimentally.

It is concluded that the evaporable water in h.c.p. is not present solely as physically adsorbed water but also as a structural component of some hydrates that are not stable with regard to changes in moisture content.

## INTRODUCTION

Knowledge of the distribution of evaporable water in h.c.p. is essential for a realistic interpretation of sorption and length change measurements. A series of measuring methods are reported in the literature by means of which attempts are made to establish criteria to distinguish between the different types of water in h.c.p. None of these methods, however, succeeds in separating quantitatively the different classes of evaporable water present in h.c.p.

In the following, such a method of determining the distribution of water in h.c.p. is demonstrated, using a semi-isothermal thermogravimetric method.

## EXPERIMENTAL

### Specimen Preparation:

A type I cement was mixed at a water cement ratio (W/C) of 0.47, cast as hollow cylindrical tubes of wall thickness 1 mm, external diameter 32 mm, and length 100 mm, in specially designed perspex moulds (1), stored at 20°C for one day in 100% R.H chamber, demoulded and then cured at 20°C in deionized water until tested.

The samples used for the determination of the distribution of evaporable water by the semi-isothermal TG/DTG method were broken pieces taken from the 1 mm tubes. The initial weight of the sample was always between 10 and 12 mg. Essentially similar results were obtained using samples in a powder form. Powdered samples were not used, however, to avoid additional carbonation occurring during conditioning, grinding and placing in the furnace.

### Apparatus and Experimental Conditions:

A TG 750-thermobalance (Stanton Redcroft, London, UK) was used with N30  $\mu$ V-preamplifier and N42 Derivative unit (Linseis Messtechnik GmbH, Selb, W. Germany). The TG, DTG and temperature curves were recorded simultaneously on a Linseis multi-pen recorder.

All semi-isothermal TG/DTG experiments were carried out at a heating rate of 5°C/min, chart speed 100 mm/h and in a dynamic atmosphere of CO<sub>2</sub> free air of constant water vapour pressure equal to the saturation vapour pressure of water at 20°C, at a rate of 25 ml/min. This relatively high water vapour pressure was chosen because it is thought to delay the start of the desorption of that part of evaporable water that is more tightly bound to the solid and consequently facilitates the separation of the peaks.

### The Semi-isothermal Thermogravimetric Procedure:

The features of the semi-isothermal technique used in this study are essentially the same as those used by El-Jazairi and Illston in reference (2). As the rate of weight change reaches a maximum (at a peak) and starts to decrease, the temperature programmer is switched from dynamic heating to the isothermal condition for 30 minutes. At the end of the 30 minutes isotherm the temperature programmer is again switched to dynamic heating until the next peak is reached.

Fig. 1: Typical semi-isothermal TG/DTG curves for a saturated sample of h.c.p.

Fig. (1) shows typical semi-isothermal TG/DTG curves for a saturated h.c.p. sample hydrated for only one day. The semi-isothermal TG/DTG method allows the separation of TWO main peaks on the DTG curve in the temperature range  $20^{\circ}$  to  $100^{\circ}\text{C}$ . The two types of water corresponding to the lower and the higher temperature peaks are designated water type "A" and water type "B" respectively.  $W_A$  and  $W_B$  are defined as the weight of water type "A" and the weight of water type "B" per unit weight of dry paste respectively.

For samples cured for one day only, the first peak occurs at about  $47^{\circ}\text{C}$  and the second peak occurs at  $78^{\circ}\text{C}$ . The temperature of each peak increases with the curing period up to 28 days, after which they remain constant at about  $54^{\circ}$  and  $90^{\circ}\text{C}$  for peak "A" and peak "B" respectively.

## RESULTS

### Effect of Curing Period:

The amount of water type "A" was found to be practically constant all through the curing period from 1 day up to 2 years. The amount of water type "B" on the other hand increases steadily with the curing period. A plot of the experimental values of  $W_B$  against  $W_n$  is shown in Fig. (2), it gives a straight line of the form

$$W_B = .023 + .276 W_n \quad \text{..... (1)}$$

where  $W_n$  is the non evaporable water per unit weight of ignited paste. Equation (1) can be used to determine the amount of water type "B" in saturated samples by measuring  $W_n$  alone. This helps to determine any changes that might occur during drying or heating in the amount of water type "B" relative to its originally saturated state without the complicating factors arising from continued hydration during relative humidity or temperature changes.

Fig. 2:  $W_B$  vs  $W_n$  plot for saturated h.c.p.

### Effect of Drying and Wetting:

In order to determine how each type of evaporable water in h.c.p. changes with relative humidity, semi-isothermal TG/DTG experiments were performed on samples conditioned to different levels of R.H. The samples were initially cured for 28 days in water before conditioning. To correct for any additional hydration that occurs during

conditioning at high levels of R.H, the quantity  $W_B/W_{B_0}$  is used instead of  $W_B$  to plot the correct isotherm of water type "B".  $W_{B_0}$  is the amount of water type "B" that should have been present in the sample if it was continuously kept in water as calculated from the value of  $W_n$  of partially dried sample, using equation (1).

Fig. 3: Adsorption - desorption isotherm of water type "A".

Fig. 4: Adsorption - desorption isotherm of water type "B".

The isotherms of water type "A" and water type "B" are shown in Fig. (3) and Fig. (4) respectively, where it can be seen that:

1. Water type "A" is present at all relative humidities and its amount decreases as relative humidity decreases.
2. The isotherm of water type "A" is reversible in the lower humidity range, a hysteresis loop is present at high humidities and closes at about 35% R.H.
3. Most of water type "B" is lost below 11% R.H.
4. Even at the highest relative humidity used (namely 94% R.H) some of water type "B" is lost from the sample.
5. Between 100 and 11% R.H a minimum is observed in the amount of water type "B" retained by the sample.
6. On adsorption,  $W_B$  increases throughout the full humidity range.

A large hysteresis loop is observed at all levels of R.H, and the difference is particularly large at 11% R.H.

Perhaps the most important result with regard to the effect of drying on the distribution of evaporable water in h.c.p. is that a definite increase in  $W_B$  occurs due to drying on rewetting. The increase in  $W_B$  (of the order of about 20%) due to a drying cycle to 11% R.H and back to saturation is about twice the increase due to drying to 44 or to 0% R.H.

#### Effect of Temperature:

Heating in the dry condition has very little effect on the distribution of evaporable water in h.c.p. as measured by the semi-isothermal TG/DTG method. Heating in water, however, produces a substantial decrease in  $W_B$ , especially at temperatures higher than about 45°C.

#### Effect of W/C Ratio:

Semi-isothermal TG/DTG runs were performed on saturated fully hydrated samples of h.c.p. made with different W/C ratios. The amount of water type "A" per unit non-evaporable water increases with W/C ratio, while the amount of water type "B" per unit non-evaporable water appears to be constant for samples made with low W/C ratio. For samples made with W/C ratios higher than about 0.4,  $W_B/W_n$  decreases with W/C ratio.

#### DISCUSSION:

The adsorption-desorption isotherm of water type "A" shows the characteristics of physically adsorbed water. Water type "A" must include both capillary and gel water according to the classification of Powers and Brownyard (3) since about 49% of the evaporable water present in samples made with W/C ratio of 0.23 (which according to Powers contains no capillary pores) is present as water of type "A".

The sorption isotherm of water type "B" shows a hysteresis loop extending over the low relative humidity range, which is a feature of crystals in which water is withdrawn from the structure.

Water type "B" is probably due to the dehydration of one or more of the hydrates in h.c.p. that are not stable with relative humidity such as C-S-H gel and ettringite.

Water in ettringite can contribute only to water type "B" that forms during the first day of hydration. The rest of water type "B", which as Fig. (3) indicates, increases linearly with  $W_n$ , would therefore be due to the dehydration of the C-S-H component of the paste.

A practical implication of the identification of water type "A" as physically adsorbed water, is that the surface area covered by water type "A" can be determined by applying the BET equation to its isotherm, without the complications arising from the loss and gain of the hydrate water type "B".

It is interesting to note that if we assume that water type "B" in C-S-H gel is present as a monolayer of water adsorbed between two surfaces and calculate the surface area covered by water type "B", the value of the total surface area covered by both types of water in saturated samples is about 680 m<sup>2</sup>/gm of dry paste. This value is in close agreement with the value of 660 m<sup>2</sup>/gm of dry paste reported by Winslow and Diamond (4) for saturated samples using low-angle X-ray scattering method. Moreover, heating at 105°C in water reduces the surface area of saturated samples irreversibly by about 50% and also reduces irreversibly the amount of water type "B" by about 50%. This suggests that water type "B" is probably present in C-S-H gel as a monolayer of water separating the basic structural units composing the gel particles.

The increase in  $W_B$  on rewetting after drying suggests that drying causes neighbouring structural units that are partially or totally separated by water type "A" in the initially saturated state to approach each other creating, irreversibly, more spaces of type "B".

#### CONCLUSIONS:

The semi-isothermal TG/DTG method described above is a useful method for studying the properties and the distribution of evaporable water in h.c.p.

Evaporable water in h.c.p. can be divided into two types. The first type includes the water present in the pores of the paste as well as the physically adsorbed water on the free surfaces of the solid, and the second type is regarded as a structural component of some hydrates that are not stable with regard to changes in moisture content such as C-S-H gel and ettringite.

# Effect of cement kind on chemical and drying shrinkage

## *Influence du type de ciment sur le retrait chimique et hydraulique*

V. DORKIN, Docent, All Union Polytechnical Institute (WZPI) Moscow, and  
Yu. ZAITSEV, Professor, All-Union Polytechnical Institute (ZWPI) Moscow, U.R.S.S.

RESUME : On a étudié séparément le retrait chimique et hydraulique sur des éprouvettes en pâte de ciments portlands ayant des teneurs différentes en  $C_3S$ ,  $C_2S$ ,  $C_3A$ .

Les déformations chimiques et hydrauliques ont été mesurées en fonction du temps. On a constaté que les retraits chimique et hydraulique dépendaient essentiellement de la minéralogie du ciment et du rapport E/C.

SUMMARY: Separately chemical and drying shrinkage of hardened cement paste on various portland cements (with different content of  $C_3S$ ,  $C_2S$  and  $C_3A$ ) has been studied.

Chemical and drying shrinkage strain values as function of time are given. It is shown that both chemical and drying shrinkage strain depends significantly on the mineralogical composition of cement. Effect of w/c ratio on chemical and drying shrinkage strain is analysed.

## INTRODUCTION

Shrinkage of hardened cement paste and concrete can be considered as consisting of 3 components: drying shrinkage, chemical shrinkage and carbonisation shrinkage (1,2). Chemical shrinkage seems to be one of the most fundamental properties of hardened cement paste, because it is connected only with hydration process and does not depend on the environment effects as the drying and carbonisation shrinkage do. Nevertheless chemical shrinkage is significantly less investigated as compared to drying shrinkage. In this study chemical shrinkage of hardened cement paste made on different cements was investigated. At the same time drying shrinkage of companion specimens was studied too.

## MATERIALS

Table 1 shows the composition of cements used in this study.

Cement paste with three fixed water/cement ratio (0.26; 0.28; 0.30) was compacted in hermetic cylindrical moulds with the following size: diameter  $d = 40$  mm, height  $h = 160$  mm. Specimens were cured at  $20 \pm 0.5^\circ\text{C}$  for a period of 18 hours (cements No. 1-4) or 2 hours (cement type No. 5). Shrinkage of the cement paste at an earlier age (i.e. plastic shrinkage) was not investigated because the chemical shrinkage does not contribute significantly to the plastic shrinkage (3,4).

## APPARATUS

Chemical shrinkage was investigated on completely sealed specimens, which were immersed into toluol. Toluol is liquid having nearly the same density as water and is practically dissoluble in it. Use of liquid insulation allowed to combine the container for specimen and the support for measurement of specimen strain. Container was made from quartz to eliminate probable deformation induced by temperature changes.

Drying shrinkage was investigated on unsealed specimens in quartz supports, by  $70 \pm 2\%$  r.h. and  $20 \pm 0.5^\circ\text{C}$  in special climatic chambers.

## RESULTS

Typical results of tests - chemical shrinkage strain  $\epsilon_{ch}$  and drying shrinkage strain  $\epsilon_{dr}$  are shown in Fig. 1.

As can be seen from Fig. 1, chemical shrinkage strain are equal to 20-30% of drying shrinkage strain. Character of chemical shrinkage curves differs significantly from that of drying shrinkage curves - the former always have an ascending

Fig. 1. Chemical and drying shrinkage as a function of time

part (dilatation of cement paste), the latter as a rule (with the exception of the cement No. 3) have it not. The effect of mineralogical composition of cement on shrinkage strain of both kinds is shown in Fig. 2, where related strain values  $\frac{ch}{ch_0}$  and  $\frac{dr}{dr_0}$  are given;  $ch_0$  and  $dr_0$  are values of  $ch$  and  $dr$  respectively at the end of the test, i.e. by  $t = 672$  h.

It can be seen from Fig. 2, that for drying shrinkage the mineralogical composition effects rather the absolute values of strain than the character of shrinkage curves; for chemical shrinkage, on the contrary, both the absolute strain values and the character of shrinkage curves (especially at the beginning of the test) are significantly affected by mineralogical composition of cement.

In an effort to find out quantitative connections between mineralogical composition of cement and shrinkage strain we have considered  $ch_0$  and  $dr_0$  values as functions of the content of  $C_3A$  - see Fig. 3. Reasons to choose the  $C_3A$  - content as a parameter were the following. On the one hand the presence of the  $C_3A$  accelerates hydration of  $C_2S$  (5), which can accelerate shrinkage process too. On the other hand

TABLE I

No.	Material	Composition, %			
		C <sub>3</sub> S	C <sub>2</sub> S	C <sub>3</sub> A	C <sub>4</sub> AF
1.	Low alumina portland cement	66	15	4	13
2.	Low alumina portland cement	56	21	4	13
3.	Middle alumina portland cement	57	14	6	15
4.	High alumina portland cement	60	12	8	14
5.	Alumina gypseous cement <sup>*)</sup>	-	-	-	-
<sup>*)</sup> Al <sub>2</sub> O <sub>3</sub> = 45.25%, CaO = 42.45%, SiO <sub>2</sub> = 9.77%, S = 1.25%; gypsum is used to regulate the hardening of cement paste.					

the content of C<sub>3</sub>A varied in our cements in a relatively wide range as compared to other components of cement. It was assumed that  $\epsilon_{ch} = 0$  at the moment of maximal dilatation of cement paste. As can be seen from Fig. 3 both chemical and drying shrinkage strain increases nearly linearly with the increasing of the C<sub>3</sub>A content. Similar results for only drying shrinkage of two kinds of cement were obtained in (6,7) by C<sub>3</sub>A content equal to 0.1% and 12%. Water cement ratio effects the shrinkage strain slightly. Nevertheless it is obvious that this effect is different for drying and chemical shrinkage: the more is W/c the more is drying shrinkage and the less is chemical shrinkage strain.

#### CONCLUSIONS

Chemical shrinkage strain are equal to 20-30% of drying shrinkage strain. Both chemical and drying shrinkage strain depends significantly on the mineralogical composition of cement. Both chemical and drying shrinkage strain increases nearly linearly with the increasing of the C<sub>3</sub>A content. Effect of W/c ratio is different for drying and chemical shrinkage: drying shrinkage strain increases and chemical shrinkage strain decreases with the increasing of W/c ratio.

# Ageing and Drying of Tricalcium Silicate Pastes

## *Vieillissement et séchage des pâtes de silicate tricalcique*

N.B. MILESTONE, Scientist, Chemistry Division, Department Scientific and Industrial Research, Petone, New Zealand.

### SUMMARY

Trimethylsilylation has been used to study changes in the silicate phase composition upon ageing and drying of tricalcium silicate pastes dried at varying relative humidities from 75% rh to 11% rh. Drying is shown to have a pronounced effect on the distribution of the silicate phases in the C-S-H gel.

Drying pastes to 33% rh or less causes irreversible changes in the distribution of silicate phases in the gel. Monosilicate is not present and the amount of polysilicate increases as drying is increased. No increase in polysilicate with time is noted.

For pastes dried to 53% or 75% rh, monosilicate is present in the gel but the amount decreases with time (half-life of approximately one and a half weeks). The amount of polysilicate in the gel increases with time without any increase in the degree of hydration indicating an ageing effect.

The ageing effect is considered to be a silicate condensation reaction and could explain the age dependent changes in creep and shrinkage of pastes and surface area changes noted by other workers.

RESUME : On a utilisé du triméthylsilyl pour étudier les variations de la composition des phases silicatées, au cours du vieillissement du séchage de pâtes de silicate tricalcique soumises à des atmosphères desséchantes, ayant des humidités relatives variant de 75 % à 11 %. On a observé que le séchage a un effet prononcé sur la distribution des phases de silicate dans le gel de C-S-H.

Les pâtes desséchées à 33 % d'humidité relative, ou moins, subissent des variations irréversibles de cette distribution du silicate dans le gel. Le monosilicate disparaît et la proportion de polysilicate augmente avec le séchage. Cette proportion de polysilicate n'augmente pas avec le temps.

Dans les pâtes desséchées entre 53 % et 75 % d'humidité relative, le monosilicate est présent dans le gel, mais sa proportion diminue avec le temps (diminution approximative de moitié en une semaine et demi). La proportion de polysilicate dans le gel augmente avec le temps, sans que l'on observe d'accroissement de l'hydratation ou du vieillissement.

Le vieillissement semble dû à une polymérisation, ce qui peut expliquer les variations avec l'âge du retrait et du fluage des pâtes et de leur surface spécifique, signalées par d'autres chercheurs.

## INTRODUCTION

Changes in some of the properties of cement and calcium silicate pastes that cannot be accounted for by changes in degree of hydration ( $\alpha$ ) or porosity have been noted by several workers. These changes may be accounted for by an ageing or maturing process, occurring in the microstructure of the CSH gel.

Parrott<sup>1</sup> noted that creep was reduced in samples stored at high humidity and loaded at later ages as compared to samples with the same degree of hydration loaded at early ages. In later work<sup>2</sup> he showed that heat treatment produced a similar effect. Parrott attributed this effect to continued polymerization of the silicate in the CSH gel after hydration had ceased and using the method devised by Funk and Frydrych<sup>3</sup>, was able to show that increased polymerization occurred.<sup>2</sup>

Hunt et al<sup>4</sup> reported that drying affected the measured values of surface areas. For pastes stored between 40 and 60% rh they found a time-dependent decrease in the surface area determined using  $N_2$  and suggested this effect was due to some form of an ageing mechanism.

Changes upon heating dried tobermorite gels were attributed to changes in silicate polymerization by Collepardi et al<sup>5</sup>. Funk<sup>6</sup>, in his studies on the ageing of tobermorite gels, was able to measure an increase in the amount of polysilicate.

Changes in silicate pastes are normally considered to occur in the C-S-H gel. The gel is amorphous and generally indirect methods must be used for study. These usually involve severe drying. Drying has been shown to affect the physical properties of amorphous C-S-H gel in cement paste. Irreversible changes in basal spacings of C-S-H(I) upon drying were noted by Gutteridge and Parrott<sup>8</sup>.

A new method, pioneered by Lentz<sup>9</sup> and perfected by Tamas et al<sup>10</sup> for cement pastes gives a direct method of examining the chemical structure of silicates in a paste without the need for harsh drying. Trimethylsilyl derivatives are formed which prevent further polymerization and permit analysis by gas-liquid chromatography (glc) and gel-permeation chromatography.

Workers at the University of Illinois<sup>11-15</sup> applied several techniques, including those of silylation, to a series of pastes subjected to creep and shrinkage. They noted that differences in drying caused differences in the nonvolatile polysilicate component of the pastes<sup>12,13</sup>. Further work on the structural properties of the pastes<sup>14</sup> showed that the amount of polysilicate correlated with time suggesting a time dependent ageing process. The percentage polysilicate in the paste was also shown to increase with temperature<sup>15</sup> and it was found that pastes hydrated at 4°C

contained monomer in the gel.

This paper describes a study of the changes in silicate structure of tricalcium silicate pastes dried to various relative humidities and the effects of storing these pastes at the different humidities.

## EXPERIMENTAL

C<sub>3</sub>S pastes (w/s = 0.5) were mixed in vials under  $N_2$  and hydrated at 21°C. After hydration the vials were opened and quickly hand-ground under a large inverted funnel through which dry nitrogen was flushed before being immediately equilibrated at relative humidities of 75%, 53%, 33% and 11% rh. Samples for derivatization were taken at 24 hours, one week, four weeks and eight weeks. The degree of hydration was determined using non-evaporable water loss and checked by X-ray diffraction (XRD) for several samples.

Derivatization was carried out using the method of Tamas et al with the quantities of the reagents doubled to counter the effects of the extra water added in the samples conditioned at high rh's. Quantitative glc was carried out using the standard described by Milestone<sup>16</sup>. Polymeric silicate (more than 6 Si-O linkages) was determined gravimetrically by heating the mixture of derivatives at 180° for 24 hours. The percentage of oligosilicates (units of 3-6 Si-O linkages) was determined by difference and is subject to an error of  $\pm 3\%$  in actual value. Results are expressed as a percentage of total silica in the paste.

## RESULTS

The amounts of the various silicate phases in C<sub>3</sub>S pastes derivatized after 24 hour equilibration are shown in Table I and monomer and polysilicate percentages plotted in Figure 1.

TABLE I					
$\alpha$	Silicate Phase	Relative Humidity

\* Percentage of gel monomer

Fig 1. Silicate Phase Changes with Drying.

At the lower degrees of hydration, the amount of monomer present can largely be accounted for by unhydrated  $C_3S$  present in pastes dried below 53% rh. At  $\alpha = 0.78$  and 0.86 only for the pastes dried at 33% rh or less can the percentage of monomer be related by to the content of unhydrated  $C_3S$ . For pastes equilibrated at higher relative humidities the percentage of monomer is greater than can be accounted for by unhydrated  $C_3S$  but as the pastes are dried the amount of monomer decreases until a constant value is obtained at 11% rh.

(See Fig 1)

Little systematic variation in percentage of dimer appears to occur as samples are systematically dried. However, there does appear to be an increase in oligosilicate on increased drying especially with  $\alpha = 0.55$  but the error in oligosilicates is so large that no significant change is noted at  $\alpha > 0.78$ .

The effects of storage at the various relative humidities on phase composition are shown in tables II-IV, selected results are plotted in figure 2.

There is little change with time for any phase in pastes equilibrated at 11% rh. However, for all pastes equilibrated at 33% rh or higher, there is an increase in polysilicate with time. This is accompanied by a decrease in monomer content and a slight increase in dimer content with time.

Results obtained from cement pastes cured in the same manner were difficult to interpret and the results are not shown. Berger et al.<sup>14</sup> suggested that foreign ions such as Al and S could cause an apparent reduction in polysilicate by substituting in the silicate structure and the presence of these ions may complicate the changes observed for the cement pastes.

Fig 2. Effect of Silicate Composition on Ageing.

#### DISCUSSION

The phase composition changes as hydration proceeded were similar to those reported by other workers<sup>9,10,12</sup>. There is a decrease in monomer content with a subsequent increase in dimer followed more slowly by an increase in polysilicate content. Small amounts of oligosilicates are present, especially those due to linear trimer and cyclic tetramer. After an initial increase in the amount of these species, there is a decrease to a low constant value as hydration proceeds.

The most marked changes occurring in the paste on drying are the decrease in monomer content, together with the general increase in polysilicate content. (Fig 1) There is little systematic change in the amount of dimer present on drying pastes at all values of  $\alpha$ . A slight increase in the amount of oligosilicates occurs upon drying but this is pronounced for  $\alpha = 0.55$ . An initial increase in the amount of trimer was noted by Sarkar and Roy<sup>17</sup> in cement pastes that had been vacuum dried. Dent Glasser et al<sup>18</sup> showed that all the monomer present in their samples could be accounted for by unhydrated  $C_3S$  in the pastes. However, their pastes were vacuum dried. Monomer contents for the pastes dried to 11% rh in this study also closely relate to the amount of unreacted  $C_3S$ . For the less severely dried pastes more monomer is present than can be accounted for by unreacted  $C_3S$  and it is thus clear that some monomer must be present in the C-S-H gel.

Rothbaum and Rohde<sup>19</sup> postulated that in silica polymerization in dilute solutions, the monomer preferentially reacted with polymeric silica units rather than another monomer unit, since the amount of dimers and higher species in solution was low. A similar reaction could explain the lack of

large dimer increase upon drying, together with the slight increase in oligosilicates and the large increase in polysilicate. In the sample with  $\alpha = 0.55$ , there is very little polymer present before drying and so condensation of monomer with dimer and oligosilicates occurs giving the large oligosilicate increase rather than a high polysilicate increase.

There is little change with time of the proportions of the silicate phases for pastes dried at 11% rh. (Tables II-IV). After the increase caused by drying no further ageing takes place. It has been noted that processes such as creep do not occur in well dried pastes<sup>20</sup> and irreversible changes occur upon drying CSH(I)<sup>8</sup>.

For  $\alpha \geq 0.65$  the changes upon ageing are significant. Polysilicate increases with time, especially in pastes equilibrated at 75% and 53% rh, with a consequent reduction in monomer (See Fig 2). The gel monomer (obtained by subtracting the silica due to unhydrated  $C_3S$  and shown by the figures in brackets in tables I-IV) decreases with an approximate half-life of 1½ weeks.

For the pastes with  $\alpha = 0.65$  and 0.86 the results plotted in Fig 2 show that the greatest changes occur when the pastes are equilibrated at 75% rh. The time-dependent monomer decrease has almost reached zero after 8 weeks for  $\alpha = 0.65$  and 10 weeks for  $\alpha = 0.86$  but the amount of polysilicate continues to increase with time. Thus ageing is not associated solely with the loss of gel monomer but there must be continued contribution from the dimer and oligosilicates. The values of  $\alpha$  in pastes equilibrated at 75% rh were analysed by XRD. Non-evaporable water analyses repeated at

the end of the experiment showed a slight decrease but XRD showed no significant change in  $\alpha$ . The decrease in non-evaporable water could be expected if a continued polymerization reaction occurred since some will escape as evaporable water.

When Bentur et al<sup>15</sup> found evidence for monomer in the gel at 4°C, the amount was pronounced only at low values of  $\alpha$  and in young pastes, and decreased with time as the polysilicate was formed. They postulated that in the process monomer  $\rightarrow$  dimer  $\rightarrow$  polysilicate, the rate determining step was that of dimer to polysilicate. However this was based on results obtained from pastes derivatized after 11% rh drying. It is clear that drying can give a false picture of the relative proportions of the various phases. Thus the rate constant for step 2 may not be very much less than that for step 1 which would mean that in the young saturated paste a considerable proportion of gel still exists as monomer. When a young paste is dried the capillary forces would force the silicate units closer together, especially those of the monomer which are likely to exist in solution, creating a condition where polymerization is likely to occur.

In an aged, but not dried, paste all the gel monomer will have reacted, although the polysilicate formed may be of a different nature. In the results discussed by Bentur et al<sup>13</sup>, drying caused large increases in polysilicate content of pastes with  $\alpha = 0.42$  but the changes were not marked in pastes with  $\alpha = 0.68$ . However, in this case the pastes had been stored for some time and so could not be considered young.

It is possible that some monomer is formed during the derivatizing process but this amount is likely to be small. Derivatization trials with 14Å tobermorite and xonotolite show that crystalline hydrous polysilicates derivatize as 97-98% of polymer<sup>21</sup>. Further after four weeks of 'ageing' at 75% rh the pastes show little more monomer than expected from unhydrated material.

The above results show that monomeric silicate exists in the C-S-H gel of fresh silicate pastes. It has not been detected previously because pastes have been severely dried.

#### CONCLUSIONS

When an immature silicate paste is dried, there is an increase in the amount of polysilicate present in the paste together with a decrease in the amount of monomer. For pastes dried at rh's higher than 33% monomer is present in the gel.

An ageing process occurs in pastes equilibrated at rh's greater than 33% rh with the greatest

change occurring at 75% rh. Polysilicate content increases with time and the gel monomer content decreases with a half-life of approximately 1½ weeks.

These processes can be explained by a process of silicate polymerization where further Si-O-Si bonds are formed on drying or ageing.

# On the effect of preventing drying shrinkage cracks of expansive cement concrete

## *Action préventive contre les fissures et retrait du ciment expansif dans les bétons*

J. ISOGAI, Senior Research Chemist

S. NAKAYA, Civil Engineer,

H. NISHIMURA, Research Chemist, Denki Kagaku Kogyo Co., Ltd., R and D Department of Omi-Plant, Japon.

SUMMARY : In the field of civil and architectural engineering in Japan, the usefulness of the calcium sulfoaluminate expansive admixture has come to gain a wide public acceptance.

In the case of concrete using the calcium sulfoaluminate expansive admixture, the amount of the free shrinkage due to drying in the nonrestraint state is less than ordinary concrete, and also the extensibility of concrete is greatly increased by expansion.

In the studies, preventive effects on the drying shrinkage cracks by the reduction of drying shrinkage and the increase of extensibility were elucidated chemically.

And, it was made clear that the extensibility of expansive cement concrete increases in proportion to the amount of capillary pores formed by expansion, and also the amount of drying shrinkage decreases in proportion to the amount of Ettringite formed in capillary pores.

RESUME : Au Japon, l'emploi, en génie civil et dans le bâtiment, d'additions produisant du sulfoaluminate de calcium expansif, connaît un certain développement.

Dans les bétons utilisant de telles additions, le retrait non contrarié, dû au séchage, est plus faible que celui des bétons ordinaires, et leur expansion en est bien augmentée.

Des études ont permis d'élucider les phénomènes chimiques qui, dans ces bétons, diminuent les risques de fissuration de retrait, par réduction de ce retrait et augmentation de l'expansion.

Il a été clairement établi que l'expansion de ces bétons croissait proportionnellement au volume des pores capillaires créés par l'expansion, et que le retrait hygrométrique diminuait proportionnellement à la quantité d'ettringite formée dans ces pores.

## 1. INTRODUCTION

In the field of civil and architectural engineering in Japan, expansive admixture of calcium sulfoaluminate type, which are being used in quantities with a purpose of reducing drying shrinkage cracks or of introducing chemical prestress, have gained a wide public acceptance because of its usefulness<sup>1)</sup>. The concrete using the calcium sulfoaluminate expansive admixture is characterized by less free shrinkage amount on drying in a nonres-trained state than ordinary concrete and also a remarkable increase in the extensibility of concrete by expansion.

In the studies, with an intention of elucidating chemically the aforesaid characteristic properties of the concrete using the calcium sulfoaluminate expansive admixture, experiments with the following three subjects were carried out:

1) the elucidation of hydration process for cement paste, 2) the elucidation of expansion phenomenon for cement mortar, and 3) the elucidation of preventive effect on drying shrinkage cracks for concrete and the quantitative grasping of its preventive effect.

## 2. EXPERIMENTS

The results of chemical analyses for the calcium sulfoaluminate expansive admixture and the normal portland cement used in the experiments are given in Table 1.

	ig. loss	in-sol	SiO <sub>2</sub>	Al <sub>2</sub> O <sub>3</sub>	Fe <sub>2</sub> O <sub>3</sub>	CaO	MgO	SO <sub>3</sub>
P.C.	0.8	0.1	21.9	5.1	3.0	64.2	1.2	2.1
C.S.A.	1.2	0.6	2.9	11.0	0.5	52.8	1.0	29.5

The main mineral composition of the expansive admixture includes 15.7%  $C_4A_3S$ , 13.0%  $C_{12}A_7$ , 16.9% free-CaO, 52.6%  $CaSO_4$  and the rest.

## 2-1 PASTE EXPERIMENTS FOR ELUCIDATING HYDRATION PROCESS

With an object of making clear the hydration process of normal portland cement paste which is added the calcium sulfoaluminate expansive admixture ( hereinafter referred to as CSA expansive admixture ). a cement paste of a water-cement ratio of 0.40 was prepared by using a 11% CSA expansive admixture-mixed normal portland cement. And, expansion due to hydration in the early period were measured by a Le Chatelier simplified expansion tester and then hydration process was investigated in detail by using X-ray diffraction, a differential thermal balance, and a scanning electron microscope.

## 2-2 MORTAR EXPERIMENT FOR ELUCIDATING EXPANSION PHENOMENON

In the experiments, with a purpose of investigating the change in the fine pore structure of hardened mortar with the hydration and expansion of expansive cement, a cement

mortar of a cement-sand ratio of 1 : 2 and a water-cement ratio of 0.45 was prepared by using 0, 7, 11, and 15% CSA expansive admixture-mixed normal portland cement. Using a scanning electron microscope, the shapes of Ettringite and calcium hydroxide, which are causative of expansion, were observed and also by a mercury porosimeter, the variation in the fine structure of hardened mortar was investigated.

## 2-3 CONCRETE EXPERIMENTS FOR MAKING CLEAR PREVENTIVE EFFECT ON CRACKS DUE TO DRYING SHRINKAGE

Table 2 shows the mix proportion of concrete and also Fig. 1 illustrates concrete specimens for crack development.

In the experiments, with a purpose of quantitatively making clear the effect of reducing drying shrinkage and the effect of preventing cracking for the case where a CSA expansive admixture-mixed ordinary portland cement concrete (hereinafter referred to as expansive concrete) was cured under water at 20°C for a definite period and then dried at 20°C, 60%RH, an examination was made of a relation between the fine structure of hydrate in paste portion of concrete and its mechanical characteristics.

	W/C (%)	S/A (%)	CSA (%)	Unit weight (kg/m <sup>3</sup> )				
				C	CSA	W	S	G
Plain concrete	537	39	0	300	0	161	753	1187
CSA concrete	537	39	10	270	30	161	753	1187

## 3. EXPERIMENTAL RESULTS AND CONSIDERATIONS

3-1 ELUCIDATION OF HYDRATION PROCESS OF PASTE<sup>2)</sup>

The early expansion developing curve of paste, obtained by a Le Chatelier simplified expansion tester, is shown in Fig. 2, and also the result on the powder X-ray diffraction for hardened cement paste is given in Fig. 3 and 4.

Fig. 2- Early expansion developing curves of paste by a Le Chatelier Simplified expansion tester.

Fig. 3- X-ray diffraction intensity of Ettringite produced at each age.

Fig. 4- X-ray diffraction intensity of  $\text{Ca}(\text{OH})_2$  produced at each age.

The crystalline Ettringite, which is considered to be one of the causes of expansion of the CSA expansive admixture, reaches a saturation at the age of approx. 16 hours regardless of curing conditions, after which no change was observed in the Ettringite. The fact gives a ground that expansion amount is not necessarily related to the amount of formation of Ettringite, similarly to the case with long ages. The early expansion developing curve as shown in Fig. 2 indicates that the crystalline Ettringite does not take part in the expansion development of hardened cement paste. The result on the dehydration curve of Ettringite obtained by a differential thermal

balance is given in Fig. 5.

Fig. 5- Relative weight loss curves of Ettringite measured by differential thermal balance.

The result shows that it is related to the early expansion developing curve shown in Fig. 2, showing the presence of noncrystalline Ettringite such that powder X-ray diffraction fail to detect. And, crystalline  $\text{Ca}(\text{OH})_2$ , as shown in Fig. 4, which is formed by the hydration of free- $\text{CaO}$ , seems to somewhat relate to the expansion of cement paste.

In consequence, it was made clear from an investigation into the hydration process of hardened CSA expansive cement paste under varying curing conditions that the hardened cement paste expanded in proportion to the amount of formation of noncrystalline Ettringite and the amount of formation of crystalline  $\text{Ca}(\text{OH})_2$ .

### 3-2 ELUCIDATION OF EXPANSION PHENOMENON OF MORTAR<sup>3)</sup>

Since the hydration process of the CSA expansive cement was made clear from basic experiments with cement paste, an investigation was made on how the constitutional structure of hardened cement mortar is changed by expansion due to hydration. The result on the observation of the fine structure of hardened cement mortar by a scanning electron microscope is given in Fig. 6, and also the result on the measurements of expansion is given in Fig. 7.

In the case of normal portland cement mortar the hexagonal calcium hydroxide crystals and calcium silicate hydrate crystals were merely observed. And, in the case of a 7% CSA-added mortar of less expansibility, comparatively large needle-like crystal suspected to be formed in voids by a through solution reaction was observed, but fine Ettringite considered to be formed by a topochemical reaction was not almost observed. For a 11% CSA-added mortar which shows optimum expansion amount, two forms of Ettringites were recognized and also  $\text{Ca}(\text{OH})_2$  crystals were observed. And, for a 15% CSA-added mortar which shows great expansion amount, great amounts of fine Ettringite were observed, indicating that the fine Ettringite crystals have a close relevance to expansion. Fig. 8 shows the pore size distribution of

capillary pores obtained by a mercury porosimeter in terms of the fine structure of hardened mortar.

Fig. 6-Scanning electron micrographs.

Fig. 7-Ratio of free expansion of expansive cement mortars.

Fig. 8-Pore size distributions of expansive cement mortars cured in water for 28 days at 20°C.

From Fig. 8, it was proved that the fine structure of hardened expansive cement mortar

is greatly increased its capillary pores of a fine pore radius of 75 to 1400 Å by expansion. In other words, the expansion phenomenon due to hydration of hardened cement mortar is proved to accompany an increase in capillary pores within a specific range.

### 3-3 ELUCIDATION OF PREVENTIVE EFFECTS ON CRACKS DUE TO DRYING SHRINKAGE FOR CONCRETE<sup>4)</sup>

As a result of basic experiments with cement mortar, the fine pores of the hardened CSA-mixed cement mortar are made clear to be increased within a specific range as a result of expansion due to hydration. Thus, experiments on the development of cracks for concrete were made with an intention of making clear preventive effects on the drying shrinkage cracks of the CSA expansive admixture having such an expansion characteristic.

In Fig. 9, the amount of free shrinkage accompanying the drying of nonrestrained test specimens is given. The amount of drying shrinkage of the CSA concrete is 10 to 30% less than the ordinary concrete, and particularly lowest in case where water curing was made for approx. 7 days in the early period.

Fig. 10 gives the change in the amount of shrinkage accompanying the drying of restrained specimens for crack development. Cracks developed at the shrinkage of  $100 \times 10^{-6}$  to  $200 \times 10^{-6}$  for the ordinary concrete, whereas for the CSA concrete, no cracks developed even at the shrinkage of  $400 \times 10^{-6}$  to  $500 \times 10^{-6}$ . In short, the CSA concrete has a greater extensibility than the ordinary concrete, indicating that cracks are hard to develop in the CSA concrete.

Fig. 9-The change of the strain due to drying shrinkage of nonrestrained test pieces.

Fig. 10-The change of the strain due to drying shrinkage of restrained test pieces.

Although little difference in mechanical properties between the CSA concrete and the ordinary concrete was recognized, the time when cracks develop in the restrained test specimens was entirely different, as shown in Fig. 10.

In the case of the CSA concrete, it is made known that the extensibility is increased by expansion arising from the formation of fine Ettringite caused by a topochemical reaction and the growth of crystals from  $\text{Ca(OH)}_2$  gel formed by the hydration of free- $\text{CaO}$ . The fine voids formed by expansion, consisting of independent fine voids of a pore radius of 75 to 1400 Å, disperse and absorb the drying shrinkage stress. From a point of view of mechanics, creep increases and an effect of relaxing internal stress (drying shrinkage stress) resulting from drying is produced, whereby suppressing the development of cracks. When being placed in a dried state, comparatively large Ettringite crystals are formed by a through solution reaction, where no expansion takes place and the constitution of hardened concrete is made denser, resulting in an effect of reducing the drying shrinkage amount of concrete. In the case of the CSA concrete, the age at which cracks develop is greatly delayed as compared with the case with ordinary concrete. However, the fact can be noticed only from the observation of cracking, but not by prediction.

Thus, the prediction of the drying shrinkage cracking resistance of the CSA concrete was tried by using the values of early expansion characteristics and strength characteristics and the following equation was proposed.<sup>5)</sup>

$$K_{cr} = \epsilon_b \times \sigma_c / \epsilon_f \quad (1)$$

Where  $K_{cr}$  is index of drying shrinkage crack durability,  $\epsilon_b$  is max. restrained expansion rate,  $\epsilon_f$  is max. free expansion rate, and  $\sigma_c$  is compressive strength at the time of max. expansion.

As understood from the equation(1), the greater the value of  $K_{cr}$ , the greater is cracking resistance.

In this report, the equation(1) is a mere proposal. Further investigations on relations between data obtained at experimental room and the data obtained from actual structures will be made and then more accurate experimental equation will be given.

#### 4. CONCLUSION

In order to elucidate effects on the drying shrinkage cracks of concrete using a calcium sulfoaluminate expansive admixture, experiments with (1) the elucidation of the hydration process of cement paste, (2) the elucidation of the expansion phenomenon of cement mortar, and (3) the development of cracks of concrete were carried out and obtained the following results:

- 1) The causative factors of expansion of the CSA expansive admixture are the formation reaction of fine noncrystalline Ettringite and the growth of crystals from  $\text{Ca(OH)}_2$  gel.
- 2) Expansion due to hydration greatly increases capillary voids of a pore radius of 75

to 1400 Å in expansive cement mortar.

3) The extensibility of expansive concrete becomes greater in proportion to the increment of capillary voids by expansion arising from the formation of needle-like fine Ettringite by a topochemical reaction during the early period of hardening and also the growth of crystals from  $\text{Ca(OH)}_2$  gel formed by the hydration of free- $\text{CaO}$ .

4) The free shrinkage amount of expansive concrete becomes smaller in proportion to the amount of formation of comparatively large Ettringite by a through solution reaction in the capillary voids, whereby the constitution of hardened concrete is made denser.

# The evolution of the structure of cement paste investigated by radiometric emanation method

## *L'évolution de la structure de la pâte du ciment étudiée par la méthode radiométrique d'émanation*

V. BALEK, M.Sc. Ph.D., Nuclear Research Institute, Rez, Czechoslovakia,  
 V. SATAVA, Prof., D.Sc., Institute of Chemical Technology, Prague, Czechoslovakia,  
 J. DOHNALEK, M.Sc., Ph.D., Building Research Institute, Technical University, Prague, CSSR.

**RESUME :** La méthode radiométrique d'émanation (MRE), fondée sur la mesure des gaz inertes radioactifs échappés des échantillons, donne la possibilité d'obtenir des informations sur la grandeur de la surface interne et sur les changements du coefficient de diffusion de ces gaz dans les systèmes étudiés. On décrit un mode d'application original de la MRE à l'étude de l'hydratation de la pâte du ciment. On a pu observer, d'une façon continue, les changements de structure au cours de tout le processus étudié, dans des conditions choisies d'humidité et de température.

Une comparaison des résultats de la MRE avec les méthodes en usage habituel démontre que la MRE livre de nouveaux aspects sur le mécanisme de la formation de la pierre du ciment; on pourrait l'appliquer par exemple à la détermination de la quantité optimum de gypse comme additif pour le réglage de la prise du clinker du ciment portland. On a aussi démontré les avantages de la mesure en continu de la vitesse d'émanation et des changements de structure de la pierre du ciment au cours du séchage et de la déshydratation. Les résultats ont confirmé l'hypothèse du caractère réversible de la structure de la pierre du ciment.

L'avantage de l'appareil MRE, produit commercial de Netzsch, consiste dans la possibilité de la mesure automatique dans un régime programmé. Du point de vue de la sécurité du travail avec les radioisotopes en question, en utilisant des concentrations en traces, un laboratoire chimique bien équipé peut effectuer ces mesures. La méthode radiométrique d'émanation peut devenir un instrument nouveau pour l'étude de l'hydratation de la pâte du ciment et de l'influence des différents facteurs.

**SUMMARY :** The radiometric emanation method (REM) based on the measurement of radioactive inert gases released from the samples studied gives the possibility of obtaining information on the size of the inner surface area and on the changes of the diffusion coefficient of these gases in the investigated systems. In this paper an original kind of application of REM in the investigation of the hydration of cement paste is described. By means of REM it was possible to study the changes of structure during the whole hydration process investigated continuously and under the conditions of the required humidity and temperature.

From the comparison of the results found by REM with those obtained by commonly used methods it follows that REM affords new insights into the evolution of the structure of a cement stone; it might be applied e.g. to the determination of the optimum amount of gypsum added to the regulation of the setting of Portland cement clinker. The advantages of the continuous measurement of emanation rate were further shown on the investigation of the changes of structure of the Portland cement stone during drying and rehydration. The results corroborated the view of reversible character of the structure changes of a cement gel.

The advantage of the REM apparatus, produced commercially by Messrs.NETZSCH, consists in the possibility of automatic measurement in a programmed regime. Even a well equipped chemical laboratory complies with the requirements of safe work with radioisotopes in question in the given trace concentration. The radiometric emanation method possesses all preconditions for becoming a new tool for the investigation of the hydration of cement paste and of the influence of various factors on this process.

## INTRODUCTION

The study of processes occurring after the mixing of cement with water usually consists in stopping the process after chosen time intervals and investigating the morphology and nature of phases present in the system. On the basis of the data obtained the hypothesis explaining the mechanism of the whole process is searched for. This discontinuous technique brings a number of experimental and interpretation difficulties.

The aim of this contribution is to show certain possibilities of studying the hydration and the setting of cement paste given by the radiometric emanation method (REM) which makes it possible to follow continuously the changes of structure in the system investigated.

## PRINCIPLE OF THE RADIOMETRIC EMANATION METHOD

The radiometric emanation method (REM) is based on the measurement of radioactive inert gases, e.g. of radon, released from the material investigated. Before the measurement, it is usually necessary to incorporate the radioactive gas into the material under study, in other words to label the material with a radioactive isotope. This labelling can be achieved by a number of methods (1), e.g. by the incorporation of trace amounts of thorium or radium isotopes into the sample. These isotopes represent a constant source of the radioactive emanation-radon. The atoms of radon  $^{220}\text{Rn}$  can be produced for example by the decay of thorium  $^{228}\text{Th}$  emitting alpha radiation

The inert gas does not react with the material under study and it is released from this material as a result of both the recoil energy - which every atom gains when formed by the decay of radium - and the diffusion to the surface of the sample. The radioactivity of gas makes possible its detection in trace amounts, causing thus the high sensitivity of the method. In practice, the rate of the release of the radioactive inert gas from the sample is measured which is denoted as the emanation rate. The relation valid (1) for the emanation rate  $E$  of a grain or of a set of isolated grains of a solid is

$$E = S \left[ k + (D/\lambda)^{1/2} \right] \rho \quad /2/$$

where  $S$  - is the specific surface area of the solid,  $k$  - is a constant independent of temperature,  $D$  - is the diffusion coefficient of radon in the material investigated,  $\lambda$  - is the decay constant of radon,  $\rho$  - is the density of the solid.

Hence, by measuring the rate of the radon release we can obtain an information on the changes of diffusion coefficient of radon in the material investigated and the chan-

ges of the boundary area between solid and liquid phases which occur during microstructural transformations in the system investigated.

## EXPERIMENTAL

## Materials used

Portland cement PC 400 (specific surface area  $0.86 \text{ m}^2\text{g}^{-1}$ )  
ground Portland cement clinker (specific surface area  $1.90 \text{ m}^2\text{g}^{-1}$ )  
precipitated gypsum, R.G. (specific surface area  $3.0 \text{ m}^2\text{g}^{-1}$ )  
The phase composition of ground Portland cement clinker was as follows:  
 $\text{C}_3\text{S}$  - 69.7 %,  $\text{C}_2\text{S}$  - 11.0 %,  $\text{C}_3\text{A}$  - 8.2 %,  $\text{C}_4\text{AF}$  - 6.4 %, free  $\text{CaO}$  1.29 %.

## Preparation of labelled samples

The procedure applied to the radioactive labelling of investigated materials consisted in the impregnation of the original feed materials with a solution containing trace amounts of parent radionuclides of the inert gas. Carrier-free parent radionuclides present in the impregnation solution are practically immediately adsorbed on the surface of the sample and as a result of the recoil of radium or radon during the radioactive decay of the parent nuclides in question they penetrate into the bulk of the material into the depth of approximately  $1 \mu\text{m}$ . In the samples of cement pastes produced from PC 400 the labelling occurred at the beginning of hydration by the adsorption of  $^{228}\text{Th}$  and  $^{224}\text{Ra}$  nuclides from the mixing water. Ground Portland cement clinker or gypsum were labelled at least one week before the mixing with water. The labelling of cement clinker was performed by its impregnation in acetone solution with trace amounts of  $^{228}\text{Th}$  and  $^{224}\text{Ra}$ . The labelled gypsum was prepared by the hydration of plaster with an aqueous solution containing trace amounts of  $^{228}\text{Th}$  and  $^{224}\text{Ra}$  radionuclides.

The activity of the samples of aqueous suspensions of binding materials was equal to  $5 \times 10^3 - 5 \times 10^5 \text{ Bq}$  at the mass of 2 g.

## Equipment for REM measurements

The REM measuring equipment is shown schematically in Fig. 1. It consists of following parts: the carrier gas circuit, the measuring cell into which the sample is placed, the system of detection and registration of radioactive gas released from the sample, the chamber with the detector of alpha activity, connected with the counts-rate meter, and the equipment keeping the sample at the required experimental conditions (temperature, humidity, chemical composition of the gas medium). The data of the counts-rate meter are presented digitally and registered by a recorder or a printer with a perforated tape output.

Fig. 1 - The scheme of the apparatus for radiometric emanation method: 1 - the carrier gas supply, 2 - flow-stabilizer and flow-meter of the carrier gas, 3 - equipment for the regulation of humidity and chemical composition of the carrier gas, 4 - measuring cell with the sample, 5 - temperature controller of the measuring cell, 6 - chamber for radioactivity detection, 7 - flow-meter for the carrier gas, 8 - counts-rate meter, 9 - digital voltmeter, 10 - printer, 11 - recorder

This equipment, which is a part of a series of equipments for simultaneous thermal analysis DTA-TG-ETA produced by Messrs.NETZSCH (3) allows to perform the measurements under various conditions maintained automatically according to the given program (temperature, humidity, flow-rate of carrier gas, gas pressure).

The measurement was carried out as follows. The vessel containing the sample of paste was placed instantly after the mixing of the binder with water into the measuring cell. Air, used as a carrier gas, passed in the immediate proximity of the sample and carried the released atoms of radon into the measuring chamber. The constant flow rate ( $0.7 \text{ ml s}^{-1}$ ), temperature ( $20 \pm 2^\circ \text{C}$ ) and relative humidity ( $95 \pm 3\%$ ) of the carrier gas were secured after passing through the measuring chamber the radioactive emanation was carried into the ventilation of the chemical laboratory. When the sensitivity of the structure of cement stone to the humidity changes of medium was investigated, the measurement was carried out in a gas (air) medium with the relative humidity of  $65 \pm 3\%$  with the aim to achieve the drying of the sample.

#### Further parameters measured

Besides REM the time dependence of other physical quantities which can characterize the course of processes taking place in the cement paste on hydration was investigated. Specific surface area ( $S$ ) was determined by the method of Nelsen and Eggertsen (2). Porosity (PS) and distribution of the size of pores in the range from 7.5 nm to 7500 nm were measured by the

method of mercury porosimetry (apparatus produced by Carlo Erba, type AG 65). Penetration resistance ( $R$ ) was determined as the ratio of the strength needed for the penetration of a cylindrical indenter into the setting cement paste to the cross-sectional surface of this indenter (4). Ultrasonic longitudinal wave propagation rate ( $v_L$ ) was determined by means of the apparatus RECO (GDR) with the transducer with natural frequency. The beginning and the period of setting, and/or the end of setting of cement paste were established by the standard Vicat test. The time course of hydration reaction was followed continuously by conductivity calorimetry (5).

## RESULTS AND DISCUSSION

### I. THE EVOLUTION OF STRUCTURE OF CEMENT PASTE DURING SETTING

Fig. 2 shows the time dependence of the rate of radon release from two samples of cement pastes prepared from the labelled PC 400 with the cement-water ratio  $w/c = 0.28$  (sample I) and  $w/c = 0.55$  (sample II). From the comparison of the curve I in Fig. 2 with the time dependence of the change of penetration resistance ( $R$ ) (Fig. 3, curve 1) and with the rate of ultrasonic wave propagation ( $v_L$ ) (Fig. 3, curve 2) it is evident that the increase of the emanation rate of the sample of cement paste corresponds to the time dependence of ( $R$ ) and ( $v_L$ ) and the beginning of the increase of the emanation rate  $E$  corresponds quite exactly to the beginning of setting determined by the Vicat test (see the hatched region in Fig. 3).

Fig. 2 - Time dependence of the emanation rate  $E$  of the samples of cement paste with the  $w/c = 0.28$  (curve I) and  $w/c = 0.55$  (curve II)

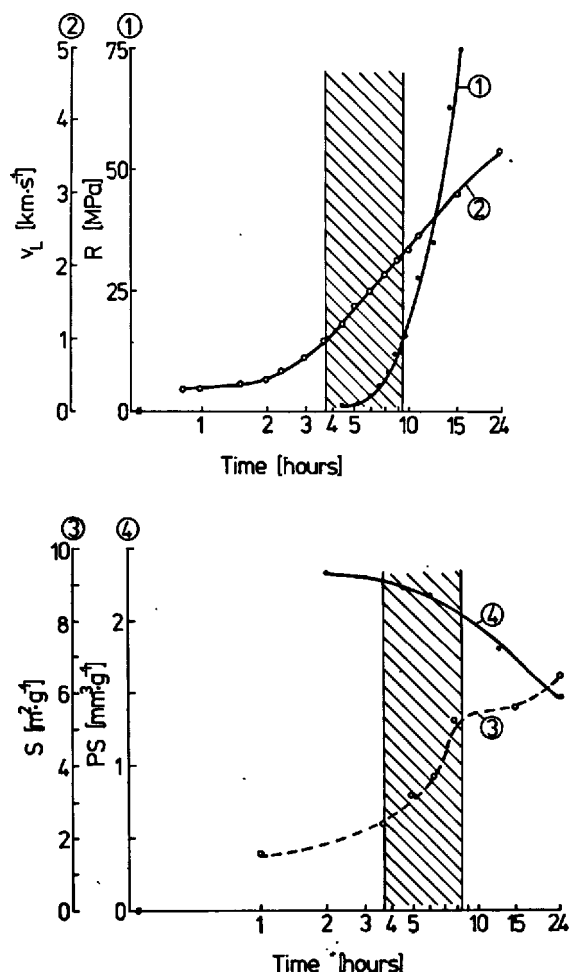

Fig. 3 - Time dependence of the measured physical parameters characterizing the hydration of the sample I (see curve I in Fig. 2):

penetration resistance (R) - curve 1; ultrasonic wave propagation rate ( $v_L$ ) - curve 2; specific surface area (S) - curve 3, and capillary porosity (PS) - curve 4.

The increase of the emanation rate in Fig. 2 is caused evidently by the increase of the specific surface area of the solid phase brought about by the rising amounts of hydration products, the specific surface area of which is by several orders of magnitude higher than the specific surface area of the original cement grains (6). The correctness of this explanation is proved also by the time course of the specific surface area shown in Fig. 3, curve 3. The decrease of the capillary porosity in the course of the process (curve 4 in Fig. 3) does not limit the curve of the emanation rate. Therefore, it can be supposed that the capillary porosity in the measured range of the pores (size from 7.5 nm to 7500 nm) does not influence the diffusion coefficient of radon in the material investigated.

Also the investigation of the structure of pores of the samples I and II led to the same conclusion. After 12 hours setting the volume ratio of capillary pores in the sample II was approximately 2x higher than in the sample I, while the emanation rate of both samples is about the same (see Fig. 2).

Thus it seems that the structure of gel hydration products is independent of the values of w/c ratios of the studied samples I and II. The plateau which appears on the curve of the emanation rate in the region of the end of setting (independent of the w/c ratio of the samples) corresponds also to the course of the specific surface area of the solid phase and it is probably caused by the decrease of the surface area of the sample. This effect can be ascribed most probably to the transition of ettringite to  $C_4ASH_{13}$  which takes place after the consumption of gypsum in the reacting system.

The following monotonous increase of the emanation rate is caused by the increase of the surface area of the hydration products of  $C_3S$  and  $C_3A$  building the cement gel.

As a further evidence of applicability of radiometric emanation method are shown the results of the investigation of the influence of gypsum admixture on the initial period of hydration of ground Portland cement clinker. The time dependence of the emanation rate of the suspension of ground clinker with the admixture of 0, 2, 4, and 6 % of gypsum together with the corresponding dependence of changes of penetration resistance are shown in Fig. 4. The specific surface area of clinker was chosen higher, in order to show the processes taking place in the suspension in the initial period of hydration more distinctly.

Fig. 4 - Time dependences of emanation rate (E), (curves A,B,C,D) and of penetration resistance (R), (curves A',B',C',D') of the samples of ground Portland cement clinker with the admixture of 0 - 6 % of gypsum: curves A,A' - sample without gypsum, B,B' - 2 %, C,C' - 4 %, D,D' - 6 % admixture of gypsum. In all samples the clinker was labelled with radioisotopes.

The increase of the emanation rate of the suspension of the ground clinker without gypsum (Fig. 4, curve A) is caused by hydration of  $C_3A$  which results in instantaneous hardening (Fig. 4, curve A'). Even if the amount of the reacted  $C_3A$  in this initial period is relatively low (7), it can be judged from the pronounced effects on the emanation curves A, A' that the product causing the hardening has a large surface area. Further increase of emanation rate accompanied with the increase of penetration resistance occurring after a certain incubation period, can be ascribed to the increase of specific surface caused by the hydration products of  $C_3S$ ,  $C_2S$  and of remaining  $C_3A$ .

The moderate decrease of emanation rate during the incubation period is probably the result of recrystallization of hydrated calcium aluminates giving most probably  $C_4AH_{13}$ . The changes of penetration resistance are less pronounced in this period.

The hydration of ground cement clinker in the presence of gypsum is also demonstrated by the increase of emanation rate (Fig. 4, curve B) which takes place, however, with a certain delay. It can be supposed that it corresponds to the formation of ettringite with a high specific surface area. From the curve B' in Fig. 4 it can be seen that this process is also accompanied with the increase of penetration resistance. However, if the system contains a higher amount of gypsum (curve C' in Fig. 4) the increase of penetration resistance of the sample is lower, goes through a maximum and decreases again.

From the course of the emanation rate (curve C in Fig. 4) it can be concluded that ettringite formed recrystallizes, its surface area decreases and also its binding abilities go down (see curve C', Fig. 4).

At an even higher content of gypsum the effect on the curve of emanation rate is less pronounced (see Fig. 4, curve D) and the effect on the curve of penetration resistance disappears completely (Fig. 4, curve D'). As the amount of the ettringite formed in all the samples studied is the same (the degree of  $C_3A$  hydration is independent of the presence of gypsum (7)) and because the emanation rate of the sample represented by the curve D, Fig. 4, increases only insignificantly, we have to suppose that relatively large particles of ettringite with a low surface area are formed in this case. The low number of the large particles of ettringite is incapable of forming a continuous structure which would result in hardening of the system investigated (curve D', Fig. 4).

The evidence that the measured emanation rate provides an information on the character of structure of newly formed phases mainly, characterized by large surface area, is demonstrated by the REM curves in Fig. 5. From this figure it follows that the character of REM curves is practically identical regardless of the fact which of the both solid phases (gypsum or ground cement clinker) is labelled with a radionuclide.

Fig. 5 - Time dependences of emanation rate (E) of samples of water suspension of Portland cement clinker with the admixture of 2 % of gypsum (curve 1 and 2) and 4 % of gypsum (curve 3 and 4). In the samples both cement clinker (curve 1 and 3) and gypsum (curve 2 and 4) were labelled with radioisotopes.

Fig. 6 - Time dependences of the release of hydration heat (curve 1), emanation rate (curve 2) and penetration resistance (curve 3) of the sample of a water suspension of Portland cement clinker with 2 % of gypsum. For REM measurements in the preparation of the sample gypsum labelled with radioisotopes was used.

Fig. 6 shows the curves obtained by three different methods during the investigation of the setting binder suspension. Each of these curves reflects the course of hydration processes from a different point of view. While the calorimetry (curve 1) provides an information only on the achieved degree of transformation of all hydration reactions, the other two methods (curve 2 and 3) give the picture of the structure

of the investigated system which occur as a result of the hydration reactions; these structure changes determine the plasticity of binder suspensions and therefore are most important from the practical point of view.

The radiometric emanation method could be applied to the determination of the optimum amount of gypsum added to the Portland cement clinker, similarly as the calorimetric method (8). Such an amount of admixed gypsum could be considered as optimum that just brings about the disappearance of the effect caused by the formation and recrystallization of ettringite (see Fig. 4). The advantage consists again in the completely continuous and fully automated measurement of emanation release rate.

## II. CONTINUOUS INVESTIGATION OF THE SENSITIVITY OF CEMENT GEL STRUCTURE TO THE CHANGES OF HUMIDITY

In the region of cement paste setting the emanation rate is controlled first of all by the increase of the surface area of hydration products. In the following stages of the process, when the hydration reaction is controlled by the diffusion of water to the non-hydrated cement grains, the change of surface area with time is low and a less pronounced rise of emanation rate gradually takes place.

However, it became evident that the pronounced changes of emanation rate occur when the cement stone is kept in the gas medium with the various water vapour pressure. Fig. 7 shows the dependence of emanation rate  $E$  of the sample of cement stone after 14 days of hydration, on the time of keeping in the air medium with a various water vapour pressure.

The samples were gradually put into air atmosphere with  $95 \pm 3\%$  humidity and then measured in a stream of air with  $65 \pm 3\%$  humidity. The saturation of the samples with water during their storage in air with  $95 \pm 3\%$  humidity results in the increase of emanation rate, while the drying in the course of measurement causes its rapid decrease. From the data obtained it also follows that with the increasing time of saturation the relative rise of emanation rate gradually decreases though its absolute values keep increasing.

Simultaneously, it was verified that on keeping the sample in the air with high relative humidity the mass of the samples rose as a result of saturation of the samples with water; during the measurement, which was carried out in the air with a lower relative humidity the mass of samples usually decreased.

The changes of the emanation rate observed cannot be caused by the changes of specific surface area which in the time period of the emanation rate measurement changes only insignificantly; thus being the result of the changes of radon diffusion rate in the system investigated. The changes of the diffusion coefficient are raised by structure transformations in the cement gel. The sensitivity of REM to the effects described is

Fig. 7 - Time dependence of the emanation rate  $E$  of the sample of Portland cement stone ( $w/c = 0.28$ , time of sample aging 14 days) on the time of storage in the air medium with various water vapour pressure. x-axis = time of storage /min/ of the sample in the air medium of  $95 \pm 3\%$  humidity, y-axis = time of storage /min/ of the sample in the air medium with  $65 \pm 3\%$  humidity, z-axis = emanation rate  $E$  of the sample /imp s<sup>-1</sup>/.

probably given by the fact that the size of gel pores is comparable with the diameter of the diffusing radon atoms  $d = 0.42$  nm; the changes of size of gel pores are therefore clearly expressed on the emanation rate curve.

A possible direct influence of water molecules on the values of the emanation rate of the cement stone samples was eliminated by following experiments. A sample of hydrated plaster was measured using the same procedure as for the cement stone. The structure of plaster has (contrary to that of cement stone) the character of a rigid skeleton which does not undergo structure changes caused by drying the sample or its saturating with water. With this sample the effects on the REM curve shown in Fig. 7 did not appear. The emanation rate values of the hardened plaster paste saturated with water and of the same sample after its drying were practically identical.

The presented results of emanation release rate measurements of the hardened cement stone suggest that during the water saturation of the sample as well as during its drying the continuous changes of its diffusion coefficient take place. If we accept the hypothesis about the layer arrangement of the C-S-H gel, the results can corroborate the views supposing that the layers of the dried C-S-H gel are not permanently

drawn together and that the action of water can cause their drawing away as a result of penetrating of water into the gel pores (9).

#### CONCLUSIONS

The potentialities of the application of the radiometric emanation method to the investigation of hydration and setting of the cement paste were shown. REM not only complements the commonly used experimental methods but also provides new views on the processes taking place during the evolution of cement stone structure.

The advantage of REM consists in the possibility of the continuous investigation of the changes of structure during the whole duration of the process of setting of the cement paste namely under the conditions of required humidity, temperature and chemical composition of the gas medium around the sample. This gives the possibility to investigate the ways of influencing the process of setting e.g. by temperature or admixtures, under the conditions interesting from the point of view of both science and technology.

We have shown the possibility of continuous investigation of the changes of cement stone structure on drying and rehydration of the sample, not necessitating any additional interference with the measured samples which would cause undesirable changes in the structure of the sample studied.

Radiometric emanation method possesses all preconditions for becoming a new source of information on the evolution of structure of binding systems.

By parallel measurement of two released radioactive gases, REM makes possible to discern also the role of surface area and diffusion in the emanation release rate of the sample measured. This can give more complete information on the structure evolution of the systems investigated.

The commercially produced apparatus for radiometric emanation measurements by NETZSCH (F.R.G.) is fully automated and a well equipped chemical laboratory is suited, complying with the requirements of the safety of work with radioactive isotopes in the trace concentration, when the REM apparatus have to be employed.

# Interaction of cement minerals with water

## *Interaction des composants du ciment avec l'eau*

P.F. RUMYANTSEV, Doctor, Institute of Silicate Chemistry of the Academy of Sciences of the USSR, Leningrad, U.R.S.S.

RESUME : Le durcissement des ciments est lié aux processus d'interaction chimique entre les composants solides du ciment et un liquide. De tels processus peuvent aussi se produire au cours de la cuisson du clinker.

Jusqu'ici on avait établi que l'interaction chimique entre les minéraux solides du ciment et les liquides, dans les systèmes de ciments, se produisait non pas régulièrement sur toute la surface des grains, mais sur des zones séparées, donc localement.

Pour représenter le processus chimique qui se produit, on a établi les équations suivantes :

$$V = \frac{A}{D} e^{-\frac{E}{RT}} \quad W = W_0 [1 - e^{-kt^n}] \quad V = \frac{\bar{u} n \epsilon S}{4 \nu}$$

L'utilisation de ces formules permet d'obtenir de nouvelles informations scientifiques sur la vitesse et le mécanisme du durcissement du ciment, et sur le processus de cuisson du clinker. Elle permet aussi d'établir un modèle mathématique pour l'automatisation des techniques de fabrication du ciment.

SUMMARY : Hardening of cements is related with the processes of chemical interaction between solid cement minerals and a liquid. Such processes can also take place during the burning of cement clinker.

It has been established hitherto that the chemical interaction between solid minerals and liquids in cement systems proceed not uniformly throughout the surface of the minerals but on its separate parts, i.e. locally.

To describe the chemical processes which proceed by the indicated mechanism, the following equations can be used:

$$V = \frac{A}{D} \cdot e^{-E/RT} ; \quad W = W_0 [1 - \exp(-kt^n)] \quad V = \frac{\bar{u} n \epsilon S}{4 \nu}$$

The use of these formulas permits to obtain new scientific information about the rate and the mechanism of hardening of cements, of the burning of clinker as well as to create the mathematical model for the automatization of technological processes in cement industry.

The processes of chemical interaction between solids and liquids are widely spread in nature and technique. They are realized during the hardening of cements and burning of clinker, and being heterogeneous in their nature they proceed according to the scheme:

If one assumes that A, B, C can be represented by several components, then it becomes apparent that the study of these processes is a complicated and difficult task. The latter may explain a considerable lag in the development of theoretical conceptions and in the establishment of kinetic regularities of such processes as compared to homogeneous.

For the last two decades several comprehensive monographs of basic importance have been published on kinetics of homophase processes /1-4/, whereas the publications on kinetics of heterogeneous processes are of less important, private character /5/. No universal methods of the determination of the rates of such processes exist.

In recent years we carried out investigations on the kinetics of interaction between cement minerals and liquids at high and room temperatures. Some common results of these studies are reported in the present communication.

The chemical interaction of solid cement minerals with a liquid proceeds in three stages:

1. Chemical interaction between the particles of solid substance and the liquid at the phase interface.
2. Diffusion of the decomposition products of solid substance or of the interaction products between solid and liquid into the bulk of the liquid.
3. The formation of new liquid and solid phases in solution up to the crystallization of the solid phase.

All these stages first proceed consecutively and then simultaneously. The rate of the process will be determined on the whole by the stage with a lower rate. Taking account of this fact and introducing the parameter characterizing the surface area of the solid body permitted to use the kinetic equations which were earlier derived for simple processes.

To describe the temperature dependence of the rate, the well-known experimental Arrhenius equation was used, the parameter taking into consideration the surface area having been introduced as a constituent member of the pre-exponential multiplier:

$$V = \frac{A}{D} \cdot e^{-E/RT} \quad (1)$$

The use of the given formula permitted to determine the effective activation energies of the processes studied and to conclude which of the stages plays the determining role in each process.

In several cases the change in value of the

effective activation energy with increasing temperature was established what permitted to reveal the new character of interaction and to fix temperatures at which these processes proceed. The reasons of non-constancy of the effective activation energies were changes in the chemical composition of the liquid phase or the appearance of the film of new formations on the surface of the primary solid sample.

The experimental data on the isothermal processes were successfully analyzed with the aid of the well-known Kholmogorov-Erofeev equation

$$W = W_0 [1 - \exp(-kt^n)] \quad (2)$$

The analysis of the above given formulas permitted to find that for the burning of cement clinker the dissolution is the limiting factor, whereas for the hydration process of calcium aluminates and for the interaction of alumina and silica with phosphoric acid it is the diffusion.

The first stage, namely the interaction on the phase interface is a less studied stage being of the greatest interest from the view-point of the kinetics of heterophase processes.

The chemical interaction on the solid-liquid interface is a topochemical process whose mechanism can be represented as follows /6-8/.

On the active surface of the mineral particles the polar molecules or ions are adsorbed what results in the formation of a polymolecular layer in which the orientation of dipoles leads to the appearance of the interphase jump of potential, therefore the dissolution of the particles is accompanied by intense diffusion flows of new formations.

The orientation of polar molecules is most expressed in the adsorption layer near the interface and it decreases with increasing distance from the surface forming chains which intergrow deep into the liquid layer.

Thus the diffusion flows during dissolution are polarizing factors.

The oriented polarization of polar groups orders and determines, under conditions of crowding, the controlled character of gel formation and crystallization. However, this concept requires precision as it is based on the more or less uniform activity of the total surface and suggests the presence of the uniform front of interaction. Under real conditions the deviation from the mechanism spoken of is observed in most cases. Thus, for example, during the dissolution of cement minerals the dispersion of the initial particles takes place in the liquid phase of clinker; during the hydration of calcium aluminates figures of etching are clearly observed; during the hydration process of calcium aluminates and interaction of single crystals of alumina and silica with phosphoric acid the new formations ap-

pear only at the separate parts of the surface and only later when these parts increase and merge the solid layer is formed.

Thus, the dissolution proceeds more preferably in the reactive parts or in the active centers which play an essential role during the dissolution of solid materials (like the case of their decomposition).

By "active centers" we mean atoms located in the crystal lattice defects emerging on the surface. Such atoms possess the lowest coordination in the lattice as compared to the other atoms on the surface, and therefore they are most reactive. The form and the area of such parts are determined by the surface defects.

The migration of atoms located in the lattice defects from the crystal to the liquid causes in turn the formation of new reactive parts the role of which is played by atoms which were formerly connected with the ones that passed into solution.

To explain the formation of new reactive parts by analogy with Garner /9/, we suggest the model of local branched chains. Recently it became clear that the group of topochemical reactions can be divided into two sub-groups. In one of them the chain branched reaction proceeds only on the surface, large parts (centers) being formed in the point of branching. In the second sub-group the chains are not limited by the points on the outer crystal surface but penetrate also into the depth thus causing the cracking of crystals. In the first case when the supersaturated solution (with respect to the other interaction products) has been formed, the layer of solid new formations may appear.

The results of many works confirm the applicability of the mechanism under discussion.

Thus, studies on the dissolution of clinker minerals in the liquid phase showed the presence of topochemical dissolution referred to the second sub-group. The branching of the chains into the depth of the crystal can proceed along the lines and planes of dislocation or along the mosaic planes. A visual example of such a mechanism is the dissolution of sugar in water or in tea.

Crystal defects are widely spread in cement minerals and, as shown in the works of Butt and Timashev /10, 11/, they influence considerably the physico-chemical properties, the activity during the interaction with water included.

Studies on the hydration of calcium aluminates performed on single-crystal samples led to establish the first type of local chain branched reactions with the formation of the film of calcium hydroaluminates which slows down considerably the interaction process between the initial solid sample and water.

Consequently, the earlier suggested scheme which describes the uniform front of interaction between the particles of liquid and

solid bodies on the surface of the latter and the diffusion of the interaction products into the deeper layers of the liquid should be corrected with taking into consideration the occurrence of local active parts on the surface. It is obvious that the front of interaction will not be uniform. It will have the form of semispheres what should cause a strong deviation from the diffusion mechanism adopted in the first scheme into the direction of its complexity. The latter can also be due to the fact that in some cases the appearance of the film formed of the liquid-solid interaction products takes place on the surface of the solid sample.

For such a mechanism, from Eq.(1), the number of acts of chemical interaction on the unit surface per unit time is equal to one fourth of the product of the average rate of the molecule motion,  $\bar{u}$ , by the number of particles (molecules) of the liquid per  $1 \text{ cm}^2$ ,  $n$ , and by the probability of reaction in collision,  $\xi$ , :

$$V_s = \frac{\bar{u} n \xi}{4} \quad (3)$$

The rate of the solid-liquid reaction can be described as the product of  $V_s$  (from formula (3)) by the full value of the solid body surface,  $S$ , divided by the volume of reactive system,  $V$  :

$$v = \frac{\bar{u} n \xi}{4} \frac{S}{V}$$

The value of the average rate of the particles (molecules) motion in these two formulas is determined following the formula

$$\bar{u} = \left( \frac{8kT}{\pi m} \right)^{1/2} \quad (4)$$

and the reaction probability in collision according to the formula

$$\xi = n_s \sigma_s p e^{-E/RT} \quad (5)$$

Here  $n_s$  is the number of active parts per unit surface;  $\sigma_s$  is the area of one active part;  $p$  is the probability of orientation or the steric factor;  $n_s \sigma_s$  is the total area of the active parts per  $1 \text{ cm}^2$  of the surface.

Thus, the rate appears to be proportional to the number of reactive particles, and the value

$$k = \frac{\bar{u} \xi}{4} \frac{S}{V}$$

can be regarded as the effective constant of the first order value for reaction of the particles with the surface.

It should be noted in this case that the value of  $n$  is the concentration of particles (the number of particles per  $1 \text{ cm}^3$ ) near the surface. If the reaction proceeds very rapidly, then as a result of consumption of the particles near the surface the concent-

ration of them will be lowered and the non-uniform distribution of particles will take place in the system. The rate of reaction will also depend on the rate of diffusion of particles towards the surface. But in those cases when the film of new formations appears on the surface of the solid body (which was already mentioned), the reaction rate will depend on the rate of diffusion of particles through the film.

Now turn again our attention to formula (4). By substituting the values of  $U$  and  $\epsilon$ , one obtains the unfolded equation of the form

$$V = \left( \frac{8kT}{\pi m} \right)^{1/2} \frac{n_s \epsilon_s p e^{-E/RT}}{4} \frac{S}{V} n \quad (6)$$

By uniting the constant values into one value, we obtain the Arrhenius equation in the form which was used by us earlier for a study of the dissolution of clinker minerals:

$$V = S A e^{-E/RT} \quad (7)$$

The given mathematical method shows, firstly, the correct use of Arrhenius equation for the analysis of our experimental results, and secondly, it discovers the meaning of the pre-exponential multiplier for the case of heterogeneous processes.

#### CONCLUSION

The use of the fundamental kinetic equations for a study of the mechanism and of the rate of interaction between cement minerals and a liquid permits to gain new information of great scientific importance which can be applied in mathematical modelling of the automatization processes of cement technology.

Further development of investigations in this field should be made using new methods and directed toward the more profound study of the elementary acts of chemical interaction, especially on the surface of cement minerals.

# Estimating strength from cement composition

## *Prévision des résistances à partir de la composition du ciment*

L.P. ALDRIDGE, Scientist, Chemistry Division, DSIR, Private Bag, Petone, New Zealand.

**SUMMARY :** Simple equations have been found which predict the compressive strength at 3, 7, 28, 91 and 365 days from the Bogue compositions of  $C_3S$ ,  $C_3S+C_2S$ ,  $C_3A$  and specific surface. The equations were determined using multiple regression analysis of data from 114 cements. The standard deviations of the calculated compressive strengths range from 2.8 to 3.6 and the square of the multiple regression coefficients ranges from 0.73 to 0.86.

The equations are empirical equations as the coefficients could not be used to predict the individual component effect. While the equations are shown to fit the strengths of concretes produced from New Zealand cements they should be used with caution by workers wishing to apply them to other cements.

The major factors influencing compressive strength were shown to be the Bogue composition and the specific surface of the cements. Minor oxides had a small effect on the compressive strength.

**RESUME :** Des formules mathématiques simples ont été établies, permettant de prévoir la résistance à la compression des ciments à 3, 7, 28, 91 et 365 jours, en fonction de leur surface spécifique et de leur composition, selon Bogue, en  $C_3S$ ,  $C_3S + C_2S$  et  $C_3A$ . Ces formules ont été établies au moyen de nombreux calculs statistiques de régression portant sur les résultats expérimentaux de 114 ciments. L'écart type des valeurs ainsi calculées varie entre 2,8 et 3,6, et les coefficients de corrélation entre 0,73 et 0,86.

Ces formules sont empiriques; aussi ne doivent elles pas être utilisées pour apprécier l'action de l'un des composants du ciment. Bien que ces formules aient montré une bonne corrélation avec la résistance des bétons confectionnés avec des ciments de Nouvelle Zélande, elles doivent être utilisées avec précaution pour être appliquées à d'autres ciments.

Les facteurs les plus importants, qui déterminent la résistance à la compression, sont la composition selon Bogue et la surface spécifique des ciments. Les oxydes mineurs ont un effet réduit sur cette résistance à la compression.

## INTRODUCTION

Despite the efforts of a number of workers the relationship between cement composition and the compressive strength is still not fully understood. Alexander (1) reviewed the attempts of some authors to relate strength to the composition and specific surface of cements. He used empirical equations, derived by multiple regression analysis, to relate the 3, 7, and 28 day compressive strength of cement pastes to the specific surface and the Bogue  $C_3S$  and  $C_3A$  composition.

There were indications from earlier work carried out by the author (2) that the compressive strength of concretes made from New Zealand cements gave better fits than Alexander's samples (1). In this study simple equations were generated to predict the compressive strengths at ages up to one year. The effects of additional variables on the regression equations were studied.

## EXPERIMENTAL

## Materials

The 114 cements studied were from a series of samples which had been taken at monthly intervals over a five year period from five cement works (A-E) and for which chemical analyses were available. The compressive strengths at 3, 7, 28, 91 and 365 days were determined using the New Zealand Standard (NZS 3122:1974) method which uses 100 x 200 mm concrete cylinders and a water cement ratio of 0.50. Coefficients of variation of the strengths have been found by repeated within-laboratory testing to be less than 2.5%. The specific surface was measured using the air permeability method. Bogue compositions were calculated after subtracting the free lime from the CaO content and assuming that all the manganese was present in the ferrite phase. Ranges of the Bogue compositions, the amount of the minor oxides, the specific surface, free lime, insoluble residue and compressive strength are shown in Table I.

## Multiple Regression Analysis

The methods and limitations of multiple regression analysis are well known (3,4). In this study  $R$  denotes the multiple correlation coefficient and gives the fraction of the total variation about the mean compressive strength explained by the regression equation,  $s$  denotes the standard error estimate, an estimate of the standard deviation of the calculated compressive strength derived from the regression equation, and  $r$  denotes a correlation coefficient between two variables. The computer program (SHARE Library Number 360D-13.6.008) used in this study has been described (3).

A number of problems in regressions involving cement composition were identified by Alexander (1). Some variables were highly

correlated with each other; these were  $C_3S$  with  $C_2S$  ( $r=0.9$ ) and  $C_3A$  with  $C_4AF$  ( $r=0.8$ ). Furthermore the sum of the variables  $C_3S, C_2S, C_3A$  and  $C_4AF$  is a constant and so these four variables are not independent.

A number of preliminary fits were carried out to determine which variables to include in the regression equations. It was then decided to use the variables in the initial equations which would be expected from cement chemistry to be the most influential. The variable  $C_4AF$  was not included in the regression equations and instead of  $C_2S$  the variable  $(C_3S + C_2S)$  or the sum of the silicate phases was used.  $C_3S$  was not highly correlated to  $(C_3S + C_2S)$  as  $r=0.35$ . Equations 1, 2, 3, 4 and 5 were fitted by multiple regression to all samples and also those from individual works; and the values of  $R^2$  obtained are shown in Table II. If the additional variables gave a significant increase to the degree of fit (determined by an  $F$  test at the 5% level) then this is indicated by an asterisk in Table II.

$$CS = b_0 + b_1 C_3S + b_2 C_3A + b_3 Sp-S \quad 1$$

$$CS = b_0 + b_1 C_3S + b_2 C_3A + b_3 SO_3 + b_4 Sp-S \quad 2$$

$$CS = b_0 + b_1 C_3S + b_2 (C_3S+C_2S) + b_3 C_3A + b_4 Sp-S \quad 3$$

$$CS = b_0 + b_1 C_3S + b_2 (C_3S+C_2S) + b_3 C_3A + b_4 SO_3 + b_5 Sp-S \quad 4$$

$$CS = b_0 + b_1 C_3S + b_2 (C_3S+C_2S) + b_3 C_3A + b_4 SO_3 + b_5 TiO_2 + b_6 MgO + b_7 Na_2O + b_8 K_2O + b_9 Mn_2O_3 + b_{10} fr-l + b_{11} IR + b_{12} Sp-S + b_{13} P_2O_5 \quad 5$$

where CS is the compressive strength,  $b_0$  to  $b_{13}$  are empirical coefficients, Sp-S is the specific surface, IR is the insoluble residue and fr-l is the free lime.

## RESULTS AND DISCUSSION

The results from Table II show that regression equation 3 gave significantly better fits than equation 1 when fitting strengths from all of the cements. Equation 5 which included the extra variables, free lime, the minor oxides and insoluble residue gave a more significant fit (at the 5% level) than equation 3 for all the compressive strengths except that at 7 days. It was not possible to determine which of the additional variables gave by itself a significant improvement to the fit. Mallow's Cp statistic (3), gave many alternative choices between combinations of variables and none of these combinations were duplicated at different ages of the compressive strength.

It is recommended that equation 3 be used for predicting the compressive strength of New Zealand cements. (See Table III). Although equation 5 gave a statistically better fit the maximum increase of  $R^2$  (0.04) does not warrant the trouble of including the additional terms. It is possible that the co-

efficients of equation 3 in Table III could apply to the compressive strengths of concretes made from any Portland cements. The equations have been derived from New Zealand cements and workers using other cements should not use these equations before testing them on cements whose composition, specific surface and compressive strength is known.

Cements from different works did not give the same coefficients in the regression equations. Table IV gives the coefficients when equation 1 was fitted to the 3, 7 and 28 day compressive strengths of cements from, all the works, works A, works E, and works A and E. Coefficients are seen to vary considerably. The coefficients of the regression equations cannot be used therefore with any confidence to predict the effect on compressive strength of individual components.

TABLE IV

Coefficients of regression equation 1

Cement Works	$b_0$	$b_1$	$b_2$	$b_3$	$R^2$	$s$
3 day						
All	-30	.79	.64	.073	.84	2.9
A	-47	.86	1.74	.032	.92	2.4
E	-26	.32	.58	.072	.93	2.5
A & E	-29	.46	1.72	.072	.92	2.6
7 day						
All	-34	.58	1.12	.078	.84	3.8
A	-32	1.09	.98	.087	.87	3.4
E	-33	.57	1.10	.079	.94	3.2
A & E	-34	.71	.75	.071	.91	3.5
28 day						
All	2.5	.45	1.14	.045	.61	4.9
A	35	.64	-.87	-.018	.68	3.1
E	9.1	.45	.22	.050	.78	4.0
A & E	12.1	.50	.22	.038	.73	4.1

The values of the standard deviations of the calculated compressive strength,  $s$ , are higher than the standard deviations of the observed compressive strength  $s_0$ . For 3 day compressive strength  $s = 2.8$  MPa and  $s_0$  lies between 0.4 and 1.0 MPa while for the 365 day strength  $s = 2.9$  MPa and  $s_0$  lies between 1.6 and 1.9 MPa. Furthermore the standard deviations of the compressive strength calculated by the method of error estimation from near neighbours (3) by the computer program was approximately the same as  $s$  suggesting that the fitting procedure could not be taken any further with the present variables.

The high values of  $R^2$  obtained when equation 3 was fitted implies that the compressive strength of concrete for New Zealand cements is largely dependent on the composition and specific surface of the cement. The fit attained is surprising considering the errors of accuracy in the Bogue compositions (6). The percentage of variance not explained when equation 5 was fitted to all of the cements varied between 12 and 22% (calculated from  $R^2$  values in Table II). This unexplained variance could be due either to the unreliability of the Bogue compositions, or to factors other than the Bogue compositions, the minor oxides and the specific surface. In an earlier paper (2) it was shown that better composition estimates gave no improvement to the degree of fit of equation 1 and therefore it can be concluded that it is the additional factors which are significant in modifying compressive strength. The nature and role of these other factors has been reviewed by Chatterjee (5) and examples of these factors are the crystal size of the alite, defects present in the alite crystals and impurities present in alite.

## CONCLUSIONS

A simple equation has been generated which predicts the compressive strength of concrete at 3, 7, 28, 91 and 365 days.

Eighty percent of the variance is explained by the regression equations and the standard deviation of the calculated compressive strength is about 3 MPa.

## ACKNOWLEDGEMENT

I would like to thank Mr J. Clelland of Central Laboratory, Ministry of Works and Development, who supplied all the compressive strength data, and for his help and advice. I also thank Mr R.A. Kennerley and Mr L.M. Smith for many useful discussions and Drs W.C. Tennant and G.J. Gainsford for their help and advice.

# The Effect of Cement Composition on the Cracking Resistance

## *L'influence de la composition du ciment sur la résistance à la fissuration*

Z. TSILOSANI, D.Eng. Professor, Head of Department,

G. DALAKISHVILI, M.Eng. Engineer, Institute of Structural Mechanics and Seismic Stability, As.Sc.GSSR.  
and

S. KAKICHASHVILI, M.Sc. Head of Department, Institute of Cybernetics, Ac.Sc.GSSR.

RESUME : Sont exposés les résultats d'étude sur la résistance à la fissuration au cours du durcissement de mortier de ciment-sable fabriqué à partir de six différents types de ciments. La naissance des fissures a été étudiée à l'aide de l'interférométrie holographique permettant de fixer l'apparition des fissures avant que cela soit possible par d'autres méthodes. Sont également décrits les dispositifs permettant d'évaluer la résistance à la fissuration au cas où le retrait du béton et la charge mécanique agissent en même temps. En plus, il a été noté que cette méthode rapprochait les résultats d'essais du béton en laboratoire de ceux obtenus au cours d'exploitation de la structure en béton.

La période entre le début de l'observation et le moment de détection des fissures sur les échantillons est prise pour la mesure de résistance à la fissuration, et l'on a effectué la comparaison des propriétés des ciments ayant différentes compositions minéralogiques et différentes teneurs en constituants non-calcinés.

Les auteurs proposent d'utiliser cette méthode d'interférométrie holographique pour déterminer la grandeur d'extensibilité limite du ciment durci et du béton.

SUMMARY: The results of studies of the cracking resistance of a hardened cement-sand solution prepared of 6 different kinds of cement are presented. Cracking is studied using the method of holography interferometry which enables to detect cracks at earlier stages than it can be done with other methods. Devices used to evaluate the cracking resistance in case of a combined action of shrinkage and mechanical load are described. The laboratory conditions for testing concrete are shown to be close to those in a real structure. Assuming the time elapsing from the beginning of observation of specimen to the moment of detection of a crack, as a measure of the cracking resistance, cements of different mineral compositions and different contents of unbaked components are compared. The authors suggest to apply the method of holography interferometry to evaluate the ultimate extensibility of cement stone and concrete.

The problem of crack formation in concrete and reinforced concrete units has long become a matter of concern of engineers and researchers. Cracks result in the decrease of the supporting power and durability of units deterioration of their service characteristics, not to mention the appearance of the structure.

Cracks are caused by various reasons-external mechanical loads or strains induced by the irregularity of settlement of supports, shrinkage and thermal strains of concrete, etc. On the other hand, resistance of concrete and reinforced concrete to cracking also depends on a number of factors, the most important among them being a tendency of concrete to an intensive development of the shrinkage strain and creep of concrete and its ultimate tensile strength.

The great variety of factors causing cracking as well as those contributing to the cracking resistance of concrete makes it difficult to predict the degree of danger. This has evidently given rise to the great number of methods created for evaluation of the cracking resistance of concrete. Hence seem to emerge different interpretations of the idea of the "cracking resistance of concrete".

An attempt has been made (1) to classify the so far suggested methods of evaluation of the cracking resistance of concrete. These are indirect and direct methods and those based on modelling a concrete structure. The indirect methods of evaluation of the cracking resistance consist in the accounting for the degree of tightness of the cement stone shrinkage strain by the counter-action of a coarse filling (with non-reinforced concrete) and reinforcement (with reinforced concrete). The cracking resistance is calculated using coefficients, the latter being derived from the concrete specifications: the ultimate tensile strength and the ultimate compressive strength, the ultimate extensibility, the elastic modulus, the shrinkage strain

value, the coefficient of internal friction, the intensity of external mass-exchange and internal moisture transfer and others. Some investigators suggest to deduce the cracking resistance from the mineral composition of cement and other factors,

It should be pointed out that the a.m. indirect methods require the knowledge of some characteristics which are not defined during standard conventional tests of concrete; for instance, the ultimate extensibility of concrete is not always evaluated and even the method of its evaluation is not unique, every investigator using different experimental means and experience, and the literature providing rather different values of the ultimate extensibility of concrete. Also the value of loose and, especially, tight settlement of concrete is not always available.

The methods of evaluation of cracking resistance based on modelling a concrete structure are doubtlessly interesting, although most of them are within the sphere of laboratory research or are too simplified and can provide results not reasonable enough practically.

The suggested direct methods of evaluation of the cracking resistance and, in particular, the method of the ring (2), which is widely used in laboratory, is quite simple, but it enables to evaluate the resistance to cracking resulting from shrinkage only; while our point of interest is the resistance to cracking resulting from shrinkage and external mechanical loads. This will bring the laboratory conditions closer to the field where the elements of constructions are subjected to the forces of shrinkage as well as forces developing from the proper weight and external mechanical load. The effect of the simultaneous forces of shrinkage and external mechanical load is not a mere sum of the effects of these two forces (3). While studying the mineral composition of cement regarding the cracking resistance, we used a special device which enabled to evaluate the cracking resistance

tance under the effects of shrinkage and external load. The method of Holography interferometry was used to observe the process of emergence and development of Cracks (4). Holography has become a widely used means of checking important parts of machines, aircraft, etc. In building it has been used but seldom, in particular, in testing concrete and reinforced concrete. However, a number of advantages of the holography methods over the conventional ones, and a common tendency to lower the prices of testing devices on the whole, rose interest to them in researchers and engineers. Thus, when the method of holography interferometry is used to test strain, it does not require any special surface characteristics (roughness, moisture), or the size of tensometers, not to mention the complicated procedure of sticking and wiring the latter, the whole picture of the strain over the surface under observation being obtained easily, which is not the case when the method of electrotensometry is used. Holography interferometry has also advantages over other optical methods, such as the method of photoelasticity, as it does not require any optically sensitive material which often fails to imitate closely the actual characteristics of concrete and reinforced concrete (5).

TABLE I

Cement No	Kind of cement	Kind and amount of unburnt component
1.	Portland cement low heat output and low alkaline content	Diatomite, 15%
2.	Portland cement	" "
3.	Portland cement	Addition, 15%
4.	Portland cement	Blast furnace granulated slag, 15%
5.	Slag Portland cement	Blast furnace granulated slag, 50%
6.	Puzzolanic Portland cement	Pumice, 35%

Below the test results of 6 kinds of cement with different mineral compositions are

given (Tables I and 2). Specimen of cement-sand mixture (maximum grain size of the filling - 5mm), 4 x 4 x 16 cm, were made, reinforced with two steel rods of 3 mm diameter. The cement-to-filling and water-to-cement ratios in the samples were the same. The samples were kept in water to avoid cracking due to heat and water treatment. The samples were loaded by means of a special device (Fig. 1). The applied force was 0.7 of the load causing observable cracks. It was defined through short-run tests of twin samples.

TABLE II

Cement No	Mineral composition				Grout of normal thickness	Strength $\frac{N}{mm^2}$
	C <sub>3</sub> S	C <sub>2</sub> S	C <sub>3</sub> A	C <sub>4</sub> AF	%	
1.	45.0	32.0	4.5	15.0	26.0	42.0
2.	60.0	17.0	4.2	15.0	23.0	50.8
3.	58.0	19.0	4.0	16.0	27.5	51.5
4.	56.1	15.9	9.4	15.7	25.0	50.2
5.	56.5	15.0	9.7	15.95	26.5	41.0
6.	37.2	35.3	14.8	9.55	32.7	39.7

To take the interferogram the loaded samples were laid on a special rack. (Fig. 2). The holograms were taken by a single-mode He-Ne laser (6328 Å wave length) of 50 mW power, using the method of double exposition and a two-beam scheme. The intervals between expositions had been defined previously, the time of each exposure was 1 minute.

Figs. 3-6 present a part of the interferograms. The specimen numbers correspond to the cement numbers given in Table 2. The first interferogram (Fig. 3) has rare broad transversal interference bands which indicate a weak development of strain along the longitudinal axis of the samples. The first specimen has a surface crack which as the subsequent interferograms

prove, does not develop any more.

Fig. 1. The loading device

Fig. 2. The rack with the specimen

For 14 hours following the loading of the specimen, the interference bands grew denser (Fig. 4), indicating an intensified process of strain of the stretched side of the specimen, which resulted from a combined effect of shrinkage and external load. After 16 post-loading hours cracks appeared in 4 specimen in the following order: 6, 3, 1 and 4. After 18 hours (Fig. 5) was seen in specimen 5, while after 20 hours (Fig. 6) in sample 5. Cracking could be observed in the shape of the interference bands. While the material under study was intact, the interference

bands were free of breaks and never crossed. As soon as cracks formed, orientation of the bands either changed, or they crossed or broke up.

Fig. 3. An interferogram of the specimen 2 hours after the loading. The numbers of the same as correspond to the numbers of the cement types in the Tables.

Fig. 4. An interferogram of the specimen 14 hours after the loading

Proceeding from the existing direct methods of evaluation of the cracking resistance, let us assume the time elapsing from loading a specimen to crack formation (i.e., the time when the typical breaks of the interference bands appear on the interferogram) as its measure. Then the kinds of cement under

study can be classified in the following way. The best crack-resistant kind is Portland-cement without any active mineral addition (cement No.1). Even a negligible amount of addition (as low as 15% of the cement weight) reduces the cracking resistance quite significantly (cement No 3).

Fig. 5. An interferogram of the specimen 18 hours after the loading.

Fig. 6. An interferogram of the specimen 20 hours after the loading

The lowest crack resistance was displayed by puzzolan Portland cement (cement No 6). It should be also noted that the mineral composition of clinker did not seem to affect the cracking resistance value of cement as active mineral additions did.

It could be thus concluded that changes in the character of the interference bands provide information on cracking much earlier than it can be observed visually or even though a 24 x magnifying glass. As the interferogram enables to evaluate also the strain value of an object, the method of holography interference can be recommended to find the values of ultimate extensibility of concrete, although it will require finding the length of the extended section as the basic value in evaluating the strain

#### CONCLUSIONS

The described method of comparative evaluation of the cracking resistance of cement stone and concrete employs the method of holography interferometry. It has been suggested to evaluate the cracking resistance under a combined action of shrinkage and external mechanical load. A special device has been designed to prove the idea; The method of holography interferometry ensures detection of a crack at an earlier stage of its development than other existing methods (visual observation of the specimen, application of tensometers, the ultrasound). Thus a better accuracy of evaluation of the ultimate extensibility of concrete is made possible.

Comparison of the cracking resistance test results for 6 kinds of cement has demonstrated that the cracking resistance depends predominantly on the active mineral additions in cement. The role of the mineral composition of cement seemed insignificant as compared with the role of additions.

# La structure de pierre de ciment de nouveaux types de béton

## *A structure of the cement stone of the new types of concrete*

K. GORIAINOV, Professeur, Chef de Chaire de Matériaux Thermo-isolants et Ceramique,  
A. STCHASTNII, Docteur ès Sciences, U.R.S.S.

**RESUME :** Cette communication expose les résultats d'observations faites au microscope électronique sur la structure fine des ciments hydratés, notamment dans des bétons à granulats de laitier. Le grossissement du microscope électronique variait de 211 à 46.800.

Les éprouvettes de ciment étaient moulées; certaines étaient comprimées sous une pression de 200 MPA. Leur résistance à la compression atteignait 70 MPA.

Des éprouvettes de béton ont été comprimées à la pression de 5 MPA ( $R_c = 90$  MPA).

On a étudié des éprouvettes de pâtes de ciment, imprégnées après durcissement jusqu'à saturation, par des suspensions de ciment.

On a constaté une disposition bien homogène des cristaux d'hydrates; dans les bétons à granulats de laitier on a observé des fils cristallins d'un diamètre compris entre 300 et 600 Å, et d'une longueur de 0,3 à 0,4 microns.

On a constaté que l'imprégnation, par une suspension de ciment, diminuait la porosité et la perméabilité des éprouvettes.

**SUMMARY:** The report gives the results of the study of the microstructure of the cement stone and concretes on the slag fillers.

There have been used an electron microscope with a resolving power from 211 till 46800.

The samples of the cement stone made under the pressure of 200 MPA and without it have been investigated. Compression strength of the samples  $R_c$  reached 70 MPA.

There have been also studied the samples from the concrete saturated with the cement suspension.

The homogeneity of disposition of the new particles have been concrete consists of crystal filaments of diameter 300-600 Å and length 0,3-0,4 MKM.

There was also proved that saturation with the cement suspension increases waterproofness of the concrete.

On a effectué des études de la structure du mortier de ciment moulée (pressée) et du béton de laitier dans les buts de fabrication des bétons à haute résistance avec une structure homogène.

On a fait aussi des études d'imprégnation de béton par solution colloïdale (suspension de ciment et d'eau) pour augmentation de résistance à la compression et d'imperméabilité à l'eau.

On a étudié l'influence de temps de durcissement sur la structure de différents types de béton au moyen de micrographie. La micrographie est faite avec orientation sur un et deux points de surface.

La caractéristique de pierre de ciment est fixé dans le tabl.I.

Tableau I

Ns	Rap- port E/C	Agrandis- sement	Mode de traitement	
			Durcissement pendant 12 h dans les con- ditions nor- males	Traitement thermique avec t° 80
1	0,28	6330	12	-
2	0,28	6330	12	4
3	0,28	6330	12	4
4	0,28	12660	12	-
5	0,1 <sup>x</sup>	6330	12	6

La micrographie a fixé le premier stade d'hydratation après 12 heures de durcissement dans les conditions normales (des.1-2). On a pu voir les particules de dimension de 1 MKM à 25 MKM. On a pu aussi fixer la structure de stratification de  $\text{Ca}(\text{OH})_2$  et C-S-H. On a pu observer les pores de dimension de 20 MKM en forme d'étoile et parallélépipède rectangle.

x) On a fait le pressage de 200 MPA/cm<sup>2</sup> pendant la fabrication de pâte de ciment avec E/C = 0,15 - 0,1

Des.1

Des.2

Après le traitement thermique pendant 4 heures on peut voir les particules lamellaires de dimension et de configuration différentes. Sur ces particules sont vus les agrégats ronds de  $\phi$  0,6-0,8 MKM. (des.3a) ainsi que les fibres (des.4). Sur les surfaces lisses de particules sont observées les pores de dimension de 500 à 4000 Å.

Des.3

Des.4

La quantité des agrégats ronds est augmentée sur les éprouvettes pressées (des.5a).

La micrographie a indiqué que la micro-structure de bétons de laitier se présente les fils cristalliques de  $\phi$  300-600 Å et de longueur 0,3-0,5 MKM (des.6).

L'espace entre les fils est remplie par les masses gélifiantes.

Des.5

Des.6

La composition de bétons de laitier était suivante: 350 kgs de ciment et 1700 kgs de laitier granulé pour 1 m<sup>3</sup> de béton. Le rapport E/C est égale de 0,6.

Les éprouvettes sont compactées par vibration et pressage. Rc de béton est égale de 92-93 MPA.

On a effectué les études de macroporosité de pierre de ciment imprégnée par suspension de ciment et d'eau sous pression.

K.Goriainov et R.Lorétova ont élaboré la méthodologie de mesure de macroporosité de pierre de ciment.

On a fait des essais de deux sortes d'éprouvettes: les éprouvettes étuvées sous l'action de t<sup>80</sup> et celles-ci imprégnées de la suspension de ciment et d'eau. On a préparé la suspension par le mélange de 2 parties d'eau et 1 partie de ciment.

Les caractéristiques essentielles de matériaux en question sont indiquées dans le tabl.II.

Tableau II

Masse volumique de mat.kg/m <sup>3</sup>	MPA	Résistance à la compression	Caractéristique
Après 28 jrs	Dans 28 jrs	Dans 28 jrs	d'éprouvettes
l'étuve	de durcissement	de durcissement	
vage	de durcissement	de durcissement	
!de dur-	!sement	!Dans 28jrs!	!d'éprou-
!cisse-	!sement	!de durcis-	!vettes
!ment	!	!sement	!
2078	2058	14,6	0,075
2150	2180	20,8	0,965
			non-imprégnées
			imprégnées

On a mesuré les pores de dimension de 10 MKM à quelques millimètres. On a fait le calcul de pores sur la surface de 2 x 2 cm.

Les résultats des essais sont fixés dans le tabl.III.

Tableau III

Ns de rectangle	Eprouvette non-imprégnée	Eprouvette imprégnée
1	25,1	13,4
2	23,6	16,1
3	10,7	12,5
4	20,4	15,9
moyenne	20%	15%

Les dimensions de pores de 75 MKM à 5 mm prédominent dans le plan de quantité les petites macropores de dimension 123-250 MKM. La superficie intérieure de pores d'éprouvettes imprégnées a été couverte de couche de suspension de ciment durcis d'épaisseur de 50-75 MKM. Ce phénomène change les propriétés d'éprouvettes imprégnées.

La structure d'éprouvettes imprégnées est plus homogène que celle-ci d'éprouvettes non-imprégnées.

Les éprouvettes imprégnées ont la plus haute imperméabilité que celles-ci non-imprégnées (0,05 MPA pour les éprouvettes non-imprégnées, 0,2-0,3 MPA pour les éprouvettes imprégnées).

#### CONCLUSIONS

1. L'essai de structure de pierre de ciment montre que non-homogénéité observée de produits d'hydratation de ciment dépend de degrés d'agrandissement.
2. On a découvert aussi que la saturation de pierre de ciment augmente la imperméabilité à l'eau et diminue sa porosité.

#### TITRES DE DESSINS

1. Micrographie à microscope de balayage de l'éprouvette de pierre de ciment à E/C de 0,23 sans pression dans 12 h de durcissement dans les conditions normales.
2. Micrographie à microscope de balayage de l'éprouvette de pierre de ciment à E/C de 0,28 sans pression dans 12 h de durcissement et 4 h de traitement thermique sous l'action de  $t^{80}$ .
- 3-4. Micrographie à microscope de balayage de l'éprouvette de pierre de ciment à E/C de 0,28 sans pression dans 12 h de durcissement et 4 h de traitement thermique sous l'action de  $t^{80}$ .
5. Micrographie à microscope de balayage de l'éprouvette de pierre de ciment à E/C de 0,1 sous pression spécifique de 200 MPA dans 12 h de durcissement dans les conditions normales et 4 h de traitement thermique sous l'action de  $t^{70}$ .
6. Béton de laitier pressé (augmentation en 12660).

# Structure and composition of compounds in some fully hydrated cement pastes

## *Structure et composition de certaines pâtes de ciment totalement hydratées*

A.E. MOORE, Materials Research Department, Cement and Concrete Association, Slough U.K.

**RESUME :** S'il est broyé jusqu'à moins de  $10\mu\text{m}$ , le clinker de ciment peut être totalement hydraté dans un délai de 60 à 90 jours. A cette finesse, les micro-cylindres ( $50\text{ mm}^2$  de section transversale) peuvent être pressés à sec pour une porosité de 60 % et un rapport d'hydratation eau/ciment de 0.5. Ils atteignent une résistance à la compression d'environ 70 MPa après 28 jours à  $20^\circ\text{C}$  et peuvent donc être considérés comme une pâte de béton.

Une étude aux rayons X révèle la formation des phases suivantes : portlandite, C-S-H, Aft et AFm. La phase C-S-H présente environ quatre réflexions hk0 mais aucune 001. La phase Aft présente un mode ettringite, y compris la diffraction 101, qui la distingue de la thaumasite. La phase AFm présente une ou deux réflexions hk0, y compris celle à 2.86 - 2.87 et une 001 ou plus.

L'étude au microscope électronique ne peut déterminer que les éléments de poids atomique de 11 et plus; l'analyse des hydrates doit donc être basée sur des proportions.

Les quatre phases contiennent les cinq éléments Ca, Si, Al, Fe et S, bien que Al et S ne soient pas toujours présents dans la phase portlandite. Les plus petites concentrations d'atomes étrangers se trouvent dans cette dernière -  $\text{Ca}(\text{OH})_2$  - soit environ 0.3 d'atomes Si et 0.05 d'atomes Fe par 10 Ca. Les autres phases démontrent une différence de composition considérable, aussi bien entre les différents échantillons que dans chaque échantillon. Les quantités totales d'atomes étrangers sont plus grandes qu'on ne pensait possible précédemment. Le rapport C/S varie en C-S-H entre 1.25 et 4.0, et le total  $\text{Al}+\text{Fe}+\text{S}$  varie de 0.1 à 0.9 du Si. La phase Aft contient du Si et du Fe, bien qu'il y ait moins de Fe que de Si et le rapport  $\text{Al}:(\text{Si}+\text{Fe})$  est environ 2:1. La phase AFm contient plutôt plus de Fe et moins de Si que la phase Aft. S est toujours insuffisant (en partie en raison de la perte dans le microscope électronique) dans la phase Aft aussi bien que dans la phase AFm.

Le rapport  $\text{Fe}/(\text{Al}+\text{Fe})$  est toujours inférieur dans les phases Aft et AFm et plus élevé dans la phase C-S-H que dans le clinker anhydre.

**SUMMARY:** Cement clinker, if ground to less than  $10\mu\text{m}$ , can be fully hydrated in 60-90 days. At this fineness micro-cylinders ( $50\text{ mm}^2$  cross-sectional area) can be dry-pressed to 60% porosity, giving 0.5 water/cement ratio on hydration. These reach a compressive strength of about 70 MPa after 28 days at  $20^\circ\text{C}$ , and may therefore be regarded as being representative of paste in concrete.

Analysis by X-ray diffraction shows the compounds formed to be portlandite, C-S-H, Aft and AFm phases. The C-S-H shows about four hk0 reflections but no 001. The Aft shows an ettringite pattern including the 101 diffraction that distinguishes it from thaumasite. The AFm phase shows one or two hk0 reflections including that at 2.86 - 2.87 and one or more 001.

Analytical electron microscopy can only determine elements with atomic number equal to or greater than 11, and analyses of hydrate phases must therefore be based on ratios.

All four phases contain the five elements Ca, Si, Al, Fe and S although Al and S are sometimes absent from portlandite. The latter -  $\text{Ca}(\text{OH})_2$  - shows the smallest concentrations of foreign atoms about 0.3 Si and 0.05 Fe atoms per 10Ca. The other phases show considerable variation in composition both between different samples and within each sample. The total levels of foreign atoms are larger than has previously been considered likely. The C/S ratio varies in C-S-H between 1.25 and 4.0, and the total  $\text{Al}+\text{Fe}+\text{S}$  varies from 0.1 to 0.9 of the Si. The Aft phase contains both Si and Fe, though less Fe than Si, with  $\text{Al}:(\text{Si}+\text{Fe})$  about 2:1. The AFm phase contains rather more Fe and less Si than does the Aft. S is always deficient (only in part due to loss in the electron microscope) in both Aft and AFm.

The ratio  $\text{Fe}/(\text{Al}+\text{Fe})$  is always lower in the Aft and AFm phases and higher in the C-S-H than in the anhydrous clinker.

## INTRODUCTION

Lawrence (1) has shown that there is a sharp change in aqueous phase composition during cement hydration when the  $(SO_4^{--})$  ion is no longer available;  $(Ca^{++})$  decreases while  $(OH^-)$  and the alkali metals increase;  $SiO_2$  also increases though it remains very low. It is well known that aluminoferrite trisulphate (AFt) phase forms before  $SO_4$  depletion and monosulphate types (AFm) thereafter, but it seemed possible that different C-S-H compositions might form during these regimes. In order to approximate the early and late hydration situations, samples were made with cement clinker or with excess gypsum added.

In addition, the XRD pattern of C-S-H<sup>\*</sup> is notoriously disordered, and it was hoped that, at full hydration it might be easier to resolve in the absence of lines from the anhydrous phases. Cement of normal fineness does not hydrate completely at normal water-cement (w/c) ratios in times up to 100 years, and even at w/c = 5 or more may require ten years to react completely. However, if the cement is ground so that no particles are larger than 10  $\mu m$ , an OPC will hydrate completely in about two months. If the ground cement is dry-pressed into small right cylinders (2) the porosity attainable is about 60%; this gives a w/c of about 0.5 when hydrated by evacuating the cylinders and allowing water to replace the vacuum. Thus a fully hydrated paste may be obtained at w/c similar to those used in practice. Another advantage of this technique is that flash set problems do not occur, and the samples may be made from ground clinker without added gypsum.

## Experimental

Three clinkers, chosen to cover a wide range of chemical and compound composition, (A, B and C in Table I) were ground in an agate swing-mill to a specific surface of about 1400  $m^2/kg$ , (this gives an average particle size of 5-6  $\mu m$ ). Clinkers B and C were also combined with gypsum (laboratory grade) in weight ratio 9:1. Specimens were prepared by compressing the dry powder into right cylinders of 50 mm<sup>2</sup> cross section with about 60% porosity; these were put in a vacuum desiccator kept at 20°C, evacuated for at least  $\frac{1}{2}$  hr and then water at 20°C was allowed to replace the vacuum. The cylinders were kept in water at 20°C until testing; two being tested for compressive strength at each age:- 1, 2, 4, 8, 16, 32 and 64 days.

The crushed cylinders from A, B and C were stored in methanol, but when it was found that AFt phase is rendered X-ray amorphous by 8 days of this treatment, samples from BG and CG were stored in iso-propyl alcohol, or taken straight from water.

X-ray diffraction photographs were taken (on a Nonius Guinier camera) as soon as possible after crushing, and XRD traces (on a Philips vertical-circle diffractometer) of the samples at maximum hydration.

Samples were prepared for analytical electron microscopy by grinding and dispersing ultrasonically in iso-propyl alcohol, and then taking up a drop of the liquid on a carbon-coated grid. The Kratos CORA

Analytical Electron Microscope allows particles in the sample to be examined in transmission and by electron diffraction, and to be analysed for elements of atomic number  $\geq 11$  by energy-dispersive analysis of X-rays emitted from the back of the sample. Thus compositions which contain H, O, N or C cannot be analysed completely and analysis must be based upon ratios of elements.

Chemical and XRD analysis of clinkers

## Identification of phases in the electron microscope

Calcium hydroxide was easily identified by its thin hexagonal plates and strong hexagonal diffraction pattern. AFt phases were prismatic and showed no diffraction pattern; they bubbled vigorously in the electron beam and probably decomposed even before counting could begin. Lachowski et al (3) showed that the AEM analysis even of natural ettringite was deficient in sulphur, and to some extent in calcium, by comparison with the classical chemical analysis, but that synthetic calcium aluminate monosulphate was much more stable: they found S/Ca = 0.23, (Theoretical 0.25).

AFm phases could sometimes be recognised as uniform thin plates, and sometimes gave one or two diffraction spots, but were generally not distinguishable from C-S-H, by morphology or electron diffraction.

C-S-H never gave diffraction patterns, and both AFm and C-S-H often showed damage after analysis.

## \* Cement chemical nomenclature

C = CaO, S = SiO<sub>2</sub>, A = Al<sub>2</sub>O<sub>3</sub>, F = Fe<sub>2</sub>O<sub>3</sub>, M = MgO, H = H<sub>2</sub>O,  $\bar{S}$  = SO<sub>3</sub>

## Results

### Strength Development (Table II)

Clinkers A and C developed strength very rapidly and were virtually completely hydrated at 16 days; addition of gypsum to C accelerated hydration slightly and increased strength by about 30%. Clinker B did not reach full hydration (even at 128 days) but showed about 30% more strength than clinkers A and C at 64 days; gypsum addition accelerated the reaction considerably and increased strength by about 25%, but hydration was still not complete at 64 days.

Both microscopy (in reflected light) and XRD confirmed the presence of small amounts of belite and  $F_{SS}$  in the B and BG samples at 64 days, and the absence of anhydrous phases in A, C and CG at 64 days was confirmed by XRD.

TABLE II					
Age	Crushing Strength (MPa)				
	A	B	C	BG	CG

Strength development of micro-cylinders

### X-ray Diffraction

As expected AFt phases were absent from A, B and C; AFm phases showed 001 reflections at 8.1 and 7.6 Å, which for pure materials would indicate carbonation; (normal care was taken to avoid CO<sub>2</sub> contamination during preparation, using CO<sub>2</sub>-free water for hydration etc., but the cylinders were exposed, damp, during compression testing). These lines are both present, though weaker, in the XRD traces from CG and that at 8.1 Å, also weak, in BG. A fairly sharp line at 2.87 Å is probably also due to an AFm (hk0) reflection, but there was no similarly shape line at 1.66 Å.

Table III lists broad reflections which were either probably or possibly due to C-S-H. Those which appear only in samples B and C are likely to be due to AFm phases, while those which appear at similar intensity in B and BG, C and CG are more likely to be due to C-S-H. The first two lines listed are overlapped by strong ettringite lines, so it is impossible to tell whether they are present in BG and CG. The reflections at 4.03 and 2.015 Å could thus be 002 and 004 for the 8.1 Å AFm phase, though the 2.015 Å are rather more alike in intensity than the 8.1 Å.

The reflections at 1.82 and 1.66 Å have a half peak width of 2 degrees 2θ (i.e. 1.84 - 1.80 Å and 1.674 - 1.654 Å) and could be said to indicate C-S-H I but none of the other lines make a convincing case for this, and the presence of a wide halo from 3.2 - 2.7 Å does not help the identification. In the light of the results to be reported from the analytical electron microscopy this is perhaps not surprising. The line at 2.275 Å is wholly unaccounted for; it has not been previously recorded for a C-S-H, but

it is present in all four diffraction patterns, at  $\frac{1}{2}$  to  $\frac{1}{3}$  the intensity of the line at 1.88 Å.

TABLE II

Broad X-ray reflections, possibly or probably due to C-S-H

### Analytical Electron Microscopy

All particles were analysed for any elements present between atomic number 11 (sodium) and 30 (zinc). Ca, Si, Fe, Al and S appeared in the great majority of analyses with Mg, Na or K in many, and Cl, Ti or Mn and occasionally Zn in a few.

It was found convenient to convert all counts to atom ratios (not molar) with a base of 10 Ca. This showed that most particles could be grouped into Si 2-10, (Al+Fe) < 2, or (Al+Fe) 2-10, Si < 2, or nearly pure Ca (i.e. calcium hydroxide). But a few particles with high Mg (1 - 2.5) fell outside this scheme. By assuming that Mg replaces Ca and re-calculating to a base of 10 (Ca+Mg) these particles fell within the high Si, low (Al+Fe) field i.e. C-S-H, and all further calculations were made to this ratio.

Of the high (Al+Fe) particles, none showed sulphur content as high as the 5.0 required for ettringite and few even the 2.5 required for monosulphate. Lachowski et al (3) finally assigned the fields shown in Fig.1 on the basis of morphology and

Fig.1 - Composition zones for hydrate phases as atom ratios to 10(Ca+Mg) with particles from B and BG plotted.

diffraction pattern, with AFm and AFt distinguished by  $S < 1.5$  and  $S > 1.5$  respectively.

The fields are defined as:-

C-S-H	$2.5 < Si < 10, (Al+Fe) < 2$
CH	$Si < 1.0, (Al+Fe) < 0.4, S \leq 0.4$
AFt	$Si < 2.5, (Al+Fe+Si) > 3, (Al+Fe) < 6.0, S \geq 1.5$
AFm	$Si < 2.5, 4.5 < (Al+Fe) < 10, S < 1.5$

Particles from samples B and BG only are shown plotted in Fig.1 to avoid confusion.

#### C-S-H

Table IV shows mean and S.D. or range for the six major elements in C-S-H particles from all five samples, calculated as atom ratios to  $10(Ca+Mg)$ , together with  $\sum Al + Fe$ ,  $\sum Al + Fe + Si$  and  $\sum Al + Fe + Si + S$ , and the ratio  $Fe/(Al+Fe)$ . The variability is very large; this was also shown by Gard et al (4) for C<sub>3</sub>S pastes and is much greater than experimental error. However, the mean composition appears to be  $Si \sim 5, (Al+Fe) \sim 1$  and  $S$ , if available, up to 1, this corresponds to a  $Ca/Si$  ratio of 2, but a  $Ca/Si$  equivalent more like 1.5. The only significant difference between the without and with-gypsum samples is that in sulphur content between B and BG.

TABLE IV					
Sample	A	B	BG	C	CG
No. of analyses	16	4	8	12	20

C-S-H Compositions Atom ratios to  $10(Ca + Mg)$

Several other parameters change consistently with gypsum addition, but with this variability and sample size these changes are not significant, although they may indicate trends.

There is some indication that mean Si content decreases as S increases, but this is not born out in individual results. However, the individual results for BG and CG do show significant positive correlations between S and  $(Al+Fe)$ . (Both significant at 0.001 level;  $Fe/S$  in BG and  $Al/S$  in CG also both significant at .001 with a slightly lower r). The author suggests that this might be due

to maintenance of charge balance ( $R_2O_3 + SO_3 \approx 3 SiO_2$ ) but Taylor (5) considers this unlikely in such a disordered structure.

The parameter with the lowest coefficient of variation is  $Fe/(Al+Fe)$  and this is clearly correlated with the same ratio for the anhydrous starting materials, which is 0.21, 0.54 and 0.19 for A, B and C respectively.

#### Calcium hydroxide

This phase is the easiest to recognise in the electron microscope and, as the electron diffraction pattern survives the analysis, there is every reason to expect the analysis to be accurate. Of 18 particles analysed, all contained Si (mean 0.34 atoms/10 Ca), none contained Mg, 14 contained Fe (mean 0.05), while only 4 contained Al, and 9, mainly from BG and CG contained S (mean 0.06).

It seems possible that this small amount of Fe, taken up in preference to Al even in the low  $Fe/(Al+Fe)$  samples, may be  $Fe^{++}$  which has survived the clinkering process in the reduced state.

#### AFt and AFm phases

Mean compositions for the same six elements are given in Table V for the samples in which these phases occurred. Samples BG and CG were expected

Compositions of AFm and AFt phases  
Atom ratios to  $10(Ca+Mg)$

to contain AFt rather than AFm and only a very few AFm were found; but there is no explanation for the difficulty experienced in finding AFm in C.

The AFm phase is only distantly related to monosulphate; it contains substantial amounts of Si, and much less S than theoretical; furthermore the  $(Al+Fe)/10 Ca$  is in many cases greater than the 5

\*Single value for  $MgO = 0.09$ , others 0.0

required to fill the octahedral site, and the excess must be accommodated in interlayer sites together presumably with  $\text{OH}^-$  and  $\text{CO}_3^{2-}$  anions, and a silicate ion of unknown constitution.

The Aft phase is neither ettringite nor iron-ettringite; it contains considerable Si and certainly less S (even allowing for loss in the electron microscope) than theoretical. Lachowski et al (3) showed that the most satisfactory way to describe the data was to assume that (Ca+Mg+K) occupy Ca sites, and (Al+Fe+Si) the octahedral sites, even though it has been shown that Si can occupy the channel sites. Because of the possible loss of Ca during the analysis they considered that attempts at further refinement are unjustified.

A most interesting point is the low Fe content in Aft from both BG and CG; the maximum  $\text{Fe}/(\text{Al}+\text{Fe})$  in BG was only 0.39 compared with 0.54 in the anhydrous clinker. It has always been assumed that, if available, Fe would enter the ettringite structure almost as easily as Al, and in this clinker there is no question of it being unavailable as there is virtually a single interstitial phase of composition  $\text{Ca}_4\text{A}_3\text{F}_{66}$ .

#### Unidentified phases

Two types of particles were not assignable to any of the compositions discussed above. Some were probably composite, with an analysis lying between AFm and C-S-H zones.

Another phase was clearly losing Ca during analysis. This was detected in samples A, B, BG and CG. When calculated as ratios to 10 Si, the analyses were fairly consistent:-

Al 0.25 - 1.0, S 0.1 - 0.55, Fe 0.2 - 0.5, (Al+Fe+S)  $\leq 1.6$ .

and by extrapolating back to the start of the analysis for one case, where three sequential counts were taken, Ca/Si about 2. Lachowski et al (3) found that gyrolite, a hydrothermally-produced calcium silicate hydrate ( $\text{C}_2\text{S}_2\text{H}_2$ ) also loses Ca during analysis, but there is no other resemblance to these particles.

#### DISCUSSION

Table VI shows  $\text{Fe}/(\text{Al}+\text{Fe})$  for the anhydrous starting materials and for the hydrate phases formed from them, together with S.D. where available. Tested as follows, the ratios differ significantly, in BG between C-S-H and Aft at .001, in CG between C-S-H and Aft at .01, in A between C-S-H and AFm at .01. This disproportionality is more likely to be due to rejection of Fe by the Aft and AFm phases rather than to preferential take-up of Fe by the C-S-H. The C-S-H structure is so disordered that it probably acts simply as a sink for Fe, the very small amount taken up by the CH being insufficient to affect the balance.

The levels of cross-contamination found in this work are somewhat greater than those found by Lachowski et al (3) for normally ground cements at ages to 28 days, as might be expected, but probably give a not unrealistic picture of the levels to be expected after long hydration times in real concrete with thermal and humidity variations to assist ionic migration.

TABLE VI

	A	B	BG	C	CG
Anhydrous clinker	0.21	0.54	0.54	0.19	0.19

S.D.	0.08	0.14	-	-	-

$\text{Fe}/(\text{Al} + \text{Fe})$  for anhydrous clinkers and hydrated phases.

The XRD and analytical results tend to support Taylor's most recent (6) views on the structure of C-S-H. The few broad C-S-H spacings are consistent with "small fragments of Ca - O layers, perhaps some tens of Å large and only rarely parallel to each other".

If Al, Fe and S were substituting for Si in a long chain polymer, then at the (Al+Fe+S) levels which have been found, Si chains would rarely exceed 3 units long, and marked differences in polymerisation would be found between  $\text{C}_3\text{S}$  pastes and cement pastes. This is not the case and hence supports Taylor's view that silica "polymerisation does not give rise to long chains but to small, roughly equidimensional clusters".

The author further suggests that the (Al+Fe+S), if they are not substituting for Si or affecting silica polymerisation, may be acting as nuclei for the growth of Aft or AFm phases and hence promoting intergrowth and bonding of hydrate phases.

#### CONCLUSIONS

The C-S-H in fully hydrated cement pastes is extremely variable in composition, Ca/Si varying from 1.25 to 4.0; with Al, Fe and S each up to  $\frac{1}{5}$  of the calcium, and (Al+Fe+S) from 0.1 to 0.9 of the Si. The structure probably does not contain either layers or chains of silicate ions, but "roughly equidimensional clusters".

The AFm phase is equally variable in composition, and probably only slightly more ordered structurally, having some evidence of plate morphology and layer structure. It contains considerable Si, more than it does S, which is well below theoretical, and takes up a lower  $\text{Fe}/(\text{Al}+\text{Fe})$  than is available from the clinker.

The Aft phase gives a complete ettringite XRD pattern, but is defective in both Al and S; there is considerable Si present and rather less Fe; some Si is certainly in octahedral sites but some may also be in channel sites.

The calcium hydroxide contains about 3 Si atoms and 0.5 Fe atoms per 100 Ca, and is well crystallised with thin hexagonal plate morphology.

Acknowledgements

The author is indebted to Prof. H.F.W. Taylor and Dr E Lachowski not only for the use of COA, but for continual help and discussion and to Mr J A Dalziel for making and testing of micro-cylinders.

# Influence of fly-ash on the rheology of cement pastes

## *L'influence de la cendre volante sur la rhéologie des pâtes de ciment*

Ya. IVANOV, Ph.D. Head of Department of Rheology, and

S. ZACHARIEVA, Eng. Central Laboratory of Physico-Chemical Mechanics, Bulgarian Academy of Sciences, Sofia, Bulgaria.

**RESUME :** Les pâtes de ciment, comme matériaux inorganiques, ont des comportements rhéologiques extrêmement complexes et différents. Ce comportement est le résultat de la composition polyminéralogique du ciment et de son processus d'hydratation. La cendre volante prend une part de plus en plus grande dans la production du ciment. Elle influence aussi bien les processus d'hydratation, le durcissement du ciment et ses propriétés mécaniques, que le comportement rhéologique des pâtes de ciment.

Cette communication analyse des résultats expérimentaux concernant l'influence de la proportion de cendre volante dans le ciment, de sa composition chimique et de sa surface spécifique sur les propriétés rhéologiques de la pâte. On montre que la cendre volante provoque un comportement non-Newtonien remarquable de la pâte. Les caractéristiques rhéologiques des pâtes augmentent avec l'augmentation de la cendre volante dans le ciment. L'incorporation de cendre volante au ciment entraîne des modifications importantes de la cohésion et du frottement interne de la pâte.

**SUMMARY:** Cement pastes as inorganic materials demonstrate an extremely complex and diverse rheological behaviour. This is due to the polymineral composition of cement and the process of hydration, progressing in time. Fly-ash finds more and more application in cement production. It influences the process of hydration and cement hardening, physico-mechanical properties as well as the rheological properties and behaviour of cement pastes.

In this contribution the influence of quantity, dispersity and chemical composition of fly-ash on the rheological properties of cement pastes is analysed. It is shown that the fly-ash induces a noticeable non-Newtonian behaviour in the pastes. The rheological characteristics increase with increasing fly-ash content. A marked change in cohesion and internal friction is observed in the case of fly-ash/cement pastes-mixtures.

## 1. INTRODUCTION

The properties of fresh concrete are of great importance to building technology. Knowledge of these extremely complex and diverse properties is conducive to the correct determination of mix proportion, the manner of transportation and placing of concrete mixtures. Cement paste is a constituent of concrete. In order to obtain a deeper understanding of the properties of fresh concrete it is necessary to understand those of cement pastes. It was shown in previously published rheological measurements [1,2,3] that the hydraulic admixtures like trass and slag changed to a marked degree the rheological characteristics of paste. This paper contains an experimental study of cement pastes with fly-ash.

The interest in the rheological properties of fly-ash cement pastes is due to the increasing use of them in the cement industry. Its influence on the process of hydration, of cement hardening, as well as on the physico-mechanical properties of the cement and concrete, were widely studied and discussed. The flow behaviour of cement pastes with fly-ash has not been studied in the past. The reasons for this lack of attention are probably the difficulty in preparing the samples, and the poor reproducibility of the fly-ash composition and properties.

## 2. RHEOLOGICAL CHARACTER OF CEMENT PASTES

Numerous investigations have shown that cement pastes are structured, disperse systems. They are on the boundary between solids and liquids on the "rheological tree" of M-Reiner. The Rheological behaviour of very highly concentrated (with low water/cement ratio) pastes can be approximated by coulomb/s equation [4,5]:

$$\tau = \sigma \operatorname{tg} \alpha + C \quad (1)$$

In this case the yield stress is proportional to the applied shear stress and the tangent of the angle of internal friction. The deformation is manifested by the shifting of layers in the contact zone. The system is a discontinuous medium whose shear resistance resembles the character of dry friction. The rheological properties of such pastes were shown in [4].

The flow behaviour of fluid and plastic cement pastes obeys Bingham's equation:

$$\tau = \tau_0 + \eta \frac{dv}{dt} \quad (2)$$

It is a case when a volumetric deformation takes place without interruption of continuity. The resistance to the deformation has a pure viscous character and depends on the deformation rate.

Most of the pastes, however, are between these boundary cases. In several conditions they possess both properties inherent to the materials with viscoplastic flow, and those with dry friction.

It has previously been shown that the rheological properties of these systems can be characterized by the following characteristics: viscosity, cohesion, internal friction and yield value [4,5].

## 3. EXPERIMENTAL RESULTS AND DISCUSSION

The rheological characteristics were obtained: (a) for the liquid pastes from a specially constructed measuring device with kungled surfaces on a coaxial cylinder rotational viscometer. Thus, slip phenomena was eliminated, and a steady shear takes place in the substance medium. The flow curves of cement pastes with different water/cement ratios and fly-ash concentrations are seen in Figs. 1-3; (b) for the very concentrated cement pastes by means of the method described in [4,5,6].

Table 1 shows the chemical composition of used fly-ash as well as its dispersity (specific surface). Their chemical activity was 36 and 63 cm<sup>2</sup> gr<sup>-1</sup>. In both cases normal portland cement with S = 3400 cm<sup>2</sup> gr<sup>-1</sup> was used.

## 3.1 INFLUENCE OF FLY-ASH ON THE RHEOLOGICAL BEHAVIOUR AND PROPERTIES OF CEMENT PASTES

Fig. 1 illustrates how the flow curves change with an increase of fly-ash in cement pastes. These curves, as well as the curves in Fig. 2 and Fig. 3 (for constant fly-ash content but different concentration of pastes), show that the pastes have non-Newtonian flow. So, they correspond to the Bingham model in the general outline. However, these exist some peculiarities in the rheological behaviour of the pastes which must be noted. In the case of lower fly-ash dispersity (No. 1) with increasing fly-ash content, the plastic flow becomes more significant (curves 1-4 in Fig. 1). Pastes with higher dispersity of fly-ash (No. 2) demonstrate the flow behaviour which seems like pseudo plastic rather than real plastic (curves 1-4). Both pastes have a Bingham yield value and, at higher shear rates, the stress increases nearly linearly with the rate of shear. Therefore, a structural (apparent or Binghamian) viscosity may be calculated from the slope of the curve. The same peculiarities can be observed in the case of a constant cement/fly-ash ratio with a change of paste concentration - water/cement ratios (Fig. 2 and Fig. 3). From these data it is seen that the pastes with high fly-ash content as well as with high concentrations (low water/cement ratios) are both characterized by a marked increase of  $\tau$  at low and high values of  $D$ . Calculations indicate an approximate dependence on the square of the concentration. Hence there is a good agreement to the theory [8]. It must be pointed out that the rise of  $\tau$  depends also on the dispersity of fly-ash. It indicates that the flow of pastes in the flocculated and flocculent state (as classified by Powers in [7]) has to be considered separately for each case.

Table 2 illustrates how  $\tau_0$  (yield value) varies with the fly-ash content for a range of water/cement ratios of cement pastes. The results show that for the same concentration of the pastes  $\tau_0$  rises exponentially with increasing fly-ash. This rise also depends on the water/cement ratios and the

dispersity of the fly-ash.

Table 3, Table 4 and Table 5 show respectively how  $\eta_0$  (maximal Newtonian),  $\eta$  (structural), and  $\eta_m$  (minimal Newtonian) viscosities vary with the content of fly-ash for different water/cement ratios of pastes. The comparison of these experimental results with those of  $\tau_0$  indicates the same relation of each of them with studied factors (fly-ash content, water/cement ratios, and dispersity of admixture). From the structural ( $\eta$ ) and minimal Newtonian ( $\eta_m$ ) viscosities data (Table 4 and Table 5), as well as the previous figures, it is seen that these pastes have lower resistance to the flow after the apparent yield (or yield value) than those of cement with trass [12]. At the same time they demonstrate a higher resistance to the flow than those of cement with slag [1,2]. The viscosity of all the systems can be represented by the modified money equation [10].

Experimental results obtained with very highly concentrated cement indicate that its pastes obey Coulomb's equation. Some of the results are shown in Fig. 4 and Fig. 5. The data from Fig. 4 illustrates how  $C$  and  $K = \tau_0 \alpha$  varies with change of fly-ash content. It is seen that for several concentrations of pastes (water/cement ratio), as well as dispersity of fly-ash,  $C$  passes through the max value (curve  $C'$  for water/cement = 0.3). When the quantity of water is different, notwithstanding that it corresponds to the "normal thickness" of pastes (measured in accordance with the standards in force for the cement), with an increase of fly-ash the rise of  $C$  was observed. Internal friction ( $K = \tau_0 \alpha$ ) indicates a decrease in both these cases.

Fig. 5 illustrates how  $C$  and  $K$  vary with the change of fly-ash content for a range of concentrations (water/cement ratios), besides those corresponding to the "normal thickness" of pastes. The change of these characteristics corresponds to the relations noted in [4]. The difference is only in the speed of the change, and in the values of  $C$  and  $K$ . Tested pastes with fly-ash have a lower speed of change and bigger values for  $C = f(w)$  and  $K = f(w)$  than those shown in [4].

#### 4. CONCLUSION

The experimental investigations indicate that fly-ash has a marked influence on the rheological behaviour and on the flow properties of cement pastes. The systems are plastic- or pseudo plastic-like flow which becomes significant for high fly-ash content. They show Bingham yield stresses. The study of very highly concentrated cement pastes with fly-ash shows the behaviour which can be characterized by the existence of  $C$  and  $K$ . The latter change with an increase of fly-ash in pastes, as well as an increase of concentration of the pastes. The reason for their change is not clearly understood yet. It may be related to the dense particle packing and to their surface characteristics, which became very important in the highly concentrated pastes.

RESUME : L'article présente une description quantitative des phases principales de formation de la structure et du développement de la résistance du ciment hydraté : la dissolution du liant, la nucléation, la formation de structures coagulantes et cristallines. L'article montre aussi le mécanisme de la soudure des cristaux.

Les principaux facteurs structurels et mécaniques qui influencent la résistance du ciment hydraté sont aussi examinés dans cet article.

Les auteurs proposent une description du mécanisme de rupture, une méthode de prévision des résistances et les moyens d'optimiser la structure.

Les auteurs montrent aussi qu'une corrélation considérable existe entre la structure du ciment hydraté et sa résistance ultérieure et que ces facteurs sont prédéterminés par la composition minéralogique et la structure géométrique du liant original.

SUMMARY: The paper quantitatively describes the main stages of structure formation and strength development of cement stone: dissolution of binder, nucleation, formation of coagulation and crystalline structures. The mechanism of crystal intergrowth is also shown.

The basic structural and mechanical factors influencing the strength of resulting cement stone are examined.

The description of failure mechanism is proposed, the strength of cement stone is estimated and means of its structure optimisation are shown.

The authors demonstrate that cement stone structure and its strength are to a considerable extent interrelated and predetermined by mineralogy and geometric structure of the initial binder.

Une description quantitative de formation des systèmes dispersés peut être réalisée à base mathématique qui fournit une description de la structure géométrique de ces systèmes.

En absence des forces de liaison entre les particules et une distribution aléatoire des particules en volume, le système peut être caractérisé par six paramètres primaires:  $\Pi_m$  - porosité,  $V_m$  - volume,

$S_m$  - superficie,  $N_m$  - nombre des particules dans l'unité de volume;  $\bar{\alpha}$ ,  $\bar{h}$  - valeurs moyennes des dimensions des particules et la distance qui les sépare. Ces paramètres sont liés entre eux par quatre équations:

$$\left. \begin{aligned} \bar{\alpha} S_m &= m_1 V_m, \quad S_m^3 = m_2 V_m N_m, \\ V_m + \Pi_m &= 1, \quad \bar{h} V_m = m_3 \Pi_m \bar{\alpha}, \end{aligned} \right\} (1)$$

où  $m_1, m_2, m_3$  - sont les modules de dispersion du système, qui réfléchit l'influence de la forme des particules et la distribution d'accord aux dimensions  $1/l$ . Pour des configurations et distributions concrètes on peut les obtenir par des calculs; pour les systèmes polydispersés ce sera:

$$m_1 = \frac{2(1+\gamma)(1+2\gamma) \Psi_1 \Psi_2}{3\gamma \Psi_3}; \quad m_2 = \frac{8(1+2\gamma)^3 \Psi_2^3}{\gamma^2 \Psi_3^2}, \quad (2)$$

où  $\gamma$  - est le paramètre de forme des particules qui est égal à la relation entre la dimension longitudinale et transversale;

$\Psi_i$  - moments de distribution de  $i$ -ième puissance (pour un système monodisperse ces seront  $\Psi_1 = \Psi_2 = \Psi_3 = 1$ ).

À la base des paramètres primaires (1) on peut calculer les paramètres secondaires; il en résultent pour les nombres  $Z_\kappa^{(2)}$ , et l'aire  $F_\kappa^{(3)}$  des contacts dans l'unité d'aire et les aires des contacts dans l'unité de volume  $F_\kappa^{(3)}$  les relations suivantes:

$$Z_\kappa^{(2)} = S_m^2 \frac{13\gamma}{2(1+2\gamma)}, \quad (3)$$

$$F_\kappa^{(3)} = V_m^2, \quad F_\kappa^{(3)} = 1/2 S_m V_m. \quad (4)$$

Après le gâchage le système du liant se dissout au cours de hydratation et par conséquent la dimension caractéristique et la quantité des particules diminuent. En considération de cette circonstance on introduit le fonction du temps  $t$ , qui représente la degré de hydratation du liant  $\theta$  ( $\theta \in [0,1], t \in [0,\infty]$ ). On peut démontrer  $1/l$  que les paramètres du système dissolvant du liant (index  $x$ ) se modifient en forme suivante:

$$\left. \begin{aligned} V_x &= V_{x0}(1-\theta), \quad S_x = S_{x0}(1-\theta)^{\frac{1+\kappa}{3}}, \\ \bar{\alpha}_x &= \bar{\alpha}_{x0}(1-\theta)^{\frac{1+2\kappa}{3}}, \quad N_x = N_{x0}(1-\theta)^{\frac{1}{3}} \end{aligned} \right\} (5)$$

où  $V_{x0}, S_{x0}, \bar{\alpha}_{x0}, N_{x0}$  - sont les valeurs des paramètres au commencement du processus;  $\kappa$  - degré, dépendant de la fonction de distribution des particules selon les dimensions (pour un système monodisperse  $\kappa=0$ , pour une distribution équilibrée  $\kappa=0,25$ ). Si  $x_0$  - représente la consommation du liant pour unité de volume de

pâte (gr./cm<sup>3</sup>),  $S_{ox}$  - superficie spécifique du liant (gr./cm<sup>2</sup>),  $\gamma_x$  - densité (gr./cm<sup>3</sup>), alors si  $t=0$ ,  $\theta=0$  on aura:

$$\left. \begin{aligned} V_{x0} &= x_0 / \gamma_x, \quad S_{x0} = x_0 S_{ox}, \\ \bar{\alpha}_x &= m_{1x} / S_{ox} \gamma_x, \quad N_{x0} = x_0 \gamma_x^2 S_{ox}^3 \end{aligned} \right\} (6)$$

Dans les systèmes sans recristallisation la quantité des cristaux du hydrate de formation nouvelle (index  $y$ ), qui est égal à la quantité des germes cristallins au début du processus, ne se change pas  $1/2$  et le processus de croissance dans un système monominéral est caractérisé pour des relations suivantes:

$$\left. \begin{aligned} V_y &= V_{y1} \theta, \quad S_y = S_{y1} \theta^{\frac{1}{3}}, \\ \bar{\alpha}_y &= \bar{\alpha}_{y1} \theta^{\frac{1}{3}}, \quad N_y = N_{y1} = \text{const.} \end{aligned} \right\} (7)$$

dont  $V_{y1}, S_{y1}, \bar{\alpha}_{y1}, N_{y1}$  - représentent les valeurs des paramètres au moment quand le processus se termine.

Si  $\mathcal{D}$  est le coefficient d'agrandissement du volume au moment de transformation du liant en hydrate,  $x_0$  - la quantité des germes du hydrate dans l'unité de superficie du liant (cm<sup>-2</sup>), alors au moment quand le processus de hydratation est fini ( $\theta=1$ ) nous aurons

$$\left. \begin{aligned} V_{y1} &= V_{x0} \mathcal{D}, \quad S_{y1} = m_{2y} V_{y1}^{\frac{2}{3}} N_{y1}^{\frac{1}{3}}, \\ \bar{\alpha}_{y1} &= m_{1y} / m_{2y}^{\frac{1}{3}} (V_{y1} / N_{y1})^{\frac{1}{3}}, \quad N_{y1} = x_0 S_{ox} x_0 \end{aligned} \right\} (8)$$

Comme l'indiquent les équations (7) et (8) la structure géométrique du hydrate est déterminée par la structure géométrique originelle du liant ( $x_0, S_{ox}$ ) et sa composition minéralogique ( $\mathcal{D}, m_i, x_0$ ).

Les systèmes des équations ci-dessus sont valides non seulement pour des liants monominéraux, mais pour des ciments aussi, bien que les paramètres dans ce cas ont un caractère integral.

Si on connaît la quantité spécifique des germes, il est possible de calculer les paramètres de structure du hydrate (7) en voie de développement. L'évaluation théorique de la valeur  $x_0$  est réalisée en forme suivante. Supposons que  $v_x$  est la vitesse de venue du matériau dissout dans la solution (selon la théorie de Nernst-Chukarev) comme conséquence de la dissolution de la phase originale,  $v_0$  et  $v_y$  - sont les vitesses de formation des germes du hydrate et leur croissance suivante (d'après Volmer) et les corrections de Polak  $1/2$ . Dans ce cas

$$v_x = K_x (\alpha_\infty - \alpha), \quad (9)$$

$$v_0 = K_0 \exp \frac{-u_0}{2n^2 \alpha}, \quad v_y = K_y \exp \frac{-u_y}{2n^2 \alpha}, \quad (10)$$

$u_0 = 2 \left( \frac{\gamma}{\kappa T} \right)^3 \chi_0, \quad u_y = 2 \left( \frac{\gamma}{\kappa T} \right)^3 \chi_y, \quad (11)$  dont  $K_x, K_0, K_y$  - sont les constants de vitesse des processus correspondants (cm./s.);  $\alpha, \alpha_\infty$  - degré actuel de sursaturation de la solution et sursaturation

sur la superficie des particules du liant,

$\varphi = 2\delta_0 \sigma$  - énergie conventionnelle d'arrachement d'une molécule,  $\delta_0$  - paramètre du réseau cristallin (cm),  $\sigma$  - énergie spécifique superficielle de la phase solide du liant dans la solution,  $0 < \chi_i < 2$  - coefficient de la inhomogénéité physico-chimique /2/.

Considérons la dimension caractéristique des germes d'après Thompson

$$a_0 = 2\delta_0 \frac{\varphi}{\kappa T} \cdot \frac{1}{\ln \chi} \quad (12)$$

En appliquant la condition d'équilibre dynamique de venue de la substance dissolvante et sa déviation pour formation des germes du hydrate après le moment de termination de la germination, on peut obtenir le rapport de  $\chi_0$  des paramètres du système

$$\chi_0 = \gamma_1 (d_\infty - d_n) \frac{\varphi}{\kappa T} \cdot \frac{\chi_y}{\delta_0^2} \cdot \frac{\ln^2 d_n \exp \frac{u_y}{\kappa T}}{\ln^2 d_n} \quad (13)$$

où  $\gamma_1$  - est le coefficient, compte tenu de la configuration du germe.

Admettant que  $\gamma_1 = 0,15 \dots 0,5$ ,  $d_\infty - d_n \approx 1,1$ ,  $\kappa\chi/\kappa_y = 10^{-5} \dots 10^{-4}$ ,  $\frac{\varphi}{\kappa T} = 2 \dots 3$ ,  $\chi_y = 0,2 \dots 1$ ,  $\delta_0 = (7 \dots 10) 10^{-8}$  cm,  $u_y = 3 \dots 8$ ,  $d_n = 3,2$  on reçoit

$$\chi_0 = 5 \cdot 10^7 \dots 2 \cdot 10^{13} \text{ cm}^{-2} \quad (14)$$

Au cours des recherches directes nous avons obtenue pour le gypse la valeur  $\chi_0 \approx 10^7 \text{ cm}^{-2}$ , mais pour le gel du ciment durci, calculé d'accord à la superficie spécifique  $\chi_0 \approx 10^{13} \text{ cm}^{-2}$ , qui correspond assez bien à cette gamme.

Les cristaux du hydrate sont les particules colloïdales, qui dans la solution propre sont entourées d'un champ de force  $\varphi(h)$ , l'intensité duquel est déterminée par des forces d'attraction de van-der-Vaals et par des forces de répulsion d'origine diverses /3/. Deriaguine, Landau, Overbeck et Fervey ont indiqués que à une distance déterminée entre les particules  $h_i$  ( $i=1,2,3$ ) les valeurs  $\varphi_i$  ( $i=1,2,3$ ) = 0; par conséquence les énergies potentielles du système  $\xi_i$  ( $i=1,2,3$ ) touchent à ses valeurs extrémales. A la distance  $h_1$  et  $h_3$  on a  $\xi_{1,\min}$  et  $\xi_{3,\min}$ ; le système est en équilibre et se forment des structures de coagulation proches et lointaines. En outre, à une distance  $h_2$  on trouve une barrière énergétique  $\xi_{2,\max}$ ; en traversant cette barrière les particules peuvent passer de la distance  $h_3$  à la distance  $h_1$  (dans ce cas  $h_1 < h_2 < h_3$ ).

Cette traversée joue un rôle très important dans le durcissement du système, parce qu'une structure cristalline peut être formée seulement à une distance de  $h_1$  et moins.

Les principes de coagulation des systèmes colloïdaux découverts par Deriaguine et al. ont été développés par les auteurs. Comme conséquence d'une fluctuation de distance  $h_1$  ou  $h_3$  des zones d'ameublissement et de consolidation se forment dans le volume du système et, sous certaines conditions,

ces zones se transforment dans des pores et des agrégats stables (fig.1). Il y a une certaine relation entre le potentiel chimique du liquide au dedans d'agregat  $\mu(h)$ , en dehors d'agregat  $\mu(\infty)$  et la pression du fractionnement  $\varphi(h)$ :

$$\mu(\infty) - \mu(h) = g_0 \varphi(h), \quad (15)$$

où  $g_0$  - est le volume d'un mole. Si  $a_\kappa$  - est le diamètre d'agregat,  $\Pi$  - la porosité interne d'agregat,  $\sigma$  - l'énergie d'interface "agregat-milieu extérieur", on peut déterminer l'énergie de formation adimensionnelle d'un agregat  $u_\kappa$

$$u_\kappa = -\frac{\pi a_\kappa^3}{6} \Pi \frac{\varphi}{\kappa T} + \pi a_\kappa^2 \Pi \frac{\sigma}{\kappa T} \quad (16)$$

Fig.1 - Schema de formation des pores et des agrégats.

La stabilité de ces agrégats, d'après Gibbs et Volmer, demande que  $du/da_\kappa = 0$ ,  $d^2u/da_\kappa^2 < 0$ , ce que donne, après des calculs simples, (eq. 16) l'énergie de formation et les dimensions des agrégats stables:

$$u_\kappa = \frac{16\pi}{3} \frac{\Pi \sigma^3}{\kappa T \varphi^2}; \quad a_\kappa = \frac{4\sigma}{\varphi} \quad (17)$$

Realisons une consolidation imaginaire du système colloïdal jusqu'à une distance entre les particules, puis séparons le système en deux et coulisons les parties jusqu'à la distance  $h_i$ ; nous pourrions observer alors la formation d'interface, qui peut être exprimée pour la formule suivante:

$$2 \Pi \sigma = \int_{h_i}^{\infty} \varphi dh \quad (18)$$

Ainsi en conditions égales  $\sigma = \sigma(h)$  et alors  $a_\kappa = a_\kappa(h)$ . Pour définir la valeur moyenne de dimension du agregat, nous considérons que la distribution des agrégats selon leur dimensions, par analogies avec les oeuvres de Volmer /7/, suivit une loi exponentielle:

$$dN_\kappa = N_{\kappa m} e^{-u_\kappa} du_\kappa, \quad (19)$$

où  $N_{\kappa m}$  - corresponde au total des agrégats. Puis nous considérons que autour de  $h_i$  ( $i=1,3$ ) la pression change d'accord à la loi linéaire:

$$\varphi = \varphi_m (\xi - 1), \quad \xi = h/h_i \quad (20)$$

Alors pour le diamètre moyen d'agregat et la quantité des particules dans un agregat nous aurons:

$$\bar{a}_\kappa = \int_0^\infty a_\kappa e^{-u_\kappa} du_\kappa = \left( \frac{h_i \kappa T}{\varphi_m} \right)^{1/2} \frac{1}{\Pi^{1/2}} \left( \frac{3}{2\pi} \right)^{1/4} \Gamma\left(\frac{5}{4}\right) (2\Pi)$$

$$\bar{n}_\kappa = V \frac{a_\kappa^3}{a^3} = \left( \frac{h_i \kappa T}{\varphi_m} \right)^{3/2} \frac{V}{\Pi^{3/2}} \left( \frac{3}{2\pi} \right)^{3/4} \Gamma\left(\frac{7}{4}\right) \quad (22)$$

Si le volume minimal d'un agregat correspond à  $\bar{n}_\kappa = 6$ , alors  $\bar{n}_\kappa > 6$  représente les

conditions de formation des agrégats. En vertu de (22) ces conditions auront la forme suivante:

$$\Omega_k = \frac{h_1 k T}{\pi a^2} \cdot \frac{V^{2/3}}{\pi^2} > 0,4, \quad (23)$$

où  $V$  - la densité (concentration de volume),  $a$  - dimension des particules dans un agrégat. La porosité interne est égal à

$$\Pi = \frac{h}{h + m a} \quad (24)$$

Si nous aurons  $m a \gg h$ , alors  $\Pi = h / m a$ . Dans ce cas nous recevrons de la formule (23) la formule suivante:

$$\Omega = \frac{k T}{\pi m h_1 a^2} \quad (25)$$

A mesure que progresse le processus de hydratation, le diamètre des cristaux de hydrate  $a$  augmente, tandis que la concentration  $C$  de la solution diminue; mais la pression du fractionnement augmente aussi. Ce pourquoi nous avons une perte totale de la capacité de formation d'une structure de coagulation dans le système. Ce fait a été prouvé en forme expérimentale par Segalova et Rebinder /4/ et la formule (25) confirme ce fait en forme théorique.

Chukine et al. /5/ dans ces études on mesure la résistance des contacts et ont établis, qu'il y a deux types des contacts, dont la valeur de résistance diffère pour deux ordres de grandeur et même plus. Les contacts plus faibles étaient formés par coagulation, tandis que les plus résistants étaient du type de cristallisation. La preuve thermodynamique de la possibilité de formation des contacts a été donnée dans nos études /6/. Le mécanisme de formation des contacts dans ce cas est connecté avec une migration bidimensionnelle des molécules dans la couche mobile d'adsorption. Les molécules individuelles ou en paires de la couche mobile d'adsorption diffusent dans l'espace libre entre les particules. Alors ces molécules d'un cristal peuvent se réunir avec les molécules du cristal opposé. Ainsi se forment des ponts stables, qui se transforment postérieurement en contacts cristallins.

Fig.2 - Schema de formation d'un contact cristallin.

Les calculs thermodynamiques /6/ confirment que la formation des ponts des contacts d'accord à la fig.2a est possible sous la condition, que la dimension de l'espace ne

soit pas en excès de la valeur-

$$h_k \approx \frac{\delta_0}{2} \left\{ \frac{\ln d}{\ln d^*} + \left[ \left( \frac{\ln d}{\ln d^*} \right)^2 + \frac{4 \varphi}{k T} \cdot \frac{1-\chi}{\ln d^*} \right]^{1/2} \right\} \chi (2 \dots 3) \quad (26)$$

La longueur du bord d'un germe stable sera égal à ( $a_2$  - le bord du germe bidimensionnel)

$$a_k = \frac{a_2}{1 + (1-\chi) a_2 / h_k} \quad (27)$$

Quand  $\chi \gg 1$ , les conditions d'assemblage deviennent défavorables; ce fait indique, que l'assemblage peut être accompli d'une façon satisfaisant seulement entre des cristaux purs et de même composition chimique.

La condensation de la phase solide dans un espace cunéiforme entre les particules (fig.2b) procède en forme automatique, toutefois que l'angle  $\beta$  soit moins d'une valeur critique  $\beta < \pi(1-\chi)$ .

En somme, la rigidité du ciment durci dépend du gel du ciment, qui est un conglomerat des cristaux, joint dans les points du contact. La caractéristique principale qualitative du gel est le haut degré de hétérogénéité mécanique et structurale. Il est exprimé par la hétérogénéité des caractéristiques de résistance des éléments structurels et, d'autre part, par l'inhomogénéité en état de tension. La dispersion des valeurs de résistance est la conséquence de la différence de dimension des cristaux /7-9/. Les dimensions typiques des cristaux des hydrates basiques (diamètre des cristaux filiformes et aciculaires, épaisseur des cristaux en forme des plaques) varient dans des bornes assez étendue: de  $5 \cdot 10^{-7} \dots 2 \cdot 10^{-6}$  cm. pour des cristaux des hydrosilicates de calcium et jusque  $10^{-4}$  cm. et plus pour des cristaux de hydrosulfoaluminate et hydroxyde de calcium.

L'influence de dimension  $d$  sur la résistance  $R_c$  pour des cristaux hydratés du ciment a été établie par Boutte et Timachev et al. /8/. Dans cette étude nous proposons la relation suivante /9/ pour description de la fonction  $R_c = f(d)$ , qui est en rapport avec les résultats des essais:

$$R_c = R_m \left( d^* / d \right)^n, \quad (28)$$

où  $R_m$  - est la résistance théorique dans la phase de cristallisation,  $d^*$  - la dimension d'un cristal "parfait",  $n$  - le taux de réduction de la résistance avec la croissance du dimension de  $d$ . L'hétérogénéité dans la distribution des tensions dans les contacts et dans les cristaux a comme base la différence dans la direction des cristaux d'un agrégat, l'inconstance des rapports entre les aires des contacts et les cristaux des éléments structurels et d'autres imperfections.

Considérons la rupture des cristaux d'un agrégat aux contacts résistants. Sans prendre en considération la déformation

des contacts et considérant la constance du module de Young, on peut dire, qu'avec des tensions uniformes nous aurons des sollicitations égales dans des cristaux ayant la même direction. En ce cas une charge extérieure détruit les cristaux faibles, avec une redistribution de la charge entre les éléments plus résistants. Dans cet état intermédiaire la charge sur l'unité d'aire peut être exprimée par l'équation:

$$R = \frac{1}{3} R_m V_m \left( \frac{d_*}{d} \right)^n \int_{d_0}^d \varphi(d) dd, \quad (29)$$

où  $\varphi(d)$  est la fonction de distribution des cristaux d'accord aux dimensions, dimension du cristal le plus grand, resté intact ( $d_m \leq d \leq d_0$ ).

Une croissance de la charge extérieure et stabilisation d'état sont possibles seulement jusqu'à un certain stade. A une certaine charge la stabilisation devient impossible et ce processus se transforme dans une avalanche destructive, qui a pour conséquence une destruction totale de tous les éléments de la structure. Ce niveau de charge critique correspond à la résistance du système cristallin  $R_{cs}$ , la valeur de cette résistance peut être reçue à l'aide d'analyse (29) à l'extremum de  $d$ . Pour une distribution régulière  $\varphi(d) = \frac{1}{d_m - d_0}$  et avec  $d_0 \gg d_*$  nous aurons

$$R_{cs} = \frac{1}{3} R_m V_m \left( \frac{d_*}{d_0} \right)^n \frac{d_0}{d_m - d_0} \frac{(n-1)^{n-1}}{n^n} \quad (30)$$

La formule (30) est juste si  $d_0 \leq d_{cr} \leq d_m$ ,  $n > 1$ . En absence des ces conditions la résistance peut être exprimée par la relation

$$R_{cs} = \frac{1}{3} R_m V_m \left( \frac{d_*}{d_m} \right)^n \quad (31)$$

Pour une distribution régulière et  $d_0 \leq d_*$  et sous la condition que  $d_* \leq d_{cr} \leq d_m$  la résistance correspond à la formule (30). Si la dernière condition n'est pas remplie, on aura:

$$R_{cs} = \frac{1}{3} R_m V_m \int_{d_0}^{d_*} \frac{1}{d_m - d} dd = \frac{1}{3} R_m V_m \frac{d_* - d_0}{d_m - d_0} \quad (32)$$

Des calculs pareils peuvent être réalisés pour d'autres fonctions de distribution normale aussi.

Une évaluation quantitative de la résistance d'un gel du ciment durci par le corps cristallin, pour plusieurs fonctions de distribution, a donnée des valeurs de résistance à la rupture de 80 à 200 MPa (dans ce cas les valeurs de repère des paramètres de la structure  $V_m \approx 0,72$ ;  $R_m \approx 4,1$  MPa;  $d_* \approx 5 \cdot 10^{-6} \dots 10^{-5}$  cm,  $d_0 \dots d_m \approx 5 \cdot 10^{-7} \dots 10^{-4}$  cm,  $n \approx 1,2 \dots 1,6$ ).

Une analyse des formules obtenues indique, que la voie principale d'accroissement de résistance des structures cristallines, ayant des contacts bien développés, est un accroissement de la dispersité des cristaux.

Si les contacts sont faibles et ont une aire limitée, la destruction de la soudure aura lieu à travers des contacts. Le mécanisme de destruction et la résistance de la structure dans ce cas seront défini par la surcharge des contacts, en relation aux cristaux correspondants et l'inhomogénéité de l'état de tension dans les contacts. Si la résistance du contact de phase est égale à  $R_m$ , la condition intermédiaire de la structure sous une charge sera défini par l'équation:

$$R = \frac{1}{3} R_m V_m h \int_0^h \varphi(h) dh, \quad (33)$$

dont  $\varphi(h)$  est la fonction de distribution de la phase cristalline sur des aires relatives  $h$ .

Une analyse d'équation (33) à l'extremum de  $h$  pour une distribution uniforme simple  $\varphi(h) = \frac{1}{h_m - h_0}$  donne des formules suivantes de résistance d'une soudure à travers des contacts:

$$R_{cs} = R_m V_m \frac{h_m^2}{12(h_m - h_0)} \text{ pour } h_0 \leq h_{m/2}, \quad (34)$$

$$R_{cs} = \frac{1}{3} R_m V_m h_0 \text{ pour } h_0 \geq h_{m/2}, \text{ et } h_{m/2} \leq h_m \quad (35)$$

Calcul de la résistance d'une soudure à travers des contacts pour plusieurs fonctions caractéristiques  $\varphi(h)$  dans le gamme de changement des paramètres  $0,2 \leq h_m \leq 1$ ,  $0,1 \leq h_0/h_m \leq 0,5$  donne une valeur de résistance à la rupture de 25 à 150 MPa.

Le durcissement de la structure dans la zone des contacts peut être obtenu en augmentant la quantité des contacts par développement d'aire des contacts et consolidation de la phase de contacts et aussi par égalisation des aires relatives des contacts. L'état de tension dans les contacts en dernier cas sera uniforme et la force portante des tous les contacts sera épuisée simultanément, avec une effectivité maximale.

Le second facteur d'influence sur la résistance du ciment durci est la porosité. Mais dans ce cas la résistance du ciment durci ne doit pas être relationnée avec la porosité capillaire, mais avec la concentration des produits de hydratation, c'est-à-dire le facteur "gel-espace"  $\Phi$ . Cette relation se doit au fait, que la superficie de destruction du ciment durci se forme à travers de la structure du gel du ciment et par des pores capillaires, laissant les inclusions dures des particules du clinker nonhydraté intacts.

La formation de la structure du ciment durci dans ce niveau se réalise par une "couverture" des floccules de la masse cristalline hydratée. L'aire des contacts entre les floccules du gel  $F_g^{(2)}$  dans la superficie de destruction peut être exprimée par la formule (4)

$$F_g^{(2)} = \Phi^2 \quad (36)$$

Si la structure est uniforme et les mailles des pores individuelles ont le même type géométrique, ayant la même charge, alors la résistance de la structure sera égale à

$$R_{cim} = R_{cs} \Phi^2. \quad (37)$$

Une structure réelle est inhomogène et ce fait est confirmé par une distribution des capacités locales  $\rho$  (facteur  $\Phi$ ), qui conduit à une tension inhomogène et une surcharge des certains microvolumes ayant des valeurs petits  $\rho$ . Le mécanisme de destruction d'une structure pareille est échelonnée et liée à une destruction anticipée des cellules surchargées  $10/1$ ; l'état intermédiaire du système sera exprimé par l'équation

$$R = R_{cs} \rho^2 \int_{\rho_0}^{\rho_m} \varphi(\rho) d\rho, \quad (38)$$

dont  $\varphi(\rho)$  - est la fonction de distribution des capacités locales  $\rho_0 \leq \rho \leq \rho_m$  acceptant que la gamme de changement du paramètre  $\rho$  est  $\Phi = \int_{\rho_0}^{\rho_m} \varphi(\rho) d\rho$ .

Pour une distribution locale uniforme la formule de résistance du matériau poreux aura la forme suivante:

$$R_{cim} = R_{cs} \frac{4 \rho_m^3}{27(\rho_m - \rho_0)}. \quad (39)$$

Cette formule est justifiée si  $\rho_0 \leq 2/3 \rho_m$ . Faut de remplir cette dernière condition alors  $R_{cim} = R_{cs} \rho_0^2$ . Une évaluation quantitative de la formule (39) et des formules correspondantes aux autres fonctions caractéristiques aussi, y compris la loi de distribution normale, indique que ces formules peuvent être approximées pour la relation, qui s'approche à la formule de Powers

$$R_{cim} = R_{cs} \Phi^s, \quad (40)$$

dont  $s = 2,5 \dots 3,5$ , dépendant de  $\varphi(\rho)$ . Les calculs ont montré, que les pertes de résistance du ciment durci, comme conséquence de la inhomogénéité mécanique et structurelle sont égales à  $50 \dots 100$ , mais comme conséquence de la porosité capillaire - à  $3 \dots 10$ .

**CONCLUSIONS:** La structure et la résistance des liants hydratés de la pierre à ciment sont prédéterminées par la minéralogie et la structure du ciment. Les états principaux de la formation de la structure sont la germination et la formation des structures coagulantes et cristallines. La résistance du ciment durci est déterminée par la résistance des cristaux individuels des hydrates, liés aux points des contacts et par la porosité aussi. Cette résistance est relativement faible à cause de l'inhomogénéité des structures géométriques et minéralogiques. À base des formules théorétiques proposées par les auteurs, on peut faire des prévisions des propriétés du ciment durci.

# Scanning Electron Microscopic Observations of Cracking in Portland Cement Paste

## *Observations des fissures de pâtes de ciment au microscope électronique*

Sidney DAIMOND, Purdue University, and  
Sidney MINDESS, University of British Columbia, U.S.A.

### SUMMARY:

A device has been designed and constructed to permit observation of cracking of specimens loaded within the stage of a scanning electron microscope. The specimen configuration is that of the "compact tension" specimens used in plane strain measurements of fracture toughness. Preliminary observations on portland cement pastes indicate that the cracks are long, narrow, approximately parallel-sided, mostly unbranched except near the tip, and only approximately straight. Close observation indicates that the cracks occur as assemblages of relatively short straight segments set at small angles to each other. The effects of successive displacements of the loading device viewed at the same place along the crack are complex.

### RESUME:

Un appareillage a été conçu et construit pour permettre l'observation de la fissuration sous charge d'échantillons, à l'intérieur d'un microscope électronique. La configuration des échantillons est du type "à contrainte concentrée", utilisé dans la mesure des déformations planes avec ruptures fragiles. Les premières observations des pâtes de ciment ont montré que les fissures sont longues, étroites, approximativement parallèles aux bords, le plus souvent non ramifiées, sauf près des extrémités, et à peu près droites. Des observations plus poussées ont montré que ces fissures se présentent sous la forme d'une suite de segments droits, relativement courts, et faisant entre eux de petits angles. L'effet de déplacements successifs de l'appareil de chargement, observé du même point le long d'une fissure, est complexe.

## INTRODUCTION

The nature of the origin and development of cracks in hardened portland cement pastes, as well as in mortars and concretes, is of continuing concern. Cracking obviously results in damage and failure of specimens in strength testing, and the propagation of cracks under mechanical loading has been the subject of much investigation and theoretical development. With cement and concrete materials, crack development and propagation at stresses far below those required to induce structural failure are common occurrences. Such cracks, arising as a result of freezing, excessive shrinkage, or attack through environmental agencies, contribute significantly to concrete durability problems by rendering access to the interior of exposed concrete structural members relatively easy.

Despite the importance of the cracking problem in concrete, understanding of how real cementitious materials behave in terms of crack initiation and propagation is meagre. Efforts to apply the concepts of linear elastic fracture mechanics, notably successful in dealing with relatively homogenous, non-particulate materials like steel, have not been particularly successful. In part this may be due to the paucity of observational information on the way in which small cracks first originate and then propagate through cement paste and mortar matrices. Observations at a level fine enough to be meaningful in this context have not heretofore been pursued with any degree of consistency in the cement field.

In the present work, we describe and illustrate preliminary results obtained with a device specially constructed to permit close observation and photomicrographic recording of cracks generated within the scanning electron microscope (SEM). The work reported here is confined to cement paste; results obtained by similar means on mortar specimens will be submitted for publication elsewhere.

## INSTRUMENTATION

The device used here is specially designed to be accommodated within the specimen stage area of the ISI Super III-A scanning electron microscope in use in the laboratory of the first-named author at Purdue University. Details of the device and its functioning will be published elsewhere (1).

The specimen configuration is essentially that of the compact tension specimen described in ASTM E 399-78, Plane Strain Fracture Toughness of Metallic Materials (2), except that the present specimens are slightly narrower. A dimensioned drawing is provided as Fig. 1. The specimen may be described as a rectangular solid with a 13-mm long narrow (0.7 mm) notch cast in one end. Steel posts 3 mm in diameter are cast on either side of the notch. In operation circular steel bearings are placed over the posts and a wedging device is advanced by electric motor so as to spread the posts apart and induce tensile stresses concentrated at the root of the notch. A drawing of the loading assemblage is given as Fig. 2. The geometry is defined in such a fashion as to permit calculation of the stress intensity factor at the root of the notch. The entire assemblage is mounted in the specimen stage of the SEM. In operation the area at the root of the notch is located and held under observation while the motor is activated to advance the wedge until cracking just

Fig. 1. Configuration and Dimensions of Cement Paste Compact Tension Specimens.

occurs. The motor is immediately shut off, and the extent and details of the crack produced are observed and microphotographs made. When this process is completed the motor is again actuated for an arbitrary period and the crack extended; then the drive is turned off and the enhanced crack configuration again documented. This process is repeated several times until the crack propagates completely across the specimen and failure occurs.

Fig. 2. Configuration of Wedge-Loading Device

Wedges of various wedge angles have been used, including 3°, 4½°, and the 6° angle shown in Fig. 2.

## SPECIMEN PREPARATION

The portland cement pastes used in this study were prepared from ordinary (ASTM Type I) portland cements and were cast into specially-designed molds machined so as to provide the configuration shown in Fig. 1. The casting process was assisted by vibration. After casting the specimens were sealed within the molds for 24 hours, then demolded, and cured under saturated limewater for various periods.

In preparing the specimens for the SEM it was found undesirable to attempt to evacuate the relatively thick specimens to permit application of a conductive coating. It was found that specimens that had been

air cured for some time could be examined in the SEM without benefit of such coatings, at least at the relatively modest magnifications required to document the crack geometry. While some loss of water undoubtedly occurs for such specimens within the SEM, this seems neither to interfere with SEM observation nor to contribute visibly to cracking or extension of cracks formed by the mechanical loading device. It was found that application of a layer of silver dag ("silver paint") on the vertical end of the specimen away from the notch, which contacts a metal plate in the specimen holding device, is sufficient to provide proper electrical grounding for the specimen, and charging effects were not a problem. The SEM was operated at 5 KeV and at 15 KeV at various times, without much difference in results being observed.

## RESULTS

The appearance of the area at the root of the cast-in-place notch of a typical cement paste specimen mounted in the SEM before application of the wedge loading is shown in Fig. 3. This specimen was cast at w:c 0.5, cured for approximately 24 hours in the mold, for an additional period of two weeks in saturated limewater, and then exposed to laboratory ambient air for several weeks before examination.

Fig. 3. Area At the Root of the Cast Notch Before Loading. Original Magnification 30x.

The appearance of the same area after application of the initial loading just sufficient to produce cracking is shown as Fig. 4.

As a result of the wedge-loading action a long, relatively narrow crack is generated. In this specimen the crack width near the root of the notch was approximately 30  $\mu\text{m}$ , and it extended to a detectable distance of approximately 10 mm away from the notch; that is, the aspect ratio of the initially formed crack was well over 300. The width of this crack gradually diminishes in the direction of propagation, approaching a minimum clear detected width of about 3  $\mu\text{m}$  near the end. This is commensurate with the sizes of the smaller hydrated cement and cement grains, and the definition of the crack is lost in the general discontinuity of the cement paste.

Fig. 4. Crack Produced in Specimen as a Result of Initial Application of Wedge Loading. Original Magnification 30x.

Fig. 5. Detailed View of Portion of Crack Shown in Fig. 4. Original Magnification 100x.

As indicated in Fig. 5, the crack is not quite straight and parallel sided, as is assumed in many fracture mechanics treatments, but rather is shown to be an assemblage in a zig-zag pattern of short segments, each of the order of 60  $\mu\text{m}$  or so in length. There are a few individual hydrated cement grains visible at the surface in Fig. 5 that have not completely separated from either side, apparently bridging over short segments of the crack; however with these few exceptions, the crack depicted in Fig. 4 seems continuous.

This is not quite true for the regions beyond that shown in Fig. 4. At two or three places near the tip of the crack where the crack has narrowed significantly, the trace of the crack at the surface appears to terminate, and a seemingly parallel crack displaced from it occurs and continues onward. In two cases a short intermediate segment extending back toward the notch and the segment extending forward toward the tip can be observed. An illustration of such an area is shown as Fig. 6. The trend of the crack direction in this area has

wandered to the left from the general upper left to lower right orientation. It should be specifically understood that only the surface of the specimen can be observed, and it is possible that the underlying crack within the specimen may be continuous despite the interruptions shown by the trace on the surface.

Fig. 6. Illustration of Apparent Discontinuity in Trace of Crack at Surface. Notch is Upward And to the Left. Original Magnification 300x.

The observations so far illustrated may be summarized as indicating that mechanically-induced cracks in cement paste specimens of this type are basically long, narrow, parallel-sided, and unbranched in character. However, when examined closely and at enlarged magnifications it appears that these descriptors are only approximately true.

The question arises as to how such cracks compare with the crack pattern produced by drying shrinkage rather than mechanical loading, for specimens of the same configuration. An answer is provided in Fig. 7, which shows the general crack pattern produced in a specimen of the same type, age, and w:c ratio as previously examined, which has been exposed to a 105° C. temperature drying oven for half an hour and then evacuated in a sputter coating device prior to examination in the SEM. No mechanical loading has been applied.

It is seen that the drying shrinkage crack originates at the root of the precast notch in the same general area as a mechanical loading crack and is in some respects similar to it. The outstanding obvious difference is that the drying shrinkage crack pattern in Fig. 7 is repeatedly branched, branching occurring at intervals of about 2.5 mm. It is apparent that the stress distribution arising from shrinkage is very much different from that designed to be induced in the specimen by the mechanical loading system.

The gold-palladium conductive coating applied to this specimen permits examination of the crack in greater detail than is possible otherwise. Fig. 8 shows the area immediately surrounding the point of intersection of the second branch crack from the root of the notch in the lower center part of Fig. 7, at an enlarged scale. The crack width here is approximately 30  $\mu$ m. The distinctly particulate character of the hardened cement paste is quite apparent, individual grains being clearly detected. Examination down the

Fig. 7. Cement Paste Specimen Showing Shrinkage Crack Pattern Arising From Partial Oven Magnification 9x.

Fig. 8. Higher-Magnification View of the Area Surrounding the Second Shrinkage Crack Branch in Fig. 7 Above. Original Magnification 500x.

crack disclosed that, as expected, the crack is approximately, but not perfectly parallel sided.

As has been mentioned previously, with the present apparatus it is possible to extend the initially-formed crack several times before failure occurs. Distinctive areas of the crack may thus be re-examined after successive displacements to form a better picture of the crack extension process.

An example of the type of comparison that is possible is provided in Fig. 9. Fig. 9A on the left is the appearance of the initial crack as it emanated from the notch in the first comparatively heavy loading of a w:c 0.5 cement paste specimen cured in lime-water for approximately two weeks and subsequently in air for a like period. Fig. 9B on the right is the same area taken at the same magnification after the crack has been extended and widened by additional displacement of the wedge.

Fig. 9. Comparison Between Appearance of Initial Crack (A, left) and Widened Crack (B, right) at Point of Initiation At Precast Notch. Original Magnification 27x.

The crack in this region is widened from approximately 60  $\mu\text{m}$  to approximately 180  $\mu\text{m}$ . The additional displacement produces an apparent straightening effect on the appearance of the crack.

A further effect is illustrated in Fig. 10. While it is usually the case that the crack starts off in a direction normal to the end of the notch, there is usually a certain amount of wander from this direction, as can be seen in the lower part of Figs. 9A and 9B. This tendency is accentuated with increasing distance from the notch. In segments not trending in the predominant crack direction the displacements produced by the extension of the crack are complex. As is particularly apparent in Fig. 10B, the crack sides are no longer parallel in such segments, and the three-dimensional geometry of the crack may be other than that inferred from its trace at the surface of the specimen. This is despite the fact that the specimen geometry is designed to insure cracking under plane strain conditions.

Fig. 10. Comparison Between Appearance of Initial Crack (A, left) and Widened Crack (B, right) In Area Where Crack Direction Has Wandered From The Designed Direction. Original Magnification 135x.

The region depicted in Fig. 10 is more than half way from the notch to the end of the specimen; the cracks here are narrower than those depicted in Fig. 9. At the widest part in Fig. 10A the crack is only about 30  $\mu\text{m}$  wide; at the narrow zone just below the sharp jog near the center of the figure it is only about 7  $\mu\text{m}$  wide. In contrast, after the crack extension, the widest part of the crack is almost 150  $\mu\text{m}$  across.

The particular crack depicted in Fig. 10 has not branched between the root and the area depicted. The first visible branch was found several mm beyond this point, and its appearance at the first stage is shown in Fig. 11A, on the left. The notch is in the upward direction. It appears that continuation of the smooth flow of crack extension would have been along the right hand branch, but that for some reason a left-hand branch intersecting the smooth path at a sharp angle was also produced. As can be seen in Fig. 11B on the right, on further crack extension, the left hand branch is clearly active and dominant, and the right hand branch is entirely unaffected by the crack extension process. This observation seems to hold good generally where branching is found; one branch is "active" and widens under the crack extension process, while the other is inactive and unaffected.

Fig. 11. Detail of Crack Extension Effects at Point of Branching Showing That Only One Branch Is "Active" in Crack Extension: A, (left) is Initial Crack, B (right) is Crack After Extension by Additional Wedge Displacement. Original Magnification 135x.

It has been mentioned previously that the initially formed cracks are difficult to trace to their tips, since they narrow and become indefinite as their width approaches that of the general run of cement paste grains. Generally some branching is found before the crack peters out completely. Fig. 12A provides an illustration of such a zone, near but definitely not at the tip of the initially formed crack. The effect of additional crack extension on such a zone is seen in Fig. 12B, on the right. While only a single crack is primarily active, and the side branches are unaffected, there seems to be a splitting action leaving the hinge configuration evident in the center of Fig. 12B.

A number of mortar specimens have also been examined by the method reported here. These examinations suggest that cracking in mortars is considerably more

Fig. 12. Detail of Branched Area Near Original Crack Tip: A (left) is Initial Crack, B (right) is Same Area After Crack Extension. Original Magnification 135x.

complex than cracking in cement pastes, due to the larger scale disturbances associated with the sand grains. The cracks bend at larger angles, branching is much more frequent, and a far less straightforward pattern results.

#### CONCLUSIONS

The present work indicates that cracks in cement paste induced by a carefully defined mechanical loading system designed to produce plane strain conditions tend to be approximately straight and to run in the defined direction. However, they actually consist of a linked series of short segments that zig-zag back and forth around the direction of propagation. The cracks are unbranched except for a very few side branches produced far from the initiating point. Where such branching occurs only one branch is mechanically active, as indicated by repeat observations after further crack extension. The cracks are approximately, but not completely parallel sided, and narrow somewhat toward the tip. The tip area itself cannot be observed with confidence with the present experimental setup.

The influence of variations in such cement paste parameters as w:c ratio, degree of hydration, presence of admixtures, etc. on the nature of the cracks developed remain to be established, but are expected to be minor.

#### ACKNOWLEDGEMENTS

This paper represents a contribution from the Joint Highway Research Project, Purdue University, in cooperation with the Department of Civil Engineering, University of British Columbia. The SEM fracture device was constructed in the latter department, and the contributions of Messrs. B. Merkli, R. Postgate and W. Schmitt to the successful development of the device are gratefully acknowledged.

# Analysis on fluidity of cement paste and mortar

## *Recherches sur la fluidité de la pâte et du mortier de ciment*

S. NAGATAKI, Dr. Associate Professor, Dept. of Civil Eng. Faculty of Eng., Tokyo Institute of Technology,  
and  
S. KAWANO, Researcher, Tunnel Section, Public Works Research Institute, Ministry of Construction,  
Japan.

RESUME : Récemment, on a fait beaucoup d'études sur la fluidité de la pâte et du mortier de ciment, dues à l'augmentation de l'emploi de ces derniers dans les matériaux d'injection tels que le béton prépaqt et le mortier liquide.

Dans les anciennes recherches, on avait l'habitude de considérer, au point de vue rhéologique, la pâte de ciment et le mortier frais, comme des corps de Bingham. Ce texte suggère que de tels fluides soient plutôt considérés comme des corps visqueux ayant des réactions chimiques et une hystérésis des contraintes. Le comportement thixotropique semble affecter la fluidité considérablement. La rationalité de la suggestion ci-dessus est confirmée par les résultats des expériences faites avec et sans emploi de plastifiants ordinaire ou super, au moyen de divers appareils tels que les viscosimètres à rotation ou à tubes, et des appareils d'essai destinés spécialement aux bétons prépakts.

SUMMARY : In recent years, with the increase in use of cement paste and cement mortar in grouting materials such as prepacked concrete and grouted mortar, there have been many studies on the fluidity of cement paste and mortar.

Whereas it was customary to regard fresh cement paste and mortar as Bingham bodies in the analysis on their fluidities in past researches, this report suggests that such fluids should rather be considered as structural viscous bodies possessing chemical reactions where the hysteresis of strain and thixotropic behavior are seemed to greatly affect fluidity. The rationality of the above proposition is substantiated with results obtained from experiments with and without the use of ordinary or super-plasticizers, by means of various apparatus such as the rotation viscometer, the tubular viscometer and testing apparatus specially designed for prepacked concretes.

## FOREWORD

Attempts have been made from a fairly long time ago to analyze the fluidity of still unhardened (hereafter called fresh) mortar by rheological techniques, but the greater part of these research works assumed fresh mortar and concrete to be Bingham bodies trying to judge their fluidities using the two rheological quantities of shearing yield value and coefficient of plastic viscosity. However, there are various problems about clarifying the fluidity of actual fresh mortar and concrete by this method, and even before that, it is difficult to measure shearing yield values and coefficients of plastic viscosity themselves. The reasons for this are cited as being the existence of slippage at the sample boundary plane and the thixotropy of cement paste in measurement with the rotation viscometer, and it may be said that practically no research has been done to analyze these phenomena. In addition, it appears difficult to clarify the special fluidities of fresh mortar and concrete using superplasticizers with the above method.

In view of the above, experiments and observations were made in the present study considering it necessary to start out with examinations of the real natures of the fluidity characteristics of cement paste and mortar in their fresh states returning to the very basis, and to grasp by all means the true picture of fluidity. In the analysis of flow characteristics in this study, it was considered that the factor making fluidity complex is the viscosity structure of cement paste, and a comparison study was made with the thinking on structurally viscous fluidities of suspension systems (1). As a result, it was concluded that cement paste possesses a reactive property, and it is more rational to handle it as a structurally viscous fluid highly influenced by hysteresis of strain.

## OUTLINE OF EXPERIMENTS

Materials Used

The materials used in the experiments were ordinary portland cement manufactured by Nihon Cement Co. (Saitama Plant), Fuji River sand of F.M. of 1.96 cut by a 1.2 mm sieve, Pozzolite No. 5L (25% solution) as a normal type of water-reducing admixture, and Mighty 150 as a superplasticizer.

Mix Proportions

From the necessity of measuring fluidity, consistency of the degree of grout mortar for so-called prepacked concrete was made the standard. The particulars are sand-cement ratios of 0, 0.5 and 1.0, water-cement ratios varied between 0.30 and 0.55, with Pozzolite added 0.25% by weight of cement, and Mighty between 0 to 0.75% by weight of cement, all of the mixes being such that fluidities could be measured with the apparatus described below within the limits that they would not segregate.

Mixing

After preparing the temperatures of the various materials so that temperature as mixed would be in the range of  $20 \pm 2^\circ\text{C}$ , sand and cement were dry-mixed for 2 minutes, and after introduction of the other materials, full mixing was done for 3 minutes. Following this, the mix was left standing for 5 minutes to eliminate the influence of false setting, and measurements were made after further mixing for 1 minute.

Measurements by Rotation Viscometer

The rotation viscometer was a coaxial-cylinder, outer cylinder-rotation type, with the outer cylinder of diameter 160mm by 180mm and inner cylinder of diameter 100mm by 120mm for sample thickness of 30mm, and the speed of the outer cylinder was 0 to 100rpm.

In order to measure the angular velocity distribution in the radial direction of samples, reference points were provided at the circular frame at radii of 55, 65 and 75 mm. Then, the movements of reference points and the outer cylinder during fluidity measurements were filmed by 16 mm camera, and this film was examined by a motion analyzer (2). The shear rate at the various points inside the rotation viscometer were obtained by the equation below according to the deviation angle  $\Omega$  between reference points.

$$\dot{\gamma}_A = 2\dot{\Omega} / (1 - (R_1/R_0)^2)$$

where

$R_1$  : inner reference point radius

$R_0$  : outer reference point radius

Measurements were made causing the outer cylinder revolutions to go from 0 to 30rpm and back, with measurements on two round trips. The apparent shear rate in these cases was about  $20 \text{ sec}^{-1}$  at maximum.

Measurements by Tubular Viscometer

With a tubular viscometer, it is possible for measurements to be made of a shear rate range of about  $5 \text{ sec}^{-1}$  to about 100-400  $\text{sec}^{-1}$ . The fluidity curve was obtained in the form of apparent fluidity curve by the equations below from the flows inside the tube and differences in head.

$$\tau_A = \frac{\rho H R_0}{2L}$$

$$\dot{\gamma}_A = \frac{4V}{R_0}$$

where

$\tau_A$  : apparent shear stress ( $\text{g/cm}^2$ )

$\dot{\gamma}_A$  : apparent shear rate ( $1/\text{sec}$ )

$R_0$  : tube diameter (cm)

$L$  : tube length (cm)

$H$  : head difference (cm)

$\rho$  : mortar density ( $\text{g/cm}^3$ )

$V$  : average flow velocity (cm/sec)

## RESULTS OF EXPERIMENTS

Fig. 1 is an example of a fluidity curve obtained from the range of diameter from

55mm to 65mm thought to be uninfluenced by wall surfaces inside a rotation viscometer. As indicated in the figure, both fresh cement paste and mortar clearly show shear rate thinning flows. However, on looking at the decreasing speed or down curves, in contrast to the increasing speed or up curves, the apparent viscosity after flow either increases or decreases. According to the classifications by Ish-Shalome (3), plain fresh cement paste presents anti-thixotropy in the initial stage after mixing where apparent viscosity is increased by flow, goes through a stage of non-thixotropy with elapse of time, and then moves on to thixotropy where apparent viscosity is increased by flow. On applying these classifications to all of the tasted fresh pastes and mortars at the initial stage after mixing, all mixes plain and using the ordinary water-reducing admixture showed anti-thixotropy, but mixes containing the superplasticizer 0.5% or more by weight of cement showed thixotropy in spite of it being the initial stage after mixing. Generally, when a superplasticizer is added 0.5% or more by weight of cement, it is said cement particles are almost completely dispersed into primary particles with flocks not formed, and consequently, it is surmised that the thixotropic character seen at the initial stage after mixing is greatly influenced by whether or not there are flocks.

Fig. 1 - Consistency curves by couette type rotation viscometer

Next, examples of fluidity curves obtained by tubular viscometer at a higher range of slip velocity are shown in Fig. 2. The fluidity curves of fresh pastes and mortars indicating thixotropy show approximately linear behaviors in this range. As for those which indicated anti-thixotropy, they show shear rate thinning flow in this range also, and it is surmised that the structure of the interior of the paste is continuing to change even in

the high shear rate range. (It may be considered that viscosity actually is changing in the direction of tube length due to thixotropic behavior, but here, in order to qualitatively grasp the fluidity of mortars, the average fluidity curves for the tube lengths were determined.)

Fig. 2 - Consistency curves by tubular viscometer

Fig. 3 - Distribution of rate of shear in a container of rotation viscometer

Fig. 3 shows the results of shear rate distributions in the radial directions of samples in the rotation viscometer followed by time intervals in accordance with rotation speed variations. This graph is of a nature that if a sample of uniform viscosity, the various measuring points when connected will

indicate a straight line. However, as shown in the figure, the tendency seen with actual fresh paste is that for the fresh paste at the left which demonstrated anti-thixotropy, it is indicated that the sample became extremely fluidized in the vicinity of the inner cylinder with increase in the angular velocity of rotation viscometer, and moreover, the shapes of the curves up and down are more or less the same. Past research works handle this phenomenon as slippage of the sample at the wall surface, but the sample is clearly extremely fluidized in observations during measurements, and it is felt necessary to analyze this phenomenon considering it as an element of the fluidity characteristics of cement mortar rather than as being due to slippage. When such a property is defined as "concentration of shear rate," this phenomenon of concentration of shear rate is thought to be a property contradictory at first glance to the property of anti-thixotropy of apparent viscosity due to flow.

On the other hand, with the fresh paste shown at the right which demonstrated thixotropy, although there is a tendency in this case also for shear rate to be concentrated at the vicinity of the inner cylinder at the start of revolution of the rotation viscometer, with increase in speed, the increase in shear rate near the inner cylinder hits a ceiling, and the portion at which shear rate increases gradually moves toward the outside (defined as "dispersion of shear rate"). And at the down curve the variation in the shear

rate becomes roughly uniform so that the curves up and down are completely different, but especially with the down curve it is indicated that the tendency is similar to that of a sample having a so-called uniform viscosity.

#### CONSIDERATIONS

In systematizing the various flows of these fresh cement pastes demonstrating anti-thixotropy and thixotropy and arranging and considering them, it appears to be rational for explanations to be made thinking of a viscosity structure introducing the reactivity of cement also in the concept of fluidity of a suspension system the viscosity of which is determined by the structural variations of flocks, in other words, agglomerated bodies. Thereupon, the viscosity structure in cement paste is considered divided into the two parts below.

Firstly, one is caused by flocks and is defined here as "primary structure." Flocks during flow show a stable agglomerated state in accordance with shear rate, and because of this, a primary structure generally shows an equilibrium flow curve. Consequently, in these experiments, it may be considered that this curve configuration indicates shear rate thinning flow.

The other viscosity structure is one that is considered to be due to causes such as gelation of leached components of cement, defined here as "secondary structure." The secondary structure is considered not to have an equilibrium flow curve, is destroyed with flow, and is indicated only by a hysteresis flow curve. In general, since relatively great energy is required for destruction or formation of a primary structure, and formation and growth of a flock require collision between primary particles or flocks, it is considered that in case an equilibrium structure is possessed at a high shear rate, formation the structure is accelerated more when flowing at low shear rate rather than when standing still.

In contrast, it appears the secondary structure is readily destroyed, and is swiftly reformed after stoppage of flow, and within the scope of these experiments, formation seemed to occur in several seconds to several tens of seconds. The strength of the secondary structure appears to be influenced by concentration of cement paste, sand-cement ratio, and water reducing admixture. However, in any event, it is thought the behavior of a secondary structure is that of a elastic one against impact stress or low stress, above which the behavior is viscous with there being a character of destruction with increase in strain.

Considering that the differences of thixotropy and anti-thixotropy appearing during measurement of flow of fresh mortar, or the phenomena of concentration and dispersion of shear rate of samples in rotation viscometers were

Fig. 4 - Consistency curves by model apparatus

produced as a result of the primary and secondary viscosity structures being tangled with each other, the following explanations may be made.

Firstly, when a superplasticizer is added in large amount, and when considering that cement is dispersed into primary particles and flocks do not exist in the cement paste, a primary structure will not exist, and the viscosity structure will be a secondary structure only. Therefore, fresh paste and mortar of such mix proportions indicate thixotropy with secondary structure, the phenomenon of dispersion of shear rate is produced.

On the other hand, in case of existence of flocks as with plain paste and mortar, the two viscosity structures of primary and secondary will exist together. In such case, the primary structure in the paste during mixing or agitation approaches equilibrium at a high shear rate, and with stopping of the mixer, the secondary structure is rapidly formed ahead of the primary structure, and the primary structure is maintained at equilibrium in a high shear rate range. (This phenomenon will be called "memory of preceding shear rate.")

In measurements by rotation viscometer, since the shear rate itself is lower than the shear rate the mortar was subjected to during agitation, after the secondary structure has been destroyed formation of the primary structure is accelerated and anti-thixotropy is produced. In this case, however, inside the sample in the rotation viscometer, the secondary structure is first destroyed in the vicinity of the inner cylinder at the start of rotation and this part is fluidized with low viscosity memorized in the high shear rate, there will be concentration of shear rate produced due to the influence of the secondary structure in farther outside. In the down part, formation of a primary structure is seen in the vicinity of the inner cylinder, and perhaps due to this in two continuous round-trip measurements there was a tendency for concentration of shear rate to be alleviated the second time compared with the first.

The secondary structure in the cement paste gradually becomes stronger with time through hydration, and as according to Ish-Shalome, paste that had shown anti-thixotropy will come to show thixotropy, and it is thought later the difference of primary and secondary disappears to proceed toward setting.

As described above, whereas analyses of fluidities of fresh mortar and concrete had been made in the past assuming Bingham bodies, the present study has carried out examinations providing fairly bold hypotheses in order to be able make explanations including the peculiar phenomena recognized when superplasticizers are used in analyzing fluidities of fresh mortar and concrete. Admittedly, there has been a fair amount of heavy-handedness in explaining the phenomena grasp-

ing the fluidities of fresh mortar and concrete as is. However, within the scope of the experiments conducted in this study, it is felt that by separating the viscosity structure of cement paste into primary and secondary structures it has been possible to adequately explain at least qualitatively the flow properties of fresh paste and mortar.

However, it was not possible to distinctly grasp the influence of sand particles in the present experiments, where especially, in case of high sand-cement ratio, there will be the influence of interlocking of sand particles. As others, there will be the influence of air bubbles, and so long as a viscosity structure itself is physico-chemical, the variation in the condition due to the influence of temperature will be a very important factor. In regard to these, while endeavoring further to make it possible to quantitatively grasp the viscosity structure, it is thought necessary to carry out further analyses on the influences of the above factors.

#### SUMMARIZATION

The results obtained in this study may be summarized as follows:

- 1) The flows of cement paste and mortar in fresh states are not simply Bingham flows, but basically are shear rate thinning flows.
- 2) When a superplasticizer is added approximately 0.5% or more by weight of cement, fresh paste and mortar show thixotropy. Following this, they show flows close to Newtonian flows. Ordinary fresh pastes and mortars other than the above show anti-thixotropy, and have a tendency of becoming extremely fluidized at the boundary plane of the rotation viscometer during flow.
- 3) Two forms are conceivable regarding the viscosity structure in cement paste. One is flocculation of cement particles, and the other is gelation of the paste as a whole. The former is viscosity structure similar to the flow of a suspended system, while the latter is one which is simply thixotropic, but in a cement paste the two influence each other, and make the flow of cement paste extremely complex through the structural form, hysteresis of strain, and time-dependent change, etc. due to reaction.

# Préhydratation superficielle des ciments et son influence sur le processus de durcissement

## *Surface pre-hydration of cements and its influence on hardening process*

**RESUME :** Il est proposé un nouveau procédé d'intensification du processus de durcissement du ciment, par un pré-traitement à l'air humide épuré de  $\text{CO}_2$ . Ceci provoque la formation sur tous les grains non encore hydratés de ciment, d'enveloppes hydratées semi-perméables; en donnant à ces enveloppes une épaisseur optimale, on accélère l'hydratation ultérieure du ciment.

On a établi que pour tous les ciments fraîchement broyés, ce traitement, poursuivi pendant un temps optimal, variable suivant le type du ciment, améliorerait les résistances, les propriétés rhéologiques et la durabilité. Cette préhydratation superficielle des ciments modifie la composition et la structure des hydrates formés au cours de l'hydratation ultérieure.

On a montré qu'il existait des différences sensibles dans la composition de ces derniers hydrates, selon que le prétraitement à l'air humide s'effectuait en présence ou en absence de  $\text{CO}_2$ .

Ce procédé : traitement du ciment par préhydratation en atmosphère humide débarrassée de  $\text{CO}_2$ , peut être recommandé pour accroître l'activité du ciment.

**SUMMARY :** A novel technique for intensifying the cement hardening process by pre-treating it with  $\text{CO}_2$ -free high-humidity air is proposed. The technique provides for creating semi-permeable shells of new formations having optimum thickness around the particles of the unhydrated cement. These shells accelerate the process of hydration of the cement.

It has been established that treatment of all freshly-ground cements by the above method at an optimum time which differs with each cement grade, improves the cement strength, plasticity and life characteristics.

Surface pre-hydration of cements and their component clinker minerals changes phase composition and structure of the hydration products at further hardening. The considerable differences in the phase composition of new formations are shown in the case of surface hydration with high-humidity air in the presence and absence of atmospheric  $\text{CO}_2$ .

The method of surface pre-hydration in a high-humidity air free from  $\text{CO}_2$  may be recommended for increasing activity of cement.

Les processus se déroulant lors du stockage du ciment dans l'atmosphère humide contiennent à attirer notre attention malgré l'expérience presque séculaire de leur étude. On sait que l'hydratation superficielle dans l'atmosphère humide entraîne habituellement le ralentissement de la prise et la diminution de l'hydraulicité du ciment. Toutefois, les exceptions, qui ne sont pas rares, à cette règle générale conduisent à la nécessité de nouvelles études. Ainsi, au IV-ième Congrès sur la chimie du ciment W.C. Hansen (1) fit la communication sur l'apparition d'une fausse prise due à l'action sur le ciment de l'air humide ; il expliqua ce phénomène par l'"ulcération" de la surface des particules, augmentant la surface spécifique de réaction lors de l'interaction ultérieure avec de l'eau. J. Gebauer (2) aboutit à la conclusion que dans ce cas c'est  $C_2S$  qui est activé avant tout, mais d'autres chercheurs sont d'avis que l'activation des aluminates exerce une plus grande influence (3). Fut également notée la désactivation de  $C_3A$  lors du stockage du ciment à l'air humide ou lors du broyage du ciment en présence d'humidité dans le broyeur (4, 5). Cette contradiction est liée au niveau de la teneur du ciment en composés alcalins et à la composition des aluminates. Selon (3), une fausse prise est due en particulier à la présence dans les aluminates de  $C_{12}A_7$ . Dans un de nos travaux nous avons montré la disposition des ciments comprenant  $NC_3A_7$  pour le mottage et la fausse prise (8, 7). L'hydratation superficielle peut avoir lieu à l'air complètement sec, car une quantité d'eau introduite dans le broyeur pour le refroidissement ou avec le laitier granulé est suffisante pour provoquer cette hydratation ; lors du stockage du ciment dans le silo la température élevée conduit à l'hydratation de  $C_3A$  par l'eau de cristallisation provenant du gypse (8). Ce phénomène s'observe également en cas de broyage fin du ciment,  $C_2S$  et  $C_3A$  étant soumis eux aussi à l'hydratation superficielle (3, 6). Ceci est dû évidemment à la formation de liaisons de valence libres saturées en eau adsorbée.

Le rôle du gaz carbonique atmosphérique présente un intérêt tout particulier. Les difficultés d'ordre linguistique sont évidemment la cause de ce que l'observation importante de B. Beke (9) sur l'adsorption de  $CO_2$  par le ciment broyé est peu connue. Ceci témoigne d'une grande activité du gaz carbonique en tant qu'agent capable de prendre part à la saturation des centres actifs de la surface du ciment. En même temps, dans les ciments finement broyés on peut observer souvent, surtout lorsqu'il y a beaucoup de vapeur dans les broyeurs, des grains de carbonates (10), ce qui témoigne d'une importance considérable de cette interaction rapide. Toutefois, on se représente le plus souvent la carbonisation comme un processus lent, ce qui est vrai pour les bétons mais ne l'est guère pour l'hydratation superficielle du ciment dans le milieu air-vapeur.

En partant de ces considérations, deux d'entre nous ont abouti à l'hypothèse que l'élimination de  $CO_2$  de l'atmosphère, lors de l'hydratation superficielle du ciment, pourrait prévenir la saturation des centres actifs avec formation de  $CaCO_3$  inerte et accélérer l'hydratation du ciment grâce à la découverte d'une nouvelle surface pour l'interaction ultérieure. Dès les premières expériences cette hypothèse fut confirmée (11). Dans cette communication on donne les résultats d'études plus détaillées de ce problème.

**MATERIAUX DE DEPART.** Dans nos expériences nous avons utilisé des constituants de clinker synthétisés par cuisson et des clinkers industriels de composition différente (Tableau I) broyés avec et sans gypse dans le broyeur d'essais jusqu'à obtenir une surface spécifique de 3000 à 3500  $cm^2/g$  (d'après la méthode de perméabilité à l'air).

**METHODOLOGIE DES ETUDES.** Les constituants de clinker et les ciments étaient soumis à la conservation dans l'atmosphère d'air humide avec et sans  $CO_2$  dans des conditions statiques (exsiccateurs) et dynamiques (suction à travers la couche) pour simuler respectivement la conservation dans les sacs et les silos à la température normale du milieu. Après la fin de la préhydratation de durée déterminée, ces matériaux étaient étudiés par les méthodes de l'analyse thermique différentielle, de l'analyse aux rayons X et par la méthode électronique microscopique et utilisés pour la préparation des éprouvettes afin de déceler l'influence des conditions de la préhydratation superficielle sur la structure d'hydratation ; ensuite la structure de leurs fragments était étudiée par les méthodes susmentionnées. Ces échantillons étaient conservés, dans les régimes habituels, à l'air humide à  $CO_2$  et dans l'eau. Pour tenir compte de la température du milieu on a procédé aux expériences dans deux cimenteries. Des silos industriels (un silo à chaque cimenterie) étaient pré-

alablement équipés d'un système d'épuration de l'air utilisé pour l'aérage contre  $\text{CO}_2$  atmosphérique. L'efficacité de l'épuration était contrôlée par titrage d'une solution alcaline barbotée par le gaz. On a étudié les échantillons moyens du ciment stocké pendant des durées différentes dans les silos aménagés et les silos ordinaires aérés par l'air avec  $\text{CO}_2$ , par les méthodes de l'analyse physico-chimique et contrôlé leur hydraulicité. Quelques résultats obtenus sont donnés plus bas.

#### RESULTATS DES EXPERIENCES. ADSORPTION DE L'EAU EN PRESENCE ET EN L'ABSENCE DE $\text{CO}_2$ .

Sur la figure 1 sont représentées les données sur la sorption pondérale de l'humidité par les minéraux et ciments en présence et en l'absence de  $\text{CO}_2$ , de l'air dont l'humidité relative est de 100 %. Les données obtenues témoignent que la série d'activité des minéraux quant à l'absorption de l'humidité sans  $\text{CO}_2$  :  $\text{NC}_8\text{A}_3 > \text{C}_3\text{A} > \text{C}_2\text{S} > \text{C}_4\text{AF} > \beta$  -  $\text{C}_2\text{S}$ , est en bon accord avec les résultats des nouvelles études sur l'absorption des agents tensio-actifs à partir des solutions benzéniques (12) et de la phase de vapeur (20) et traduit donc l'activité relative et la concentration des microzones de réaction sur la surface des minéraux. La série d'activité pour l'absorption d'humidité en présence de  $\text{CO}_2$  se présente sous une autre forme :  $\text{NC}_8\text{A}_3 > \text{C}_4\text{AF} > \text{C}_3\text{A} > \text{C}_2\text{S} > \beta$  -  $\text{C}_2\text{S}$ .

Une analyse plus détaillée d'un échantillon d'alumoferrite utilisé dans ces expériences a montré que dans ce dernier il y a des marques de décomposition réductrice avec la formation éventuelle des microzones de  $\text{C}_2\text{A}$ , conformément au mécanisme proposé dans (13) :  $\text{C}_4\text{AF} = \text{C}_2\text{A} + \text{C}_2\text{F} + \text{CF} + \text{C}$ . Cependant ceci n'influaient pas sur l'activité du minéral en l'absence de  $\text{CO}_2$ . La présence de  $\text{CO}_2$  augmente en général la quantité d'humidité absorbée par les minéraux, de sorte qu'on ne peut pas parler de l'"intoxication" des zones de réaction actives en présence de  $\text{CO}_2$ , c'est pourquoi on préfère le terme de "saturation". La vitesse et le degré d'absorption de l'humidité par les ciments est en somme en bon accord avec les données pour les minéraux, compte tenu d'une composition en phases différente des ciments. Ceci n'est pas étonnant : dans les conditions de l'expérience on a exclu l'effet d'écran exercé sur un minéral dans le ciment par un autre et si l'humidité du milieu était de 100 %, les différences connues dans le submicrorelief de la surface des minéraux séparés n'avaient pas d'importance (10) ; pour une pression relative plus basse de la vapeur d'eau, ces différences conduisaient à une adsorption prédominante de l'humidité sur  $\text{C}_2\text{S}$  (du milieu dont l'humidité relative est inférieure à 70 %) en comparaison de  $\text{C}_3\text{A}$  dans le travail (3). Ce fait explique également les données de Gebauer (2) sur l'activation de l'alite.

Il faut tout spécialement souligner une activité superficielle élevée du ciment contenant  $\text{NC}_8\text{A}_3$  qui dépassait tous les autres en ce qui concerne la vitesse et la

Fig. 1 - Cinétique de la sorption de la vapeur d'eau par a) les constituants de clinker et b) les ciments. a) 1<sub>1</sub>; 2<sub>1</sub>; 3<sub>1</sub>; 4<sub>1</sub>; 5<sub>1</sub> -  $\text{C}_2\text{S}$ ;  $\text{C}_3\text{A}$ ;  $\text{C}_4\text{AF}$ ;  $\text{NC}_8\text{A}_3$  - courbes d'absorption d'humidité sans  $\text{CO}_2$ ; 1<sub>2</sub>; 2<sub>2</sub>; 3<sub>2</sub>; 4<sub>2</sub>; 5<sub>2</sub> - idem, en présence de  $\text{CO}_2$  atmosphérique. b) 1<sub>1</sub>; 2<sub>1</sub>; 3<sub>1</sub>; 4<sub>1</sub>; 5<sub>1</sub>; 6<sub>1</sub> - courbes d'absorption d'humidité par les ciments de 1 à 6 sans  $\text{CO}_2$ ; 1<sub>2</sub>; 2<sub>2</sub>; 3<sub>2</sub>; 4<sub>2</sub>; 5<sub>2</sub>; 6<sub>2</sub> - idem, en présence de  $\text{CO}_2$  atmosphérique.

quantité d'humidité absorbée, surtout en présence de  $\text{CO}_2$ . D'autre part, il est bien connu que  $\text{NC}_2\text{A}_2$  présente une activité moindre que  $\text{C}_2\text{A}$  lors de l'hydratation dans le milieu aqueux (14). Pour expliquer cette contradiction, on peut évidemment s'adresser aux idées développées dans le travail (15) où  $\text{NC}_2\text{A}_2$  est considéré comme un système complexe comprenant les microzones des oxydes de Na et de Ca libres ainsi que de  $\text{C}_2\text{A}$ . Il va de soi que la diminution de solubilité de la chaux grâce aux ions Na dans la phase liquide, qui limite l'activité hydraulique de  $\text{NC}_2\text{A}_2$ , est remplacée par l'intensification de l'adsorption de  $\text{H}_2\text{O}$  et de  $\text{CO}_2$  atmosphériques sur la surface contenant  $\text{Na}^+$ . L'activité de  $\text{C}_2\text{A}$  s'explique partiellement par la présence sur sa surface d'électrons libres (14).

Comme il fallait s'y attendre, les études de la composition en phases des hydrates superficiels formés montrèrent la formation de  $\text{CaCO}_3$  et des carbo-aluminates ou de leurs solutions solides avec ferro-aluminates lors de l'hydratation de  $\text{C}_2\text{S}$ ,  $\text{C}_2\text{S}$  et de  $\text{C}_2\text{A}$ ,  $\text{C}_4\text{AF}$  respectivement, sous l'action de  $\text{CO}_2$  de l'air. Les autres produits d'hydratation superficielle étaient identiques dans les deux milieux, mais il y avait les distinctions principales quantitatives et structurales suivantes. Lors de la préhydratation dans le milieu avec  $\text{CO}_2$ , il se forme sur la surface des particules de ciments et de  $\text{C}_2\text{S}$  des quantités importantes de  $\text{Ca(OH)}_2$  cristallin fixé nettement par toutes les méthodes physico-chimiques, alors que les hydrosilicates de calcium formés ne sont repérables, même dix jours durant, ni par méthode pétrographique ni aux rayons X. Lors de la préhydratation dans le milieu sans  $\text{CO}_2$ , il se forme principalement  $\text{Ca(OH)}_2$  amorphe et on peut fixer les hydrosilicates de Ca bien qu'en petite quantité. Par conséquent, en présence d'humidité  $\text{CO}_2$  sature les microzones actives de la surface des constituants de clinker et en accélère, lors de l'hydratation superficielle, la destruction du réseau cristallin en contribuant à la séparation des complexes calcio-oxygénés au profit de la couche externe des particules. Il faut prendre en considération que les centres actifs dans les microzones de réaction de la surface de tous les constituants de clinker ne sont représentés que par les ions Ca et O (18). En détachant les ions Ca et O, le  $\text{CO}_2$  contribue à la formation dans la couche externe des particules de centres de cristallisation tout faits - germes en  $\text{Ca(OH)}_2$  cristallin moins soluble dans l'eau lors de l'hydratation ultérieure que  $\text{Ca(OH)}_2$  amorphe. On peut supposer que les hydrosilicates qui apparaissent après la préhydratation dans le milieu privé de  $\text{CO}_2$  peuvent également servir de centres de cristallisation pour  $\text{C}_2\text{S-H}$  (II) lors de l'hydratation "aqueuse" ultérieure. On en vient ainsi à la conclusion que la présence de  $\text{CO}_2$  dans l'air peut conduire à l'augmentation de la teneur en portlandite lors de l'hydratation ultérieure du ciment, et l'effet utile de la préhydratation du ciment par l'air humide li-

bre de  $\text{CO}_2$  (11) est dû à la diminution de la teneur relative en portlandite et à l'augmentation de la part des hydrosilicates de calcium.

**ACTIVITE D'HYDRATATION DE  $\text{C}_2\text{S}$  ET DES CEMENTS APRES LA PREHYDRATATION SUPERFICIELLE DANS DEUX MILIEUX.** En résumant brièvement les résultats des expériences, notons que le traitement de  $\text{C}_2\text{S}$  et des ciments par l'air humide au cours de 1 à 10 jours en présence de  $\text{CO}_2$  atmosphérique entraîne une perte considérable de l'hydraulicité de 20 à 70 % à mesure que le temps de traitement croît. Par contre, en l'absence de  $\text{CO}_2$ , l'activité de  $\text{C}_2\text{S}$  et des ciments augmente (tableau II). Dans ce cas l'optimum de temps de traitement est de 3 à 7 jours. Le gain de résistance est de 20 à 50 % de la résistance des échantillons témoins (et même beaucoup plus si l'on tient compte de la diminution d'activité en présence de  $\text{CO}_2$ ). Le traitement ultérieur dans ce milieu diminue la résistance tant dans les conditions statiques que dynamiques. Les expériences industrielles ont confirmé le fait que l'absorption de  $\text{CO}_2$  à partir de l'air d'aération peut être appliquée en pratique pour augmenter l'activité du ciment (voir tableau II). Dans ce cas le temps de conservation ultérieure dans le silo du ciment traité n'est pas limité.

d'après GOST 310-60. \*\*) Après la conservation de 6 mois.

Il est établi également que cet effet ne concerne pas seulement l'accroissement de résistance, car après le traitement le besoin en eau diminue et la maniabilité des matériaux à base de ce ciment se trouve améliorée. Lors de son stockage ultérieur à l'air, l'activité ne diminue pas au cours de 6 mois. Nous expliquons ce fait par un effet d'écran exercé sur les particules par une couche comprenant C-S-H (II) dont la carbonisation, comme il est connu de (19), est de trois ordres de grandeur plus lente que celle de la portlandite.

ETUDE DE LA COMPOSITION EN PHASES DES PRODUITS D'HYDRATATION ET DE LA STRUCTURE D'HYDRATATION DE C<sub>3</sub>S ET DES CEMENTS PREHYDRATES DANS DEUX MILIEUX. On a mis à l'étude les échantillons de C<sub>3</sub>S et de ciments durcis sans préhydratation et après la préhydratation dans deux milieux : avec CO<sub>2</sub> et sans CO<sub>2</sub>. Comme on supposait, les résultats de l'analyse thermique différentielle et de l'analyse aux rayons X avaient permis de fixer après 3, 7, 28 jours de durcissement l'accroissement de teneur en portlandite dans une série d'échantillons II > T > I tant dans C<sub>3</sub>S que dans les ciments hydratés étudiés. Il est difficile de faire une évaluation quantitative sûre de la teneur en hydrosilicates, c'est pourquoi on a préféré l'étude de la submicrostructure par la méthode électronique microscopique, ce qui a permis d'obtenir certaines preuves d'une cristallisation complète et nette d'hydrosilicates de Ca dans les échantillons préhydratés en l'absence de CO<sub>2</sub>.

Dans l'immédiat nous nous proposons de publier les données obtenues pour les autres minéraux et ciments. On y observe des différences notables dans la teneur des échantillons en carboaluminates et en C<sub>3</sub>AH<sub>6</sub> ainsi qu'une formation anormale du gel d'hydroxyde de Al. Ces différences exercent une influence considérable sur la résistance du matériau. Font-ils exception les matériaux à aggrégats carbonates, car on sait que la formation des carboaluminates dans les zones de transition a un effet positif (19).

# Structure and thermal creep of cement paste

## *Structure et fluage thermique de la pâte de ciment*

L.J. PARROTT, Dr, Cement and Concrete Association, Slough, U.K.

**SUMMARY :** The effects of temperature history upon the creep of concrete must be considered if analyses of the stresses in engineering structures are to be realistic. Recent studies indicate that the creep behaviour of concrete subjected to variable temperatures is largely controlled by the cement paste matrix. An important feature of the creep of cement paste is that heating prior to loading reduces creep while virgin heating after loading greatly increases creep. The objectives of the present work are to identify changes in cement paste that cause or correlate with this particular creep behaviour, so that reliable advice concerning the prediction and control of thermal creep can be provided. Heating a mature, saturated cement paste from 20°C to 60°C was found to have little effect upon the bound water content as determined by thermogravimetry. Quantitative X-ray diffraction results also indicated that continued hydration of the cement minerals was not significant. Changes in silicate structure due to heating were observed and in particular an increase in polysilicate formation was noted. Some changes in sorption behaviour were also observed. The measured creep rates correlated closely with changes in polysilicate formation for a variety of conditions which included heating prior to loading and heating after loading. The results are considered in terms of a simple hypothesis in which the creep rate increased when a load-bearing part of the cement paste structure suffered a phase change. Thus heating prior to loading limited the potential for further phase change and consequently reduced creep whilst virgin heating after loading produced a large phase change and a substantial increase in creep.

**RÉSUMÉ :** Les effets de la température sur le fluage du béton doivent être pris en considération si l'on veut que les analyses de contraintes dans les ouvrages de génie civil soient valables. De récentes études indiquent que le fluage du béton soumis à des températures variables est largement contrôlé par le comportement de la pâte de ciment. Une caractéristique importante du fluage de la pâte de ciment réside dans le fait que son chauffage avant mise en charge réduit considérablement le fluage alors que son chauffage uniquement après mise en charge l'augmente considérablement. Le but des travaux actuels est de déterminer quels changements se produisant dans la pâte de ciment provoquent ce comportement directement ou indirectement afin que des conseils plus judicieux puissent être offerts à l'égard de la prédiction et du contrôle du fluage thermique. Le chauffage d'une pâte de ciment saturée ayant atteint maturation, de 20°C à 60°C, s'avéra avoir peu d'effet sur la teneur en eau latente déterminée par thermogravimétrie. Les résultats d'une radiodiffraction quantitative indiquèrent également que l'hydratation permanente des minéraux du ciment n'était pas significative. Des changements furent observés dans la structure des silicates; une augmentation des polysilicates fut en particulier notée. Des changements d'absorption furent également observés. Les taux de fluage mesurés étaient étroitement liés aux changements observés dans la formation de polysilicates dans diverses conditions y compris le chauffage avant mise en charge et après mise en charge. Les résultats permettent d'émettre le simple hypothèse selon laquelle le taux de fluage augmente lorsqu'une partie portante de l'ouvrage en pâte de ciment subit un changement de phase. Ainsi, le chauffage de la pâte avant la mise en charge limite les possibilités d'autres changements de phase et réduit donc le fluage alors qu'un chauffage uniquement après la mise en charge entraîne un changement de phase important et par conséquent une augmentation considérable du fluage.

## INTRODUCTION

An earlier report showed that the creep of cement paste was very sensitive to temperature history and that heating of even a mature cement paste after loading increased creep considerably (1). This increase was not associated with continued hydration of the cement as assessed by quantitative X-ray diffraction measurements or thermogravimetry (2). There were indications that the pore structure of the paste was modified during heating (2) and this may have influenced the creep behaviour. Changes in the silicate structure of the paste were also observed and these changes and their relationship with the measured creep are the main subject of the present paper.

## EXPERIMENTAL

The creep experiments have already been reported in detail (1) so only the main features of the experiments will be described here. 12 x 12 x 110 mm prisms of saturated, hardened cement paste (water/cement ratio = 0.47 by weight) were loaded at ages of 28 or 189 days and creep strains were measured at 20°C. The temperature of certain prisms was raised from 20°C to 60°C (8°C/hour) at ages of 42 or 203 days and the resultant increase in creep was observed. Control samples of the cement paste were crushed and ground to a fine powder (particle size <0.3 mm) at preselected intervals throughout the creep test. Immediately after grinding, the powder was used for analysis of the silicate structure of the cement paste. The method (3) involved dissolving the powdered cement paste in methanolic hydrochloric acid to yield a silicic acid and then complexing the silicic acid with ammonium molybdate. The formation of the resulting, yellow coloured molybdosilicic acid complex was monitored continuously with the aid of a spectrophotometer. The rate of formation of the molybdosilicic acid complex was slower the higher the degree of condensation of the original silicic acid. With suitable analysis of the reaction curve (3) the silicate structure of a cement paste could be determined in terms of:

- Proportion of silicate present as monomer
- " " " " " dimer
- " " " " " polymer
- Complexing reaction rate constant for polysilicate, which is related to its degree of condensation
- $S_{300}$ , the amount of silica unreacted after 300 seconds of complexing.  
This is a parameter that is approximately proportional to the product of the proportion of polysilicate and its average degree of condensation (3).

## RESULTS AND DISCUSSION

The creep results shown in Figure 1 clearly illustrate the large increases in creep that are associated with heating after loading. Figure 1 also shows the development of  $S_{300}$  with age at 20°C and after heating to 60°C: it can be observed that there is a striking similarity to the creep curves. One aim of this study was to check the hypothesis that a phase change in a load-bearing part of the cement paste structure would increase creep because of the local increase in compliance associated with the molecular rearrangement. The changes in creep after heating

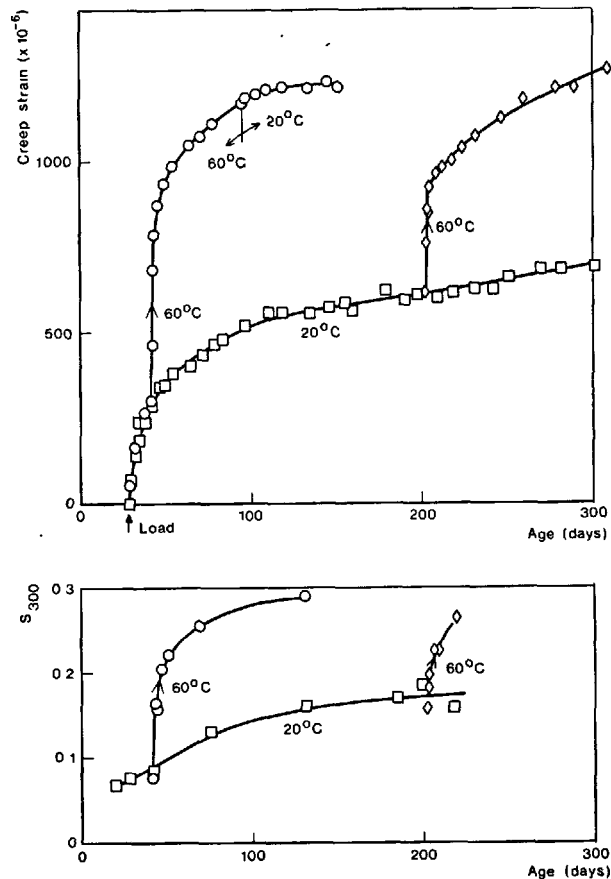

Fig. 1 Development of creep strain and  $S_{300}$ , a measure of polysilicate formation, with age and temperature.

Fig. 2 Change in creep versus corresponding change in polysilicate as indicated by  $S_{300}$ .

are plotted in Figure 2 against the corresponding estimates of the changes in  $S_{300}$ . Figure 2 also contains data pertaining to creep and polysilicate development at 20°C. It can be seen that although there is some dispersion of the results, for different temperature histories the measured creep is fairly closely related to concurrent changes of the polysilicate and may thus be regarded as consistent with the hypothesis above. It should be noted, however, that the initial creep measured at 20°C during the two weeks after loading develops very rapidly and does not correlate with  $S_{300}$ . It seems from creep recovery tests that the initial creep is associated with the development of a small recoverable component of creep while the creep that correlates with polysilicate development is mainly irrecoverable. The mainly irrecoverable nature of the creep associated with heating would be expected from the hypothesis above and is consistent with earlier work (4) which demonstrated that heating prior to loading reduced the irrecoverable component of creep but not, to any great extent, the recoverable component.

The nature of polysilicate formation was studied using the analytical technique outlined in reference 3. At 20°C hydration of the Portland cement involved very little change in the proportion of polysilicate between ages of 28 and 220 days and the increase in  $S_{300}$  could be attributed mainly to an increase in the degree of condensation of the polysilicate. However, heating at 60°C increased both the proportion of polysilicate and its degree of condensation. The increase in proportion of polysilicate after the start of heating was accompanied by a decrease of similar magnitude in the proportion of dimer. Heating to 60°C at an age of 203 days did not cause any significant change in the proportion of monomer. This was consistent with the observed constancy of the alite and belite concentrations and of the bound water content (2) under the same conditions, if it was assumed that monosilicate derived from the anhydrous cement. Such an assumption seems reasonable on the basis of the  $C_3S$  hydration studies of Dent Glasser et al (5). Thus it appears that at 60°C polysilicate is formed at the expense of disilicate hydrates while at 20°C polysilicate development involved conversion of existing polysilicate to a more highly condensed form. This difference in behaviour at the two temperatures may be partly responsible for the dispersion of the results in Figure 2.

The present study has some bearing upon the prediction and control of creep in concrete structures, particularly where the concrete is likely to be heated. It appears from Figure 2 that the components of creep strain that were termed flow and transitional thermal creep by Illston and Sanders (6) may be similar in nature. It may therefore be profitable to relate the sum of these components (i.e. the total irrecoverable creep) to a function that embodies the relationship between temperature history and polysilicate development. A further corollary of the present study is that a major part of creep seems to be related to changes in the main hydration products of Portland cement, the calcium silicate hydrates. Thus control of creep is unlikely to be affected by controlled selection of the aggregate or the cement. The most effective means of minimising creep at the present

time is to heat the concrete before loading; however this may not completely eliminate transitional thermal creep (1).

Relationships between the creep and microstructure of calcium silicate hydrates (CSH) have recently been examined by workers at the University of Illinois (7). Their results showed that basic creep (i.e. creep without drying) was associated with an increase in surface area measured by nitrogen although the surface area measured by water and the silicate structure were unaffected by sustained loading. The data were interpreted in terms of new surface being exposed to nitrogen as a result of micro-shearing or relative sliding of CSH crystallites. Distortion and buckling of the thin crystallites under sustained load could presumably cause an increase in surface available to nitrogen also. This second possibility can explain the high creep strains that were observed in the present study after the creep prisms had been heated:- Redistribution of water in the micropores of cement paste occurs after heating but published data (8) and the present results on unloaded prisms indicate that equilibrium is achieved very rapidly (i.e. a few hours) compared with the development of transitional thermal creep. Indeed close examination of initial transitional thermal creep strains indicates that during the first 10 hours after heating only 10% of the additional creep developed. Thus enhanced micro-shearing of water between crystallites was not thought to be a dominant process for creep at 60°C. However internal rearrangement of silica at 60°C could enhance distortion of the crystallites under sustained load and the rate of creep would then be related to the rate of polysilicate development, as indicated in Figure 2.

On a more general level it should be noted that the concept of creep being related to a phase change is not confined to the effects of silicate structure changes. Greenwood and Johnson (4) accounted for the increase in creep of metals during heating by a thermally induced structural transition. Also reanalysis of some earlier work by the author (10) indicates that carbonation can induce internal changes in cement paste that enhance creep. The effect is illustrated in Figure 3 and can be

Fig.3 Increase in creep versus weight gain for carbonating cement paste

explained by a mechanism similar to the one proposed by Powers (11) for carbonation shrinkage: creep is increased due to chemical erosion of the load-bearing cement hydrates. There is also evidence to suggest that with very early ages of loading (i.e. less than 7 days) creep is enhanced by simultaneous hydration of the cement (12).

The present work is in its infancy and before any mathematical models of creep can be reliably developed further experimental data on creep and changes in structure are required. In the author's laboratory a study of the relationship between creep and the physical and chemical structure of hydrated  $C_3S$  is in progress. The study will include a close examination of pore structure changes for a range of load and temperature histories.

#### CONCLUSION

The experimental results relating to creep, physical structure and chemical structure of a saturated cement paste suggested that long-term creep at 20°C and the increase in creep after the temperature of the loaded prism was raised to 60°C were closely related to the development of polysilicate in the cement hydrates.

#### ACKNOWLEDGEMENTS

The author gratefully acknowledges the assistance of the following members of the Materials Research Department of the Cement and Concrete Association with the experimental work and the reporting of this project: Mr W A Gutteridge, Mr J A Martin, Dr C D Pomeroy and Mr M G Taylor.

# The effect of the water reducer addition on the rheological properties of cement pastes

## *L'influence de l'addition de fluidifiants sur le comportement rhéologique de pâtes de ciment*

R. LAPASIN, Istituto di Chimica Applicata e Industriale, Università di Trieste,  
V. LONGO, Istituto di Chimica Applicata e Industriale, Università di Trieste,  
S. RAJGELJ, Istituto di Scienza delle Costruzioni, Università di Trieste, Italie.

RESUME : On a étudié l'influence de l'addition de trois fluidifiants à base de lignosulfonates et d'un superplastifiant à base de résines de mélamine sur le comportement rhéologique de pâtes de ciment.

Les essais expérimentaux effectués ont permis de déterminer, pour différentes vitesses de déformation, la contrainte de cisaillement maximale, la cinétique de destruction et la contrainte de cisaillement d'équilibre.

On a observé la présence, pour chaque fluidifiant examiné, d'une concentration critique relativement aux divers aspects considérés : la dépendance du temps, la contrainte de cisaillement d'équilibre et maximale, le comportement thixotropique. En ce qui concerne le comportement en fonction du temps (du type partiellement thixotropique), on a trouvé que la fonction de transfert  $\tau-t$  peut être décrite par deux modèles, pour des valeurs de  $\dot{\gamma}$  différentes, et que le type de fonction de transfert ne dépend pas de la nature et de la concentration du fluidifiant, tandis que son amplitude est affectée par la concentration en fluidifiant. La concentration atteint une valeur critique au minimum de l'amplitude. L'étude des valeurs d'équilibre et maximales montre que, lorsque la concentration du fluidifiant augmente, la viscosité d'équilibre diminue, tandis que la viscosité maximale atteint un minimum et ensuite augmente dans le cas des lignosulfonates et reste presque invariable dans le cas du superplastifiant. Le comportement thixotropique a été caractérisé par des grandeurs significatives, en particulier par un paramètre structurel; le paramètre de distance  $d$ , évalué sur la base d'essais effectués précédemment sur des pâtes sans additifs pour différents rapports eau/ciment et SSB. La destruction thixotropique maximale a lieu à la concentration critique. L'étude de l'influence des additifs sur le paramètre  $d$  a montré que l'adsorption superficielle ne suffit pas à expliquer entièrement l'action des fluidifiants à base de lignosulfonates.

SUMMARY : In the present work the influence of the addition of three lignosulphonate-based water reducers and of a melamine resin-based superplasticizer on the rheological behavior of cement pastes is evaluated.

The experimental tests permitted the determination, at different shear rates, of maximum shear stress, breakdown kinetics and equilibrium shear stress.

It was observed that, for each water reducer tested, there is a critical concentration relative to the various aspects considered: time-dependence, equilibrium and maximum shear stresses, thixotropic behavior. As regards the time-dependent behavior (partially thixotropic type), it was found that the transient  $\tau-t$  can be described by two models, for different  $\dot{\gamma}$  and that the type of transient is unaffected by the type and concentration of the water reducer, while its amplitude is dependent on the water reducer concentration. The concentration reaches its critical value, when the amplitude is at a minimum. An examination of equilibrium and maximum values shows that, as the water reducer concentration increases, equilibrium viscosity decreases, while maximum viscosity reaches a minimum beyond which it increases for the lignosulphonates and remains nearly constant for the superplasticizer. The thixotropic behavior was characterized through significant quantities, among which a structural parameter, the distance parameter  $d$  as derived from previous tests on pastes without additives at different water/cement ratio and SSB. The maximum thixotropic breakdown is reached near the critical concentration. The study of the influence of additives on the parameter  $d$  showed that the action of lignosulphonates-based water reducers cannot be fully accounted for by surface adsorption.

## INTRODUCTION

The characteristics of a hardened cement paste such as compressive strength, compactness, impermeability, dimensional stability etc. improve with decreasing water content, upon which the workability of the fresh paste, necessary for a correct placement, is inversely dependent. The water content of the mix must be properly selected to realize a compromise between the characteristics of the paste in the hardened and in the fresh state.

When it is necessary to obtain mixes with both high fluidity and excellent mechanical properties, water reducing admixtures, are added to the cement pastes.

In fact, when treated with water reducers, cement pastes undergo significant changes in rheological behaviour. Their viscosity decreases in the fresh state, while the characteristics of the pastes do not change appreciably in the hardened state.

So, it is possible to improve the workability of a mix at a given water content and to reduce the water content of a mix without modifying its workability.

The viscosity reduction can derive from the adsorption of water reducers onto cement particles and/or hydration products. The adsorption determines the breakage of inter particles links and the resulting dispersion of the particles (1-6). The dispersing effect can be connected with variations of zeta potential, and solid-liquid affinity, and/or steric hindrance action(7). Besides, admixtures can exert a physical action by lowering the surface tension of dispersing medium (1, 8-9). The addition of water reducers can result in a strong reduction of the rate of hydration process so that part of the hydration water remains free and can contribute to the fluidity of paste (10-11). The mode of action and effectiveness in improving the rheological properties of a paste depend on the chemical composition of the additive. Some admixtures which provide a particularly good dispersion of the cement agglomerates and are known as "superplasticizers" are based essentially on sulphonated naphthalene formaldehyde polymers or sulphonated melamine-formaldehyde polymers.

Studies carried out on different products have made it possible to locate optimum concentrations of water reducers in correspondence of which maximum viscosity reduction is attained (3-4). For superplasticizers, the viscosity reduction does not change appreciably beyond the optimum concentration. Therefore the effectiveness and the optimum concentration of a water reducing admixture has to be evaluated chiefly from the results of rheological measurements.

Many studies have been carried out on the rheological behavior of cement pastes, but many problems are still open, concerning the preparation of specimens, the character

istics of the measuring instruments and the experimental procedures.

In the present work, the variations of shear- and time-dependent properties of cement pastes with the addition of different types of water reducing admixtures and different concentrations of a same water reducing admixture were investigated with the aim to evaluate their effectiveness and to determine their optimum concentrations with respect to the properties considered.

For a global estimation of optimality from the technological point of view, a number of additional tests will be needed, to check that there are no adverse side effects, that the mechanical behavior in the hardened state is good, and, in the rheological field, the workability loss with time is negligible.

## MATERIALS AND EXPERIMENTAL PROCEDURE

All the pastes were prepared from Portland Cement 425 (density  $d = 3060 \text{ Kg/m}^3$ , specific surface  $S_s = 1.105 \text{ m}^2/\text{cm}^3$  (equivalent to Blaine surface area  $SSB = 361 \text{ m}^2/\text{Kg}$ ), over-size screening residue: 1.2 on  $90\mu$  and 2.9 on  $63\mu$ ) and tap water (hardness  $20^\circ\text{F}$ , pH 7.5).

The added water reducers were:

F1, .25  $\pm$  2% referred to cement weight  
F2, .10  $\pm$  2% referred to cement weight  
F3, .10  $\pm$  2% referred to cement weight  
F4, .25  $\pm$  4% referred to cement weight  
F1, F2, F3 belong to the class of lignosulphonates, while F4 is a superplasticizer based on melamine resins.

The cement volume fraction  $\phi$  is .449 (equivalent to water/cement ratio  $w/c = .4$ ), in some checking tests .483 (equivalent to  $w/c = .35$ ).

Each mix was prepared first by hand with a spatula and then mixed in a vanomixer, at two speeds, according to the following stirring time sequence (as specified for the mixing of standard mortar specimens): 30s at  $v_1$ , 30s at  $v_2$ , 90s at rest, 60s at  $v_2$  ( $v_1 = 36.65 \text{ rad/s}$ ,  $v_2 = 45.03 \text{ rad/s}$ ).

The rheological measurements were carried out at  $25^\circ\text{C}$ , with the rotating coaxial cylinder viscometer Rotovisko Haake 1, using the measuring heads Mk 50 and 500 and the device MV III with smooth cylinders (cup diameter 42 mm, bob diameter 30.4 mm, bob height 60 mm).

The measurable shear stress range is 15  $\pm$  510 Pa.

Several experimental approaches have been proposed for the rheological characterization of cement pastes. They differ in the instruments and methods employed, so that the results obtained often differ too. The majority of the approaches are based on the use of coaxial cylinders viscometers, with smooth or serrated surfaces, with large or small clearance. The most frequently used method is the hysteresis cycle and either the up-curve or the down-curve is

taken as the representative flow curve. Both curves depend upon the shear acceleration and the maximum shear rate reached in the cycle, and therefore they cannot characterize uniquely the rheological behavior of a material.

In this work the rheological tests were performed at constant shear rates by using a new fresh sample for each shear rate. In this manner it was possible to determine, at different shear rates, the maximum shear stress, the breakdown kinetics and the equilibrium shear stress and from these values to draw the equilibrium flow curve.

## RESULTS AND DISCUSSION

### Transient behavior

When subjected to shear, cement pastes undergo a breakdown of their structure, which is not rebuilt in rest conditions. Fig. 1 gives an example of the partially thixotropic breakdown of the pastes, as it appears from the transient shear stress  $\tau$ -time  $t$  obtained at constant shear rate  $\dot{\gamma}$ .

Fig. 1 - Typical transient behavior at constant shear rate

At low shear rates, the transients  $\tau$ - $t$  can be described satisfactorily by the model I:

$$\tau = \tau_e + C \exp(-Bt) \quad [1]$$

$$C = \tau_{\max} - \tau_e \quad [2]$$

and, at higher shear rates, by the model II:

$$\tau = \tau_e + C_1 \exp(-B_1 t) + C_2 \exp(-B_2 t) \quad [3]$$

$$C_1 + C_2 = \tau_{\max} - \tau_e \quad [4]$$

Similar transients have been determined by Tattersall (12) in a study of the influence of various technological parameters on the time dependent behavior of pastes. Tattersall states that different transient types can be noticed only by using coaxial cylinders with smooth surfaces.

The concentration and the type of water reducer do not substantially affect the type of transient. The transient amplitude (measured by  $C$  or  $C_1 + C_2$ ) is larger at higher shear rates. The water reducer con-

centration influences the transient amplitude more than the breakdown kinetics, and a concentration can be found at which the transient amplitude reaches its minimum value.

### Equilibrium and maximum shear stresses

As regards the equilibrium flow curves, it is impossible to find, among the models proposed (13-16), a single one suitable for all the pastes examined. In fact the progressive addition of water reducer influences the shape of the curves, as Fig. 2 shows.

Fig. 2 - Equilibrium shear stress vs. shear rate for cement pastes containing F2 ( $\phi = .449$ ;  $c = 0$  (●), .1 (◊), .3 (■), .5 (■), 1 (□), 1.5 (▲))

Thus, the effect of the water reducer addition on the equilibrium behavior can be examined by comparing the viscosity values  $\eta_e$  at the various shear rates. Fig. 3 shows how viscosity decreases with increasing concentration of the water reducer. The maximum viscosity reduction amounts to 60% for F1, F2, F3 and to 85% for F4.

Fig. 3 - Equilibrium viscosity vs. F1 concentration ( $\phi = .449$ ;  $\dot{\gamma} = 216 \text{ s}^{-1}$  (●),  $108 \text{ s}^{-1}$  (▲),  $36 \text{ s}^{-1}$  (■))

The initial stress overshoots  $\tau_{\max}$  determined at the various shear rates and the corresponding viscosity  $\eta_{\max}$  define the rheological behavior of the structure initially present in the material at rest. Fig. 4 shows how the progressive addition of water reducer determines the pronounced shifting of  $\tau_{\max}$  curves towards the  $\dot{\gamma}$  axis.

Fig. 4 - Maximum shear stress vs. shear rate for cement pastes containing F2 ( $\phi = .449$ ;  $c = 0$  (●), .1 (◊), .3 (□), .5 (■), 1 (□), 1.5 (▲))

Fig. 5 - Maximum viscosity vs. F1 concentration ( $\phi = .449$ ;  $\dot{\gamma} = 216 \text{ s}^{-1}$  (●),  $108 \text{ s}^{-1}$  (▲),  $36 \text{ s}^{-1}$  (■))

By plotting  $\eta_{\max}$  versus the concentration of water reducer  $c$ , as in Fig. 5, it can be noted that there exists a critical concentration  $c_c$  at which  $\eta_{\max}$  reaches its minimum value. The critical  $c_c$  is about .5 for F1, F2 and F3, and the corresponding reduction of  $\eta_{\max}$  is about 65-70 per cent. For F4, the critical concentration  $c_c$  is about 2.5 with a  $\eta_{\max}$  reduction of about 85 per cent.

For concentrations higher than  $c_c$ ,  $\eta_{\max}$  increases with addition of water reducer for F1, F2 and F3, while  $\eta_{\max}$  remains nearly constant for F4. It is shown in Fig. 6 which reports the  $\eta_{\max}$  values relative to the highest shear rate tested. A similar comparison is impossible at lower shear rates owing to the too low viscosity values for F4.

Fig. 6 - Maximum viscosity vs. water reducer concentration at  $\dot{\gamma} = 216 \text{ s}^{-1}$  ( $\phi = .449$ ; F2 (■); F4 (●))

Fig. 7 - Maximum viscosity vs. F1 concentration ( $\phi = .483$ ;  $\dot{\gamma} = 216 \text{ s}^{-1}$  (●),  $108 \text{ s}^{-1}$  (▲),  $36 \text{ s}^{-1}$  (■))

Similar results are obtained at a cement volume fraction of .483 for both equilibrium and maximum data. The viscosity reduction is less marked, as it can be seen in Fig. 7.

### Thixotropic behavior

A comparison between the equilibrium and maximum values of shear stress shows the marked effect of the water reducer addition on the amplitude of the thixotropic behavior. The variation of amplitude with shear rate can be described, according to Lin (17), by the parameter  $\lambda$ :

Fig. 8 - Parameter  $\lambda$  vs. shear rate at different F3 concentrations ( $\phi = .449$ ;  $c = 0$  (O), .3 ( $\Delta$ ), .5 ( $\diamond$ ), .75 ( $\square$ ))

As shown in Fig. 8,  $\lambda$  increases as  $\dot{\gamma}$  increases. At any shear rate, the minimum value of  $\lambda$  is reached near the critical concentration  $c_c$ .

For a comparison between different systems, it is more convenient to consider the area  $A$  comprised between the curves  $\tau_e - \dot{\gamma}$  and  $\tau_{\max} - \dot{\gamma}$  in the  $\dot{\gamma}$  range considered (18). The breakdown area  $A$  can be interpreted as a measure of the density of power expended to break part of the interparticle links initially present in the structure at rest and to pass to an equilibrium structure.

The plots of  $A$  vs. water reducer concentration clearly indicate that the amount of thixotropic behavior is reduced to its minimum value near the critical concentration  $c_c$ . Fig. 9 reports the plot  $A$  vs.  $c$  relative to F3.

For F4 it was impossible to determine the values of the breakdown area  $A$  at the highest water reducer concentration, because the viscosity values corresponding to the lowest shear rates were too low to be experimentally determined.

In a previous paper (18), the breakdown area  $A$  has been correlated with a distance parameter  $d$ , defined by:

$$d = \frac{1 - \phi}{\phi} \frac{1}{S_s} = \frac{w/c}{SSB} \quad [6]$$

through the relationship:

$$A = D \exp(-fd) \quad [7]$$

Fig. 9 - Breakdown area  $A$  vs. F3 concentration ( $\phi = .449$ )

where  $D = 1.24 \cdot 10^6 \text{ J} \cdot \text{m}^{-3} \cdot \text{s}^{-1}$  and  $f = 51 \text{ kg} \cdot \text{m}^{-2}$ . From the value of the breakdown area it is possible to determine, through eq. [7], an equivalent distance parameter, and hence to individuate the water/cement ratio of the pastes without water reducer having an equivalent time dependent behavior.

Table I

water reducer type	$c_c$	w/c	(w/c) <sub>eq.</sub>	$c_c$	w/c	(w/c) <sub>eq.</sub>
F1	.5	.40	.50	.5	.35	.38
F2	.5	.40	.47	.5	.35	.40
F3	.5	.40	.51	.5	.35	.40
F4				2.5	.35	.48

Table I reports examples of such an equivalence for the optimum water reducer concentrations. The comparison of the equivalent w/c ratios clearly shows the effectiveness of the superplasticizer F4.

It is interesting to compare the results obtained for different systems having different  $\phi$  and water reducer concentration on the basis of the  $d/d_c$  ratio (where  $d$  and  $d_c$  are the distance parameters of the systems with and without water reducer, respectively) and of a concentration parameter  $k$ , defined by:

$$k = \frac{c_s}{\phi} \quad [8]$$

where  $c_s$  is the surface concentration of water reducer

$$c_s = \frac{c \rho_c}{S_s} \quad [9]$$

Thus, it is possible to give a generalized representation of all the results relative to a given water reducer, for all the reducers belonging to the class of lignosulphonates.

Fig. 10 - Ratio  $d/d_0$  vs. concentration parameter  $k$  for F2 ( $\phi = .449$  (○),  $.483$  (■))

Fig. 10 shows that the maximum increase of the distance parameter (and, correspondingly, the maximum reduction in the thixotropic behavior of the pastes) is reached in the vicinity of a well defined  $k$  value, namely  $k_c$ . If  $c_s$  and  $C$  are the  $c_s$  value and the concentration of water reducer (expressed in  $g/m^3$ ), corresponding to the maximum increase of  $d/d_0$ , respectively, it follows that:

$$c_{sc} = k_c \phi \quad [10]$$

$$C_c = k_c S_s \phi^2 = k_c \cdot (S_s \phi) \phi \quad [11]$$

The condition of maximum reduction is obtained for a surface concentration  $c_{sc}$ , proportional to the cement volume fraction  $\phi$ . If the mode of action of the water reducer (lignosulphonate) should derive only from the adsorption of water reducer on the surface of the cement particles, the above mentioned condition would be reached for a well defined value  $c_s$ , independent of the cement volume fraction  $\phi$ . The optimum concentration of the water reducer  $C_c$  is proportional to the product of the total surface of the cement particles and the total cement volume (see eq. [11]). Therefore, the mechanism through which a water reducer acts cannot be explained merely through its adsorption on the cement particles. The results of the rheological tests appear to agree with those of the chemical and microscopical analyses reported in the literature (19).

#### CONCLUSIONS

The transients  $\tau$ - $t$  can be described satisfactorily by two models, for different  $\dot{\gamma}$ . The concentration and the type of water reducer do not substantially affect the type of transient, while its amplitude is dependent on the water reducer concentration. A concentration can be found at which the transient amplitude reaches its minimum value.

As the water reducer concentration increases,

$\eta$  decreases, while  $\eta_{max}$  reaches a minimum value beyond which it increases for the lignosulphonates and remains nearly constant for the superplasticizer.

The thixotropic behavior is characterized through significant quantities, as the  $Lin$  parameter, the breakdown area and the distance parameter. The maximum thixotropic breakdown is reached near a critical concentration. The study of the influence of a concentration parameter on the distance parameter shows that the action of lignosulphonates-based water reducers cannot be fully explained by surface adsorption.

# Sorption of $N_2$ and $n-C_4H_{10}$ on hydrated cements

## *Etude porométrique de ciments hydratés par adsorption de $N_2$ et de $n-C_4H_{10}$*

C.D. LAWRENCE, Materials Research Department, Cement and Concrete Association, Slough, and  
 F.G.R. GIMBLETT, and  
 K.S.W. SING, School of Chemistry, Brunel University, Uxbridge, U.K.

RESUME : L'observation porométrique révèle un affaissement de la microstructure des ciments hydratés, au cours d'un séchage normal. En comparant des pâtes soumises à différents séchages isothermes, on a constaté que des micropores présents dans les pâtes rapidement séchées et conservées à température ambiante étaient absents dans les pâtes lentement desséchées.

Des analyses  $\alpha_s$ , utilisant la silice TK 800 comme étalon, ont donné des résultats semblables avec l'azote à  $-196^\circ\text{C}$  et avec du butane à  $1^\circ\text{C}$ . Pour les pâtes rapidement séchées et conservées à température ambiante, les diagrammes  $\alpha_s$  s'infléchissent au-dessus d'une pression relative de 0,4, ce qui indique, à la fois, la présence de mésopores en forme de fissures, et l'absence de condensat capillaire pendant l'adsorption. Le condensat capillaire est présent, au cours de l'adsorption de  $N_2$  ou de  $n-C_4H_{10}$  par des pâtes lentement desséchées, ou par des pâtes traitées à l'autoclave.

SUMMARY : Sorption data give evidence for a partial microstructural collapse in hydrated cements during normal drying. From a comparison of a large number of isotherms, it is deduced that micropores are present in rapidly dried pastes that have been cured at room temperature, but are possibly absent from slowly dried systems.  $\alpha_s$  analyses, using silica TK 800 as a reference, are similar for nitrogen at  $-196^\circ\text{C}$  and butane at  $1^\circ\text{C}$ : on rapidly dried pastes cured at room temperature, the  $\alpha_s$  plots are curved above a relative pressure of 0.4, indicating both the presence of slit-shaped mesopores and the absence of capillary condensate during adsorption. Capillary condensate is present during  $N_2$  or  $n-C_4H_{10}$  adsorption on slowly dried pastes, or on autoclaved systems.

## INTRODUCTION

Variations in the method and rate of drying result in microstructural changes which complicate the interpretation of sorption isotherms on hydrated cements. Reported investigations have usually employed a single standardised preparation procedure, thus avoiding this difficulty, but in so doing have failed to detect a basic characteristic of these systems (1,2). Uncertainty in the qualitative interpretation of data arises because reference isotherms are not available on materials closely related to hydrated cements. To circumvent these difficulties, approximately 350  $N_2$  isotherms have been determined on 60 specimens, making it possible to eliminate random discrepancies and arrive at well-founded data for the different preparation procedures; an initial analysis is carried out by comparing the shapes of  $N_2$  isotherms within this set of data.

## Experimental

Hardened cement pastes and hydrated suspensions were prepared at room temperature from commercial cements and from laboratory cements made in the  $CaO-SiO_2-Al_2O_3-Fe_2O_3$  system (Table I identifies the systems discussed in this report). Some cement/water mixes were hydrated for limited periods at 190°C in an autoclave or laboratory bomb, but most systems were stored under water at room temperature for most of their cure. At the beginning of the study, samples were generally dried by evacuation at room temperature for extended periods through a trap cooled at -79°C (d-dried) then stored dry until a final outgassing at room temperature through a trap cooled with liquid nitrogen, immediately before determining the sorption isotherm. Most of the isotherms subsequently obtained were on freshly crushed hydrated systems placed in the sorption apparatus while still saturated with water, and dried by direct outgassing through a trap cooled with liquid nitrogen. Solvent replacement procedures (3,4) were adopted towards the end of the study as a means of removing some of the free water, before outgassing.

The quantity of nitrogen sorbed at -196°C was determined in a conventional volumetric apparatus (5), and a gravimetric procedure was employed to obtain butane isotherms at 1°C. Two microbalances (C.I. Electronics Ltd, Mk2C) were incorporated in the butane system, so allowing two samples to be examined at the same time; butane gas was admitted from a cylinder of Instrument Grade n-butane (99.5% purity) and withdrawn by a rotary pump via two solenoid valves which were operated by a Data General Nova 2 computer,

controlling the pressure of butane to preset points throughout the isotherm. Weight changes were recorded at 100 mg full scale sensitivity to 0.01 mg,

and pressures were recorded to 0.0001 atmospheres by means of a pressure transducer (Druck Ltd, PDCR60, 1 bar).

 $N_2$  Sorption Data

The shapes of nitrogen adsorption isotherms on hydrated cements conform to Type 2 in Brunauer's classification, and show Type B or D hysteresis loops between adsorption and desorption branches in de Boer's classification which close or almost close at relative pressure 0.45. Wide ranges of isotherm shape have been obtained in the present study. To analyse the cause of this variability, the data have been divided into groups of similarly shaped isotherms, after normalising at relative pressure 0.4, treating the lower and upper pressure regions independently. The number of separate sorption runs in each group varies between 10 and 60; representative isotherms have been drawn through each group. Data on hydrated cements in the lower relative pressure region are illustrated in Figure 1A by isotherms B to I which show a trend to a flatter shape; the corresponding isotherm for silica TK 800,

Fig. 1 - Representative  $N_2$  isotherms on hydrated cements normalised at a relative pressure 0.4: 1A, low pressure; 1B, high pressure

a well-documented hydrous oxide (6), is isotherm A. Sorption data at higher relative pressures are treated similarly and are illustrated in Figure 1B by representative isotherms 1 to 5; they show a trend to steeper rates of  $N_2$  uptake; the corresponding data for silica TK 800 is isotherm 8. A positive correlation is indicated between these two groups, suggesting that it may not be permissible to interpret the lower and upper regions of isotherms independently.

When samples are directly outgassed from the saturated state, the nitrogen sorption data at low relative pressures can be represented by isotherms B, F, G, or H; these same isotherms are found with d-dried samples and with samples dried at 100°C; they have relatively sharp knees. When organic solvents are employed to displace free water, nitrogen sorption data can be represented by isotherms C, E or I at low relative pressures; these isotherms have relatively rounded knees. At higher pressures, drying by direct outgassing usually results in isotherms 2 or 3, while drying at 100°C or d-drying leads to isotherm 4 for porous pastes and to isotherm 5 for dense pastes. After displacement of free water with methanol, specimens usually yield  $N_2$  sorption data approximating to isotherms 1 or 2. At low relative pressures nitrogen sorption data on autoclaved specimens may usually be represented by isotherm H, and these data are unaffected by pretreatment with methanol. Soaking a d-dried specimen in methanol causes sorption data to change from isotherm G to isotherm I. The additional effect on isotherm shape of prolonging pretreatment with methanol is negligible for paste specimens, but  $N_2$  isotherms on suspension hydrated cement become steeper with increasing period in methanol.

For the specimens examined, BET surface areas lie between 0.4 and 183.3  $m^2/g$ , on the basis of out-gassed sample weights; BET 'C' constants for hydrated cements lie about a mean of 82 with a standard deviation for the population of 42.

Specimen	Drying procedure	$N_2$ BET surface $m^2/g$	Butane uptake at $P/P^0 = .4$ g/g
SRPC1/.5/347	direct outgas	89.6	.0134
OPC1/.5/1081	d-dried + badly stored	-	.0040
OPC1/.5/1081	d-dried	82.5	.0194
OPC1/.5/2500	methanol	119.9	.0258
C3S3/.4/415	100 dried	-	.0245
C3S1/.47/1	direct outgas	8.3	.0019
C3S1/.47/7	methanol	106.2	.0190
C3S1/.47/28	methanol	138.3	.0277
C3S1/.47/42	methanol	139.8	.0210
C3S1/.47/42/2H	methanol	113.4	.0259
C3S1/.47/42/4H	methanol	128.6	.0336
OPC2/10/4750	methanol	183.1	.0355
silica TK 800	direct outgas	155.1	.0325

Outgassing of saturated samples directly produces larger surface areas than either d-drying or drying at 100°C; also dry storage causes a significant reduction in surface. Drying by displacing free water with methanol usually results in a substantial increase in surface; BET 'C' constants are significantly reduced by pretreatment with methanol,

e.g. they are reduced on average from 106 to 59 in the case of dense pastes.

The surface areas of paste specimens OPC1/.5/1081 and SRPC1/.18/505 are increased after 15 day's soaking in methanol but are not further changed by prolonging the period in methanol; BET 'C' constants are also unchanged by prolonging the soaking in methanol. In contrast the suspension hydrate OPC2/10/4750 at first continues to increase in surface area with increasing time in methanol, but at 330 days the surface area falls unexpectedly after an accidental halt to agitation of the methanol suspension, then increases again at 380 days when agitation has recommenced; during this halt the suspension settles and forms a dense sediment which gives a reduced surface area of about 1/3 the previous value.

#### $n-C_4H_{10}$ Results

A limited number of butane sorption isotherms are available at the present time, however it seems possible to state that isotherm shapes on hydrated cements are modified by the method of sample preparation adopted. As the isotherms exhibit very shallow knees, an analysis of this region of the isotherms is not feasible; differences in the shapes of hysteresis loops at moderate and high relative pressures are clearly visible and examples of three these isotherms are illustrated in Figures 2 to 4. The desorption isotherms for samples pretreated with methanol have a relatively acute approach to the ordinate at  $P/P^0=1$ , in contrast to the asymptotic approach of nitrogen isotherms, suggesting that a definite mesopore volume is defined by butane but not by nitrogen. The weights of butane sorbing onto samples at relative pressure 0.4 are compared to nitrogen BET surface areas in Table II: a general correspondence between these values is apparent though some exceptions may be genuine; a detailed analysis may be possible when more data are available.

Fig. 2 - Butane isotherm on hydrated cement paste OPC1/.5/1081 d-dried and badly stored.

Fig. 3 - Butane isotherm on hydrated alite cement paste C3S3/.4/415 dried at 100°C.

#### DISCUSSION

The nitrogen sorption results seem to provide evidence for a collapse of pore structure, leading to loss of free surface during drying under normal conditions that may be prevented, at least partially, by pretreatment with methanol. The evidence from pretreatment of d-dried specimens with methanol suggests that methanol does not readily open up pores that have already collapsed, though the behaviour of the suspension hydrate specimen shows that slow expansion of some microstructures can take place in methanol. The erratic changes in surface area of the suspension hydrated cement suggests that its morphology is one that allows close packing of particles when agitation ceases, so forming loose aggregations which can exclude nitrogen from a substantial fraction of their surface after removal of methanol. The obvious model for these hydrate particles is a platelet. When saturated cement specimens, cured at room temperature, are treated with methanol, usually both the quantities of nitrogen sorbed (or the BET surface areas) and the shapes of isotherms at low relative pressures are changed. The results for different specimens after pretreatment with methanol are:-

- (a) OPC2/10/4750; a large change in isotherm shape plus an erratic change in surface area, depending on the degree of agitation.
- (b) OPC1/.5/1081; some change in isotherm shape plus a large increase in surface area.
- (c) C2S1/.5/2267; some change in isotherm shape plus an initial increase in surface area followed by a reduction to the surface area of the untreated sample.
- (d) OPC1/.5/2500; a change in isotherm shape but no change in surface area.
- (e) SRPC1/.18/505; a change in isotherm shape plus a large increase in surface area.
- (f) OPC1/.5/1081 (d-dried); a large change in isotherm shape but no change in surface area.

Fig. 4 - Butane isotherm on hydrated  $C_3S$  paste C3S1/.47/42/4H dried by presoaking in methanol.

A change in isotherm shape is thus universally obtained when samples are pretreated with methanol but the quantity of nitrogen sorbed is not always increased. A possible explanation is that the chemical nature of the solid surfaces is modified to different extents for the different specimens by chemisorption of methanol: sorption isotherms of certain alcohols on hardened cement pastes provide evidence for this chemisorption (8); the reduction in  $N_2$  BET 'C' constants after pretreatment with methanol may also be considered evidence for this effect.

Nitrogen is physically sorbed onto solid surfaces at  $-196^\circ\text{C}$ , but changes in the chemical nature of surfaces can somewhat influence the data since the nitrogen molecule contains an electrical quadrupole which interacts with any charged species in the surfaces (7). For butane and other aliphatic hydrocarbons, electrical quadrupoles and dipoles are absent so their sorption data are less sensitive to the chemical nature of the surface. If it is provisionally assumed that pretreatment with methanol results in an energetically more uniform surface chemistry for the outgassed specimens, then patterns of nitrogen sorption that reflect physical structure may be revealed among these treated specimens. Experimentally all methanol soaked room temperature cured paste specimens produce low relative pressure sorption data represented by isotherms C or E, with the exception of the very dense specimens C3S2/.08/2297 which gives isotherm I; suspension hydrate OPC2/10/4750 yields isotherm G and d-dried OPC1/.5/1081, isotherm I; autoclaved pastes yield isotherm H. From these results normal density pastes may be provisionally assigned the largest volume of micropores since these pastes give isotherms with most pronounced knees, the presence of micropores resulting in enhanced sorption in this region of the isotherm. From considerations of  $N_2$  isotherm shapes and the degree of crystallinity shown in Stereoscan pictures, autoclaved pastes may contain a negligible volume of micropores.

The shapes of isotherms in the higher relative pressure region, where multilayer adsorption and

capillary condensation can occur, are probably less influenced by specific interactions between nitrogen molecules and solid surfaces: experimentally isotherms on silica TK 800 are similar in shape to isotherms 2 or 3 on hydrated cements, in the relative pressure interval 0.4 to 0.75. Those hydrated cements yielding isotherms 4 or 5 show enhanced rates of uptake of nitrogen compared to non-porous silica, thus capillary condensation is probably taking place during adsorption. Hydrated cement specimens giving nitrogen sorption data represented by isotherms 1, 2 and 3 have similar or reduced rates of uptake compared to non-porous silica; several possible explanations may be given for this behaviour:-

(i) Specimens may be non-porous or only contain very large diameter mesopores (isotherms may then be expected to be identical to the TK 800 standard).

(ii) Specimens may contain slit-shaped pores that fill with liquid nitrogen at high relative pressures only when multilayers of nitrogen molecules adsorbing on the flat opposing faces of the slits eventually touch, as the relative pressure rises.

(iii) Micropore filling takes place in specimens at lower relative pressures, resulting in higher sorbed volumes at relative pressures below 0.4 than are required by simple multilayer sorption on the open surface remaining at  $P/P^0=0.4$ .

Examination of the data shows that all rapidly dried pastes produce sorption data that may be represented by isotherms 1, 2 or 3. Since the discussion of low relative pressure isotherms given above has suggested that micropores are present in these specimens, explanation (iii) is the most likely.

A standard method of elucidating microstructures from sorption isotherms is the construction of  $\alpha_s$  plots (7). The normalised isotherms are plotted against those of a non-porous reference material of similar chemical constitution: a straight line plot along the diagonal is obtained when the shape of the hydrated cement isotherm is identical to that of the reference. Deviations above this diagonal at higher

Fig. 5 - Nitrogen  $\alpha_s$  plot on hydrated belite cement paste C2S1/.5/2267 directly outgassed while saturated.

relative pressures are generally interpreted as capillary condensation while deviations below this diagonal may be interpreted to indicate the presence of slit-shaped mesopores or the presence of micropores. Examples of  $\alpha_s$  plots are shown in Figures 5 to 7 using silica TK 800 as the reference. Capillary condensation occurs during adsorption in:-

- Autoclaved specimens
- Specimens dried at 100°C
- Dense d-dried paste specimens
- Some d-dried porous paste specimens

Fig.6 - Butane  $\alpha_s$  on hydrated alite cement paste C3S3/.4/415 dried at 100°C.

Fig. 7 Butane  $\alpha_s$  plot on hydrated  $C_3S$  paste C3S1/.47/42 dried by presoaking in methanol.

A downward deviation of the  $\alpha_s$  plots occurs in the case of isotherms on:-

- (e) Room temperature cured specimens that are outgassed directly from the saturated state in the sorption apparatus (with the exception of the suspension hydrate)
- (f) Room temperature cured specimens that are pre-treated with methanol (with the exception of the suspension hydrate)
- (g) Most porous d-dried specimens.

In agreement with the contention that methanol pretreatment prevents collapse of micropores, paste samples pretreated with methanol show increased downward deviations in their  $\alpha_s$  plots compared to those on the corresponding untreated pastes. The  $\alpha_s$  plots for butane isotherms show a general similarity to those for nitrogen isotherms: because of the less specific nature of the interaction between the butane molecule and solid surfaces, the interpretation of butane  $\alpha_s$  plots, especially at low relative pressures, can be more certain - deviations above the diagonal at relative pressures below 0.4 provide additional evidence for the presence of micropores. The fact that  $\alpha_s$  plots continue to deviate from the diagonal line at relative pressures above 0.4 suggests that a slit-shaped mesopore model is appropriate. A rigid slit-shaped pore model has been adopted for clay mineral compacts that yield nitrogen isotherms with the characteristics of isotherms 1, 2 and 3 (9), but if the hydration products are flexible lamellae, slit-shaped pores may be expected to form between them that are able to swell to limited extents as gas is condensed; unlike a rigid structure, the filling of pore space could be complete below the limiting pressure for capillary condensation (at  $P/P^0=0.45$ ) (10) and still account for the sorption data.

#### CONCLUSIONS

The structure of hydrated cement pastes cured at room temperature and rapidly dried, appears to be dominated by platy particles or lamellae that form slit-shaped mesopores and micropores. Small pores develop if these lamellae are allowed to collapse together, for example during slow drying, that behave as hollow cylinders or spheres in which  $N_2$  or  $n-C_4H_{10}$  condenses during adsorption.

# Réglage de la formation de la structure et des propriétés du ciment

## *Control of structure formation and properties of cement*

I.F. PONOMAREV, Directeur de l'Institut,

I.A. KRYJANOVSKAIA, Candidat ès Sciences Techniques,

A.G. KHOLODNYI, Candidat ès Sciences Techniques, Institut "Youjguiprotzement", U.R.S.S.

RESUME : On a étudié le mode de réglage, dans de larges limites, des propriétés du ciment par introduction dans sa composition de diverses quantités d'un composé cristallisé sulfoaluminosiliceux. On a montré que lors du broyage du mélange des trois constituants (clinker-portland, gypse et cristallisé), on peut obtenir, par la seule variation du rapport entre constituants, un ciment portland très résistant et des ciments expansifs, dont le temps de prise peut varier des valeurs ordinaires jusqu'aux valeurs très petites, de 5 à 8 minutes.

A l'aide d'un ensemble de méthodes d'étude physico-chimiques (radiographie, spectroscopie infrarouge, dérivatographie, microscopie électronique), on a mesuré les variations en quantité des hydrosilicates, des hydrosulfoaluminates et de l'hydroxyde de calcium qui se forment lors du durcissement des ciments à teneur différente en composé sulfoaluminosiliceux et on a montré que ces variations conditionnent les différentes propriétés techniques des ciments.

SUMMARY: A method of controlling cement properties within a wide range has been investigated. The method resides in introduction of different amounts of a crystallizing component of sulfoalumosilicate composition into the cement. It is proved that when crushing a three-component charge of conventional portland cement clinker, gypsum and crystallizing component, it will suffice to vary relationship of the components for obtaining high-strength portland cement and expanding cements the setting periods of which may be varied from regular to very short ones (5 to 8 min).

A complex of physical and chemical methods of investigations has been used (radiography, IRS, derivatography, electronic microscopy) to determine variations of the amounts of hydrosilicates, hydrosulfoaluminates and calcium hydroxide formed at hardening of cements with different content of the sulfoalumosilicate component and it has been shown that these variations dictate different technical properties of cements.

Introduction of the sulfoalumosilicate component into cement considerably increases homogeneity of the cement structure thus increasing cement strength.

Pour produire des ciments de types spéciaux on met habituellement en jeu les divers procédés technologiques qui introduisent des restrictions indésirables à tous les stades de production, à partir du choix des matières brutes pour la cuisson du clinker jusqu'aux paramètres de broyage du ciment. Afin de simplifier le processus technologique on a mis au point le mode de réglage des propriétés du ciment au stade de son broyage par introduction des constituants de cristallisation spéciaux dont la composition peut être assez variée. Dans ce travail on donne les résultats des recherches sur l'utilisation du constituant de cristallisation sulfoalumosiliceux.

La composition en phases du produit sulfoalumosiliceux (ou PSAS) est très complexe. D'après les données des analyses pétrographiques, aux rayons X, électrono-microscopiques, spectroscopiques aux rayons infrarouges \*), les composés siliceux PSAS se caractérisent par la présence de couches  $(\text{Si}_2\text{O}_5)_n$  à structure perturbée et du complexe absorbé, qui font preuve de l'activité élevée lors de l'interaction avec la solution aqueuse du ciment durcissant. La présence dans la composition de PSAS de composés solubles dans l'eau qui alimentent la phase liquide de la pierre de ciment durcissante en ions  $\text{Al}^{3+}$ ,  $\text{Ca}^{2+}$  et  $\text{SO}_4^{2-}$  est aussi une particularité de ce produit.

L'étude des propriétés des ciments, contenant une quantité différente de PSAS et du gypse, a permis d'établir qu'avec accroissement de la teneur en ces additions le temps de prise devient plus court et l'expansion du ciment augmente, tandis que les indices de résistance commencent par croître pour diminuer ensuite. Ceci rend possible, en faisant varier le rapport entre le clinker-portland, PSAS et le gypse, l'élaboration du ciment portland très résistant et des ciments expansifs à prise différente, en utilisant le même clinker pour la production de ces ciments spéciaux à destination différente.

L'étude des processus d'hydratation et de durcissement des ciments contenant les différentes quantités du produit sulfoalumosiliceux et du gypse était effectuée avec utilisation de la microscopie électronique, de la spectroscopie infrarouge, de la radiographie quantitative, de la dérivatographie, de l'analyse chimique des solutions aqueuses de la pierre de ciment durcissant. À titre de comparaison on a étudié également le ciment portland ordinaire. L'analyse de la composition de la solution aqueuse des échantillons de ciment durci montre que le durcissement des ciments avec PSAS a lieu en conformité avec les lois caractéristiques du ciment portland ordinaire. On peut voir nettement l'interliaison entre la

concentration de  $\text{CaO}$  et de  $\text{R}_2\text{O}$  dans la solution. Il est établi que la chimisorption des ions de métaux alcalins par les constituants PSAS amorphisés en forme de gel entraîne la diminution de la concentration de  $\text{R}_2\text{O}$  et l'accroissement de la teneur en  $\text{CaO}$  dans la solution, ce qui provoque l'augmentation dans la composition des ciments avec addition PSAS de la quantité de l'ettringite (grâce à la diminution de sa solubilité) et du gel hydrosiliceux (vu l'adsorption plus intense de  $\text{CaO}$  à partir de la phase liquide par les constituants PSAS). Une concentration accrue de  $\text{Al}_2\text{O}_3$  et  $\text{SiO}_2$  dans la solution aqueuse des ciments contenant PSAS confirme également le fait que l'addition prend une part active dans les processus d'hydratation.

Selon les données de l'analyse aux rayons X, de la spectroscopie infrarouge et de la dérivatographie, les ciments durcissants ayant une teneur différente en PSAS se caractérisent par une composition des phases similaire des hydrates et une succession analogue de leur formation au cours du durcissement. Le premier des hydrates (4 mn d'hydratation) qui apparaît toujours dans la pierre de ciment est l'ettringite (réflexions à 9,8; 5,6 Å sur les radiogrammes, bandes d'absorption de  $1130\text{ cm}^{-1}$ ,  $3450\text{ cm}^{-1}$  sur les spectres infrarouges, endoeffet avec le minimum à  $140^\circ\text{C}$  sur les dérivatogrammes); ensuite on fixe la formation de  $\text{Ca}(\text{OH})_2$  (réflexions à 4,9; 2,6 Å;  $500$  à  $540^\circ\text{C}$ ) et d'hydrosilicates de calcium (bande d'absorption de  $970$  à  $980\text{ cm}^{-1}$  sur le spectre infrarouge, endoeffet dans l'intervalle de  $160$  à  $180^\circ\text{C}$  sur les dérivatogrammes). Un trait distinctif des spectres infrarouges des ciments avec PSAS est l'élargissement des bandes d'absorption dans le domaine de  $970$  à  $980\text{ cm}^{-1}$  avec accroissement de la quantité de PSAS dans le ciment, ce qui témoigne de l'augmentation de la quantité des hydrosilicates de calcium amorphisés dans la composition des hydrates.

La caractéristique qualitative des ciments analysés témoigne donc du fait que les hydrates de ciment durci sont principalement représentés par l'ettringite, les hydrosilicates et l'hydroxyde de calcium. La quantité de ces phases dans les ciments analysés, déterminée à l'aide de la radiographie et de la dérivatographie, est donnée dans le tableau ci-dessous. Dans ce tableau les ciments sont disposés dans l'ordre d'accroissement de leur teneur en PSAS.

Le degré d'hydratation de l'alite était déterminé de façon radiographique d'après l'intensité de réflexion à  $1,76\text{ Å}$  selon la méthode proposée par M.E.Jmodikova, V.I.Korneev (1) et la quantité de l'ettringite, d'après l'intensité de réflexion à  $9,8\text{ Å}$  selon Kh.G.Smoltchik (2). La quantité de  $\text{Ca}(\text{OH})_2$  était déterminée d'après les dérivatogrammes. Les données obtenues témoignent de l'accroissement de la teneur des échantillons en ettringite avec augmentation de la quantité de PSAS dans le ciment. La plus grande différence dans la teneur en ettrin-

gite est observée aux stades précoces de durcissement (jusqu'à 3 jours). L'hydroxyde de calcium cristallin entre en quantité maximale dans la composition des échantillons du ciment portland. Avec augmentation de la part de PSAS dans le ciment, la concentration de  $\text{Ca}(\text{OH})_2$  dans la pierre de ciment diminue. Ce phénomène est dû évidemment à la variation du degré d'hydratation de l'alite, à l'interaction de la chaux avec l'addition PSAS, à la formation de  $\text{Ca}(\text{OH})_2$  sous forme de gel. Le degré d'hydratation maximal de l'alite est observé dans le ciment expansif; un accroissement ultérieur de la teneur en addition PSAS conduit au ralentissement de l'hydratation de l'alite, ce qui est dû évidemment au blocage de ses grains par une quantité complémentaire de l'hydrogel qui se forme à partir de PSAS.

Il est établi que la structure de la pierre de ciment avec addition PSAS se distingue de la structure des échantillons en ciment

portland par une plus grande homogénéité. Les facteurs contribuant à l'accroissement du degré d'homogénéité sont: 1) disposition uniforme des particules finement dispersées de PSAS dans le volume des échantillons du ciment; 2) formation simultanée à partir des particules de PSAS de l'ettringite et des hydrosilicates de calcium qui se trouvent en contact étroit; 3) réduction de la quantité et de la dimension des cristaux de  $\text{Ca}(\text{OH})_2$ . Le deuxième facteur est le plus important parmi les facteurs énumérés d'accroissement du degré d'homogénéité de la structure du ciment durci. La figure 1 donne différentes variantes de disposition mutuelle des hydrosilicates de calcium et de l'ettringite.

La structure du ciment-portland durci sans addition PSAS se caractérise par ce qu'après 7 jours de durcissement les cristaux d'ettringite sont enchevêtrés avec les hydrosilicates de calcium fibreux (fig.1a). Aux stades suivants de durcissement (28 jours) les régions de la structure, formée par l'ettringite et les hydrosilicates de calcium fibreux, se trouvent en contact avec des agglomérations serrées des particules le plus finement dispersées du gel hydrosiliceux (fig.1b).

Comme on le voit sur le dessin, les agglomérations serrées d'hydrosilicates de calcium ne sont pas en contact avec tous les cristaux d'ettringite mais seulement avec ceux qui se trouvent disposés à la périphérie de la région formée par l'ettringite et des hydrosilicates de calcium fibreux. Dans le ciment avec addition PSAS (fig.1c,d), lors de l'interaction avec la solution aqueuse de la pierre durcissante, les particules de PSAS donnent, comme on le voit sur la photo, l'ettringite et les hydrosilicates de calcium le plus finement dispersés, qui sont étroitement enchevêtrés l'un avec l'autre. Il est indéniable que ces régions de la structure se caractérisent par une plus grande homogénéité que les contacts entre la structure compacte d'hydrosilicates et la structure plus meuble d'hydrosilicates et d'hydrosulfoaluminates du ciment portland durci.

En évaluant les différences entre la structure de la pierre de ciment portland ordinaire et celle de ciment avec addition PSAS il convient donc de souligner qu'en l'absence d'addition la structure de la pierre de ciment se caractérise par la présence des régions séparées de la pierre formées par les agglomérations serrées des particules d'hydrosilicates et les cristaux prismatiques d'ettringite. Dans les ciments avec addition PSAS, grâce à la formation des cristaux d'ettringite et d'hydrosilicates de calcium finement dispersés à partir de la même phase initiale - particules de PSAS - la disposition spatiale des hydrates étant conservée, à la place des particules de départ il se forme une structure plus homogène de la pierre de ciment. La différence entre les structures de types décrits de la pierre de ciment est schématisée sur la figure 2.

Fig.1. Disposition mutuelle des cristaux d'ettringite et des hydroxylates de calcium dans la structure de la pierre de ciment. a - ciment portland ordinaire après 7 jours de durcissement; b - idem après 28 jours; c - ciment avec addition PSAS après 7 jours de durcissement; d - idem après 28 jours. 1 - ettringite; 2 - hydroxylates de calcium fibreux; 3 - agglomérations serrées des hydroxylates de calcium finement dispersés; 4 - particules de PSAS; 8000 $\times$ .

En comparant les résultats obtenus lors de l'analyse de la formation de gel du ciment durci avec les données de la détermination quantitative des hydrates on aboutit à la conclusion suivante: l'accroissement de la résistance du ciment avec addition PSAS aux différents stades de durcissement (jusqu'à 7 jours) s'explique par l'augmentation de la quantité de l'ettringite et une structure plus homogène de la pierre. L'accroissement de la résistance des échantillons de ce ciment après 28 jours de durcissement, lorsque la quantité des hydrates y est à peu près au niveau du ciment portland ordinaire, s'explique par une structure plus homogène de la pierre de ciment.

Comme le montrent les études, l'expansion du ciment durcissant avec addition PSAS a lieu pour la teneur en ettringite de 8 à 9%. On sait (3,4) qu'une teneur considérable de la pierre durcissante en ettringite est une condition nécessaire mais non pas suffisante pour l'expansion. L'expansion peut apparaître seulement dans le cas où la croissance des cristaux d'ettringite a lieu au stade de formation des contacts de cristallisation dans la structure qui rendent le système cohérent et déterminent un certain niveau de résistance mécanique.

Dans les ciments analysés avec addition PSAS, l'enveloppement des cristaux d'ettringite par les particules d'hydrogel, qui crée le niveau requis de résistance de la structure formée, est un des facteurs contribuant à l'expansion.

La non-coïncidence dans le temps de la fin de l'expansion du ciment durci (3 jours) et l'obtention d'une quantité maximale de l'ettringite (dans les limites de 12 h) s'expliquent par ce que l'expansion continue grâce à la recristallisation et à la croissance des cristaux d'ettringite sans variation ou même avec diminution de leur quantité totale (Fig.3).

En même temps cette croissance des cristaux grâce à laquelle l'expansion ne cesse pas ne détermine pas par elle-même la cinétique de l'expansion. Ainsi, lors du durcissement du ciment expansif et du ciment expansif à prise rapide la croissance des cristaux d'ettringite a lieu avec une vitesse différente, et la cinétique de l'expansion de ces ciments est pratiquement identique.

La cinétique de l'expansion dépend essentiellement de la quantité du gel d'hydroxylate, de la valeur de l'adhésion du gel d'hydroxylate aux cristaux d'ettringite

Fig.2. Représentation schématique des structures de la pierre de ciment a) sans PSAS, b) avec PSAS. 1 - restes des grains initiaux du ciment; 2 - régions de la structure compacte secondaire d'hydrosilicates; 3 - ettringite; 4 - hydrosilicates de calcium fibreux; 5 - particules de PSAS restantes; 6 - régions de la structure compacte et secondaire d'hydrosilicates entre cristaux d'ettringite.

et du degré d'homogénéité de la structure du ciment durci. Ces facteurs ont des valeurs proches pour les deux ciments expansifs étudiés.

Sur la base des recherches effectuées, on peut donc conclure que l'addition PSAS agit sur des aspects différents du processus de durcissement du ciment portland. Le plus important est que l'addition est une source des nouvelles formations d'hydrosilicates et d'hydrosulfoaluminates. Ceci conduit à une variation notable de la formation de structure. Les cristaux d'ettringite apparaissent près des particules de départ de PSAS se trouvent en contact étroit avec les agglomérations serrées des particules finement dispersées d'hydrosilicates de calcium. Quant au ciment portland ordinaire, le nombre de ces contacts y est petit grâce à la formation des régions de cristaux d'ettringite isolées du reste de la structure.

Cette différence de principe dans la formation de gel avec les variations de quantité des hydrates de ciment durci fait que la même addition peut communiquer au ciment des propriétés différentes.

Il est expérimentalement établi que la durabilité de la pierre de ciment avec PSAS ne cède pas à celle du ciment portland. Ceci est lié à la composition des hydrates caractéristique du ciment portland et à leur disposition qui est dans la structure du ciment durci plus uniforme que dans le ciment portland et qui exclue le danger de contraintes internes.

### CONCLUSIONS

On a étudié le mode de réglage dans de larges limites des propriétés du ciment en introduisant lors du broyage du clinker-portland les diverses quantités du constituant

Fig.3. Variation de dimension des cristaux d'ettringite dans la pierre de ciment avec le durcissement —▲—▲— ciment portland très résistant, —■—■— ciment expansif, —●—●— ciment expansif à prise rapide.

de cristallisation sulfoalumosiliceux. Ceci permet d'élaborer sur la base d'un seul clinker des ciments spéciaux à destination différente: ciment portland très résistant et ciments expansifs dont le temps de prise peut être réglé dans de larges limites.

A l'aide d'un ensemble de méthodes d'études physico-chimiques on a établi qu'à la base de ce mode de réglage des propriétés du ciment se trouvent les variations de quantités des hydrosulfoaluminates, de l'hydroxyde et des hydrosilicates de calcium, qui

se forment au cours du durcissement, et l'accroissement de l'homogénéité de la structure du ciment durci en présence d'addition sulfoalumosiliceuse.

# Influence de la composition chimique des lignosulfonates sur l'hydratation et la plastification des ciments

## *Influence of chemical structure of lignosulfonates on hydration and plastification of cements*

G.M. TARNAROUTSKI, Candidat ès Sciences Techniques, NIITzement, Moscou,

N.V. GRIBANOVA, Ingénieur, Filiale de VNIIB, Perm.,

G.M. TELYCHEVA, Candidat ès Sciences Chimiques,

V.N. SERGUEEVA, Docteur ès Sciences Chimiques, de l'Académie des Sciences de Lettonie, Institut de la Chimie du Bois de l'Académie des Sciences de Lettonie, Riga, U.R.S.S.

**RESUME :** On a établi l'augmentation et la diminution respectivement des effets plastifiant et entraîneur d'air des lignosulfonates dans les systèmes ciment-eau lorsque la masse moléculaire croît jusqu'à 14 000 - 16 000, l'optimum d'après le critère de plastification. L'accroissement de l'entraînement d'air est obtenu par diminution de la masse moléculaire et du rapport molaire des groupes sulfo- et méthoxyles. On peut accélérer l'hydratation des ciments avec lignosulfonates et augmenter l'effet plastifiant de ces derniers en introduisant dans la partie liophobe de leurs molécules les groupes polaires amines et en augmentant le pourcentage de la fraction molaire des groupes hydroxyles. En choisissant un lignosulfonate de masse moléculaire et de composition fonctionnelle données et le procédé de modification de sa structure, on peut obtenir un plastificateur pour ciment, aux effets plastifiant et entraîneur d'air requis, qui ne ralentit pratiquement pas l'hydratation et le durcissement du ciment.

**SUMMARY :** Increase and decrease of plastifying and air-entraining effects respectively of lignosulfonates in cement-water systems at increase of molecular weight to 14 000 - 16 000 (optimum as regards the plastification criterion) have been established. Increase of air-entraining is achieved by decreasing molecular weight and the molar ratio of sulfo and methoxy groups. Acceleration of hydration of cements with lignosulfonates and intensification of the plastifying effect of the latter are due to introduction of amino-containing polar groups into lyophobic part of their molecules and by increasing content of molar fraction of hydroxy groups.

By selecting lignosulfonates with preset molecular weight and functional composition, as well as the method of modifying of its structure it is possible to obtain a plastifier for cement with the required plastifying and air-entraining action which practically does not decelerate hydration or hardening of cement.

**INTRODUCTION.** Vu l'effet technique et économique obtenu grâce à l'introduction dans les ciments et bétons des plastifiants, le volume de leur application dans l'industrie des matériaux de construction pour le réglage des propriétés techniques et de construction et la diminution de la consommation de ciment ainsi que pour l'accroissement de la longévité des pièces en béton et en béton armé, croît constamment. En tant que ressources de matières premières pour la production industrielle en grande série de ces additions, on utilise largement les lignosulfonates techniques (LST).

Un grand nombre de travaux est consacré à l'étude du problème de l'influence des caractéristiques du ciment, de la composition du mortier et du béton, des régimes de mélangeage, de compactage et de durcissement sur l'efficacité de l'action des LST. On a prêté beaucoup moins d'attention à la dépendance entre les propriétés chimiques et physico-chimiques des lignosulfonates et leur qualité en tant que plastifiant (1).

L'hétérogénéité de la lignine naturelle, les particularités des processus de délinification du bois ainsi que de la transformation biochimique et de la concentration par évaporation des lessives déterminent une composition chimique différente des lignosulfonates, en particulier leur polydispersité. Des données disponibles (2) témoignent de la dépendance qui existe entre les propriétés constantes et rhéologiques des systèmes de ciment et l'action dispersante des lignosulfonates qui est déterminée principalement par leur masse moléculaire (MM) et la composition fonctionnelle.

Dans la présente communication on envisage l'influence qu'exercent les lignosulfonates de MM et de composition fonctionnelle différentes sur l'hydratation et la plastification du ciment.

**MATERIAUX ET TECHNIQUE D'ETUDES.** Des lignosulfonates de sodium purs furent obtenus à partir des LST, le produit marchand obtenu par transformation biochimique de la lessive sulfite provenant de la cuisson du bois à base de Na ou à base mixte de Ca-Na. L'élimination des hydrocarbures et le fractionnement étaient réalisés par des méthodes fondées sur la capacité des lignosulfonates de former des complexes (3, 4). La destruction d'un complexe formé était réalisée par la solution alcaline. En éliminant les cations des lignosulfonates contenant un excès d'alcali, on a obtenu des acides lignosulfoniques à partir desquels, par substitution au cation d'hydrogène d'autres cations de valence différente, on a obtenu des lignosulfonates (LS) de sodium, d'ammonium, de calcium et de fer. La distribution des masses moléculaires (DMM) des LS est établie sur des colonnes chromatographiques remplies de gel Sefadex G-75(5). Le calcul des MM était effectué d'après les gel-chromato-

grammes des LS dans le diméthylsulfoxyde d'après la méthode (6).

On a obtenu un grand nombre de fractions dont les fractions extrêmes étaient utilisées dans les expériences en tant que fractions macromoléculaire (FMM) et bas-moléculaire (FEM).

Pour expliquer l'influence du rapport des groupes hydrophiles et hydrophobes dans les LS, on a déterminé la teneur en groupes méthoxyles ( $\text{OCH}_3$ ) et sulfoxyles ( $\text{SO}_3\text{H}$ ) d'après la méthode (7). Pour déterminer la teneur en groupes acides, y compris les groupes sulfoxyles et carboxyles, ainsi qu'en hydroxydes phénoliques, on a utilisé la méthode de conductimétrie à haute fréquence.

On réduisait la quantité de groupes hydroxyles dans la molécule de LS par leur "fermeture", c.-à-d. par la formation des éthers avec le sulfate de diméthyle. La teneur totale en groupes hydroxyles était déterminée par la méthode d'acétylation dans des micro-ampoules scellées.

En plus de LST et de fractions certaines de LS, on a utilisé, dans les expériences, des échantillons de lignosulfonates techniques modifiés (LSTM) et de fractions macromoléculaire (FMMM) et bas-moléculaire modifiées (FBMM) de LS obtenues par le traitement des LST et des fractions correspondantes de LS par les amines et leurs dérivés.

Dans les expériences on a utilisé le clinker de composition chimico-minéralogique suivante (% en masse) : pertes à la calcination = 1,47,  $\text{SiO}_2$  = 21,66,  $\text{Al}_2\text{O}_3$  = 4,61,  $\text{Fe}_2\text{O}_3$  = 4,89,  $\text{CaO}$  = 65,22,  $\text{MgO}$  = 1,46,  $\text{SO}_3$  = 0,15,  $\text{R}_2\text{O}$  = 0,44,  $\text{CaO}_{\text{libre}}$  = 0,32,  $\text{C}_3\text{S}$  = 61,  $\text{C}_2\text{S}$  = 15,  $\text{C}_3\text{A}$  = 5,  $\text{C}_4\text{AF}$  = 15.

Les plastifiants étudiés étaient introduits dans la composition du ciment lors de son broyage ou avec l'eau de gâchage lors de la préparation du mortier. Les ciments étaient élaborés par broyage, dans un moulin d'essais à deux chambres, jusqu'à  $S = 3000 \pm 100 \text{ cm}^2/\text{g}$ . L'action plastifiante des agents tensio-actifs était évaluée d'après l'étalement du cône standard sur la table vibrante (d'après GOST 310.4-76, annexe 1), ainsi que d'après la valeur de viscosité de la pâte à structure non détruite avec le rapport E/G = 0,50, en qualité de capteur de viscosité on a utilisé un viscosimètre rotatif "Réotest 2".

Pour évaluer l'influence des plastifiants sur la cinétique et le degré d'hydratation du ciment, on a étudié la composition de la phase liquide de la pâte, et les échantillons durcis étaient soumis à l'analyse thermique différentielle et à l'analyse aux rayons X.

La teneur en air du mortier était évaluée par la méthode de compression et les indices de résistance, d'après GOST 310.4-76 lors du durcissement normal et de l'étuvage.

**RESULTATS DES EXPERIENCES.** L'efficacité d'action des IS, qui se distinguent par leur MM et la composition fonctionnelle, était comparée pour un effet plastifiant égal s'exprimant par un accroissement de 15 à 25 % de la plasticité du mortier et par une diminution de 1,5 à 3 fois de la viscosité de la structure pratiquement non détruite de la pâte de ciment ( $\eta_0$ ). La quantité de IS nécessaire pour obtenir cet effet était de 0,10 à 0,17 % \*) (fig. 1). L'augmentation de la quantité de plastifiant jusqu'à 0,30-0,50 % s'accompagnait d'un accroissement de plasticité du mortier de 1,5 à 2 fois et d'une diminution de la grandeur  $\eta_0$  de 8 à 10 fois. Parallèlement, la limite conventionnelle de la fluidité et la contrainte de cisaillement limite de la pâte de ciment se trouvaient diminuées. Les données obtenues témoignent que les FMM des IS se caractérisent par une action plastifiante plus élevée en comparaison des FBM dans l'intervalle de dosage de 0,10 à 0,20 %. Les MM des fractions de IS avec action plastifiante maximale se trouvaient dans les limites de 10 000 à 15 000. L'extension des limites supérieure et inférieure conduisait en règle générale à la diminution de l'effet de plastification. Toutefois, lorsque la quantité d'agent tensio-actif s'élève jusqu'à 0,50 %, l'action plastifiante de FBM augmente beaucoup plus que pour FMM. L'effet plastifiant le plus élevé était observé lorsqu'on utilisait IS d'ammonium.

La capacité d'entraînement d'air de IS, indépendamment du cation, augmentait avec la diminution de MM. On observait l'effet maximal d'entraînement d'air lors de l'introduction de FBM de IS d'ammonium et surtout de sodium. L'augmentation dans la molécule de IS des groupes hydrophiles, tout d'abord grâce à l'augmentation de la quantité d'hydroxyles phénoliques et des groupes sulfoniques, de même que leur modification par les amines et leurs dérivés, contribue au renforcement de l'action plastifiante et à la diminution de l'effet d'entraînement d'air complémentaire des IS.

D'après les données de l'analyse thermique différentielle, de l'analyse aux rayons X et la cinétique de la variation de composition de la phase liquide, l'introduction de 0,10 à 0,17 % de plastifiants étudiés ne conduit pas à un ralentissement notable de l'hydratation du ciment (Tableau I). En font exception seulement FBM de sodium et FBM de fer. Il faut noter qu'un ralentissement plus considérable des processus d'hydratation était observé lors de l'introduction de FBM.

\*) Ici et dans le texte suivant la quantité de IS est calculée pour le corps sec en % de la masse du ciment.

Fig. 1 - Action plastifiante des IS.

1 - IST, 2 - FMM de Na, 3 - FMM de  $\text{NH}_4$ , 4 - FMM de Ca, 5 - FMM de Fe, 6 - FBM de Na, 7 - FBM de  $\text{NH}_4$ , 8 - FBM de Ca, 9 - FBM de Fe, 10 - FMM de Na, 11 - FMM de Na

Avec l'augmentation de la quantité d'agents tensio-actifs jusqu'à 0,30-0,50 %, on observait le ralentissement des processus d'hydratation du système indépendamment de MM : l'aire de l'effet de déshydratation des hydrosulfoaluminates sur les thermogrammes diminuait, ce qui témoignait de la diminution de la quantité d'étringite et

du degré d'hydratation ; à côté de la forme cristalline de  $\text{Ca}(\text{OH})_2$  (480 °C) était fixé l'effet étendu de l'hydroxyde de calcium amorphe (420 à 450 °C). Le degré d'hydratation du ciment avec agent tensio-actif diminuait de 20 à 40 %. FEM de IS de sodium manifesta la plus forte action ralentissante. On observait une influence positive des IS sur les processus d'hydratation après le traitement par les amines et leurs dérivés.

TABLEAU I				
Influence des IS sur le degré d'hydratation du ciment				
Dénomination de l'addition	Degré d'hydratation d'après $C_2S$ %			
	1 jour		28 jours	
	Quantité d'addition, %			
	0,15	0,50	0,15	0,50
Sans agents tensio-actifs	38	38	82	82
LST	37	24	81	74
FMM de Na	34	22	83	77
FMM de $NH_4$	39	27	80	76

FEM de Na	30	19	82	71
FEM de $NH_4$	40	24	82	77
FEM de Ca	34	22	80	76
FEM de Fe	28	21	77	72
FMMM de Na	39	32	85	80
FMMM de Na	34	28	82	78

L'action ralentissante sur l'hydratation du ciment des hydrates de carbone et des acides organiques, entrant dans la composition de l'échantillon étudié des LST en quantité de 8,5 %, ne devenait assez perceptible que lors de l'introduction des LST en quantité de 0,50 %. Toutefois il faut noter que les LST épurés d'hydrates de carbone, surtout leurs FMM, diminuaient sensiblement, dans nombre de cas, le temps de prise du ciment.

Les données obtenues sur la résistance des échantillons (Tableau II) montrèrent qu'indépendamment de la quantité de surfactifs, les FMM étaient plus efficaces que les FBM en cas de traitement à la chaleur humide. Lors du durcissement normal des échantillons, surtout lorsqu'on introduit des quantités élevées de plastifiant, l'effet des IS dépend faiblement de MM. L'accroissement de la quantité de groupes hydroxyles et la modification des IS indépendamment de leur MM entraîneront l'augmentation des indices de résistance du ciment.

**DISCUSSION DES RESULTATS.** Les différences notées plus haut en ce qui concerne l'efficacité de l'action des IS de MM différente s'expliquent par leur pouvoir d'adsorption

TABLEAU II				
Dénomination des additions et leur quantité, %	Entraînement d'air complémentaire, %	Résistance limite à la compression, MPa, des échantillons d'après

différent sur la surface des particules du ciment et de ses nouvelles formations hydratées. On sait que, les autres conditions étant égales, le pouvoir d'adsorption des IS croît avec leur MM (1). L'effet dispersif des IS dans les systèmes de ciment augmente avec l'augmentation de leurs MM jusqu'à une limite déterminée, après quoi il commence à diminuer (2). Ceci est en accord avec nos données sur une action plastifiante plus élevée des FMM en comparaison des FBM.

Selon l'hypothèse faite dans (8), l'action plastifiante des agents tensio-actifs dans les systèmes ciment-eau peut être expliquée par la formation des systèmes de faibles H-liaisons, due à l'interaction de l'eau avec les centres électronégatifs de la partie lyphobe des molécules du surfactif. Les autres effets sont secondaires. Comme le montrent les spectres infrarouges, de "fortes" H-liaisons se forment dans la couche potentielle remplie d'eau près de la surface des particules du ciment (9). Pour prévenir leur formation, il faut recouvrir cette couche par la partie lyphobe d'une molécule du surfactif. C'est pourquoi l'action plastifiante des agents tensio-actifs doit croître avec la longueur de la partie lyphobe jusqu'à ce qu'elle atteigne l'épaisseur critique de la couche potentielle, i.e. avec l'augmentation de leurs MM. En effet, les FMM des IS en quantité (0,10 à 0,15 %), assurant le recouvrement des centres actifs de la surface, sont plus efficaces que les FBM dont la quantité doit être sensiblement plus gran-

de pour atteindre le même but. Toutefois, lors de l'introduction d'une quantité élevée de surfactif ce qui fait qu'un grand nombre de molécules restent non adsorbées, la capacité du surfactif de diminuer la tension superficielle, à la limite phase liquide-air, devient un facteur important. Grâce à la solubilité plus élevée, cette capacité croît plus fortement pour les FBM, ce qui est peut-être la cause d'un renforcement sensible de leur action plastifiante lors de l'introduction du surfactif en quantité à peu près égale ou supérieure à 0,50 %.

Outre une longueur correspondante de la partie lyophobic de la molécule du surfactif, la plastification nécessite le blocage des fortes H-liaisons des molécules d'eau par les systèmes ("icebergs") de "faibles" H-liaisons. C'est pourquoi l'effet de plastification doit croître lorsqu'on introduit dans la partie lyophobic des molécules, des groupes polaires renforçant l'électronégativité de leurs centres actifs. Ceci explique l'augmentation de l'effet plastifiant lors de la substitution au cation d'ammonium du cation de sodium et de la modification des lignosulfonates par les amines et leurs dérivés. La valeur de l'effet dépend alors de la structure du groupe aminé joint et se détermine principalement par la densité électronique sur l'atome d'azote.

Lors de l'introduction des agents tensioactifs hydrosolubles, l'effet d'entraînement d'air complémentaire s'explique par la réduction de la tension superficielle sur l'interface solution du surfactif-air, qui dépend de la concentration des molécules du surfactif restant dans la solution après son adsorption. C'est pour cette raison que les FBM de IS, qui possèdent un pouvoir adsorbant réduit en comparaison des FMM, se caractérisent par une action d'entraînement d'air et moussante plus élevée. Ces effets augmentent avec l'accroissement de la concentration des IST dans la solution, la diminution de MM et du degré de sulfonation des IS (2). Les IST à base d'ammonium possèdent le plus grand pouvoir moussant tandis que les IST à base de sodium se caractérisent, même aux faibles concentrations, par une grande stabilité de la mousse (10). Ces derniers possèdent également une action d'entraînement d'air plus élevée par rapport aux IS de calcium et de fer. La modification des IS conduit à l'accroissement de leur MM et respectivement à la diminution de leur pouvoir d'entraînement d'air et de leur pouvoir moussant.

L'influence des lignosulfonates sur les indices de résistance du ciment dépend de leur action ralentissante sur les processus d'hydratation du ciment et du pouvoir d'entraînement d'air des IS, le premier facteur exerçant une influence plus sensible sur la résistance du ciment au cours du durcissement normal et le second, lors du traitement à la chaleur humide. Il con-

vient aussi de noter l'importance de l'élévation du pouvoir plastifiant des IS, ce qui permet d'obtenir le même effet plastifiant avec une quantité moindre d'addition et, donc, d'affaiblir les facteurs négatifs influant sur la résistance du ciment.

## CONCLUSION

L'analyse des données obtenues témoigne de la nécessité d'aborder de manière différentielle le problème d'élaboration des additions sur la base des IST en fonction de leur destination. On a établi qu'il est possible d'obtenir un plastifiant pour le ciment à base des IS, qui aurait une action plastifiante et d'entraînement d'air requise et qui ne ralentirait pratiquement pas l'hydratation et le durcissement du ciment.

# Testing methods for the set of pastes and mortars

## *Méthodes de détermination de la prise des pâtes et mortiers*

Dr. M. MAULTZSCH and

U. MEINHOLD, Federal Institute for Testing Materials (Bundesanstalt für Materialprüfung (BAM)  
Berlin, R.F.A.

RESUME : Des mesures de la prise des pâtes et mortiers de ciment ont été faites par différentes méthodes et comparées entre elles. La prise des pâtes est déterminée par un essai de pénétration, notamment par l'aiguille de Vicat. Sous certaines conditions et en choisissant convenablement le corps de pénétration, on peut caractériser de façon qualitative l'influence de certains facteurs sur l'évolution de l'hydratation. Les facteurs pris en compte ont été : le rapport E/C, la température et le dosage en adjuvant.

Les essais de prise sur mortiers normalisés sont plus proches des exigences de la pratique. Ainsi des changements, en fonction du temps, du comportement plastique, peuvent être décelés par le "flow test". La fausse prise, le raidissement prématuré et d'autres irrégularités du processus de prise peuvent être ainsi déterminés quantitativement, ainsi que l'action des adjuvants. Des exemples montrent que les résultats obtenus sur les pâtes se transposent difficilement aux mortiers, alors que les résultats obtenus sur mortiers et sur bétons sont comparables.

SUMMARY: Measurement data of cement pastes and mortars are compared. The set of pastes is tested with the penetration method e.g. according to Vicat. Under special conditions and selecting a suitable penetration body it is possible to record qualitatively certain influences on the process of hydration, namely the water/cement ratio, the temperature and adding quantity of chemical admixtures for concrete. More suitable for the requirements in practical use are set tests on standardized mortars. Thereby the temporal change of the plastic behaviour is to be determined by the flow test. False set, premature stiffening and other irregularities in the process of setting as well as the action of admixtures, can be recorded quantitatively. By examples it is shown, that test results of set for pastes are only comparable to a certain extent to those of mortars, whereas mortar and concrete react comparable with each other.

## INTRODUCTION

The setting of cement pastes and mortars is being tested according to the penetration test of Vicat (1) since the beginning of the 19th century. Originally this was done to distinguish qualitatively between the fast setting within a few hours and the slow setting within any length of time. The development of cement and concrete technology during the last decades has made it necessary to get more exact knowledge of the setting process. As far as the Vicat test was used quantitatively it has been overestimated in many cases with regard to the certainty and the importance of the measurements. On the other hand there is no other method for cement pastes that gives us any reliable data comparatively as little expended energy as this test.

Besides insufficient attention is paid to the differences of changes in consistency of mortars and concretes referred to the setting of cement and those of pastes.

## SETTING OF CEMENT PASTES

The needle penetration method of Vicat may provide reasonable set test values for normally setting cements. Prerequisite is always keeping precisely the same conditions and a careful test procedure (2). The fixings of this point by international standards are not sufficient.

The penetration depth of the needle, plotted versus time, shows a more or less steep s-like shape as a rule (figure 1 top). This shape of the curve does not even change if a cement tends to "false set" or "premature stiffening". However, if irregularities of setting become stronger the penetration depth values may vary erratically so that only a fitting curve leads to a result. In figure 1 bottom the setting of a paste containing a retarder admixture is plotted. Apparently this admixture has promoted the formation of spacially limited portions, stiffening starts from these. In former studies this effect sometimes is mentioned as "insular formation". It causes an irregular penetration of the slim Vicat needle. It shall be remembered here that the volume displaced by the Vicat needle is a very small one indeed, but the needle regarded as a pressure foot causes the considerable compressive stress of  $3 \text{ N/mm}^2$ .

The above mentioned irregularities of the test values do not occur if a conical penetrator instead of the needle is used because its penetration volume is larger. McCormick and Cowgill (3) had already pointed to the greater precision of the test working with a cone, two inches in base diameter, to determine the water content of mortars. The slender cone proposed by us makes it possible for example to find out the "false set" and the "premature stiffening" or the stiffening secondary effect due to some concrete admixtures. The curves for instance drawn in figure 2 are based on numerous measurements

with a conical penetrator the diameter of which is 1 mm at the bottom and 9 mm at the height of 40 mm respectively. Using this cone one cannot measure the setting time as defined in the standards, but it makes perceptible such properties of cements that influence directly the consistency changes dependent on time.

Fig. 1 - Vicat test on cement pastes. Penetration depth versus time.

Fig. 2 - Modified Vicat test on cement pastes. Penetration depth of a conical penetrator versus time.

The regulations for setting time determination laid down in cement standards do not make much sense. This is because they are based on penetration depth values lying within the respective flat sections of the s-like curve. That means of course that the spread of the values is very large. For the determination of setting times it is more suitable to elect a point out of the steep curve path, e.g. at the penetration depth of 20 mm. In most cases the spread will be re-

duced to  $\pm 5$  minutes. In this way the influence of the water/cement-ratio can be determined on a large scale (fig. 3). In these experiments two ordinary portland cements Z 45 F of nearly equal fineness were used. It is significant that small variations of the w/c-ratio produce large changes of setting time only for one of the cements.

Fig. 3 - Influence of the w/c-ratio on the setting time of cement pastes for two different cements "A" and "B".

Figure 4 shows the influence of the dosage rate of a retarding admixture on the setting time of a portland cement. The amount of time in which the needle reached only 20 mm penetration depth was defined as the setting time in this case too. Initial or final setting time values as defined by standards could not be determined at all or with sufficient precision for most of the mixtures. With a certain quantity of admixture depending on the w/c-ratio slow-setting is reverted to quick-setting rather abruptly. The importance of these measurements with regard to practical use will be referred to later.

#### SETTING OF MORTARS AND CONCRETES

The purpose of determining the setting times of cements is, with regard to practical application, to point out the length of time during which mortars and concretes are workable. It has been proven, however, that the stiffening behaviour of cements in pastes is

Fig. 4 - Setting time of cement pastes versus quantity of retarder admixture.

different from that in mortars or concretes. But it is a disadvantage that stiffening tests on concretes are very laborious. Furthermore most of the methods for testing the consistency of concretes fail in accuracy, or their applicability is limited (4). Particularly the penetration tests on concretes hardly indicate any useful results.

During the last years we made numerous measurements of the time-dependent consistency changes of concretes using the German standard flow table. The flow development in time has been mentioned on other studies referring to the influences of some admixtures, particularly of plasticizers (5, 6). But the extent of these investigations is not adequate to evaluate the workability in principle. Working with this background, investigations with the aid of flow tests on standardized mortars added satisfactory results (7). Provided with a suitable test procedure, it is possible to even quantitatively recognize factors of influence on the stiffening behaviour.

The flow of mortars is determined by the flow table apparatus standardized in DIN 18 555 (similar to that in ASTM C 230-68). The conical mold for the mortar has a basic diameter of 10 cm. The table is to be dropped through a height of 10 mm once per second and the flow is the resulting diameter of the mortar mass after a certain number of drops.

In order to precisely determine the stiffening the flow value should originally be on a high level, and test mortars initially should have a good flow capability. This may be affected by the cement content, the water/cement-ratio, and the number of drops. Originating with the standard mortar specified for testing cements, a small increase of cement content proved to be favorable. The investigations described subsequently were carried out with mortars of mix proportion 1 : 2.7 by weight. If the water/cement-ratio is varied within a reason-

able range, flow values correspond directly and linearly, even after some hours after mixing and additionally affected by admixtures (figure 5).

Fig. 5 - Flow of mortars with and without admixture at different hydration times versus water/cement-ratio.

Figure 6 shows the flow correlating to the number of drops while different w/c-ratios are given. With growing numbers of drops flow values increase a little underproportionally. For further investigations the w/c-ratio was fixed at 0,50 and the number of drops at 20. Under these conditions most of the cements produce initial flows of about 20 cm.

Fig. 6 - Flow of mortars with different w/c-ratios versus number of drops.

The hydration process leads to the stiffening of the mortar and to a continuous decrease of the flow depending on time. The values of normal setting cements generally fall into the hatched area of figure 7. But otherwise this test method makes it possible to definitely recognize setting irregularities such as false set or premature stiffening. False set always leads to a slight increase of flow values during the initial time period. On the other hand premature stiffening can be recognized by a remarkable steep fall of the curve within the first hour after mixing.

Fig. 7 - Flow of modified standard mortar versus time.

In many cases of practical use concrete admixtures are added to affect consistency or stiffening. The mode of action of these reagents, such as plasticizing, retarding, accelerating, may be determined with sufficient accuracy by the proposed test method. Here also the modified standard mortar with increased cement content and the w/c-ratio 0,50 stood the test. During the first hours measurements of flow should be performed in 30 min intervals at the most. When testing admixtures of accelerating or stiffening effect, time intervals should be shortened (8).

This way for example many setting retarders were tested. With respect to numerous different cements it could be proven that retarding effects, i.e. to preserve a certain consistency, did not occur before 2,5 - 4 hours after mixing, while within the initial period a conspicuous stiffening of the mortar was observed. Figure 8 shows flow curves of mortars with various quantities of retarder

admixtures in comparison to non-retarded mortars, using three different w/c-ratios.

Fig. 8.- Effect of a retarder on the flow of mortars. The hatched area covers the values for different admixture quantities.

The admixture's influence on the consistency within the first half hour is evident. It should be mentioned that the non-retarded mortar tended to false set due to the chosen cement. During the next 2 hours all retarded mortars show nearly the same stiffening behaviour as those without admixtures. Only later the retarded mortars stiffen slowly as compared to the normal set of the non-retarded mortars. This behaviour seems to be independent of the water/cement-ratio. Merely the premature stiffening effect becomes stronger with the decrease of w/c-ratio and the increase of dosage. Other retarders, those without plasticizing effect, also led to flow development in time that differed from that of admixture-free mortars not before 2,5 - 4 hours.

Figure 9 answers the question regarding the influence of the dosage that was already mentioned. Immediately after mixing, the retarder used here plasticizes the mortar more and more with increasing addition, as is well

known of lignosulphonates. But the early stiffening effect grows at the same rate. Therefore after one hour all the mortars have the same flow independent of the dosage of retarder. Further stiffening is affected differently only by very small additions, but exceeding a certain quantity the dosage does not induce any differences in stiffening behaviour. All measured values are covered by the hatched area in the graph, i.e. in spite of increasing admixture quantities the setting of the mortars is retarded equally. This result appears to be in contradiction to the values determined by needle penetration tests on pastes of the same cement and retarder (see fig. 4). There is no reversion to quick-setting of the mortars. It must be concluded that with respect to the workability of mortars and concretes the needle test is unsuitable and may even cause an erroneous rating of consistency behaviour. Results of tests on the setting of cement pastes cannot be transferred to the consistency development in time of mortars and concretes. On the other hand it was previously deduced that flow values of modified standard mortars determined by the proposed method correlate very well at any time to those of comparable standardized concretes (7).

However, the Vicat needle test may point to discontinuities of the hydration process with certain addition quantities. For example the mortars with high retarder content being of good workability even after six hours failed in strength development. Finally they crumbled if stored under water. In this case the striking reversion in set observed in the tests on pastes indicates problems with the hardening process rather than trouble with the workability.

#### CONCLUSIONS

With regard to tests on the set of pastes three conclusions result from the investigations and interpretations of many references as well: 1st, the traditional Vicat test should be improved by recording continuously the determined values of penetration depth versus time and by redefinition of the setting time on the basis of a medium penetration depth; 2nd, results of penetration tests on pastes should not be the only criterion for the setting of mortars and concretes; better results will be obtained using a conical penetrator; 3rd, the needle test is suitable to detect qualitatively certain effects on the hydration process.

Setting tests on mortars require an acceptable expenditure of work. Under certain conditions the results correspond to those obtained by tests on concretes. Based on satisfactory experiences on a large scale, a method of setting test is proposed using a standardized mortar with increased cement content. Normal setting, false set, and premature stiffening respectively may be determined by this method.

Furthermore effects of admixtures on the

Fig. 9 - Flow of modified standard mortar versus quantity of retarder admixture at different hydration times.

consistency or the stiffening may be characterized even quantitatively. However, it must be pointed out that a favorable workability of mortars or concretes, particularly of those containing admixtures, does not necessarily guarantee favorable hardening and strength development.

# Influence des sulfates sur les comportements rhéologiques des pâtes de ciment et sur leur évolution

## *Influence of sulfates on the rheological behavior of cement pastes and on their evolution*

J.P. BOMBLED, C.E.R.I.L.H., France

### RESUME

Les sulfates jouent un rôle important non seulement en fabrication des liants mais encore et surtout lors de leur utilisation dans les mécanismes rhéologiques et d'hydratation ainsi que pour la durabilité.

Pour chercher à comprendre leur action sur le plan rhéologique à l'état frais et sur les évolutions précoces (prise, raidissements) ou ultérieurs (résistances, variations dimensionnelles) on a étudié d'une part différents sulfates calciques (gypse, plâtre, anhydrite naturel, phosphogypse) et d'autre part un certain nombre de sulfates non calciques (Li, Na, Mg, Al, K, Mn, Fe, Cu, Zn, Ba, Pb,  $\text{NH}_4$ ) ; les essais ont porté sur deux clinkers de teneur différente en  $\text{C}_3\text{A}$  (3 et 14 %).

Comme les cinétiques et les équilibres de dissolution régissent en grande part tous les phénomènes initiaux, l'étude a débuté par l'examen de la solubilité et de la vitesse de dissolution ainsi que les facteurs qui l'influencent (température, finesse, ions communs) ; y compris la répercussion du moment d'incorporation du sulfate (au broyeur, dans le clinker broyé, dans l'eau, dans le malaxeur).

Il ressort des essais que la rhéologie des pâtes de ciment fraîches résulte de la conjonction de l'effet de floculation et de l'action retardatrice sur l'hydratation précoce des aluminates : selon la composition minéralogique du clinker et la cinétique de dissolution, l'incorporation d'un sulfate peut se traduire, soit par une fluidification (apparente), soit par une rigidification.

L'évolution dans les premières heures (période de mise en œuvre) montre aussi que, suivant la quantité de sulfate disponible ou non consommée, on peut voir l'action fluidifiante ou rigidifiante suivie soit par un effet retardateur soit par un effet accélérateur sur la phase silicate.

D'une façon générale, les activités observées dans presque tous les cas se classent à peu près dans l'ordre des vitesses de dissolution.

Les conséquences sur les propriétés des pâtes durcies confirment ce qui est déjà bien connu dans ce domaine.

### SUMMARY

The sulfates play an important role, not only in the fabrication of binding materials, but also and chiefly in their use in rheological and hydration mechanisms, and for the durability.

Different calcium sulfates (gypsum, plaster of Paris, natural anhydrite, phosphogypsum) and on the other hand sulfates of other metals (Li, Na, Mg, Al, K, Mn, Fe, Cu, Zn, Ba, Pb,  $\text{NH}_4$ ) were studied in order to attempt an understanding of their action on the rheological field at fresh state and upon early (set, stiffening) or further (strength, dimensional variations) evolutions ; the tests were made on two clinkers with different  $\text{C}_3\text{A}$ -contents (3 and 14 %).

As dissolution kinetics and equilibriums govern in a large extent all initial phenomena, the research began with the examination of the solubility and speed of dissolution as well as factors which influence on it (temperature, fineness, common ions), including the effect of the point of time of the incorporation of the sulfate (into the mill, into the ground clinker, into the water, into the mixer).

The tests show that the rheology of fresh cement pastes results from the conjunction of the effect of floculation and of the retarding action upon the early hydration of the aluminates : according to the mineralogical composition of the clinker and to the dissolution kinetics, the incorporation of a sulfate determines either a seeming fluidization or a stiffening.

The evolution during the first hours (pouring period) shows also that according to the disposable or unconsumed quantity of sulfates, the fluidizing or stiffening action can be followed either by an extended retarding effect or an accelerating effect on the silicate phase.

Generally, the activities observed in almost all the cases are classed approximately in the same order as the dissolution speeds.

The consequences on the properties of hardened pastes confirm what is already well known in that field.

## 1. INTRODUCTION

Les sulfates et notamment les sulfates calciques peuvent jouer un rôle soit en fabrication (minéralisateurs, fabrication combinée clinker-SO<sub>4</sub>H<sub>2</sub>), soit comme composants de liants (sursulfatés, expansifs,...), soit comme adjuvant modifiant la rhéologie et les vitesses d'hydratation (accélération des silicates et du laitier, retardement des aluminates,...) ; les ions sulfates interviennent aussi dans les problèmes de durabilité (attaques d'eaux agressives par exemple).

Ajoutons que le souci de protection de l'environnement et de valorisation de déchets industriels rend disponibles des quantités considérables de sulfates de calcium "chimiques" (phosphogypse par exemple) dont l'incorporation dans les ciments est envisagée.

Il en résulte qu'une meilleure connaissance des mécanismes d'action des divers sulfates sur le comportement rhéologique à l'état frais et sur l'évolution ultérieure (prise, raidissements, durcissement, variations dimensionnelles) revêt un intérêt capital.

## 2. GENERALITES

### 2.1 Floculation

A partir du contact eau-ciment, dans la séquence des phénomènes (mouillage, floculation, pénétration, hydrolyse, dissolution, solvation, hydratation, diffusion, sursaturation et précipitation) c'est en particulier la floculation qui conditionne le comportement rhéologique de la pâte fraîche ; néanmoins, il ne faut pas oublier que les premières liaisons dues à l'hydratation précoce peuvent aussi empiéter sur la période de mise en œuvre (état frais).

Nous avons montré depuis longtemps [1] que l'état de floculation des pâtes de ciment dépend de la nature des minéraux (potentiel de surface et homogénéité de répartition des charges) et de la nature (valence, dimension) des ions compensateurs provenant des éléments dissous ou des adjuvants (épaisseur de la double couche de Gouy, quantité d'eau "bloquée").

Il ressort de nos études antérieures que la floculation est en grande partie responsable du comportement visco-plastique Binghamien des pâtes de ciment fraîches (cohésion, thixotropie,...) et ipso facto de la cohésion de la pâte interstitielle des bétons, grandeur qui est une des composantes de la plasticité des bétons frais [2].

### 2.2 Dissolution

Comme pour les minéraux du clinker, les conditions du passage en solution des sulfates (et surtout leur vitesse) est l'élément capital pour comprendre les mécanismes rhéologiques précoces qui nous intéressent. Mais il faut aussi tenir compte du phénomène très important de solvation (dû à l'interaction des ions avec les molécules du solvant), c'est-à-dire la fixation autour des ions d'un essaim considérable de molécules d'eau, ce qui modifie la mobilité, la diffusion, la quantité d'eau libre, etc...

Rappelons que l'équilibre ionique des solutions est régi par la loi de dilution d'OSTWALD:

$$\text{Produit de solubilité: } K_{ps} = \frac{[A^+][r^-]}{A \Gamma} = \frac{\alpha^2}{1-\alpha} C^n \quad (1)$$

(pour fixer les idées, à 18/25 °C :

$K_{ps} = 2,5 \cdot 10^{-5}$  pour  $SO_3Ca \cdot 2H_2O$

$= 1,3 \cdot 10^{-5}$  "  $Ca(OH)_2$  ).

L'évolution, dans les premiers instants, sera la conjonction des cinétiques de dissolution des éléments très rapidement solubles (C<sub>3</sub>A, sulfates, éléments alcalins, grains "colloïdaux") en résumé :

La solubilité des sulfates calciques dépendra :

- de leur taux d'hydratation (et éventuellement des conditions de déshydratation ; cf paragraphe 3),
- de la température, la solubilité décroît pour les dissolutions exothermiques et pour les corps formant des hydrates (ce qui est le cas), figure 1 (a),
- de la conséquence de la loi de dilution par la présence d'autres ions, communs (Ca<sup>++</sup>, SO<sub>4</sub> des clinkers) ou non (hydroxyle OH<sup>-</sup> par exemple), figure 1 (b).

La vitesse de dissolution dépendra de la surface en contact (figure 2), de la constitution du sulfate (figure 3) et dans une certaine mesure de l'agitation et de l'ordre d'incorporation, on peut noter sur la figure 2 qu'au-delà de ~ 3000 cm<sup>2</sup>/g, la surface spécifique du gypse joue peu, la dissolution est quasi instantanée.

Fig 1 - Solubilité des sulfates calciques.

Fig 2 - Vitesse de dissolution et aire massique.

### 2.3 Corollaire

Le comportement rhéologique à l'état frais sera le résultat de la conjugaison de plusieurs processus plus ou moins échelonnés dans le temps :

- les gros anions (SO<sub>4</sub><sup>--</sup>, OH<sup>-</sup>) viennent préférentiellement se fixer sur les grains électropositifs des aluminates et modifier l'équilibre électrocinétique des interactions intergranulaires (liaisons de floculation).

- par ses ions Ca<sup>++</sup>, le sulfate de calcium joue le rôle de réducteur de solubilité à l'égard du C<sub>3</sub>A et par conséquent retarde l'apparition de liaisons d'hydratation précoces [3] et [4].

- l'affinité des sulfates et des aluminates conduit aussi à la formation de sulfo-aluminates qui consomment les ions SO<sub>4</sub><sup>--</sup> dont l'épuisement permet à nouveau, à terme, la reprise de la dissolution et de l'hydratation du C<sub>3</sub>A avec le raidissement concomitant.

- enfin comme anions forts (donnant des sels calciques plus solubles que les silicates de Ca), s'ils ne sont pas épuisés les ions  $\text{SO}_4^{--}$  contribuent à accélérer l'hydratation de  $\text{C}_3\text{S}$  d'où de nouvelles liaisons prenant le relai dans les premières heures pendant l'évolution rhéologique.

### 3. MATERIAUX UTILISES

#### 3.1 Clinkers (Tableau I)

Deux clinkers, de teneurs en  $\text{C}_3\text{A}$  différentes, et broyés à deux finesses ont été sélectionnés.

Tableau I

Clinker	Analyses minéralogiques par diffraction X (%)				Teneur en éléments mineurs (%)					Aire massique Blaine ( $\text{cm}^2/\text{g}$ )	
	$\text{C}_3\text{S}$	$\text{C}_2\text{S}$	$\text{C}_3\text{A}$	$\text{C}_4\text{AF}$	$\text{SO}_3$	$\text{K}_2\text{O}$	$\text{Na}_2\text{O}$	$\text{MgO}$	chaux libre		
A	77	15	3,2	4,3	0,43	0,25	0,13	0,86	0,40	I 3600	II 4600
						$\Sigma 0,38\%$					
B	62	18	14	5	0,44	1,10	0,28	1,04	1,25	I 3600	II 4600
						$\Sigma 1,38\%$					

\* forme cubique \*\* orthorhombique

#### 3.2 Sulfates (Tableau II)

Quatre sulfates de Ca, parmi lesquels deux ont été broyés à deux finesses, ont été choisis.

Tableau II

Sulfates (provenances)	Minéraux	Déterminations chimiques				Aire massique Blaine ( $\text{cm}^2/\text{g}$ )
		p f	$\text{SO}_3$	$\text{Na}_2\text{O}$ $\text{K}_2\text{O}$	$\text{MgO}$	
gypse (Vaux/Seine)	$\text{SO}_4\text{Ca}, 2\text{H}_2\text{O}$ + quartz et calcite	22,0	43,3	0,10	abs	(1) 3800 (2) 5500
Anhydrite naturel (Thionville)	$\text{SO}_4\text{Ca}$ contient aussi du gypse	5,1	54,1	0,20	0,60	(1) 3500 (2) 7200
Plâtre (Prolabo)	$\text{SO}_4\text{Ca}, 0,5\text{H}_2\text{O}$ + anhydrite	7,9	50,2	0,03	0,80	2700
Phosphogypse neutralisé épure (Douvrin)	presque entièrement forme de semi-hydrate	5,6	53,5	abs	0,40	6900

\* impureté majeure soluble :  $\text{P}_2\text{O}_5$  8 mg/l

Pour les sulfates non calciques on a choisi : Li, Na, Mg, Al, K,  $\text{NH}_4$ , Mn, Fe, Cu, Zn, Ba et Pb.

La Figure 3 illustre les vitesses de dissolution.

Fig 3. Vitesse de dissolution des différents sulfates.  
(eau distillée 20°C)

Ce qu'il faut retenir de la Figure 3, c'est que les sulfates calciques ont une solubilité intermédiaire entre des substances quasiment insolubles ( $\text{SO}_4\text{Ba}$ ,  $\text{SO}_4\text{Pb}$ ) et la plupart des autres sulfates choisis et, par ailleurs, l'extrême rapidité de la plupart des dissolutions ( $\sim 80$  à  $90\%$  de la saturation après 10 secondes); notons que l'anhydrite naturelle est presque aussi soluble que le gypse mais sa vitesse de dissolution est plus lente.

#### 4. MOMENT D'INCORPORATION DU GYPSE

Dans la suite des essais, pour des raisons pratiques, les sulfates seront homogénéisés à sec dans le clinker broyé; comme les équilibres de solubilité sont liés au passage en solution d'autres éléments très solubles provenant du clinker, il était utile de connaître l'influence du moment d'incorporation du sulfate. Dans ces conditions, 5 mélanges ont été étudiés avec 5 % en poids du gypse G1.

- (a) gypse et clinker broyés ensemble,
- (b) gypse et clinker mélangés à l'état de poudre,
- (c) gypse mêlé à l'eau de gâchage,
- (d) gypse introduit au début du malaxage (1 min après le mouillage du clinker),
- (e) gypse incorporé en fin de malaxage (1 min avant la fin d'un malaxage de 5 min).

Le Tableau III résume quelques uns des principaux résultats.

Tableau III

 f (exigence en eau inverse) et prise cf. fig 4 et 5.

Fig 4. Mesure du seuil de cisaillement f au viscosimètre.

Fig 5. Evolution de la prise au rheographe BOMBLED.

Notons que dans le cas du broyage simultané, les finesses respectives sont certainement en raison inverse des broyabilités et sont par conséquent différentes de celles des Tableaux I et II.

Le renflement caractéristique de la courbe de la pâte sans gypse (fig. 5) et les effets fluidifiant initial et accélérateur ultérieur seront explicités au chapitre 6 (figure 14).

## 5. RHEOLOGIE DE LA PATE INTERSTITIELLE DE CIMENT FRAICHE

Toutes les mesures ont été faites au viscosimètre à cylindres coaxiaux CERILH [5] ; la figure 6 montre les différents aspects possibles des rhéogrammes enregistrés et les divers comportements rhéologiques observables.

Fig 6. Différents types de rhéogrammes.

La grandeur la plus significative de ces fluides Binghamiens (ou pseudo) étant leur seuil de cisaillement, c'est celui-ci qui sera étudié (les mesures ont toutes été effectuées 5 min après la fin du malaxage).

### 5.1 Influence de la teneur en $C_3A$

Nous avons montré, dans une étude précédente [1], que, dans l'eau pure, les aluminates sont initialement défloculés et dispersés ; en revanche, ils forment très rapidement des liaisons en fonction des conditions spatiales (serrage et teneur en eau) : le comportement des pâtes de ciment sera donc la combinaison de ces deux effets contradictoires (figure 7).

Fig 7. Rheologie et teneur en  $C_3A$ .

Par conséquent, les corps qui présentent en même temps une action floculante et un effet retardateur du  $C_3A$ , comme c'est le cas généralement pour les sulfates, conduiront à un comportement différent selon la teneur en  $C_3A$  du clinker.

Sur la figure 8 qui illustre la conclusion précédente dans le cas des clinkers "A" et "B", on peut faire les observations suivantes :

- E représente la différence d'exigence en eau à caractéristique rhéologique égale (pour 2 teneurs en  $C_3A$ ),
- J même signification que figure 7,
- F effet floculant (rigidifiant),
- R action retardatrice initiale sur le  $C_3A$  dans les premiers moments (fluidification apparente).

Fig 8. Seuil de cisaillement en fonction du rapport  $E/C$ .

On peut noter que l'influence de la finesse de mouture se répercute moins sensiblement sur le clinker à faible teneur en  $C_3A$ .

### 5.2 Action des sulfates calciques

L'incorporation de sulfates conjugue les deux effets indiqués ci-dessus et conduit à une courbe de principe analogue présentée figure 9 et confirmée par les nombreux résultats qui ont permis de construire la figure 10.

Fig 9. Schéma de l'action des sulfates calciques.

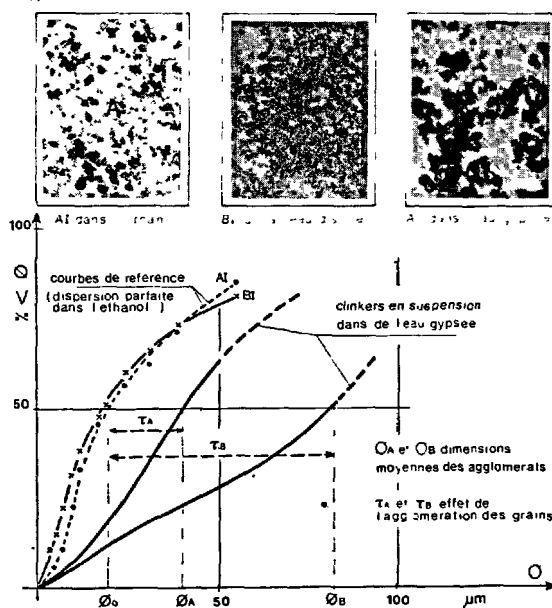

Fig 10. Résultats des essais ramenés à seuil de cisaillement initial  $f_0$  égal.

Ces courbes font toutefois ressortir très nettement l'effet limité de la floculation dans le cas du clinker pauvre en  $C_3A$ .

D'une façon générale, il apparaît que l'action des sulfates calciques, aussi bien floculante que retardatrice, s'échelonne à peu près dans le rapport de leur vitesse de dissolution (sauf pour l'action retardatrice du phosphogypse à cause de ses impuretés solubles).

La figure 11 illustre l'effet d'agglomération des grains et l'influence d'un sulfate.

### 5.3 Action des sulfates non calciques

L'action fluidifiante (apparente ou retardatrice) ou les raidissements observés sont résumés sur la figure 12.

## 6. EVOLUTION RHEOLOGIQUE DE LA PATE DE CIMENT PENDANT LES PREMIERES HEURES

### 6.1 Moyen d'étude

L'évolution du seuil de cisaillement a été suivie à l'aide du rhéographe, mis au point au CERILH [6] et [7], lequel permet des mesures depuis la fin du malaxage jusqu'au-delà de la fin de prise VICAT et fournit un certain nombre de grandeurs (figure 13).

La figure montre que des raidissements précoces peuvent ne pas être décelables avec les moyens habituels trop peu sensibles et que seule une méthode comme celle-ci peut y parvenir.

Néanmoins, même s'ils ne sont pas mesurables facilement, ces raidissements pendant la période de mise en œuvre sont toujours rédhibitoires pour la maniabilité et ce doit être, par conséquent, le domaine de choix des études rhéologiques.

### 6.2 Action des sulfates calciques

Le renflement caractéristique des raidissements est systématique pour les pâtes de clinker broyé non gypsées. La figure 14 montre plusieurs cas possibles de l'action d'une addition.

L'effet (3) devrait plutôt se produire s'il reste suffisamment de sulfate "libre", c'est-à-dire : soit pour une forte teneur en sulfate, soit pour une faible teneur en aluminat, ou encore une vitesse de dissolution lente (anhydrite naturel, broyage grossier, chaleur).

Les essais ont porté, comme pour la viscosimétrie, sur les 2 clinkers, les 2 finesses de mouture et les 4 sulfates à trois teneurs ; les figures 15 et 16, sélectionnées parmi les résultats, confirment bien le schéma précédent.

### 6.3 Action de sulfates non calciques

Les résultats obtenus sont résumés pour le clinker BI sur la figure 17 ci-après ; on peut diviser les modes d'action en trois catégories :

- les cations accélérateurs (Li, Na, K),
- les ions colmateurs très retardateurs et généralement fluidifiants (Pb, Ba),
- les substances gélifiant l'eau interstitielle, provoquant un raidissement notable (Al, Zn, Fe).

Fig 17 - Evolution de la prise pour les sulfates non calciques.

### 7. ACTION DES DIFFERENTS SULFATES ETUDIES SUR LES PROPRIETES DES PATES DURCIES

La figure 18 illustre les résultats obtenus pour les résistances en compression en pâte pure à 1 et 28 jours avec les deux clinkers, pour les sulfates de Ca et avec le clinker BI seulement pour les non calciques.

Fig 18 - Résistances en compression.

La figure 19 donne un aperçu des variations dimensionnelles pour les mêmes matériaux.

On sait que la teneur en sulfate doit être modulée à la composition minéralogique du clinker, à sa teneur en éléments rapidement solubles ( $C_3A$ , alcalins) et à la finesse de mouture ainsi qu'à la vitesse de dissolution du sulfate ; il existe généralement à chaque âge un optimum donnant les résistances maximales et le retrait minimal.

Parmi les non calciques, les sulfates de Cu et de Pb semblent donner des résistances comparables à celles des sulfates de Ca (en particulier, le sel de Pb qui allonge notablement les temps de prise mais accroît sensiblement les résistances à 1 et 28 jours), en revanche les retraits sont toujours plus élevés.

Fig 19

### 8. CONCLUSION

L'action des sulfates sur les clinkers est multiple : floculants, réducteurs de solubilité des aluminates, colmateurs, accélérateurs des silicates.

Le seuil de cisaillement des pâtes fraîches de ciment Portland est le résultat des liaisons de floculation et d'hydratation précoce : les sulfates augmentent les premières et diminuent les secondes en fonction de la teneur en  $C_3A$  (et de la solubilité et de la teneur en sulfate) ; il peut y avoir prédominance de l'un ou de l'autre effet (de même pour l'exigence en eau à cohésion égale). L'évolution de la prise étaye ces observations et y ajoute l'accélération éventuelle des silicates par le sulfate non consommé par les aluminates. L'action sur les pâtes durcies confirme la nécessité des sulfates calciques pour de bonnes performances des ciments.

# Effect of mix rheology, admixtures and salts upon physical and mechanical properties of hardened cement pastes

## *Action combinée des adjuvants et des additions de sel sur les propriétés physiques et mécaniques des pâtes de ciment durcies*

B.E. SCHEETZ, Research Associate,

E.L. WHITE, Research Associate,

D. WOLFE-CONFER, Senior Research Technician, and

D.M. ROY, Professor, Materials Research Laboratory, The Pennsylvania State University, University Park, Pennsylvania 16802, U.S.A.

**SUMMARY:** The interrelationships between the rheological properties of ordinary cement slurries and viscous pastes and the mechanical and physical properties of their hardened composites have been investigated. The cement slurries, made from an ASTM Type I and an API Class C cement, were modified by addition of two superplasticizing admixtures, a sulfonated melamine formaldehyde condensate (A14) and a sulfonated naphthalene formaldehyde condensate (A3). The interactions between the admixtures and brines are important since these composites may be exposed to brines at elevated temperatures (geothermal applications) and to bedded evaporite deposits (in a possible nuclear waste disposal site).

Rheological properties of cement slurries were measured at different shear rates to explore properties related to pumpability in the mixes. The shear stress for both the Type I and the Class C cement slurries was found to decrease with increasing superplasticizer concentration and with increasing salt content at a 1% admixture concentration. However, the rheological properties of both cement pastes were very erratic below 15 wt/o NaCl. In the presence of 25 wt/o NaCl the fluidities of the pastes were 2 to 3 times greater at  $\leq 1\%$  superplasticizer concentrations but changed rapidly in contact with additional amounts of either superplasticizer.

The setting times for the Type I cement slurries systematically increased with increased admixture concentrations; however, the Class C cement had the opposite trend. The possible reason for these behaviors are discussed. The bulk densities for all specimens were measured and variations with curing time, admixture content, and nature of mixing waters were discussed.

The microhardness measurement was utilized as a criterion to determine the strength of a specimen. Generally, the hardness increased with increasing curing time. Variation in hardness values for samples prepared from various cements and mixing water (with or without additives) were also discussed. A very distinct difference in hardness between the samples prepared with deionized water and admixture and saturated sodium chloride and admixture exists. The deionized water prepared samples were fully 40% stronger than the salt-admixture prepared samples.

### RESUME :

Les relations entre les propriétés rhéologiques de barbotines de ciments ordinaires ainsi que de pâtes visqueuses et les propriétés mécaniques et physiques de leurs composés durcis ont été étudiées. Les barbotines de ciment, préparées à partir de ciments ASTM type I et API Classe C, furent modifiées par l'ajout de deux adjuvants superplastifiants, un condensé sulphoné de formaldéhyde de mélamine (A14) et un condensé sulphoné de formaldéhyde de naphthalène (A3). Les interactions entre les adjuvants et les saumures sont importantes vu que ces composites peuvent être exposés à des saumures à des températures élevées (applications géothermales) ainsi qu'à des dépôts d'évaporite (dans un site éventuel de stockage de déchets radioactifs).

Les propriétés rhéologiques des barbotines de ciment furent mesurées à différentes vitesses de cisaillement afin d'explorer les propriétés en rapport avec l'aptitude au pompage des mélanges. La force de cisaillement pour les pâtes du Type I et de la Classe C diminue lorsque la concentration de superplastifiant augmente ainsi qu'avec une augmentation du taux de sel lorsque l'on utilise 1% d'adjuvants. Toutefois, les propriétés rhéologiques des deux pâtes de ciment deviennent erratiques lorsque l'on utilise moins de 15% (en poids) de NaCl. En présence de 25% (en poids) de NaCl, les fluidités des pâtes sont 2 à 3 fois supérieures pour des concentrations de superplastifiants  $\leq 1\%$ , mais changent rapidement au contact d'ajouts supplémentaires d'un des deux superplastifiants.

Le temps de prise des pâtes de ciment du Type I est systématiquement allongé lorsque l'on augmente la concentration des adjuvants contrairement au ciment de la Classe C. Les raisons possibles pour ces phénomènes sont exposées. Les densités de tous échantillons furent mesurées et leurs variations avec le temps de prise, le taux d'adjuvants et la nature des eaux de mixage sont rapportées.

La microdureté fut utilisée comme critère pour déterminer la résistance d'un échantillon. En général, la microdureté augmente avec le temps de prise. La variation de la dureté d'échantillons préparés à partir de différents ciments et eaux de mixage (avec ou sans additifs) est aussi rapportée. Il existe une différence très nette entre la dureté d'échantillons préparés avec de l'eau dé-ionisée et des adjuvants et celle d'échantillons préparés avec de l'eau saturée en chlorure de sodium et des adjuvants. Les échantillons préparés avec de l'eau dé-ionisée sont 40% plus résistants que ceux préparés avec l'eau saturée en NaCl.

## INTRODUCTION

Effective sealing of penetrations into a nuclear waste repository (1), or through rock strata made for the purpose of extracting geothermal energy (2,3) will demand the development of cementitious composite materials for closure of the holes, or for cementing of the casings. The composites will need to possess long-term stability (4) coupled with ease of emplacement. Fundamental to the geothermal applications is the exposure of these cementitious composites to mineral-laden brines at elevated temperatures (2,3); while, for the nuclear waste disposal application, the most conceptually-advanced repository in the U.S. (5) is designed for siting in bedded evaporite deposits. The research results presented here were carried out to address certain intrinsic materials performance and property questions, dictated by the requirements of potentially important applications of cementitious materials where they will perform in the presence of halide phases:

(1) Effects upon the chemical and physical properties of such composites prepared with superplasticizing admixture and salt combinations: Are there potential interactions that would affect the integrity of the composites?

(2) Effects of alkali halides and superplasticizers upon the rheological properties of "pumpable" cementitious slurries: Because cement formulations for down-hole emplacement are usually designed to be pumped under turbulent flow conditions (large Reynold's numbers) it is necessary to determine any such effects.

(3) Interactions of halides with the superplasticizers, that will affect the "pumpability" of the slurries: Do any significant changes occur with time? The purpose of the following experiments was therefore to address the questions of potential interaction between halide phases present in the expected geological environment and the cementitious mixes that might be emplaced in the geomedium.

## EXPERIMENTAL

Ordinary commercial cements were used in these studies as much as possible, modified by chemical additions to achieve additional desirable chemical and physical properties. The cements used included an ASTM Type I and an API Class C. Table 1 gives chemical analyses of these cements. Three commercial superplasticizers, one sulfonated melamine formaldehyde condensate (A14), and one sulfonated naphthalene formaldehyde condensate (A3), were employed in the studies.

All cement preparations were conducted following ASTM C305 procedures; samples were mixed with either de-ionized water, or sodium chloride saturated solutions and maintained at a w/c of 0.3, compacted into polyethylene molds on a vibrating table for 60 seconds, and cured for 24 hours at greater than 90% relative humidity (1). The molds were then removed, and the samples were cured under selected fluids, saturated  $\text{Ca}(\text{OH})_2$  or saturated NaCl, contained in sealed glass jars at room temperature and 60°C. The nomenclature used is as follows:

cement	w/c	mixing	%	curing	curing
type	:	water	admixture	water	temp.
I	0.3	NaCl*	1	$\text{Ca}(\text{OH})_2$	RT
I	0.3	DW	0	NaCl	60.

\*The concentration of NaCl in the solution is not included as solid in the designated water:solid ratio; DW = deionized water.

Table 1.  
Chemical composition  
(major constituents) of  
Type I and Class C cements

	Type I (I-5)	Class C (C-2)
$\text{SiO}_2$	20.82	21.2
$\text{Al}_2\text{O}_3$	5.24	2.7
$\text{Fe}_2\text{O}_3$	2.90	5.1
CaO	62.88	65.4
MgO	3.20	0.8
$\text{SO}_3$	2.88	2.5
$\text{CO}_2$	ND	ND

Compressive strength (ASTM C109), microhardness (Vicker's), density (1), water and gas permeability (6), bond strength, phase composition by x-ray diffraction, setting times (ASTM C191), and rheological properties (7) were determined to aid in the interpretation of potential interactions.

## RESULTS AND DISCUSSION

These experiments were designed to investigate various properties of cementitious materials relevant to their placement and performance in contact with salt-saturated environments. Initial experiments were designed to compare the effects of deionized mixing water vs. saturated NaCl mixing water; the effect of the interaction of a fixed concentration (1%) of a superplasticizer with NaCl added to the mixing water; the effect of the type of curing water [sat.  $\text{Ca}(\text{OH})_2$  or sat. NaCl], and in a limited number of tests the effects of curing at elevated temperatures.

X-ray Diffraction Phase Determination. Very little difference in the resultant hydration products could be recognized between the samples that were prepared with and without an admixture. The phases identified by x-ray diffraction (XRD) were portlandite [ $\text{Ca}(\text{OH})_2$ ],  $\beta\text{-C}_2\text{S}$ ,  $\text{C}_3\text{S}^*$  and the calcium chloroaluminate hydrate "Friedel's salt" (8). Also recognized in these diffractograms were a large amorphous contribution to the x-ray diffraction pattern centered at  $\sim 25^\circ 2\theta$ , and the contribution of a phase that possesses intense low angle diffuse background which usually left the chart, beginning in the range of from 6 to  $10^\circ 2\theta$ . Table 2 is a summary of the recognized phases. The present XRD data were obtained for qualitative phase identification; the references therefore necessarily reflect only trends of the reactions.

<sup>†</sup>Nomenclature in order: w/c ratio, mixing water, curing water, curing temperature.

P = portlandite, B =  $\beta\text{-C}_2\text{S}$ ; C =  $\text{C}_3\text{S}$ ; 1b = low angle background; k = Friedel's salt ( $3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{CaCl}_2 \cdot 10\text{H}_2\text{O}$ ); — = 60°C cured sample; a = amorphous background; A3\* = sulfonated naphthalene formaldehyde condensate.

\*Cement abbreviations: C = CaO, S =  $\text{SiO}_2$ , A =  $\text{Al}_2\text{O}_3$ , F =  $\text{Fe}_2\text{O}_3$ .

**Bulk Density.** Bulk density is a routinely measured control property which, when all other factors are equal, confirms reproducibility of sample preparation (i.e., replicates should agree within a high degree of precision). It is also a useful measurement for indicating trends. Therefore, such densities were measured for each sample in this series of experiments, as mass per unit volume, after removal from the curing solution, saturated, surface dry (see Table 3).

The relative comparisons are as follows: (1) With the exception of two compositions which showed significant departures, a specimen of a particular composition was found to maintain its density (within  $\pm 1.5$  percent), not changing with curing time (8 of 12 were within  $\pm 1$  percent). (2) The admixture-containing samples as a group showed the lowest overall variation as a function of time. (3) The de-ionized water preparations showed less variation than the salt-saturated mixing water specimens. (4) Within the deionized mixing water group, samples prepared with admixtures at a single age were essentially identical.

It should be noted that the specimens made with saturated NaCl mixing water actually contain considerably higher total solids content. Thus it had been expected that this group of samples would possess considerably higher densities. In fact, only a single sample set (that with both NaCl mixing and curing water, no admixture, and cured at room temperature) showed considerably higher densities than other comparable samples. Thus, the salt-saturated samples departed significantly from expected ideal behavior.

**Microhardness.** Following earlier work (9) which showed that a relationship exists between microhardness and porosity for certain families of cement-like materials, a relation between microhardness and bulk density was also established (10,11), which is indirectly

related to strength. The microhardness of every sample was determined using the Vicker's technique (10); data are given in Table 4. The general trend found for all samples was an increase in hardness with increasing curing time. The hardness increase ranged from 10% to 70% in some instances with the average increase approximating 30%. The reference neat paste (without admixture or NaCl) cured at 60°C showed the most rapid increase in hardness and also possessed the greatest hardness. Generally the samples prepared with deionized water and Type I cement were harder than those prepared with salt. All of the samples using deionized mixing water produced harder products than those samples prepared with salt mixing water. The former samples generally maintained their strength with respect to the latter samples as a function of time. A very distinct difference in hardness exists between the admixture-containing samples prepared with deionized water and those prepared with saturated sodium chloride. The samples prepared with deionized water are fully 40% stronger than the salt-admixture prepared samples.

**Permeability.** One of the most effective predictive measures of the potential for mass transport through a particular medium is its permeability (6). If a cementitious material is going to be an effective barrier to the transfer of fluids and their contents, it must possess a permeability less than or equal to that of the surrounding rock. The permeability measurements recorded in this experimental sequence were all made with nitrogen, using the Klinkenberg extrapolation to infinite pressure, giving an approximate liquid permeability. The values obtained for the entire specimen set, range from about 0.1 microdarcy to tens of microdarcies. No obvious trend is apparent in these data as a function of the admixture's presence. All those samples prepared with deionized water appear to have permeabilities that are less than or equal to the values obtained for the saturated sodium chloride mixing water samples. The data are reported elsewhere (12).

#### OVERVIEW OF PHYSICAL PROPERTIES

Microhardness measurements showed a general increase with curing time, which would be indicative of generally increased strength. The samples prepared with deionized water were generally superior to those prepared with saturated salt solutions. This gives rise to a suggestion that optimized cementing compositions possibly may not involve preparation with saturated salt solutions. On the other hand, samples prepared with deionized water and cured in a 20% salt solution were generally equal to or superior to any of the former samples.

Further, it is realized also that microhardness of the present samples cannot be expected to follow a strictly linear relationship with bulk density for two reasons: (1) The salt-saturated samples cannot be compared strictly with ordinary silicate cement samples because of major compositional difference. NaCl intrinsically has a lower hardness than silicates; although its addition serves to increase density of the composites, it does little to increase the hardness. (2) The density of samples containing only bound (non-evaporable) water would be the more appropriate property for correlation with microhardness, rather than the saturated bulk density, which includes a component of non-structural water. The latter adds little to the strength. Therefore, the above correlation, while showing trends, does not

See Table 3, page VI-175

\*with admixture

constitute a quantitative relationship. It will be important to find whether there are correlations with dry (110°C) density, and to further characterize the cement composites' mechanical properties.

Although general trends can be ascertained that suggest that the sodium chloride based formulations do not form as good a composite as similar formulations without the salt, there was no specific evidence of superplasticizer-salt interactions.

**Rheological Properties.** The questions addressing the potential influence upon the setting times and rheological properties, which affect pumpability do indirectly suggest that interactions occur.

Literature references (13,14) state that in the presence of brines no adverse effects occurred between the saline mixing waters and commercial oil well cementing admixtures. Both of the above references, however, failed to identify the general class of admixtures or to provide any specific details of the nature of any experimentation that was conducted.

All viscosity measurements were made on a Brookfield Model 5X HBT. Other measurements in the laboratory have been carried out with a Haake Rotovisco instrument (7), and calibrations using standard Newtonian liquids have shown agreements in calculated viscosities from the two instruments to within 3-6% (15). The Brookfield instrument was chosen for the current studies for convenience, as well as for the instrument's ability to permit measurement of mortars as well as pastes. The torques at 8 different shear rates were determined in successive order from the largest to the smallest (measurement duration 1 min.), followed by a 1 minute rest, then determined with successively larger shear rates. The total time required for the measurement after mixing was approximately 17 minutes.

Figures 1 and 2 contain data sets for the instrument reading given in millivolts, which is proportional to rheological shear stress, versus added sodium chloride solids in weight percent. The data are graphically presented for one rotor speed (10 rpm), which is proportional to shear rate; this represents an intermediate value of the 8 rates determined. The data in Figure 1 suggest a nearly monotonically decreasing shear stress with increasing salt content (at 1% concentration: wt admixture solids/weight cements, of both the sulfonated naphthalene and melamine formaldehyde condensate superplasticizers). The Type I cement alone undergoes somewhat more erratic behavior but with roughly the same trend. The Class C cement in Figure 2 behaves in a similar fashion with a monotonically decreasing shear stress with increased salt concentrations. The exception to this is the mixture of Class C cement with the sulfonated naphthalene superplasticizer (A3) which is approximately a factor of 3 more fluid than the remaining 2 samples. In both sets of experimental data, erratic behavior occurs in the rheological properties of the pastes below 15 wt/o NaCl.

Typical of the rheological properties with varying superplasticizer concentrations are the data presented in Figure 3, where the shear stresses with increasing superplasticizer concentration generally appear to decrease monotonically. However, in the presence of 25 wt/o sodium chloride, the pastes typically are a factor of 2 to 3 more fluid at low superplasticizer concentrations (less than or equal to 1%) but rapidly

Figure 1. Viscometric response of paste vs. % NaCl in mixing water.

Figure 3. Viscometric response of a Type I (I-5) cement paste to different concentrations of admixtures and NaCl.

change in their fluidity in contact with larger concentrations of either superplasticizer.

**Setting Times.** Extensive measurements were made of setting times of the variety of pastes (1,16). Initial measurements performed on the neat cement Type I (I-5) pastes with increasing admixture concentrations

Figure 4. Effects on initial setting time of Type I cement of varying amounts of water-reducing agents in the presence of 25 wt/o NaCl.

Figure 5. Effects on initial setting time of Class C cement of varying amounts of water-reducing agents in the presence of 25 wt/o NaCl.

indicated a systematic increase in setting times with increasing admixture content. Variations due to the chemical type of admixture were observed especially at the large concentration levels (Figure 4). The Class C (C-2) cement, however, exhibited the opposite trend of setting faster with increased admixture concentrations with very erratic results occurring for the chemically different admixtures at concentrations above 1 wt/o (Figure 5).

The explanation for these observations may lie in a combination of the physical properties of the individual grinds for each cement, and its chemistry. The chemical compositions given in Table 1 show both a lower alumina (and resultant lower  $C_3A$ ) and slightly lower  $SO_3$  content in cement C-2; and C-2 has a slightly higher specific surface area.

The setting times of the Type I (I-5) cement (Figure 4) in the presence of 25 wt/o NaCl generally indicate a trend toward the retardation of setting with increased admixture concentrations. The sulfonated naphthalene formaldehyde condensate A3 behaves erratically, acting as an accelerator at low concentration and as a retarder at higher concentrations. The Class C (C-2) cement exhibited a trend of acceleration of the setting with increased admixture concentrations.

In the four data sets presented, the sulfonated melamine formaldehyde condensate for the most part behaves in a more nearly predictable manner than the sulfonated naphthalene but the Class C (C-2) cement responds in a more predictable manner than the Type I.

Additional experiments with 1% admixture and varying salt concentrations up to saturation further substantiate these observations (16).

#### CONCLUSIONS

Phase characterization of cement pastes prepared with various combinations of ingredients (including presence or absence): mixing water, admixture, curing water; and curing temperature was made. The calcium chloroaluminate hydrate, Friedel's salt, was characteristic of many specimens which either included NaCl in their mix or curing solution. Physical properties studies of the products of cement pastes prepared with superplasticizers in the presence of sodium chloride suggest that the cured products typically are less predictable and often inferior to those of the analogue formulations prepared without the presence of sodium chloride. E.g., these are typified by similar permeability values but with a larger, more erratic scatter in the measured values for the salt-containing samples.

Investigations of the rheological properties of these pastes in the presence of sodium chloride are more revealing experiments. The data presented herein suggest that potential interactions do exist between the superplasticizers (irrespective of the formulation or type of admixture) and salt to produce erratic behaviors. Fortunately, the erratic behavior appears to be limited to low salt concentrations (at low superplasticizer levels) or at relatively high superplasticizer concentrations at more nearly typical working salt-concentrations. This trend, fortunately, will minimize their erratic behavior for certain applications: during emplacement of a slurry the mix most likely will become enriched in salt as it is pumped into an evaporite formation. Data in Figures 2 and 3 would suggest that this circumstance will have little effect upon the rheological properties as compared to the impossible circumstance in which the concentration of admixture increased.

When designing cementitious mixes for geothermal cementing, there would appear to be little advantage, and possible disadvantage, to including salts in the initial mixes (2,3). For plugging applications in evaporites, factors involved with the individual situation would have to be considered. From the present data, either salt-containing mixes or non-salt-containing ones apparently could be employed; but other factors relating to longevity would also have to be considered for their final evaluation (4).

#### ACKNOWLEDGEMENT

## Influence of structure on fracture mechanism of hardened cement paste

### *L'influence de la structure sur le mécanisme de rupture des pâtes de ciment durcies*

Yu. ZAITSEV, Professor, All-Union Polytechnical Institute (WZPI) Moscow, U.S.S.R.

RESUME : On a étudié l'influence de la structure poreuse des pâtes de ciment durcies sur le mécanisme de leur rupture et sur leur résistance mécanique. On en a déduit un modèle mathématique du processus. Ce modèle tient compte de la distribution différente des pores dans la pâte de ciment. On a analysé le développement de la rupture par la méthode de Monte-Carlo.

SUMMARY: Influence of porous structure of hardened cement paste on its fracture mechanism and mechanical strength is investigated. A mathematical model of fracture process is developed. The model takes into account different distribution of size of pores in a sample of hardened cement paste. Using Monte-Carlo method crack propagation is analyzed.

## INTRODUCTION

Many contributions devoted to deformation and fracture of hardened cement paste, mortar and concrete are to be found in the literature (1-3). Most attempts, however, are mainly based on phenomenological approach and do not analyze theoretically the basic laws of fracture process.

In an effort to fill this gap we have made attempt to give a theoretical description of crack propagation and fracture process in a porous and viscoelastic material such as hardened cement paste.

## DEVELOPMENT OF INITIAL CRACKS

Let us examine the process of crack propagation in the porous material under uniaxial compression. The simplest element to be investigated in an idealized structure of a porous material is a cylindrical hole in a homogeneous and isotropic plate. For a short time loading it is possible to neglect the phenomenon of creep and to assume that the large mass of the material outside the zone adjacent to the crack acts elastically. The stress distribution around a cylindrical hole is well known (Fig. 1). Methods of fracture mechanics make it possible to define the relation between a value of the external load  $q(q > 0)$  and length of a crack at the lines of maximum tensile stress. This relation is given by the following expression (4):

$$q = \sqrt{\frac{\pi E \gamma}{2r}} \sqrt{\frac{(1+\lambda)^2}{(1+\lambda)^2 - 1}}, \quad (\lambda = l/r)$$

where  $E$  is elastic moduli and  $\gamma$  is the effective surface energy density of hardened cement paste. Experimentally estimated values of  $\gamma$  are given in (5).

## SIMULATION OF CRACK PROPAGATION IN HARDENED CEMENT PASTE

Expression given above can be applied as long as the crack length  $l$  is small as compared to the distance of individual pores, i.e. as long as the interaction between two mutual approaching cracks is negligible. Therefore the propagation of two interfering cracks (Fig. 2) and finally the crack propagation in a material with pores distributed at random (Fig. 3,a) has been studied. In this model which is fairly close to a realistic porous structure of hardened cement paste. The random pore distribution was generated by a digital computer. The results obtained by one computer realization of Monte Carlo method are shown in fig. 3,b,c. Mathematical basis for such calculation uses the methods of fracture mechanics and was described in (4). The sum of the length of all individual cracks

as a function of the applied load has been calculated. Each time two pores become connected by merging of two growing cracks there is a sudden increase in the total crack length until a critical value is reached when the cracks propagate without any increase of external stress.

Simulation of crack propagation described above makes it possible to estimate the effect of pore size distribution on the fracture mechanism, mechanical strength and strain behavior of hardened cement paste. It was found that with the increasing mean size of pores by the constant quantity of pores, the ultimate load will decrease.

With the increasing maximum size of pores by the constant mean size and the constant quantity of pores, the ultimate load will decrease too. The main results are shown in fig. 4. It was also found that with the increasing mean and (or) maximum size of pores by the constant quantity of pores, or with the increasing number of pores of constant size, the probability of a splitting mode of fracture (as shown in fig. 3,c) will decrease and the probability of shear mode of fracture will increase. At the latter case an inclined crack crossing the areas mostly weakened with pores will propagate (fig. 3,d).

## CONCLUSION

A new and basic approach to simulate crack propagation in hardened cement paste has been described. Simulated crack patterns agree reasonably well with experimental findings. Therefore it seems that a solid basis for further investigation has been provided.

# Capillary pore structure and permeability of hardened cement paste

## *Structure des pores capillaires et perméabilité des pâtes durcies de ciment*

B.K. NYAME and Dr. J.M. ILLSTON, Division of Civil Engineering,  
The Hatfield Polytechnic, Hatfield, Herts, U.K.

RESUME : La relation entre la perméabilité à l'état saturé, la porosité et la distribution des pores dans les pâtes de ciment durcies, a été étudiée par la méthode de porométrie au mercure et séchage à 105°C, pour des valeurs variées, du rapport eau/ciment, et des durées d'hydratation.

On a trouvé que la relation entre la perméabilité et la porosité, en fonction du rapport eau/ciment variait avec la durée de l'hydratation. Un maximum a été observé dans la courbe de distribution des pores; ce maximum est relié étroitement et uniquement à la perméabilité, indépendamment de la durée de l'hydratation et du rapport eau/ciment.

SUMMARY:- The relationships between saturated permeability, porosities and the pore size distributions of hardened cement paste as influenced by water/cement ratios and times of hydration were studied by the techniques of mercury porosimetry and drying at 105°C.

It was found that the permeability - porosity relationship for hardened cement paste of different water/cement ratios is not the same for different times of hydration. A maximum continuous pore size was identified from the pore size distributions which closely and uniquely relates to permeability irrespective of time of hydration or water/cement ratio of the pastes.

INTRODUCTION:

It is known that the permeability of hardened cement paste is mainly dependent on the capillary pore volume (1). Studies of the pore size distributions of hardened cement paste (2,3,4) generally indicate the existence of a threshold diameter, which is interpreted to correspond to the 'minimum geometrically continuous' pore size in hardened cement paste. The present work was performed to enable a closer study to be made of the relationship between the permeability of hardened cement paste and its porosity and pore size distributions with the particular purpose of finding the significance of the threshold diameter in relation to permeability.

EXPERIMENTATION:

Ordinary Portland cement (D25) with composition C<sub>3</sub>S; 64%, C<sub>2</sub>S; 13%, C<sub>3</sub>A; 6.8%, C<sub>4</sub>AF; 7.3%, CaSO<sub>4</sub>; 3.6% was mixed with distilled water at w/c ratios in the range 0.23 to 1.00, and hydrated continuously in water for periods up to 20 months. Truncated conical shaped samples of between 10 - 20mm thick were used for the steady state permeability tests. The steady state permeability method used is described elsewhere (5); it basically involves the use of silicone rubber sealing jacket cut to fit tightly to the sides of the specimens prior to mounting in high pressure permeameters. The conical shape of the specimens aids the formation of a seal between the silicone rubber jacket and the specimen. Steady state flows were measured with cathetometers by monitoring the changes in level of the water meniscus in outflow capillary tubes.

The total porosity, from the saturated and surface dry condition, was estimated from the water contents determined by drying at 105°C. The pore size distributions were determined by mercury intrusion porosimetry (Carlo Erba Series 200 model) for the samples at the conclusion of the steady state permeability measurements. The pore radius was calculated using equation 1 for cylindrical pores, a contact angle of 140° and a surface tension of mercury of 0.48N/m<sup>2</sup> being assumed.

$$r = \frac{75,000}{P} \quad (1)$$

where  $r$  = pore radius (Å)  
 $P$  = applied pressure (kg/cm<sup>2</sup>)

The differential pore size distributions were evaluated from equal volume divisions of the penetrated pore volume and equation 2. (6)

$$\frac{dv}{d \log r} = \frac{P}{2.303} \frac{dv}{dp} \quad (2)$$

where  $v$  = intruded pore volume (cm<sup>3</sup>/g)

The maximum continuous pore radius,  $r_{\infty}$ , was defined to correspond to the pore radius at which  $dv/dp$  has a maximum value.

RESULTS:

Fig. 1. shows the effects of hydration on permeability for pastes of water/cement ratios 0.23, 0.47, 0.71 and 1.00. The permeability values represent the mean values obtained from between 3 to 8 samples, and typically the coefficients of variation for permeability at each w/c ratio were in excess of 50%.

Fig.1.- Effects of hydration on permeability of hardened cement pastes of different water/cement ratios.

The pore size distributions for the age at 28 days are given in Figs. 2a and 2b, again showing the differences between the four water/cement ratios. The values of the maximum continuous pore radius, as previously defined are identified on Fig. 2b and located on the cumulative pore size distributions of Fig. 2a.

Fig.2a: Effect of water/cement ratio on the cumulative pore size distributions of hardened cement pastes hydrated in water for 28 days.

Fig. 2b: Effect on water/cement ratio on the differential pore size distributions of hardened cement pastes hydrated in water for 28 days.

Fig. 3. shows the variation in the maximum continuous pore size with w/c ratios and time of hydration, and it can be seen that, except at the highest w/c ratio,  $r_{00}$  reduces to a steady-state value after 28 days of hydration.

Fig. 3: Effect of water/cement ratio and time of hydration on the maximum continuous pore radius of hardened cement paste.

The results are summarised in Figs. 4 and 5 which show the multivalued nature of the relationship between permeability and total porosity, which contrasts with the unified relationship of permeability to the maximum continuous pore radius.

Fig. 4: The relationships between total porosity and saturated permeability of hardened cement paste.

Fig. 5: The relationship between the maximum continuous pore radius and saturated permeability of hardened cement paste.

The relationship between the maximum continuous pore radius and permeability of hardened cement paste was found by linear regression to be

$$K = 1.684 r_{\infty}^{3.284} \times 10^{-22} \quad (3)$$

with a correlation coefficient of 0.9576 where

$$K = \text{permeability (m/s)}$$

$$r_{\infty} = \text{maximum continuous pore radius (Å)}$$

The constants for the relationship between total porosity,  $\epsilon$ , and permeability,  $K$ , fitted to the equation of the form

$$K(t) = K_0(t) \cdot \epsilon^{b(t)} \quad (4)$$

are given in Table 1.

Table 1: Constants of regression for the relationship between total porosity and permeability of hardened cement paste.

Time of hydration (days)	$K_0(t)$ m/s	$b(t)$	Correlation Coefficient
3	$4.19 \cdot 10^{-5}$	16.18	0.8811
7	$3.00 \cdot 10^{-7}$	12.98	0.8323
28	$1.57 \cdot 10^{-10}$	9.02	0.7031
10month	$2.25 \cdot 10^{-11}$	6.44	0.9378
20month	$3.88 \cdot 10^{-10}$	7.95	0.9661

#### DISCUSSION:

It is often considered that, as a first approximation, permeability and porosity of hcp are uniquely related. Fig.4. clearly demonstrates that this is reasonably true only for different water/cement ratios at a given time of wet curing; it does not hold when the changes in porosity are caused by continuing hydration. In other words, the changes in pore structure resulting from hydration are very different from those resulting from different water/cement ratios. The reduction in permeability accompanying hydration is shown in Fig. 1, which also indicates that there may be a reversal of this trend if wet curing is prolonged. It is noticeable that Figs. 1 and 3 exhibit similar patterns, so that permeability and the maximum continuous pore radius are apparently related. That this is indeed so, is evident from Fig. 5.

The general shapes of the differential pore size distributions (Fig. 2b) include a maximum peak towards the upper end of the range of pore sizes, and it follows that the radius corresponding to this peak is representative of a considerable proportion of the pore volume. Winslow and Diamond<sup>2</sup> visualised the penetration of mercury at the upper end of the pore size spectrum to be analogous to flow through the main continuous channels of a river system whilst the penetration below the peaks correspond to flow through local side channels. Since the larger pores are likely to offer the least resistance to water flow, it is not unreasonable to deduce that the majority of the flow will occur in the volume represented by the peak radius i.e. by the maximum continuous pore radius. The reasonable correlation of Fig. 5. certainly supports this view, and it may

be further concluded also that the considerable proportion of small pores carry very little of the permeating water.

The changes in the maximum continuous pore radius with water/cement ratio and hydration (Fig. 3.) suggest that it is representative of the spaces between cement grains, which become partially filled with the advance of hydration products. While no geometrical description is possible, it is of interest that, with the exception of the 1.00 water/cement ratio, the partial filling appears to cease at 28 days, thus implying that hydration after this time consists of a densification of existing structures rather than the deposition of new material within the maximum continuous pore channels between adjacent grains.

#### CONCLUSIONS:

(1) Total porosity of hardened cement paste is not uniquely related to permeability but depends on whether the change in porosity derives from differences in water/cement ratio or times of hydration.

(2) The maximum continuous pore radius, as defined here, is related to permeability and is representative of the size of pore in which the water flows.

## Influence des résines de synthèse fluidifiantes sur la rhéologie et la déformation des pâtes de ciment avant et en cours de prise

### *Influence of fluidifying synthetic resins on the rheology and deformation of cement pastes before and during the setting*

A.M. PAILLÈRE, Docteur ès Sciences, Chef de Section "Produits Nouveaux" au Département des Bétons et Métaux, Laboratoire Central des Ponts et Chaussées, Paris, et  
Ph. BRIQUET, Ingénieur E.C.S., Chef de groupe "Adjuvants et additifs" à la Section des Produits Nouveaux, L.C.P.C. Paris, France.

RESUME : La différence de comportement entre les résines de synthèse tensioactives et les lignosulfonates est surtout mise en évidence en étudiant l'action de ces produits lorsqu'ils sont introduits au cours de la prise du ciment.

Leur effet défloculant devient très marqué par rapport aux plastifiants réducteurs d'eau à base de lignosulfonate dans le cas des éléments de diamètre inférieur à 20  $\mu$ . Cette défloculation agit sur le comportement rhéologique du béton et sur l'hydratation du ciment.

Les déformations en cours d'hydratation de la pâte semblent être sensiblement modifiées par le naphthalène sulfonate lorsque ce produit est introduit dans l'eau de gâchage, c'est-à-dire dans des conditions ne correspondant pas à son effet optimum.

Ceci se traduit sur béton par un temps de fissuration plus avancé.

SUMMARY : The difference about the behaviour between synthetic tensioactive resins and lignosulfonates is particularly shown up by studying the action of these products when put during the setting of cement.

Their defloculating effect becomes very pronounced with regard to water-reducing plasticizers containing lignosulfonates in case of particles below 20 micrometers. This defloculation influences the rheological behaviour of concrete and the hydration of cement.

The deformations in process of hydration of the paste seem to be appreciably modified by naphthalene sulfonate when this product is introduced in batch water i.e. in its not optimum use.

So, the cracking time of concrete takes place sooner.

## INTRODUCTION

Les exigences croissantes des techniques et des chantiers, les ouvrages d'art à ferrailage souvent très dense, ont eu pour conséquence, au cours des dernières années, d'estimer que, pour certaines réalisations, les adjuvants "classiques" n'étaient plus adaptés. Pour répondre aux besoins des utilisateurs, on a vu apparaître des produits à formule chimique très élaborée qui, en apportant des améliorations notables à certaines caractéristiques du béton, permettent d'élargir les domaines d'emploi de celui-ci. C'est le cas tout particulièrement des résines de synthèse qui sont à la base de la composition d'une nouvelle famille de produits ayant une action particulière sur la maniabilité ou fluidité des mortiers et bétons hydrauliques. Dès la commercialisation de ces produits qui ont reçu des appellations diverses, telles que "superplastifiants", "superfluidifiants" ou "fluidifiants", il s'est posé la question de savoir s'ils constituaient une nouvelle famille par rapport aux plastifiants "classiques" et si leur mode d'action était différent.

Du point de vue chimique, ce sont des solutions aqueuses à pH neutre de mélamine formaldéhyde ou de dinaphtyl-méthane sulfonate de sodium ou de calcium. Leur action fluidifiante, qualifiée par certains de spectaculaire, est très variable et assujettie à de nombreux paramètres. Les recherches et expérimentations sur chantier ont montré qu'elle ne se produit de façon incontestable que lorsque les produits sont introduits après confection des mortiers ou bétons hydrauliques, de préférence juste avant leur mise en oeuvre (1). Mélangés à l'eau de gâchage, c'est-à-dire utilisés au moment de la fabrication du béton, les résines de synthèse agissent de façon analogue aux lignosulfonates ou autres produits tensioactifs qui constituent les plastifiants.

#### Influence des résines de synthèse sur la rhéologie des pâtes de ciment

La différenciation entre les deux familles d'adjuvants (plastifiants et fluidifiants), basée sur le comportement rhéologique du béton final, a été mise en évidence sur pâte de ciment en mesurant sa viscosité à l'aide du viscosimètre à cylindres coaxiaux type CERILH (2) (3).

En effet, tel qu'il apparaît dans les figures 1a et 1b, l'introduction de lignosulfonate (produit n° 3) ou de résines de synthèse (produits n° 1 et n° 2) au moment de la confection de la pâte, n'entraîne, du point de vue de la viscosité, aucune différence caractérisant chacune des familles chimiques. En revanche, introduits en différé, c'est-à-dire 30-60-120 minutes après fabrication de la pâte de ciment, les fluidifiants conduisent à des viscosités comprises entre 0,4 et 1,6 Poises et ceci 2h après fabrication. Quant au plastifiant, il n'améliore plus de façon notable, à partir d'une heure la viscosité de la pâte qui devient même supérieure à celle du témoin quand le plastifiant est introduit 2h après confection.

Afin d'approfondir ces résultats marquant la différence d'action entre les diverses familles chimiques d'adjuvants, nous avons effectué des mesures de viscosité des pâtes, dans lesquelles les produits, dont la composition chimique variable est donnée dans le tableau n° I, étaient introduits en différé jusqu'à 3h après confection.

Fig. 1 : Viscosité des pâtes de ciment adjuvantées en fonction du temps d'attente et de leur nature chimique.

TABLÉAU N° I

Nature chimique des adjuvants utilisés

Code	Extrait Sec (%)	Nature Chimique
N° 1	20	Résine mélamine formaldéhyde sulfonate de sodium
N° 2	40	Dinaphtylméthane sulfonate de calcium (poids moléculaire 500)
N° 3	39	Lignosulfonate de sodium + ester phosphorique
N° 4	16	Lignosulfonate de sodium + traces de naphthalène sulfonate
N° 5	27	Dinaphtylméthane sulfonate de sodium (65 %) lignosulfonate de sodium (35 %)
N° 6	35	Lignosulfonate de calcium
N° 7	30	Lignosulfonate de sodium + alkylphenol oxyéthylène
N° 8	40	Naphtalène formaldéhyde sulfonate de sodium (poids moléculaire 2000)
N° 9	30	Gluconate de calcium + alkylaryl sulfonate

Les essais effectués confirment les résultats précédents et la mesure de la viscosité à 3h montre que le classement, du point de vue rhéologique, s'effectue de façon très nette en fonction de la nature chimique des produits (Figure 2).

Viscosité des adjuvants introduits en différé en fonction du temps d'attente et de leur nature chimique Figure 2

Viennent en tête, du point de vue pouvoir fluidifiant, avec des viscosités à 3h de la pâte, comprises entre 2 et 2,6 poises :

- la résine naphthalène sulfonique de poids moléculaire  $> 2000$  (n° 8),
- la résine mélamine (N° 1).

Ensuite on trouve avec des viscosités plus élevées (3,8 à 4 P) :

- le naphthalène sulfonate à poids moléculaire  $\approx 500$  (n° 2),
- le mélange 65 % naphthalène sulfonate à poids moléculaire  $\approx 500$  et 35 % de lignosulfonate (N° 5).

Avec une viscosité de la pâte de 4,5P, le produit n° 4 (riche en lignosulfonates avec de très faibles proportions de naphthalène sulfonate) se place très près des produits n° 3 et 6 (plastifiants classiques à base de lignosulfonate).

Le produit n° 9, constitué de gluconate de calcium conduit à la pâte la plus visqueuse (6 Poises).

Il apparaît ainsi que l'introduction en différé des fluidifiants est bien le mode d'utilisation optimum de ces produits. Leur action devient dans ce cas très marquée et ils se distinguent très nettement des plastifiants. La mesure de la viscosité des pâtes adjuvantées semble permettre de classer les produits suivant leur efficacité et leur nature chimique.

#### Pouvoir défloculant des résines de synthèses

L'abaissement du seuil de cisaillement des pâtes de ciment constaté avec les fluidifiants est relié au pouvoir défloculant des produits. De nombreuses recherches ont été effectuées sur les propriétés défloculantes des composés tensioactifs (4) (5).

L'effet plastifiant et retardateur des lignosulfonates a été expliqué en partie par l'état défloculé des grains de ciment en présence de ces produits. Nous avons donc recherché s'il existait une différence significative entre le pouvoir défloculant des résines de synthèse et les lignosulfonates et si cette caractéristique n'était pas sélective vis-à-vis de la granularité des grains de ciment.

L'étude de l'aptitude à la défloculation ou dispersion des grains de ciment dans l'eau a donc été menée sur les produits caractérisant chacune des familles d'adjuvants (fluidifiants et plastifiants) sur un ciment brut et sur les trois coupes granulométriques suivantes :

- ultrafines (0/10  $\mu$ ) comprenant 98 % d'éléments  $> 5 \mu$ ,
- fines moyennes (0/20  $\mu$ ) comprenant 78 % d'éléments compris entre 5 et 20  $\mu$ ,
- gros éléments (0/100  $\mu$ ) comprenant 80 % d'éléments compris entre 20 et 80  $\mu$ .

La distinction entre les fluidifiants et les plastifiants étant très nette du point de vue de la viscosité, dans le cas de l'introduction du produit différé après confection de la pâte, nous avons recherché si ce phénomène se reflétait de même dans la défloculation des grains de ciment.

Les essais ont donc été réalisés sur chaque produit du tableau n° I, introduits, d'une part dans l'eau de dispersion du ciment, et d'autre part avec un temps d'attente après le mélange eau-ciment variant entre 5 minutes et 2h 30.

Le tracé des courbes granulométriques des ciments a été reconstitué à partir des mesures de défloculation effectuées à l'aide du sédimentomètre Prot et de la pipette d'Andreasen.

Les mesures de défloculation des grains avec les adjuvants, mélangés à l'eau avant dispersion du ciment, ne laissent pas apparaître de différence significative de comportement entre les diverses compositions chimiques des produits (Fig. 3).

Figure N° 3. COURBES GRANULOMÉTRIQUES

Reconstituées à partir des grains de ciment défloculés (Sédimentomètre Prot).

L'état de floculation des grains de diamètre compris entre 0 et 45  $\mu$  est total dans le cas du ciment seul: aucun grain inférieur à 45  $\mu$  n'a été mesuré, les éléments fins se sont groupés en donnant de gros grains. La granularité se trouve de ce fait complètement modifiée, tout semble se passer comme si le ciment était constitué de grains de dimensions comprises entre 45 et 100  $\mu$ .

En revanche l'addition de lignosulfonate ou de résines de synthèse conduit à une dispersion meilleure des éléments fins qui se trouvent partiellement individualisés. Cette dispersion est sensiblement la même quelque soit le produit utilisé.

Lorsque l'emploi de l'adjuvant a lieu en différé, (Fig. 4) on constate que la défloculation des grains 0/20  $\mu$ , obtenue avec les résines de synthèse (N° 2 - 15 - 8), est plus élevée que dans l'expérience précédente. Ceci est fortement marqué dans le cas du naphthalène sulfonate commercialisé en tant que fluidifiant (produit n° 2). Par contre, les produits à base de lignosulfonate en fortes proportions (3 - 4 - 6) défloculent moins bien que lorsqu'ils sont introduits dans l'eau de gâchage.

Une étude plus approfondie par coupe granulométrique confirme que la dispersion des grains de ciment obtenue avec les résines mélamine et naphthalène sulfonate est supérieure à celle des lignosulfonates dans le cas des ultrafines et fines moyennes, c'est-à-dire pour les grains compris entre 0 et 25  $\mu$  (Fig. 5a, 5b, 5c).

Figure N° 4.

## COURBES GRANULOMÉTRIQUES

Reconstituées à partir des grains de ciment défloculés (Sédimentomètre Prot).

(Adjuvants introduits après 2h30 d'attente.)

Ainsi la floculation des ultrafines (grains de 0 à 10  $\mu$ ), qui est de 82 % pour le témoin sans produit et de 73 % pour le lignosulfonate, passe à 36 % et 30 % pour la résine mélamine et le naphthalène sulfonate respectivement.

COURBES GRANULOMÉTRIQUES Reconstituées à partir des grains défloculés (adjuvants introduits après 2h30)

Dans le cas des fines moyennes (5/25  $\mu$ ), on constate que les courbes granulométriques obtenues avec les suspensions de ciment contenant du naphthalène sulfonate et de la résine mélamine sont très proches (ou confondues) jusqu'à la granulométrie de 8  $\mu$ , de celle déterminée au laser. Pour 10  $\mu$ , la floculation est d'environ 20 à 15 % pour les résines de synthèse et de 25 % pour le lignosulfonate.

Pour les grains supérieurs à 40  $\mu$ , la différenciation n'est pas significative (Fig. 5d), les granularités obtenues avec les différents produits étant sensiblement les mêmes.

D'une façon générale on peut dire que les fluidifiants dispersent plus efficacement que les plastifiants les éléments fins du ciment, c'est-à-dire les grains entre 0 et 20  $\mu$ . On remarque de même que la floculation des grains, due à l'absence de produit tensioactifs, conduit à des courbes granulométriques témoin totalement différentes des courbes réelles obtenues par laser. Par contre, les tensioactifs en général permettent d'obtenir des dispersions granulaires dans l'eau conduisant à des courbes granulométriques ayant même allure générale que celle dé-

terminée au laser. Toutefois, quel que soit le produit, la défloculation des éléments fins n'est pas totale et il subsiste toujours un pourcentage variable de grains agglomérés. Ceci entraîne un plus fort pourcentage de grains de dimensions supérieures que celui existant réellement dans le ciment.

Si l'efficacité, du point de vue de la défloculation des grains, est systématiquement plus importante dans le cas des fluidifiants, elle est variable suivant le produit et le moment auquel il a été introduit dans le milieu eau-ciment. La figure 6 montre l'évolution de l'aptitude à la défloculation des grains de ciment de 20  $\mu$  que possèdent les principaux fluidifiants et plastifiants en fonction du temps auquel ils sont introduits.

Ainsi l'utilisation optimale, du point de vue de la défloculation, de la résine mélamine (N° 1) se place après un temps d'attente compris entre 60 et 120 minutes après dispersion du ciment dans l'eau. Le comportement du naphthalène sulfonate à poids moléculaire  $\approx 500$  (n° 2) ainsi que du mélange 65 % de naphthalène sulfonate et 35 % de lignosulfonate (n° 5) semble moins pointu que la résine mélamine. Toutefois, l'efficacité de ces deux produits, est plus accentuée vers 120 minutes pour le n° 5 et 150 minutes pour le n° 2.

Le naphthalène sulfonate à plus haut poids moléculaire (n° 8) présente un pouvoir de défloculation assez constant entre 15 et 20 minutes pour diminuer rapidement après.

Les lignosulfonates (n° 4 et 6) possèdent un maximum d'aptitude à la défloculation entre 5 et 60 minutes.

Pour chaque fluidifiant, l'efficacité du point de vue de l'amélioration des propriétés rhéologiques des mortiers et des bétons sera fonction, en plus de sa composition chimique, d'une part du moment auquel il sera introduit dans le mélange eau-granulats-ciments, et d'autre part de la granularité du ciment lui-même.

Dans le cas d'un ciment riche en éléments fins, les fluidifiants, et tout particulièrement le naphthalène sulfonate du même type que celui du produit n° 2, présentent une efficacité très marquée. Cette efficacité diminuera ou s'atténuera d'autant plus que la mouture du ciment sera plus grossière. Pour certaines granularités et temps d'introduction, il n'y aura pas de

différence sensible entre un lignosulfonate et une résine de synthèse fluidifiante.

Figure 6

Toutefois, ces qualités défloculantes et fluidifiantes des produits, liées à la granularité des grains de ciment, ne sauraient être dissociées de la nature chimique des constituants prépondérants dans les fractions granulaires étudiées (Tableau II).

TABLEAU II

Analyse chimique des différentes fractions granulaires (CPA 55)

	Ultra fines	Fines Moyennes	Gros grains	Ciment CPA 55 non fractionné
Chaux libre	1,25	1,04	0,25	0,59
Ca SO <sub>4</sub>	31,48	9,69	2,78	5,10
Ca SO <sub>4</sub> 2H <sub>2</sub> O	39,82	12,26	3,53	6,45
C <sub>4</sub> AF	4,92	5,83	6,32	6,08
C <sub>3</sub> A	9,06	12,79	12,58	12,71
C <sub>3</sub> S	64,82	66,62	45,21	63,43

La fixation préférentielle du fluidifiant par le C<sub>3</sub>A a été montrée au cours de recherches antérieures (6). Cependant, compte-tenu que ces fractions granulaires d'ultrafines et fines moyennes ont relativement la même teneur en C<sub>3</sub>A que le ciment, mais sont par contre surdosées en SO<sub>4</sub> (ou en gypse : Ca SO<sub>4</sub> 2H<sub>2</sub>O), il semble bien qu'il y ait ainsi une adsorption préférentielle des résines de synthèse sur le gypse. Cette adsorption préférentielle, liée à des familles de produits (structures globulaires pour le naphthalène sulfonate et filandreuse pour le lignosulfonate par exemple), conduit à une configuration du film de produit fixé sur les grains de ciment plus épaisse dans le cas de la résine mélamine et du naphthalène sulfonate (Fig. 6a) que dans le cas des lignosulfonates (fig.6b)

La séparation entre les grains est donc favorisée et la défloculation est, de ce fait, plus marquée.

#### Déformations de la pâte de ciment en cours d'hydratation

Compte-tenu de ces résultats, il était permis de penser que la présence de fluidifiant dans une pâte de ciment en cours d'hydratation devait se traduire par un comportement différent de celle-ci. En effet, l'étude des courbes de déformation aux jeunes âges des pâtes de ciment en fonction du temps, avec et sans adjuvants, à l'aide de l'appareil de mesure du second retrait (7) fait apparaître, lorsque les adjuvants sont introduits dans l'eau de gâchage, qu'il existe une différence très nette dans l'allure de la partie "gonflement" des courbes de déformation des pâtes de

ciment contenant du naphthalène sulfonate, par rapport aux pâtes contenant des produits à fort pourcentage en lignosulfonates (Fig. 7).

Fig. 6a : 0,1 mm

Fig. 6b : 0,1 mm

La présence de naphthalène sulfonate entraîne systématiquement un gonflement de la pâte en cours d'hydratation, très supérieur à celui de la pâte témoin ou adjuvantée avec d'autres produits. Toutefois, les vitesses maximales de second retrait ne se différencient pas significativement d'une famille chimique à une autre.

FIG. 7 INFLUENCE DE LA NATURE CHIMIQUE DE L'ADJUVANT SUR LES COURBES RETRAIT-GONFLEMENT DES PÂTES DE CIMENT

Ce gonflement très élevé, qui se produit entre 7h et 65h après gâchage de la pâte de ciment dans l'eau adjuvantée de naphthalène sulfonate, ne se produit plus

lorsque ce produit est introduit en différé (1h après confection dans l'exemple présent). Au contraire, il semblerait que, dans ce cas, le gonflement mesuré, bien qu'inférieur à celui du témoin, soit plus important dans le cas des lignosulfonates.

Ce phénomène de gonflement élevé de la pâte de ciment en cours d'hydratation se répercute sur la fissuration du béton. Ainsi l'étude comparative faite au banc de fissuration L.C.P.C. (8) entre des bétons avec et sans lignosulfonate et naphthalène sulfonate montre que ce dernier, mélangé à l'eau de gâchage, entraîne une fissuration du béton légèrement retardée par rapport au témoin mais nettement plus rapide par rapport au lignosulfonate (Tableau III).

TABLEAU III

	Âge du béton au moment de la fissuration	
	Produit introduit dans l'eau de gâchage	Produit introduit 1h après confection du béton
Béton témoin	20h	-
Béton+lignosulfonates	73h	44h
Béton+naphthalène sulfonate	32h	72h

A l'instar des constatations faites sur les courbes de gonflement des pâtes de ciment, ce comportement est inversé lorsque le naphthalène sulfonate est introduit 1h après confection du béton. Dans ce cas, la fissuration est retardée alors qu'elle devient plus précoce (comparativement) avec le béton adjuvanté au lignosulfonate.

Par ailleurs, les courbes des contraintes engendrées par les déformations en fonction du temps, enregistrées dès la mise en place du béton dans le banc de fissuration, ont des allures totalement différentes dans l'un ou l'autre cas.

Les contraintes engendrées par le retrait du béton dans lequel le naphthalène a été introduit dans l'eau de gâchage sont enregistrées à partir de 21h et entraînent rapidement la fissuration (32h). Alors que dans l'autre cas, elles ne se développent qu'à 33h, c'est-à-dire après la fissuration intervenue dans le béton précédent. Le rapport des vitesses de retrait respectives est de 2,13.

#### CONCLUSION

Cette étude a permis de cerner le mode d'action des résines de synthèse fluidifiantes (mélatène et naphthalène sulfonate) et de les différencier des tensioactifs (lignosulfonates, etc...) employés habituellement en tant que plastifiants.

Il est apparu ainsi que l'efficacité de ces produits est étroitement liée au moment de leur introduction dans le mélange eau-ciment-granulats. D'une façon générale, et quelle que soit la nature chimique, les résines de synthèse utilisées en différé (30 minutes et plus après fabrication des mélanges hydrauliques) présentent un effet fluidifiant très élevé, les démar-

quant nettement des lignosulfonates.

En revanche, il n'existe pas de différenciation significative entre les divers adjuvants lorsqu'ils sont introduits dans l'eau de gâchage.

Cette fluidification est reliée à une défloculation notable des grains de ciment de diamètre  $< 20 \mu$ .

Le pouvoir défloculant des résines de synthèse dépend aussi du moment d'introduction du produit et semble lié à une adsorption préférentielle sur les grains de gypse et de  $C_3A$  du ciment Portland.

Une particularité des fluidifiants à base du naphthalène sulfonate est qu'ils entraînent une augmentation importante du gonflement des pâtes de ciment en cours d'hydratation lorsqu'ils sont utilisés dans l'eau de gâchage, c'est-à-dire au minimum de leur performance. Ceci n'est pas sans influence sur la fissuration du béton qui se trouve être accélérée dans ce cas et pour cette famille chimique de produits.

Le comportement à la fissuration d'un béton additionné de naphthalène sulfonate peut être donc complètement différent suivant le mode d'introduction du produit. Ceci peut revêtir une grande importance dans le cas des constructions en béton.

# Effect on micro-additives on properties of concretes

## *Influence des micro-additifs sur les propriétés des bétons*

L.N. POPOV, Dr. Sc. All-Union Polytechnical Institute (WZPI), Moscow, U.R.S.S.

**RESUME :** Le processus de durcissement du béton de ciment et de formation de sa structure et de ses propriétés dépend non seulement du ciment portland utilisé pour sa fabrication, mais aussi des micro-additifs dispersés dans le ciment. Les micro-additifs sont introduits dans le ciment portland au broyage du clinker de ciment avec des roches ou des déchets industriels. Ils peuvent aussi être introduits dans le béton, lors de son malaxage, sous forme d'agent dispersif, ou bien sous forme de fraction des agrégats. Il ne faut pas considérer le micro-additif comme un adjuvant inerte. L'examen de la structure et des propriétés des bétons de ciment à agrégats fins a mis en évidence que les micro-additifs améliorent la granulométrie générale du béton, ce qui garantit une certaine diminution de la consommation du ciment. Les bétons à agrégats fins avec addition de micro-additif ont une structure dense et ont les mêmes grandeurs de résistance et de déformabilité que celles des bétons ordinaires.

**SUMMARY:** Process of hardening of concrete and formation of its structure and properties depends not only on the portland cement but also on the disperse additives - microaggregate. Microaggregate can be inserted into Portland cement composition together with rock products or waste products of the industry during grinding of cement clinker.

Microaggregate is a disperse fraction of aggregate and can be inserted also into concrete mixture together with its other component.

Microaggregate cannot be considered as an inert additive. Investigation of the structure and properties of fine-corned cement concretes has been showed that the addition of microaggregate improves the general granulometric composition of aggregate and allows to decrease cement content in concrete. At the same time fine-corned concretes with added microaggregate have the same strength- and strain-properties as common plain concretes.

## INTRODUCTION

Hardened cement paste is a three-phase system (solid phase - water - air) and has a capillar-porous structure. It consists of clinker particles not fully hydrated; gel, including gel pores; crystals of calciumoxyhydrat etc.; and also capillar pores and air voids (1). Hardened cement paste can be considered as "microconcrete". Clinker particles have not only higher strength as compared to cement gel, but also high bond strength with gel. Thus "microconcrete" can be considered as a composition material, reinforced with clinker particles (2).

Structure and strength of hardened cement paste depends significantly on the fineness of pulverizing and granulometrical composition of Portland cement (3,4).

In some investigations it was found that mostly active part of cement consists of the fraction 5-20 mcm; the fraction 20-40 mcm can also be considered as an active. On the other hand the fraction 40-60 mcm and more coarse particles play a role of micro-aggregate. It is found that these particles have a positive effect on the structure and properties of hardened cement paste. It can be assumed that use of special microaggregate can also lead to a positive effect.

As such microaggregate can be used rock materials and disperse waste product of the industry (ash, slays, etc.) (5).

Microaggregate can be inserted into Portland cement composition together with rock products or waste products during grinding of cement clinker. Microaggregate can be also inserted into concrete mixture together with other components (6).

Microaggregate cannot be considered as an inert additiv. Using different experimental methods (chemical, physico-chemical etc.) it is possible to appraise the activity of microaggregate of a given kind and to analyse its effect on structure and strength of hardened cement paste (7).

It can be supposed (analogously to common plain concrete) that the weakest link in the structure of hardened cement paste is the interface between microaggregate particles and matrix.

Thus the density and strength of the interface effects significantly the strength and strain behaviour of cement concretes.

## MICROSCOPICAL INVESTIGATION OF THE INTERFACE MICROAGGREGATE-MATRIX

Fine-corned concrete with aggregate consisting of waste product from the mining industry - oreless particles of quartzit, both sand-like and with 5 - 20 mm dimensions is a relatively new kind of concrete.

These materials can be used as aggregates for fine-corned concrete. This kind of con-

crete will be widely used for manufacturing of thin-walled and other reinforced concrete structures.

Fine-corned concrete has higher homogeneity, higher tensile strength, higher water resistance and higher dynamic strength as compared to common plain concrete (8). Waste products contains disperse particles (<100 mcm) which can be considered as microaggregate.

We have investigated interface between these particles and matrix (hardened cement paste) with the help of electron microscope UEMV-100 K. This investigation was based on the replic method and used specimens of hardened cement paste at the different age (from some days to 3 months).

Fig. 1. Electron micrograph of hardened cement paste with microaggregate particles at the age of 90 d.

From Fig. 1 it can be seen than microaggregate formed particles have dense contacts with hardened cement paste. Boundaries are "smeared", which indicate on the chemical reaction between quartzit particles and hydration products of Portland cement (9). On the investigated areas of specimen practically no pores, cracks or voids was observed. It confirms a positive influence of microaggregate on the structure of hardened cement paste.

## INVESTIGATION OF MICROHARDNESS OF THE INTERFACE MICROAGGREGATE-MATRIX

Microhardness was investigated with the help of microhardness measuring apparatus PMT-3. It was found that microhardness of the interface between microaggregate and matrix was higher than the microhardness of matrix, but a little lower than for interface between quartz particles and matrix - see Fig. 2.

It was also found that at the age of 30 d the maximal depth of the interface layer between microaggregate particles and matrix is equal to 20-30 mcm.

Fig. 2. Microhardness of microaggregate particles hardened cement paste (0); of the interface between matrix and quartzite (1); of the interface between matrix and quartz (2): • - experimental data; ▲ - interpolated values of microhardness.

#### COMPRESSION STRENGTH OF HARDENED CEMENT PASTE CONCRETE WITH MICROAGGREGATE

It was found, that by the replacement of 10%; 20% and 30% from clinker to the respective quantity of microaggregate the strength of hardened cement paste at the age of 28 d decreases (by 7, 14 and 20% respectively). On the other hand, the coefficient of use of clinker was found to be higher as compared to the hardened cement paste on the pure Portland cement. The coefficient of use of clinker was found to be much higher for concrete made with addition of microaggregate (6).

We have also investigated strength and strain behavior of fine-corned concrete, made with aggregate consisting of waste product of mining industry (fine sand and oreless particles 5-20 mm). Disperse waste product of mining industry (ferro-quartzite) was also used as microaggregate instead of 25% of common sand.

The investigation has showed that microaggregate improved the general granulometric composition of aggregate. It was possible to get fine-corned concrete with the cubic strength of 44, 55 and 67 N/mm<sup>2</sup> at the age of 28d by cement expense 300, 400 and 500 kg/m<sup>3</sup> respectively. These values are approximately by 10% higher as compared to the strength of common concrete with aggregate of crushed granite.

It was also found that the fine-corned concrete described above has lower (or equal) shrinkage and creep strains as compared to the common concrete with aggregate of crushed granite.

The results described above have been used for design and manufacture of reinforced concrete slabs for industrial buildings in the USSR.

#### CONCLUSIONS

Microaggregate inserted into concrete mixture improved its general granulometric composition. Microaggregate cannot be considered as an inert additive. Particles of microaggregate have dense contacts with the hardened cement paste. Fine-corned concrete with aggregate of waste products of mining industry with addition of microaggregate have approximately the same strength and strain properties as the common concrete with aggregate of crushed granite.

# Conceptual and mathematical models for tricalcium silicate hydration

## *Modèles qualitatifs et quantitatifs pour l'hydratation du silicate tricalcique*

James M. POMMERSHEIM, James R. CLIFTON, Geoffrey FROHNSDORFF, U.S.A.

**SUMMARY :** Based on conceptual models for the stages in the hydration of tricalcium silicate, a mathematical model was formulated and solved using analytical techniques and the computer. The separate resistances in the mathematical model correspond to the phenomenological stages of the conceptual models. The mathematical model accounts for both diffusion through growing, interpenetrating spherical product layers and chemical reaction at the hydrate-cement interface, as expressed by a dimensionless modulus proportional to the ratio of the diffusion rate to the reaction rate.

Low values of the modulus indicate that chemical reaction rate controls the hydration process while high values indicate that hydrate diffusion is the controlling mechanism. The model assumes quasi-steady-state growth but allows for the depletion of water from solution as hydration proceeds. Model input allows for different particle sizes, water to cement ratios; and initial temperatures, while model output predicts the degree of hydration, the porosity and the overall structure of the hydration products, all as functions of time. Comparison of model output with available degree of hydration data gave a reasonable fit between the model and the data, with physically realistic values found for model constants.

**RESUME :** En se basant sur des modèles qualitatifs de l'hydratation du silicate tricalcique, un modèle mathématique a été imaginé, puis calculé grâce à des analyses techniques et en utilisant un ordinateur. Les résistances indiquées par le modèle mathématique correspondent aux phases phénoménologique des modèles qualitatifs. Le modèle mathématique tient compte à la fois, de la diffusion à travers la structure, et de la réaction chimique à l'interface eau-ciment; il dépend d'un facteur sans dimension, proportionnel au rapport de la vitesse de diffusion à la vitesse de réaction.

Les basses valeurs de ce facteur correspondent au cas où le processus d'hydratation est commandé par la vitesse de la réaction, alors que ses hautes valeurs correspondent au cas où ce processus est commandé par la vitesse de diffusion. Ce modèle permet de représenter la croissance dans un état quasi stable; mais il permet aussi de représenter ce qui se passe quand on vide l'eau qui servait à l'hydratation. Le modèle est valable pour diverses granulométries et divers rapports E/C; il indique en fonction du temps et de la température initiale, le degré d'hydratation, la porosité et la structure interne des produits de l'hydratation. En comparant les résultats du modèle et ceux de l'expérimentation, on constate un accord raisonnable, pourvu que les constantes physiques du modèle soient bien choisies.

### Introduction

To develop an improved method for predicting the performance and durability of cement and concrete, the mathematical modeling of the hydration of portland cement and dependent phenomena has been undertaken [1]. Because tricalcium silicate ( $C_3S$ )\* is the major constituent of portland cement, and since it, along with dicalcium silicate, is principally responsible for the strength development of cement, the hydration of  $C_3S$  was mathematically modeled. The model allows prediction of the degree of hydration and the amounts of reactants consumed and hydration products formed. The major details of this model are outlined in this paper.

In a recent review article [2] the mathematical modeling of cement systems, including  $C_3S$ , has been summarized. The mathematical model developed by Kondo and Ueda [3], although similar in some respects to that developed here, is less comprehensive. Their model is based upon an analogous three layer system which takes into account the disappearance of the middle layer. However, it does not allow for resistance due to the hydration reaction itself and, in addition, the model was found to be improperly derived. Further, Kondo and Ueda did not test their model against the hydration data presented in the same paper [3].

### Development of the Model

The mathematical model was developed based upon generally accepted conceptual models [3, 4, 5] which describe the principal stages in  $C_3S$  hydration (refer to table 1).

In developing the model it was presumed that the system of hydrating particles remains isothermal and that their hydration rate is not dependent on their position within the system. In addition,  $C_3S$  particles were presumed to be uniform in size and spherical as were the hydrate layers forming around the particles.

Basically the problem is conceived as involving diffusion of chemical reactant species (water and ions)

through ever-thickening spherical layers of precipitated porous products to the interface between the  $C_3S$  core and the innermost hydrate layer [3], dissolution of ions from the  $C_3S$  and their hydration near this interface, diffusion of soluble product ions back out through deposited hydrate layers, and precipitation of insoluble products. Insoluble species precipitate as separate C-S-H hydrate layers (so-called inner and outer hydrate) both within and on the outside of the growing hydrated particles. A middle product (or barrier) layer is postulated as forming between the inner and outer hydrate layers at very early times and then disappearing [3]. It acts as a barrier to the diffusion of water into the particle and/or the diffusion of ions away from the particle. The middle product layer may be an impermeable solid which dissolves (or becomes more permeable) with time [3], or it may consist of a diffuse layer of adsorbed calcium ions contributing to an electrical double layer around the particle [4]. Its disappearance may mark the end of the induction period and the beginning of the acceleratory period [3-7].

Most growth of calcium hydroxide crystals occurs in the bulk solution between particles. It is postulated that the growth of calcium hydroxide and the outer hydrate layers decreases the (intergranular) porosity and results in restricted or hindered diffusion of chemical species to the particle surface.

Figure 1 is a schematic representation of a single spherical hydrating  $C_3S$  grain shown sometime before the acceleratory period has been completed [7]. Both inner and outer hydrate layers are shown along with the middle product layer. Inner hydrate is presumed to form only within the original boundary (radius  $R$ ) of the  $C_3S$  grain. The hydrate layers consist of two different (C-S-H) gels that are formed in different stoichiometric amounts,  $b_i$ , but in constant proportion to one another. The hydrates can have different C/S ratios. Dimensions shown in Figure 1 include  $R$ , the original radius of the particle;  $r_i$ , the radius of the unhydrated solid  $C_3S$  core;  $r_o$ , the outside (particle) radius; and  $x$ , the thickness of the barrier layer. Concentrations of species in solution (between grains) are denoted as  $C_o$ .

Considering the system to be the pores of the particle depicted in Figure 1, and assuming spherical particle symmetry with no internal production or consumption of chemical species and constant diffusivity  $D$ , a mass balance for the pore liquid for each species yields:

\* Conventional cement chemistry nomenclature is used here:

$$\frac{D}{r^2} \cdot \left[ \frac{\partial}{\partial r} r^2 \frac{\partial C}{\partial r} \right] = \frac{\partial C}{\partial t} \quad (1)$$

$$0_i < r < r_o < r$$

The concentrations  $C$  will vary with both radial position  $r$  and time  $t$ . Equation (1) will be valid for each chemical species in the hydrate layers surrounding the particles. It will apply to the pores of the inner and outer hydrates as well as those of the middle layer. In each region equation (1) is subjected to two boundary conditions and one initial condition. The initial condition for the model presumes uniform concentrations at time zero. Boundary conditions are prescribed at the interfaces between regions. There is equality of component fluxes at  $r = R$  and  $r = R + x$ . At the outside of the particle, where diffusivities are much greater than within the hydrating mass, concentrations are taken equal to the concentrations present in the bulk liquid.

At the unhydrated core ( $r=r_i$ ) the boundary condition equates the flux of the diffusing reactant species  $N$  to the surface rate of chemical reaction  $R$ , so that:

$$-N = -D \frac{\partial C}{\partial r} = R = kC \quad (2)$$

Equation (2) describes a first order irreversible reaction with reaction velocity constant  $k$ . If the temperature is constant,  $k$  will also be constant.

To obtain an expression for the degree of hydration  $\alpha$ , a mass balance is made at the hydrating interface:

$$-\rho a \frac{dr_i}{dt} = D \left( \frac{\partial C}{\partial r} \right)_{r=r_i} \quad (3)$$

where  $a$  is the moles of water reacted per mole of  $C_3S$  consumed and  $\rho$  is the solid molar density of  $C_3S$ . In this development a single chemical reaction is presumed whose overall stoichiometry is presented in Figure 1.  $a$ ,  $b$  and  $c$  are stoichiometric coefficients. Equation (3) equates, on a surface area basis, the moles of solid  $C_3S$  which dissolve to the moles of water which react with the  $C_3S$  at the particle core.

Application of the given boundary and interface conditions to equation (1) yields the following differential equation:

$$-\frac{dt}{\tau} = \left( \frac{1}{my^2} + \frac{1}{y} - 1 \right) + \frac{D_i}{D_x} \frac{x}{R}$$

Resist- ances	Reaction/Diffusion in Inner Hydrate	Middle Layer Diffusion	
	$+ \left( \frac{D_i}{D_o} \left( 1 - \frac{R}{r_o} \right) \right) y^2 dy$		(4)
	Diffusion in Outer Hydrate		

where:

$\tau$  is the characteristic time,  $\frac{aR \rho^2}{C_o D_i}$

$y$  is the reduced radius,  $r_i/R$

$D_x$  is the diffusivity through the middle layer

$D_i$  is the diffusivity through the inner hydrate layer

$D_o$  is the diffusivity through the outer hydrate layer

$m$  is  $kR/D_i$  (reaction-diffusion modulus)

The development of equation (4) presumes that the thickness of the barrier layer  $x$  remains much less than the particle size  $R$  and also presumes that the growth of the precipitate layers is quite slow so that quasi-steady state can be assumed. This assumption has been tested mathematically using available hydration data [3] and found to be reasonable. The solution of the equation with its one initial condition ( $y = 1$  at  $t = 0$ ) will predict the radius of the unhydrated core  $r_i$  as a function of time. It will also predict the degree of hydration  $\alpha$  since:

$$\alpha = 1 - y^3 \quad (5)$$

#### Hydration Sub-models

To solve equation (4) separate geometric and mass transfer sub-models have been developed for the geometric ratio  $r_o/R$ , the diffusivity ratios  $D_x/D_i$  and  $D_o/D_i$ , and the middle layer thickness  $x$ .

The sub-model for the geometric ratio  $r_o/R$  was developed by accounting for the volume of the outer hydrate formed at a given degree of hydration. The sub-model for the barrier layer thickness was derived allowing the barrier layer to disappear at a rate proportional to the product of its surface area and the liquid concentration gradient between the surface of the barrier layer and the bulk solution.

$D/D_i$ , the ratio of diffusivities of the barrier layer to the inner hydrate, was set constant, while  $D_o/D_i$ , the ratio of diffusivities of the outer to the inner hydrate was expressed as a power function of solution-porosity [8]. As the porosity of the solution decreased, this ratio became much less corresponding to increased diffusional resistance in the outer hydrate. Solution porosity was determined as a function of the degree of hydration by accounting for the total volume of solid products which are formed.

Equation (4) is written in dimensionless form. Each term on the right side represents a separate resistance to diffusion. This includes resistances to reaction and diffusion in the inner hydrate, diffusion in the middle layer, and diffusion in the outer hydrate. The dimensionless time  $dt/\tau$  can be viewed as a measure of the sum of the times needed for the diffusing molecules to pass through each of the separate resistances. The resistance to diffusion in the outer hydrate is initially zero since  $r_o = R$ . As time proceeds and the particle radius  $r_o$  increases, the resistance to diffusion through the outer hydrate eventually becomes the dominant resistance.

The first term in the right side of equation (4) represents the resistance to diffusion through the inner hydrate along with reaction at the interface between the inner hydrate and the unhydrated core. The modulus  $m$  (equal to  $kR/D_i$ ) is a dimensionless parameter which measures the relative importance of reaction to diffusion. If the rate of hydration is high (large  $k$ ), or the  $C_3S$  particles are large

(large  $R$ ), or the diffusion coefficients are low (small  $D_i$ ),  $m$  will be large and diffusion through the inner hydrate will be the controlling resistance. Any one of high  $k$ , large  $R$  or small  $D_i$  can make the modulus  $m$  significantly greater than unity. In this case, the controlling factor is the diffusion process since it will determine the overall rate of hydration. Diffusion will be more likely to control the process when the permeability or porosity of the inner hydrate is low, resulting in low values of  $D_i$ , and when the temperature is high, resulting in higher values of  $k$ . Increases in temperature raise the reaction rate much more rapidly than the diffusion rate.

The analysis of the model as well as numerical solutions to the model indicates that each resistance listed below equation (4) becomes dominant in turn. Thus, at early times (before formation of any middle layer), the combined effects due to reaction and diffusion in the initially thin inner hydrate predominate. At later times (induction period and beginning of the acceleratory period) the resistance of the middle layer becomes dominant. At still later times, in the final period of hydration, the dominant resistance shifts to diffusion through the outer hydrate layers. The transition between periods is more or less abrupt depending on the specific values of model parameter sets. An advantageous feature of the model is its ability to give estimates of the relative values of the three resistances.

#### Model Output

The general mathematical model and the geometric and mass transfer submodels can be solved using numerical techniques and the computer. The following output variables can be obtained as a function of time:

- (1) degree of hydration and hydration rate,  $\alpha$  and  $d\alpha/dt$ , (2) core and particle radii,  $r_i$  and  $r_p$ , (3) amount of free and combined water, (4) amount of calcium hydroxide formed (5) amount of C-S-H gel formed (6) intergranular porosity, and (7) rate controlling process.

To illustrate the application of the model consider Figure 2 which shows a plot of  $\log(1-y)$  vs.  $\log t/\tau$ .  $(1-y)$  is the radius fraction of hydration while  $t/\tau$  is a dimensionless hydration time. Experimental hydration data, indicated by circles, is shown from one hour to six months after mixing of  $C_3S$  with water. This data, taken from Kondo and Ueda [3], was collected under controlled conditions and represents what is considered to be the best current available set of  $C_3S$  hydration data. Particle sizes had a range from 2 to  $5\mu m$ , the ratio of water to  $C_3S$  was 1.0, and the temperature was  $25^\circ C$ .

The solid curve was taken from a computer output of the mathematical model. Known parameters were substituted into the model and sub-models while unknown parameters were selected which gave a reasonable fit between the model and the data. In all cases parameters were chosen which had physically realistic values. For parameter sets which give reasonable fits to experimental data, sensitivity analyses were performed on each parameter to determine effects on the deviations between the measured and predicted variables. In addition, as parameters of particular interest, particle size, hydration temperature, and water to  $C_3S$  ratio, were varied over suitable ranges

and their effects determined using the computer model. In addition, overall hydration curves have been determined using the model for the hydration of particles exhibiting a range of particle sizes.

Recent conceptual models [8,9] consider the possibility that a barrier layer may form just outside the core of the unhydrated particle with two additional hydrate layers located outside the barrier layer. The barrier layer is postulated to be a semi-solid having a low C/S ratio. The present model can be modified to treat this case. In this way the sensitivity of the model to the location of the barrier layer could be tested. The general mathematical model will be applied to the hydration of  $C_2S$  and other simple cement systems. It is also planned to determine if the model can be used to predict the performance characteristics of portland cement.

# Répartition des différentes formes d'eau dans la structure des pâtes pures des $C_3S$ et de ciment Portland

## *Distribution of different forms of water in the structure of pure slurries of $C_3S$ and Portland Cement*

R. SIERRA, Docteur ès Sciences Physiques, Laboratoire Central des Ponts et Chaussées, Paris, France.

RESUME : En associant les méthodes de la spectroscopie moléculaire (spectrométrie infrarouge, résonance magnétique nucléaire et méthode diélectrique de spectroscopie d'absorption hertzienne) avec les méthodes d'analyse thermique, il a été possible d'établir la répartition des diverses formes d'eau, moléculaire et hydroxylique, dans la structure des pâtes de  $C_3S$  ou de ciment Portland.

Cette répartition de l'eau est faite tant sur le plan de la localisation que du mode de liaison des molécules d'eau et des hydroxyles. Elle permet ainsi de compléter le schéma de l'unité structurale du C-S-H. En outre, elle montre que l'eau des micropores n'est pas une eau simplement adsorbée mais une eau structurée, donc rigidifiée, par liaison hydrogène.

SUMMARY : By associating the methods of molecular spectroscopy (infrared spectrometry, nuclear magnetic resonance and the dielectric method of hertzian absorption spectroscopy) with thermal analysis methods, it was possible to establish the distribution of the different forms of water (molecular and hydroxylic) in the structure of slurries of  $C_3S$  or portland cement.

This distribution of water is done both from the viewpoint of location as well as from that of the bonding of the molecules of water and hydroxyls. It thus makes it possible to complete the diagram of the structural unity of C-S-H. In addition, it shows that the water in the micropores is not simply adsorbed water but one which is structured and, hence, rigidified by hydrogen bonding.

## I. INTRODUCTION

La pâte de ciment durcie est un corps cohérent poreux. Sa matrice solide est constituée par les produits d'hydratation du ciment initial dont l'agencement détermine la porosité. L'extrême division des produits d'hydratation fait que la taille des vides est essentiellement du domaine des micropores.

L'eau, toujours présente dans une pâte durcie est répartie à la fois dans les micropores et dans la structure des hydrates. Dans les micropores, ses propriétés varient suivant les paramètres géométriques, physico-chimiques et structuraux de la matrice solide. On distingue en général : l'eau libre, l'eau de sorption (chimisorbée ou physisorbée) l'eau combinée qui peut être soit moléculaire (cas de l'eau de cristallisation ou d'encathration), soit hydroxylique. Dans la texture de la pâte, l'eau est essentiellement une eau de sorption, l'eau libre n'existant que dans les macropores et les cavités.

Les méthodes de spectroscopie moléculaire sont les plus adaptées à l'étude de l'eau adsorbée. Nous les avons appliquées aux pâtes de ciment durcies en les associant avec l'analyse thermogravimétrique type Mac Bain qui permet de faire le bilan du contenu en eau. Par l'interprétation des résultats obtenus, nous avons essayé d'établir un schéma textural. Pour des raisons évidentes de simplification, nous avons axé l'investigation sur les pâtes de  $C_3S$ .

## II. TECHNIQUES EXPERIMENTALES

1) Thermogravimétrie en atmosphère contrôlée (à la thermobalance type Mac Bain).

Le tableau I et la figure 1 résument les résultats obtenus pour un hydrosilicate calcique du type C-S-H(I) et pour un gel de C-S-H extrait d'une pâte durcie.

Etat d'hydratation	Conditions de dessiccation	C-S-H (I)	Gel C-S-H
2	Après $\frac{1}{2}$ à température ambiante en atmosphère saturante	$C_{1,52} S H_{2,42}$	$C_{1,75} S H_{2,58}$
1	Sous 14 torrs de vapeur d'eau : palier entre 40 et 70°C		$C_{1,75} S H_{1,59}$
	Sous $\frac{1}{2} \cdot 10^{-2}$ torr de vapeur d'eau : palier entre 20 et 40°C	$C_{1,52} S H_{1,56}$	
0	Après dessiccation équivalente à séchage D, ( $0,5 \cdot 10^{-3}$ torr).	$C_{1,52} S H_{1,02}$	$C_{1,75} S H_{1,11}$

Tableau 1 - Détermination des états d'hydratation d'un gel de C-S-H et de C-S-H(I) par thermogravimétrie sous vapeur d'eau.

Fig 1 - Courbes d'analyse thermogravimétrique isobare de deux échantillons de gel C-S-H.

Bien qu'il existe une certaine imprécision sur le rapport molaire eau sur silice donc sur H, on voit qu'il existe trois états d'hydratation. Le premier état correspond au séchage D ; il n'y a pas d'eau de sorption. Le second, "état 1", est tel qu'approximativement une demi-mole d'eau reste fixée par "mole" de silicate. Le troisième, "état 2", est tel qu'une mole d'eau environ s'est ajoutée à la mole silicatée, par rapport à l'état précédent.

2) Spectrométrie infrarouge

La spectrométrie infrarouge permet de distinguer aisément l'eau hydroxylique de l'eau moléculaire. Dans certains cas, elle peut renseigner sur la localisation, l'orientation et même l'environnement des molécules d'eau, lorsque celles-ci sont adsorbées.

Nous avons plus particulièrement examiné la réponse donnée dans la gamme spectrale 2500-4000  $cm^{-1}$ , en opérant avec la résolution maximale du spectromètre Leitz III G, soit 300 traits par millimètre.

Le spectre présenté figure 2 correspond à un gel de C-S-H extrait d'une pâte durcie et séché sous vide primaire. Il consiste en un énorme massif dissymétrique dont l'importance, tant en absorbance qu'en largeur spectrale (3700 à 2500  $cm^{-1}$ ) indique le grand nombre d'hydroxyles mis en jeu et surtout l'importante dispersion des fréquences de vibration de

Fig.2 - Spectre d'absorption infrarouge d'un gel C-S-H extrait d'une pâte durcie ; domaine des vibrations de valence des hydroxyles.

valence des liaisons O-H. La partie comprise entre 3400 et 2500  $\text{cm}^{-1}$ , restant stable après chauffage prolongé ou après deutériation, correspond à des vibrations d'hydroxyles internes (association de tétraèdres  $\text{SiO}_4^{4-}$  par liaison H. Entre 3600 et 3400  $\text{cm}^{-1}$  on a les vibrations correspondant aux liaisons H des hydroxyles superficiels.

### 3) Résonance magnétique nucléaire

La résonance magnétique des spins protoniques appliquée à l'étude de l'eau dans les argiles, gels de silice, zéolites, etc... a donné des résultats intéressants, notamment en ce qui concerne la mobilité et parfois la localisation des molécules d'eau dans la couche adsorbée.

Nous avons utilisé la technique à large bande. Celle-ci s'avère nécessaire chaque fois que l'on a affaire à des structures gelées, ce qui est le cas des couches d'eau au contact du solide.

Les mesures faites à la température de 21 °C, sont récapitulées dans le tableau II. Les résultats, donnés en largeur de raies et en temps de relaxation transversale  $T_2$  sont déduits de l'enregistrement de la dérivée première de la courbe d'absorption.

Echantillon			Caractéristiques de résonance (largeurs de raies $\Delta H$ en gauss et $T_2$ calculé en microsecondes).					
N°.	Désignation	Etat d'hydratation	1		2		3	
			$\Delta H$	$T_2$	$\Delta H$	$T_2$	$\Delta H$	$T_2$
A	Gel C-S-H $C_{1,75} S H_{1,11}$ après suchage D	0			Néant			
B	Id. $C_{1,75} S H_{2,28}$ après $p/p_0 = 0,71$	1 & 2	0,15	440	~0,67	~103	1,03	67
C	Id. après $\tau$ avec vapeur $D_2O$ à $p/p_0 = 0,84$	1 & 2	0,13	530	~0,56	~124	0,99	67
D	Id. tel quel $C_{1,75} S H_{2,58}$	2	0,125 à 0,13	551 à 530	-	-	-	-
E	Pâte $C_3S + D_2O$ $E/L = 3$	1 & 2	0,125	451	?	?	~0,95	68

Tableau II - Résultats de résonance magnétique nucléaire.

Dans une étude combinant A.T.D., R.M.N. large bande et R.M.N. à écho de spin, Englert et Wittman (1) ont proposé les attributions suivantes : 0,2 oe pour l'eau des macropores ( $r_h > 10^{-5}$  cm), 0,3 oe pour l'eau des micropores et 0,6 oe pour celle des espaces interfoliaires. Compte tenu de l'acquis des méthodes d'investigations précédemment examinées, nous proposons : que le premier signal,  $\Delta H=0,1$  à 0,2 oe corresponde à l'eau multicouche des micropores ; que le second corresponde à l'eau adsorbée en première couche monomoléculaire et le troisième à une eau interfeuillelet (dont les protons ne sont pas échangeables par les deutérons).

### 4) Spectroscopie hertzienne d'absorption diélectrique

Cette étude, décrite par ailleurs (2) nous a permis d'appréhender le comportement diélectrique de l'eau adsorbée sur les pâtes de C-S-H et de ciment durcies en procédant par analogie avec le comportement sur les gels de silice.

L'absorption qui se produit à la fréquence de 1 kHz dans le domaine de température 140-175° K ressort d'une polarisation dipolaire du type Debye de l'eau adsorbée. Nous avons mis en évidence que ce domaine était en réalité constitué de deux bandes. La première  $B_0$  se situant vers 140-150° K se caractérise par une énergie libre d'activation de l'ordre de 0,37 eV. Elle ne se manifeste que pour de très faibles valeurs du taux de recouvrement moléculaire ( $\theta < 1$  ou 2). Elle résulterait d'un mécanisme d'orientation des molécules d'eau, après rupture pour chacune d'elles de la liaison hydrogène qu'elle possède avec le site d'adsorption hydroxylique du produit. La seconde bande  $B_1$  se produit à plus haute température (160-175° K) et nécessite une énergie libre d'activation de 0,58 eV. Elle serait due à un mécanisme de polarisation par orientation de molécules d'eau avec rupture pour chacune d'elles, des deux liaisons hydrogène qui la relie à deux sites hydroxyliques voisins.

### III. PROPOSITION DE REPARTITION DES DIVERSES FORMES D'EAU

#### 1) Eau dans la structure du gel C-S-H

Il est maintenant bien établi que la particule élémentaire de gel de C-S-H est une lamelle constituée selon Kantro et al (3) de deux ou trois feuilletts (fig.3).

Fig. 3 - Modèles de la structure du C-S-H (a - à deux feuilletts ; b - à trois feuilletts).

Nos résultats de mesure de surface spécifique ( $227 \text{ m}^2 \cdot \text{g}^{-1}$ ) et de composition chimique ( $C_{1,77} S H_{1,25}$ ) sont compatibles avec le modèle à trois feuilletts pour lequel les valeurs théoriques correspondantes sont  $252 \text{ m}^2 \cdot \text{g}^{-1}$  et  $C_{1,72} S H_y$ .

Nous définissons une unité structurale comme étant le motif atomique de la lamelle. Elle comprend trois pseudo-mailles (ou motif atomique du feuillet) dont les paramètres ont été établis par Megaw et Kelsey (4). Par pseudo-maille, il y a deux "molécules"  $C_x S H_y$  et sa section basale est de  $20,35 \text{ \AA}^2$ .

a) eau hydroxylique

Nous avons montré qu'après séchage D, seule l'eau hydroxylique subsiste (I.R., R.M.N.). La thermogravimétrie à la balance Mac Bain permet de préciser qu'il y a deux molécules d'eau hydroxylique par pseudo-maille (cas de l'échantillon dont la maille contient deux "molécules"  $C_{1,75} S H_{1,11}$ ).

Ces hydroxyles, d'après la spectrométrie infrarouge sont en partie internes (vibration de valence vers  $3650\text{ cm}^{-1}$  et en partie externes (silanols libres vibrant vers  $3700\text{ cm}^{-1}$ ). Ils peuvent être portés, soit par des atomes Si, soit par des atomes Ca (notamment par les ions  $Ca^{2+}$  fixés sur la surface pour compenser l'électronégativité de la surface). Or, par section basale, ils ne peuvent être plus de deux. Il n'y a qu'un tétraèdre et demi de  $SiO_4$  par couche dans la maille. De toute manière, ils ne peuvent se lier au maximum qu'à deux molécules d'eau (au premier niveau) puisque l'aire d'encombrement moléculaire de celle-ci est de  $11,4\text{ Å}^2$ .

b) eau interfeuillet

La thermogravimétrie à la balance Mac Bain nous a indiqué que, pour une hygrométrie comprise entre le vide donné par le silica-gel (soit environ  $10^{-2}$  torrs) et 80 %, la pseudo-maille contient une molécule d'eau supplémentaire. Cette eau ne peut être qu'interfeuillet. La R.M.N. révèle en effet une eau moléculaire de faible degré de liberté donnant un signal vers 1 oe et un temps de corrélation de  $5.10^{-7}\text{ s rad}^{-1}$ . La méthode diélectrique montre que jusqu'à  $\theta = 1$ , il n'y a pas d'absorption dipolaire Debye.

2) Eau dans les pores

Il s'agit plus précisément de l'eau adsorbée à la surface des lamelles.

Lorsque la pression relative est de l'ordre de 0,8, on a d'après les résultats de la thermogravimétrie isobare, l'état 2 d'hydratation ; la "molécule de C-S-H" ou demi-pseudo-maille contient 2,5 molécules d'eau globale. L'unité structurale qui comprend trois de ces pseudo-mailles renferme donc une quinzaine de molécules d'eau dont six sous forme hydroxylique et quatre dans les espaces interfoliaires. Il reste donc en moyenne cinq molécules fixées sur les deux faces basales de la lamelle. L'eau des faces latérales est négligeable, l'épaisseur étant de la trentaine d'ångströms par rapport à des longueur et largeur de l'ordre de plusieurs microns.

La spectro-infrarouge et la R.M.N. mettent en évidence la présence d'une eau moléculaire relativement liée ; la première par la manifestation des vibrations d'hydroxyles liés par pont d'hydrogène (entre  $3400$  et  $3600\text{ cm}^{-1}$ ) ; la seconde par un signal de largeur de raie d'environ 0,6 oe.

La méthode diélectrique donne une bande d'absorption  $B_\alpha$  lorsque  $\theta$  est compris entre 1 et 2 à 3. Les molécules d'eau concernées,

qu'elles soient fixées sur un hydroxyle isolé appartenant au support ou qu'elles soient liées à d'autres molécules d'eau, ne peuvent se réorienter sous l'effet du champ que si leur liaison se fait par un seul pont H.

Nous sommes maintenant en mesure de donner une représentation de l'eau fixée à la surface des lamelles. Compte tenu de ce qu'il ne peut y avoir plus de deux molécules d'eau par section basale, les raisons étant les mêmes que pour l'eau interfeuillet, nous pouvons envisager deux schémas (fig.4). Ceux-ci diffèrent avec le plus ou moins grand rapprochement des silanols superficiels : A correspond à des silanols adjacents, B à des silanols isolés. Le bilan du contenu en eau joint à la figure permet de se rendre compte que les valeurs du taux de recouvrement  $\theta$  et de teneur en eau  $y$  (rapportée à la demi-pseudo-maille) concordent avec les déterminations expérimentales.

b)	Contenu en molécules d'eau selon			Résultats expérimentaux
	Schéma A	Schéma B		
- Eau dans l'unité structurale				
- Eau sous forme hydroxylique	$N_{OH}$	6	6	
- Eau interfeuillet	$N_I$	4	4	
- Eau globale externe	$N_E$	6	4	
Total	$N_T$	16	14	environ 15.
- Eau monocouche sur faces externes	$\Sigma$	4	4	
- Taux de recouvrement - $\theta$ apparent	$\frac{N_T + N_E}{\Sigma}$	$10 = 2,5$	$8 = 2$	
- $\theta$ - relaxation $B_\alpha$		2	2	2
- Rapport eau sur silice $y = n/5$	$\frac{N_T}{5}$	$16 = 2,65$	$14 = 2,34$	2,5

Fig. 4 - Schéma (a) et bilan (b) de répartition de l'eau pour une lamelle de C-S-H de composition  $C_{1,75} S H_{2,5}$  (estimation du contenu correspondant à une maille de section basale de l'ordre de  $20,35\text{ Å}^2$ ).

Il ressort de cette discussion que pour  $p/p_0 = 0,8$ , l'eau extérieure aux lamelles est une eau adsorbée en première couche dont les molécules sont disposées suivant les schémas A et B en fonction de la densité hydroxylique superficielle.

L'eau adsorbée au-delà de la première couche n'a pas été spécialement étudiée. Elle est également liée mais d'une façon nettement plus lâche que la précédente, et ce, d'autant plus que l'on s'éloigne de la surface du solide. C'est elle qui est à l'origine du premier signal R.M.N. ( $\Delta H \approx 0,13\text{ oe}$ ) et de la bande  $B_\beta$  d'absorption diélectrique.

## IV. SCHEMA TEXTURAL PROPOSE

Pour des raisons exposées par ailleurs (2), nous avons retenu comme modèle de texture celui proposé par Feldman et Sereda (5) et que nous représentons figure 5.

Fig. 5 : Modèle de texturation du gel C-S-H  
A - soudures ou liaisons interparticulaires  
B - feuillets de C-S-H  
X - eau interfeuillet  
O - eau adsorbée.

Nous allons examiner plus particulièrement les formes de liaison de l'eau dans les espaces vides de la texture.

## 1) Micropores interlamellaires

Les micropores qui représentent une part très importante du volume total et par suite de la surface totale des vides de la pâte, ont, un rayon hydraulique moyen de l'ordre de  $5 \text{ \AA}$ , alors que les pores dits "plus gros" ont un rayon moyen de l'ordre de  $10 \text{ \AA}$  (6).

A un rayon hydraulique de  $5 \text{ \AA}$  correspond un espacement interlamellaire de  $10 \text{ \AA}$ . Dans de tels espaces, l'eau soumise aux effets des champs de forces des surfaces qui se font vis-à-vis est en quelque sorte polarisée dans toute son épaisseur et par suite présente une structuration. Le schéma de la figure 6A donne un exemple de la façon dont les molécules d'eau sont liées et de ce fait agencées dans un micropore d'une dizaine d'angströms. Rappelons que l'épaisseur moyenne d'une monocouche d'eau définie statistiquement lors d'une physisorption est de l'ordre de  $2,5 \text{ \AA}$ , soit le diamètre de la molécule. Ce schéma nous a été inspiré par celui que Hair et Hertl (7) ont proposé pour l'eau adsorbée sur un gel de silice et soumise aux effets d'une seule surface du solide (un gel de silice a de relativement gros pores (fig. 6B). La validité du schéma se trouve justifiée par les résultats de l'étude diélectrique. Le recouvrement de chaque surface se fait de telle sorte que pour la quantité d'eau correspondant à une monocouche physique, les molécules d'eau sont nécessairement disposées en deux niveaux. Tant que les deux seconds niveaux ne sont pas remplis, les molécules donnent, sous l'effet du champ alternatif, une bande d'absorption Debye dipolaire du  $B_{\alpha}$  correspondant à une énergie libre d'activation  $U$  de  $0,37 \text{ eV}$ , ce qui traduit l'existence de liaison H simple. Lorsque les

deux niveaux médians sont remplis, on a une structuration telle que toutes les molécules d'eau sont doublement liées par pont H, d'où une absorption du type  $B_{\beta}$  ( $U = 0,58 \text{ eV}$ ).

Fig. 6 - Représentation de la disposition des molécules d'eau adsorbées

A - modèle proposé pour l'eau dans les espaces interlamellaires du gel C-S-H.  
B - modèle d'Hair et Hertl pour l'eau adsorbée dans les pores du gel de silice.

## 2) espaces interfoliaires

L'eau de ces espaces est considérée comme partie intégrante du schéma structural de C-S-H. Par conséquent, elle apporte une contribution à la cohésion intrinsèque de la lamelle, en liant les trois feuillets qui la composent.

La nature de cette liaison peut être précisée par l'étude diélectrique. En effet, lorsque le taux de recouvrement est égal ou inférieur à 1 il n'y a pas d'absorption de relaxation. D'après la figure 4, il n'y a au plus pour  $\theta = 1$  que deux molécules d'eau par section basale logées dans les espaces interfoliaires. Cette eau qui ne se manifeste dans la mesure diélectrique ni à  $U = 0,37 \text{ eV}$ , ni à  $0,58 \text{ eV}$  doit être encore plus fortement liée. Nous suggérons, en nous inspirant du modèle retenu par Mamy pour la montmorillonite (8) que chaque molécule d'eau soit triplement liée, donc comme dans la glace (fig. 7).

Fig. 7 - Représentation de la disposition des molécules d'eau adsorbées :

A - modèle proposé pour l'eau dans les espaces interfoliaires du gel C-S-H.  
B - modèle de Mamy pour l'eau dans les espaces interfoliaires de la montmorillonite.

## V. CONCLUSION

L'association des méthodes de spectrométrie moléculaire nous a permis d'une part, de répartir les différentes formes d'eau dans la structure et la texture d'une pâte durcie de  $C_3S$  et/ou de ciment, d'autre part d'apprécier les énergies de liaison des molécules d'eau, soit entre elles, soit avec la matrice solide. Nous avons ainsi montré que l'eau des micropores interlamellaires présente une structuration résultant de liaisons H et que celle des espaces interfoliaires est rigidifiée comme la glace. Il paraît donc certain que ces deux formes d'eau contribuent pour une certaine part à la cohésion des pâtes de ciment et ce, sur la base de liaisons hydrogène.

# Pore size distribution and permeability of hardened cement pastes

## *Distribution de la Taille des pores et perméabilité des pâtes de ciments durcies*

P.K. MEHTA and D. MANMOHAN, Université de Californie, Berkeley, U.S.A.

SUMMARY: Portland cement pastes hydrated with different water-cement ratios from 0.3 to 0.9 were investigated at 28 days, 90 days, and 1 year for pore size distribution and permeability. The pore size analyses were carried out by mercury intrusion technique, and the permeability was determined from flow of water under pressure in thin specimens of hardened cement pastes.

A correlation was found between the permeability of cement paste and the volume of pores greater than 1320 Å diameter. Irrespective of the age of hydration and water-cement ratio, as long as a specimen of hardened paste did not contain pores greater than 1320 Å, its permeability remained insignificantly low.

RÉSUMÉ: Des pâtes de ciment hydratées à différents rapports eau/ciment (de 0,3 à 0,9) ont été étudiées à 28 jours, 90 jours et 1 an quant à leur distribution de la taille des pores et leur perméabilité. Les mesures de la taille des pores ont été effectuées par la technique de pénétration du mercure et la perméabilité a été déterminée à partir d'un écoulement d'eau sous pression dans des échantillons minces de pâtes de ciment durcies.

Une corrélation a été trouvée entre la perméabilité de la pâte de ciment et le volume des pores de diamètre supérieur à 1320 Å. Indépendamment du temps d'hydratation et du rapport eau/ciment et aussi longtemps que l'échantillon de la pâte de ciment ne contenait pas de pores supérieurs à 1320 Å, sa perméabilité est restée insignifiante.

## VII - 2

### INTRODUCTION

It is generally known that durability of concrete exposed to aggressive aqueous environments is greatly affected by the permeability of the hardened cement paste which is the binder in concrete. Powers (1) reported the influence of water-cement ratio on porosity and permeability of portland-cement pastes, however, there is little information in published literature on the relationship between pore-size distribution and permeability. In this paper, the results of an investigation on determination of this relationship are described.

### PROCEDURE

A commercial ordinary portland cement with the following potential composition was used for this investigation: 63% C<sub>3</sub>S, 17% C<sub>2</sub>S, 6% C<sub>3</sub>A, and 7% C<sub>4</sub>AF. Using 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, or 0.9 water-cement ratio by weight, cement pastes were molded in plastic vials into 25 by 38 mm cylindrical specimens. Special techniques reported in detail elsewhere (2) were adopted to prevent bleeding and air entrainment. At 24 hours, the specimens were demolded and stored in lime water until ready for testing at 28 days, 90 days and 1 year.

For measurement of pore size distribution, 3-4 g pieces were cut from the cylindrical specimens. Hydration was stopped with an acetone wash, and the remaining pore water was removed by drying the specimens to constant weight at 70°C under vacuum for 24 hours. Data on bulk density and total porosity was also obtained from these specimens. In addition, degree of hydration was determined on 100°C-dried specimens by igniting them at 900°C. The pore size analysis was carried out by a commercial mercury intrusion apparatus capable of recording pore diameters down to 45 Å. Permeability was determined by applying D'Arcy's equation to the flow rate of water through cylindrical specimens of 25 mm diameter and 7.5 ± 0.5 mm thickness. The water pressures applied ranged from 1.4 MPa for the high water-cement ratio specimens, to 10.3 MPa for water-cement ratios 0.6 and less. Reproducibility of the data was ensured by duplicate or when necessary by triplicate tests.

### RESULTS AND DISCUSSION

The results from the tests on permeability, bulk density, total pore volume and degree of hydration are shown in Table I. The results show that for water-cement ratios of 0.3 and 0.4, with increasing hydration, the bulk density increased significantly with corresponding reduction in total pore volume. However, in the 0.5-0.9 water-cement ratio range, the bulk density as well as the total porosity remained essentially unchanged between 90 days and 1 year. The pastes made with 0.6, 0.7, 0.8 and 0.9 water-cement ratios were about two-third hydrated at 28 days, three-fourth at 90 days, and about 80 percent at 1 year. Correspondingly, there were significant changes in the physical characteristics of the pastes between 28 and 90 days curing period, but only insignificant changes were observed between 90 days and 1 year. Since similar degrees of hydration at given periods were recorded for the pastes made with water-cement ratios 0.6 and above, the pore size distribution data for these pastes only is used below for discussion purposes.

Table I Characteristics of cement pastes made with varying water-cement ratios

water-cement ratio	age	bulk density, g/cc	total pore volume cc/g	degree of hydration, percent	permeability, $\times 10^{-11}$ cm/sec
0.3	28 days	1.89	n.a.	54.59	1
	90 days	1.88	0.117	57.34	0.6
	1 year	1.94	0.130	64.68	0.4
0.4	28 days	1.65	n.a.	61.93	2.0
	90 days	1.70	0.196	64.68	1.0
	1 year	1.75	0.184	71.56	1.0

### EFFECT OF WATER-CEMENT RATIO ON PORE SIZE DISTRIBUTION

The pore size distributions for all the 28-day pastes are compared in Fig. 1. From the plots it can be concluded that with increasing water-cement ratios, the cumulative volume of pores at any given diameter and the threshold diameter increased significantly. The threshold diameter is the diameter of the largest pore present at which mercury begins to penetrate into the pores of the specimens.

Fig. 1 The effect of varying water-to-cement ratio on pore size distributions, 28 days.

From Fig. 1, two distinct slopes are apparent in the 0.6, 0.7, 0.8 and 0.9 water-cement ratio plots, the breakpoint being 1320 Å; and in the range 45 to 1320 Å the plots appear to be parallel to each other. The data for the above specimens was then replotted in Fig. 2 after subtracting the volume of pores > 1320 Å from the total mercury-intrusion pore volume.

Fig. 2 The pore size distribution of < 1320 Å pores in 0.6-0.9 water-to-cement ratio specimens, 28 days.

Surprisingly, it was found that a single curve could fit the 1320-45 Å pore size distribution data of the 28-day old cement pastes made with 4 different water-cement ratios (Fig. 2). This shows that in hardened cement pastes, the increase in total porosity resulting from increasing water-cement ratios manifests itself in the form of large pores only. In this study, the large pores are defined as those which were intruded by mercury at or below 9.0 MPa applied pressure, i.e., the pores greater than 1320 Å diameter. It is possible that this breakpoint at which the small pores end and the large pores begin (the pores representing the unfilled void spaces between clusters of the hydration products) is influenced by the materials and the methods used in this investigation. However, the present investigators are convinced that for the purposes of understanding and control of the engineering properties of hardened cement pastes, an arbitrary breakpoint value, for instance at about 1000 Å or 0.1 μm, between the large or macro pores and small pores would be useful. It may be noted that the small pores envisaged here include the gel pores (6-16 Å) of Powers (1) and the meso pores of Brunauer et al (3).

#### EFFECT OF AGE OF HYDRATION ON PORE SIZE DISTRIBUTION

The pore size distribution plots for the 0.9 and 0.7 water-cement ratio pastes at the three ages of hydration, namely, 28 days, 90 days, and 1 year, are shown in Figs. 3 and 4. The plots in Figs. 3 and 4 are typical of the plots obtained for the other water-cement ratio pastes. In general, with increasing age of hydration there was reduction in the threshold diameter, and the cumulative volume of pores at any given diameter. It was observed that the pore size distributions were not uniformly affected by increasing age of hydration. This is probably because as long as there are sufficient void spaces in a hydrating cement system, viz pores > 1320 Å, then following the path of least resistance the hydration products tend to fill these voids first, thus causing little or no change in the 1320-45 Å range. This phenomenon is associated with a significant decrease in the threshold diameter but only insignificant decrease in the volume of pores > 45 Å. Once the larger spaces, in this instance > 1320 Å are filled, further hydration appears to effect the entire pore size distribution.

Fig. 3 The pore size distributions, 0.9 water-to-cement ratio.

Fig. 4 The pore size distributions, 0.7 water-to-cement ratio.

For example, with increased hydration, the 0.9 water-cement ratio paste (Fig. 3), which had a large volume of pores > 1320 Å present at all test ages, showed major changes in threshold diameter but little change in the total volume of pores > 45 Å. However, in the 0.7 water-cement ratio paste (Fig. 4) for which most pores > 1320 Å were filled between 28 and 90 days, there was correspondingly a large decrease both in the threshold diameter and the volume of pores > 45 Å. Once the > 1320 Å pores were filled, the pore size distributions changed uniformly with further hydration between 90 days and 1 year.

#### RELATIONSHIP BETWEEN PERMEABILITY AND POROSITY

From the data in Table 1 it is concluded that the experimentally determined values of the permeability coefficient ( $K_1$ ) are in general agreement with Powers (1). For instance, at any age, the permeability coefficient increased exponentially with increase in water-cement ratio or total pore volume of the cement pastes. Also generally, the permeability coefficient decreased exponentially with increasing age or degree of hydration.

However, it is also concluded from the data that a knowledge of the total volume of pores is not sufficient to accurately predict the permeability of a cement paste. For example, the permeability coefficient for the 1-year old 0.8 water-cement ratio paste was found to be much lower than the 28-day old 0.7

water-cement ratio paste in spite of the fact that the former had a greater total pore volume. On examining the pore size distribution and permeability data it is apparent that large pores, viz  $> 1320 \text{ \AA}$ , played a more important role in determining the permeability than the smaller pores. In the case under discussion, the large pores in the 0.8 water-cement ratio paste were filled at 1 year, whereas in the 0.7 water-cement ratio paste at 28 days, a substantial volume of these pores was still present. This shows that in order to develop a more reliable relationship between pore structure and permeability of a hardened cement paste, it would be better to take into consideration several parameters from the pore size distribution, rather than depend on the total porosity alone.

#### PREDICTING PERMEABILITY FROM PORE SIZE DISTRIBUTION

Using certain parameters from the pore size distribution data as independent variables and the permeability coefficient as the dependent variable, a multiple regression analysis was carried out for setting up a mathematical model from which permeability could be predicted. The pore size distribution was arbitrarily divided into volume of pores  $> 1320 \text{ \AA}$ , and volume of pores in the  $290\text{--}1320 \text{ \AA}$  range. Dividing these volumes by the total mercury intrusion porosity, the effect of pore volume in the  $45\text{--}290 \text{ \AA}$  range was taken into consideration. These normalized values of pore volumes in the  $> 1320 \text{ \AA}$  and  $290\text{--}1320 \text{ \AA}$  range were designated as  $V_1$  and  $V_2$ , respectively. Threshold diameter (TD), the largest pore diameter at which the flow of mercury is established in the specimen, was visualized as another important parameter influencing the permeability of a cement paste. Finally, the modified total porosity (MTP), which is equal to total pore volume divided by the degree of hydration, was another parameter used in this study. The modified total pore volume was found more useful to the model than the unmodified pore volume, because reduction of large pores which affected permeability greatly is a function of the degree of hydration. It should be noted that three of the four independent variables proposed here are available from the pore size distribution analysis, and the modified total porosity is obtained from the experimental data on total porosity and degree of hydration.

Table II Input data for the computer program

Water-Cement Ratio	Age	$\ln K_1$	$V_1$	$V_2$	TD	MTP
0.3	90 days	-0.51	0.000	0.735	600	0.267
	1 year	-0.92	0.000	0.719	560	0.200
0.4	90 days	0.00	0.000	0.609	760	0.302
	1 year	0.00	0.000	0.559	760	0.256
0.5	28 days	1.099	0.000	0.628	1000	0.466
	90 days	1.099	0.000	0.632	860	0.356
	1 year	0.00	0.000	0.548	720	0.329
0.6	28 days	3.135	0.189	0.552	2200	0.652
	90 days	1.099	0.000	0.653	1150	0.497
	1 year	0.693	0.000	0.618	1100	0.470
0.7	28 days	5.394	0.278	0.481	4600	0.734
	90 days	2.890	0.029	0.676	1400	0.552
	1 year	2.639	0.000	0.662	1250	0.536
0.8	20 days	6.870	0.385	0.440	7800	0.817
	90 days	4.344	0.250	0.523	3500	0.668
	1 year	3.807	0.051	0.633	1550	0.629
0.9	28 days	8.319	0.442	0.404	14000	1.080
	90 days	5.165	0.300	0.500	4000	0.829
	1 year	4.331	0.234	0.503	2600	0.774

Plots of permeability coefficient against each one of the independent variables suggested the exponential relationship of the type:

$$K_1 = \exp(aV_1 + bV_2 + cMTP + dTD + e)$$

where  $a, b, c, d$ , and  $e$  are constants. Therefore, the permeability values were converted to their natural logarithm ( $\ln K_1$ ) before input into the computer for the multiple regression analysis. The analysis was carried out using the canned program SPSS (Statistical Package for Social Sciences). The input data for this program is shown in Table II. The results gave the following values of the constants for determining the coefficient of permeability of a specimen, with a known mercury intrusion pore size distribution and a known degree of hydration:

$$K_1 = \exp(3.84V_1 + 0.20V_2 + 0.56 \times 10^{-6}TD + 8.09MTP - 2.53) \quad (i)$$

The accuracy of prediction of permeability by this equation, as reflected by the statistical  $r^2$  value, was found to be 95 percent. In other words, in the present study 95 percent of the variation in the permeability results could be taken care of by the independent variables  $V_1$ ,  $V_2$ , TD, and MTP. Thus, the model for predicting permeability of hardened cement pastes can be used with a good degree of accuracy. Calculations show that on average, the predicted value of the permeability coefficient will deviate from the actual value by 0.61 cm/sec only.

The relationship between permeability and  $V_1$ , permeability and MTP, and permeability and TD were also investigated separately. The significant effect of  $> 1320 \text{ \AA}$  pores on permeability is evident from the plot in Fig. 5 which shows an exponential increase in  $\ln K_1$  with increasing  $V_1$ . Straight line relationships, also shown in Fig. 5, were found when  $\ln K_1$  was plotted against either MTP or  $\ln TD$ . The corresponding mathematical expressions for these relationships are

$$\ln K_1 = 2.85 \ln TD - 18.51 \quad (ii)$$

$$\ln K_1 = 10.91 MTP - 3.38 \quad (iii)$$

The coefficients of determination calculated for equations (ii) and (iii) are 0.96 and 0.94, respectively. These coefficients are a measure of the accuracy of the fit for the experimental data; and for a perfect linear fit the value is 1.

#### CONCLUSIONS

Investigations on the pore size distribution and permeability of portland cement pastes hydrated with 0.3 to 0.9 water-cement ratios showed that the pastes made with 0.6 to 0.9 water-cement ratios contained substantial volume of large pores, i.e., pores  $> 1320 \text{ \AA}$  diameter. In these high water-cement ratio pastes, the pore size distribution at 28 days was found to remain essentially the same in the  $45\text{--}1320 \text{ \AA}$  range, because with the increasing water-cement ratio the increased porosity manifested itself in  $> 1320 \text{ \AA}$  pores.

Since the large pores were found to have a greater influence on permeability than small pores, it is concluded that the pore size distribution data, rather than total porosity, provides better opportunity for developing accurate correlations with permeability. It is also concluded that permeability can be computed from a mathematical model which uses input from the pore size distribution data.

## Liaison pâte de ciment Portland - Granulats naturels

### *Bond between Portland cement paste and native aggregates*

B. CARIOU, Ingénieur, Laboratoire de Recherche appliquée Lafarge S.A., France.

**RESUME :** La liaison pâte granulat entre des ciments riche et pauvre en  $C_3A$  et des granulats naturels, quartz et calcaire, a été étudiée en mesurant son interaction sur les résistances en flexion et en compression de mortiers d'un type spécial, et en déterminant le nombre de granulats cassés à la rupture.

Des essais complémentaires avec le calcaire ont mis en évidence l'influence de la forme des granulats et de leur rugosité de surface sur les propriétés mécaniques de ces mortiers.

Des observations en microscopie électronique à balayage ont permis de suivre, en fonction de l'échéance, le déplacement des surfaces de moindre résistance par rapport à l'interface pâte-granat.

**SUMMARY :** The cement paste - aggregate bond was studied by measuring tensile and compressive strengths of special type mortars which allowed to determine the number of aggregates fractured during the flexion shear. Two industrial Portland cements, respectively  $C_3A$  - poor and  $C_3A$  - rich, and two native aggregates, quartz and limestone, were used for the study.

In the case of limestone, supplementary tests showed the influence of the shape and surface texture of the aggregates on the mechanical properties of mortars.

Scanning electron microscopy investigations allowed to follow the shift versus time, of the lower strength surfaces from the cement paste - aggregate boundary.

L'étude des liaisons entre granulats et pâte de ciment a fait l'objet de nombreux travaux et tous les auteurs s'accordent à considérer que ces liaisons jouent un rôle prépondérant dans l'acquisition des propriétés mécaniques des bétons. Le développement des caractéristiques de ce matériau hétérogène est lié à de très nombreux paramètres et si les problèmes attachés au choix des granulats ou des liants et à leurs conditions de mise en œuvre ont été depuis longtemps étudiés, l'examen des mécanismes de liaison entre la pâte de ciment et les granulats n'a été abordé que beaucoup plus récemment.

C'est ainsi que FARRAN (1), l'un des premiers à envisager de manière systématique l'étude des mécanismes de liaison et à en souligner les divers types, a montré que l'adhérence n'est pas simplement due à la forme et à l'état de surface des grains, mais que la nature minéralogique des granulats et celle des hydrates qui se forment à leur contact jouent un rôle prépondérant. Ces résultats soulignent le caractère hétérogène du matériau étudié. Cette idée, reprise par MASO (2), conduit à envisager l'existence autour des granulats d'une auréole de cohésion variable, plus faible que celle de la masse du liant. Des mesures de microdureté (3) et la mise en évidence, au niveau de la zone de transition de variations de composition de la pâte (4), confirment cette hypothèse.

Beaucoup d'autres travaux ont été poursuivis selon diverses voies, s'attachant à préciser les types de liaison (5) et leurs mécanismes de formation, mettant notamment en évidence l'influence des réactions entre le calcaire et les phases alumineuses des liants sur la formation de liaisons de type épitaxique dues à la présence des hydrates formés et à la nature minéralogique des granulats (6 à 10).

D'autres études ont permis de préciser la morphologie de la zone de contact (11, 12, 13), soulignant soit l'enrichissement en portlandite de la couche de contact (14, 15, 16), soit les caractéristiques physiques de l'auréole de transition, notamment les variations d'épaisseur et de porosité qui expliquent l'existence d'une zone de moindre cohésion (17, 18).

Enfin, certains travaux ne considèrent que les caractéristiques mécaniques des liaisons pâte/granulats et précisent les conditions de développement des microfissures dans le béton (19, 20). Malgré l'abondance des résultats déjà acquis, il a semblé utile de préciser les relations entre les types de liaisons pâte/granulats et les propriétés mécaniques des bétons. On entend par types de liaison ceux qui peuvent être définis par des paramètres faciles à appréhender et aisément mesurables à une échelle relativement grossière, tels que la présence de composés chimiques définis à l'interface granulats/liants ou la nature, la forme, l'état de rugosité de la surface des granulats. Cette approche ne préjuge donc nullement de la nature exacte, mécanique, physique ou chimique de la liaison.

Nous présentons les principaux résultats de nos essais destinés à préciser l'importance des différents types de liaisons précédemment définies. Les examens ont été faits d'une part à l'échelle macroscopique, au niveau des performances et de l'aspect des ruptures ; d'autre part, à l'échelle microscopique, par l'observation au microscope électronique à balayage.

#### METHODES EXPERIMENTALES

Pour faciliter les observations, nous avons utilisé des mortiers 1/1 à 1/1,5 de granulats monodimensionnels (entre 4 et 5 mm de diamètre). Nous avons adopté un E/C pondéral voisin de 0,30 qui conduit à une bonne aptitude à la mise en place, sans ségrégation des granulats.

Les éprouvettes 4 x 4 x 16 cm ont été conservées à 20°C, pendant 24 heures en salle humide puis sous eau jusqu'aux

échéances de 2 - 7 - 28 et 90 jours. Nous avons alors mesuré les résistances à la flexion et à la compression, et déterminé par comptage la proportion de granulats cassés sur la surface de rupture par flexion.

Tous les échantillons, aux échéances de 7 et 90 jours, ont été examinés au microscope électronique à balayage. Pour cette étude, les restes d'éprouvettes, après mesure des résistances, ont été fracturés au marteau, et les surfaces de fracture fraîches ainsi dégagées ont été immédiatement mises sous vide et métallisées pour éviter toute hydratation et carbonatation ultérieures. Le fait de préparer les échantillons par fracture au marteau crée des contraintes, et entraîne la formation de fissures qui n'existaient pas initialement dans l'éprouvette de mortier. Mais ceci n'est pas en fait un inconvénient car ces fissures provoquées passent par les surfaces de moindre résistance et nous renseignent sur leur cheminement au voisinage des granulats.

Outre ces examens sur fractures, des sections polies ont été exécutées à l'échéance de 2 jours pour observer au microscope optique la répartition, entre les granulats, des grains de ciment en fonction de leur taille.

#### RESULTATS MACROSCOPQUES

Deux séries d'essais ont été réalisées : l'une, avec deux granulats roulés et deux ciments différents pour étudier l'éventualité des liaisons physicochimiques et leur rôle sur les résistances ; l'autre avec un seul ciment et un seul type de granulat diversement traité, pour tester l'influence de sa forme et de son état de surface sur les propriétés mécaniques.

##### Première série d'essais

Des mortiers 1/1 au E/C = 0,30 ont été réalisés avec deux ciments Portland du type CPA 400, l'un riche en  $C_3A$  : 13 %, l'autre pauvre en  $C_3A$  : 3 %.

Nous avons utilisé du calcaire dur roulé très pur (type urgonien provenant d'alluvions fluvio-glaciaires würmiennes de la région d'Auberive en Royan - Isère, de résistance à la pénétration 2100 MPa) et du quartz roulé très pur (gisement de sable kaolinique de la région de Barbières - Drôme).

Nous recherchions, en employant des granulats roulés, à minimiser les accrochages mécaniques liés à leur forme et à leur état de surface. En réalité, nous avons pu constater par observation au microscope électronique à balayage, que l'un et l'autre de ces granulats présentent une même rugosité de surface, importante au niveau du micron. De ce fait, des accrochages mécaniques sont possibles avec la pâte, liés à cet état de surface, mais du même ordre de grandeur avec les deux séries de granulats.

Les résultats (tableau 1) font apparaître globalement un pourcentage de granulats cassés très faible, même à 90 j.

TABLEAU 1					
ciment à	granulats	2 jours		90 jours	
		Flexion MPa	% granulats cassés	flexion MPa	% granulats cassés
3 % $C_3A$	calcaire	5,4	3	9,1	22
	quartz	5,8	5	9,1	18
13 % $C_3A$	calcaire	8,0	13	9,3	14
	quartz	7,9	9	8,7	15

Pour une même échéance, les résistances à la flexion sont indépendantes du granulat : elles ne font que refléter la meilleure résistance initiale du ciment riche en  $C_3A$ .

Cependant, à l'échéance de 90 jours, et avec le ciment riche en  $C_3A$ , la diffraction X nous a révélé, au contact du seul granulat calcaire, la présence de monocarboaluminate de calcium hydraté :  $C_3A, CC, 12H$ . Il existe donc bien une réaction chimique dans ce cas, mais qui ne paraît pas entraîner une amélioration significative de la résistance du mortier correspondant.

Elle ne paraît pas non plus favoriser l'adhérence pâte-granulat puisque, pour une échéance donnée, les pourcentages de granulats cassés par la rupture ne sont pas significativement différents.

Ces résultats permettent de conclure, puisque les granulats ont des possibilités d'accrochage mécanique voisines (même rugosité - même forme roulée) les réactions physico-chimiques qui se produisent avec la pâte n'influencent pas l'accrochage, tout au moins aux échéances examinées.

#### Deuxième série d'essais

Le fait de n'observer qu'un pourcentage de granulats cassés relativement faible doit pouvoir s'expliquer par l'utilisation de produits roulés. C'est pourquoi nous avons réalisé une autre série d'essais, avec un seul ciment CPA 400 de teneur moyenne en  $C_3A$  : 7 % et un seul granulat calcaire, de

même origine que précédemment, mais de formes et d'états de surface variés. Ces granulats ont été :

- polis par usure dans un broyeur sans boulet avec de l'alumine comme abrasif pour obtenir des formes arrondies et de faibles rugosités de surface ce qui entraîne peu d'accrochages mécaniques
- concassés ce qui donne des formes anguleuses et des rugosités de surface plus grandes d'où de bons accrochages mécaniques (voir fig. 1 - 2)
- attaqués par une solution d'acide chlorhydrique diluée ce qui permet d'obtenir des formes et des rugosités de surface intermédiaires entre les granulats polis et les granulats concassés.

Les mortiers 1/1,5 ont été gâchés au E/C de 0,28.

Comme précédemment, les conditions de préparation des mortiers étant identiques, toute différence entre les résultats obtenus ne pourra provenir que de différence au niveau de l'adhérence pâte-granulat. Globalement, on observe (Tableau 11) qu'en fonction de l'échéance le % granulats cassés et les résistances en compression et flexion augmentent régulièrement avec les granulats concassés. Alors qu'avec les granulats polis le % granulats cassés est faible et n'évoque pas, la résistance à la compression n'augmente que faiblement et la résistance à la flexion presque pas du tout. Avec les granulats attaqués à l'acide, les résultats sont in-

FIGURE 1 - Formes - (a) Granulats polis, (b) Granulats concassés

FIGURE 2 - Aspect de la surface - (a) Granulats polis, (b) Granulats concassés

5 μm

TABLEAU II					
avec granulats	Échéances en jours	2	7	28	90
polis	% Granulats cassés	7	17	11	11
	Flexion MPa	7,5	8,0	7,9	8,3
	Compression MPa	46,6	61,4	73,4	76,8
	Compression/Flexion	6,2	7,7	9,3	9,3
attaqués à l'acide	% Granulats cassés	28	32	33	27

	Compression/Flexion	6,8	7,0	7,6	8,3

termédiaires, plus proches de ceux obtenus avec les granulats polis.

Nous avons porté les résultats de compression et flexion en fonction du % granulats cassés (Figure 3). On remarque que la résistance à la compression dépend de l'échéance, donc de la résistance de la pâte, et aussi du % granulats cassés lorsque celui-ci augmente, la résistance propre des granulats participant alors à la résistance du mortier. Ce nombre de granulats cassés dépend lui-même de la qualité de l'adhérence pâte-granulat. On voit que la résistance à la compression dépend de la résistance de la pâte et de l'adhérence pâte-granulat. La résistance à la flexion, par contre, paraît dépendre principalement du % de granulats cassés, et moins de l'évolution de la résistance de la pâte. Les résultats se regroupent sur une courbe d'allure exponentielle qui met en évidence l'intérêt d'obtenir, par une bonne adhérence pâte-granulat, un % granulats cassés élevé. La résistance à la flexion apparaît donc, proportionnellement, plus liée à la qualité de l'adhérence pâte-granulat que la résistance à la compression d'où une diminution du rapport compression/flexion lorsque l'adhérence pâte-granulat s'améliore.

A partir de la même variété de granulats calcaires durs et en ne faisant varier que leurs formes et leurs états de surface, nous avons pu obtenir, à 90 jours : une adhérence médiocre (polis) ne conduisant qu'à 11 % de granulats cassés à la fracture et une très bonne adhérence (concassés) entraînant 62 % de granulats cassés à la fracture avec une amélioration de 17,3 MPa en compression et 3,0 MPa en flexion. Ceci montre bien l'importance de la contribution des accrochages mécaniques à l'adhérence pâte-granulat.

#### RESULTATS MICROSCOPIQUES

L'examen à 2 jours des sections polies en microscopie optique fait apparaître dans tous les cas un enrichissement en fines particules de ciment autour des granulats. On a là un effet semblable à celui de la peau du béton : les gros grains de ciment ne peuvent pas être au contact du granulat, car, même s'il y a contact en quelques points, il y aura toujours de la place entre eux et le granulat pour des grains plus fins. Mais il peut aussi se produire, en plus, un effet d'attraction électrostatique sur les particules fines.

Cet enrichissement en fines particules explique l'hydrata-

FIGURE 3 : Granulats polis  $\circ$ , attaqués acide  $\bullet$ , concassés  $+$ .

tion, un peu plus rapide au contact des granulats qu'au coeur de la pâte, observée en diffraction X.

L'examen au microscope à balayage à 7 jours et 90 jours des fractures des mortiers dans lesquels on a fait varier respectivement le ciment (un riche en  $C_3A$ , un pauvre en  $C_3A$ ), la nature des granulats (un calcaire, un quartz) et l'état de surface des granulats (calcaire poli, concassé, et attaqué par HCl dilué) permet de dégager les conclusions suivantes :

- 1) il y a enrichissement en  $Ca(OH)_2$  au contact des granulats dans tous les cas et aux 2 échéances considérées. Cet enrichissement en  $Ca(OH)_2$  peut s'expliquer par l'augmentation locale du E/C due au mouillage des granulats, favorisant la précipitation de gros cristaux de  $Ca(OH)_2$ . Mais on n'observe pas d'orientation préférentielle de ces cristaux de chaux que la fracture fait apparaître stratifiés par clivage (fig. 4),
- 2) il n'y a pas de différence décelable de comportement à l'interface pâte-granulat entre les 2 ciments pour un même granulat, ni entre les 2 granulats pour un même ciment.
- 3) statistiquement, l'accrochage de la pâte de ciment sur le granulat, se fait aussi bien avec  $Ca(OH)_2$  qu'avec le CSH (fig. 5).
- 4) dans tous les cas, les surfaces de moindre résistance s'éloignent de l'interface pâte-granulat quand l'échéance

FIG. 4 : Précipitation de  $\text{Ca(OH)}_2$  auprès des granulats 5  $\mu\text{m}$

FIG. 5 : Accrochage de CH et CSH sur les granulats 1  $\mu\text{m}$

FIGURE 6 : Echéance 7 jours - (a) Granulats polis, (b) Granulats concassés, G = Granulat 5  $\mu\text{m}$

FIGURE 7 : Echéance 90 jours - (a) Granulats polis, (b) Granulats concassés, G = Granulat, P = Pâte 5  $\mu\text{m}$

augmente ; mais, à une échéance donnée, il y a une influence significative de la rugosité et de la forme des granulats sur la distance entre la surface de moindre résistance et l'interface pâte-granat : celle-ci augmente progressivement quand on passe des granulats polis (de forme arrondie et lisse) + granulats attaqués à HCl dilué (de forme arrondie mais un peu rugueux) + granulats concassés (anguleux et très rugueux) (fig. 6, 7).

Ce dernier point peut s'expliquer ainsi : quand un mortier subit un choc, s'il n'y a pas du tout d'adhérence entre le granulat et la pâte, la fissure suivra l'interface pâte-granat. Par contre, dès qu'il commence à y avoir adhérence pâte-granat, il y a compétition (au niveau de la résistance globale) entre une ligne de rupture longue suivant le contour du granulat, et une ligne droite, plus courte, dans la pâte, et ceci entraîne, aussi bien l'éloignement statistique dans le temps de la surface de rupture par rapport à l'interface pâte-granat que son éloignement en fonction de la rugosité.

#### CONCLUSION

L'utilisation de mortiers de granulats monodimensionnels et la détermination des résistances de ces mortiers avec évaluation du pourcentage de granulats cassés à la rupture en flexion, se sont avérées une méthode très riche pour évaluer l'adhérence pâte-granat et son interaction sur les propriétés mécaniques. La microscopie électronique à balayage a permis de compléter ces résultats par observation directe de l'interface pâte-granat.

Bien que l'on ait confirmé l'existence de réactions chimiques entre le calcaire et le  $C_3A$  du ciment, nos essais ont montré qu'au moins jusqu'à 90 jours et pour les granulats étudiés, les accrochages mécaniques liés à la rugosité et surtout à la forme des granulats sont prépondérants pour l'adhérence.

Une amélioration dans l'adhérence influe directement sur les résistances en flexion et dans une moindre part sur les résistances en compression.

On a confirmé la précipitation préférentielle de CH auprès des granulats. Mais surtout on a mis en évidence l'existence d'une surface de moindre résistance qui est à l'interface pâte-granat aux courtes échéances, et qui s'éloigne ensuite dans la pâte et ce d'autant plus que les granulats sont rugueux et anguleux. Cette surface de moindre résistance paraît être l'équivalent des zones de transition souvent signalées, et nous pensons que les recherches futures devraient porter sur les moyens les plus judicieux à utiliser (granulats spéciaux ou synthétiques, traitement de surface de granulats traditionnels) pour diminuer la faiblesse de cette zone.

# Approche analytique de la dédolomitisation des granulats dans le béton durci

## *Analytic approach of dedolomitization of aggregates in concrete*

F.X. DELOYE, Docteur Ingénieur,  
A. BERNARD, Chef du Groupe "Méthodes Thermiques",  
A. POINDEFERT, Assistante,  
Laboratoire Central des Ponts et chaussées - Service de Chimie, France.

RESUME : La dédolomitisation est susceptible d'affecter les bétons confectionnés à partir de calcaires dolomitiques. Ce phénomène est régi par le couple de réactions de double décomposition :  $\text{CaMg}(\text{CO}_3)_2 + 2\text{NaOH} \rightarrow \text{CaCO}_3 + \text{Mg}(\text{OH})_2 + \text{Na}_2\text{CO}_3$ , puis :  $\text{Na}_2\text{CO}_3 + \text{Ca}(\text{OH})_2 \rightarrow \text{CaCO}_3 + 2\text{NaOH}$ , où l'hydroxyde alcalin est régénéré tant que le béton contient de la portlandite. Il s'agit donc en fait d'une catalyse homogène.

En raison de la nature des oxydes mis en cause, la détection de la dédolomitisation n'est pas possible par analyse chimique. Seule l'investigation minéralogique fine est en mesure de le faire.

D'une part, la thermogravimétrie en atmosphère inerte permet le dosage de la portlandite ( $\text{Ca}(\text{OH})_2$ ) et de la brucite ( $\text{Mg}(\text{OH})_2$ ). D'autre part, l'association du dosage précis de  $\text{CO}_2$  avec l'analyse thermique différentielle sous anhydride carbonique permet la détermination simultanée de la dolomite ( $\text{CaMg}(\text{CO}_3)_2$ ) et de la calcite ( $\text{CaCO}_3$ ).

L'introduction de ces données dans l'analyse minéralogique d'un béton durci contenant des granulats dolomitiques permet de mettre en évidence une éventuelle dédolomitisation et d'en connaître le degré d'avancement.

SUMMARY : Dedolomitization might affect concretes made up from dolomitic limestones. This phenomenon is governed by following reaction pair of double decomposition :  $\text{CaMg}(\text{CO}_3)_2 + 2\text{NaOH} \rightarrow \text{CaCO}_3 + \text{Mg}(\text{OH})_2 + \text{Na}_2\text{CO}_3$ , then :  $\text{Na}_2\text{CO}_3 + \text{Ca}(\text{OH})_2 \rightarrow \text{CaCO}_3 + 2\text{NaOH}$ , where alkali is regenerated as long as concrete contains portlandite. Thus, it is in fact an homogeneous catalysis.

Because of the nature of the oxides involved, it is not possible to detect the dedolomitization by means of a chemical analysis but this can be attained by a detailed mineralogical investigation.

On one hand, thermogravimetry in inert atmosphere allows to determine the proportions of portlandite and brucite, on the other hand, the combination between the precise determination of the proportions of  $\text{CO}_2$  and the differential thermal analysis in a carbon dioxide medium makes it possible to simultaneously determine the dolomite ( $\text{CaMg}(\text{CO}_3)_2$ ) and the calcite ( $\text{CaCO}_3$ ).

With help of these data, the mineralogical analysis of hardened concrete containing dolomitic aggregates allows for an eventual dedolomitization to be detected and thus for its progress to be known.

La dolomite est le nom du minéral constitutif des dolomies ; sur le plan chimique il s'agit du carbonate double de calcium et de magnésium de formule  $\text{CaMg}(\text{CO}_3)_2$ .

On rencontre communément la dolomite en association avec la calcite dans les marnes et certains calcaires appelés pour cette raison "calcaires dolomitiques" lesquels sont souvent assez durs. Ceci explique qu'en France dans le Midi Méditerranéen où ils sont abondants, ces derniers aient été fréquemment utilisés dans la construction et employés sans précaution particulière pour la confection des mortiers et bétons.

La dolomite est difficilement attaquée par l'acide chlorhydrique à froid (1) et sa solubilité dans l'eau pure est légèrement inférieure à celle de la calcite, par contre au sein du béton fortement basique la présence d'alcalis libres peut déclencher un cycle dit de dédolomitisation (2) caractérisé par la chaîne de réactions :

Il s'agit d'une catalyse homogène que l'on peut écrire :

où l'alcali libre, catalyseur est perpétuellement régénéré, donc une faible proportion de celui-ci dans le béton est parfaitement capable de provoquer la dédolomitisation jusqu'à carbonatation complète de la portlandite, pouvant entraîner la décohésion du liant.

La nature des oxydes mis en cause dans cette réaction  $\text{CaO}$ ,  $\text{MgO}$ ,  $\text{Na}_2\text{O}$  ou  $\text{K}_2\text{O}$ ,  $\text{CO}_2$ , qui appartiennent tous à la fois au ciment et aux granulats du béton ne permet pas de mettre en évidence par voie chimique une éventuelle dédolomitisation. Seule une investigation minéralogique fine est en mesure de déterminer si celle-ci a effectivement eu lieu.

Sur le plan minéralogique la chaîne de réactions fait intervenir quatre minéraux : dolomite, portlandite, calcite et brucite, dont les trois premiers sont initialement présents dans le béton.

En raison de la solubilité très faible de la brucite, le phénomène est nécessairement lié à la présence de ce minéral détectable par diffractométrie des rayons X ; mais cette présence n'est pas suffisante, en effet la brucite observée peut dans certains cas

provenir de l'action prolongée d'eaux contenant de la magnésie même en faible quantité. Ceci est particulièrement vrai pour les bétons de fondation.

En pétrographie, on peut distinguer la dolomite de la calcite par coloration spécifique (3) et observer une éventuelle épigenie. Mais si cette technique s'applique fort bien aux roches compactes, sa transposition au béton se heurte à la présence de la pâte de ciment.

En fin de compte, la dédolomitisation ne peut être mise en évidence et surtout quantifiée avec certitude qu'à l'aide d'un bilan minéralogique complet du matériau.

Tout d'abord, grâce à "l'analyse allégée" (4), il faut établir la composition que devait avoir le béton lors de sa mise en place, y compris la composition approchée du ciment. Ensuite, à l'aide des méthodes spécifiques à l'analyse minéralogique (5), il est nécessaire de déterminer les teneurs respectives, actuellement présentes des quatre minéraux mis en cause par la réaction. Enfin le calcul du bilan minéralogique réel et sa comparaison avec la composition initiale doit permettre de rendre compte du phénomène par le transfert d'une partie de la dolomite et de la portlandite vers la calcite et la brucite. La comparaison en question repose essentiellement sur le dosage précis de ces quatre minéraux dans le béton.

En raison de sa sensibilité trop faible, la diffractométrie des rayons X ne peut pas être mise à contribution pour doser directement ces minéraux alors qu'elle est d'un grand secours pour les identifier. Par ailleurs, ceux-ci ont leurs anions en commun deux à deux,  $\text{OH}^-$  et  $\text{CO}_3^{2-}$ .

Les méthodes thermiques choisies pour effectuer les dosages font intervenir la dissociation en utilisant les départs d'eau ou d'anhydride carbonique. Mais dans les conditions opératoires, certaines recombinaisons ont lieu et il est important d'en tenir compte. Il en résulte que les dosages des quatre minéraux sont liés.

#### DOSAGE DE LA BRUCITE ET DE LA PORTLANDITE

En thermogravimétrie, sous atmosphère inerte, avec une vitesse de montée en température relativement lente (60 °C par heure), les paliers de déshydratation de la brucite et de la portlandite sont séparés et bien définis, 300 °C à 330 °C pour la brucite et 360 °C à 450 °C pour la portlandite.

En conséquence, le dosage de ces deux espèces minérales à partir de leur eau de constitution ne présente pas de difficulté, des vérifications ayant été faites pour avoir la certitude que dans le cas d'un béton de ciment portland aucune décomposition d'aluminate ne vient se superposer aux effets thermiques précédents.

Fig. 1 - Thermogravimétrie d'un béton dolomitique.

La courbe (figure 1) montre le thermogramme d'un béton dolomitique auquel 2 % environ de brucite a été ajoutée pour bien montrer la séparation des deux paliers de déshydratation.

#### DOSAGE DE LA DOLOMITE ET DE LA CALCITE

La détermination simultanée des teneurs en calcite et en dolomite est plus délicate car, d'une part la dolomite est un carbonate double et d'autre part la calcite provient de différentes origines. C'est pourquoi le dosage de ces deux minéraux est effectué par une combinaison de l'analyse thermique différentielle sous atmosphère  $\text{CO}_2$  et du dosage chimique de l'anhydride carbonique.

Plusieurs méthodes ont été publiées pour déterminer d'une façon précise la teneur en  $\text{CO}_2$  d'origine minérale d'un béton (5), (6). Elles sont toutes pondérales mais fondamentalement différentes. Aussi semble-t-il opportun de rappeler le principe de celle qui paraît donner le meilleur résultat et dont la normalisation a été proposée (7).

Le matériau est attaqué à chaud par une solution d'acide orthophosphorique, en présence d'acétate de cuivre destiné à fixer l'hydrogène sulfuré éventuellement formé. L'anhydride carbonique libéré par cette attaque est entraîné par un gaz vecteur inerte, séché puis recueilli sur un absorbant spécifique et pesé.

En analyse thermique différentielle, le thermogramme d'un béton dolomitique réalisé sous atmosphère  $\text{CO}_2$  avec enregistrement  $\Delta t$ -temps, présente les différences suivantes par rapport à celui obtenu dans l'air (figure 2).

- Disparition du pic endothermique à 480 °C dû à la déshydratation de la portlandite : ce minéral se carbonate.

- Dans la zone de température 700 °C-1000 °C remplacement du pic multiple par deux pics endothermiques bien distincts : le premier vers 770 °C correspond à la décarbonation de la partie magnésienne de la dolomite. Le second vers 925 °C est dû à la dissociation de la partie calcique de la dolomite et de différents carbonates de calcium (calcite des granulats et de carbonatation du ciment ainsi que le carbonate formé en cours d'essai à partir de la portlandite).

Les aires de ces deux pics de décarbonation sont proportionnelles aux teneurs en  $\text{CO}_2$  lié à  $\text{MgO}$  et à  $\text{CaO}$ , leur utilisation permet donc en tenant compte des recombinaisons et de la teneur en  $\text{CO}_2$  "total" de doser simultanément la calcite et la dolomite présentes dans l'échantillon. La justification complète de ces dosages sortirait du cadre de la présente communication (8).

La méthodologie suivante a été retenue pour la réalisation du dosage des quatre minéraux impliqués dans la dédolomitisation :

- 1) Déterminer par thermogravimétrie en atmosphère inerte les teneurs en brucite et en portlandite à partir de leur eau de constitution.

Fig. 2 - Analyse thermique différentielle d'un béton dolomitique.

2) Déterminer la teneur en anhydride carbonique d'origine minérale selon le processus décrit précédemment (7).

3) Soumettre la béton à l'analyse thermique différentielle en atmosphère  $\text{CO}_2$  et mesurer les aires des deux pics de décarbonatation.

4) Calculer les teneurs en calcite et en dolomite à partir de ces éléments (8). Dans les calculs la teneur en  $\text{CO}_2$  "total" à prendre en compte est la somme :  $\text{CO}_2$  d'origine minérale plus  $\text{CO}_2$  correspondant à la carbonatation de la portlandite pendant l'essai.

5) Déduire de la teneur en calcite ainsi calculée, la teneur en carbonate de calcium correspondant à la carbonatation de la portlandite. Il est alors possible d'effectuer les calculs de transferts minéraux qui permettent de conclure à l'existence d'une dédolomitisation.

## CONCLUSION

Les développements qui précèdent ont montré que l'on pouvait quantifier une dédolomitisation éventuelle à partir des bilans minéralogiques. Ceci grâce à la détermination précise des teneurs en calcite, dolomite, portlandite et brucite d'un béton dolomitique.

A l'heure actuelle aucune dédolomitisation n'a pu être mise en évidence avec certitude dans les échantillons que nous avons examinés, ce qui ne signifie pas que le phénomène en question n'ait pas lieu dans les bétons. Par ailleurs, la cinétique de cette réaction est très lente.

Il faut enfin remarquer que la nature même du cycle de réactions mis en jeu limite, en l'absence d'apport alcalin par le milieu extérieur, la transformation, à la quantité de dolomite correspondant à la carbonatation de la totalité de la portlandite présente.

# Cement paste-quartz bond in autoclaved concretes

## *Adhérence ciment-quartz dans les bétons autoclavés*

F. MASSAZZA, Professor of Applied Chemistry, Italcementi, Laboratorio Chimico Centrale, Bergamo, Italy,

M. PEZZUOLI, B.Ch. Italcementi, Laboratorio Chimico Centrale, Bergamo, Italy.

RESUME : En employant des granulats de quartz, les bétons autoclavés peuvent atteindre des résistances supérieures à 150 N/mm<sup>2</sup>. Cette résistance élevée doit être partiellement attribuée à des réactions qui se produisent à l'interface pâte de ciment-quartz. Les observations au MEB ont indiqué que dans ces bétons l'adhérence du quartz à la pâte de ciment est plus forte que la cohésion de la pâte de ciment même. L'analyse à la microsonde électronique a montré que la zone intermédiaire entre le quartz et la pâte de ciment devient plus riche en calcium et plus pauvre en silicium en s'éloignant du granulat.

Les mesures de microdureté ont montré que la couche intermédiaire est plus dure (et a donc une résistance mécanique plus élevée) que la masse de la pâte.

Les surfaces de quartz polies autoclavées dans de l'eau additionnée de ciment ont été profondément corrodées et couvertes de cristaux fibreux de tobermorite 11 Å.

Sur la base des résultats expérimentaux, on peut supposer que la forte liaison à l'interface granulat-pâte dépend de

- l'interconnexion mécanique de la pâte de ciment avec la surface corrodée du quartz,
- l'accrolement épitaxial des cristaux de tobermorite sur ceux de quartz.

SUMMARY: By using quartz aggregates, autoclaved concretes can attain compressive strengths over 150 N/mm<sup>2</sup>. This high strength must be partially attributed to reactions occurring at the cement paste-quartz interface. SEM observations indicated that in these concretes the adhesion of the quartz to the cement paste is stronger than the cohesion of the cement paste itself. Electron microprobe analysis showed that the intermediate zone between quartz and cement paste becomes richer in calcium and poorer in silicon by moving away from the aggregate.

Microhardness indentations showed that the intermediate layer is harder (and therefore it has higher mechanical strength) than the bulk paste.

Polished quartz surfaces autoclaved in mother cement liquor appeared to be deeply corroded and covered with fibrous crystals of 11 Å tobermorite.

Based on the experimental evidence, it can be assumed that the strong bond at the aggregate-paste interface depends on

- the mechanical interlock of the cement paste with the corroded quartz surface
- the epitaxial intergrowth of the tobermorite crystals on the quartz ones.

## 1. INTRODUCTION

It has recently been proved that autoclaved concretes whose mechanical compressive strengths attain 180 N/mm<sup>2</sup> or anyhow exceed 150 N/mm<sup>2</sup> can be obtained. An important aspect of these results lies in the fact that they can be made by usual materials and procedures. The only concern consists in selecting the materials and the working modes (1).

Compared with identical concretes cured under ordinary conditions, these concretes have quadruple compressive strength, triple modulus of rupture and splitting tensile strength and nearly double modulus of elasticity (2).

Other peculiar characteristics are the almost linear trend of the curve  $\epsilon = \epsilon(\sigma)$  and the conchoidal fracture which passes through both the mortar and the aggregate grains and does not follow the boundaries of the grains, as it occurs in ordinary concretes.

It must be noticed that these results without precedent were obtained by using quartz aggregates whereas the outcome was less brilliant with other materials: for instance strength was less than the half by utilizing calcareous aggregates (3).

If the apparent ductility of ordinary concrete under short-term loading, shown by the curving shape of the stress-strain curve, represents the cumulative effects of progressive microcracking (4), the almost rectilinear trend of the curve  $\epsilon = \epsilon(\sigma)$  found for very high strength concretes (1) proves that in this case microcracks only form immediately before failure.

All these facts lead to think that the exceptional mechanical characteristics of these autoclaved concretes must be attributed not only to the known improvement in strength of the cement paste (cement+silica powder) (5) but also and chiefly to the paste-aggregate bond.

In the present paper the particular conditions occurring at the aggregate-cement paste interface are examined and the experimental results explaining the exceptional mechanical characteristics of this new concrete are shown.

## 2. EXPERIMENTAL

To determine the causes of the strong bond between cement paste and aggregate owing to the hydrothermal treatment, the alterations suffered by the quartz surface when it comes into contact with cement paste or cement mother liquor were examined.

2.1 The initial tests were carried out on mortar cubes made as shown in table I.

Table I - Composition of the steam cured mortars		
Binder	Rapid hardening portland cement	50 g
	ground silica	20 g
Crushed quartzite (fract. 0-2 mm)		120 g
	(fract. 2-3 mm)	20 g
Water		30 g
Superplasticizer (25 wt.% solution)		1.5 g

The binder consisted of a homogeneous mix of 50 weight parts of a rapid hardening portland cement and 20 parts of silica powder ground to a Blaine specific surface of 4500 cm<sup>2</sup>/g. The aggregate was a quartz sand (SiO<sub>2</sub> = 98%) having a continuous particle size distribution already used in previous works (1). It was deprived of the coarser fractions to facilitate the microscopic study of the autoclaved material.

A superplasticizer was used to reduce the water/binder ratio and thus to improve the compactness of the mortars.

After mixing, the samples were introduced into 17.3x17.3x17.3 mm metal cubic moulds, compacted on a jolting table and prestored at 20°C and 100% R.H. for 5-8 hours.

Afterwards the cubes were removed from the moulds, introduced into a small laboratory autoclave and subjected to a double steam curing: 5 hours at atmospheric pressure at 70°C and 15 hours under pressure at 190°C.

A heating rate of 0.7°C/min. and a cooling rate of about 1.0°C/min. were maintained in all the preparations.

The X-ray diffraction analysis of the autoclaved material showed the presence of quartz and 11 Å tobermorite, typical product of the hydrothermal reactions between cement and quartz (6)(7)(8) as well as lime and quartz (9)(10)(11).

After curing, the cubes were crushed and the obtained fragments, after metalization with Au, were examined under the scanning electron microscope.

Figures 1 and 2 show that the fracture surface con-

FIG. 1 - Broken surface of autoclaved concrete - S.E.I. 1000 X

cerns both the quartz aggregate (upside) and the cement paste. By examining the two figures it is also possible to notice that the contact between cement paste and aggregate is continuous and intact as well as that the fracture lines do not coincide with the cement paste-quartz interface.

This means that the steam curing yields a stronger quartz-cement paste bond than the cohesion of the cement paste itself. This result is opposite to what found for concretes cured at ordinary temperature, where the fracture almost always occurs along the boundaries of the aggregate (4)(12)(13).

FIG. 2 - Detail of the preceding micrography - S.E.I. 6000 X

The alterations suffered by the quartz surface because of the combined action of cement and steam curing were observed on a quartz fragment ground, polished and covered with the paste of the binder.

After the aforesaid curing cycle, the fragment was sectioned perpendicularly to the polished surface in order to examine the quartz-cement paste interface. One of the obtained sections was polished and metalized with Be.

Figures 3, 4 and 5, taken by the scanning electron microscope, show that the boundary between quartz and cement paste is no longer sharp and rectilinear but appears to be more or less modified.

FIG. 3 - Polished surface of autoclaved concrete - S.E.I. 1000 X

This is the evidence that a chemical reaction has altered the interface.

A confirmation of this change is given by the electron microprobe analysis of the contact zone quartz-cement paste: by passing from the first to the second, a decrease in the Si content and an increase in the Ca one is observed, as figures 6 and 7 show.

FIG. 4 - Preceding surface. Distribution image of silicon -  $SiK_{\alpha}$  1000 X

FIG. 5 - Preceding surface. Distribution image of calcium -  $CaK_{\alpha}$  1000 X

FIG. 6 - Polished surface of autoclaved concrete - Line profile of silicon ( $SiK_{\alpha}$ ) S.E.I. 2000 X

The trend of the two concentration curves shows that a layer about 5  $\mu m$  thick, having progressively varying composition, is in contact with quartz. These data seem to prove that AITKEN and TAYLOR'S (8) hypothesis

is right. These Authors assume that, around the quartz grains, there is probably a zoning of calcium silicate hydrate characterized by a low C/S ratio near the quartz grains and by a higher ratio a little farther.

FIG. 7 - Preceding surface. Line profile of calcium ( $\text{CaK}_\alpha$ ). S.E.I. 2000 X

The different composition of the intermediate layer with respect to the cement paste affects its mechanical properties. In fact its mean microhardness has appeared to be twice that of the paste and 1/6 of that of quartz. It is reminded that the intermediate layer of ordinarily cured concretes is, on the contrary, weaker and has a microhardness half that of the paste (14).

Because of the extremely small sizes of the crystals forming the intermediate layer and the cement paste, the microhardness indentation has simultaneously concerned many crystals and therefore the obtained values are the result of an integration. This consideration is not valid for the quartz aggregate grains which are composed of  $\sim 4 \times 10 \mu\text{m}$  crystals and for which the indentation (diagonal  $\sim 6.5 \mu\text{m}$ ) can have only concerned one or some contiguous crystals.

The mechanical strength of cement pastes can be calculated by determining the corresponding microhardness (15)(16) but, for the purposes of this work, it is sufficient to state that the higher microhardness of the intermediate layer also means higher mechanical strength than that of the bulk paste.

To show the changes caused by the hydrothermal treatment to the surface of the aggregate, a fragment of quartz was ground, polished, maintained in diluted HCl (1:10) for 30 minutes and finally washed with distilled water. The paste of the binder was applied on the polished surface and the whole was steam cured by following the above mentioned working modes.

After the thermal treatment the paste was removed, partly mechanically and partly by diluted HCl (1:10) and, after metalization with Au, the quartz surface was re-examined under the scanning microscope. As figure 8 shows, the quartz surface appears to be irregularly but clearly corroded.

2.2 Since quartz is very likely to be attacked by the mixing water rather than the cement, a fragment of quartz having a ground and polished surface was steam cured in cement mother liquor. The mother liquor was prepared by shaking one part of rapid hard-

ening portland cement with 10 parts of  $\text{CO}_2$  free distilled water for 30 minutes and then by filtering it.

FIG. 8 - Surface of quartz polished, covered with cement paste, autoclaved and washed with HCl 1:10. S.E.I. 3000 X

After autoclaving, the fragment was washed with water, vacuum dried, metalized with Au and observed under the scanning electron microscope. As figure 9 shows, the polished surface appears to be covered with a layer of fibrous entangled crystals, obviously produced by the reaction between quartz and mother liquor.

FIG. 9 - 11 Å tobermorite developed on a quartz surface polished and autoclaved in cement mother liquor. S.E.I. 3000 X

The solubilization of these newly formed crystals by diluted HCl (1:10) has evidenced the quartz surface which has appeared corroded (see figure 10). The appearance of the surface also indicates that the quartz crystals have undergone a different attack depending on their orientation.

The product formed on the quartz surface was not enough to be easily examined and studied. For this reason, that is to increase the yield of the reaction, steam curing was repeated by replacing the quartz fragment with an equal amount of quartz sand having the same origin but a surface higher by about 100 times.

FIG. 10 - Preceding surface after washing with HCl 1:10 - S.E.I. 1000 X

The quartz grains autoclaved in the cement liquor were washed before with distilled water and then with ethanol. Afterwards they were vacuum dried at room temperature.

The autoclaved material was subjected to X-ray diffraction analysis and it showed to be only formed of quartz and 11 Å tobermorite.

The tobermorite fibres covering the aggregate were solubilized by cold diluted HCl (1:10) and analyzed by atomic absorption. Different preparations gave a C/S ratio equal to 0.90 on the average.

The hydrothermal reaction is accompanied by a decrease in the pH and the CaO content of the contact solution.

### 3. DISCUSSION

In the steam cured very high strength concretes (compressive strength  $>150 \text{ N/mm}^2$ ) the cracked surfaces show that the cement paste-quartz bond is stronger than the tensile strength of the cement paste.

The examination under the electron microscope showed that an intermediate layer having different composition from that of the cement paste forms in contact with the quartz aggregate. In fact the C/S ratio the more increases the farther the interface.

This layer has a microhardness ( $\sim 10 \text{ N/mm}^2$ ) which is twice that of the cement paste.

Microhardness is usually measured on individual crystals and therefore its high values do not necessarily involve a high mechanical strength of the bulk material.

Nevertheless when the fineness of the structure is such that each indentation involves many crystals, the microhardness is indicative of the mechanical characteristics of the bulk material. This condition occurs in the cement paste and it was proved that microhardness is representative of its compressive strength and its modulus of elasticity (15)(16).

Therefore the higher microhardness of the intermediate layer with respect to the paste, found in the present work, corresponds to a higher mechanical strength. This fact can be related to the different C/S ratio.

As for the strong bond existing at the aggregate-paste interface, it can be observed that the intermediate layer is deeply embedded in the grains of the aggregate because of the corrosion suffered by quartz. This fact positively affects the bond but such a factor is probably secondary and the strong adhesion between cement paste and quartz must mainly be attributed to the overlap and the epitaxis intergrowth of the tobermorite crystals on the quartz ones. The process of epitaxis intergrowth is not a mere absorption caused by London-van der Waals' forces but a real crystallochemical reaction involving the lattices of the two phases as though a two-dimensional chemical compound were formed by the action of chemical valences (17).

This explanation is strengthened by the fact that the mechanical strengths of these steam cured concretes do not decrease as the ambient moisture increases (18), as on the contrary it is noticed in ordinary concretes (19) and in cement pastes (20)(21).

This decrease is due to the disjoining action of water when it penetrates among the particles forming the cement paste or between cement and aggregate and which is able to considerably reduce van der Waals's force (22).

Since in the epitaxis intergrowth the distance between the two crystalline phases is of the order of magnitude of the lattice distances, no phase, liquid or gaseous, can penetrate into the interface between the two phases (23).

Therefore the material subjected to the compressive test must not show a different strength depending on whether the environment is wet or dry.

Other factors can have favoured an epitaxis overgrowth of tobermorite on quartz. For example, epitaxis is favoured by the temperature rise (17) and this can explain the fact that the strong quartz - cement paste bond does not occur at ordinary temperature.

Also the differences of composition noticed for the cement paste, richer in silica at the interface with the aggregate, can have facilitated the epitaxis overgrowth of tobermorite on quartz by an increased analogy of their crystal lattices.

### 4. CONCLUSIONS

By autoclaving concretes containing quartz aggregates, compressive strengths over  $150 \text{ N/mm}^2$  are obtained. This result is partly related to the fact that the aggregate-cement paste bond is, in this case, stronger than the cohesion of the paste itself. This can be attributed to both a deeper embedding of the hydration products in the quartz grains corroded by the contact solution and the epitaxis intergrowth of 11 Å tobermorite crystals on the quartz ones.

# Etude du contact zinc - Pâte de ciment Portland

## *Study of the contact zone between zinc and Portland cement paste*

G. ARLIGUIE, Assistante,  
J. GRANDET, Professeur : I.N.S.A. Département du Génie Civil, U.P.S. Toulouse,  
R. DUVAL, Professeur, France.

RESUME : On étudie d'abord le comportement électrochimique du zinc dans des solutions simulant le milieu pâte de ciment Portland, puis les constituants formés à l'interface zinc-pâte de ciment Portland.

En immergeant des éprouvettes de zinc dans des solutions saturées de chaux, on décèle la formation sur la surface du métal d'un composé complexe et insoluble d'hydroxyzincate de calcium. Les mesures électrochimiques ont montré que ce composé passivait le zinc.

Après ces expériences effectuées en solution de simulation on a étudié, par diffractométrie X, la nature des constituants hydratés de la pâte de ciment durcissant au contact d'une éprouvette de zinc. On a pu mettre en évidence l'existence d'ettringite et d'hydroxyzincate de calcium dans la zone de pâte proche du métal ; par contre, on ne décèle pas de portlandite dans les premiers jours suivant la prise. L'observation des surfaces de rupture entre le zinc et la pâte de CPA a été faite au microscope optique puis au microscope électronique à balayage. Nous avons ainsi pu déterminer la limite de la zone d'influence du zinc dans la pâte et son évolution en fonction du temps.

SUMMARY : We studied firstly the electrochemical behaviour of zinc immersed in the solution representing the fresh Portland cement paste. Then, we observed the constituents formed at the interface between zinc and Portland cement paste.

By immersing the zinc specimens in the saturated lime solution, we found the formation of an insoluble composite of calcium hydroxyzincate. The electrochemical measurements showed that this composite formed the passive zinc.

We also studied the hydrated constituents setting up at the contact between cement paste and zinc by the X-ray diffraction analysis. The results showed that the existence of ettringite and calcium hydroxyzincate occurred in the zone of cement paste nearly to the metal. On the other hand, we have not found portlandite in this zone during the first days after setting.

The breaking surface between zinc and Portland cement paste was also observed by the optical microscope and the scanning electron microscope. Consequently, we can determine the boundary of the influence zone of zinc in the cement paste and its evolution in the function of time.

Pour obtenir une protection des armatures d'acier noyées dans un béton soumis à des milieux agressifs, on a parfois recours à la galvanisation. Cependant, le comportement du zinc au contact d'un béton n'est pas encore totalement éclairci (1 à 7).

Nous avons procédé d'une part à l'étude du comportement électrochimique du zinc dans des solutions simulant le milieu pâte de ciment Portland, et d'autre part à l'analyse par diffractométrie X des constituants formés dans la zone de contact zinc-pâte de ciment Portland.

#### ETUDE ELECTROCHIMIQUE

Le comportement électrochimique de matériaux métalliques au contact de béton a déjà été abordé en utilisant des solutions de simulation approchées, le plus souvent des solutions saturées de chaux. Ces études ont apporté des renseignements intéressants sur les produits de corrosion formés en milieu basique, mais ce dernier est différent du milieu complexe créé par la pâte de ciment Portland. Par la suite, des travaux effectués par P. LONGUET et COLL (6) ont permis d'extraire et d'analyser le liquide interstitiel existant à l'intérieur d'un béton.

Nous avons tout d'abord entrepris l'étude électrochimique du comportement du zinc dans des solutions de simulation tenant compte du milieu réel afin de voir quelle était l'influence des divers composants de cette solution sur le métal. Nous avons utilisé des solutions saturées de chaux, des solutions alcalines, et enfin des solutions mixtes chaux-alcalins.

Dans des solutions saturées de chaux, nous avons mis en évidence la formation, sur la surface du zinc, d'une couche passive constituée par un composé complexe insoluble d'hydroxyzincate de calcium  $\text{Ca Zn}_2 (\text{OH})_6, 2 \text{H}_2\text{O}$ . Nous avons pu constater que ce composé jouait un rôle protecteur vis-à-vis de certains agents agressifs, plus particulièrement des ions chlorures (7).

Dans des solutions alcalines, le zinc est fortement attaqué avec formation de zincates solubles.

Enfin, nous avons réalisé des essais dans des solutions mixtes chaux-alcalins, de façon à approcher la composition du milieu interstitiel réel de la pâte de ciment. Cette étude a montré le rôle particulier de la chaux qui contribue à former l'hydroxyzincate de calcium. Pour des concentrations faibles en potasse la couche d'hydroxyzincate recouvre totalement la surface du zinc. Pour des concentrations plus fortes, on observe une attaque parfois importante due à un mécanisme de corrosion par micropiles galvaniques ; de l'oxyde de zinc se forme au détriment de l'hydroxyzincate de calcium passif. La présence d'oxyde de zinc n'est décelable que pour de fortes teneurs en alcalins.

Après ces expériences effectuées en solution de simulation nous avons étudié, par diffractométrie X, la nature des constituants hydratés formés par une pâte de ciment Portland durcissant au contact du zinc.

#### PREPARATION DES ECHANTILLONS

Les éprouvettes de zinc se présentent sous forme de cylindres dont une section plane ( $1 \text{ cm}^2$ ) a été polie sur papier abrasif jusqu'au grain 1200.

La teneur en zinc des échantillons utilisés est de 99 %.

Après polissage, les cylindres de zinc sont soumis aux ultra-sons, rincés à l'alcool, puis séchés. Une pâte de ciment CPA 55 R dont le rapport E/C est égal à 0,29 est coulée sur la section polie. Tous les échantillons sont conservés dans une ambiance à  $20^\circ \text{C}$  et 100 % d'humidité relative.

#### METHODE D'ETUDE

Après démoulage, on rompt mécaniquement l'éprouvette mixte. On analyse, par diffractométrie X, les sections de rupture côté pâte.

L'épaisseur de la pellicule adhérente au métal est déterminée par microscopie optique. Ensuite, on observe les surfaces de rupture au microscope à balayage. Puis on étudie des sections de pâte de ciment parallèles à la surface de rupture. Pour cela, on enlève des couches de pâte de ciment par abrasion et on détermine la quantité recueillie par double pesée afin d'en déduire l'épaisseur de la couche détachée (8).

Chaque nouvelle section obtenue est examinée par diffractométrie X. On peut ainsi dresser la carte des constituants présents depuis la surface du métal jusqu'au cœur de la pâte de ciment.

#### CONSTITUANTS DANS LA ZONE DE CONTACT

Nous avons étudié des éprouvettes mixtes à différents âges. Les résultats sont présentés d'une manière schématique dans la figure 1.

A un jour, le diagramme X effectué sur la face de rupture côté zinc montre la présence d'hydroxyzincate de calcium et, en quantité beaucoup plus faible, d'oxyde de zinc et d'ettringite. La portlandite n'apparaît pas. De nombreux grains de ciment anhydre restent accrochés sur le métal (raies de diffraction de  $\text{C}_3\text{S}$ ). L'observation au microscope à balayage nous permet de voir que l'hydroxyzincate de calcium recouvre déjà en grande partie la surface du zinc.

Sur la face de rupture côté ciment, on ne décèle pas de portlandite par diffraction X, et le diagramme obtenu traduit une faible hydratation de la pâte. Par abrasions successives parallèlement à la surface de rupture, les raies de diffraction X de la portlandite n'apparaissent qu'à une distance de  $100 \mu$  du contact et augmentent au fur et à mesure que l'on s'en éloigne. L'ettringite est présente dès le contact, mais en faible quantité. On note l'absence d'hydroxyzincate de calcium sur cette face. La rupture s'est donc produite à la limite de la zone constituée essentiellement par l'hydroxyzincate de calcium. Ce composé se forme par action de la chaux sur l'oxyde de zinc, ce qui explique l'absence de portlandite dans les 100 premiers microns, de la pâte.

A deux jours, la rupture de l'éprouvette mixte se produit en laissant, comme précédemment, une fine pellicule adhérente sur la surface du métal et quelques amas de grains de ciment.

Côté zinc, le diagramme de diffraction X indique la présence des mêmes composés qu'à un jour ; on note que l'hydroxyzincate de calcium et l'ettringite apparaissent en quantité un peu plus importante.

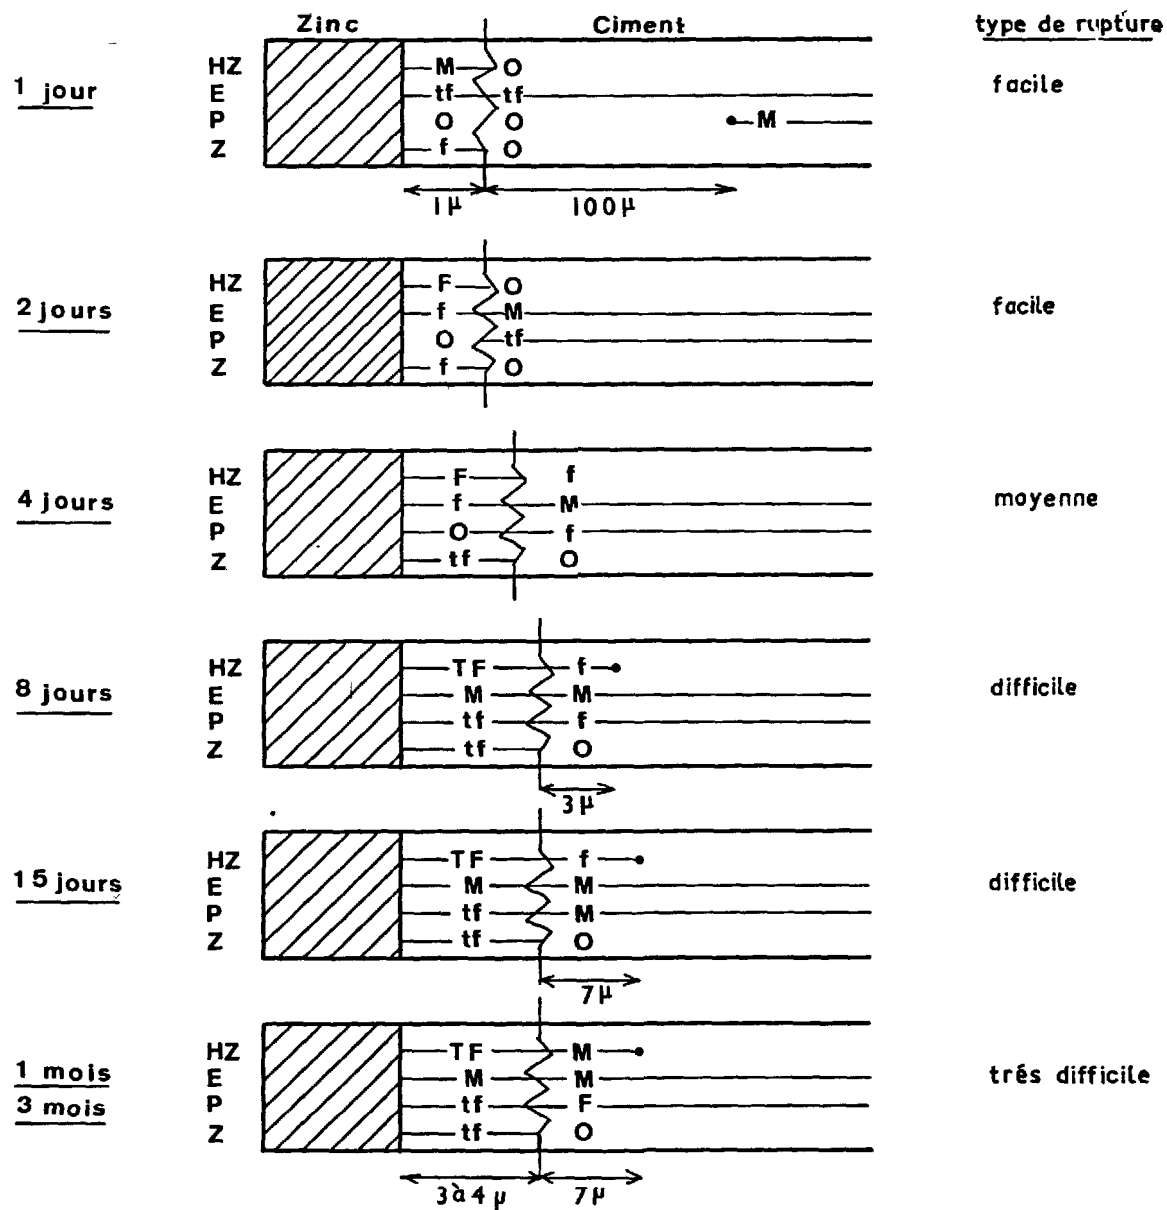

FIGURE 1 - "Evolution de la zone de contact en fonction du temps"

Notations utilisées : HZ = hydroxyzincate de calcium  
E = ettringite

P = portlandite  
Z = oxyde de zinc

Intensité du pic principal de diffraction du composé : TF = très importante  
F = importante

M = moyenne  
f = faible  
tf = très faible

Absence du composé : 0

Limite du domaine d'existence du composé : —●

Au microscope à balayage, on observe que l'hydroxyzincate est le premier dépôt sur le zinc, la pâte de ciment la recouvrant par endroits (figure 2)

FIGURE 2 : "Surface de rupture côté zinc après un contact de 2 jours" -(x 2000)-

Côté pâte, il apparaît un peu de portlandite. Le diagramme obtenu sur cette face de rupture montre que l'hydratation de la pâte est retardée par la présence du zinc : les raies de  $C_3S$  sont plus importantes qu'au coeur de la pâte.

A quatre jours, les résultats sont très différents. Au voisinage du contact, l'hydratation du ciment s'est accélérée : l'intensité des raies du  $C_3S$  est analogue à celle obtenue au coeur d'une pâte de ciment de même âge.

L'hydroxyzincate de calcium se trouve en quantité notable de part et d'autre de la rupture. Sur la face de rupture côté zinc, nous n'avons que les raies principales de l'hydroxyzincate, alors que toutes les raies apparaissent sur la face ciment (figures 3 et 4). Sur cette dernière, on remarque que la portlandite se trouve encore en quantité plus faible que dans le coeur de la pâte. Par contre, la formation de l'ettringite n'est pas influencée par la présence du zinc ; elle présente une cristallisation analogue à celle observée au contact de supports inertes.

A quinze jours, la séparation mécanique entre le cylindre de métal et la pâte est très difficile. La mesure de l'épaisseur de la pellicule adhérente au microscope optique donne des résultats variables selon la zone observée, en moyenne  $4 \mu$ .

FIGURE 3 : "Enregistrement diffractométrique de la surface de rupture côté zinc après un contact de 4 jours"

FIGURE 4 : "Enregistrement diffractométrique de la surface de rupture côté ciment après un contact de 4 jours.

La rupture se fait dans la couche d'hydroxyzincate de calcium puisqu'il apparaît sur les diagrammes de rayons X de chaque surface de rupture. Ceci est confirmé par l'observation au microscope à balayage qui montre des fractures sur les cristaux d'hydroxyzincate, la couche d'hydroxyzincate recouvre la quasi-totalité de la surface du zinc (figure 5). Par abrasions successives et analyses par diffractométrie X, on décèle la présence d'hydroxyzincate jusqu'à une distance de 10  $\mu$  du zinc.

A un mois de durcissement, on ne note plus d'évolution quant aux constituants présents sur les surfaces de rupture.

Au contact de la pâte de ciment Portland, l'oxyde de zinc se trouve en quantité très faible, parfois, il n'est même pas décelé. Ceci confirme les résultats obtenus par les essais électrochimiques effectués en

solution de simulation.

FIGURE 5 : "Surface de rupture côté zinc - Cristaux obtenus à 15 Jours" -(x 1500)-

#### CONCLUSION

- L'étude du contact entre le zinc et les pâtes de ciment Portland confirme les résultats obtenus en solution de simulation : l'hydroxyzincate de calcium forme, à partir de la chaux, une couche continue et protectrice sur le zinc.

De plus, la méthode employée nous a permis de suivre l'évolution des constituants dans la zone de rupture. Nous avons tout d'abord noté qu'au contact du zinc, l'hydratation de la pâte de ciment Portland est retardée pendant les quatre premiers jours suivant la confection des éprouvettes mixtes. Nous avons d'ailleurs obtenu des résistances mécaniques faibles. Par la suite, l'accrochage entre la pâte de ciment et la surface polie du zinc est efficace ; il est ainsi fréquent d'obtenir des amas de pâte de ciment restant accrochés sur la surface métallique.

L'hydroxyzincate de calcium se forme dès le premier jour suivant le gâchage. Le rôle essentiel de la chaux dans la formation de ce composé est mis en évidence par le fait qu'on ne décèle pas de portlandite dans la zone de pâte proche du métal. La composition de cette zone évolue jusqu'à l'obtention d'une couche d'hydroxyzincate recouvrant la quasi-totalité de la surface du zinc. Une fois la formation de l'hydroxyzincate de calcium achevée, l'hydratation de la pâte se poursuit normalement.

# Electrochimie des pâtes de ciment

## *Electrochemistry of cement pastes*

V.I. BABOUSHKINE, Professeur, Docteur ès Sciences Techniques, VODGEO,

A.S. KOCHMAI, Ingénieur,

O.P. MTCHEDLOV-PETROSSIAN, Professeur, Docteur ès Sciences, Techniques, KhICI, U.R.S.S.

**RESUME :** L'hydratation et le durcissement des pâtes de ciment engendrent des processus électrochimiques dont la spécificité est conditionnée par les propriétés semi-conductrices des minéraux du clinker, la présence de défauts structuraux et de lacunes chargées. L'interface des phases solide et liquide d'un liant en voie d'hydratation peut être assimilée à un système de couches bipolaires en interaction. Le phénomène d'hydratation du ciment s'accompagne d'une séparation volumétrique de charges et de l'apparition de forces pondéromotrices, ce qui est une des raisons possibles de la manifestation de propriétés liantes.

Il est établi de façon expérimentale l'existence d'une sensible différence de potentiels entre les phases dans le système "liant-eau" engendrée par une distribution déséquilibrée de charges, du type Donnan, et des courants de diffusion.

On montre que toutes les pâtes de ciment en voie de durcissement possèdent une haute activité électrochimique. Par suite la phase liquide contenue dans les micropores du gel-ciment se trouve dans un état particulier et ne s'identifie pas à la phase liquide dégagée.

La détermination des potentiels de diffusion et électrocinétiques des pâtes de ciment permet de décrire de façon judicieuse le phénomène de durcissement surtout à ses débuts.

**SUMMARY :** Hydration and hardening of cement pastes are accompanied by electrochemical processes the peculiarities of which are dictated by semiconductor properties of clinker minerals, presence of structural defects and charged vacancies. The boundary between the solid and liquid phases of the binder being hydrated may be considered as a system of interacting double electric layers. The cement hydration process involves spatial separation of charges and appearance of ponderomotive forces which is one of the possible reasons for manifestations of the binding properties.

It has been found out experimentally that the binder-water system comprises considerable inter-phase difference of potentials stemming from unbalanced distribution of Donnan type charges and diffusion flows.

It has been shown that hardening cement pastes feature high electrochemical activity. Therefore, the liquid phase contained in micropores of cement gel is in a particular state and does not correspond to the liquid phase liberated.

Determination of diffusion and electrokinetic potentials of cement pastes provides for rational description of the hardening processes, especially at the initial stages thereof.

La pâte de ciment qui durcit constitue un système colloïdo-cristallin déséquilibré hétérogène. Après gâchage sur l'interface des phases solide et liquide se forme une charge électrostatique et une couche bipolaire (CB) que cette charge conditionne. Dans les pâtes de ciment sont ainsi amorcés des phénomènes électrochimiques qui jouent un rôle important dans le mécanisme commun de durcissement. C'est la raison de l'intérêt croissant pour l'électrochimie des liants. Toutefois nos idées en ce domaine ont un caractère fragmentaire et se rapportent pour l'essentiel aux propriétés électrocinétiques des pâtes de ciment (1, 2, 3).

Dans les pâtes de ciment s'amorcent des phénomènes électrochimiques déjà observés dans les colloïdes, les suspensions et les corps capillaires-poreux, mais la spécificité du système "ciment-eau" engendre des phénomènes particuliers. Cette spécificité est due à la structure des substances liantes de départ, à leur métastabilité par rapport à l'eau et la nature exothermique de l'hydratation.

Il est établi que les minéraux du clinker - portland possèdent des propriétés de semi-conducteurs (5). Cela signifie que la distribution de la charge de la CB du côté de la phase solide n'est pas localisée à la surface mais pénètre dans le volume. L'existence de défauts structuraux et de lacunes chargées conditionne la réactivité des minéraux du clinker. Quant aux impuretés on peut leur imputer la variation du mode de conductibilité d'un quelconque des minéraux du clinker et l'accroissement de concentration de défauts structuraux. Une grande concentration de défauts à la surface de l'alite accroît brusquement son pouvoir absorbant. Des études ont montré qu'à la surface de  $C_3S$  se rencontre des centres actifs où s'effectue le transfert d'électrons aux molécules absorbées avec formations d'ions chargés négativement (6).

Le déplacement de CB sur l'interface "minéral de clinker-eau" dans le volume des phases liquide et solide assure un caractère volumétrique aux phénomènes superficiels pendant l'hydratation des liants. Des forces pondéromotrices sont ainsi engendrées auxquelles on peut attribuer l'action à grande distance observée des formations hydratées.

Les grandeurs mesurables pouvant caractériser la CB est sa capacité et son potentiel électrocinétique  $\zeta$ . Dans les pâtes de ciment le potentiel  $\zeta$  est de nature complexe, car les différentes composantes des systèmes étudiés varient en grandeur et par le signe de leur charge superficielle. Les études réalisées ont montré que les minéraux du clinker  $C_3S$ ,  $C_2S$  et les produits de leur hydratation rappelant le tobermorite, ont une charge superficielle négative.  $C_3A$ ,  $C_4AF$  et les produits de leur hydratation, de même que le gypse, l'ettringite,  $Ca(OH)_2$  ont au contraire une charge superficielle positive dans le milieu aqueux. Le potentiel  $\zeta$  total des pâtes de ciment est négatif et conserve cette polarité durant tout le pro-

cessus de durcissement ne variant qu'en grandeur absolue.

Les particularités de structure de la CB dans le système "liant-eau" se manifestent le plus nettement dans le cas de  $C_3S$ . Selon les conceptions modernes il se produit au début une absorption de molécules d'eau à la surface de l'alite et une dissolution congruente avec formation d'un hydrosilicate primaire du type  $C_3S \cdot nH_2O$ . Sous l'effet de pénétration du champ de molécules de  $H_2O$  adsorbées à travers la surface  $C_3S$ , les groupements siloxanes  $\equiv Si - O - Si \equiv$  se polarisent, et, en se rompant partiellement, forment les groupements silanols  $\equiv Si - OH$ . L'hydrosilicate  $C_3S \cdot nH_2O$  joue le rôle de pellicule de gel semiperméable et déséquilibré qui empêche le contact direct de l'alite avec l'eau. La vitesse d'hydratation chutant, on passe à la période dite "d'induction". Durant cette période l'hydrosilicate  $C_3S \cdot nH_2O$  est métastable par rapport à l'eau, s'hydrolyse rapidement en formant des pellicules en hydrosilicates secondaires avec  $CaO$

$SiO_2$  (3). Ces processus provoquent la saturation et la sursaturation de la phase liquide par rapport à  $Ca(OH)_2$ .

Il se produit sur les groupements  $\equiv Si - OH$  une adsorption orientée des molécules polaires de l'eau. En remplissant le rôle de lents états de surface, les groupements  $\equiv Si - OH$  constituent un écran pour le volume du semiconducteur  $C_3S$ , le champ de molécules de  $H_2O$  adsorbées n'agissant que sur la partie diffuse de la CB en phase liquide. À la surface des hydrosilicates secondaires il peut alors s'amorcer une absorption partielle de co-ions  $OH^-$  de sorte que la concentration maximale de contre-ions  $Ca^{2+}$  se produit avant celle d'ions  $OH^-$ .

Cette hypothèse permet d'expliquer pourquoi avec l'hydratation de  $C_3S$  il se forme à la fin de la période d'induction un excès d'ions  $Ca^{2+}$  perturbant l'électroneutralité de la phase liquide (7). La figure 1 montre la formation de la CB lors de l'hydratation du  $C_3S$  en conformité avec le modèle du processus décrit.

Evidemment il se forme dans ce cas un système de CB en interaction. La première CB (interne) se forme sur l'interface de  $C_3S$  et du gel d'hydrosilicate qui passe par trois stades de développement et contient des quantités variables de  $H_2O$  et de concentrations d'ions  $Ca^{2+}$  et  $OH^-$  en état de saturation et de sursaturation. La seconde CB (externe) se forme sur l'interface du gel d'hydrosilicate et de la phase liquide libre.

Au cours du processus d'hydratation on voit de nouvelles interfaces entre les phases solide et liquide, tandis que les porteurs de charge de la substance de départ se trouvant au début dans la phase solide près de l'interface s'en éloignent en profondeur de l'épaisseur de la couche de nouvelles formations hydratées. Les ions  $OH^-$  étant absorbés de façon sélective par le gel d'hydro-

silicate et les contre-ions  $\text{Ca}^{2+}$  de signe opposé repoussés par l'interface qui se déplace, il se forme dans les phases solide et liquide des charges volumétriques de signe opposé. Il se produit une différenciation de charges qui dure tant que la différence de potentiels amorcée entre les phases solide et liquide ne soit compensée par la différence des potentiels électrochimiques entre les ions correspondants des deux phases.

Fig.1. Structure de la couche bipolaire dans le système " $\text{C}_3\text{S} - \text{H}_2\text{O}$ "

Avec l'acquisition d'une certaine grandeur  $\Delta\psi$  un flux de diffusion électrique d'ions peut se mettre à traverser la pellicule de gel et, partant, la phase liquide se trouve surchargée en ions  $\text{Ca}^{2+}$ , qui sont partiellement retenus par les hydrosilicates. Il se forme ainsi un gel stable (tertiaire) d'hydrosilicate de calcium à teneur élevée en chaux mais en maintenant le rapport  $\frac{\text{CaO}}{\text{SiO}_2} < 3$ .

Le flux de diffusion électrique élève fortement la perméabilité de la pellicule de gel. La période d'induction s'achève et une hydratation intense du liant s'amorce.

On a étudié la différence de potentiels entre les phases solide et liquide dans les suspensions et les pâtes en voie d'hydratation. Le rapport eau-ciment des suspensions du liant était de 5,0. La différence de potentiels était mesurée entre deux électrodes en chlorargent placées respectivement dans le précipité et au-dessus de la solution de la suspension. Le potentiel d'asymétrie des électrodes ne dépassant pas 0,5 mV. Le rapport eau-ciment des pâtes était de 0,5. Dans ce cas la différence des potentiels était mesurée au cours du filtrage sous pression de la phase liquide, l'une des électrodes en chlorargent contactant avec la pâte de ciment et l'autre avec la solution séparée. La grandeur de la pression de régime était 146 MPa.

La figure 2 montre la variation de la dif-

férence de potentiels ( $\Delta\psi$ ) entre les phases solide et liquide de la suspension de ciment (courbe I) et de la pâte de ciment (courbe II) en fonction du temps d'hydratation ( $\tau$ ). Dans les deux cas il est possible d'établir les mêmes régularités.

Fig.2. Variation de la différence de potentiels entre les phases  
I) dans les suspensions de ciment,  
II) dans les pâtes de ciment

Au début de l'hydratation de la suspension durant 4 à 5 minutes, la grandeur  $\Delta\psi$  atteint rapidement 15 mV. Ensuite,  $\Delta\psi$  s'accroît lentement durant 14 heures, phénomène s'expliquant par la différenciation des charges. La diminution subséquente de la grandeur  $\Delta\psi$  est, vraisemblablement, due au flux de diffusion électrique à travers le gel de ciment. La seconde hausse de  $\Delta\psi$  est également en rapport avec la différenciation des charges engendrée par la formation du gel au cours de l'intense hydratation. Simultanément il se produit un développement de la structure de la suspension du liant. Au début de l'hydratation de la pâte de ciment (6 à 8 min) la grandeur  $\Delta\psi$  monte à 160 mV. Ensuite en une heure  $\Delta\psi$  s'accroît jusqu'à 250 mV. Vraisemblablement, c'est dû à la séparation des charges durant la période d'induction. A la fin de la période d'induction le flux de diffusion électrique provoque la diminution de  $\Delta\psi$ . La seconde élévation de  $\Delta\psi$ , comme précédemment, est en rapport avec la différenciation des charges engendrée par la formation ultérieure du gel. En même temps s'amorce le processus de prise de la pâte de ciment en voie de durcissement. A la fin de prise, après 3,5 heures de durcissement, l'élévation de  $\Delta\psi$  se ralentit fortement.

La différenciation des charges n'est pas la seule cause de l'apparition de la différence de potentiels entre les phases solide et liquide de la pâte ou de la suspension de ciment. L'autre raison de l'engendrement de  $\Delta\psi$  est la distribution irrégulière d'ions entre la phase liquide composant les micelles colloïdales du gel de ciment et la

phase liquide libre. Cette distribution est propre à tous les systèmes colloïdaux et aboutit en conditions d'équilibre, à l'apparition du potentiel de Donnan

$$\varphi_D = \frac{RT}{Z_1 F} \ln \frac{a_1}{\bar{a}_1} \quad (1)$$

où  $a_1$  est l'activité du 1-ème ion dans la solution libre;  $\bar{a}_1$  - l'activité du 1-ème ion dans la solution liée;  $R$  - la constante de gaz parfaits;  $F$  - le nombre de Faraday;  $Z_1$  - la charge du 1-ème ion (compte tenu de son signe).

Cependant le gel de ciment de la pâte qui durcit se trouve dans un état qui est loin de l'équilibre thermodynamique. Aussi dans le cas étudié ne peut-on parler que du potentiel du type Donnan ( $\varepsilon_D$ ) mais dans des conditions de déséquilibre et transitoires. La différence entre  $\varphi_D$  et  $\varepsilon_D$  a un caractère de principe et la grandeur  $\varepsilon_D$  ne peut être calculée sur la base de l'équation (1).

Outre la grandeur  $\varepsilon_D$  il faut tenir compte des potentiels liés aux flux de diffusion dans les microcapillaires. On sait que le gel de ciment est traversé par de nombreux microcapillaires dont le rayon est de l'ordre de l'épaisseur de la CB. Dans ces capillaires la phase liquide est soumise à une forte action des surfaces chargées. Ceci a des effets sur de nombreuses propriétés physico-chimiques de la solution, en particulier sur la viscosité, la permittivité, la force ionique. Sous l'effet de la charge superficielle l'activité des ions de la phase liquide et leur mobilité se modifient. Le nombre de transfert de co-ions diminue donc, tandis que celui de contre-ions augmente. Il en résulte des courants de diffusion ainsi qu'un phénomène de conductibilité superficielle dont il faut tenir compte au cours de la détermination de la grandeur du potentiel  $\varepsilon$ , d'après les mesures électrocinétiques.

Ainsi donc la différence entre les potentiels des phases solide et liquide se détermine dans le gel de ciment par le potentiel du type Donnan ( $\varepsilon_D$ ) et le potentiel de diffusion  $\varphi_D$ . La somme de ces potentiels doit être considérée comme le potentiel de la membrane du gel de ciment:  $\varphi_m = \varepsilon_D + \varphi_D$ .

L'apparition du potentiel de diffusion au cours du durcissement de la pâte de ciment a été étudié dans la chaîne électrochimique

où  $m_1$  et  $m_2$  sont les molalités des solutions de KCl;  $E/C$  étant le rapport eau-ciment dans la pâte.

La figure 3 montre la variation de la grandeur  $\varphi_d$  en fonction du temps de durcissement de la pâte de ciment (courbe I). La nature de la courbe  $\varphi_d = \varphi(t)$  témoigne que la pâte de ciment, déjà dès le début de gachage modifie sensiblement le nombre de transfert de co-ions et de contre-ions, c'est-à-dire possède une activité électro-

chimique marquée. Le nombre de transferts peut être calculé d'après la formule connue

$$t_+ = \frac{\varphi_d}{\frac{RT}{2ZF} \ln \frac{f_1 \bar{a}_1}{f_2 \bar{a}_2}} \quad (2)$$

où  $t_+$  est le nombre de transferts du cation;  $f_1$  et  $f_2$  - les coefficients d'activité des solutions KCl.

Fig.3. Caractéristiques électrochimiques des processus de durcissement de la pâte de ciment

I) par rapport au potentiel de diffusion  
II) par rapport au potentiel électrocinétique

Après le choix des molalités le nombre de transferts d'ions  $K^+$  ( $t_{K^+}$ ) dans la solution libre équivaut à 0,49. Deux minutes après gachage  $t_{K^+}$  atteint 0,53 (point "a"),  $\Delta t$  étant égal à 8%. Une heure et demi après le début du durcissement (point "b")  $t_{K^+} = 0,58$ , tandis que  $\Delta t = 19\%$ . Ensuite les nombres de transferts varient brusquement et au point "c" correspondant à 3,5 heures de durcissement  $t_{K^+} = 0,85$ , tandis que  $\Delta t = 73\%$ .

La période de durcissement entre les points "b" et "c" correspond évidemment à celle de l'épaississement de la pâte de ciment par coagulation et formation de nombreux micropores ainsi que du fait de l'amorçage du développement de la structure. Après 8 heures de durcissement  $t_{K^+}$  atteint dans la pâte

0,88 et  $\Delta t$  79% (point "d"). Par la suite la grandeur  $t_{K^+}$  commence à diminuer et après un durcissement de 18 jours la pâte acquiert une valeur stable égale à 0,56 ( $\Delta t = 14\%$ ). La chute de  $\Delta t$  est une indication de l'affaiblissement de l'activité électrochimique après la transformation de la pâte en pierre de ciment. La raison en peut être la variation de la structure de la CB comme celle du rayon des pores. Aussi

pour une description complète des phénomènes électrochimiques dans les pâtes de ciment faut-il étudier la variation du potentiel  $\xi$  au cours du durcissement. Si l'on introduit une correction à la conductibilité superficielle, la grandeur  $\xi$  sera indépendante du rayon des capillaires et des pores.

La figure 3 représente la variation de la grandeur du potentiel  $\xi$  en fonction du temps de durcissement de la pâte de ciment (courbe II). Au début de durcissement le potentiel  $\xi$  atteint -24 mV (point "k"), ensuite, durant environ une heure, il diminue en valeur absolue jusqu'à -12 mV (point "l"). La diminution du potentiel  $\xi$  est due à la saturation électrolytique de la phase liquide du fait d'intenses processus d'hydratation. Ensuite, durant la période d'induction on assiste à la formation de la pellicule de gel qui absorbe de façon spécifique les cations de la solution. De ce fait la concentration de la charge électrostatique superficielle augmente. Ces deux processus aboutissent à la compression de la partie diffuse de la CB et, partant, à la diminution du potentiel  $\xi$ .

D'un autre côté la différenciation volumétrique des charges et la diminution de la concentration d'ions dans la phase liquide par cristallisation conduit à une forte augmentation de la grandeur  $\xi$  (intervalle m - n). L'apparition de courants de diffusion et la poursuite de l'hydratation de particules originaires du liant ralentissent la croissance du potentiel  $\xi$  puis l'obligent à diminuer (intervalles n - o et o - p). Le développement de structures cristallines du liant en voie de durcissement et le réarrangement des ions dans la CB par absorption sélective provoquent de nouveau l'élévation de la grandeur  $\xi$  (intervalle p - q).

La confrontation des courbes  $\varphi_d = \varphi(\tau)$  et  $\xi = \xi(\tau)$  montre que malgré une différence apparente elles caractérisent de façon univoque le processus de durcissement. C'est ainsi qu'à la période d'accroissement de l'activité électrochimique de la pâte de ciment correspond une rapide augmentation du potentiel  $\xi$ . Le ralentissement de l'activité électrochimique s'accompagne de celui de la grandeur  $\xi$ . La diminution du potentiel  $\xi$  s'amorce durant la période de la baisse d'activité électrochimique de la pâte.

Habituellement la coagulation de particules hydratées du liant est reliée à la diminution de la grandeur du potentiel  $\xi$ . Mais pour les systèmes lyophiles auxquels appartiennent les pâtes, cette interdépendance n'est pas obligatoire. De surcroît les expériences montrent que le développement de la structure primaire irréversible dans les pâtes de ciment débute au cours de l'élévation du potentiel  $\xi$ . Selon nous la coagulation et la prise des pâtes de ciment est due à l'action des forces pondéromotrices apparaissant avec la différenciation volumétrique des charges. L'effet de différenciation des charges au cours de l'hydratation

des ciments peut être considéré comme une des causes de l'apparition de propriétés liantes. Si l'on admet que l'énergie de différenciation des charges est fournie par la chaleur d'hydratation il devient alors clair pourquoi tous les liants interagissent avec l'eau de façon exothermique.

## CONCLUSIONS

L'analyse théorique ainsi que des études expérimentales ont montré que la pâte de ciment doit être considérée comme un système électrochimique particulier. L'interface des phases solide et liquide d'un liant qui s'hydrate est constitué par un ensemble de couches bipolaires en interaction. Les forces pondéromotrices développées au cours de la séparation volumétrique des charges peuvent être l'une des raisons de la manifestation des propriétés liantes.

Cette hypothèse est confirmée par l'existence d'une différence importante de potentiels entre les phases au cours de la décantation des suspensions de liant et le filtrage sous pression de la phase liquide à partir des pâtes de ciment. La différence de potentiels entre les phases dans le système "liant - eau" est loin d'être un artifice, elle est due à une distribution déséquilibrée des charges du type Donnan et d'une importante activité électrochimique des suspensions et des pâtes de ciment.

Dans des systèmes colloïdaux équilibrés la différence entre les potentiels chimiques des phases liée et libre se compense par la pression osmotique. La différence de potentiels chimique entre les ions de même signe liés et diffusant librement se compense par la pression osmotique et la différence entre les phases des potentiels électriques. Dans le système déséquilibré "liant - eau" par contre la compensation ne s'établit pas et la pression osmotique atteint même 19 à 54 MPa (4). La scission provoquée par cette pression aboutit à la déformation et à la rupture de nouvelles formations de gel ainsi qu'à la dilatation sensible du liant en cas de cohésion du système.

La différence de potentiels entre les phases solide et liquide doit être prise en compte au cours des études des processus d'hydratation et de durcissement. Il faut souligner tout particulièrement que la mesure des paramètres tels le pH, la concentration active d'ions, la conductivité électrique, etc. doit être faite directement sur la pâte de ciment et non pas sur la phase liquide extraite de cette dernière (8).

Le développement de connaissances sur les processus électrochimiques dans les pâtes de ciment, sur leur nature et leurs particularités peuvent être utilisées de façon efficace dans le but de modification orientée des propriétés des liants. Cela concerne en premier lieu le choix d'adjuvants chimiques et d'actions électromagnétiques externes à des fins de réglage des délais de prise et des conditions de durcissement des pâtes de ciment.

## Some aspects and a new method of evaluating the sulphate resistance of cements

### *Quelques considérations sur la résistance des ciments à l'action des sulfates ; nouvelle méthode de mesure de cette résistance*

M. REVAY, Ph.D. Senior Sci. Officer, Central Research and Design Institute for Silicate Industry, Budapest, Hungary; and

R. KOVACS, Ph. D., Deputy Head of Sci. Department, Central Research and Design Institute for silicate Industry, Budapest, Hungary.

RESUME : Les causes des variations de la résistance à l'action des sulfates de divers ciments ont été étudiées, en examinant leurs compositions de phase et leurs textures; on a tenté d'en déduire une explication précise du mécanisme de la corrosion par les sulfates.

Au cours de ces recherches (en utilisant et en améliorant les méthodes actuelles, bien connues, d'appréciation de la résistance aux sulfates) une méthode plus sensible, relativement rapide, fiable, en bonne concordance avec l'expression pratique et susceptible d'une normalisation internationale a été élaborée, pour apprécier la résistance des ciments à l'action des sulfates.

SUMMARY: The causes of the different sulphate resistance of various types of cements were interpreted using phase composition and texture investigations and an attempt was made to find a more accurate explanation of the sulphate corrosion mechanism.

In the course of the research - using and further developing the elements of some well known methods of investigating the sulphate resistance - a more sensitive, relatively rapid, reliable method well conforming the practical experience and being suitable for international standardization was elaborated for the investigation and evaluation of the sulphate resistance of cements.

## INTRODUCTION

The predominant part of subsoil waters in Hungary have high sulphate concentration. That is why the study of the causes bringing about sulphate corrosion, the factors influencing the sulphate resistance of cements and the methods of its testing are of great importance for us. In the following besides the discussion of some theoretical problems a short summary of our recent work made in this field is given.

## VOLUMETRIC CHANGES AND SULPHATE CORROSION

As it is known the volume of the compounds formed during the hardening of a cement-water mix is smaller than the total volume of the cement and water /1,2/. Thus after the solid structure has been developed a cement stone of considerable porosity is formed which usually shows some shrinkage later on.

The frequently observed swelling phenomenon cannot thus be understood in the first moment since in the porous cement stone there are always enough free room for the new formations. There is no doubt that the expansion is caused by processes accompanying the volumetric increase of the solid phase but although hydration is also of similar nature it does not cause expansion. According to some authors /3,4,5/ expansion takes place when the crystalline pressure of the new compounds formed during topochemical processes affects the solid structure, while others/6,7/ deny the possibility of such processes.

As it is known, sulphate corrosion is caused by the expanding effect of the sulphate-containing secondary hydrate compounds formed due to the sulphate ion penetration from subsoil waters into the cement stone /3,4,5,6/.

As a fact, the higher quantity of the  $Al_2O_3$  content of the cement is bound in the form of  $C_3A$  the stronger tendency to sulphate corrosion can be observed /9,10/. Calcium-aluminate-sulphate-hydrates, however, may develop also from other  $Al_2O_3$ -containing phases so it is not quite clear why  $C_3A$ -less ferro-Portland cements are more sulphate resistant than ordinary cement containing practically the same amount of  $Al_2O_3$ . The "protecting effect" of the iron hydroxide gel suggested by some authors does not explain the smaller sulphate sensibility of the  $Al_2O_3$  being present in the vitreous phase in the calcium aluminates of lower lime saturation /e.g.  $C_2A$ / and in hydraulic admixtures /2,3,8/, as well as the better sulphate resistance of high aluminate cements containing little  $Fe_2O_3$  /11/.

Our experiments were devoted to find answers to the above questions.

## INVESTIGATIONS ON THE MECHANISM OF SULPHATE CORROSION

In our experiments 20x20x80 mm cement paste specimens were prepared from cements of

quite different sulphate resistance with a water/cement ratio of 0.26. One part of them was stored in water while the other part transferred for storage into a 4.4%  $Na_2SO_4$  solution after two weeks. Strength tests of these specimens were carried out at ages from 1 to 365 days whereafter their pieces were subjected to various physical-chemical investigations.

The results of strength-tests proved the exponential relationship between porosity and strength stated by many authors /12,13,14/ to be valid for the cements stored in water but not for those stored in sulphate solution. This shows that for the latter ones the strength is determined not by their porosity but by micro- and macrocrackings. An explanation is attempted on the base of structural investigations.

Fig.1 shows some typical X-ray diffractograms.

Fig.1 - X-ray patterns of various type cements after curing 14 days in water and further on in sulphate solution  
a/ Portland cement; b/ moderate sulphate resistant and c/ sulphate resistant cement  
E = ettringite; M = monosulphate; G = gypsum  
F = ferrite phase; P = portlandite

It can be observed that in Ferrari-type cements the intensity of the calcium-aluminate-ferrite peaks is quite remarkable even after storing in sulphate solution for a relatively long time. This indicates that the dissolution rate of the  $Al_2O_3$  content of the cement is considerably less than that of the cements containing alumina mostly in  $C_3A$  phase. Concentration relations in this

case enable the  $Al_2O_3$  content of the cement to practically crystallize in the form of primary calcium-aluminate-sulphate-hydrates. This process keeps going on even with sulphate ions penetrating from outside. If a large amount of  $C_3A$  is, however, present, the initial aluminium-ion concentration will be higher and the amount of the dissolving sulphate is not sufficient to form from the dissolved ions exclusively sulphate containing hydrate compounds so a certain amount of primary calcium aluminate hydrates also precipitates beside them. The latter, upon the effect of the sulphate solution penetrating from outside convert into secondary calcium-aluminate-sulphate-hydrates. Textural investigations give information on the mechanism of their formation. These results are illustrated by pore size distribution diagrams of some typical probes obtained by the mercury penetration method /Fig.2./.

Fig.2 - Pore size distribution curves of a Portland cement after curing in water for a/ 1 day; b/ 28 days; c/ 1 year

On the differential pore size distribution curves of the cements stored in water two peaks of pore size frequency can be identified the position of which is shifted towards smaller pore diameters with the progress of the hydration. The phenomenon can be so interpreted that the location of the peak corresponding to the larger pore radii represents the average distance between the

individual cement particles which decreases with the new formations precipitating up on them as upon nucleation bases. The peak corresponding to the smaller pore radius represents the distance between the particles of the new formations and also decreases with the progress of the hydration accompanied with their growth.

Upon the effect of sulphate solution the change in the pore structure of various cements shows significant differences depending on their sulphate resistance /Fig.3/.

Fig.3 - Pore size distribution curves of various type cements after curing 14 days in water and further on in sulphate solution

a/ Portland cement; b/ Portland blastfurnace slag cement; c/ sulphate resistant cement

On the pore size distribution curves of the most sulphate resistant /Ferrari-type/ cements the peak corresponding to the larger pore radius decreases considerably while that one belonging to the pores of smaller diameters broadens remarkably. This phenomenon - although less definitely - can be observed for heterogeneous cements, too. At the same time it cannot at all be seen in the case of cements containing  $C_3A$ .

This shows that in cements of higher sulphate resistance the primary sulphate hydrates due to the change in the concentration relations and to the more free migration of ions, are formed in larger pores thus increasing the density. In less sulphate resistant cements, however, the dominant part of the secondary sulphate hydrates are formed in the smaller pores among the previously developed hydrate compounds. As far as these

smaller pores contain oversaturated solutions the process due to the hindered diffusion takes place much more localizedly /a "quasi topochemical process"/. This causes expansion and cracking while the pores of large size are preserved, so in case of Ferrari type cements the formation of secondary sulphate hydrates is hindered by the slower dissolution of  $Al_2O_3$  while for heterogeneous cements - by the lower concentration of calcium ions.

These regularities, however, bear only of tendentious character and due to differences in production technologies there are significant variations even in the sulphate resistance of identical type cements. Therefore the solution prescribing the application of certain type cements at places of sulphate corrosion danger cannot be regarded as safe. It would be necessary to determine the effective sulphate resistance of the cements by testing. That is why we have dealt in detail with the problems of testing the sulphate resistance of cements too.

#### ELABORATION OF A NEW METHOD FOR TESTING THE SULPHATE RESISTANCE OF CEMENTS

The numerous known testing methods may, on the base of qualifying parameters, be classified into three groups. These are methods based on:

- chemical analysis
- the measurement of changes in the length of specimens /with supplementary gypsum addition or without it/
- the measurement of the changes in the strength of specimens

The most important methods were controlled by laboratory experiments. The results are summarized in the following:

The methods based on chemical analysis may at most be only informatory.

The methods testing the decrease in strength are on the one hand very time-consuming /although the modification - elevation of the temperature of the sulphate solution - suggested by Mehta and Gjorv/8/ may help in this/, on the other hand the opposite /porosity-decreasing and expanding/ effects of the volume growth of the solid phases make, in the initial one-two months, the results uncertain.

Among the methods based on measuring the expansion the main shortcoming of the methods using gypsum-overdosage is that they under estimate the sulphate-resistance of the cements containing hydraulic admixtures. Moreover, these methods characterize rather the tendency of the cement to gypsum expansion than its sulphate resistance. By methods without gypsum-overdosage even after a relatively long time cannot be achieved such big variations in the expansion of the different type cements that would enable a reliable evaluation. For these reasons we attempted to elaborate a more rapid and more sensible method.

In this work we started from the following considerations:

- the new method should fit well to the standard prescriptions of the physico-mechanical testing of cements;
- the size of the specimens should not be too small in order to diminish the standard deviation of results but it should have the largest possible surface-volume ratio and a porous structure in order to secure the better sulphate effect;
- the sulphate resistance of the cement should be evaluated through the expansion value.

In developing the new method we set out from the Locher-method /15/ since it contained some elements of the above requirements. /The essence of it is that test specimens of  $10 \times 40 \times 160$  mm size made of standard cement mortar are at first stored in water for 14 days and then transferred into a 4.4% sulphate solution, the sulphate resistance being estimated on the base of the expansion measured at the age of 56 days./ With the intention to accelerate the method and to improve its sensitivity we applied

- steam-curing for the pre-hardening of the specimens and
- standard sand of incomplete granulometry for preparing the specimens in order to increase their porosity.

Concerning steam-curing a worry may rise that compared with hardening at normal temperature in this case a cement stone of different phase composition and texture may form, that may influence the sulphate corrosion, too. On the other hand, however, it should be taken into account that a large amount of steam-cured concrete is also being exposed to sulphate effect and to determine their corrosion resistance just such a method is expected to give adequate results.

The phase composition investigations proved, in agreement with other authors /7,18/ that regarding the composition of the hydrate phases formed there is no significant difference between the two ways of hardening.

Further, the textural investigations /Fig.4/ proved that among the steam-curing parameters /75; 85; 95° and 2; 4 and 24 hours/ the curing at 85°C for 2 hours ensures a pore structure most similar to that developed at normal temperature /see curves a/ and b/ in Fig.2/.

Fig.5 shows the influence of the hardening parameters upon the sulphate expansion of a cement. It can be seen that by a properly chosen steam curing /85°C, 2 hours/ the absolute value of expansion can be considerably increased as compared to that after a two-week pre-hardening at normal temperature. This makes the evaluation easier and improves the reliability of the testing method.

The density of the specimens was decreased in such a way that - preserving the 1:3 cement/sand ratio - the fine fraction of the three ones of sand was omitted.

Results here not cited show that incomplete granulometry itself does not cause a significant change if the pre-hardening takes

Fig. 4 - Pore size distribution curves of a Portland cement after steam-curing for a/ 2 hours at 85°C b/ 24 hours at 85°C

Fig. 5 - Sulphate expansion of Portland cement specimens cured in water for 14 days/1/ and steam-cured for 24 hours at 75°C /2/, 2 hours /3/ and 4 hours /4/ at 85°C

place at normal temperature. At the same time its simultaneous application together with pre-hardening by steam-curing results in a manifold increase of the expansion value.

Fig. 6 proves that the sequence of sulphate

Fig. 6 - Sulphate expansion of various type cements by the new method  
1 - Portland cement; 2 - Portland blastfurnace slag cement; 3 - Portland fly ash cement; 4 - moderate sulphate resistant cement 5 and 6 - sulphate resistant cements

resistance of various cements as tested by the new method is in good agreement with the practical experience and the results got by the Locher method, the difference being in the much higher expansion values of the individual cements considerably exceeding the error limit of the measurement.

Reproducibility tests were conducted in our institute as well as by some home and foreign institutions. The reassuring results made it possible to publish the method in the "Technical Prescriptions" /19/ organically fitted into the Hungarian Standard series for cement testing.

Concerning the sulphate resistance of the main Hungarian cement types on the base of

Fig.6 it can be stated that as it was expected, the most sulphate resistant one is the Ferrari type cement not containing  $C_3A$  and the less resistant the pure Portland cement of high  $C_3A$  content.

It is noteworthy from the point of effectively covering the demands on sulphate resistant cements that the expansion practically does not increase remarkably up to an AM value of about 1,2 on the one hand and that the sulphate resistance of heterogeneous cements, including fly ash cements, is also considerable on the other.

However, as it has been pointed out, reliable meeting the requirements in sulphate resistant cements is only possible on the base of factual testing. This became practicable due to the relative rapidity /28 days/ of the suggested new method.

On the base of the experiences and results got thus far a prescription was elaborated in which the selection of cements applicable in subsoil waters of different sulphate concentration is based up on the chemical and physical composition /aluminate module,  $C_3A$ -content/ of the cement but upon the sulphate expansion determined by our method.

Fig.7 - Diagram for the determination of the applicability of cements in sulphate containing waters of various concentration based on their expansion as tested by the new method

Fig.7 shows the permissible sulphate ion concentrations as a function of the 28 days swelling value.

This solution gives the possibility to exclude the cements of although appropriate chemical composition but of poor sulphate resistance /due to some production technological causes/ and to utilize the cements

having a less advantageous chemical composition but showing better sulphate resistance as determined by our method. Such a practice enables the more secure and more economic covering the demands on sulphate resistant cements.

# Effects of Raw Materials and Addition of Alkali on the Hydrothermal Reaction in Quartz and Lime System

*Influence des matières premières et d'une addition d'alcali sur la réaction hydrothermique entre quartz et chaux*

K. ASAGA, Dr. Research Associate,

R. KONDO, Dr. Professor,  
Dept. of Inorganic Materials, Tokyo Institute of Technology, Japan.

RESUME : Cette étude concerne la synthèse de cristaux aciculaires ou fibreux d'hydrates et de silicates de calcium par le traitement hydrothermique d'un ensemble quartz-chaux. Dans cette synthèse, il est nécessaire de diriger la solubilité et la vitesse de dissolution des matières premières.

L'étude a été exécutée à 150°C-210°C, employant  $\text{CaCO}_3$ ,  $\text{Ca(OH)}_2$ , et  $\text{SiO}_2$  comme matières premières et des alcalis comme additifs.

La solubilité et la vitesse de dissolution de la chaux ont diminué quand on a employé  $\text{CaCO}_3$  et  $\text{Ca(OH)}_2$  avec des additifs alcalins.

Par contre, la solubilité et la vitesse de dissolution de  $\text{SiO}_2$  ont augmenté avec l'addition d'alcalis. Ces additifs alcalins ont aussi affecté la stabilité des hydrates.

Dans le système  $\text{Ca(OH)}_2$  -  $\text{SiO}_2$  -  $\text{NaOH}$ , un cristal aciculaire de pectlite a été formé. Dans le système  $\text{Ca(OH)}_2$  -  $\text{SiO}_2$  -  $\text{KOH}$ , la tobermorite est devenue stable en augmentant la concentration en  $\text{KOH}$ , même à température élevée, et la proportion molaire  $\text{Ca/Si}$  des matières premières s'est étendue. On a obtenu des cristaux de tobermorite longs et fibreux de 200  $\mu\text{m}$  de longueur dans le système  $\text{CaCO}_3$  -  $\text{SiO}_2$  -  $\text{KOH}$ ; et on a observé un cristal aciculaire non identifié, mais semblable à un zéolite dans le système  $\text{CaCO}_3$  -  $\text{SiO}_2$  -  $\text{K}_2\text{CO}_3$ .

SUMMARY : This study concerned with the synthesis of needle or fibrous crystals of calcium silicate hydrates by hydrothermal reaction. In the synthesis of these fibrous crystals, it is very necessary to control the solubility and the rate of solution of raw materials. The study was carried out at 150°-210°C using  $\text{CaCO}_3$ ,  $\text{Ca(OH)}_2$  and  $\text{SiO}_2$  as raw materials and alkalis as additives.

The solubility and rate of solution of lime when using  $\text{CaCO}_3$  and  $\text{Ca(OH)}_2$  with alkaline additives decreased.

On the other hand the solubility and rate of solution of  $\text{SiO}_2$  increased by the addition of alkalis. Alkaline additives also affected the stability of hydrates.

In the system  $\text{Ca(OH)}_2$  -  $\text{SiO}_2$  -  $\text{NaOH}$ , needle crystal of pectlite was formed. In the system  $\text{Ca(OH)}_2$  -  $\text{SiO}_2$  -  $\text{KOH}$ , tobermorite became stable with the increase of  $\text{KOH}$  concentration at higher temperatures and wider  $\text{Ca/Si}$  molar ratio of raw materials. Very long fibrous tobermorite of about 200  $\mu\text{m}$  in length was obtained in the system  $\text{CaCO}_3$  -  $\text{SiO}_2$  -  $\text{KOH}$  and also unidentified but zeolite-like needle crystal was observed in the system  $\text{CaCO}_3$  -  $\text{SiO}_2$  -  $\text{K}_2\text{CO}_3$ .

## INTRODUCTION

Asbestos have long been used as the alkali resistive fiber in many building materials, but it is going to be difficult to use a large quantity because of the shortage of resources and injury to human body. It will be necessary to develop the new alkali resistive fiber instead of asbestos. Tobermorite and xonotlite are the typical fibrous or needle hydrates obtained from hydrothermal reaction in the system of silica and lime, and have been studied from the view points of phase equilibrium, crystal chemistry and kinetics of reaction (1, 2, 3, 4, 5). It is necessary to control the solubility and the rate of dissolution of raw materials, in order to synthesize these fibrous crystals.

It is effective to use the additives to control the solubility of raw materials. The effects of aluminum ion have recently been clarified (2, 4, 5, 7, 8, 9). There were also lots of studies on the effects of alkalis (6, 10, 11, 12, 13). But the role of those additives has not been discussed precisely. In addition to these studies, products and reaction rate were investigated by using the various kind of silica and lime materials (2, 14, 15). But there were very few studies using  $\text{CaCO}_3$  as raw materials because of the very low solubility.

In the present study, the effect of various alkalis on the hydrothermal reactions in the  $\text{Ca}(\text{OH})_2$  or  $\text{CaCO}_3$ - $\text{SiO}_2$ - $\text{H}_2\text{O}$  system, and the reactivity of  $\text{CaCO}_3$  were systematically studied. And the synthesis of needle or fibrous crystals was attempt in the above hydrothermal system.

## EXPERIMENTAL PROCEDURES

Quartz, with the particle diameters of 6-10 $\mu\text{m}$  and 10-20 $\mu\text{m}$ ,  $\text{Ca}(\text{OH})_2$  and  $\text{CaCO}_3$  were used as the raw materials.  $\text{LiOH}$ ,  $\text{NaOH}$ ,  $\text{KOH}$ ,  $\text{K}_2\text{CO}_3$  and  $\text{Na}_2\text{CO}_3$  solutions were used as the alkali resorces. 1-4g of raw mixes, with the  $\text{Ca}/\text{Si}$  ratio of 0.6-1.2, and water or alkali solutions were thoroughly mixed to having the w/c ratio between 10 and 40. Then they were processed at 150-210°C, for 1-10 days in the 60ml autoclave rotated at 25rpm. The products were dried at 110°C and examined by X-RD, SEM, TG-DTA and so on.

The solubility of  $\text{SiO}_2$ ,  $\text{Ca}(\text{OH})_2$  and  $\text{CaCO}_3$  was measured by colorimetric and atomic absorption.

## RESULTS AND DISCUSSION

 $\text{Ca}(\text{OH})_2$  -  $\text{SiO}_2$  - alkali system

Unreacted  $\text{Ca}(\text{OH})_2$  and  $\text{SiO}_2$  were not detected by X-RD, in the alkali free system when processed at 180°C and 210°C for 3-10 days. Tobermorite was produced at c/s = 0.8, and xonotlite at c/s = 1.0, 1.2. These results agreed with the Kondo(2) and Taylor(1).

(1)  $\text{Ca}(\text{OH})_2$  -  $\text{SiO}_2$  -  $\text{NaOH}$ ,  $\text{Na}_2\text{CO}_3$  system

Pectolite was produced in 1 N  $\text{NaOH}$  at 180°C or 0.15 N  $\text{NaOH}$  at 210°C. The range of pectolite formation was agreed with the results of Blakman(12) and Nelson(13). Pectolite was formed as needle crystals similar to xonotlite with maximum length 150 $\mu\text{m}$ . The pectolite crystal seemed to grow larger than that of xonotlite. The same results were obtained when  $\text{Na}_2\text{CO}_3$  was used instead of  $\text{NaOH}$ .

(2)  $\text{Ca}(\text{OH})_2$  -  $\text{SiO}_2$  -  $\text{KOH}$ ,  $\text{K}_2\text{CO}_3$  system

The results in this system were very different from the Na containing system, and tobermorite or xonotlite were obtained. Fig.1 shows the products after 3-10 days reaction in the presence of  $\text{KOH}$ . The unreacted  $\text{Ca}(\text{OH})_2$  and  $\text{SiO}_2$  were also not detected by X-RD. The conditions of the formation of tobermorite and xonotlite did not differ from alkali free system when  $\text{KOH}$  concentration was lower than 0.3 N. But at high  $\text{KOH}$  concentration, the formation of tobermorite was extended to the range of higher c/s and higher temperature. These tobermorite had the lath shape and grew larger than those in alkali free system, as shown in Fig.2

Fig. 1 - Reaction products of the  $\text{Ca}(\text{OH})_2$ - $\text{SiO}_2$  -  $\text{KOH}$  system after treated for 3-10 days

Fig. 2 - The SEM photographs of the tobermorite c/s = 0.8, 180°C, 5 days

X-RD pattern had more sharp peak, and the peak of (400, 008) separated to (400) and (008). These results suggested that KOH increased the crystallinity of tobermorite and retarded the transformation to xonotlite.

Fig.3 shows the change in the values of  $d(hkl)$ , (220), (400), (008) of tobermorite with the concentration of KOH.

Fig. 3 - Changes in the  $d(h.k.l)$  of the tobermorite with concentration of KOH; 180°C, 3 days. and Changes in the  $d(h.k.l)$  of the tobermorite obtained at 1 N KOH, with the washed with water.

The peak near the 2.80Å separated into 2 peakes, and the values of  $d(400)$  became larger, the values of  $d(008)$  became smaller. The values  $d(002)$  and (0010) became smaller too. However the other values did not change largely. Accordingly,  $K^+$  ions seemed to exist in the interlayer spaces of the tobermorite. The values of  $d(008)$  did not change with concentration of KOH, suggesting the limited amount of  $K^+$  ions, which could enter between tobermorite layers.

The values of  $d(008)$  became larger, when the tobermorite was washed with distild water, and (400) peak and (008) peak became nearly one peak as shown in Fig.3.  $K^+$  ions were liberated into the washed water. It was suggested that the  $K^+$  ions existed in the interlayer spaces of the tobermorite were loosely bounded and easily dissolved.

### (3) $Ca(OH)_2 - SiO_2$ - mixed alkali system

Fig.4 (a) shows the products obtained by reaction at 180°C for 3 days, in the mixed alkali solutions. The total alkali concentration was 1 N, and c/s and w/s were 0.8 and 20. Tobermorite and pectolite coexisted at the condition of  $KOH : NaOH = 0.2 : 0.8$ ,  $K_2CO_3 : Na_2CO_3 = 0.2 : 0.8$ . At the heigher concentration of KOH or  $K_2CO_3$ , tobermorite was the only product. Pectolite was produced as increasing the  $Na^+$  ion concentration without effected from the KOH.

T; tobermorite  
A; AB; needle crystal  
X; not reacted

Fig. 4 - Reaction products of the  $Ca(OH)_2$ ,  $CaCO_3$  - mixed alkali solution system, c/s = 0.8. concentration of alkali 1 N, 180°C, 3 days.

### (4) $Ca(OH)_2 - SiO_2 - LiOH$ system

The reaction with LiOH was very different. Considerable amounts of unreacted  $Ca(OH)_2$  and  $SiO_2$  were observed, and  $Li_2SiO_3$  was obtained as the products and no hydrate was detected by X-RD. Fig.5, shows the S.E.M. microphotograph of the sample treated at 180°C for 3 days.

Fig. 5 - Reaction products of the  $Ca(OH)_2 - SiO_2 - LiOH$  system; c/s = 0.8, 1 N LiOH, 180°C, 3 days.

The prismatic or polyhedral crystals of  $\text{Li}_2\text{SiO}_3$  were observed, but lath or fibrous crystals did not exist in the samples. Lots of quartz particles were covered with small dense products which seemed to retard the reaction.

### 3 - 2 $\text{CaCO}_3$ - $\text{SiO}_2$ - Alkali system

No products was obtained; in the systems of  $\text{CaCO}_3$  -  $\text{SiO}_2$  and  $\text{CaCO}_3$  -  $\text{KOH}$ , at  $180^\circ\text{C}$  for 5 days.

#### (1) $\text{CaCO}_3$ - $\text{SiO}_2$ - $\text{KOH}$ system

The experiments were carried out in 0.5 N - 2 N  $\text{KOH}$  solution at  $150$ - $210^\circ\text{C}$  for 3-10 days. The unreacted or insoluble  $\text{SiO}_2$  was not detected, but unreacted  $\text{CaCO}_3$  was observed in the all experiments. The only products was the tobermorite except the case of 0.5 N  $\text{KOH}$ , where the gel products were obtained. These tobermorite crystals had the same character as the products in  $\text{Ca}(\text{OH})_2$  -  $\text{SiO}_2$  -  $\text{KOH}$  system. Fig.6 shows the change in the morphology of the products. The morphology of the tobermorite changed from lath to fibrous crystal with the processing time.

Fig. 6 - Change in the morphology of the products in the  $\text{CaCO}_3$  -  $\text{SiO}_2$  -  $\text{KOH}$  system;  $c/s = 0.8$ , 1 N  $\text{KOH}$ ,  $180^\circ\text{C}$ .

Fig.7 shows the long fibrous tobermorite with the length of  $200\mu\text{m}$ . The mix with  $c/s = 0.8$  was treated in 2 N  $\text{KOH}$  solution at  $180^\circ\text{C}$  for 10 days.

Fig. 7 - SEM photograph of the long fibrous tobermorite;  $c/s = 0.8$ , 2 N  $\text{KOH}$ ,  $180^\circ\text{C}$ , 10 days.

Fig.8 shows the changes in the amounts of reacted  $\text{CaCO}_3$  with the concentration of  $\text{KOH}$ . The amounts of reacted  $\text{CaCO}_3$  were measured from weight loss by T.G. The reaction rate of  $\text{CaCO}_3$  increased with the increasing  $\text{KOH}$  concentration. About 80% of the  $\text{CaCO}_3$  was reacted at the 2 N  $\text{KOH}$  within 3 days, but reaction did not proceed over 85% even after 10 days. It seemed to be difficult to react until the  $\text{CaCO}_3$  was completely consumed.

Fig. 8 - Changes in the amounts of reacted  $\text{CaCO}_3$  with the concentration of  $\text{KOH}$ ;  $c/s = 0.8$ ,  $180^\circ\text{C}$ , 3 days.

Fig.9 shows the change in  $\text{SiO}_2$  and  $\text{CaO}$  concentration of solution with the processing time, in the system  $\text{CaCO}_3$  -  $\text{SiO}_2$  -  $\text{KOH}$ . The methods of measurement was mentioned in the previous paper (16). The concentration of  $\text{SiO}_2$  was about  $2\text{g/l}$  at 6hr of proceeding time and did not change largely as the time proceeded. This concentration was much larger

than that case without alkali. On the other hand, the concentration of CaO increased slowly as the time proceeded, and kept almost constant at about 0.3mg/l after 3 days, which was extremely smaller than the SiO<sub>2</sub> concentration.

Fig. 9 - Changes in SiO<sub>2</sub> and CaO concentration of the solution in the CaCO<sub>3</sub> - SiO<sub>2</sub> - KOH system with the processing time, c/s = 0.8, 180°C, 3 days.

Tobermorite grew surrounding the CaCO<sub>3</sub> particles and detected by X-RD after 1hr. The crystallization of tobermorite was more rapid than the case of Ca(OH)<sub>2</sub> - SiO<sub>2</sub> - KOH system. α-C<sub>2</sub>SH or C-S-H grew the SiO<sub>2</sub> particles in the Ca(OH)<sub>2</sub> - SiO<sub>2</sub> - KOH, in which concentration of CaO was larger than that of SiO<sub>2</sub> at early stages. The reaction products should grow surrounding the particles having relatively smaller solubility. These results suggest the reaction mechanisms of this system should be as follows. At first, SiO<sub>2</sub> was dissolved by KOH, and the concentration of SiO<sub>2</sub> increased. Then SiO<sub>2</sub> reacted with CaCO<sub>3</sub> producing the tobermorite around the CaCO<sub>3</sub> particles. The reaction began retarded when product layer became thick.

#### (2) CaCO<sub>3</sub> - SiO<sub>2</sub> - K<sub>2</sub>CO<sub>3</sub> system

The reaction was carried out at 150-210°C for 3-5 days, with c/s = 0.5-1.0, w/s = 20 and 1-4 N K<sub>2</sub>CO<sub>3</sub>. Needle shaped crystals are shown in Fig.9. CaCO<sub>3</sub> but no SiO<sub>2</sub> was observed in all samples. The crystal sizes were about 50-200 μm in length. From the results of the D.T.A, T.G, IR, X-RD and chemical analysis, the chemical composition of this crystal was found to be K<sub>2</sub>O·2CaO·10SiO<sub>2</sub>·6H<sub>2</sub>O. And it was dehydrated with 2 steps at 195-380°C. This was supposed to be a new compound which could be similar to some kind of zeolites such as rhodesite [KNaCa<sub>2</sub>(H<sub>2</sub>Si<sub>8</sub>)<sub>5</sub>H<sub>2</sub>O] or mountenite [KNaCa<sub>2</sub>(HSi<sub>8</sub>O<sub>2</sub>)<sub>5</sub>H<sub>2</sub>O].

No reaction product was observed in the system of CaCO<sub>3</sub> - SiO<sub>2</sub> - Na<sub>2</sub>CO<sub>3</sub> at 150°C-210°C

Fig. 10 - SEM photograph of the needle crystal produced in the CaCO<sub>3</sub> - SiO<sub>2</sub> - K<sub>2</sub>CO<sub>3</sub> system; c/s = 0.8. 2 N K<sub>2</sub>CO<sub>3</sub> 180°C, 3 days.

#### (3) CaCO<sub>3</sub> - SiO<sub>2</sub> - mix alkali system

Fig.3 (b) shows the products obtained by the reaction of the mixture of 1 N alkali at 180°C for 3 days. Where, A is the needle crystal above mentioned, AB is the needle crystal had the slightly different X ray pattern, which could not be identified whether it was consisted only one crystal or mixture of two crystals. Tobermorite and these needle crystals were not produced together at the same time, and no crystal but gel material was observed at the condition of KOH : K<sub>2</sub>CO<sub>3</sub> = 0.5 : 0.5. Comparing the results of Ca(OH)<sub>2</sub> and CaCO<sub>3</sub> system, tobermorite and pectolite were produced when either alkali or calcium resources was the carbonate, however needle crystals were only produced when both alkali and calcium resources were carbonate and the solution had to include K<sup>+</sup> ions.

The precise reaction mechanism could not be discussed by these results but the role of CO<sub>3</sub> was very significant and interesting, in spite of CO<sub>3</sub> was not included in both the products as tobermorite and the needle crystals.

#### CONCLUSION

The hydrothermal reactions in Ca(OH)<sub>2</sub> - SiO<sub>2</sub> and CaCO<sub>3</sub> - SiO<sub>2</sub> system were studied at 150-210°C using various kind of alkali solutions. Pectolite was produced, in the Ca(OH)<sub>2</sub> - SiO<sub>2</sub> system at 180°C with 1 N NaOH or Na<sub>2</sub>CO<sub>3</sub>, or at 210°C. When the concentration of NaOH or Na<sub>2</sub>CO<sub>3</sub> was higher than 0.1 N. The pectolite was needle or fibrous crystal with maximum length of 150μm. Tobermorite and xonotolite were produced in the Ca(OH)<sub>2</sub> - SiO<sub>2</sub> system treated with KOH or K<sub>2</sub>CO<sub>3</sub>. Tobermorite became stable with increase of KOH or K<sub>2</sub>CO<sub>3</sub> concentration at high temperature and wide c/s ratio of raw materials. No hydration product but

$\text{Li}_2\text{SiO}_3$  was obtained in the presence of  $\text{LiOH}$ . The tobermorite obtained in the presence of  $\text{KOH}$  or  $\text{K}_2\text{CO}_3$  contained  $\text{K}^+$  ions in the interlayer space. X-RD pattern of (400) and (008) peaks separated. The interlayer distance was 11.15Å which was slightly smaller than that of usual tobermorite, and easily shifted to usual distance by dissolving the  $\text{K}^+$  ions from the interlayer site when samples were washed with water. The thermal analysis suggested that it was anomalous type.

No reaction was observed without alkali, in the  $\text{CaCO}_3 - \text{SiO}_2$  - system, but about 80% of  $\text{CaCO}_3$  reacted within 3 days in the presence of 1 N  $\text{KOH}$ . The same products in the case of the  $\text{Ca(OH)}_2$  system were obtained with  $\text{NaOH}$ ,  $\text{KOH}$  and  $\text{LiOH}$ , which were pectolite, tobermorite and xonotrite, and  $\text{Li}_2\text{SiO}_3$  respectively. These hydrates seemed to be grown longer compared with  $\text{Ca(OH)}_2$  system. The long fibrous tobermorite with the length of 200µm was obtained in the presence of 1 N  $\text{KOH}$ . In this system the solubility of  $\text{CaCO}_3$  and  $\text{SiO}_2$  were about 0.3 mg/l and 2g/l respectively. A new compound of needle shaped crystal the chemical composition of  $\text{K}_2\text{O} \cdot 2\text{CaO} \cdot 10\text{SiO}_2 \cdot 6\text{H}_2\text{O}$  was obtained in the presence of  $\text{K}_2\text{CO}_3$ . The long needle crystal with 150µm with length was obtained. This needle crystals were obtained only when both of alkali and Calcium resources were carbonate, and the solution had to include the  $\text{K}^+$  ions.

# Volume Instability of Porous Solids : Part I

## *Instabilité en volume de solides poreux*

G.G. LITVAN (Senior Research Officer),  
Division of Building Research, National Research Council of Canada, Ottawa, Ontario, Canada.

RESUME : L'adsorption de  $\text{NO}_3\text{Na}$  en solution aqueuse fait subir à un verre poreux de silice saturé d'eau une variation de longueur de  $27 \times 10^{-5}$ . L'échantillon a subi une variation irréversible de longueur de  $50 \times 10^{-5} \Delta l/l$ . L'isotherme ressemble beaucoup à celle obtenue pour l'adsorption de la vapeur d'eau par le verre sec et présente une hystérésis sur l'ensemble des concentrations. L'expansion de  $325 \times 10^{-5} \Delta l/l$  a été trouvée, lors de l'attaque du verre poreux par  $\text{NaOH}$  0.2 N; et un changement de longueur de  $125 \times 10^{-5} \Delta l/l$  a eu lieu durant la dissolution en  $\text{C}_2\text{H}$  1.0 N d'un échantillon de ciment hydraté ( $e/c = 0.6$ ).

Lorsqu'on a lessivé la chaux d'une pâte de ciment ( $e/c = 0.6$ ) avec du glycol d'éthylène, on a observé une variation de  $120 \times 10^{-5} \Delta l/l$ . Ces résultats introduisent une donnée additionnelle qui pourrait expliquer le processus de détérioration des solides poreux exposés à certains produits chimiques, par exemple l'attaque par le sulfate et par l'eau de mer, et la réaction alcali-agrégat.

SUMMARY: A  $27 \times 10^{-5}$  fractional length change occurred in a water-saturated porous silica glass on adsorption of  $\text{NaNO}_3$  from aqueous solution. The specimen suffered a  $50 \times 10^{-5} \Delta l/l$  irreversible length change after determination of the extension adsorption isotherm. The isotherm greatly resembles that obtained on water vapour adsorption by dry glass, and exhibits marked hysteresis in all concentration regions. An expansion of  $325 \times 10^{-5} \Delta l/l$  was found while porous glass was under attack from 0.2 N  $\text{NaOH}$ ; and  $125 \times 10^{-5} \Delta l/l$  length change occurred during the dissolution in 1.0 N  $\text{HCl}$  of a 0.5 W/C hydrated cement specimen. On leaching lime from 0.6 W/C cement paste with ethylene glycol,  $120 \times 10^{-5} \Delta l/l$  was observed. These results introduce an additional factor that may explain the deterioration process of porous solids exposed to some chemicals, for example, in alkali aggregate reaction, sulfate attack and seawater attack.

Fig.2 - Extension isotherm of the porous 96% silica glass - aqueous  $\text{NaNO}_3$  solution system.

Fig.3 - Extension isotherm of the porous 96% silica glass-water system.

At low concentrations the curve for the  $\text{NaNO}_3$ -glass system rises rapidly to  $27 \times 10^{-5} \Delta l/l$ ; at concentrations higher than 1 mole/l it decreases slightly, but monotonously, reaching  $21 \times 10^{-5} \Delta l/l$  at 5 molar concentration. This is the only major difference

from the water extension isotherm (Fig.3), which undergoes a large expansion of approximately  $100 \times 10^{-5} \Delta l/l$  in the final stages of saturation (i.e. between points C and D).

Amberg and McIntosh (5) attribute the expansion between C and D (Fig.3) to flattening of the menisci, increasing spreading force of the adsorbed film in filled pores, and further adsorption in wide channels. Because no menisci are present in adsorption from solution, no expansion at high concentrations is to be expected in the present experiments. Its absence supports the meniscus flattening hypothesis postulated for the vapour adsorption method.

The desorption branch of the  $\text{NaNO}_3\text{-H}_2\text{O}$ -glass system differs from that of the water-glass system in at least two major aspects: there is no contraction on diminishing saturation, and the volume changes are not reversible in any concentration region. Most significantly, hysteresis and continuous expansion were observed on decreasing concentrations.

II. The dimensional changes observed during dissolution of porous glass in 0.2 N NaOH are shown in Fig.4. The 5 mm thick glass disintegrated in 82 h. Except for the last 3 min, the sample expanded continuously. The total fractional expansion was  $326 \times 10^{-5} \Delta l/l$ . Feldman and Sereda (7) reported expansion at a rapid but decreasing rate on treating porous silica glass with alkali, but their experiment was not carried to complete dissolution. The present findings appear to be consistent with the results obtained on leaching of sodium borosilicate glasses with sulfuric acid. Krasikov et al (8) found 0.16 to 0.2% expansion on complete leaching of 2 mm thick glass specimens. The observed 0.326% ultimate increase in length on dissolution of glass, though very substantial, is merely a fraction of that obtained in other similar experiments (to be reported elsewhere). The magnitude of expansion depends on several factors, but the weight of the extension rod and transformer core assembly in the present experimental arrangement is considered to have decreased it.

Fig.4 - Length changes of a porous 96% silica glass immersed in 0.2 N aqueous NaOH, as a function of time.

III. On immersion of a water-saturated hydrated cement paste specimen in aqueous 1.0 N HCl solution, monotonous expansion was observed until nearly complete disintegration. The dimensional change versus time of contact plot (Fig.5) is very similar to that of Fig.4, although there are some differences. The magnitude of the expansion is about one third that of the glass-NaOH system. The curve is slightly convex rather than somewhat concave, as in the previous case, and the dissolution occurred after 10.6 instead of 82 h of contact time.

Fig.5 - Length changes of a hydrated cement paste specimen (W:C = 0.5), immersed in 1.0 N aqueous HCl, as a function of time.

IV. Calcium hydroxide can be leached from portland cement paste with ethylene-glycol (9). The concomitant length changes associated with leaching a water-saturated hydrated neat cement specimen (W:C = 0.6) are shown as a function of time in Fig.6.

An over-all expansion of  $110 \times 10^{-5} \Delta L/L$ , with respect to the fully water-saturated state, took place after approximately 800 h of leaching at room temperature.

An unusual feature of the curve is the fairly substantial contraction,  $-26 \times 10^{-5} \Delta L/L$ , recorded in the first 5 h following replacement of water with ethylene glycol.

Very recently, Midgley (10) reported that ethylene glycol leached out the free lime in cement paste and also attacked the calcium bearing phases. These findings have to be kept in mind when considering the implications of the present results.

#### DISCUSSION

Although expansion of active carbon on adsorption from solution was observed by Pawlow (11) over 50 years ago, it appears that a detailed extension

isotherm has not been reported until now and its existence was not really expected. It is surprising that on immersion in  $\text{NaNO}_3$  solution the glass specimen expanded  $25 \times 10^{-5} \Delta L/L$  units beyond the length it reached on complete saturation with water (Fig.2). This expansion is about half as much as that which takes place when dry glass becomes 80% saturated with water (see Fig.3, sections A to C).

The relatively large effect of an inorganic salt on dimensions is even more significant in view of the well-documented phenomenon of salt rejection (12,13). In fact, the adsorption isotherm for water on porous silica glass containing various amounts of NaCl strongly suggests that salt is excluded from the first monolayer (13,14). The length changes observed in the present work seem to be due to concentration changes of the liquid held in the centre of the capillaries, separated by at least one water layer from the glass surface. Further marked decrease in length as the  $\text{NaNO}_3$  concentration increased beyond 1 mole/l may be caused by decrease in adsorption in the vicinity of the surface, as has been reported by Mukerjee and Anavil for the ionic surfactants-porous glass system (14).

The pronounced hysteresis of the  $\text{NaNO}_3$ -glass isotherm (Fig.2) indicates that on traversing the concentration region that extends from pure water to saturated solution, length changes were probably caused by more than a mere change in the concentration, or by the structure of the ionic double layer on the surface. The length in pure water is greater by approximately  $50 \times 10^{-5} \Delta L/L$  after the run. This is a preliminary value only, subject to change when equilibrium will have been reached. The possibility that irreversible change was caused by corrosion of the substrate must also be considered.

Fig.6 - Length changes of a hydrated cement paste specimen (W:C = 0.6), immersed in ethylene glycol, as a function of time.

The similarity of curves obtained on the dissolution of porous glass in NaOH and hydrated cement paste in HCl in the first instance, and on leaching of porous glass in acid and cement paste in ethylene glycol in the second, suggests that the reported results are of general validity. For the purpose of this discussion, this hypothesis will be accepted and some very brief comments concerning the implications for hydrated cement will be made.

The very large expansion during complete dissolution is an important factor with regard to an explanation of the mechanism of volume expansion due to chemical attack. Osmotic pressure, crystallization pressure, and mechanical pressure exerted by the volume requirement of the reaction product, which is greater than the space available, plus gel formation followed by water adsorption have all been suggested as causes of volume expansion of cement on chemical attack. It is fair to say, however, that none of these theories is entirely satisfactory.

In searching for understanding of the causes of volume instability of porous solids under chemical attack the solid matrix itself has not been considered responsible for volume change, but was assumed to expand passively in response to an internal pressure generated in the void space (e.g. crystallization or osmotic pressure). The present results, although preliminary, clearly indicate that changes occurring on the surface - whether sorption of inert ions or dissolution of either a constituent of a non-homogeneous matrix or a portion of the entire solid - result in expansion of a magnitude that induces cracking. It appears that such alteration of the surface energy is sufficient for the disjoining pressure to become dominant. If correct, this assumption offers a simple, credible and unified explanation of a number of deterioration processes leading to excessive volume instability and cracking.

#### ACKNOWLEDGEMENT

The author is indebted to H. Schultz for carrying out the experimental work.

# Studies on unsoundness of clinker with below 3.5 percent MgO content

*Etudes sur le manque de solidité d'un clinker d'une teneur en MgO inférieure à 3,5 pour cent*

S.K. CHOPRA, K.C. NARANG, S.P. GHOSH and  
K.M. SHARMA, Cement Research Institute of India, New Delhi, India.

**RÉSUMÉ** Bien qu'il y ait différents points de vue sur les limites admissibles de teneur en MgO des ciments, la limite maximale permise par les spécifications internationales sur le ciment portland ordinaire est de 6 pour cent. Par ailleurs, les chercheurs sont généralement d'accord sur le fait que les clinkers ayant une teneur en MgO de 3,5 pour cent ou moins ne manqueront pas de solidité. Cependant, dans certains cas exceptionnels, les clinkers ayant une teneur en MgO inférieure à 3,5 pour cent ont manifesté un manque de solidité, et la présente communication rend compte des recherches sur les causes du manque de solidité de ces clinkers. Des études sur des clinkers de laboratoire, spécialement préparés et ayant une teneur en MgO de moins de 3,5 pour cent ont montré qu'en plus de la finesse du mélange cru, du ciment définitif et des conditions de refroidissement, plusieurs autres paramètres tels que la teneur en C<sub>3</sub>A, la morphologie et la microstructure des phases du clinker jouent un rôle important dans l'expansion autoclave des ciments. La corrélation entre le manque de solidité des clinkers, c'est à dire l'expansion autoclave, et leurs propriétés minéralogiques microstructurelles et autres propriétés physico-chimiques a fait l'objet d'une étude. Certaines directives pour prévoir le caractère peu solide du clinker sur la base des propriétés physico-chimiques et minéralogiques des clinkers sont aussi proposées.

**SUMMARY** : Although there are different opinions about the permissible limits of MgO content in cements, the maximum which is permitted in some of the world standard specifications on ordinary portland cement is 6 percent. Also, there is general agreement amongst the researchers that clinkers having MgO content of 3.5 percent or less will not be unsound. However, in certain exceptional cases clinkers having MgO content below 3.5 percent have shown unsoundness and this paper reports the investigations on the causes of unsoundness in such clinkers. Studies on specially prepared laboratory clinkers with less than 3.5 percent MgO content have indicated that in addition to the fineness of the raw mix, final cement and the conditions of cooling, several other parameters, such as C<sub>3</sub>A content, morphology and microstructure of clinker phases also play a significant role in causing autoclave expansion in cements. The inter-relations between unsoundness of clinkers i.e., autoclave expansion, and their mineralogical, micro-structural and other physico-chemical characteristics have been studied. Certain guidelines for predicting unsound character of clinker on the basis of physico-chemical and mineralogical properties of clinkers have also been suggested.

## INTRODUCTION

While it is generally understood (1,2,3) that the autoclave expansion in clinkers with MgO content higher than 5% suddenly jumps to higher values, a paradoxical situation prevails as some clinkers with higher MgO content ( $>5\%$ ) are observed to be sound and on the other hand clinkers with MgO content much below this level show unsoundness ( $>0.8\%$  autoclave expansion). Number of reports (2,3,4) have appeared dealing with unsoundness of high magnesia ( $>5.0\%$ ) clinkers but a few deal (5,6,7) with problems facing some of the plants where at times clinkers with lower MgO content show autoclave unsoundness. This cannot be straightforwardly explained either on the basis of level of MgO content,  $SO_3$  or alkali content which generally are of the same magnitude or even  $C_2A$  content which on the average ranges between 5 and 12 percent in the Indian clinkers.

Studies on some commercial clinkers and specially prepared laboratory clinkers were therefore taken up to examine the unsound behaviour in low MgO clinkers and to determine the relative importance of different factors responsible for autoclave unsoundness. Based on these studies, a hypothesis which could explain the causes of unsoundness in low MgO clinkers, is proposed.

**Experiments:** The occurrence of expansive constituents and their physical state is directly governed by the properties of raw materials, raw mix fineness, burning and cooling schedule etc (8). While the influence of these parameters is known for the manufacture of high MgO clinkers, experiments were designed to study their influence in the manufacture of lower MgO content clinkers. Raw mixes with following potential phase composition were planned and studied in 2 series of experiments:  $C_2S \approx 45$  and  $\approx 55$  percent;  $C_3A \approx 7-8\%$ ,  $10-14\%$  and  $14-15$  percent;  $MgO \approx 0.2$ , 1, 3 and 4 percent.

**Series 1** Raw mixes with three different levels of fineness i.e. 1, 3% on 72 mesh sieve and 10% on 170 mesh sieve were prepared and their potential phase composition varied in terms of MgO content (1 and 3%) and  $C_3A$  level (7-15%). The mixes were fired in a laboratory kiln at  $1450^\circ C$  and cooled under normal ambient conditions.

**Series 2:** Raw mixes with different potential phase composition were fired at  $1450^\circ C$  for same retention time and subjected to two different cooling rates:

- a) Clinker removed from furnace at  $1450^\circ C$  and cooled to ambient temperature (rapid cooling);
- b) Clinker cooled in the furnace at the rate of  $8-10^\circ C/min$  upto  $1100^\circ C$  and cooled in air to ambient temperature (slow cooling)

Clinkers obtained for series 1 and 2 were examined using standard analytical, XRD and microscopic techniques. Cements prepared from these clinkers (with optimum  $SO_3$  content and fineness  $3000 cm^2/g$ ) were studied for their expansion and strength characteristics. The autoclaved cement pastes were examined by XRD, IR spectroscopy, electron and optical microscopy for determining the nature of autoclaved products.

**Series 3:** Mineralogical, physical & microstructure properties of two unsound commercial clinkers with MgO content below 5 percent were also examined. Cements were prepared at various fineness levels ( $2250-5000 cm^2/g$ ) to investigate the influence of

fineness of cement on autoclave expansion in these two clinkers.

## Results and Discussions

**Series 1: Effect of fineness of raw mix:** In addition to the mineralogical composition, the reactivity of the raw mix components is known (8) to be significantly influenced by homogeneity and fineness. It is reported that not more than 0.5 percent of silica particles above 0.2mm size and 5 percent calcite particles above 0.15mm size should generally be present in high LSF (0.95) mixes. For raw mixes of lower LSF value, relatively higher proportions of coarse particles can, however, be tolerated. The rate of reaction is greatly affected by grain size which in turn affects the formation and distribution of alite, belite and minor phases in them. For our studies raw mixes with LSF 0.89-0.95 have been used as shown in Table 1:

Table 1: Properties of Raw Mixes

Raw Mix No.	HM	AM	LSF	SM	Clinker No
1	1.96	1.55	0.90	1.84	1, 2 and 3
2	1.89	1.10	0.91	1.58	4, 5 and 6
3	2.06	1.58	0.89	2.81	7 and 8
4	2.02	2.44	0.93	1.81	24
5	1.99	1.46	0.90	2.08	28
6	1.90	1.74	0.91	1.50	30
7	2.08	3.0	0.91	2.33	32
8	2.16	1.48	0.95	2.44	33
9	2.17	2.23	0.95	2.50	34

Results in Table 2A show that mineral composition of clinkers in series 1 appears to be close to the potential, phase composition except for clinker 3 and 6 which have been prepared from raw mixes with 10% residue on 170 mesh sieve. Clinker 3 and 6 have also shown a tendency to dust on cooling and storage due to conversion to  $C_2S$  phase. Free lime content of all the clinkers was found to be low and as a result all the clinkers passed the Leebateller expansion test (expansion  $<10mm$ ).

Optical microscopic studies also show that except clinker 3 and 6, all other clinkers in the series have well developed alite and belite grains, alite being predominantly in hexagonal shape and almost free from belite inclusions. Intergranular alite and belite assemblage, is also rare. The interstitial phase occurs as ground mass preferably around  $C_2S$  grains. Presence of periclase crystals in clinkers with MgO content  $>1\%$  is largely observed & wherever observed occasionally varies in 2-6  $\mu$  size range. In clinkers with MgO content  $\approx 3\%$  the size of periclase is of the order of 4-12  $\mu$ . XRD lines for major phases do not show any significant shift thus indicating that formation of normal phases has occurred in clinkers of series 1.

Results in Table 2B show good development of strength of cements made from clinkers of series 1 which are also affected by change in raw mix fineness. Cement 3 and 6 which show overall poor strength are also the cements observed to be poor

Table 2A : Effect of fineness of raw mix on clinker composition and autoclave expansion - Series 1

in C<sub>3</sub>S content. Lechatelier expansion, autoclave expansion and setting time characteristics have not been affected directly and all the cements are observed to be sound in autoclave test.

#### Series 2 : Role of C<sub>3</sub>A, MgO content in clinkers and effect of cooling rates:

From the results in Table 3A it can be observed that neither the level of C<sub>3</sub>A nor the cooling rate of clinkers with 1% and below MgO content is decisive for soundness of clinkers as both the rapid and the slowly cooled clinkers are observed to be sound. Lechatelier expansion of all the clinkers was found to be below 2mm eliminating thereby the effect of free lime and SO<sub>3</sub> contributions to autoclave expansion. The effect of C<sub>3</sub>A content becomes however, apparent for clinkers with MgO level about 3% in which case the autoclave expansion increases suddenly for slowly cooled clinkers with high C<sub>3</sub>A content. While clinkers with about 7% C<sub>3</sub>A and 3% MgO levels are observed to be sound, clinkers with 15% C<sub>3</sub>A and 3% MgO become unsound in autoclave test. These results lead to conclusions that rapidly cooled clinkers allow high MgO content compared to slowly cooled clinkers and this tolerance of MgO in slowly cooled clinkers decreases with increasing C<sub>3</sub>A content. This is further supported by the data in Table 3A, as the slowly cooled clinkers with MgO content  $\approx$  4% are observed to be unsound at all levels of C<sub>3</sub>A (> 7%) even when C<sub>3</sub>S content is maintained as high as 56%. A direct application of these results in India could be that in plants where cooling rates are likely to be rather slow and MgO content in raw materials relatively higher, a lower alumina

modulus of raw mix may be designed in order to obtain sound clinkers.

The data in Table 3B show that among the three parameters i.e. C<sub>3</sub>A, MgO and rate of cooling the last has more significant effect on strength characteristics. Slowly cooled clinkers show invariably poor strength development. Comparatively lower strengths of slowly cooled clinkers is more significant at 28 days age. The drop in strength is also affected by C<sub>3</sub>A level as when it is high in clinkers, the drop in strength is maximum.

#### Microstructure of sound and unsound clinkers:

Rapidly cooled clinkers with upto 4 percent MgO and 15 percent C<sub>3</sub>A content show good granulometry and are characterised by idioblastic C<sub>3</sub>S and C<sub>2</sub>S grains in separate clusters. Sizes of C<sub>3</sub>S grains range from 4-18 $\mu$  for smaller grains and 40-80 $\mu$  for larger grains. Prismatic elongated grains of C<sub>3</sub>S are predominant (Fig 1 and 2). C<sub>2</sub>S grains range between 4-16 $\mu$  for smaller and 40-75 $\mu$  for larger grain. Ferrite and aluminates phase is evenly distributed between both C<sub>3</sub>S and C<sub>2</sub>S. MgO inclusions are fairly uniform and vary in size range between 12-16 $\mu$  in C<sub>3</sub>S and 4-12 $\mu$  in C<sub>2</sub>S, on average being >10 $\mu$  in size.

Slowly cooled clinkers are distinctly poorer in granulometry, have relatively more and larger inclusions specially of MgO grains. Cluster formation, large crystal growth and instability of phases appear to be the main features of these clinkers. C<sub>3</sub>S grains are larger 40-120 $\mu$  and

have less defined boundaries. Periclase grains vary in 5-25 $\mu$  size range.  $C_2S$  grains are also relatively larger (35-90 $\mu$ ) and mostly irregular in shape. MgO inclusions are present frequently in liquid phase as periclase crystals ranging in size from 20-25 $\mu$  (Figs 3 and 4).

From all the above results it appears that sudden increase in autoclave expansion of slowly cooled clinkers may be due to differential rate of hydration of alite/belite and periclase crystals. In rapidly cooled clinkers which are characterised by small grains of alite as also of periclase, the strength development appear to be faster due to hydration of alite & the structure of cement paste can accommodate the expansion of periclase which itself is finely and uniformly divided. On the other hand in slowly cooled clinkers, the larger grains of alite/belite appear to hydrate rather slowly and hence show poor strength development. The structure of cement paste in this case appears to be unable to contain the expansion due to periclase hydration which is also not uniformly distributed. This hypothesis also seems to be supported by the results in Table 4 which shows that periclase quantity alone can not explain the unsound behaviour of slowly cooled clinkers. Results of IR spectroscopy, electron microscopy (Fig 5) and XRD studies on autoclaved products of various clinkers also support the observations. Fig 6 shows a clear brucite peak at 3700  $cm^{-1}$ , the intensity of which increases with larger MgO and  $C_3A$  content in clinkers. XRD studies of autoclaved products also show similar pattern.

### Series 3: Effect of fineness of cement on unsoundness

Table 5 shows the physicochemical and mineral characteristics of two commercial clinkers with MgO content lower than the permissible limit of 6%. Various studies including XRD and optical microscopy investigations show that these clinkers are characterised by low free lime, high large size alite, high periclase content and very poor granulometry (Fig. 7) Autoclave expansion of cements of normal fineness (3000 cm<sup>2</sup>/g) is observed to be very high. The data also shows that the autoclave expansion of these clinkers can be reduced significantly by increasing fineness, so much so that one of the clinker becomes sound (<0.8% expansion) (Fig.8). Refiring of these clinkers followed by rapid cooling also renders the clinkers sound. In general the two clinkers show characteristics of slowly cooled clinkers.

Fig 5: Scanning Electron microphotographs of autoclaved cement paste of (a) sound and (b) unsound clinkers.

#### CONCLUSIONS

Amongst the different factors responsible for the manifestation of autoclave unsoundness in low MgO clinkers,  $C_3A$  content, rate of cooling and granulometry of clinkers have been found to be the more important parameters. Unsound clinkers prepared in the laboratory were found to be characterised by unevenly distributed larger than usual alite and periclase crystals inspite of total MgO content being less than 4%. These clinkers are also characterised by relatively poorer strength development when compared with sound clinkers. The sudden jump in autoclave expansion may be explained on the basis of hydration characteristics of various phases in particular the alite and periclase grains. Alite particles being larger and more ordered in slowly clinkers, appear to hydrate slowly and result in poor strength development under autoclave conditions which is not sufficient to contain the expansion due to hydration of periclase and thus resulting in failure in the soundness test (autoclave expansion 0.8%). On the other hand small size and disordered alite in rapidly cooled clinkers hydrates rapidly to develop good strength to contain the periclase expansion and may accomodate expansion, even when MgO content in clinkers is upto the maximum permissible limit (6%).

The occasional unsoundness in commercial clinkers with MgO content below permissible limit can also be ascribed due to these reasons in addition to the presence of large size periclase crystals in such clinkers. However, in such cases fineness of the ground cement also becomes an overriding parameter because it reduces the size of both the alite and periclase grains as is evident from the fact that one of the clinkers becomes sound when ground to a particular fineness. For situations in plants where such occurrence is likely, either the rate of cooling or the raw mix properties should be adjusted so as to achieve a microstructure in clinkers which allows the formation of small sized alite grains only, alternatively in clinkers where microstructure of the desired granulometry is not obtained, grinding the clinkers to higher fineness could be adopted as an effective measure to obtain sound cement.

# Mechanisms and Kinetics on Neutralization of Concrete in Sea Water

## *Mécanisme et cinétique de la neutralisation des bétons dans l'eau de mer*

T. AKIBA, Senior Research Chemist,  
K. MINEGISHI, Dr. Eng., Chief Research Chemist, and  
G. SUDOH, Dr. Eng., Manager of Research Department, Chichibu Cement Co., Ltd, Japan.

**SUMMARY :** Concrete structure in sea water suffer attack owing to the chemical reaction between cement components, either unhydrated or hydrated, and dissolved salts. Studies were made on mechanisms of sea water attack, mainly in relation to kinetics on neutralization of hardened concrete.

The rate of neutralization can be expressed as  $L^2 = k_e (t - t_i)$  in the first approximation, where  $L$  is the neutralized depth,  $k_e$  the neutralization rate constant experimentally obtained,  $t$  the time of immersion, and  $t_i$  the induction period. The above equation suggests that the rate determining process of neutralization in sea water is diffusion process.

Chemical reaction by sea water attack is assumed to occur at a boundary which corresponds to the neutralized depth. Thus, we can apply the following equation:

$$k_t = \frac{2D\epsilon\Delta C}{C_0 \xi} = f k_e$$

The rate constant of neutralization is calculated in consideration of the material transfer of Cl ion. In consideration of the magnitude of the  $f$  value, the above rate equations seem to be reasonable and applicable to the practice.

**RESUME :** En eau de mer, les ouvrages en béton sont soumis à des attaques dues à des réactions chimiques entre les constituants, hydratés ou non, de leur ciment et des sels dissous dans l'eau de mer. Des études ont été entreprises sur le mécanisme de cette attaque de l'eau de mer, principalement sur la cinétique de la neutralisation du béton durci.

En première approximation, la vitesse de la neutralisation peut être représentée par la formule :  $L^2 = k_e (t - t_i)$  où  $L$  est la profondeur neutralisée,  $k_e$  une constante qui est déterminée expérimentalement,  $t$  le temps d'immersion, et  $t_i$  le "temps de latence".

Cette équation suggère que le processus de neutralisation du béton dans l'eau de mer est un phénomène de diffusion.

La limite de la zone atteinte par la réaction chimique de l'attaque par l'eau de mer correspond à la profondeur neutralisée. Nous pouvons alors appliquer l'équation suivante :

$$k_t = \frac{2 D \cdot \epsilon \cdot \Delta C}{C_0 \xi} = f \cdot k_e$$

La constante de la vitesse de neutralisation est calculée en fonction de la diffusion des ions Cl. Compte tenu de l'importance de la valeur  $f$ , les équations ci-dessus sont applicables, raisonnablement, dans la pratique.

## INTRODUCTION

Studies on the durability of cement mortar and concrete in sea water have been made mainly in connection with the resistivity of cement hydrates and corrosion of reinforcing steel. Sea water attack which seems to be unavoidable on hardened cement is regarded as an example of the reaction of porous solid with gas or liquid which diffuses into the former.

One of the authors (1)(2) has studied the rate of neutralization of cement mortar in relation to the carbonation mechanisms, and found a relationship between the rate and the pore structure.

In a similar way, studies were made on sea water attack to make clear the mechanisms and kinetics. In this experiment, the degree of sea water attack, penetration rate of Cl ion, neutralized depth and pore size distribution of concrete were measured and the rate of neutralization due to sea water attack were discussed.

## SEA WATER ATTACK AND NEUTRALIZATION

There are many causes affecting the durability of concrete in sea water, such as the chemical action of dissolved salts, the crystallization of salts within the concrete under condition of alternate wetting and drying, the frost action, the mechanical attrition and impact by waves, the bacterial oxidation and the corrosion of reinforcement embedded in it.

It is considered that the stability of concrete depend on three factors: denseness, cement content and chemical resistance of the cement hydrates to sea water.

Many investigations on sea water attack of hardened cement studied by tricalcium aluminate and lime content in relation to the expansive crystallization of ettringite due to the presence of sulfate, however recently some studies (3)(4) have been made on the influence of Cl ion on cement products. R. Kondo et al. (5) have studied the rate of diffusion of various ions in cement paste and showed the importance of the rate of neutralization on hardened cement in relation to the corrosion of reinforcing steel.

Neutralization of concrete is important phenomenon not only on resistivity of cement hydrates but on the corrosion of reinforcing steel. The corrosion rate indicated is proportional to the diffusion of oxygen on steel surface in the presence of the corrosive

medium. The final result of the corrosion process is the formation of a thick rust layer which exerts sufficient tensile forces within the concrete to crack and cause spalling of the concrete cover.

In an alkaline solution, such as the calcium hydroxide solution in set cement, a protective oxide film forms over the steel. The stability of the film depends on the maintenance of certain minimum pH value, 10.5(6).

Thus the rate of neutralization should be taken into account. In the later part of this paper, it will be discussed in relation to pore structure.

## EXPERIMENTAL

To examine the durability of concrete in sea water, long time soaking test was started at 1973, and five years test was carried out. In this report, studies were made on the mechanisms of sea water action mainly in connection with the neutralization.

In this experiment, ordinary portland cement (O), moderate heat portland cement(M) and sulfate resisting cement(S) as shown in Table I were used in comparison, and the mix properties of concrete are given in Table II.

The size of the specimens molded is  $\phi 15 \times 30$  cm. After being cured in water for 7 days, the specimens were soaked in sea water at tidal zone or the place in which tidal action was excluded for selected times of exposure. Chemical composition and some properties of the sea water are shown in Table III.

After the compressive strength measurement, each exposed specimen was cut perpendicular to the length with a diamond cutter and the penetration depth of Cl ions was determined with colorimetric method (7), then the neutralization depth was determined with 1% phenolphthalein solution.

Some of the sea water attacked specimens were sliced perpendicular to the direction of penetration. And samples of surface part and inner part were crushed for such tests as the quantification test by X-ray diffraction, chemical analysis containing water soluble Cl ion and IR.

The pore size distribution of mortar parts separated from several specimens were also measured with a mercury pressure porosimeter.

## RESULTS

Table I Chemical analysis of cement used

		Composition (%)							
		ig-loss	insol	SiO <sub>2</sub>	Al <sub>2</sub> O <sub>3</sub>	Fe <sub>2</sub> O <sub>3</sub>	CaO	MgO	SO <sub>3</sub>

#### Degree of Sea Water Attack

The writers (8) reported on the chemical resistivity of cements in sulfate solutions and artificial sea water, and found a relationship between the amount of C<sub>3</sub>A and deterioration. In this experiment, the difference in cements on compressive strength measurement seem to have no significant effect.

Fig. 1 shows the x-ray diffraction intensity of ordinary portland cement concrete soaked at tidal zone in relation to the depth in specimens and the soaking time.

The amount of calcium hydroxide decreases in the surface layer after 3 years immersion, and gradually decreases in inner parts.

Hydrated chloroaluminate (Fridel's salt) is found at the 7 cm depth on the 3 years soaking specimen, and decreases in later stage.

In the case of the investigation about the low C<sub>3</sub>A content cements, similar results to the O<sub>2</sub> cement as illustrated in Fig. 1 are obtained.

The exact consideration in relation to sea water action will be discussed separately.

Fig. 2 Pore size distribution of specimens exposed for 1 year

— : showing the ascending  
 --- : showing the descending  
 shaded : showing the C.P.V.

### Pore Size Distribution

The determination of pore size distribution is useful in consideration of the mechanism of sea water attack on set cement.

The pore size distribution of O and S cement concrete immersed for 1 year at tidal zone are shown in Fig. 2.

The measurement of pore size distribution by mercury pressure porosimeter based on the model of cylindrical pores, but hysteresis in mercury porosimetry is due to the existence of the ink-bottle pores. Such a pore consists of a big cavity connected with the remaining pore system by a narrow neck.

In this experiment, the Reverberi method (9) which utilizing the difference between the ascending and descending branches of the curve for evaluating the broad and narrow part of the pores independently, was applied on hardened cement.

One of the authors (2) has studied the through pore size distribution determined by back diffusion and applied to the rate of neutralization by carbonation reaction.

In Fig. 2, T.P.V. shows the total accessible pore volume calculated by ascending branch and Retention means the volume of mercury by descending way. C.P.V. shows the cylindrical pore volume which seems to be comparable with the through pore.

Fig. 3 Pore size distribution of specimens exposed for 5 years

In the case of the determination of micro through pore under  $0.1 \mu\text{m}$  diameter, the measurement by mercury porosimeter is superior to gas diffusion determination on account of the reason that the latter can not determine the pore size distribution of micro through pore under  $0.1 \mu\text{m}$  diameter.

The pore size distribution of specimens cured for 5 years are illustrated in Fig. 3. By the reaction of sea water attack, the pore structure of hardened cement is affected and the great difference is the increase of large accessible pores which seems to be due to the leaching of calcium hydroxide. The increase in O cement is slightly greater than in S cement.

#### Penetration Rate of Cl Ions

The penetration of calcium chloride were studied in connection with de-icing agents in cement, and it was found that the phenomenon was governed by diffusion process (7). We studied the rate in relation to the rate of neutralization and the corrosion of steel.

The penetrated depth of Cl ions in concrete are shown in Fig. 4. The linear plot of depth as a function of  $\sqrt{t}$  supports the rate determining process is diffusion. The value of diffusion coefficient of O1, O2, S1 and S2 are  $2.2, 3.5, 2.5$  and  $9.2 \times 10^{-8} \text{ cm}^2/\text{sec}$  respectively. These values are about thousand times smaller than the diffusion coefficient of chloride ion in water as mentioned in other papers (5)(7)..

The chemical reaction of chloride with hydrates and the interaction between the surface and diffusing ions could be responsible for the decrease in the diffusion coefficient of chloride. The reason that the value of S cement is greater than other cements also could be considered in view of above mentioned and the difference of C.P.V..

Fig. 4 Relationship between penetrated depth of chloride and time

In this experiment, the corrosion of steel embedded in 5 cm depth was not observed even at 5 years test.

#### Neutralization Rate of Concrete

The neutralization rate of the specimens are illustrated in Fig. 5.

The rate of neutralization can be expressed as  $L = k(t - t_i)$ , in the first approximation where  $L$  is the neutralized depth,  $t$  is time,  $t_i$  is induction period and  $k$  is a constant. Therefore the value  $k$  shows the ease of neutralization.

The difference in cements seems to have no significant effect. The water-cement ratio shows the greatest effect. The values of the rate constant of each specimens are compared in Table IV.

In this experiment, the difference in exposed places was not observed.

Fig. 5 Relationship between neutralized depth and time

#### DISCUSSION ON THE RATE OF NEUTRALIZATION

##### Induction Period in Neutralization

Neutralization does not occur immediately even on the surface which is in direct contact with sea water. The length of the induction period varies with the water-cement ratio of specimen, and in the case of  $W/C = 0.65$  and  $0.5$ , the length of the induction period are 1 year and 2 years respectively. These differences occur depending chiefly on their pore structure and the rate of chemical reaction of pore surface between cement hydrates and sea water components.

##### Rate Equation on Neutralization

The rate of neutralization of various

specimens are shown in Fig. 5. In the first approximation, the rate can be expressed by the equation,

$$L^2 = k_e (t - t_1) \quad (1)$$

where

$L$  is the neutralized depth

$t$  is the soaking time

$t_1$  is the induction period

$k_e$  is the neutralization rate constant experimentally obtained

The equation suggests that the rate determining process is diffusion, because this type of equation can be derived when the rate of reaction controlled by diffusion as shown in the former study (1).

Nevertheless the boundary between the two parts, neutralized and unneutralized, can not be clearly distinguished, the chemical reaction by sea water attack is assumed to occur at the boundary, and the concentration of chloride in solution is zero at the boundary. Thus, we can apply the following equation,

$$k_t = \frac{2D\xi AC}{C_s \rho} = f \cdot k_e \quad (2)$$

where

$D$  is the diffusion constant of  $Cl$

( $1.763 \times 10^{-5} \text{ cm}^2/\text{s}$ )

$AC$  is the difference of concentration of  $Cl$

( $4.8 \times 10^{-4} \text{ mol/cm}^3$ )

$\xi$  is the porosity of the specimen ( $\text{cm}^3/\text{cm}^3$ )

$C_s$  is the amount of free calcium hydroxide

( $\text{mol/g mortar}$ )

$\rho$  is the density of the mortar ( $\text{g/cm}^3$ )

$k_t$  is the theoretical neutralization rate constant

$f$  is the tortuosity

#### Rate Constant of Neutralization

The rate constant of neutralization is calculated in consideration of the material transfer of  $Cl$  ions, and the calculated values for specimen O1, O2, S1 and S2 are shown in Table IV.

As for the value of  $\xi$ , C.P.V. ( $\xi_c$ ) were adopted. The amount of calcium hydroxide assumed the reactant is calculated based on the result that the cement paste contains 0.22g calcium hydroxide on ignited sample. The value is multiplied by 2 because of the molar ratio correction.

Table IV Rate constant and tortuosity

	O1	O2	S1	S2
$Co_p$	$3.16 \times 10^{-4}$	$2.42 \times 10^{-4}$	$3.08 \times 10^{-4}$	$2.38 \times 10^{-4}$
$\xi_c$	0.0024	0.0093	0.0065	0.0104
$k_e$	$2.1 \times 10^{-9}$	$4.8 \times 10^{-9}$	$2.1 \times 10^{-9}$	$4.8 \times 10^{-9}$
$k_t$	$1.3 \times 10^{-8}$	$6.5 \times 10^{-8}$	$3.6 \times 10^{-8}$	$7.4 \times 10^{-8}$
$f$	6.1	14	16	15

In consideration of the magnitude of the  $f$  value which is empirically expected to be in the order of 10, the equation seems to be applicable to the neutralization of hardened cement in sea water.

#### CONCLUSION

In this report, the rate of neutralization of concrete in sea water was studied in relation to the pore structure, and it is found that the equation (1) and (2) seem to be applicable in practice.

The rate constant of neutralization in sea water is  $2.5 \times 10^{-9} \text{ cm}^2/\text{s}$  and it is interesting that the value is similar to the rate constant of neutralization by carbonation measured by Hamada;  $4.3 \times 10^{-9} \text{ cm}^2/\text{s}$  (10).

# Orientation des hydrates au contact des granulats

## *Orientation of hydration products near aggregate surfaces*

J. GRANDET, Professeur,

J.P. OLLIVIER, Maître-Assistant

I.N.S.A., Département de Génie Civil - Université Paul Sabatier, Toulouse, France.

RESUME : La croissance orientée des cristaux de Portlandite dans l'auréole de transition qui entoure les granulats du béton y favorise la propagation des fissures et influe sur les résistances mécaniques. Nous avons étudié l'orientation des cristaux de  $\text{Ca}(\text{OH})_2$  dans la pâte de ciment Portland durcissant contre différents supports (quartz, calcaires, polyéthylène). Nous avons réalisé des enregistrements diffractométriques X sur des sections de pâte parallèles à l'interface pâte-support, et tracé sur les courbes  $I = f(\log d)$ .  $I$  est un indice d'orientation qui prend une valeur supérieure à 1 lorsque le cristal est orienté et  $d$  la distance entre le plan d'analyse et l'interface pâte-support. Jusqu'à une distance  $d_0$  du support appelée limite d'orientation,  $I$  est supérieur à 1 et  $I = f(\log d)$  est représenté par une droite. Au-delà de  $d_0$ , on n'observe plus d'orientation préférentielle.

Parmi les paramètres étudiés, nous montrons que la limite d'orientation des cristaux de Portlandite dépend de la quantité d'eau de gâchage :  $d_0$  augmente avec E/C.

La pente de la droite  $I = f(\log d)$   $\{d < d_0\}$  dépend, parmi les paramètres étudiés :

- de la nature du support ;
- de l'âge des éprouvettes ;
- de l'hygrométrie de conservation.

Cette pente caractérise l'aptitude des granulats à orienter les cristaux de Portlandite et la croissance de cet hydrate sur les germes déjà existant.

SUMMARY : The oriented growth of Portlandite crystals in the interfacial zone around aggregates, allowing the evolution of hair-cracks, influences the mechanical resistance. In this paper, we study the orientation of  $\text{Ca}(\text{OH})_2$  crystals in Portland cement paste hardening with different aggregates (quartz, polyethylene, limestone). Successive sections of cement paste parallel to the contact interface are studied by X-ray diffraction. The curves  $I = f(\log d)$  are then plotted ; where  $I$  is an orientation index which is greater than 1 when the crystal is oriented,  $d$  is the distance between the contact interface and the analysed section. It is obvious that  $I$  is greater than 1 at the distance up to  $d_0$ , so-called the limit of orientation, and  $I = f(\log d)$  is represented by the straight lines. Beyond the distance  $d_0$ , the Portlandite crystals have no particular orientation.

Among parameters studied, it is shown that the orientation limit of Portlandite crystals depends on the amount of mixing water :  $d_0$  increased with E/C ; the slope of curves  $I = f(\log d)$ , for  $(d < d_0)$ , depend on :

- the nature of aggregate ;
- the curing time ;
- the humidity of conservation.

This slope characterizes the aptitude of aggregates for the orientation of Portlandite crystals and the growth of this hydrate from the nucleus.

Dans un béton la croissance des cristaux de Portlandite à l'intérieur de l'aurole de transition qui entoure les granulats joue un rôle important dans la mesure notamment où la formation de couches cristallines orientées favorise la propagation des fissures et contribue à diminuer les résistances mécaniques. Nous avons montré, dans une autre communication à ce Congrès International de la Chimie des Ciments (1), qu'il était possible de caractériser cette orientation en déterminant par diffractométrie X, la variation de l'ordre cristallin et la limite  $d_0$  de la zone orientée dans la pâte, cette valeur  $d_0$  pouvant être considérée du point de vue de l'orientation comme la limite d'influence du granulat dans la pâte.

Nous rappelons brièvement le processus expérimental mis au point à cette fin. Des éprouvettes cylindriques sont confectionnées dans des moules en matière plastique de la manière suivante : le granulat cylindrique de diamètre 2 cm est poli sur une face, l'état de surface final étant obtenu avec du diamant de finesse 5  $\mu\text{m}$ . Dès la fin du polissage, la pâte de ciment est coulée sur cette face. Le ciment utilisé est du ciment Portland CPA 55 R (Norme N F P 15 - 301) dont les caractéristiques sont données dans le tableau I.

Composition chimique : (%)		Composition de Bogue (%)	
Insolubles	1,08	$\text{C}_3\text{S}$	55

Tableau I : Caractéristiques du ciment utilisé  
(CPA 55 R)

Les éprouvettes sont conservées dans l'air à  $20^\circ\text{C} \pm 0,2^\circ\text{C}$  et à humidité relative contrôlée. Après durcissement, les collages sont rompus et l'orientation de la Portlandite dans la zone de contact côté pâte est analysée en fonction de la distance  $d$ , plan d'analyse-face du granulat, par diffractométrie X.

Dans ce travail, nous appliquons cette méthode à l'analyse d'un certain nombre de paramètres susceptibles de modifier la croissance des cristaux de Portlandite : la nature du granulat, la quantité d'eau de gâchage, la durée et l'humidité relative de conservation. Au cours de ces essais, nous n'avons modifié ni la nature du ciment, ni la température de cure.

## I - RESULTATS EXPERIMENTAUX

Dans cette dernière partie, nous exposons l'influence des différents paramètres étudiés sur les courbes  $I = f(\log d)$ , en particulier sur la limite d'orientation  $d_0$  et sur la pente de la droite obtenue pour  $d < d_0$ . Nous analyserons la signification de ces grandeurs et leur variation dans une seconde partie.

### I.1 - Influence de la nature du granulat

Les paramètres constants ont les valeurs suivantes :

- E/C de gâchage = 0,29 liant : CPA 55 R ;
- conservation à  $20^\circ\text{C}$  et 100 % d'humidité relative ;
- durée de conservation = 1 jour ;

Les granulats utilisés sont :

- marbre de Mosset, grosseur moyenne  $\approx 2 \text{ mm}$  ;
- marbre de Calacata, grosseur moyenne des grains  $\approx 40 \mu\text{m}$  ;
- quartz de Montredon Labessonnie ;
- polyéthylène.

Avec ces granulats, la rupture se produit dans la pâte, l'épaisseur de la pellicule adhérent sur le support, généralement quelques micromètres, est mesurée par microscopie optique. L'orientation de la Portlandite, caractérisée par son indice  $I$  - rapport du quotient de l'intensité des raies (001) et (101) à la valeur 0,74 caractéristique de la désorientation statistique - varie dans la pâte en fonction de la distance  $d$  à l'interface selon les courbes de la figure 1.

Les différentes courbes  $I = f(\log d)$  correspondant aux divers granulats convergent toutes vers le point  $\{\log 40 \mu\text{m}, 1\}$ . Les cristaux de Portlandite restent donc orientés sur une distance de  $40 \mu\text{m}$ , comptée à partir de l'interface, ceci, quel que soit le granulat utilisé. Par contre, les pentes des courbes varient selon la nature des supports, ces derniers ayant donc une propension différente à orienter les cristaux de Portlandite.

Côté support, il est encore possible de déterminer l'indice d'orientation des cristaux de Portlandite par diffractométrie X, les valeurs trouvées sont très élevées (souvent supérieures à 50). Comme nous le

FIGURE 1 : Influence de la nature des granulats

montrons par ailleurs (1), celles-ci ne peuvent pas être portées sur la courbe  $I = f(\log d)$ , néanmoins, ce résultat permet de confirmer que dans le voisinage immédiat des granulats, les cristaux de CH croissent avec leur axe [001] perpendiculaire à l'interface.

#### I.2 - Influence du rapport E/C de gâchage

Les éprouvettes sont préparées avec du marbre de Calacata et conservées 3 jours à 20°C et 100 % d'humidité relative.

Les courbes  $I = f(\log d)$  obtenues avec différentes valeurs de E/C de gâchage sont représentées à la figure 2. Les limites  $d_0$  d'orientation de la Portlandite augmentent avec la quantité d'eau de gâchage. Les pentes des droites  $I = f(\log d) \{d < d_0\}$  restent identiques pour un granulat et un ciment donnés.

#### I.3 - Influence de la durée de conservation

Des éprouvettes analogues aux précédentes sont confectionnées avec une pâte E/C = 0,29 et des éprouvettes de marbre de Calacata. Conservées à 100 % d'humidité relative, elles sont rompues à différents âges.

Les courbes de la figure 3 représentent la variation de l'indice I en fonction de  $\log d$  : au cours du vieillissement des éprouvettes, la limite d'orientation  $d_0$  des cristaux de Portlandite n'est pas modifiée : par contre, la pente des droites  $I = f(\log d) \{d < d_0\}$  augmente avec l'âge. En outre, pour des durées de conservation supérieures à deux mois, la méthode d'analyse ne permet pas de déceler de modification de cette pente.

L'ordre des pentes des droites  $I = f(\log d) \{d < d_0\}$  observé à 1 jour avec différents granulats (marbre de Mosset, marbre de Calacata, quartz, polyéthylène) est conservé au cours du vieillissement des éprouvettes.

#### I.4 - Influence de l'humidité relative du milieu de conservation

Des pâtes de ciment gâchées avec E/C = 0,29 sont coulées sur des granulats de quartz et conservées 8 jours dans des atmosphères à 50, 75 et 100 % d'humidité relative.

Les courbes  $I = f(\log d)$  sont tracées après rupture

FIGURE 2 : Influence du E/C de gâchage

FIGURE 3 : Influence de la durée de conservation

des éprouvettes. Les droites obtenues (figure 4) convergent toutes vers le point  $\{\log 40 \mu\text{m}, 1\}$ , la limite d'orientation  $d_0$  n'est donc pas influencée par l'hygrométrie de l'ambiance de conservation ; par contre, la pente des droites  $I = f(\log d)$   $\{d < d_0\}$  augmente avec l'humidité relative.

## II - ANALYSE DES RESULTATS

Avant de proposer une analyse de ces courbes, il est utile de remarquer que l'indice d'orientation ne représente pas la quantité de Portlandite et de noter que des résultats analogues à ceux présentés sont obtenus lorsque les paramètres fixés varient : les valeurs absolues de  $d_0$  et de la pente des courbes peuvent alors être modifiées mais les sens de variation observés restent analogues à ceux indiqués précédemment.

Les courbes  $I = f(\log d)$  permettent de caractériser l'orientation des cristaux de Portlandite dans la pâte de ciment à la distance  $d$  du granulat. En-deçà de la limite d'orientation  $d_0$ , l'indice  $I$  varie et les modes de germination et de croissance des cristaux sont tels que  $I = f(\log d)$  est une droite. La pente de cette droite peut traduire deux phénomènes :

- l'aptitude des granulats à orienter les germes de Portlandite à leur contact ;
- la croissance en cours d'hydratation des cristaux de Portlandite sur ceux déjà existant.

Les résultats de la figure 1 montrent que la taille des grains et la nature minéralogique des granulats influencent l'orientation des cristaux de Portlandite formés à leur voisinage dans la pâte de ciment ; elle augmente lorsque les grains du support sont plus petits et quand sa surface est plus réactive. Il est peut-être possible d'expliquer ces résultats par le fait que la germination des cristaux d'hydrates se produit en priorité sur les défauts de la structure du support, en particulier sur les joints de grains. Par contre, lorsque le granulat réagit avec la pâte de ciment, la formation des couches orientées de Portlandite est perturbée par la libération d'ions et la constitution de composés intermédiaires qui en résultent. La nature des granulats n'affecte pas la limite d'orientation  $d_0$ , celle-ci n'étant fonction, parmi les paramètres étudiés, que de la quantité d'eau de gâchage.

La durée de conservation ne modifie pas l'ordre des pentes observé sur la figure 1 (marbre de Mosset, marbre de Calacata, quartz, polyéthylène). Ainsi, si si l'on admet que, pour un âge et une pâte donnés, la quantité de Portlandite à une distance  $d$  quelconque du granulat est la même, quel que soit la nature de celui-ci, les résultats que nous avons obtenus expliquent, en partie, les bonnes propriétés mécaniques des bétons de granulats calcaires (2) : la propagation des fissures à travers les cristaux de Portlandite y serait rendue plus difficile du fait de leur orientation plus faible.

FIGURE 4 : Influence de l'humidité relative de conservation

Les autres courbes correspondent à des modifications de l'état d'hydratation de la pâte. Lorsque cette hydratation est plus avancée du fait de l'augmentation de l'hygrométrie ou de la durée de conservation, la pente de la droite  $I = f(\log d) \{ d < d_0 \}$  augmente. Ainsi, à une distance de l'interface inférieure à  $d_0$ , l'orientation des cristaux de Portlandite augmente avec le degré d'hydratation. Ce résultat pourrait s'expliquer par le mode de croissance des cristaux sur des germes déjà existant. A cet égard, des essais complémentaires en microscopie électronique à balayage ont montré qu'au voisinage du marbre, la croissance de la Portlandite était de type dendritique selon des directions  $[u, v, o]$  (figure 5), ce qui entraîne un renforcement de l'orientation existant aux premiers âges.

### III - CONCLUSION

Nous avons montré que la pente de la droite  $I = f(\log d) \{ d < d_0 \}$  et la limite d'orientation  $d_0$ , traduisent de manière notable des différences de cristallisation de la Portlandite dans l'auréole de transition. Cette technique peut donc être utile à l'étude de l'influence des différents paramètres de composition et de cure sur le comportement mécanique des bétons et, par voie de conséquence, aider à indiquer dans quel sens il conviendrait d'agir sur les constituants et les conditions d'hydratation pour améliorer la liaison pâte de ciment-granulat.

# Effect of pozzolanic reactions on the mechanical properties of glass fiber reinforced cement

## *Les effets des réactions pouzzolaniques sur les propriétés mécaniques de ciment armé de fibres de verres*

S. OHSAWA, Officier de Technique, et  
R. KONDO, Dr. Professeur,  
Dept. Inorg. Matières, Faculté de Technologie Institut de Technologie de Tokyo, Japon.

**RESUME :** Pour diminuer l'alcalinité de la matrice ciment, dans le ciment armé aux fibres de verre et réduire ses dégradations, on ajoute au ciment portland diverses sortes de pouzzolanes et de laitier. Des éprouvettes ont été confectionnées avec des ciments comportant de tels ajouts, et des fibres de verre résistant aux alcalis, ou fibres de verre du type E. Après conservation humide, on a examiné la corrosion des fibres de verre de ces éprouvettes, et mesuré la réduction de leurs propriétés mécaniques.

Les résultats ont montré que, même avec les verres résistant aux alcalis, les résistances mécaniques des éprouvettes diminuaient avec le temps. Mais la corrosion des verres résistant aux alcalis est seulement superficielle, et elle provoque une augmentation de l'adhérence des fibres à la matrice. Ce phénomène peut être attribué au fait que les hydrates du ciment pénètrent à l'intérieur des bottes de fibres. Le résultat est cependant une augmentation de la fragilité.

En remplaçant une partie du ciment par un zéolite, du métakaolin ou du verre de silice, on diminue la corrosion des fibres. En somme, les pouzzolanes, qui ont une grande affinité pour la chaux, sont efficaces pour réduire cette corrosion.

**SUMMARY :** For the purposes of decreasing the alkalinity of cement matrix in glass fiber reinforced cement and to minimize the degradation of mechanical properties of the composite, various kinds of pozzolanic materials or slag are added to portland cement. The composites consisted of the above materials, cement and alkali-resistant glass fibers or E-glass fibers are prepared and cured. The corrosion of glass fibers is compared and the changes of mechanical properties of composites are determined.

The results show that even alkali-resistant glass fiber is used, the strength of the composites decreases with passage of curing time. As alkali-resistant glass fiber is corroded only slightly and sticks with matrix so tightly, the reverse effect of cement to the reinforcing fiber is considered. This phenomenon must be attributed to the packing of cement hydrates into the bundle of fibers resulting in increasing the brittleness.

Replacing a part of portland cement by either zeolite, metakaolin or silica glass, the corrosion of glass fibers effectively decreases. On the whole, the pozzolanic material which has high reactivity with  $\text{Ca(OH)}_2$ , is effective for decreasing the corrosion of glass fibers.

## INTRODUCTION

As a representative of ordinary glass fibers, E-glass fiber is easily deteriorated with time in high alkali environment as in hardened portland cement. In order to prevent this phenomenon, plastic coating etc. have been attempted on the glass fibers. Still, there is insufficient success reported. At present, the following methods are considered to be the solution:

1. To produce the excellent alkali-resistant glass fibers.
2. To make the cement matrix lower in alkali content.

Concerning the first method, it is well known that  $ZrO_2$  is effective in increasing alkali resistance. Majumdar and Ryder (1), on the basis of data obtained by Bacon and Raggon (2), confirmed that the glass in  $Na_2O-SiO_2-ZrO_2$  system was excellent in alkali resistance. These glass fibers are called "Cem-FIL" and commercially available nowadays. The effectiveness of  $ZrO_2$  on the alkali resistance has been confirmed by several scientists (3, 4, 5).

Concerning the second method, it is believed that the alkalinity of cement matrix can be lowered by substituting a part of portland cement with pozzolan. Addition of pozzolans is also favorable for energy saving in cement production, and reducing of heat liberation in the hydration of cement.

In connection with pozzolan, Massazza (6) published a general report. Costa and Massazza (7) showed that the hydration of Italian pozzolan slowed down at a certain stage, and about 70% of pozzolan still remained at 90 days. Majumdar (8) reported that the decrease in strength of glass fiber reinforced cement could be improved by adding fly ash. However, the reactivity of fly ash was found to be unexpectedly small by Kondo and Ohsawa (9).

As mentioned above, Italian pozzolan is not always highly reactive like fly ash. Further, as suggested by the authors (9), Italian pozzolans contain considerable alkali, which is released gradually during hydration.

The first purpose of this study is to find the pozzolanic materials which are effective for preventing the corrosion of glass fibers. The second purpose is to clarify the possibility of preventing the decrease of strength of glass fiber reinforced cement by protecting the glass fibers from corrosion.

Excellent quality pozzolanic materials such as hakudo (porous opal), opal, zeolite etc. are produced in Japan. Therefore, by substituting a part of portland cement with such materials, the corrosion of glass fibers is expected to be prevented.

## MATERIALS AND EXPERIMENTAL METHOD

Glass Fibers, Cement and Pozzolanic Materials

The physical properties, chemical composition and density of the glass fibers used are tabulated in Table 1 and 2. The glass fibers are chopped E-glass fibers and chopped alkali-resistant glass fiber "Cem-FIL".

Ordinary portland cement is used, and Italian pozzolans (Segni, Bacoli, Baia and Sacrofolano), opal, hakudo (porous opal), zeolite (clinoptilolite), metakaolin, fly ash, silica gel and silica glass are used as substituting materials. In addition, granulated blast-furnace slag (called "slag" for simplification) having latent hydraulic property is also used. The chemical composition of these materials is tabulated in Table 3. The nature and sources of these materials, except the opal used in this experiment (from Satsuma-Ioojima), were previously noted elsewhere by the authors (9).

Italian pozzolans, opal, zeolite and silica gel are ground, sieved and only those finer than  $88\mu m$  are used. Hakudo, metakaolin, silica glass and slag are originally finer than this size. The particle size distribution, Blaine fineness and density of these materials are shown in Fig. 1.

Preparation and Curing of Specimens

Before using, pozzolanic materials and slag are kept at  $35^\circ C$ , 100% RH until saturated. However, the moisture absorption of the materials used is less than 5 wt% except that of silica gel which is about 30 wt%. Therefore, the moisture content of each material is not taken into consideration.

According to the composition, the specimens used in this experiment are divided into three groups.

1. 100 wt% portland cement, and 70 wt% portland cement + 30 wt% pozzolanic material (or slag) dried at  $105^\circ C$
2. Specimen 1 + 5 wt% E-glass fibers
3. Specimen 1 + 5 wt% Cem-FIL

The size of the specimen is  $2 \times 2 \times 8 cm$  and water to solid ratio is 0.4.

Since the fluidity of the cement paste con-

Slag	34.13	16.25	tr.	41.52	4.82				{MnO 0.50, P <sub>2</sub> O <sub>5</sub> tr., Fe 0.68, FeO 0.87, S 1.02

taining slag and fly ash is remarkable, 50 wt% of sand (standard quartz sand for cement testing) has to be added. In this series of experiment, 5 wt% of glass fibers is added to the mixture of cement, fly ash (or slag) and sand.

After mixing by automatic cement mixer, the slurry of the mixture is molded into a rectangular specimen and cured at 35°C, 100% RH for 24 h. Then it is removed from the mold, and subjected to different curings as follows:

1. Directly cured at 80°C, 100% RH for 24 h.
2. Specimen, after having been treated as in 1, is subjected to further curing at 35°C, 100% RH for 3 months.
3. Same as 2 but curing time is 6 months.
4. Directly cured at 35°C, 100% RH for 4 weeks.
5. Directly cured at 35°C, 100% RH for 3 months.
6. Directly cured at 35°C, 100% RH for 6 months.

For the specimens without glass fibers and for those with E-glass fibers, all the above curings are performed, and for those with Cem-FIL, the curings of 1, 3, 4 and 6 are performed. Further, for the specimens containing Sacrofano, only those curings of 1, 3, 4 and 6 are performed on the specimens without glass fibers and with Cem-FIL, and the specimens with E-glass fibers are not made due to lack of the quantity of Sacrofano.

#### Measurement of Strength

After a certain period of curing, bending and compressive strengths of the specimens are measured. Then, the hydration of specimens is stopped by D-dry method (10).

#### Determination of Free CaO and Free Alkali

The amount of free CaO of the specimens without glass fibers is determined by using glycerol and ethyl alcohol as the solvent (11).

The determination of free alkali is as follows: the specimen without fibers is ground, sieved and the particles between 44 and 88  $\mu$ m in diameter are collected. 0.5 g of these particles is put in a beaker and 50 ml of de-ionized water is added. The suspension is stirred for 30 min. at room temperature to let the alkali dissolve, and then filtered. The filtrate is analyzed by flame emission spectrophotometer.

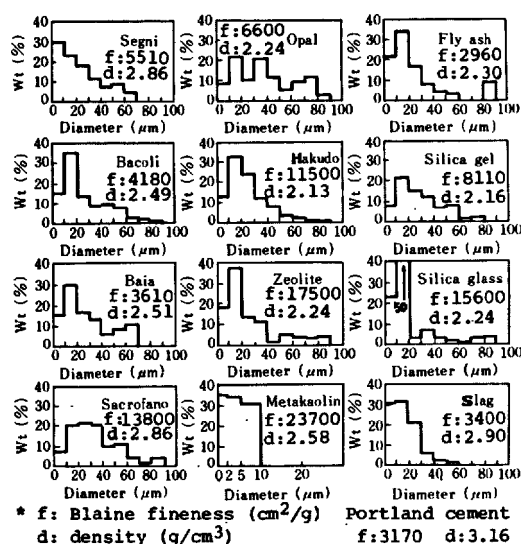

Fig. 1 - Particle size distribution, fineness and density of the materials used.

#### Observation by SEM

The degree of corrosion of glass fibers is observed by scanning electron microscope (SEM). The hydrates stuck around the fibers are removed by washing the specimen in 2N HCl for a few minutes.

#### RESULTS

##### Free CaO and Free Alkali

The relation between free CaO and curing time is shown in Fig. 2. For convenience, the amount of free CaO is calculated on ignited basis and per unit weight of cement. In both curings, the specimens with either metakaolin, silica gel, zeolite, silica glass or Sacrofano contain small amount of free CaO. The authors studied pozzolanic reactivity thermodynamically, and metakaolin was proved to have an excellent reactivity (9).

The amount of free alkali is tabulated in Table 4. The amount of free Na and K shows the similar tendency depending on the added

pozzolan. However, there is no relation between the amount of free alkali and the tendency in corrosion of glass fibers.

Fig. 2 - Relation between the amount of free CaO and curing time.

Table 4 - Free alkali in the specimen cured at 35°C for 6 months (wt%)

	Na	K
Portland cement	0.17	0.27
Segni	0.16	0.65
Bacoli	0.31	0.69
Baia	0.34	0.66

Silica gel	0.02	0.01
Silica glass	0.12	0.18
Slag	0.15	0.23

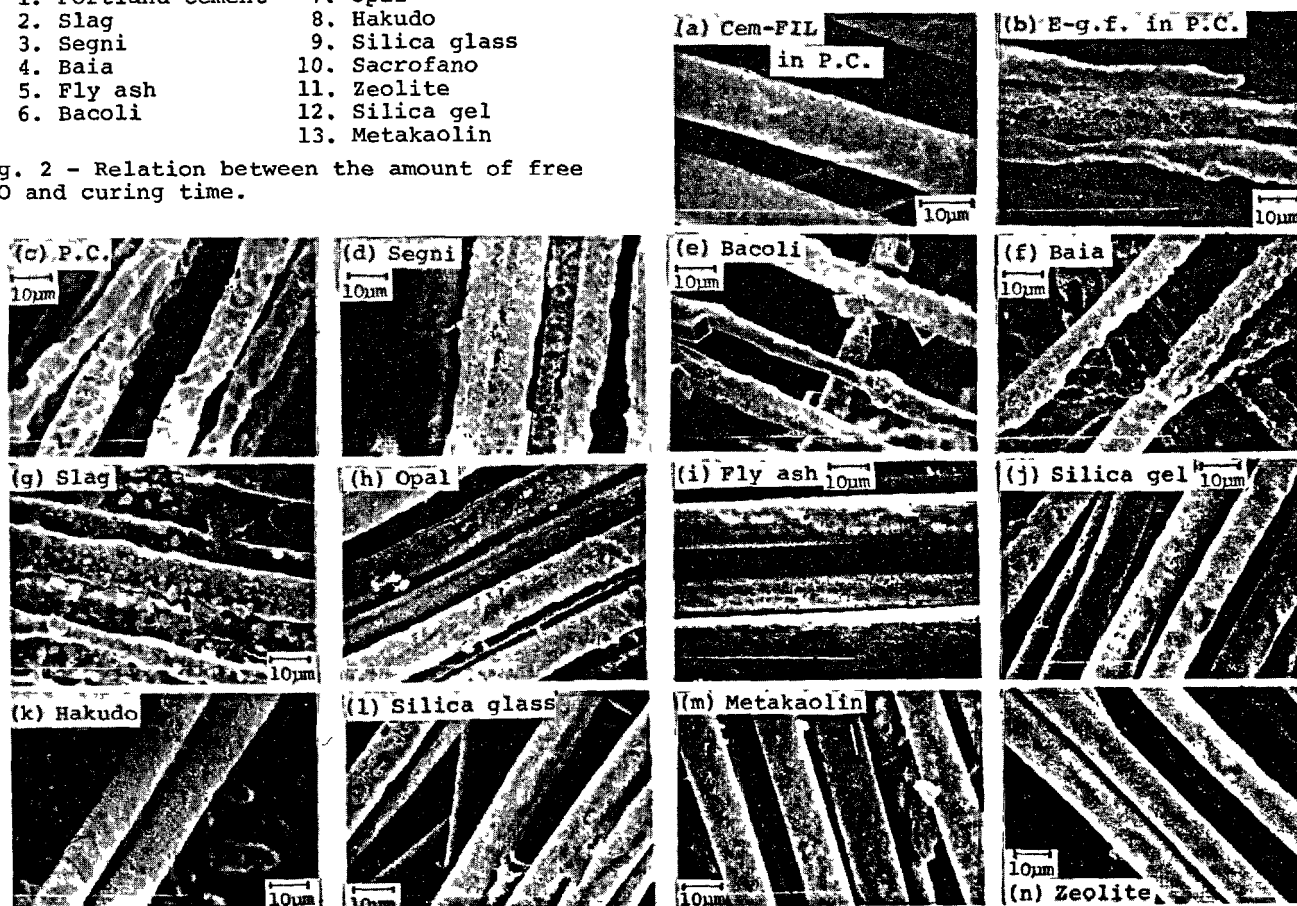

Fig. 3 - Scanning electron micrographs of the surfaces of extracted glass fibers.\*

\*E-glass fibers except (a) which is Cem-FIL; cured at 35°C for 6 m after curing at 80°C for 24 h except (b) which is cured at 35°C for 3 m after curing at 80°C for 24 h.

#### Observation by SEM

Fig. 3 (a) shows Cem-FIL in the specimen of portland cement only, cured under the condition 3 mentioned above. Although this is the most severe curing condition against glass fibers, remarkable corrosion can not be seen. The effectiveness of preventing the corrosion is shown in comparison with each other in Fig.

3. By the micrographs, the degree of corrosion of glass fibers can be arranged in the following order: portland cement=Segni=Bacoli=Baia=slag=opal=fly ash=silica gel=hakudo=silica glass=metakaolin=zeolite. In the specimens containing a little amount of free CaO, i.e., those with highly reactive pozzolanic materials, the corrosion of glass fibers is decreased.

## DISCUSSION

## Bending Strength

The reinforcement of hardened cement with fibers is effective especially for tensile strength. It is difficult to discuss directly on the results of bending strength of the specimens containing fibers since the strength varies with time. Majumdar (8) used the following equation, and Clifton and Frohnsdorff (12) introduced the original reference of the equation:

$$\sigma_c = \eta_0 \eta_1 \sigma_f V_f + \sigma_m V_m \text{ ----- 1}$$

where,  $\sigma_c$ ,  $\sigma_f$  and  $\sigma_m$  are the strength for the composite, fiber and matrix respectively;  $V_f$  is the volume fraction of the fiber and  $V_m$  is the volume fraction of the matrix; and  $\eta_0$  and  $\eta_1$  are efficiency factors for the orientation and effective length of the fibers, respectively.

The authors incorporate the strength decreasing parameter K of the matrix due to pores into equation 1, then, it is as follows:

$$\sigma_c = \eta_0 \eta_1 \sigma_f V_f + K \sigma_m V_m \text{ ----- 2}$$

By using equation 2, the strength charged by glass fibers can be shown as follows:

$$\eta_0 \eta_1 \sigma_f = \frac{\sigma_c - K \sigma_m V_m}{V_f} \text{ ----- 3}$$

$\eta_0$  and  $\eta_1$  can not be estimated, but these values are constant independent of curing time. Therefore, the effectiveness of reinforcement of fibers in composite can be clarified by estimating  $\eta_0 \eta_1 \sigma_f$ . In general, mixture rule deals with tensile strength, but it is postulated in this study that bending strength is nearly proportional to tensile strength.

K is estimated by postulating that the first term of equation 2 is 0 in the specimen of portland cement only, cured under above condition 3, which is the most severe condition and E-glass fibers are supposed to be completely corroded. Substituting the values,  $\sigma_c=115$ ,  $\sigma_m=178$ ,  $V_m=0.968$  into equation 2, K equals 0.667. This value is used for all the calculations. The relation between  $\eta_0 \eta_1 \sigma_f$  and curing time is shown in Fig. 4. The results of the specimens with Italian pozzolans are omitted since they are remarkably corroded.

Fig. 4 - Relation between  $\eta_0 \eta_1 \sigma_f$  and curing time.

The following aspects can be clarified from Fig. 4.

1. Comparing the specimens cured at 80°C for 24 h and those cured at 35°C for 4 w, the strength of fibers in former one is lower.
2. In the specimens directly cured at 80°C for 24 h at first, the strength at 3 m increases except those with metakaolin or fly ash, while, those cured at 35°C, the strength at 6 m increases except that of portland cement.
3. The fibers in the specimen with metakaolin shows considerably high strength initially, but deteriorate with time and at 6 m, the strength is almost the same as the others.

Considering the results by SEM and the value,  $\eta_0 \eta_1 \sigma_f$ , the above result 1 may be attributed to the higher corrosion of E-glass fibers in the specimen cured at 80°C for 24 h. The result 2 may be attributed to the increase in effectiveness of reinforcement, caused by the sticking of glass fibers with matrix. And the increase in effectiveness of reinforcement must be greater than the decrease of strength caused by the corrosion of E-glass fibers. Further the hydration proceeds, the tight sticking results in increasing the brittleness of the structure, and thus, the effectiveness of reinforcement is decreased.

Grimer and Ali (13) indicated that the strength of the composites made from E-glass fibers and low alkaline matrices such as super sulphated or alumina cements decreased at long curing ages. Cohen and Diamond (14) found that the strength of AR-glass fibers removed from cast composite retained the same level of strength as they had at initial stages. According to Nair (15), the effectiveness of the fibers decreased by the packing of cement hydrates into the bundles of fiber strands.

The result 3 seems to be attributed to the decrease of reinforcement of E-glass fibers since the packing may be remarkable in the specimen with metakaolin which is very fine and excellent in reactivity. As seen in Fig. 3, the corrosion of E-glass fibers is comparatively slight in the specimen with metakaolin.

Table 5 shows  $\eta_0 \eta_1 \sigma_f$  of the specimens reinforced with Cem-FIL. The values at 6 m are smaller than those at 4 w.

Table 5 -  $\eta_0 \eta_1 \sigma_f$  of the specimens reinforced with Cem-FIL

	$\eta_0 \eta_1 \sigma_f$ ( $\times 10^3$ )	
	35°C, 4w	35°C, 6m
Portland cement	5.72	2.45
Segni	6.97	3.09
Opal	10.25	5.07
Zeolite	8.91	5.70
Metakaolin	12.94	10.83
Fly ash	6.52	6.02

As shown in Fig. 3, Cem-FIL is corroded only slightly and sticks with matrix so tightly, the reverse effect of cement to the reinforcing fiber is considered. This phenomenon must be attributed to the packing of cement hydrates into the bundle of fibers resulting in increasing the brittleness.

### Relation between Compressive Strength and the Amount of Free CaO

The effect of reinforcement of fibers is small against compressive strength, and strength is rather decreased due to pores included with fibers at preparation of specimens. The following correlation can be given between the ratio of compressive strengths of the specimens with fibers to that without fibers and the amount of free CaO.

$$\frac{S_c}{S_m} = a - b \ln L$$

$S_c$  and  $S_m$  are compressive strengths of the specimen with and without fibers respectively;  $L$  is the amount of free CaO per unit weight of matrix; and  $a$  and  $b$  are constants. The relation between  $S_c/S_m$  and the amount of free CaO is shown in Fig. 5.

Fig. 5 - Relation between  $S_c/S_m$  and the amount of free CaO.

The following results are obtained from Fig. 5:

1. The lower the amount of free CaO, the higher the value  $S_c/S_m$ .
2.  $S_c/S_m$  is higher in the specimens with Cem-FIL than that with E-glass fibers.
3.  $S_c/S_m$  is higher at short curing time than that at long curing time.

Compressive strength can be considered to be a kind of shear strength. Therefore, compressive strength is decreased if the effectiveness of reinforcement of fibers is decreased. The phenomena 1, 2 and 3 can be considered to be attributed to the corrosion of glass fibers, "packing" and "tight sticking" mentioned above.

### ACKNOWLEDGMENT

The authors wish to thank Prof. F. Massazza for supplying the Italian pozzolans.

# Bond strength in very high strength concrete

## *L'adhérence dans le béton à très haute résistance*

G.P. TOGNON, Chem. Eng., Italcementi S.p.A. - Laboratorio Chimico Centrale - Bergamo (Italy),  
 P. URSELLA, Chem. Eng., Italcementi S.p.A. - Laboratorio Chimico Centrale - Bergamo (Italy),  
 G. COPPETTI, Chem. Eng., Italcementi S.p.A. - Laboratorio Chimico Centrale - Bergamo (Italy).

**SUMMARY:** The exceptional mechanical properties of autoclaved concretes (VHSC, compr. strength  $\geq 150 \text{ N/mm}^2$ ) are attributed to a strong chemical bond between cement matrix and aggregate. This bond and consequently the mechanical and elastic properties of these concretes decrease if the quartz aggregates are substituted for others partially or not reactive with the hydrolysis lime of cement.

By using quartz, jasper, granite, basalt and limestone, autoclaved concretes and, as a comparison, normally cured concretes were made. The carried out tests show that the ratios of the mechanical strengths of the autoclaved concretes to those of the corresponding normally cured ones are a function of the aggregate reactivity and, in particular, of its quartz content. These ratios range between 1.18 for limestone and 2.29 for quartz.

The type of aggregate and the thermal treatment do not cause considerable variations in the moduli of elasticity of concrete, but they strongly modify the stress-strain curves.

The inelastic phenomena, such as the local plasticization and microcracking, appear the more intense the stronger the bond at the interface. Subsequent loading and unloading cycles applied to normally cured concretes give similar  $\sigma - \epsilon$  curves, independent of the aggregate and characterized by large hysteresis areas. On the contrary the same cycles applied to autoclaved concretes produce a drastic reduction in these areas. This decrease appears to be particularly marked in the concrete containing quartz aggregates, which indicates the formation of a strong aggregate-cement matrix bond.

The comparison of the elastic yields (ratios of the areas under the loading and unloading curves) of the autoclaved concretes further confirms the importance of this bond. In fact a rapid decrease in the elastic yield occurs in concretes containing not reactive aggregates for stresses over 60%, whereas this yield is nearly constant and very high (90%) up to failure in concretes containing quartz aggregates.

**RESUME:** Les caractéristiques mécaniques exceptionnelles des bétons autoclavés (VHSC, résistance à la compres.  $\geq 150 \text{ N/mm}^2$ ) sont attribuées à la présence d'une forte liaison chimique entre matrice en ciment et agrégat. Cette liaison, et donc les caractéristiques mécaniques et élastiques des bétons, diminuent en remplaçant les agrégats quartzueux par d'autres partiellement ou pas du tout réactifs avec la chaux d'hydrolyse du ciment.

En employant quartz, jaspe, granite, basalte et calcaire, on a préparé des bétons autoclavés et, par comparaison, des bétons durcis dans des conditions normales. Les essais effectués ont mis en évidence que les rapports entre les résistances mécaniques des bétons autoclavés et celles des correspondants bétons non autoclavés sont fonction de la réactivité de l'agrégat et, en particulier, de sa teneur en quartz. Ces rapports sont compris entre 1.18 pour le calcaire et 2.29 pour le quartz.

Le type d'agrégat et le traitement thermique n'entraînent pas de variations considérables des modules d'élasticité du béton, mais ils modifient nettement les courbes contrainte-déformation.

Les phénomènes non élastiques, tels que la plasticisation locale et la microfissuration, se manifestent d'une intensité d'autant plus basse que l'adhérence à l'interface est plus forte. Des cycles successifs de chargement et de déchargement appliqués aux bétons durcis dans des conditions normales ont donné des courbes  $\sigma - \epsilon$  pareilles, indépendantes du type d'agrégat et caractérisées par des aires d'hystérésis larges. Au contraire les mêmes cycles appliqués aux bétons autoclavés ont causé une réduction drastique de ces aires. Cette réduction a été particulièrement marquée pour le béton contenant des agrégats quartzueux, ce qui indique la formation d'une forte liaison entre agrégat et matrice en ciment.

La comparaison des rendements élastiques (rapport entre les aires au-dessous des courbes de chargement et de déchargement) des bétons autoclavés a ultérieurement confirmé l'importance de cette liaison. En effet, pour des contraintes supérieures à 60% de la charge maximale dans les bétons contenant des agrégats non réactifs, il y a une diminution rapide du rendement alors que dans les bétons contenant des agrégats quartzueux, ce rendement est presque constant et très élevé (90%) jusqu'à la rupture.

## 1. INTRODUCTION

The mechanical strength and the inelastic deformation of concretes under load are affected by the composite nature of the material and particularly by the matrix-aggregate interface, the latter being the weakest point of the concrete (1)(2)(3)(4)(5).

The mechanical properties of very high strength concretes (VHSC, compr. strength  $\geq 150 \text{ N/mm}^2$ ) (6) and their elastic behaviour are not justifiable if a substantial improvement in the interface bond is not recognized. The strengthening of such a bond, which appears as a "weld bead" between cement matrix and siliceous aggregate, was already pointed out in a previous paper (7) and justified by electron microscope observations and microhardness measurements (8). In order to verify the relationship between interface bond and elastic and mechanical properties of VHSC made with quartz aggregates, the effects caused by the substitution of quartz for aggregates having different nature were evaluated in the present work.

## 2. EXPERIMENTAL

### 2.1 The materials used for the tests were:

#### a) Aggregates

The concretes were made with five different aggregates, all excellent for the preparation of ordinary concretes which, owing to the different chemical composition, showed different capabilities of fixing the hydrolysis lime of cement in autoclave.

Table I shows the five aggregates together with the respective total and quartz  $\text{SiO}_2$  content and their mechanical properties measured on 50 mm diam., 100 mm high cylindrical specimens.

The same table gives their "reactivity" with respect to cement, expressed as mechanical strength of autoclaved specimens consisting of 55 parts of 525 Ptl cement and 45 parts of aggregate ground to a Blaine specific surface of  $4500 \text{ cm}^2/\text{g}$ .

Table I: Properties of the aggregates

Aggregate	Compressive strength $\text{N/mm}^2$	Modulus of elasticity $\text{N/mm}^2$	Poisson's ratio	Total $\text{SiO}_2$ %	Quartz $\text{SiO}_2$ %	Reactivity $\text{N/mm}^2$
Barzana quartz	n.d.	72150	0.05	95.9	86.2	152.5
Jasper	n.d.	76500	0.11	85.1	54.4	109.5
Granite	226	33600	0.09	72.9	30.8	82
Limestone	174	58500	0.17	0.4	0.3	55
Basalt	334	103500	0.24	43.6	1.1	53
Cement paste	-	-	-	-	-	80

Mixing water: 26%

Curing cycle: presteaming 16 h at  $20^\circ\text{C}$   
autoclaving 10 h at  $190^\circ\text{C}$

The aggregates, divided into four fractions, had a maximum diameter of about 8 mm.

#### b) Binder

A mixture of high strength and rapid hardening port-land cement (525 class) and quartz ground to the same fineness as the cement was used.

#### c) Water

The w/b ratio was maintained rather low owing to the use of a superplasticizer assuring a good workability of the mix.

#### d) Superplasticizer

A naphthalene sulphonate formaldehyde condensate (25

wt % solution) was used.

The concretes were made according to the proportions and the working modes already used (6) and summarized in Tables II and III.

Concretes cured under normal conditions ( $T = 20^\circ\text{C}$ , R.H. = 100%) were made as a comparison; in this case the binder was only cement.

TABLE II: Composition of concretes

Concretes cured at $20^\circ\text{C}$ , R.H.100%	Components of the mixture	Autoclaved concretes
500 } 500 $\text{kg/m}^3$	<b>Binder</b> 525 Ptl cement Ground silica	410 } 610 $\text{kg/m}^3$
1650 $\text{kg/m}^3$	<b>Aggregate</b> fract. 0-1.5 mm 20% 1.5-3 mm 35% 3-6 mm 20% 6-8 mm 25%	1550 $\text{kg/m}^3$

0.42	<b>Water/binder ratio</b>	0.35

TABLE III: Thermal treatment

Presteam	about 17 h at $20^\circ\text{C}$
Low pressure steam curing	8 h at $60^\circ\text{C}$
Rate of temperature rise	$0.7^\circ\text{C/min}$
High pressure steam curing	24 h at $190^\circ\text{C}$
Rate of temperature rise	$0.7^\circ\text{C/min}$

### 2.2 Testing modes

The concretes were cast into prismatic moulds and, after autoclaving or a 21 day curing, they were cored to obtain 70 mm diam., 200 mm high cylinders. These leveled and ground up to a flatness allowance lower than  $25 \mu\text{m}$ , were used to determine the compressive strength, the elastic properties and the strain energy ratios.

The strains were measured by eight resistance strain gauges having a 30 mm gauge length: four of them were directed to the load and four were orthogonal to it. The detection system was a data logger arranged so as to give the deformation values with a sensitivity of  $1 \cdot 10^{-6}$  or  $0.1 \cdot 10^{-6}$  and the stress values with a sensitivity of  $0.01 \text{ N/mm}^2$ .

The data were taken every 60 min up to 90-95% of the maximum load and afterwards every 10 sec. The testing machine operated at constant increase of load equal to  $2 \cdot 10^{-6}/\text{sec}$ .

The strain energies were measured by using the same working modes, except that the transducers were inductive instead of resistive. The samples were submitted to a series of 5 or 6 loading and unloading cycles; after each cycle, the load was increased by about 1/5 of the maximum strength of the specimen. By repeating the sequence of the cycles on several specimens, one per each cycle, significant differences in the hysteresis loop did not appear.

### 3. RESULTS

The values of mechanical strength are shown in Table IV. The secant moduli of elasticity and Poisson's ratios, given in Table V, were determined for stresses ranging between 2 and 22 N/mm<sup>2</sup>.

TABLE IV: Compressive strength (N/mm<sup>2</sup>) of normally cured and autoclaved concretes  
(70 mm diam., 200 mm high cylindrical specimens)

Concretes with aggregates of	Normally cured		Autoclaved
	28 days	60 days	
Limestone	68	75	88.5
Basalt	82.5	91.5	117
Granite	72.5	86.5	141.5
Jasper	69.5	71.5	148
Quartz	72.5	78	179

TABLE V: Secant modulus of elasticity and Poisson's ratio

Stresses between 2 and 22 N/mm<sup>2</sup>

Concretes with aggregates of	E(N/mm <sup>2</sup> )		Poisson's ratios ( $\mu$ )	
	normally cured	autoclaved	normally cured	autoclaved
Limestone	38650	34540	0.270	0.235
Basalt	42050	47270	0.220	0.230
Granite	24680	28210	0.170	0.160
Jasper	35510	39620	0.170	0.168
Quartz	37790	45050	0.171	0.137

In a second series of tests, the samples were deformed up to and beyond the maximum load, by determining the values of  $\sigma_z$ ,  $\epsilon_z$  towards the load axis and the circumferential strain  $\epsilon_\theta$ . It was possible to plot the  $\epsilon_z = \epsilon_z(\sigma_z)$ ,  $\epsilon_\theta = \epsilon_\theta(\sigma_z)$  curves and those of the derivative variables  $\mu(\sigma_z) = \frac{\epsilon_\theta}{\epsilon_z}$  and  $\frac{\Delta V}{V}(\sigma_z) = \frac{|\epsilon_z| - 2|\epsilon_\theta|}{3}$ . The  $\sigma_z = \sigma(\epsilon_z)$  curves were interpolated by a parabola passing through the origin (for 10 or more degrees of freedom, the determination index  $\geq 0.999$ ) (9)(10).

The values of the coefficients "b" and "c" of the interpolating parabolas are shown in Table VI (for  $\sigma$  in N/mm<sup>2</sup>).

Table VII gives the values of the critical loads, expressed as percentage of the maximum load:  $\sigma'$  relevant to the load at which the curve  $\mu(\sigma_z)$  deviates from the rectilinear trend and  $\sigma''$  corresponding to the load at which  $\Delta V/V(\sigma_z)$  reaches the maximum value.

Based on the loading and unloading  $\sigma$ - $\epsilon$  curves, the strain energy was determined by integrating the area under the curves themselves; the ratio of the strain energy during unloading to the one during loading was defined as "elastic yield".

Table VIII shows the values of the elastic yields for loads as percentage of the maximum load.

### 4. DISCUSSION

- The ratio of the mechanical strength of autoclaved concretes to the one of the corresponding concretes

Granite	85.00	91.94
Jasper	78.69	93.97
Quartz	89.23	97.69

normally cured for 60 days varies versus the aggregate. The values of 1.18 and 1.28, obtained by using limestone and basalt respectively, indicate that autoclaving does not improve strengths considerably. On the contrary, different results are obtained with granite, jasper and quartz whose ratios increase to 1.64, 2.07 and 2.29.

As previously pointed out (6), it is the quartz content of the aggregate that has a determining effect on the strength increase.

- The thermal treatment in autoclave does not involve appreciable variations in the secant moduli of elasticity (Young's modulus): the latter increase by about 10-20%, except for concretes containing limestone. This result is in agreement with the fact that the modulus of elasticity of the matrix, made up of the finest part of the concrete, rises by about 30% after autoclaving.

TABLE VIII: Elastic yield versus load (in % with respect to the maximum strength of the sample)

Granite	87	87	87	84	83	n.d.
Jasper	98	97	96	94	92	n.d.
Quartz	97	97	96	94	93	n.d.

- On the contrary the stress-strain curves, determined up to cracking and represented by the interpolating parabola, depend on both the autoclaving and the aggregate.

This deviation from the ideal elastic trend (rectilinear) was related, by different Authors (11)(12), to the formation of microcracks and local phenomena of plasticization.

The results of Table VI show that the values of the coefficient "c" for the concretes with quartz, granite and jasper reduce, after autoclaving, by about one third of the corresponding values of normally cured concretes. For the concrete with calcareous and basaltic aggregates, the thermal treatment does not involve considerable variations of "c".

By assuming that the matrix, notwithstanding the different nature of the fine part of the aggregates, can be considered substantially the same for all the types of concrete, the variations of "c" must be attributed to the reaction between silica of the aggregates and lime of the matrix. Therefore it must be thought that the inelastic phenomena, such as the local plasticization and microcracking, proceed with much lower intensity versus the applied load when the reaction at the interface occurs.

- By examining the values of  $\sigma'$  and  $\sigma''$  shown in Table VII, it can be noted an obvious difference between autoclaved and normally cured concretes as regards the first critical load corresponding to the beginning of the microcracking indicated by the increase in Poisson's ratio (2)(13). On the contrary, no significant difference is observed for the second critical load. This should lead to suppose that once cracking has begun, even if for higher loads, the percent load of the initial increase of the concrete volume (maximum value of  $\Delta V/V$ ), is about equal for autoclaved and normally cured concretes.

- To catch the difference in the elastic behaviour of the different concretes, it is useful to represent their  $\sigma$ - $\epsilon$  curves in subsequent loading and unloading cycles (14). Figures (1a) and (1b) relevant to two concretes cured under normal conditions, containing basalt and quartz aggregates respectively,

show substantially analogous curves. After autoclaving, the behaviour of the concretes themselves is modified: the hysteresis areas undergo a considerable reduction, as shown in figures (2a) and (2b); this decrease appears to be particularly marked in the quartz concrete owing to the formation of an aggregate-cement matrix bond.

FIGURE 1a:  $\sigma$ - $\epsilon$  curves in subsequent loading and unloading cycles for normally cured concrete containing basalt aggregateFIGURE 1b:  $\sigma$ - $\epsilon$  curves in subsequent loading and unloading cycles for normally cured concrete containing quartz aggregateFIGURE 2a:  $\sigma$ - $\epsilon$  curves in subsequent loading and unloading cycles for autoclaved concrete containing basalt aggregate

The comparison among the behaviours is more significant if the values of the elastic yield, given in Table VIII, are examined. All the autoclaved concretes, for stresses up to 50% of the applied load, have about the same elastic yield; for higher stresses, the elastic yield is nearly constant and very high up to about failure in concretes containing quartz aggregates (quartz and jasper), whereas a rapid decrease occurs in concretes with not reactive aggregates. In

fact 90% is exceeded for stresses of 90% of the maximum load. As regards the same concretes cured under normal conditions, 90% of the elastic yield is obtained by not exceeding 20-40% of the maximum load.

FIGURE 2b:  $\sigma$ - $\epsilon$  curves in subsequent loading and unloading cycles for autoclaved concrete containing quartz aggregate

The foregoing is pointed out by the curves shown in Fig. 3 concerning the elastic yield of the concrete containing not reactive aggregates (basalt) and of the one with highly reactive aggregates (quartz). The difference in the two behaviours for loads over 60% is an index of the increase in the load at which cracking begins, owing to the formation of an interface bond having higher strength.

FIGURE 3: Elastic yield versus percentage of maximum load for autoclaved concretes containing salt and quartz aggregate

## 5. CONCLUSIONS

Since it was possible to obtain a significant gain in strength in a VHSC by transforming it from binary sy-

stem, typical of an ordinary concrete, to an almost homogeneous product, the main phenomena of this conversion due to the silica-lime reaction at the interface were investigated.

Actually the VHSC containing reactive aggregates show, when the "weld bead" has formed, only a slight deviation under load from the theoretical linear trend (elastic trend). Moreover the elastic yields, related to the formation of cracks at the interface (the weakest point of concrete), strongly increase, that is they shift towards higher percent values of the maximum load.

# Some problems of the chemistry of adhesion, Cement hardening and the strength of cement stone

## *Adhérence aux granulats, durcissement et résistance de la pâte de ciment durcie*

M.M. SYCHEV, Leningrad Lensoviet Technological Institute, Leningrad, U.S.S.R.,  
L.B. SVATOVSKAYA, Leningrad Institute of Railway Engineers, Leningrad, U.S.S.R.

**RESUME :** En prenant pour base les transferts, entre atomes, de leurs électrons périphériques, on a élaboré un modèle chimique, qui permet l'étude de l'adhérence du ciment aux granulats; il permet aussi d'examiner les aspects chimiques de la cohésion des pâtes de ciment durcies, et de la résistance des mortiers.

**SUMMARY:** The role of phenomena connected with electron transfer, the chemical model, of cohesion and adhesion contacts, are presented and the chemical aspects of cement adhesion are considered and the nature of cement stone strength is discussed.

Some problems connected with the chemistry of cement pastes and mortars condensation including the problems of hydration mechanism are dealt with.

**Initial Hydration Stages Connected with the Transfer of Charges-** electrons, protons. One of the stages of cementing phase formation is the breaking of the bonds  $-O-Ca-O-$  in cement minerals which are partly polarised, nevertheless they cannot be broken by the water polar molecules and are most probably broken by protonation (1,2). The bonds of  $-O-$  type are broken only in the alkali medium as a result of complex-formation with  $OH^-$  groups increasing silicon coordination number to five or six (3). The protons concentration is not great in water, it is determined by the degree of water dissociation. The authors think, however, that the supplier of protons in water may also be dissociative adsorption, i.e. the dissociation of water molecules on the active centres of solid phase surface. The adsorption on the active centres is accompanied by partial transfer of electron density according to the link: active centre - adsorbed molecule. The process of charge transfer, therefore, may be influenced from outside by introducing corresponding substances - activators. Activators may be substances with electron-donor or acceptor properties, these are oxidizing or reducing agents. Their influence will be felt at the stage of donor-acceptor element of hydration mechanism of cement minerals and of hardening kinetics. Experiments made by the authors showed (4,5) that the activators introduced into cement paste in the amounts of 0.5 - 3% produce great effect upon the kinetics of hydration and hardening. Substances containing free and easily excited electrons such as d-10 metals (Cu, Zn), p-metals with high quantum number n (Pb), simple and complex slightly soluble semiconductors (B,  $Si_2O$ ,  $Sb_2S_3$ ) i.e. electron donors inhibit the hydration and hardening processes often reducing early strength (24 hours) to zero. While electron acceptors d 2-8 metals, substances containing elements with high and mean oxidation degrees (inorganic oxidizing agents), lead to the acceleration of hydration and to a considerable growth of early strength.

Physico-chemical investigations showed that the inhibition of hydration and hardening due to substances which are electron-donors takes place as a result of stopping or inhibiting the hydration of silicate cement component while the aluminate component is often hydrated in a usual manner. In the contact of cement minerals with an electrolyte into which an oxidizing or reducing agent is introduced the change of oxidation-reduction potential of the solution leads to the change of electrostatic potential in the interface as a result of which the interchange of charges may take place through the interface boundary - the injection of electrons or holes (i.e. the mineral surface will lose some of its electrons) that will affect the concentration of active

centers.

The process of deactivation in introducing powdered copper which loses its electron according to the schedule:

is reduced to the transfer of an electron onto the surface of silicate minerals probably according to the system of H-bonds:

As a result of this process the proton loses its activity and for some time it does not decompose the silicate. But the electron may happen to reach an active centre of the silicate and to attenuate it.

Atoms of oxygen concentrating positive charges (holes) around themselves are likely to be taken for active centres. The result of this electron effect is the retardation of hydration and hardening decreasing the amount of combined water, the absence in the X-ray patterns and derivatopatterns of  $Ca(OH)_2$  effects. Activation process should in this case be concerned with the increase of active centres concentration due to the transfer of electrons from the surface of the clinker minerals to an acceptor and due to the increase of holes concentration. Besides, the acceleration of the proton transfer according to Scheme 2 by H-bonds may also lead to activation. And, indeed, in the presence of d 2-8 metals (acceptors) and also of certain oxidizing agents the increase of combined water amounts takes place along with the growth of early strength as well as the increase of the intensity of  $Ca(OH)_2$  effects.

**Cement Paste Condensation.** The reaction of powder and mixing liquid leads to the increase of S/l relation developing with time (selfdrying of the system), to the increase of solid phase surface at the expense hydrate generation up to 100-500  $m^2/gr$  and to warming up due to hydration heat. The inter-grain condensation beside these processes is connected with the interaction of the liquid with the surface of cementing phases and the filler, the initial action of which is the process of wetting and the formation of hydrogen and donor-acceptor bonds. At the early stages of hardening up to 50% of water is bound by the surface forces according to the NMR data which results in the structured state of the greater part of the liquid for which quasisolid properties are characteristic. So, the initial strength of the stone during setting is partly determined by the cohesion properties of water interlayers enveloping solid particles.

Continuous combination of water into hydrates and the inner suction (drawing off) lead to the reduction of water interlayers among solid particles. In the outcome the water molecules from aqueous interlayers are transformed into surface hydrate phases - the components of hardening structure:

The fact that the grains may be linked by surface hydrates is due to bridge water molecules being a liquid phase component and a cementing phase structural component simultaneously, the saturated solutions of crystalline hydrates being relative in composition to their crystal structure.

Warming up of the system due to the hydration heat, metastability of the amorphous hydro-silicate phases, local pH change contribute to the proceeding of polycondensation processes:

and to the formation of strong contacts owing to the bonds  $\text{Si-O-Si}$  playing considerable part in forming the strength of cement stone, 50% of the strength being connected with the contacts of polycondensation nature.

**Chemistry of Cement Stone strength.** The authors showed (6,7) the existence of correlation between crystallochemical, energy and thermodynamical characteristics of the phases of new formations and the strength of cement stone. Lafuma considered cement stone strength to be determined by hydrogen bonds. Calculations showed (8), however, that the activation energy of bonds breaking up in the destruction of cement stone is 26 k. cal/mole, it supports the conception of one of the authors (9) that the donor-acceptor bonds of the type:  $\text{Ca}-\text{O} \begin{smallmatrix} \text{H} \\ \text{H} \end{smallmatrix} \text{O} =$  con-

tribute to the strength properties as well as the bonds formed on the basis of polycondensation processes (10). According to (11), the activation energy of bonds breaking up in the destruction of cement stone dehydrated at 400°C (when up to 50-60% strength is lost) is equal to 95 k. cal/mole this value is equal to the bond energy which corresponds to the contacts of polycondensation nature.

The experiments made by the authors (12) showed that the early strength of cement stone is connected with the amount of combined water by power relation  $\sigma = kC^n$ , where  $n$  is the exponent that is greater than 1 and it may reach the values equal to 2 or even 3. It supports the necessity to form at the early stages of hardening the phases with large quantities of crystal water of complex compound type or double salts (13) which are the carriers of cement stone early strength in quick-hardening cements such as hydro-halogen-sulpho-aluminate and sulpho-ferrite cements.

**Chemical Aspects of Cement Stone Adhesion.** It should be taken into consideration in the analysis of chemical aspects of cement adhesion that the surface of the filler, binding agent (a binder) and cementing phases are presented by oxygen, calcium, silicon and aluminium, aluminium and silicon atoms appearing on the surface being hydroxylable ( $\text{Al-OH} = \text{Si-OH}$ ). In the hardening cement dispersion one may distinguish the following types of contacts; a) a section of a binder particle surface - a part of the surface of cementing phase particle (adhesion contact), b) the contact of the sections of cementing phase particle surfaces between themselves. Such a contact may be both of cohesion character (two particles of hydrosilicates and an adhesion one (hydro-silicate particle -  $\text{Ca(OH)}_2$  crystal), c) a section of cementing phase surface - a section of the filler surface (an adhesion contact), d) the section of a cementing phase particle - the surface of cementing part (a brick or a concrete one) - an adhesion contact.

The foundation of the initial adhesion contacts is wetting connected with the formation of hydrogen bonds with surface hydrogen atoms which occupy a great part of the surface, being of larger size. Hydrogen bonds play a great role in forming the initial strength of torkret-compositions connected with the quasisolid properties of boundary water films linking solid phase particles. The cohesion properties of such films are also connected with hydrogen bonds. Adhesion contacts, however, are stronger because they are formed due to hydrogen bonds polarized by surface atoms. Besides, they introduce stronger donor-acceptor bonds into the strength of adhesion contacts

ion exchange processes play a certain part in forming adhesion contacts with the filler surface.

# Nouvelle méthode d'étude des interfaces ciment-granulats

## *New method for the study of cement-aggregate interfaces*

J. GRANDET, Professeur,  
J.P. OLLIVIER, Maître-Assistant,  
I.N.S.A., Département de Génie Civil - Université Paul Sabatier - Toulouse, France.

**RESUME :** Un granulat modifie dans son voisinage la cristallisation des hydrates d'une pâte de ciment. On décrit une technique d'étude permettant de mettre en évidence l'orientation de cristaux d'hydrates dans la zone proche du granulat.

Des enregistrements diffractométriques X sont réalisés sur des sections de pâtes de ciment, parallèles à l'interface pâte-granulat et de plus en plus éloignées de celle-ci. L'étude est effectuée sur une zone d'environ 100  $\mu\text{m}$  autour des granulats. L'orientation des cristaux, notamment de Portlandite, est mesurée à partir des intensités des raies caractéristiques de différentes familles de plans cristallographiques. On définit un indice d'orientation indépendant de la puissance délivrée par le tube de rayons X, ainsi que de la quantité de cristaux d'hydrates présents dans le volume de pâte analysé.

Les différentes sections de pâtes étudiées sont obtenues par abrasion. Il est possible de réaliser des analyses sur des sections distantes entre elles d'environ 1  $\mu\text{m}$ . On montre que cette technique ne modifie pas, à l'échelle des mesures effectuées, l'organisation géométrique des hydrates dans la zone analysée. Cette méthode permet de déterminer la variation de l'indice d'orientation des cristaux à partir de l'interface pâte-granulat et de délimiter la zone d'influence du granulat dans la pâte de ciment.

**SUMMARY :** The crystallisation of hydration products around aggregates is not of the same manner as occurred in the bulk portland cement paste. The orientation of hydrated crystals in the contact zone is studied with a new method.

Different sections parallel to the cement paste-aggregate interface are observed by XED technic. These investigations were done around aggregates up to 100  $\mu\text{m}$  thick. The orientation of crystals, Portlandite for example, is measured from the intensity ratio of diffraction peak characteristics. We defined an orientation index which is independent of the power delivered by X ray tube and the quantity of hydrate crystals contained in the volume of analysed paste.

The different sections of studied pastes are obtained by the abrasion. The distance between two successive sections is about 1  $\mu\text{m}$ . We found that the geometrical arrangement of crystals in the analysed zone is not destroyed during the preparation of specimens. It is then possible to study the variation of the orientation index in the interfacial zone and to define the influence zone of aggregate in the cement paste.

Dans un béton de ciment Portland, la pâte forme autour des granulats une auréole de transition (1) dans laquelle la cristallisation des hydrates est différente de celle existant dans une pâte pure. Cette auréole est le point faible des bétons car il s'agit d'une zone de moindre cohésion dans laquelle se propagent les fissures. Plusieurs auteurs ont signalé que dans cette zone, la Portlandite (CH) se formait en grande quantité relativement au reste de la pâte et cristallisait en couches orientées, l'axe [001] étant perpendiculaire au support (2,3). Ce type de croissance étant évidemment favorable à la propagation des fissures par clivage des cristaux, nous avons mis au point une méthode permettant d'étudier, suivant des plans parallèles au support, l'orientation des cristaux de Portlandite dans la zone constituant l'auréole.

La diffractométrie X sur échantillons en masse est une technique bien adaptée à ce problème car la variation de l'orientation des plans réticulaires d'une espèce cristalline se traduit par une modification des intensités relatives des raies observées sur le diagramme de diffraction.

#### REALISATION DES EPROUVETTES D'ESSAIS

Il n'est pas facile d'étudier dans un béton, la croissance cristalline des hydrates au voisinage d'un granulat de forme quelconque ; aussi, nous avons choisi un modèle simple, constitué d'une éprouvette mixte granulat-pâte de ciment.

Le granulat se présente sous forme d'un cylindre de 2 cm de diamètre (la hauteur du faisceau X étant de 1 cm, on évite ainsi l'influence des parois latérales).

La pâte de ciment Portland est coulée contre une section plane du granulat dont le polissage a été effectué avec différents abrasifs jusqu'à une granulométrie de 5  $\mu\text{m}$ , de manière à obtenir un état de surface permettant d'une part la localisation de l'interface après confection des éprouvettes et, d'autre part, la réalisation dans la pâte, de tranches successives de quelques micromètres d'épaisseur parallèles au support.

Les éprouvettes, placées dans leur moule en matière plastique ( $\varnothing$  2 cm), sont conservées dans des atmosphères contrôlées à  $20^\circ\text{C} \pm 0,2^\circ\text{C}$  et sous différentes humidités relatives. Au moment choisi pour son observation, l'éprouvette est démoulée, puis rompue. Avec les granulats utilisés (quartz, marbre, polyéthylène) et le mode de conservation choisi, la rupture se produit dans la pâte selon un plan parallèle au support et à une distance très faible de ce dernier.

Pour chaque essai, la section polie du granulat est observée au microscope optique ( $\times 625$ ), afin de mesurer l'épaisseur de la pellicule de pâte adhérente. On constate qu'elle est formée d'un tapis continu de cristaux présentant quelques aspérités. Du fait de celles-ci et compte tenu de la profondeur de champ du microscope optique, l'incertitude sur la mesure de l'épaisseur de la pellicule peut être estimée à 1  $\mu\text{m}$ .

#### REALISATION DES SECTIONS DROITES SUCCESSIVES PARALLELES AU PLAN DE L'INTERFACE

L'étude de la variation de l'orientation des cristaux de Portlandite dans la pâte de ciment à partir de la face de contact nécessite la réalisation de sections droites successives et parallèles au plan du granulat. Nous avons procédé par abrasion. On peut penser a priori que cette technique risque de modifier l'arrangement des cristaux ; nous étudierons ce problème dans la suite de ce travail. La face plane de pâte de ciment révélée par la rupture de l'éprouvette mixte est polie à sec sur un disque d'abrasif de grain 22  $\mu\text{m}$ . Le disque est placé dans un récipient en matière plastique de manière à recueillir tous les produits d'abrasion dont la masse est ensuite mesurée par double pesée au 1/10<sup>ème</sup> de mg.

Pour connaître l'épaisseur de pâte enlevée, nous avons supposé, en première approximation, que la masse volumique des constituants de l'auréole était identique à celle du reste de la pâte. Nous avons donc déterminé, par pesée hydrostatique, les masses volumiques d'échantillons témoins coulés et conservés dans les mêmes conditions que les pâtes des éprouvettes mixtes.

#### ENREGISTREMENTS DIFFRACTOMETRIQUES

L'orientation d'un constituant cristallin peut être caractérisée au moyen d'un couple de raies de diffraction : celles-ci doivent appartenir à deux familles de plans différentes, le plan d'orientation du cristal étudié faisant partie de l'une d'elles. En outre, il faut éviter le choix de raies perturbées par un autre constituant.

Ainsi, pour caractériser l'orientation des cristaux de Portlandite dont le plan (001) -  $d = 4,90 \text{ \AA}$  - a tendance à croître parallèlement au support (ce qui se vérifie en faisant diffracter la pellicule adhérente sur le support), nous avons choisi la raie de diffraction correspondant à ce plan, ainsi que celle indexée (101) -  $d = 2,628 \text{ \AA}$  - qui n'est que peu perturbée par la raie du silicate tricalcique située à 2,59  $\text{\AA}$ .

Les diagrammes ont été réalisés au moyen d'un goniomètre équipé d'un tube avec anticathode de cuivre. Une fois le couple de plans réticulaires choisi, nous avons mesuré, sur l'enregistrement diffractométrique de la face étudiée, les intensités des pics correspondant par rapport au fond continu et calculé leur rapport

$$R = \frac{I(001)}{I(101)}$$

Nous avons opéré de même, figure 1, sur le diagramme de poudre d'une pâte de ciment Portland - E/C = 0,29 - âgée de 1 jour. Le rapport  $R_0 = \frac{I(001)}{I(101)}$  trouvé, est égal ici à 0,74, valeur donnée par les fiches ASTM pour ces raies de la Portlandite\*.

\* De même que certains auteurs (4,5), nous avons parfois constaté de légères variations de ce rapport. Toutefois, l'imprécision commise en mesurant les hauteurs de pics au lieu de leur surface nous autorise à utiliser la valeur habituelle 0,74.

FIGURE 1 : Mesure de l'intensité des raies du diagramme de diffraction

## DEFINITION D'UN INDICE D'ORIENTATION

Pour quantifier l'orientation observée sur le diagramme, nous définissons l'indice d'orientation :

$$I = \frac{R}{R_0}$$

Dans le cas des cristaux de Portlandite, l'indice vaut :

$$I = \frac{I(001)/I(101)}{0,74}$$

Cet indice est indépendant de la puissance délivrée par le tube de rayons X, ainsi que de la quantité d'hydrates formés dans le volume analysé. Il ne caractérise pas uniquement l'orientation des cristaux de la face apparente de l'éprouvette car le faisceau diffracté intègre l'orientation des cristaux situés en arrière de cette face, dans la masse de l'échantillon où le rayonnement incident pénètre. La pénétration du faisceau suit la loi  $i = i_0 \exp(-\mu \rho x)$  dans laquelle  $i$  est l'intensité transmise à travers l'épaisseur  $x$  d'un matériau de masse volumique  $\rho$  et de coefficient d'absorption massique  $\mu$  ;  $i_0$  étant l'intensité incidente. La pénétration du faisceau est indépendante, pour une longueur d'onde du faisceau  $\lambda$  donnée, des conditions d'analyse.

Ainsi, nous voyons que l'indice  $I$  ne représente pas l'orientation des cristaux de la seule face apparente mais intègre les orientations de tous les cristaux du volume analysé. Compte tenu de la loi de variation exponentielle, un plan intervient d'autant plus dans l'intensité recueillie qu'il se trouve plus proche de la surface apparente.

L'analyse diffractométrique, côté support, de la pellicule de ciment adhérent sur le granulat après rupture permet également de définir un indice d'orientation. Sa valeur numérique est supérieure à celle obtenue par l'analyse de la surface côté pâte de ciment alors que l'orientation statistique des cristaux situés sur les deux faces révélées par la rupture est vraisemblablement la même. En fait, les valeurs de ces deux indices ne peuvent pas être égales car la mesure du premier intègre, vers le support, une fine pellicule de cristaux très orientés, alors que dans la détermination du second, ce sont des cristaux moins orientés, situés vers le coeur de la pâte de ciment, qui participent à l'intensité diffractée.

## REPRESENTATION GRAPHIQUE

Après mesures de l'épaisseur de la pellicule adhérent sur le support, de la masse prélevée par abrasion et de la masse volumique de la pâte, il est possible de

situer la face apparente de l'échantillon par rapport au support ; soit  $d$  cette distance.

Les intensités des raies de diffraction d'un constituant, ainsi que la valeur  $I$  de l'indice d'orientation, varient avec  $d$ . A titre d'exemple, la figure 2 représente cette évolution pour un contact quartz-pâte de ciment ( $E/C = 0,29$ ) conservé 7 mois à  $20^\circ\text{C}$  en atmosphère saturée.

FIGURE 2 : Evolution du diagramme de diffraction d'une section de la pâte avec  $d$ , distance au granulat

Si l'on construit, en coordonnées semi-logarithmiques la courbe  $I = f(\log d)$ , on constate qu'elle est formée de deux demi-droites (cf. la figure 3, relative au contact étudié figure 2). La forme de cette courbe permet de définir  $d_0$ , limite d'orientation des cristaux de Portlandite dans la pâte de ciment. En-deçà de cette limite, l'orientation des cristaux de Portlandite croît lorsque l'on s'approche du granulat ; au-delà, elle est totalement désorientée. La pente de la droite  $I = f(\log d) \{ d < d_0 \}$  est une autre caractéristique de ces courbes dont nous montrons par ailleurs (6) qu'elle représente l'aptitude du granulat à orienter les cristaux de Portlandite ainsi que le mode de croissance de cet hydrate dans l'auréole de transition.

FIGURE 3 : Variation de l'indice d'orientation  $I$  de la Portlandite en fonction de la distance  $d$  au granulat

#### ANALYSE DE LA METHODE D'ETUDE

Nous avons montré que cette méthode permet de caractériser les variations de l'orientation des cristaux de Portlandite au voisinage d'un granulat. Afin de s'assurer que ce résultat n'était pas dû à l'abrasion mécanique, nous avons effectué des mesures analogues sur un échantillon dont les faces successives étaient obtenues par amincissement ionique. Dans l'appareillage utilisé (EDWARDS IBMA2) l'éprouvette de pâte est bombardée sur toute sa section par 13 faisceaux d'ions argon, ce qui réalise un décapage uniforme. Avec ce procédé d'amincissement très lent (environ  $0,5 \mu\text{m}$  par heure), l'arrangement des cristaux n'est pas modifié et les courbes d'orientation  $I = f(\log d)$  sont analogues à celles obtenues par abrasion. D'autres essais effectués suivant notre méthode (7) ont, en outre,

montré que le polissage mécanique d'une pâte pure ne créait pas d'orientation préférentielle des cristaux de Portlandite.

Cette méthode d'étude, dont nous avons pu constater la fidélité, permet donc de caractériser la variation de l'orientation des cristaux de Portlandite dans une pâte de ciment Portland située au voisinage d'un granulats et de délimiter la zone d'influence de celui-ci. Cette méthode peut également être utilisée pour étudier l'orientation d'autres hydrates des liants hydrauliques dans le cas où ils cristallisent en quantité suffisante, les aluminates de calcium hydratés des ciments alumineux, par exemple.

## Effects of interface reaction between blast furnace slag and cement paste on the physical properties of concrete

### *Effets de la réaction d'interface entre le laitier de haut-fourneau et la pâte de ciment sur les propriétés physiques du béton*

S. NAGATAKI, Dr. Associate Professor, Dept. of Civil Eng. Faculty of Eng. Tokyo, Institute of Technology and

M. TAKADA, Researcher, Central Research Lab., Nisso Master Builders Co., Japon.

RESUME : Dans les dernières années, à cause du manque d'agréats fins de bonne qualité et de l'économie des ressources, on a tenté d'utiliser le laitier granulé de haut fourneau comme agrégat fin du béton. Pourtant, selon les résultats des expériences de laboratoire, on a trouvé que si le béton contenant le laitier de haut fourneau est gardé en atmosphère sèche, il aura tendance à perdre peu à peu sa résistance, après une période d'à peu près 6 mois. De plus, on a trouvé que, dans les mêmes conditions, le retrait par dessèchement est plus petit que dans le cas où on a employé des agrégats ordinaires, tandis que la valeur du fluage est à peu près la même. On pense que cela est dû à la réaction d'interface entre le laitier de haut fourneau et la pâte de ciment; par conséquent, des recherches ont été faites sur les substances formées en surface au moyen de SEM et EPMA. Les résultats montrent que, par dessèchement, des fissures se forment sur cette surface et les fissures déterminent largement les propriétés physiques du béton gardé en atmosphère sèche.

SUMMARY : In recent years, in view of a shortage of good quality fine aggregates and saving of resources, attempts have been made in the application of granular blast furnace slag as fine aggregate in concrete. However, according to results from experiments in the laboratory, it is found that if the concrete having blast furnace slag as fine aggregate were to be kept under dry atmosphere, then there will be a tendency for the strength to fall after the age of approximately 6 months. Also, it is found that under similar dry atmospheric condition, drying shrinkage is smaller than when ordinary fine aggregate is used but the amount of creep is approximately the same. The reason is assumed to be due to the interface reaction between the blast furnace slag and the cement paste and investigations were therefore made on the substances formed on the boundary surface by means of SEM and EPMA. Results indicated that upon drying, cracks develop on this surface and the existence of such cracks determines greatly the physical properties of concretes kept under dry atmosphere.

## FOREWORD

In recent years, because of the shortage of good-quality fine aggregates brought about as river aggregates have become depleted, and with the objective of effective utilization of blast furnace slag being produced in excessive quantity as a by-product, research and development for application of blast furnace slag sand (hereafter abbreviated as slag sand) as fine aggregate for concrete have been actively going on in the steel industry to begin with and in the Japan Society of Civil Engineers, the Architectural Institute of Japan and the construction industry, and progress has been made to a point that a proposal for standards for using slag sand has been prepared based on the results of these research works.

However, it was only 5 or 6 years ago that work was started on the applicability of slag sand at the various research institutions, and therefore, it cannot be said that confirmation of macroscopic characters such as mechanical properties and durability at long-term age of concrete using slag sand, and evaluation of the potential hydraulicity of slag sand are adequate.

In view of the above, the study reported here was made on the influence on the physical properties of concrete, particularly, long-term soundness, of the existence of a hydration reaction layer produced through the potential hydraulicity of slag sand. Parenthetically, the bond mechanism and micro structure at the interface between slag sand and cement paste were observed by scanning electron microscope, and the correlations with macroscopic properties such as strength, modulus of elasticity and volume change properties of mortar at long-term age are discussed.

## OUTLINE OF EXPERIMENTS

Materials Used and Mix proportions

The cement used was ordinary portland cement, the results of physical tests thereof being as shown in Table 1. The fine aggregates were the 2 varieties of slag sand (A, B) as shown in Table 2 and a river sand used for comparison purposes.

In the mix proportions of mortar used for the experiments, water-cement ratios were of the three levels of 0.40, 0.50 and 0.65, flow values were maintained constant at  $190 \pm 5$  mm in all cases, and the fine aggregate quantities satisfying these conditions were obtained by preliminary tests. The unit contents for the various mix proportions are given in Table 3.

Strength Tests and Length Change Tests

The respective tests were performed on specimens kept under the curing conditions indicated in Table 4. The specimen dimensions were 10 dia.  $\times$  20 cm ht. for strength tests, 10  $\times$  10  $\times$  50 cm for drying shrinkage tests, while

creep test specimens were uniaxially re-strained specimens of the kind shown in Fig. 1, the cross section being 10  $\times$  10 cm and length 40 cm. Measurements of drying shrinkage of creep specimens were made following the dial gauge method according to JIS A 1124.

Scanning Electron Microscope (SEM) Examinations

SEM examination specimens were taken breaking specimens which had been used for length change tests. The sizes of specimens were about 0.5 cm in length, 0.5 cm in width and 0.3 cm in thickness, and those specimens happening to contain numerous particles of sand not more than 1 mm in size were selected and used for examinations.

## INTERFACE REACTION BETWEEN SLAG SAND AND CEMENT PASTE

### Hydration Reaction of Slag Sand

Photo. 1 is from SEM examination of slag sand (A) mortar continuously cured in water for 2 years. This photomicrograph clearly shows that a hydration reaction layer is produced between slag sand and cement paste during long-time curing in water, and moreover, that the hydration reaction layer has grown to a thickness of about  $3\mu$ .

Photos. 2-4 are of slag sand (B) mortar cured in water for 7, 28 and 91 days, respectively, and then dried in air for 2 years under the conditions of  $20^{\circ}\text{C}$ , 50% RH. Since these were dried for a long period after curing in water the conditions are different from the result shown in Photo. 1, and these photomicrographs show that with mortar cured in water for short periods (N-7, N-28), the hydration layer is thin (about  $0.3\text{--}1.0\mu$ ) and of porous constitution, but as the period of curing in water becomes long (N-91), the hydration reaction layer is of denser and thicker constitution (about  $2\mu$ ).

The thickness of the hydration reaction layer of granulated slag, according to the method of Kondo and Osawa<sup>1)</sup> (quantification of unhydrated granulated slag in cement using the methanol salicylate method), is about  $0.5\mu$  at the age of 7 days, but retardation of reaction is said to begin occurring when the thickness of the reaction layer becomes  $0.35\text{--}0.50\mu$ . However, the results of examination by SEM as shown in Photos. 2-4 appear to indicate that the hydration reaction layer surrounds the unhydrated part of slag sand along the interface between slag sand and cement paste and fills the gap with the cement paste in the form of gradual growth with increased age of curing in water.

An example of river sand mortar is shown in Photo. 5 for comparison, and quite naturally, in spite of the outer sides of particles being covered by crystals of  $\text{Ca}(\text{OH})_2$ , there is no reaction layer to be seen at all inside river sand.

### Influence of Drying on Hydration Reaction Layer

Photos. 2-4 indicate the forms of hydration layers in case of drying under fairly severe conditions for a long period of time, but as can be seen in Photos. 2 and 3, the hydrated layers of slag sand are fairly coarse compared with the case of continuous curing in water, and along with something gap-like recognized, there are microcracks (about  $0.1\mu$ ) existing along the interface between hydrated layer and cement paste.

Regarding the widths of these microcracks, when taking into account problems in examination techniques such as that examination specimens were prepared breaking beam specimens, or that specimens were dehydrated

because of the high-vacuum conditions when making SEM examinations, it cannot be simply concluded that such crack widths are produced only due to air-drying. However, as a result of SEM examinations of replica films prepared by the single-stage replica method in order to differentiate from cracks produced due to being maintained in a condition of high vacuum, when curing in water was continued formation of cracks was not seen, but in case of dry-curing, microcracks were formed along the interface, while with river sand mortar observed in a state of high-vacuum as shown in Photo. 5 such microcracks were not recognized, and so it is thought the abovementioned cracks were unmistakably formed at the interfaces during the long-term drying process.

It should be noted though, that at the present stage it is not clear whether the cause is brittleness of the hydration reaction layer produced on slag sand due to drying, or slight tensile stresses produced from drying where bond between the hydration reaction layer and cement paste was weak.

## PHYSICAL PROPERTIES OF CONCRETE

Mechanical Properties

Regarding the mechanical properties of concrete using slag sand, as already described in detail in many research reports, when continuously moist-cured over a long period of time, the characteristic is for strength to gradually increase, and it has been confirmed that this strength is equal to that when good-quality river sand has been used. However, these experimental results were obtained under conditions favorable to slag sand, in effect, in a moist state where the potential hydraulicity can be readily brought out, whereas it has been reported that when dried for a long period of time there is a tendency for compressive strength and static modulus of elasticity to be greatly inferior compared with concrete using river sand<sup>2)</sup>. It is thought such a characteristic of the macroscopic properties suggests that there are close relationships with the microscopic and the physical properties of concrete. Therefore, in this study, the properties of strength variations accompanying drying were compared by coefficient of brittleness considered to be the index of existence of microcracks first produced in concrete.

Fig. 2 and 3 show the results of strength tests of mortar using the slag sands A and B and the river sand indicated in Table 2 by the relations between compressive strength ( $\sigma_c$ ) and coefficient of brittleness ( $\sigma_c/\sigma_t$ ). Fig. 2 gives the results after curing in water and Fig. 3 those after dry-curing under the conditions shown in Table 4. After water-curing (before drying), the strength properties of slag sand mortar show a trend more or less similar to those of river sand mortar. However, after dry-curing for 2 years (after drying), the coefficient of brittleness becomes fairly high compared with river sand mortar as shown in Fig. 3, and it is clearly indicated that reduction in tensile strength due to drying is especially prominent.

Fig. 4 gives the result of measurements of dynamic modulus of elasticity, also an index sensitively indicating the existence of microcracks in concrete, and as it clear in this graph it is recognizable that deterioration in quality due to drying is greater than for river sand mortar.

Fig. 2. The relations between  $\sigma_c$  and  $\sigma_c/\sigma_t$  (before drying)

Fig. 3. The relations between  $\sigma_c$  and  $\sigma_c/\sigma_t$  (after drying)

Fig. 4. The relations between compressive strength and dynamic modulus of elasticity

Volume Change Properties Under Water-Curing Conditions

The formation of hydration reaction products of slag sand, as confirmed by SEM examination is that of growth toward the interior of the particle with the original shape of the particle intact. Accordingly, if the reaction were to progress continuously over a long term taking this form, it is thought there is no possibility for expansion and cracking of concrete due to reaction products of slag sand or for breakage of particles accompanying progress in reaction.

Fig. 5 indicates an example of expansive strain of slag sand mortar in moist condition (20°C, in water) in relation to age cured in water. According to this graph, regarding the expansive strain of slag sand mortar, although there is a slight difference in trend compared with river sand mortar such that expansion appears at an early stage, it is not a significant difference, and it may be said that soundness is roughly equal to that of

river sand.

Fig. 6 indicates the creep properties similarly under water-curing conditions, the relation between specific creep and age after loading, when loading was done after standard curing for 28 days followed by continued curing in water. The specific creep of slag sand mortar is larger than that of river sand mortar and the difference gradually increases with increased age after loading. The reason for this is thought to be that slag sand mortar requires a higher unit paste content to obtain the same flow as river sand mortar, and compared by specific creep/unit cement content also, since the value for slag sand mortar is still larger, it is thought the plasticity of the hydrated layer produced at the slag sand influences the creep properties of slag sand mortar.

Fig. 5. Expansive strain of slag sand mortar (in water)

Fig. 6. The creep properties under water-curing conditions

#### Volume Change Properties Under Dry-Curing Conditions

Fig. 7 shows the volume change properties at drying age of 6 months in terms of the relation between drying shrinkage and specific creep. There is a tendency recognized where in spite of slag sand mortar having drying shrinkage smaller than for river sand mortar, its specific creep is equal or larger.

In general, the drying shrinkage of concrete using slag sand is said to be smaller than in the case of using river sand, and the causes of this are thought to be the latent hydraulicity of slag sand, the finely-divided

powder effect, and water retention. However, in order to comprehensively explain such phenomena as the results in Fig. 3 and Fig. 7, in effect, that strength reduction due to drying is prominent, and that drying shrinkage is small but specific creep is of about the same degree as river sand mortar, it was thought reasonable to consider them assuming that microcracks are formed in the interior of slag sand mortar.

Fig. 7. The relations between drying shrinkage and specific creep

#### AFTERWORD

As a result of examination of the relationship between the microscopic form of hydration reaction layers produced in slag sand and the macroscopic properties of slag sand mortar, it was confirmed that the various properties of slag sand mortar may be aptly explained by the interface reaction between slag sand and cement paste.

However, there are still many points remaining unclarified about hydration of blast furnace slag, and regarding also the hydration reaction layer produced at the surface of slag sand observed in the present study, the reaction mechanism, the process of reaction layer formation, and crystallization of hydrates are completely unexplained. Therefore, it is necessary for further close investigations to be made of the hydrate structure of the hydration reaction layer and the characteristics of the hydrates, and their relationships with the macroscopic characters indicated by mortar and concrete to be examined.

# L'influence des procédés de fabrication des clinkers sur la résistance des ciments à l'action des eaux sulfatées

## *Influence of the manufacturing processes of clinkers on the cement resistance to sulphate waters action*

M. NADU, Ingénieur docteur, Chercheur scientifique principal, Institut de Recherches Hydrotechniques (I.C.H.), Bucarest, Roumanie.

**RESUME:** On présente une étude comparative de laboratoire concernant le degré de corrosion par les eaux sulfatées, d'éprouvettes de mortier confectionnées avec plusieurs ciments.

### Les clinkers des différents ciments :

- sont caractérisés par diverses teneurs potentielles des principaux constituants, notamment  $C_3S$ ,  $C_3A$  et  $C_4AF$ ;

- proviennent de cimenteries équipées d'installations différant entr'elles par la voie de fabrication (humide ou demi-sèche) et par le régime thermique de cuisson et de refroidissement.

### L'analyse des résultats prouve que :

- la structure réelle et la résistance des ciments à l'action des eaux sulfatiques s'avèrent parfois plus sensiblement influencées par certains paramètres de fabrication que par la composition potentielle des clinkers ;

- parmi ces paramètres, ceux qui concernent le régime de cuisson et le régime de refroidissement du clinker (dans la zone finale du four et dans le refroidisseur), sont particulièrement importants.

**SUMMARY :** A comparative laboratory investigation on the sulphate waters corrosion degree of mortar test is presented. The cement clinkers :

- are characterized by various potential contents of the main constituents :  $C_3S$ ,  $C_3A$  and  $C_4AF$  ;

- come from cement plants equipped with installations differing by the manufacturing process (wet or semi-dry) and by the thermal burning and cooling conditions .

### The results analysis proves that :

- the real structure and the resistance of the cements to the action of sulphate waters are sometimes more sensitive to the influence of certain manufacturing parameters than to the potential phase composition of the clinkers ;

- between those parameters, the clinker burning and cooling conditions in the final zone of the kiln and in the cooler are particularly important.

Notations et abréviations utilisées :

- $C_3A$ ,  $C_3S$  ou  $V$  : teneur réelle des constituants respectifs du verre
- $C_3A$ ,  $C_3S$  ou  $V$  : teneur calculée pour le clinker trempé à partir de 1450° (Dahl/1/)
- $\overline{C_3A}$ ,  $\overline{C_4AF}$ ,  $\overline{C_3S}$ ,  $\overline{C_2S}$  : teneur potentielle en  $C_3A$  etc
- CPA: ciment portland artificiel
- $\Delta$  :  $C_4AF + C_3A$  ou  $\overline{C_4AF} + \overline{C_3A}$
- $\Delta'$  :  $C_4AF + 2C_3A$  ou  $\overline{C_4AF} + 2\overline{C_3A}$
- E, F et T : symboles pour les cimenteries
- E, F', X, Y, Z: symboles pour les fours et pour les ensembles d'échantillons des clinkers (ou des ciments obtenus d'eux)
- $K_n$ : coefficient de stabilité, après n mois de conservation des éprouvettes dans la solution agressive, calculé par la relation :
- $$K_n = \frac{R_{ns}}{R_{ne}} \quad \text{où } R_{ns} \text{ (et } R_{ne})$$
- sont les résistances moyennes des éprouvettes conservées en solution agressive (et en eau)
- $K_{nE}$  ou  $K_{nX}$  etc.:  $K_n$  moyen pour les ciments de l'ensemble E (ou X) etc.
- m.s.: "migration sélective" ou deshomogénéisation de la phase liquide du clinker
- M: intensité présomptive de la m.s.
- $M_E$  ou  $M_X$  etc.: M-moyenne pour les ciments de l'ensemble E (ou X) etc.
- $Q_{sp}$ : consommation spécifique de combustible du four (Kcal/Kg clinker)
- R: vitesse présomptive de refroidissement du clinker
- $R_f$ : R à la zone aval du four
- $R_{fE}$  ou  $R_{fX}$  etc.:  $R_f$  moyenne pour les clinkers de l'ensemble E ou X etc.
- $R_r$ : R ou refroidisseur
- $R_{rE}$  ou  $R_{rX}$ :  $R_r$  moyenne pour les clinkers de l'ensemble E (ou X) etc.

Introduction

Dans les laboratoires de l'ICH de Bucarest on utilise depuis 20 ans une méthode directe proposée par Kind/2/, pour déterminer la résistance des ciments à l'action des eaux sulfatées. Normalisée en Roumanie, sur la base des avantages qu'elle présente /3a/, cette méthode consiste à suivre le comportement en solution agressive de petites éprouvettes prismatiques de mortier. Le critère quantitatif pour l'appréciation de l'agressivité d'une solution sur le ciment

donné, est exprimé par la valeur  $K_n$ . Des différences de 0,1 sur les  $K_n$  de deux ciments comparés s'avèrent significativement différentes de zéro, si le mode opératoire normalisé (standard roumain STAS 2633-74) est soigneusement suivi. L'eau agressive utilisée pour les recherches présentées, c'est une solution saturée de  $CaSO_4 \cdot 2H_2O$ , donc pas trop riche en ions  $SO_4^{2-}$  (1500 mg/dm<sup>3</sup>), proche des eaux séléniteuses naturelles. Les exigences des normes pour les CPA résistants aux eaux sulfatées contiennent des restrictions pour les teneurs potentielles des phases du clinker. Il s'agit des restrictions pour les phases aluminoferritiques qui peuvent être conçues biunivoquement s'il s'agit d' $\Delta$ , de  $C_3A$ , de  $C_4AF$ , de  $\Delta$  ou de  $\Delta'$  sur un graphique  $F=f(A)$  et des restrictions pour les silicates. On peut remarquer que les exigences valables en divers pays différent, souvent, moins au fond qu'au modalités formelles de symboliser les restrictions (Fig.1). Le support scientifique principal de ces normes, c'est le comportement spécifique aux sulfates des ciments à constituants purs, bien que maintes travaux expliquent que ces ciments sont exempts de la présence des constituants mineurs, des solutions solides et des particularités structurales des clinkers industriels: l'hydratation des ciments industriels riches en  $C_4AF$ , conduisent à des solutions solides résistants aux eaux sulfatiques (Cirilli et Malquori); cf. à Carlson, la formation des hydrogranates stables à ces eaux est possible à des températures usuelles etc. (cf. réf./3b/.

On va exemplifier pour des situations particulières, l'influence des procédés de fabrication des clinkers sur la résistance sulfatique des ciments.

Procédés de fabrication et valeurs  $K_n$ 

La plupart des ciments étudiés sont préparés par mouture de laboratoire, en conditions comparables de clinkers industriels dont le tableau 1 précise brièvement les procédés de fabrication. Il faut excepter une série de

Figure 1: Exigences des normes pour les CPA résistants aux eaux sulfatées à  $C_3A \geq 0$

TABLÉAU I

Cimenterie	Four et refroidisseur	Nombre d'échantillons	Type de clinker	Procédé de fabrication des clinkers analysés	$Q_{sp}$ Kcal/Kg
E	E	18	Ferropertland $A/F < 1,38$	Voie demi-sèche, four "Lepel", $\varnothing 3,2 \times 32m$ , refroidisseur rotatif	$\sim 1600$
F	F	20		Voie humide, four $\varnothing 3 \times 88m$ , refroidisseur planétaire	$\sim 1600$
T	X	2	Portland $A/F=2,16$	Voie humide, four $\varnothing 2,7 \times 2,9 \times 50m$ , refroidisseur rotatif	$\sim 2000$
T	Y	2		Voie humide, four $\varnothing 3 \times 88m$ , refroidisseur planétaire	$\sim 1600$
T	Z	2		Voie humide, four $\varnothing 4 \times 3,6 \times 150m$ , refroidisseur à grille	$\sim 1350$

15 ciments aluminoferritiques (ferropertland) qui proviennent de composants purs synthétisés et meulés en laboratoire par Velica /4/ et dont le tableau II présente la composition et les valeurs  $K_A$ . D'autres données résultent:

- du tableau III, on l'en compare la variation de composition et l'incidence de cette variation sur les  $K_A$ , pour trois ensembles de ciment ferropertland: ceux à constituants purs et ceux provenant des 18 clinkers E et des 20 clinkers F;

- du tableau IV pour exemplifier l'incidence de la différenciation des compositions potentielles et réelles sur  $K_{AF}$  et sur  $K_{AF}'$

- du tableau V pour la composition potentielles et les  $K_A$  des 6 CPA normaux X, Y et Z. La simultanéité de chaque échantillonnage a été assurée.

A noter que: (1) les données expérimentales des tableaux II, III et IV sont complémentaires à celles d'une communication anté-

rieure /3b/; (1,1) hormis les échantillons du four X qui contiennent de la chaux libre ( $\sim 0,8\%$ ), la présence du C libre n'a pas été signalée.

## Analyse des résultats

Les présomptions basées sur les paramètres technologiques du tableau I et les données expérimentales sont comparées au tableau VI. Pour le mieux comprendre s'avère utile un court rappel de quelques publications tenant de la technologie chimique de la fabrication des clinkers.

Theorie de la m.s. D'après Titeiu qui a étudié le phénomène, il s'agit d'une migration de la phase liquide, du noyau vers la périphérie du granule; elle est sélective par ce que M est plus intense pour F et C que pour A et S. Implications; il

Y a plus de  $C_3A$  à l'intérieur qu'à la périphérie, d'où l'on voit l'effet négatif de la m.s. sur la résistance sulfatique des ciments. Titeiu a remarqué aussi que M est en hausse: (i) pour les crus qui développent une phase liquide abondante et fluide; (i,i) au cas d'une flamme ferme (d'une zone courte de clinkerisation)/5/.

A partir du tableau I on peut présumer selon le critère (i,i) les inégalités 1 et 4 (tableau VI).

Sur le refroidissement du clinker. Il y a deux étapes où R influence la structure et les propriétés des clinkers, notamment les  $K_n$ : (i) pendant la solidification de la phase liquide, (i,i) après solidification par transformations polymorphes des silicates.

L'étape (i) a lieu dans la zone aval du four et (s'il y a encore de phase liquide dans les granules sortis du four), dans le refroidisseur. A propos de l'influence de R (soit  $R_n$  ou  $R_f$ ) sur les  $K_n$ , on admet: (j) qu'au fur et à mesure d'une hausse de R, la teneur en  $C_3A$  devient plus petite que celle de  $C_2A$ , au compte des aluminates de basicité réduite, des solutions solides ou du verre; (jj) que le  $C_3A$  est plus sensible aux sulfates que les autres formes des aluminates de calcium; (jjj) que, finalement une hausse de R implique une hausse des  $K_n$ . Comme on verra, cette théorie reste valable, même pour les ciments pauvres en  $C_3A$  (à rapport A/F < 1,38) bien qu'il est vrai que pour des tels clinkers, la trempe rapide conduit à moins de  $C_3S$  que le  $C_2S$ , à une mauvaise cristallisation de l'alite et donc à des ciments à propriétés techniques générales moins favorables /6-10/.

TABLEAU VI

No.	Présomptions basées sur les paramètres technologiques	Conclusion des essais
1	$M_E > M_F \rightarrow K_{nE} < K_{nF}$	Cf. tableau IV et /3b/: $K_{nE} < K_{nF}$
2	$R_{fE} < R_{fF} \rightarrow K_{nE} < K_{nF}$	
3	$R_{rE} < R_{rF} \rightarrow K_{nE} < K_{nF}$	
4	$M_X > M_Y > M_Z \rightarrow K_{nX} < K_{nY} < K_{nZ}$	Cf. tableau V: $K_{nX} < K_{nY} < K_{nZ}$
5	$R_{fX} > R_{fY} > R_{fZ} \rightarrow K_{nX} > K_{nY} > K_{nZ}$	
6	$R_{rX} < R_{rY} < R_{rZ} \rightarrow K_{nX} < K_{nY} < K_{nZ}$	

Interprétation: Excepté les inégalités 5, les présomptions basées sur les paramètres technologiques concordent aux conclusions des essais.

Au point de vue des paramètres thermiques des installations du tableau I, on peut admettre théoriquement:

- que  $R_f$  dépend essentiellement du débit d'air secondaire, donc pour un même excès d'air on aura une fonction croissante  $R_f = f(Q_{sp})$ . Si cette implication s'avère pratiquement importante on peut présumer les inégalités 2 et 5 (tableau VI). S'il y a encore de phase liquide dans le clinker sorti du four, des inégalités analogues sur les  $R_r$  sont également possibles;
- que pour des raisons thermiques (transfert de chaleur, étanchéité de joints four-refroidisseur), les  $R_r$  baissent en ordre suivant des types de refroidisseur: à grille, planétaire, rotatif /11/. On peut donc présumer valables les inégalités 3 et 6 (tableau VI).

L'étape (i,i) a lieu généralement au refroidisseur. Les phases solidifiées subissent au cas des petites  $R_n$  les transformations:  $C_3S \rightarrow \beta C_2S + C$  à 1250°C et  $\beta C_2S \rightarrow \gamma C_2S$  à 650°C. La dernière (accompagnée par<sup>2</sup> pulvérisation) ne s'est pas produite pour aucun des clinkers étudiés. Quant à la première (si elle n'est pas évitée par une hausse de  $R_n$  quand le  $C_3S$  reste en état de surfusion), on peut l'identifier par la présence de la chaux libre, dont l'influence négative sur les  $K_n$  est connue /6,7/.

C'est une nouvelle raison de considérer valable l'inégalité 6 (tableau VI).

L'examen de résultats conduit aux remarques suivantes:

- Les exigences des normes pour les CPA sulfatoresistants sont justifiées par les recherches présentées:
  - totalement au cas des essais sur constituants purs; les valeurs  $K_n$  baissent sensiblement (jusqu'à zéro) si la composition des clinkers à  $C_3A \geq 0$  est en dehors des limites de la figure 1. Les résultats du tableau II concordent tant aux normes qu'aux conclusions des travaux classiques;
  - en moindre mesure et seulement par rapport au  $C_3A$  au cas des essais sur clinkers industriels. Les autres caractéristiques n'influencent pas significativement les  $K_n$ , même s'ils sont en dehors des exigences normalisées (tableaux III, IV et /3b/).

b) Il y a des différences essentielles de sensibilité aux sulfates des clinkers ferro-portland produits par les cimenteries E et F'. Du à un cumul de causes, les valeurs  $K_n$  s'avèrent plus grandes et moins influencées par les variations de composition (notamment pour le  $C_3A$ ) pour les ciments de la série F', par rapport à ceux de la série E. Les incidences du spécifique du cru (structure, teneur en alcalis etc), de la façon dont chaque cimenterie et chaque cuiseur conduit le processus, ainsi que d'autres facteurs, sont évidemment possibles. Mais toute une série d'explications, liées aux caractéristiques des procédés de fabrication des clinkers, capables d'impliquer des différenciations du traitement thermique de cuisson et de refroidissement, restent irréfutables.

c) L'incidence des paramètres technologiques sur les  $K_n$  des CPA provenant des clinkers (produits par les fours X, Y et Z) de la cimenterie T est évidente. Les  $K_{nX}$  diffèrent sensiblement des  $K_{nY}$  et essentiellement des  $K_{nZ}$ , malgré que les compositions potentielles des clinkers X, Y et Z sont les mêmes. Des clinkers également riches en  $C_3A$  peuvent conduire à des CPA très sensibles aux sulfates (pour les échantillons X), mais aussi à des CPA de résistance sulfatique relativement élevée (pour les échantillons Z).

d) Pour les cimenteries E et F', toutes les prévisions basées sur les paramètres technologiques envisagés (valeurs  $M$ ,  $R_f$  et  $R_p$ ) paraissent expliquer, en même sens, les valeurs différentes pour les  $K_n$  (les inégalités 1, 2 et 3 du tableau VI). Mais, pour la cimenterie T, seuls les paramètres  $M$  et  $R_p$  conduisent à des prévisions similaires aux conclusions des essais (les inégalités 4 et 6). Quant aux valeurs présumées pour  $R_{fx}$ ,  $R_{fy}$  et  $R_{fz}$ , l'inégalité 5 conduit à une fausse prévision. Pour le cas des fours de la cimenterie T, les implications sur la résistance sulfatique de la relation  $R_p = f(Q_{sp})$ , (implications assez désobligeantes pour les actuels efforts d'économie de combustible) se prouvent exemptes d'importance pratique.

### Conclusions

Le traitement thermique dans la fabrication du clinker (c'est-à-dire le caractère du chauffage et la vitesse de refroidissement), peut affecter, plus qu'on puisse croire, favorablement ou défavorablement, la résistance aux sulfates du ciment obtenu.

Les chemins d'obtenir des CPA résistants aux eaux sulfatées, doivent être cherchés, non seulement à partir de la composition et de la réactivité des crus, de la qualité de diriger le processus de cuisson, etc.

Il y a des cimenterie qui, en fonction de la conception des installations thermiques disponibles, peuvent réaliser du ciment à résistance sulfatique satisfaisante, à partir de crus de composition normale. Les exemples donnés prouvent l'opportunité d'une étude systématique de l'influence des divers types de fours, de refroidisseurs et de procédés de fabrication sur la résistance sulfatique des ciments.

# Effect of chloride penetration on the properties of hardened cement pastes

## *Effet de la pénétration des chlorures sur les propriétés des pâtes de ciment durcies*

H.G. MIDGLEY and J.M. ILLSTON, Division of Civil Engineering, The Hatfield Polytechnic, Hatfield, Herts, U.K.

RESUME : Les effets des ions de chlorures ayant pénétré dans la pâte durcie du ciment ont été étudiés par DTG, QXRD, analyse chimique et la porosimétrie. On en a déduit que plus la proportion de E/C est élevée, plus la pénétration des ions de chlorure est profonde; la concentration en ions Cl suit une loi déterminée, en fonction de la profondeur de la pénétration. Les chlorures réagissent avec les aluminates de chaux du ciment pour former un chloro-aluminate complexe :  $C_3A \cdot CaCl_2 \cdot 12 H_2O$ . Tout le chlorure présent n'est pas fixé dans ce complexe; une partie reste libre. La quantité de chlorure fixé ne dépend pas de la teneur en  $C_3A$  du clinker, puis des hydrates des aluminates de chaux coexistent avec le chloro-aluminate. La pénétration du chlore altère les pores; plus la concentration en chlorures est élevée et plus petits sont les pores attaqués.

SUMMARY: The effects of chloride ions penetrating hardened cement pastes (hcp) have been investigated by DTG, QXRD, chemical analysis and mercury intrusion porosimetry. It has been found that the higher the w/c ratio the greater the penetration of chloride ions; the concentration with depth of penetration follows a power relationship. Chloride reacts with the calcium aluminates in the cement to form the complex chloroaluminate  $C_3A \cdot CaCl_2 \cdot 12H_2O$ . Not all the chloride present is bound up in the mineral some is left as free chloride. The quantity of bound chloride found does not depend on the amount of  $C_3A$  in the unhydrated cement since calcium aluminate hydrates occur in the hcp with the chloroaluminate. Chloride penetration alters the pores in the hcp, the greater the chloride concentration the smaller the pores formed at the expense of the slightly larger ones.

INTRODUCTION:

Chloride ions present for example in sea water can penetrate hardened cement pastes (hcp) with either deleterious effects due to reaction with the calcium aluminates in the cement, or beneficial effects due to changes in the form of hydration of calcium silicates.

To investigate these effects hcp's of 0.23, 0.47 and 0.71 w/c ratio using an ordinary Portland cement were prepared as cylinders 70mm high x 23mm diam. They were moist cured for 24 hours; demoulded and placed in water at 20°C for 1 month. The cylinders were then protected on the long side and at one end by tightly fitting rubber sheaths. The protected cylinders were placed in 3 conditions, maintained at 20°C;

- (a) Water(w)(Ca(OH)<sub>2</sub>) solution produced by keeping hcp in the water.
- (b) Sodium chloride solution 30g/litre (s) (equivalent to sea water concentration) and sodium chloride solution 150g/litre (5s) (equivalent to 5 x sea water concentration).

After 6 months the cylinders were removed from the solutions, demoulded from the sheaths and split into 5 equal mini cylinders. Each mini cylinder was examined by the following techniques: Derivative Thermogravimetry (DTG); Semi isothermal Derivative Thermogravimetry (SiDTG); Quantitative X-ray diffraction (QXRD); chemical analysis for chlorides and pore size distribution and porosity by mercury intrusion porosimetry.

RESULTS

The total chloride penetration was found to obey a power relationship, Table 1, where it can be seen that there was only a slight penetration in the specimens made with a w/c ratio of 0.23; the values of chloride as wt% were for the top 14mm 0.26 for s and 0.46 for 5s. For the 0.47 w/c ratio specimen there was more penetration to a greater degree; the wt% chloride for s was 0.55 and for 5s 0.90. The 0.71 w/c ratio specimens had about the same depth of penetration but there was a greater concentration at the top 1.12% for s and 2.43 % for 5s conditions; roughly twice for the higher w/c ratio.

The chloride ions which penetrate the hcp may react with the calcium aluminates to form the complex calcium chloroaluminate  $3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{CaCl}_2 \cdot 12\text{H}_2\text{O}$ ; or react with the calcium silicates to form complex chloride bearing calcium silicate hydrates (C-S-H); or they may remain as free chloride ions in the fine capillaries.

Table 1

Penetration of chloride ions into hcp at 6 months.

$$c = kd^{-m}$$

c = concentration of chloride ion wt%

d = distance into hcp in mm

k = constant reflecting depths of penetration

m = slope of relationship  $\log c = \log k + m \cdot \log d$

r = correlation coefficient of linear regression.

Mark	k	m	r	Chloride wt% in	
				bottom 14mm	top 14mm
0.23/s	17.3	-0.08	0.82	0.00	0.26
0.23/5s	22.4	-0.10	0.73	0.00	0.46
0.47/s	27.6	-0.68	0.99	0.03	0.55
0.47/5s	27.6	-0.42	0.85	0.02	0.90
0.71/s	27.6	-0.75	0.85	0.10	1.13
0.71/5s	27.6	-0.65	0.83	0.14	2.43

QXRD determination of the calcium chloroaluminate hydrate shows that there is a considerable proportion of the chloride ions not locked up the crystalline salt but must be present in the C-S-H. or as free ions.

The general mineralogy of the hcp as determined by DTG, SiDTG and QXRD shows that chloride penetration into the hcp has little effect on the quantities of calcium aluminate hydrates; the calcium sulfoaluminate hydrates or calcium hydroxide present. The chloroaluminate hydrate does not appear to be formed at the expense of the other calcium aluminate hydrates and so must be formed by reaction with the anhydrous aluminates in the unhydrated cement present.

No detectable increase in the quantity of C-S-H with chloride penetration was found for specimens made with w/c ratios of 0.23 and 0.47; but with the hcp of w/c ratio 0.71 a detectable increase in C-S-H was found for the specimen stored in sodium chloride solutions.

The results of the porosity and pore size distribution as measured by mercury intrusion porosimetry are given in Table 2. From this data it can be seen that specimens made with a w/c ratio of 0.23 have a large maxima of pores at 560Å pore radius with smaller maxima.

Table 2

Porosity  $\text{cm}^3/\text{g}$ ; Pore volume  $\text{cm}^3/\text{g}$ ; at selected pore radii for hcp.

Pore value at - Å

Mark	Porosity	560	400	335	270	230
0.23/w	0.058	0.0029	0.0168	0.0087	0.0049	0.0027
0.23/s	0.058	0.0025	0.0167	0.0101	0.0056	0.0035
0.23/5s	0.058	0.0005	0.0035	0.0119	0.0124	0.0030
0.47/w	0.122	0.0671	0.0147	0.0098	0.0136	0.0109
0.47/s	0.146	0.0006	0.0043	0.0195	0.0176	0.0122
0.47/5s	0.132	0.0000	0.0032	0.0156	0.0136	0.0130
0.71/w	0.265	0.0098	0.0261	0.0185	0.0243	0.0191
0.71/s	0.278	0.0201	0.0329	0.0193	0.0249	0.0215
0.71/5s	0.221	0.0037	0.0221	0.0281	0.0233	0.0162

at 400 and 355Å pore radii. With exposure to NaCl solutions (150g/l) the largest maxima shifts to 400Å pore radius, and there is an increase in the pore volumes at 335 and 270Å pore radii.

For the hcp made with a w/c ratio of 0.47 the pore volumes at 560 and 400Å pore radii are roughly equal in water storage; with exposure to sodium chloride solutions the absolute pore volume at 560Å decreases, as does that at 400Å but to a small degree while the pore volume of pores of radii 335 and 270Å increase.

With hcp made with a w/c ratio of 0.71 the pore volume of pores of 400Å pore radius reduce in the presence of chloride ions, pore volume of pores of 335Å radius increases slightly, but no change in the pore volume of pores of 220Å radius could be detected.

#### GENERAL CONCLUSIONS

- (1) Chloride ions penetrate hcp, the greater the w/c ratio the greater the amount of penetration
- (2) At the highest w/c ratio used, (0.71), more C-S-H is produced in the presence of sodium chloride.
- (3) Chloride ions react with the calcium aluminate ( $3\text{CaO} \cdot \text{Al}_2\text{O}_3$ ) of the unhydrated cement to form  $3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{CaCl}_2 \cdot 12\text{H}_2\text{O}$ , but not all chloride ions present so react.
- (4) Chloride ion penetration into hcp alters the pore size distribution, the greater the chloride present the smaller the pores formed.

# Résistance du béton aux attaques physico-chimiques

## *Resistance of concrete to physico-chemical attack*

M. REGOURD, H. HORNAIN, P. LEVY, B. MORTUREUX, C.E.R.I.L.H., France

### RESUME

La résistance du béton aux attaques physico-chimiques dépend d'un grand nombre de paramètres dont certains ont été considérés séparément : composition chimique et minéralogique du ciment (teneur en  $C_3A$ , nature de la phase ferritique, teneur en laitier et en pouzzolanes), composition du béton (nature minéralogique des granulats), milieu de conservation (eau de mer artificielle, mer Méditerranée, Océan Atlantique, solutions de  $MgSO_4$ ), traitement préalable (carbonatation).

Les mécanismes de dégradations ont été reliés à l'évolution de la microstructure du matériau, à l'aide du microscope électronique à balayage (MEB), de la microsonde électronique de Castaing, de la diffraction des rayons X (DRX). Les examens ont été complétés par des mesures de gonflement et de résistances mécaniques.

### SUMMARY

The resistance of concrete to physico-chemical attack depends on a large number of parameters of which certain were considered separately : the chemical and mineralogical composition of the cement ( $C_3A$  content, nature of the ferrite phase, slag and pozzolana content), composition of the concrete (mineralogic nature of the aggregates), area of conservation (artificial sea water, Mediterranean Sea, Atlantic Ocean,  $MgSO_4$  solutions), pre-treatment (carbonation).

The degradation mechanism has been related to the evolution of the microstructure of the material by means of Scanning Electron Microscope, Electron Probe Microanalysis and X-ray Diffraction. The examinations were completed by measurements of swelling and mechanical resistances.

Bien composé et correctement mis en œuvre, le béton est généralement stable vis-à-vis des agents agressifs courants. Toutefois, tous les facteurs conditionnant la pérennité d'un ouvrage en béton n'étant pas toujours maîtrisés, il importe de prendre un certain nombre de précautions destinées à prévenir les dégradations ultérieures. Le mécanisme de ces dégradations fait intervenir de nombreux paramètres en relation avec les caractéristiques du ciment et du béton, la nature de l'agent agressif, les conditions d'exposition. Nous considérerons ici quelques uns des facteurs qui conditionnent la résistance chimique du ciment vis-à-vis des sulfates et de l'eau de mer, et dans le cas de la réaction alcalis-granulats.

# 1. RESISTANCE CHIMIQUE DES CEMENTS VIS-A-VIS DES SULFATES ET DE L'EAU DE MER

## 1.1 Mécanisme d'attaque

Deux phénomènes physico-chimiques principaux entrent en jeu :

- (1) Expansion et fissuration par formation très localisée d'ettringite. Les contraintes sont dues à une ettringite "naissante" mal cristallisée (fig. 1). Les cristaux bien formés n'apparaissent qu'après fissuration quand ils disposent de l'espace nécessaire à leur croissance.
- (2) Dissolution de  $\text{Ca}(\text{OH})_2$  et des C-S-H qui deviennent plus poreux (fig. 2). Selon P.K. MEHTA, le gonflement de l'ettringite serait dû à une adsorption d'eau [1,2].

En eau de mer, la cristallisation de chloro-aluminates  $\text{C}_3\text{A} \cdot \text{CaCl}_2 \cdot 10\text{H}_2\text{O}$  ralentit l'attaque du ciment. Dans les solutions contenant des ions  $\text{Mg}^{2+}$  (eau de mer,  $\text{MgSO}_4$ ), l'échange  $\text{Mg}^{2+} + \text{Ca}^{2+}$  conduit à la formation de  $\text{Mg}(\text{OH})_2$  et de C-S-H où la chaux peut être remplacée

progressivement par le magnésium pour donner des (C,M)-S-H ainsi que le montre l'analyse des silicates hydratés de la zone superficielle d'une éprouvette de pâte pure de CPA ayant séjourné 3 mois en eau de mer (tableau I).

	Zone superficielle	Zone interne
CaO	18,2	37,5
SiO <sub>2</sub>	29,2	27,1
MgO	22,4	0,7
Al <sub>2</sub> O <sub>3</sub>	2,3	2,8
Cl	~ 3,6	~ 4,6
SO <sub>3</sub>	~ 1,5	~ 0,6
C/S	0,7	1,5
C+M/S	1,8	1,5

Tableau I - Analyse à la microsonde de Castaing des C-S-H dans un CPA conservé 3 mois en eau de mer.

Les chloro-aluminates et les sulfo-aluminates ne sont pas stables à long terme dans l'eau de mer et les solutions chargées en sulfates. Dans une solution à 5% de  $\text{MgSO}_4$ , ils donnent naissance au gypse (fig. 3). En eau de mer, le chloro-aluminate se transforme en ettringite (fig. 4) qui peut disparaître à son tour de sorte que dans les zones fortement altérées de bétons anciens on ne retrouve parfois que  $\text{CaCO}_3$  et des M S H [3].

L'hydrotalcite  $\text{Mg}_2\text{Al}_2\text{CO}_3(\text{OH})_{16}\text{H}_2\text{O}$  en plaquettes hexagonales (fig. 5) a pu être mise en évidence dans certains produits, notamment dans un mortier de ciment alumineux conservé en eau de mer depuis 1920.

Fig. 1 - Ettringite expansive.

Fig. 2 - C-S-H alvéolaire.

Fig. 3 - Transformation chloro-aluminate-gypse dans  $\text{MgSO}_4$ .

Fig. 4 - Transformation chloro-aluminate-ettringite en eau de mer.

Fig. 5 - Hydrotalcite

Fig. 6 - Thaumasite.

L'altération des mortiers riches en chaux peut être en relation avec la formation de thaumasite  $\text{CaCO}_3 \cdot \text{CaSiO}_3 \cdot \text{CaSO}_4 \cdot 15\text{H}_2\text{O}$  qui résulte souvent de la transformation d'ettringite avec laquelle elle coexiste, par fixation de  $\text{CO}_2$  et  $\text{SiO}_2$  [4]. Ce minéral a été observé dans différents ouvrages maritimes où il correspondait à un stade avancé de dégradation (fig. 6).

### 1.2 Influence de la composition minéralogique du ciment.

La composition potentielle de Bogue ne donne souvent que des valeurs indicatives différentes de celles plus exactes mesurées par diffraction des rayons X (Tableau II).

1.2.1 Teneur en C<sub>3</sub>A : C<sub>3</sub>A est le minéral déterminant dans le processus d'expansion, mais d'autres facteurs peuvent interférer tels que le taux de gypse, la composition de la phase ferritique, etc ... Le tableau II regroupe les résultats obtenus sur 12 ciments dont 7 CPA. Après deux ans de conservation, en immersion totale, en eau de mer naturelle, en laboratoire les éprouvettes 2 x 2 x 16 cm de mortier ISO confectionnées à partir des CPA à faible teneur en C<sub>3</sub>A ont des gonflements faibles. Toutefois, les ciments 6 et 8 contenant respectivement 9,5 et 6 % de C<sub>3</sub>A ont un comportement médiocre : le CPA n° 6 est surgypé ; le CPA n° 8 contient une phase ferritique réactive plus alumineuse que C<sub>4</sub>AF (Tableau IV).

Une deuxième série d'essais a été effectuée sur 12 clinkers synthétisés en laboratoire où l'on a fait varier les teneurs en  $C_3S$ ,  $C_2S$ ,  $C_3A$  et  $C_2(A,F)$ . A partir de ces clinkers broyés à  $3500\text{ cm}^2\cdot\text{g}^{-1}$  et gypsés ont été confectionnés des prismes  $2 \times 2 \times 16\text{ cm}$  de mortier ISO conservés en eau de mer artificielle pendant 4 ans. Les résultats sont rassemblés dans le tableau III et illustrés par la figure 7. Les ciments à teneur en  $C_3A$  supérieure à 10 % ont été détruits.

N°	C <sub>3</sub> A	C <sub>4</sub> AF	C <sub>3</sub> S	C <sub>2</sub> S	Gonglements en $\mu\text{m.m}^{-1}$

Tableau II - Composition minéralogique, finesse et gonflements en eau de mer après 2 ans.

**1.2.2 Teneur en phase ferritique :** Tous les essais indiquent que les ciments à forte teneur en  $C_4AF$  sont stables dans l'eau de mer. La cristallisation "ménagée" d'ettringite à partir de la solution n'est pas expansive. Toutefois les compositions se rapprochant de  $C_6A_2F$  se comportent moins bien [5]. C'est le cas du ciment n° 8 qui, malgré sa faible teneur en  $C_3A$  (6 %), se dégrade. Ce CPA contient 12 % d'une phase ferritique plus riche en chaux et en alumine que  $C_4AF$  (tableau IV).

MgO	Al <sub>2</sub> O <sub>3</sub>	SiO <sub>2</sub>	CaO	Fe <sub>2</sub> O <sub>3</sub>	A/F	C/A + F
3,5	20,8	4,1	51,7	19,8	1,64	2,81

Tableau IV - Analyse à la microsonde de la phase ferritique du ciment n° 8.

**1.2.3 Teneur en silicate tricalcique :** La résistance chimique des ciments à teneur élevée en  $C_3A$  est d'autant moins bonne que leur teneur en  $C_3S$  est plus élevée. C'est le cas des ciments 22, 23 et 24 contenant 13 % de  $C_3A$  et respectivement 57, 47 et 39 % de  $C_3S$  (tableau III et fig. 7). L'influence de  $C_3S$  est moins nette dans les ciments où  $C_3A$  est inférieur à 10 %.

**1.2.4 Teneur en  $SO_3$  :** Des essais de laboratoire ont montré qu'il existe un gypsage optimal qui dépend de la composition minéralogique et de la finesse du ciment. Les ciments fins à granulométrie resserrée, gypsés à l'optimum, ont un comportement amélioré dans l'eau de mer. L'amélioration est en relation d'une part avec leur plus grande compacité et leur taux d'hydratation plus élevée et d'autre part avec la présence d'une plus grande quantité de  $C_3A$  disponible rapidement pour former de l'ettringite primaire non expansive. Les proportions d'alumine restant pour une cristallisation ultérieure d'ettringite expansive sont réduites.

### 1.3 Influence des ajouts sur la résistance des ciments vis-à-vis de l'eau de mer et des sulfates.

**1.3.1 Teneur en laitier :** Tous les ciments contenant au moins 60 % de laitier sont stables. En deça de cette valeur, la tenue du ciment dépend de la composition du clinker et de celle du laitier [6]. La bonne résistance chimique des ciments de laitier est due à leur teneur en chaux plus faible que celle des CPA et à la nature des hydrates formés dont la composition, la concentration, la distribution et la texture sont différentes.  $Ca(OH)_2$  est moins abondant ; les C S H sont plus riches en  $Al_2O_3$  et  $MgO$  mais moins riches en  $CaO$  (tableau V).

	CPA - (3 mois)		CLK - (3 mois)	
	eau douce	eau de mer	eau douce	eau de mer
C/S	1,8	1,8	1,5	1,5
$Al_2O_3$	3,1	2,4	8,0	6,0
$MgO$	~ 1,0	~ 1,0	n.d.	~ 5,0

Tableau V - Composition des C-S-H au contact des grains de clinker dans un CPA et dans un CLK (microsonde de Castaing).

Les examens et analyses au microscope électronique à balayage montrent que les C-S-H formés sont compacts et que leur composition demeure relativement proche de celle du laitier anhydre (fig. 8). Les quantités d'ettringite et de chloro-aluminates formés dans les ciments au laitier conservés en eau de mer sont généralement plus importantes que dans les CPA.

Mais la cinétique et le mode de cristallisation sont différents : l'ettringite apparaît par un processus relativement lent de passage en solution et de cristallisation. La distribution des cristaux est plus diffuse. Ils sont plus courts, plus fins, souvent intimement mélangés aux C-S-H et peu visibles en fractographie au MEB dans les échantillons compacts.

Les ciments n° 1 à 12 décrits dans le Tableau II font l'objet d'une étude à long terme dans le cadre de la COPLA (Commission Permanente des Liants Hydrauliques et Adjuvants) en collaboration avec les Laboratoires maritimes et le Laboratoire Central des Ponts et Chaussées.

Fig. 8 - Texture et composition des C-S-H au contact d'un grain de laitier dans un CLK.

**1.3.2 - Teneur en pouzzolanes :** Cinq pouzzolanes dont les caractéristiques générales sont rassemblées dans le tableau VI ont été testées en eau de mer artificielle, [7].

Pouzzolane	Type	Finesse $2^{-1}$ $cm^2 \cdot g$	Fixation de $CaO$ Unités arbitraires
Tuff	Zéolithe	5600	100 à 21 jours
Trass	Zéolithe	7000	93 "
Phlégréenne	Verre 50 %	2900	47 "
Volvic	Verre 20 %	4300	39 "
Cendre vol.	Verre 90 %	5000	30 "

Tableau VI - Caractéristiques des pouzzolanes.

Cinq CPAZ (20 % pouzzolane) ont été confectionnés avec un même ciment de composition : 60 %  $C_3S$  ; 15 %  $C_2S$  ; 8,5 %  $C_3A$  ; 5 %  $C_4AF$  ; 3,4 %  $SO_3$  ; 2 %  $MgO$  ; 1,5 %  $CaO$  libre. Deux séries de prismes  $2 \times 2 \times 16$  cm de mortiers ISO conservés préalablement 28 jours en atmosphère humide ont été immergées l'une dans l'eau douce, l'autre dans l'eau de mer artificielle. Les résistances en compression et les gonflements, après 2 ans en eau de mer, sont donnés respectivement sur la fig. 9 et dans le tableau VII.

Fig. 9 - Résistances en compression des CPAZ conservés 2 ans en eau de mer artificielle.

D'après ces résultats on observe que : le CPA demeure assez stable après 2 ans ; le trass, très réactif, donne de bons résultats ; les cendres volantes, qui ne commencent à réagir que tardivement, ont un bon comportement ; la pouzzolane phlégréenne de granulométrie grossière a des résistances faibles mais sensiblement constantes ; le tuff, très réactif, donne des résultats satisfaisants en eau douce mais moins

bons en eau de mer où, dès 3 mois, le gonflement est supérieur à celui des autres ciments ; la pouzzolane Volvic réagit lentement et dans les conditions de l'essai son influence n'est pas très favorable.

	3 mois	6 mois	1 an	2 ans
CPA	470	750	1130	1340
Tuff	630	1030	1220	1560
Trass	470	840	1160	1440
Phlégréenne	380	470	750	1090
Volvic	440	690	1130	1410
Cendre vol.	340	720	810	1130

Tableau VII - Gonflements des CPAZ en  $\mu\text{m.m}^{-1}$ .

Les analyses par DRX des mortiers conservés en eau de mer révèlent la présence d'ettringite et de chloro-aluminates. Mais les différences essentielles portent sur l'intensité des raies de  $\text{Ca}(\text{OH})_2$  dont la diminution n'est pas due uniquement à l'effet pouzzolanique comme le montre la comparaison avec les enregistrements effectués sur les mêmes échantillons en eau douce. Ainsi dans le CPAZ au tuff, la dissolution de la chaux est maximale [fig. 10 (a) et 10 (b)].

Fig. 10 - Enregistrements diffractométriques du CPAZ au tuff conservé 2 ans en eau douce (a) et en eau de mer (b).

Le CPAZ à la pouzzolane phlégréenne est peu altéré. De même le ciment au trass renferme encore des quantités appréciables de  $\text{Ca}(\text{OH})_2$ . Le ciment aux cendres contient, à deux ans, beaucoup d'ettringite et de chloro-aluminates ; la dissolution de la chaux y paraît importante. L'altération de ce ciment se traduit par une chute importante des résistances en flexion. Le CPAZ à la pouzzolane de Volvic, peu réactive, contient beaucoup d'ettringite dont les raies sont 4 à 5 fois plus intenses que dans le CPA témoin ou le CPAZ au trass.

Les résultats obtenus montrent que la tenue des CPAZ en eau de mer dépend de leur composition chimique et minéralogique, de leur réactivité, de leur finesse et vraisemblablement de la composition du clinker de base (teneur en  $\text{C}_3\text{A}$ ). Leur stabilité n'est pas toujours en relation avec l'effet pouzzolanique, comme le montre l'exemple du tuff très réactif, mais donnant un comportement médiocre en eau de mer.

#### 1.4 Influence du mode conservation

Le tableau II indique que l'eau de la Méditerranée est moins agressive que l'eau de l'Atlantique.

L'immersion alternée, jointe aux variations climatiques (gel, ensoleillement), est parfois plus préjudiciable au béton que l'immersion totale. L'abaissement de la température accroît le gonflement des CPA ; mais l'addition de laitier améliore le comportement du ciment ainsi que le montre la fig. 11 relative à des essais de laboratoire sur prismes  $4 \times 4 \times 16 \text{ cm}$  conservés 1 an en eau de mer artificielle.

Fig. 11 - Gonflement en fonction de la teneur en laitier et de la température en immersion totale.

La carbonatation naturelle ou artificielle des bétons renforce leur résistance aux sulfates [8, 9]. Des essais effectués sur mortier ISO confectionnés à partir de 3 ciments A, B, C renfermant respectivement 15, 9, 5 % de  $\text{C}_3\text{A}$ , conservés dans une solution de 5 % de  $\text{MgSO}_4$ , ont montré qu'un traitement préalable sous  $\text{CO}_2$  annulait le gonflement des 3 ciments (fig. 12) et diminuait fortement la pénétration des ions  $\text{Cl}^-$  (tableau VIII).

Fig. 12 - Gonflements dans  $\text{MgSO}_4$  des mortiers carbonatés (immersion totale), et non carbonatés.

		Conservation préalable	
		60j $\text{CO}_2$	60j $\text{H}_2\text{O}$
Ciment à 11 % de $\text{C}_3\text{A}$	0 - 2 mm	0,110	0,380
	2 - 4 mm	0,089	0,361
	4 - 6 mm	0,005	0,291

Tableau VIII - Dosage potentiométrique de  $\text{Cl}^-$  (10 jours dans l'eau de mer).

## 2. INFLUENCE DE LA NATURE MINÉRALOGIQUE DES GRANULATS

La présence dans le béton de granulats feldspathiques et micacés (schistes, gneiss, granites) peut être à l'origine de dégradations à la suite de réactions du type alcalis-silicates, qui conduisent à la formation de gels expansifs contenant  $\text{SiO}_2$ ,  $\text{CaO}$ ,  $\text{Na}_2\text{O}$ ,  $\text{K}_2\text{O}$ ,  $\text{H}_2\text{O}$ . Les gels se forment au contact du granulat et parfois sur le granulat entre les lits micacés. La composition moyenne suivante a été observée :  $\text{CaO} = 16\%$  ;  $\text{SiO}_2 = 53\%$  ;  $\text{K}_2\text{O} = 3\%$  ;  $\text{Na}_2\text{O} = 6\%$ . Les gels sont associés à des cristaux en plaquettes, plus ou moins efflorescents, déposés sur les granulats [fig. 13 (a) et 13 (b)]. Il s'agit de silicates de calcium et de potassium du type tobermorite dont la teneur en K est d'autant plus élevée qu'on avance vers l'intérieur du granulat. On observe que l'ettringite et la thaumasite sont fréquemment associées aux dégradations dues aux réactions alcalis-silicates.

Fig. 13 - Texture et composition du gel (a) et des cristaux (b) en contact avec le granulat

## 3. CONCLUSIONS

- L'expansion des bétons dans les eaux sulfatées est due à la formation "d'ettringite naissante" mal cristallisée.
- Pourvu qu'ils soient correctement gypsés et qu'ils ne contiennent pas d'autres phases réactives, les ciments où  $\text{C}_3\text{A}$  ne dépasse pas 10 % sont stables en eau de mer.
- Les ciments à forte teneur en  $\text{C}_4\text{AF}$  sont stables. Mais le comportement est moins bon dans le cas des solutions solides proches de  $\text{C}_6\text{A}_2\text{F}$ .
- Une grande finesse combinée à un gypsage optimal améliore la tenue aux sulfates.
- L'addition de laitier est favorable. Les C-S-H sont plus compacts et de composition moins riche en chaux et plus riche en  $\text{Al}_2\text{O}_3$  et  $\text{MgO}$  que celle des CPA.

- L'effet des pouzzolanes, généralement favorable, ne dépend pas seulement de leur activité pouzzolanique.
- La carbonatation renforce la résistance chimique des ciments.
- La présence de granulats feldspathiques ou micacés peut entraîner des dégradations du type alcalis-réaction indépendamment de la teneur propre en alcalins du ciment.

# Fly Ash and Alkali Aggregate reaction

## *Les cendres volantes et l'alcali-réaction des agrégats*

W. GUTT, P.J. NIXON, M.E. GAZE, Grande-Bretagne.

RESUME : On étudie les réactions qui se produisent dans le système eau,  $C_3A$ ,  $Ca(OH)_2$ ,  $K_2SO_4$  avec et sans addition de cendres volantes. On confirme le rôle des sulfates alcalins neutres, qui augmentent la teneur en hydroxyde des solutions des pores de ciment; on montre que la présence de cendres volantes accroît le taux de réaction aux premiers âges de durcissement. On discute les résultats expérimentaux par rapport au mécanisme par lequel les cendres volantes peuvent réduire la dilatation due à l'alcali-réaction des agrégats (ARA). La question de savoir si les cendres volantes peuvent avoir en pratique une influence sur la neutralisation de l'ARA reste un sujet discutable.

SUMMARY : The reactions occurring in the system water,  $C_3A$ ,  $Ca(OH)_2$ ,  $K_2SO_4$  with and without the addition of fly ash have been studied. The role of neutral alkali sulphates in increasing the hydroxyl content of cement pore solutions has been confirmed and the presence of flyash has been shown to increase the rate of reaction at early ages. The experimental results are discussed in relation to the mechanism by which flyash can reduce expansion due to alkali aggregate reaction. Whether flyashes can be relied upon to counteract AAR in practice, remains an issue which is controversial.

## INTRODUCTION

Soon after Stanton discovered that alkali aggregate reactivity (AAR) was the cause of damage to concrete in the USA(1) he found that such damage could be alleviated by adding finely ground reactive material to the concrete mix. Since then it has been claimed that a wide variety of natural and artificial pozzolanas and materials such as granulated blastfurnace slags with latent hydraulic properties can mitigate damage due to AAR. A series of eleven flyashes from different British power stations have been investigated at BRE for their effectiveness in preventing deleterious expansion due to AAR using the ASTM test (C441) which employs pyrex glass as the standard reactive aggregate. All the ashes tested reduced expansion and there were only small differences between the effectiveness of the different ashes. The differences that were found between ashes did not correlate with the alkali content of the ash and the best correlation was found with some measure of the pozzolanic activity of the ash, in particular with the results of the Lea test(2). The results of this investigation will be published in more detail.

In order to gain a more basic understanding of the mechanism by which flyashes can reduce expansion due to AAR a series of experiments have been started to examine the composition of solutions in contact with flyash/Portland cement mixtures. As a preliminary step the reaction by which the alkalinity of the pore solution in Portland cement concrete is enhanced in the presence of alkali metal salts and the effect of flyash on this reaction has been investigated.

In Portland cement clinker the alkali metals occur preferentially in a potassium-sodium sulphate solid solution and in this form they are most readily soluble. Diamond(3) has proposed that enhanced hydroxyl ion concentrations in the pore solution of hydrated cement come about when the sulphate ions react with the calcium aluminates in the cement, precipitating ettringite. This enables the dissolution of more calcium hydroxide (produced by the hydration of the calcium silicates) thus preserving the solution equilibria of a saturated solution of calcium hydroxide. In fact for this to happen calcium ions in the solution must also be involved in the reaction. A possible reaction sequence would therefore be:

The final result would be precipitation of ettringite and a pore solution richer in alkali hydroxides.

As a first step in the investigation we have therefore examined the reactions taking place between tricalcium aluminate, potassium sulphate and a saturated lime solution and the effect that the presence of flyash has on these reactions.

## EXPERIMENTAL

In the first series of reactions approximately 0.5 g

of laboratory prepared tricalcium aluminate was reacted in a sealed plastic flask with 75 ml of water, 25 ml of 0.4N  $\text{K}_2\text{SO}_4$  and about 1 g of freshly ignited  $\text{CaO}$ . The quantity of  $\text{CaO}$  was judged sufficient to provide an excess over that required for reaction. The contents of the flask were stirred with a magnetic stirrer and the reaction was carried out at room temperature. After the designated reaction period the solid material was separated from the solution by centrifuging and the solution was transferred to a 200 ml volumetric flask. The solids were washed once with distilled water, re-centrifuged and the washings transferred to the volumetric flask which was then made up to 200 ml with distilled water. 25 ml aliquots of this solution were used for the determination of:

- total alkalinity by titration against N/20  $\text{HCl}$
- calcium by titration against EDTA
- sulphate gravimetrically by precipitation as  $\text{BaSO}_4$

The separated solids and portions of the diluted solutions were evaporated to dryness and examined by X-ray powder diffraction using a Guinier Focussing camera.

The second series of reactions was carried out similarly but with the inclusion of 5 g of flyash. The ash used had the following characteristics:

total alkali metals - 3.35 wt% as equivalent  $\text{Na}_2\text{O}$

available alkali metal - 1.58 wt% as equivalent  $\text{Na}_2\text{O}$   
(determined according to ASTM C311)

pozzolanic activity according to Lea test(2) - a strength difference of  $17.6 \text{ MN/m}^2$  for a mix containing 30% ash. This classifies it among the more pozzolanic flyashes.

## RESULTS

The results of the chemical analyses of the solutions from the two series of reactions are given in Table 1 and the phases identified by X-ray powder diffraction in the residues after evaporation of the reaction solutions and in the solids separated by centrifuging are listed in Table 2.

The chemical analytical results for both series show the removal of calcium and sulphate ions from solution. The precipitate is shown by the X-ray diffraction results to be calcium sulpho-aluminate hydrate, both 'high' and 'low' sulphate forms being detected. The solution becomes effectively one of potassium and hydroxyl ions with increased alkalinity compared with the initial calcium hydroxide solution.

In the presence of flyash however the reaction proceeds very much more quickly, going to completion by 7 days whereas without the flyash the reaction is not complete at 28 days. In the solution containing flyash there is a slight reduction in alkalinity at 28 days and also a slight rise in the sulphate content of the solution although the calcium level in solution has continued to fall.

## DISCUSSION

The results obtained for the solution containing  $\text{C}_3\text{A}$ ,  $\text{Ca(OH)}_2$  and  $\text{K}_2\text{SO}_4$  support Diamond's proposal(3)

TABLE 1

Mix	Reaction period	Composition of 25 ml aliquots of reaction solution				% of $K_2SO_4$ reacted(b)
		Total alkalinity (ml of N/20 HCL required to neutralise)	Alkalinity from Reaction(a)	CaO (mg/25 ml)	$SO_4^{2-}$ (mg/25 ml)	
$C_3A/K_2SO_4/Ca(OH)_2$	7 days	25.5	12.5	18.3	28.0	53
	14 days	23.35	16.0	10.3	18.55	69
	28 days	26.3	20.1	8.6	7.3	88
$C_3A/K_2SO_4/Ca(OH)_2$ + flyash	1½ hours	19.6	2.3	24.3	-	9(c)
	1 day	20.05	7.0	18.3	43.7	27
	7 days	26.9	24.95	3.05	nd	100
	14 days	26.55	24.7	2.5	nd	100
	28 days	23.85	23.7	0.2	3.0	95

nd - not detected

(a) - total alkalinity less the calculated  $OH^-$  from residual CaO(b) - calculated from the residual  $SO_4^{2-}$  in solution except (c) which was calculated from the alkalinity

TABLE 2

Mix	Reaction period	Phases detected by X-ray powder diffraction	
		Residue after evaporation of solution to dryness	Solids separated by centrifuging
$C_3A/K_2SO_4/Ca(OH)_2$	7 days	$\left\{ \begin{array}{l} K_2SO_4 \\ K_2Ca(CO_3)_2 \end{array} \right.$	$\left\{ \begin{array}{l} Ca(OH)_2, CaCO_3, \\ \text{strong ettringite} \\ \text{some 'low sulphate'}(a) \end{array} \right.$
	14 days		
	28 days		
$C_3A/K_2SO_4/Ca(OH)_2$ + flyash	1½ hour	$K_2SO_4, Ca(OH)_2$	$Ca(OH)_2$ , some 'low sulphate'(a)

	28 day	$K_2Ca(CO_3)_2$	

(a) the low sulphate form of calcium sulpho-aluminate hydrate

regarding the mechanism whereby neutral alkali sulphates can increase the hydroxyl content of a cement pore solution. It has been shown that removal of sulphate ions from solution is coupled with the appearance in the solid precipitate of ettringite and/or the 'low sulphate' form of calcium sulpho-aluminate and at the same time the alkalinity of the solution is raised above that of a saturated  $\text{Ca}(\text{OH})_2$  solution and is finally almost completely converted to a KOH solution. Similar observations have been made by Lawrence(4).

When flyash is added to the reactants the same removal of calcium and sulphate ions from solution accompanied by an increase in the alkalinity of the solution is observed but the rate of reaction is greatly accelerated and the reaction is complete within 7 days. A similar acceleration in the rate of removal of calcium hydroxide from a paste of  $\text{C}_3\text{A}$ ,  $\text{Ca}(\text{OH})_2$  and gypsum when natural pozzolanas were present has been noted by Collepardi et al(5). They commented that the rate of reaction was too rapid to be accounted for by the usual lime-pozzolana reaction. In the reaction observed here there is evidence of the effect of the lime-pozzolana reaction continuing to reduce the lime in solution after all the sulphate has been precipitated as calcium sulpho-aluminate but in this initial period the main reaction seems to be the same as in the system without flyash.

The reactions occurring at early ages are of particular importance in seeking an explanation for the action of pozzolanas in reducing the expansion due to alkali aggregate reaction as in the experiments carried out at BRE in which pyrex has been used as the reactive aggregate in mortar bars with a high alkali content, the effectiveness or otherwise of the pozzolana is clearly apparent by the time of the 14 day measurement. It is therefore reasonable to look for explanations in the results described above.

The most obvious explanation for the action of pozzolanas in reducing expansion due to AAR is that they reduce the alkalinity of the pore solution by removing the free lime which is the primary source of hydroxyl ions. However the results reported here show that on the contrary, at these early ages the alkalinity of the pore solution is enhanced in the presence of flyash. Alternatively then it could be that the rapid increase in alkalinity in the flyash system induces reaction at such an early age that the cement matrix is soft enough to accommodate it and that all available alkalis or reactive aggregate is consumed in this early reaction.

The other relevant feature of the results is the very rapid removal of the calcium from solution by precipitation as calcium sulpho-aluminate. This depletion of calcium (and possibly the release of alkali metal ions from the flyash) means that the gel produced by attack of the alkaline solution on the siliceous aggregate has a relatively much higher alkali metal to calcium ratio. Vivian has shown(6) that if the ratio of alkali to reactive material is very high the expansion is reduced and has suggested that this is because a gel with a high alkali to silica ratio is fluid and does not produce expansive pressure whereas Krogh(7) has investigated synthetic gels and found that gels with a high percentage of calcium are rigid and non-expansive. It can therefore be postulated that gels with a high alkali/low

calcium content may be too fluid to cause expansion. Although there is as yet no direct experimental evidence for this, Chatterji(8) has demonstrated that the complete removal of free  $\text{Ca}(\text{OH})_2$  suppresses alkali-silica reaction even when excess alkali metal salt, including hydroxide, is present in the structure.

There must always be some doubt about the extent to which the rates of reaction found in these very dilute solutions relate to those in a cement paste. Lawrence(4), however, has studied the rates of combination of sulphate and release of alkali in cement-water systems with water/cement ratios varying from 0.5 to 50 and has found that they were independent of the water/cement ratio provided a saturated lime solution could be formed very quickly by the cement.

#### CONCLUSIONS

Studies of the reactions occurring in the system water,  $\text{C}_3\text{A}$ ,  $\text{Ca}(\text{OH})_2$ ,  $\text{K}_2\text{SO}_4$  confirm the role of neutral alkali sulphates in increasing the hydroxyl content of a cement pore solution. Similar reactions have been found in the presence of flyash but the rate of reaction is very much greater. No reduction in alkalinity at early ages due to the presence of flyash has been found but there is much more complete removal of calcium from solution.

These observations suggest that the action of pozzolanas in reducing expansion due to AAR may either be due to an acceleration of the rate of reaction so that it takes place while the cement matrix is still soft or to the rapid and complete removal of calcium ions from solution and the consequent effect on the properties of the gel.

Whether flyashes can be relied upon to counteract AAR in practice remains an issue of some controversy requiring further research.

#### ACKNOWLEDGEMENT

The work described has been carried out as part of the research programme of the Building Research Establishment of the Department of the Environment and this paper is published by permission of the Director.

# Importance et conditions d'une étude et d'une évaluation rationnelle de la durabilité et de la sécurité à long terme du béton dans les eaux agressives

## *Importance and conditions of rational study and design of the durability and long-term safety of concrete in aggressive waters*

O. VALENTA, Ingénieur-Docteur, Prague, Tchécoslovaquie.

**RESUME :** L'étude de la sécurité et de l'économie des constructions en béton, soumises à des eaux agressives, doit être basée sur une méthode rationnelle nouvelle, et sur des notions scientifiques de caractère quantitatif.

Dans le monde entier, les méthodes actuellement utilisées sont empiriques et imprécises; de plus elles ne se prêtent pas à une approche rationnelle de l'effet à long terme des diverses ambiances. La prévision quantifiée à long terme, de l'action du milieu ambiant doit être faite, en tenant compte de la durabilité recherchée et de l'évolution de l'ambiance.

Une solution rationnelle doit être fondée sur le choix des matériaux du béton, sur la technologie de fabrication et le contrôle du béton, sur la cinétique du mouillage et sur les réactions chimiques d'attaque du ciment. Elle doit tenir compte notamment des recherches de base sur la cinétique de ces réactions chimiques, en fonction de la nature du ciment.

**SUMMARY:** Safe and economic design of concrete structures in aggressive waters must be based on the new rational method and scientific notions of quantitative character.

Empiric and inaccurate methods used by the standards of the whole World do not provide the possibility of such a rational access to the complex question of the long-term effect of any liquid environment.

Quantification of the long-term effect of environment in the period of required durability on the base of objective prognosis for the environment development.

Conditions of rational solution based on complex access and regulation of effect; choice of materials (cement), technology and control of concrete, kinetics of its wetting, of the proper chemical reactions and of concrete structure deterioration.

Need of systematic scientific and basic research and of quantitative kinetics of the main chemical reactions with cement of different character. Importance and application of functional models.

New requirements on hydrogeological investigation and acquaintance of basic properties of concrete mainly of the pore-system in relation to the water and to its chemical effect on concrete and its components including the reinforcement. Claims on the research and testing of concrete and its components.

Requirements of the world practice, research and the conception of the theme VII of the Congress 1980.

## 1. INTRODUCTION

Les questions de la durabilité des ouvrages d'art en général et du béton et des constructions en béton en particulier sont devenues dans tout le monde techniquement développées par principe une question de la qualité et de l'économie de long terme. Il s'agit des questions de caractère scientifique, technique et économique qui ont une relation étroite à l'optimisation de la solution complexe basée sur la minimisation des dépenses totales: d'investissement, d'exploitation, d'entretien, de protection et de la liquidation.

On se trouve aussi dans le stade de la responsabilité morale des ouvrages qui doivent servir aussi aux générations futures et on se trouve inévitablement devant la nécessité de révaloriser les critères incorrectes de l'économie de court terme, des épargnes momentanées surtout dans les dépenses d'investissement au préjudice des possibilités de développement future et de la durabilité des ouvrages de génie civil et des dépenses de maintenance élevées liées aux exigences élevées sur la maintenance par le travail manuel et qualifié.

Malgré que les questions de la durabilité du béton et d'autres matériaux poreux, non-métalliques ne sont pas encore complètement résolues surtout pour l'action combinée des conditions réelles et par rapport à la cinétique quantitative de la détérioration - il est nécessaire de résoudre dans cet état des notions incomplètes dans tout le monde - avec sûreté et rationnellement le choix des matériaux, la technologie propre du béton et d'autres matériaux ainsi que les travaux de construction, du point de vue de la durabilité définie et exigée par le maître de l'oeuvre dans les conditions spécifiques de long terme du milieu hydrogéologique, climatique et d'exploitation.

## 2. LES METHODES UTILISEES JUSQU'A PRESENT POUR LA SOLUTION DE LA SECURITE A LONG TERME ET DE LA DURABILITE DES OUVRAGES DE GENIE CIVIL SUR LA BASE DES RECOMMANDATIONS ET DES DIRECTIVES

L'analyse des normes valables dans différents pays techniquement développés montre leur insuffisances quant à l'application à la solution rationnelle, objective et quantitative des questions de la durabilité spécifiée du béton dans un milieu agressif en général et sous l'action des eaux agressives en particulier.

Le besoin d'assurer la sécurité des parois des tunnels du Metro de Prague pour la période de 100 ans a introduit dans la solution scientifique et technique le facteur décisif de l'action à long terme du milieu sur les matériaux et les constructions: le temps défini. Aucune norme dans tout le monde ne donne pas la solution objective

et d'un dimensionnement des ouvrages souterrains comme murs des tunnels. Il était alors nécessaire de chercher, de formuler et d'appliquer une solution, une méthode nouvelle et convenable sur la base de l'effet quantifié de l'action de long terme du milieu des eaux agressives souterraines.

De l'autre côté, même les propriétés du béton et de son système poreux décisives pour la réaction des eaux agressives avec le béton: la perméabilité, l'élévation capillaire et la surface interne ouverte n'étaient pas jusqu'à présent l'objet d'une quantification compétente et de l'expression en unités mesurables et contrôlables. La perméabilité du béton et d'autres matériaux poreux en est le facteur le plus important une fois exprimé par le coefficient de perméabilité  $k$  en cm/sec. Malheureusement, les essais normalisés dans différents pays ne offrent pas du tout, malgré son importance pour l'évaluation quantitative de l'effet des eaux agressives sur la structure et les propriétés du béton dans une période définie et par suite sur la durabilité des bétons. Le coefficient de perméabilité seul, proprement déterminé par une méthode convenable est l'indicateur quantitatif de la perméabilité des matériaux poreux comme béton. Ceci conduit à la revendication catégorique de la détermination et du contrôle du coefficient de la perméabilité  $k$  cm/sec par un essais convenable, non seulement pour le béton mais aussi pour le terrain ambiant.

Les normes existantes ne fournissaient aucun guide dans ce sens ni pour les essais propres ni du point de vue de la nécessité d'une expression quantitative de la perméabilité du béton. La connaissance de ce coefficient est nécessaire non seulement pour le béton seul mais aussi pour les matériaux ambiants (le terrain), qui décident de l'accès des eaux agressives vers la surface de la construction en béton et joue le rôle décisif dans la cinétique de la détérioration du béton, qui après tout est la résultante de la cinétique résultante de l'écoulement des eaux agressives dans le milieu ambiant et dans le béton ainsi que de la cinétique des réactions agressives des eaux souterraines avec les composants du béton surtout avec le ciment.

Pour la détermination rapide et sûre du coefficient de la perméabilité  $k$  cm/sec du béton et d'autres matériaux poreux - nouvelle méthode introduite et vérifiée par l'auteur et basé sur la cinétique de l'écoulement non-stationnaire à travers le système poreux est recommandé comme la base de l'étude théorique et expérimental de la cinétique de la détérioration des matériaux par les eaux agressives.

Les normes existantes de tout le monde ne connaissent pas en général cette méthode objective de la solution quantitative de l'effet de longue durée du milieu agressif, liquide sur le béton et n'offrent pas même les bases nécessaires pour une solution logique, quantitative et objective de la

durabilité et de la sécurité à long terme des ouvrages de génie souterrain. Même par leur conception générale elles sont insuffisantes et non-convenables pour une solution économiquement importante.

### 3. LES CONDITIONS ET LE CADRE D'UNE SOLUTION RATIONNELLE, OBJECTIVE ET QUANTITATIVE DE LA SECURITE A LONG TERME ET DE LA DURABILITE DES CONSTRUCTIONS EN BETON DANS DES EAUX AGRESSIVES

Une solution objective et sûre de la sécurité à long terme et de la durabilité des constructions en béton dans le milieu agressif de n'importe quel caractère et intensité est possible seulement sur la base de l'effet quantitatif de longue durée des agents du milieu sur le matériel de construction et sur la construction dans la période planifiée ou exigée de l'exploitation de la construction. L'effet du milieu naturel est donné par l'ensemble des effets des agents différents séparément et en combinaisons, que l'on peut définir par l'analyse du milieu et par la cinétique de la teneur (concentration) des agents différents. La condition d'une solution avec succès consiste dans l'accès complexe à la question compliquée à résoudre et dans les solutions convenables de tous les étapes partielles de l'action des eaux souterraines sur le béton.

La condition principale y est dans la connaissance des conditions réelles du milieu des eaux souterraines qui vont exercer une action sur le béton et sur la construction en béton pendant une longue période surtout du point de vue hydrogéologique et de l'écoulement des eaux souterraines une fois l'ouvrage terminé.

L'étude hydrologique du chantier futur doit alors s'occuper de ces stades importants:

- a) nature et état de long terme des eaux souterraines avant l'ouverture des travaux, les travaux de terrassement,
- b) importants stades transitoires pendant l'exécution des travaux,
- c) long terme conditions de l'écoulement des eaux souterraines dans les conditions nouvelles modifiées et de leur variations quant à leur caractère - ce qui représente le stade le plus important pour la durabilité d'un ouvrage concret. Ceci souligne l'importance d'un pronostic scientifique et objectif des conditions hydrogéologiques de l'ouvrage terminé pendant son exploitation de long terme.

Le facteur principal des exigences sur la solution technique et économique de la sécurité à long terme d'un ouvrage est représenté par l'action propre à long terme de l'eau agressive souterraine sur le béton et l'ouvrage en béton, ses parties importantes et sur son ensemble - la cinétique de la détérioration progressive proprement dite et son effet intégré dans la période de la durabilité exigée de l'ouvrage  $T_r$ . Et de

cet effet intégré résultent tous les mesures logiques et objectives qui doivent assurer la durabilité exigée de l'ouvrage et que l'on peut diviser en ces groupes:

a) aménagement convenable de l'ambiance aqueuse de l'ouvrage et de la construction conduisant à la réduction de l'effet nocif sur le béton et l'ouvrage y compris le traitement des eaux;

b) la technologie du béton proprement dite basée sur le choix des matériaux convenables et sur la perméabilité réduite du béton;

c) protection superficielle du béton contre le contact excessif avec l'eau.

Ce travail prétentieux doit faire l'objet principal de l'étude approfondie et des travaux propres du projet d'exécution dans le stade de la préparation des travaux.

La solution réussite de cette question doit être assurée aussi par une collaboration étroite avec la recherche qualifiée et ses travailleurs d'une part et avec les organisations de l'investigation du sol et du milieu agressif de la construction d'autre part.

Quant à la recherche propre de la technologie du béton durable on doit affronter toute une série des questions nouvelles jusqu'à présent non-résolues, surtout de la cinétique des procès physiques et chimiques accompagnant la détérioration progressive du béton avec perte de ses propriétés fondamentales et importantes: perméabilité, résistance mécanique et l'homogénéité.

Trois méthodes existent pour la solution de la cinétique propre de la détérioration du béton:

a) étude théorique de la cinétique quantitative des procès et réactions chimiques se trouvant à la base l'action de la détérioration progressive du béton et de ses composantes par les eaux souterraines. De cet étude peuvent sortir les guides pour la mise en oeuvre du béton et son traitement par les moyens convenables du caractère physique et chimiques.

b) étude expérimentale sur les modèles fonctionnels en béton (Fig. 1)

c) long terme observation scientifique de l'effet quantitatif du milieu sur le béton et ses propriétés.

Dans l'intérêt de la solution accélérée et objective de ces questions insistantes et importantes de la sécurité à long terme, de l'économie et de la durabilité des ouvrages en béton souterrains, il est nécessaire de profiter des avantages et des succès de chacune d'eaux. En même temps il faut se rendre compte que l'observation à long terme des ouvrages choisis a un caractère plutôt vérificatif que théorique malgré le fait qu'elle exige un contrôle complexe des matériaux, de la technologie et des propriétés du béton pendant la mise en oeuvre des ouvrages choisis pour une telle

observation scientifique. C'est une tâche très prétentieuse même pour la coopération internationale effectuée dans le cadre des commissions spéciales techniques comme celle de la RILEM - CDC.

Fig. 1 - Modèle fonctionnel de l'étude et de contrôle de l'effet des eaux souterraines - agressives sur le béton.

L'étude de cette commission a effectué la classification internationale quant à l'importance des différents agents agressifs du milieu pour les constructions en béton avec ce résultat:

1. corrosion de l'armature
2. les sulfates,
3. gel et mouillage alterné et les acides.

Il est dommage que ce résultat d'une enquête internationale ne fut pas respecté dans le choix et la formulation des thèmes concernant la sécurité de long terme et la durabilité des constructions en béton.

# Alkali Aggregate Reaction with Opaline Sandstone

## *La réaction alcaline des agrégats avec du grès opalin*

Dennis LENZNER and Udo LUDWIG, Institut für Gesteinshüttenkunde, RWTH Aachen, R.F.A.

**RESUME :** Les résultats de quelques recherches en laboratoire sur l'alcali réaction des agrégats (RAA) dans le béton sont exposés.

Il est démontré que la réactivité dangereuse de l'agrégat est inversement proportionnelle à sa porosité.

Le développement de la dégradation est mieux déterminé par la mesure du gonflement en combinaison avec la mesure de la fréquence de résonance que par la mesure du seul gonflement.

L'humidité atmosphérique minimale nécessaire pour le développement de la RAA est déterminée à 85 % hr. Au-dessus de cette limite, la vitesse de la réaction est proportionnelle à l'humidité.

Une accélération de la RAA, par exemple par une élévation de la température, par une augmentation de l'humidité ou par un fin broyage des agrégats réactifs, réduit la dégradation finale.

Un conditionnement à sec initial du béton augmente la dégradation par la RAA. Avec des grains gros (plus de 0,5 mm de diamètre), seules des expériences de longue durée donnent des résultats certains.

**SUMMARY:** The results of some laboratory investigations on the concrete damaging alkali-aggregate reaction (AAR) with opaline sandstone are reported:

It is shown that the damaging reactivity of the aggregate is inversely proportional to its porosity. The development of the damage is better detected by measurement of the expansion together with resonance frequency measurement than by the observation of the expansion alone.

The minimum atmospheric humidity needed for a progressing AAR is discovered to be 85 % rh. Above this limit, the reaction rate is proportional to the humidity.

An acceleration of the damaging AAR, i.e. through raised temperature, high humidity, or fine crushing of the reactive aggregate reduces the final damage.

Initial dry storage of the concrete increases the damage due to the AAR.

With coarse reactive aggregate (more than 0.5 mm in diameter) only long-term tests give reliable results.

## INTRODUCTION

The alkali-aggregate reaction (AAR) may cause considerable damage to concrete which contains soluble silica within its aggregate. By the reaction between the alkalis solved in the pore solution and the reactive aggregate components, locally osmotic pressures are built up if sufficient humidity is available, which may exceed the strength of the concrete. Part of the then generated cracks are microscopically small. They cause an extension and a loosening of the structure which can be measured through macroscopic extension and decrease of strength.

In the following some results of research on the influence of different parameters on the AAR are presented. Some of these tests have been running for more than four years.

## EXPERIMENTAL

To determine the dangerous alkali reactivity of an aggregate, mortar bar tests show the most reliable results.

The mortar used in the following experiments is made with a Portland cement (PZ 45 F) with an alkali content of 0.9 wt-%  $\text{Na}_2\text{O}$  equivalent.

In contrast to other published investigations, no special cement-rich mix is used, but the mortar is composed and prepared according to the German standard DIN 1164, which means the composition of cement: aggregate: water being 1:3:0.5. The aggregate is standard sand. The opaline sandstone is crushed to a grain size of 0.09 to 0.5 mm and is added in amounts of 4 wt-% of the aggregate as replacement of the corresponding sand fraction. With this mortar in any case six prismatic specimens of the dimensions 1 x 4 x 16 cm are made. For the extension measurement the bars are equipped with gauge points to fit into a comparator. After 24 h of humid storage, the specimens are demolded. They are stored in slightly evacuated desiccators above water.

To determine the progressing damage due to the AAR at different intervals mass, length change and resonance frequency are measured. The comparator is equipped with a dial gauge with a resolution of 0.01 mm. The zero measurement is performed after the demolding of the specimens.

The resonance frequency is measured with the EG-meter according to Kottas (1). Together with the density and the length of the specimen, the resonance frequency yields Young's modulus, which is proportional to the square of the resonance frequency. In all the reported tests, the length change and the change of the bulk density are small compared to the change of the resonance frequency. Therefore an increase of the resonance frequency indicates an increase of Young's modulus which means a consolidation of the structure whereas a decrease of the resonance frequency suggests a weakening of the specimen.

## REACTIVE AGGREGATE

Throughout all tests opaline sandstone from Schleswig-Holstein was used as reactive aggregate. The modifications of the reactive aggregate in Schleswig-Holstein are described by Niemeyer (2).

Sixty percent of the opaline sandstone which was at the authors' disposal looked grey-white, the rest

grey-green. First investigations revealed considerable differences in its mineralogical composition and its porosity.

See figure 1

page VII - 123

Fig. 1 X-ray deflection pattern of opaline sandstone with different bulk densities

The x-ray deflection pattern shows that the material with bulk densities of more than 2.1 g/cm<sup>3</sup> only contains quartz and calcite. The less dense material contains cristobalite and only small amounts of quartz and calcite. Therefore the aggregate was as-sorted according to its colour and its bulk density. Table 1 shows the porosity, the specific surface area, and the calcite content of the different fractions which was measured thermogravimetrically.

	bulk density g/cm <sup>3</sup>	density g/cm <sup>3</sup>	porosity vol-%	sp. sur- face area m <sup>2</sup> /g	calcite content wt-%
grey- white	1.13	2.53	55.3	15.1	8.5
	1.47	2.62	45.8	20.5	30
	1.87	2.57	27.2	10.1	35
	2.34	2.74	15.0	1.9	96.6
grey- green	1.20	2.84	57.8	35.3	2
	1.37	2.75	50.2	34.8	6
	1.70	2.61	34.9	26.1	2
	1.91	2.44	21.7	30.7	2.8
	2.05	2.38	13.9	18.0	7.7
	2.60	2.72	4.4	4.2	55.7

Tab. 1 Properties of opaline sandstone

Ludwig and Bauer (3) have already reported, that the porous opaline sandstone causes no damage. The tests were extended to lower porosities. Fig. 2 shows the expansion and the resonance frequencies of the specimens containing different fractions of the opaline sandstone. The least porous reactive aggregate causes the most severe damage.

Fig. 2 Expansion and resonance frequency of mortar bars containing opaline sandstone with different bulk densities

The material with a bulk density of  $2.6 \text{ g/cm}^3$  does not contain opal, which shows cristobalite structure in the x-ray analysis (see Fig. 1), and is not reactive. The tests show that opaline sandstone with a porosity of 50 vol-% or more does not cause damage within the test period of nearly 500 days when reacting with the cement alkalis. The osmotic pressures are then degenerated within the pore space of the aggregate and not transmitted to the concrete structure. At lower porosities the damage is inversely proportional to the porosity the lower limit being determined by the mineralogical composition.

#### MINIMUM HUMIDITY

For the AAR to proceed, the concrete must contain free water. The diffusion processes which lead to the AAR presuppose a pore liquid in the concrete. On the other hand, the osmotic pressures result from the imbibition of water by the reaction products. In order to determine the minimum atmospheric humidity required for the AAR, one series of specimens at a time was cured at different humidities. The opaline sandstone in these tests has a bulk density of  $1.9 \text{ g/cm}^3$ .

To adjust the atmospheric humidity, sulphuric acid of different concentrations is used. In the first instance, the humidities are adjusted to about 40 % rh, 60 % rh, 80 % rh, 90 % rh and more than 95 % rh.

Fig. 3 Expansion and resonance frequency of mortar bars stored at different relative humidities

The specimens stored above water already expand clearly within 15 days and after about 100 days, they reach their final expansion of  $2.8 \text{ mm/m}$ . At the lower humidity of 90 % rh the AAR cannot be observed before about 50 days. The expansion increases more slowly due to the lower water supply. The reduction of the resonance frequency, however, is more pronounced than that of the specimens stored above water. The specimens stored at humidities of 80 % rh and less only show drying shrinkage. Therefore, after 42 days, the specimens are rearranged from 60 % rh and 40 % rh to more than 95 % rh and 95 % rh. Then these specimens expand rapidly and their resonance frequency decreases accordingly. Again, the specimens stored above water expand faster and reach their final expansion earlier than those stored at the lower humidity of 95 % rh. The former reach their final expansion of  $6 \text{ mm/m}$  after about 200 days. This value is about twice as much as the expansion reached by the specimens which were stored above water from the beginning of the test.

The specimens rearranged from 40 % rh to 95 % rh expand more slowly but the reduction of their resonance frequency and therewith their structural damage is more severe. They do not reach their final expansion until after 900 days.

The results show that a reduced moisture availability does not diminish the damage due to the AAR but only delays it. Because of the longer reaction period, the concrete damages are more severe at the lower humidity. Furthermore, a high humidity is necessary for the rehealing process. This is an additional reason for the greater damage at the lower humidity. The same holds true for the specimens stored at 90 % rh. They expand very slowly. After 360 days their expansion amounts to only  $1.6 \text{ mm/m}$ . This expansion, however, is accompanied by a marked decrease in the resonance frequency.

The storage at 80 % rh does not cause an expansion or a decrease in the resonance frequency within the period of 360 days. Therefore, in order to determine the minimum humidity needed for the AAR, the specimens stored initially at 80 % rh and 90 % rh are rearranged to about 85 % rh after 360 days.

Thereafter, the specimens formerly stored at 80 % rh do not show effects of the AAR up to 1000 days. The rearrangement from 90 % rh to 85 % rh results in a delay in the expansion reaction. After a dormant period of about 200 days, the specimens expand a little. This inferior expansion is accompanied by a distinct decrease in the resonance frequency, a clear indication of the recommencing AAR. The results show that for a damaging AAR a minimum humidity of about 85 % rh is needed.

#### RESIDUAL HAZARD

After a test period of 1000 days all specimens were rearranged to the high humidity of more than 95 % rh in order to determine the residual reaction potential of the reactive aggregate. To accelerate the reaction, two specimens from each series were stored at 40°C. The specimens which had been stored above water before show no reaction. Their content of opaline sandstone has reacted completely.

Fig. 4 Residual hazard after 1000 days storage at different humidities

The specimens which have been stored near the minimum humidity expand after the rearrangement by up to 9 mm/m. This expansion is more than the expansion

of the specimens which were rearranged to the high humidity at earlier ages. The higher temperature causes an acceleration of the reaction. This acceleration, however, reduces the final damage as detected in other test series (4).

The decrease in the resonance frequency of the specimens formerly stored at 80 % rh is stronger than that of the specimens rearranged from 90 % rh. The structure of the latter, at the time of the rearrangement, is damaged to such an extent that the reaction intensified by the high humidity hardly causes new microcracks. The expansion is achieved by the widening of the existing cracks. This has no effect on the natural frequency. On the other hand, the structure of 80 % rh-specimens is at the time of the rearrangement practically undamaged. The osmotic pressure due to the AAR causes the generation of microcracks and this is indicated by the decrease in the resonance frequency.

The results show that an aging of concrete in a dry atmosphere markedly increases the risk of damage through the AAR. The explanation is that fresh concrete can yield to swelling pressures through plastic deformation. Thereby part of the pressure is cancelled. But the rigid structure of older concrete does not allow plastic deformations. Therefore more cracks are formed and the damage is more severe.

#### GRAIN SIZE OF THE REACTIVE AGGREGATE

Another example of a delayed reaction's causing more damage than a fast reaction is provided by the investigation of the influence of the grain size of the reactive aggregate on the AAR. Four test series with the granulometric fractions 0.09 - 0.5 mm; 0.5 - 1 mm; 1 - 3.15 mm; 3.15 - 5 mm of the opaline sandstone were prepared.

Fig. 5 Expansion and resonance frequency of mortar bars containing opaline sandstone of different grain sizes

The specimens containing the finest reactive aggregate (0.09 - 0.5 mm) attain their ultimate expansion after a period of about 100 days humid storage. Then their resonance frequency increases continuously.

The structure reheals as the first reaction products solidify through the reaction with lime and thus cement the cracks.

The specimens containing the fraction 0.5 - 1 mm exceed the expansion of the former after 225 days and reach their final expansion only after more than 900 days. This slow expansion is accompanied by a continuous decrease in the resonance frequency. The frequency does not indicate the beginning of the re-healing process until after more than 800 days.

The mortar bars containing the coarser reactive aggregate fractions expand more slowly but after 1200 days the expansion of the specimens containing the fraction 1 - 3.15 mm exceed the expansion of the bars with the finest fraction. The decrease in the resonance frequency of the specimens with the coarse fractions after 1000 days clearly indicates the progress of the damage due to the AAR.

Another result of these tests is that investigations over limited periods of one or two years may in some cases only give limited information about the parameters influencing the AAR.

## Resistance of hardened cement mortar to magnesium chloride solution

### *Résistance d'un mortier au ciment durci à une solution de chlorure de magnésium*

Y. SUZUKAWA, Dr. Central Research Laboratory, Ube Industries, Ltd. Japan.

RESUME : Des échantillons de mortier faits avec divers types de ciment commercial ont été immergés dans des solutions contenant 1, 4, et 25 g. de  $MgCl_2$ /l pendant un an.

Les résultats de l'essai ont montré que le ciment Portland de laitier de haut fourneau, avec une teneur élevée en laitier a une bonne résistivité, comme nous l'avons décrit précédemment dans notre rapport. Aucune relation n'a été observée entre la diminution de la résistance du mortier et la teneur en  $C_3A$  du ciment Portland.

La détérioration du mortier de ciment durci est principalement due à une augmentation de la porosité du mortier produite par la dissolution de  $Ca(OH)_2$ .

SUMMARY : Mortar specimens made with various types of commercial cement were immersed in solutions containing 1, 4, and 25 g.  $MgCl_2$ /l. up to 1 year.

Test results showed that portland blast-furnace slag cement with a higher content of slag has a good resistivity as reported previously. No relationships were observed between the decrease in mortar strength and the  $C_3A$  content of portland cement.

The deterioration of hardened cement mortar is due mainly to an increase in the porosity of mortar caused by the dissolution of  $Ca(OH)_2$ .

Four types of portland cement, i.e., ordinary (1), moderate heat of hydration (2), high early strength (3), and sulfate resistant (4), portland blast-furnace slag cement (5), and portland fly-ash cement (6) were used. Chemical compositions and Blaine specific surface are shown in (Table I).

## EXPERIMENT AND RESULTS

Mix proportion of cement : sand : water of the mortar used is 1 : 2 : 0.65. Size of specimen for compressive strength test is 4 x 4 x 16 cm. and that for expansion test is 1 x 1 x 11.25 inch.

After molding, these specimens were cured in moist closet for 1 day and then cured in water for 6 days. After this period, they were cured in water or in MgCl<sub>2</sub> solution at 20°C until the time of test. The concentration of MgCl<sub>2</sub> solution used is 1, 4, and 25 g. MgCl<sub>2</sub> per litre, respectively.

At the ages of 1, 4, 13, 26, and 52 weeks, mortar strength and expansion were measured. After strength test, mortar specimens were cut from the surface at an interval of 5 mm. into four parts with equal thickness. These cutting specimens were subjected to chemical and X-ray analyses and electron microscopic observation. Total pore volume and pore size distribution were also measured.

Compressive strength ratio of mortars cured in solution containing 25 g. MgCl<sub>2</sub>/l. and those cured in water up to the age of 52 weeks is shown in (Table II).

Within the scope of this experiment, no relations were observed between the decrease in compressive strength ratio and the content of C<sub>3</sub>A in portland cement.

TABLE II

Sample No.	Compressive strength ratio		
	Curing period in weeks		
	4	26	52
1	84	64	47
2	87	63	58
3	91	67	62
4	88	65	53
5	104	100	94
6	95	65	63

In the expansion of mortar cured in MgCl<sub>2</sub> solution, portland fly-ash cement mortar showed a little higher value, but the other cement mortars showed approximately the same value as compared with the expansion of corresponding specimens cured in water.

The surface of mortar specimens immersed in MgCl<sub>2</sub> solution was covered with a white colour film, consisting mainly of Mg(OH)<sub>2</sub>, as reported by Kalousek and Benton (1), and the formation of C<sub>3</sub>A·CaCl<sub>2</sub>·10H<sub>2</sub>O was also found.

Riedel (2) has already reported that in solution containing a large amount of MgCl<sub>2</sub>, magnesium oxychloride Mg<sub>2</sub>(OH)<sub>3</sub>Cl·4H<sub>2</sub>O is formed. In the present experiment up to the concentration of 25 g. MgCl<sub>2</sub> per litre, however, no formation of this compound was found.

The amount of water-soluble  $\text{Cl}^-$  ion of each cutting specimens of hardened cement mortar cured in 25 g.  $\text{MgCl}_2$  per litre solution is shown in (Figure 1).

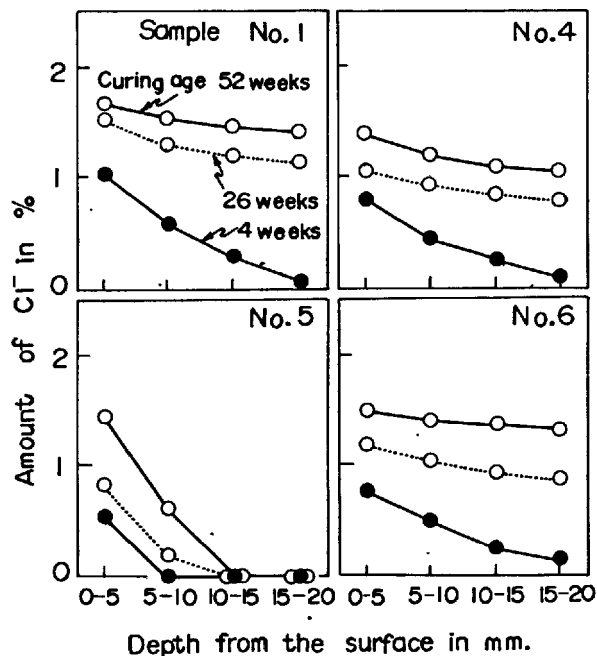

Fig. 1 - Amount of water-soluble  $\text{Cl}^-$  ion

The results showed that in portland and portland fly-ash cement mortar the penetration of  $\text{Cl}^-$  ion reaches already up to the centre portion at the age of 26 weeks and in portland blast-furnace slag cement mortar the penetration occurs up to 10-15 mm. from the surface at the age of 52 weeks.

Total pore volume was measured with sample crushed into a size of 5-1.2 mm. by using the mercury porocimeter. These values of specimens cured in water and of those cured in 25 g.  $\text{MgCl}_2$ /l. solution are shown in (Figure 2).

Figure 2 showed that only a slight difference is observed at the age of 4 weeks. However, at the age of 52 weeks, the value showed a large difference with the exception of portland blast-furnace slag cement mortar.

Based on the results obtained in Table II and Figure 2, the decrease in compressive strength ratio is related intimately to the increase in total pore volume.

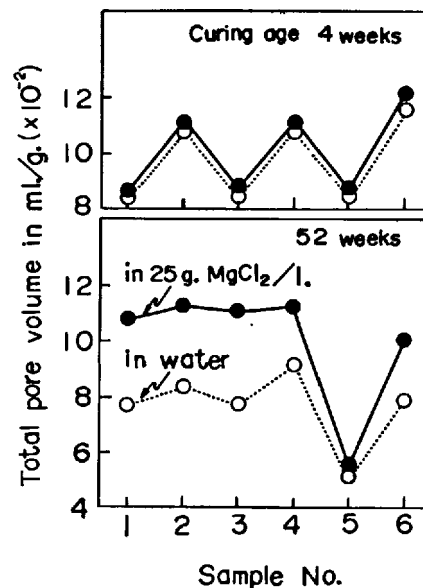

Fig. 2 - Total pore volume

#### CONCLUSION

The deterioration of hardened cement mortar in  $\text{MgCl}_2$  solution is due mainly to an increase in the porosity of mortar caused by the dissolution of  $\text{Ca}(\text{OH})_2$ . This dissolution is expressed by the following chemical equation:

No relations were observed between the decrease in mortar strength in  $\text{MgCl}_2$  solution and the  $\text{C}_3\text{A}$  content of portland cement.

# Morphology and microstructure of cement paste/rock interfacial regions

## *Morphologie et microstructure de la pâte de ciment à la surface des granulats*

C.A. LANGTON, Graduate Assistant, and  
D.M. ROY, Professor of Materials Science, Materials Research Laboratory, The Pennsylvania State University, University Park, U.S.A.

**RESUME :** Cette étude est basée sur le fait qu'une relation importante peut exister entre, d'une part la structure et la morphologie de la zone interfaciale entre la pâte de ciment et les agrégats et, d'autre part, la formation et la propagation de microfissures. Les éprouvettes ont été préparées à 27, 60 et 90°C sous des pressions de 0,1, 6,9 et 68,9 MPa. La morphologie et le mode de fracture le long de la zone interfaciale du ciment Portland et des cailloux dépendent de la réactivité des agrégats ainsi que du taux d'hydratation de la pâte de ciment.

Une région formée de deux couches apparaît dans la zone interfaciale entre les agrégats non réactifs et la pâte du ciment. La morphologie interfaciale est caractérisée par un film mince de C-H (C-S-H) à partir duquel des particules de C-H-S semblent croître. En plus des particules de C-H-S, des cristaux de plus grande taille de  $\text{Ca}(\text{OH})_2$  semblent rattacher la zone interfaciale à la pâte et, par conséquent, les agrégats à la pâte. Lorsque le taux d'hydratation augmente, une plus grande quantité de pâte est fixée à la zone interfaciale. Des examens tous les 6 mois montrent que la zone interfaciale conserve une structure formée de 2 couches.

Contrairement à la région à 2 couches formée sur un agrégat non réactif et contrairement aussi à ce qui a été publié sur les surfaces réactives, nous avons trouvé 4 couches interfaciales sur des surfaces réactives. La surface réactive des agrégats est d'une manière typique recouverte d'une couche de S-C-K-H à partir de laquelle des particules de S-C-K-H semblent croître. Ces deux couches forment la Zone I. Les particules S-C-K-H de la Zone I sont recouvertes d'un second film de C-S-H (C-H) contenant relativement plus de calcium que de silicium et pas d'alcalis. Ici encore les particules de C-H-S semblent croître à partir de cette couche, rattachant ainsi la zone interfaciale à la pâte de ciment.

Des groupes indépendants de fissures dues au retrait sont observés dans les Zones I et II. Toutefois, ces fissures sont beaucoup plus nombreuses dans la Zone I (S-C-K-H). La fracture se propage typiquement en marches à travers chaque couche de la zone interfaciale.

Des pressions élevées furent utilisées pour augmenter les contacts entre la pâte et la surface des cailloux et furent aussi combinées avec une température élevée pour accroître la vitesse d'hydratation. La rugosité du gravier n'a pas d'effet majeur sur la structure de base de l'interface.

**ABSTRACT:** The present investigation was based on the likelihood that an important relationship might exist between the structure and morphology of the cement paste/aggregate (wall rock), interfacial region and the initiation and propagation of microcracks. Curing conditions included temperatures of 27, 60, and 90°C and pressures of 0.1, 6.9, and 68.9 MPa. The morphology and mode of fracture at the interfacial region formed between portland cement and rock were both dependent on reactivity of the aggregate and degree of hydration of the cement paste. A two layered zone developed in the interfacial region between non-reactive aggregates and portland cement paste. The interfacial morphology is characterized by a thin film of C-H (C-S-H) from which C-S-H particles appear to be growing. In addition to C-S-H particles, larger crystals of  $\text{Ca}(\text{OH})_2$  appear to attach the interfacial region to the bulk paste and thereby the aggregate to the bulk paste. As the degree of hydration increased, more bulk paste became attached to the interfacial region. Where the interfacial region was exposed in six month runs it still appeared as a two layer zone.

In contrast to the two-layered region formed on an unreactive aggregate and previously reported on reactive surfaces, four interfacial layers were characteristically present on reactive surfaces. The reactive aggregate surface was typically overlain by a S-C-K-H film from which S-C-K-H particles appeared to be growing. These two layers make up Zone I. S-C-K-H particles on Zone I were attached to an overlying second film containing relatively more calcium than silicon and no alkali, C-S-H (C-H) film. Again, C-S-H particles appeared to be growing from this film and attaching the interfacial region to the bulk paste. Independent sets of shrinkage cracks were observed in both Zones I and II. However, they were much more abundant in Zone I (S-C-K-H Zone). Fracture typically took place in a step-like manner across each layer of the interfacial region.

The effect of elevated pressures was to increase the contact between paste and rock surface and, when combined with elevated temperature, to increase also the hydration rate. Surface roughness of the rock resulted in no major effect upon the basic structure of the interface.

## INTRODUCTION

The present investigation is based on the likelihood that an important relationship exists between the structure and morphology of the interfacial region formed at a cement paste/aggregate (wall rock) contact, and the initiation and propagation of microcracks. The characteristics of this region may be responsible for eventual failure through decreased strength and/or permeability. Previously, little attempt has been made to relate microstructure to microcracking or to evaluate them in terms of measurable physical properties (1-3). Characterization of the morphology of the interfacial region formed between portland cement and various substrates is particularly important if cement or concrete is to be used as a containment material for potentially harmful substances, such as radioactive waste stored in mined underground repositories. The type of interfacial morphology developed on specific rocks is a means of classifying them as reactive or nonreactive. Accurate characterization of the interfacial region also may be a method of early detection of reactive materials. Data concerning the morphology of the interfacial region are presented here; the relation between cement/rock interfacial regions and permeability and bond strength are discussed elsewhere (4,5).

## EXPERIMENTAL PROCEDURE

Curing conditions chosen for this study included temperatures of 27, 60 and 90°C and pressures of 0.1, 6.9, and 68.9 MPa. Experiments conducted at ambient temperature, 0.1 MPa, were carried out in temperature-controlled, constant-humidity chambers; higher pressure runs were made in stainless steel autoclaves. Temperatures below 100°C were regulated in a water bath. Mineral oil was used as the heat-transfer medium in longer term runs. Curing times of relatively short duration (most of which were less than three days) were intended to study the interfacial morphology as a function of temperature and pressure with little or no cement/aggregate interaction. Longer term experiments, up to six months, were also conducted to determine the nature and extent of the aggregate/cement reaction.

Pastes were prepared according to ASTM procedure C305 using a low alkali portland type I cement. Low-alkali cement was chosen to prevent extensive rapid reaction from masking the interfacial morphologies and time-dependent characteristics. A w/c ratio of 0.40 was used. Chemical analysis of the cement is as follows:

## Portland Type I Cement

CaO = 64.99	MgO = 2.09
SiO <sub>2</sub> = 21.00	SO <sub>3</sub> = 2.61
Al <sub>2</sub> O <sub>3</sub> = 5.22	Na <sub>2</sub> O = 0.08
Fe <sub>2</sub> O <sub>3</sub> = 2.90	K <sub>2</sub> O = 0.74

"Aggregates" (rock slices) used included: Tuscarora quartzite, 95% quartz with a silica cement; a siltstone member of the Juniata formation containing approximately 25-30% matrix of illite and about 65% quartz; the Valentine limestone, 99.9% calcium carbonate; Beltane opal from Sonoma county, California, containing cristobalite and minor amounts of tridymite and alunitite.

These rocks were slabbed, cored, and cut into discs 19.1 mm in diameter and 6.4 mm thick. One face was ground to 600 grit; the other left as sawn. Rock

samples were stored at room temperature and 100% relative humidity according to ASTM procedure C227.

The cement paste/rock disc samples were cast in polyethylene molds and set for 12 hours at 25°C and greater than 95% relative humidity. The specimens were then cured for 1, 3, 7, and 28 days. Three- and six-month runs also were made. Some high-temperature, high-pressure experiments were also conducted in which setting and curing conditions were identical. Sample geometry is illustrated in Figure 1.

After samples were removed from the autoclaves, the cement cylinders were cut longitudinally and placed in liquid nitrogen for 15 minutes. The samples were then freeze-dried on a cold-plate vacuum desiccator for 48 hours to stop further hydration and to remove free water. One longitudinal half of the sample was fractured along the interface and the complementary halves (paste and aggregate) were gold coated. In some cases, the other longitudinal half of the sample was used to make polished sections perpendicular to the interface. All samples were stored over magnesium perchlorate until viewed under a Scanning Electron Microscope with energy dispersive x-ray analysis.

## RESULTS

In preliminary experiments, samples were set at 25, 60, and 90°C and 100% relative humidity for 12 and 24 hours. The result of increasing setting time and temperature was to increase the degree of hydration. However, the basic structure of the interfacial region remained relatively unchanged after the setting period (even for the opaline aggregate).

Figure 2 shows the morphology of the interfacial region formed on a Valentine limestone surface. The sample was cured for 24 hours at 60°C and 0.1 MPa pressure. This morphology is representative of the interfacial

Figure 1. Geometry of sample preparation.

regions formed with other types of rock when samples were subjected to similar curing conditions. In all cases, fracture occurred through void spaces between hydrating cement grains and through voids formed between the hydration of shells of partially hydrated cement grains and their unhydrated cores. The rock portion of the fractured surface appears coated with fine acicular C-S-H gel and hexagonal  $\text{Ca(OH)}_2$  crystals ranging in size up to about 20  $\mu\text{m}$ . In addition, numerous partially hydrated cement grains are attached to the rock surface.

The paste half of the sample appears as partially hydrated cement grains covered with fine C-S-H gel growing perpendicular to the grain surfaces and hexagonal  $\text{Ca(OH)}_2$  crystals growing in some of the pore spaces.

Figure 3 shows the morphology of the interfacial region formed on a similar limestone surface in a sample cured for three days at 60°C and 0.1 MPa pressure. The structure formed after three days is similar to that formed after 24 hours. However, fewer partially hydrated cement grains are attached to the rock surface and, therefore, the layer of C-S-H gel is more clearly exposed.  $\text{Ca(OH)}_2$  crystals are still attached to the rock surface and in some places are coated with patches of acicular C-S-H gel.

The paste half of the sample is more hydrated after three days. Patches of well-crystallized equant hydrogarnets were also observed and are more common at the higher temperatures. Hexagonal  $\text{Ca(OH)}_2$  crystals were found in pores and between hydrating cement grains.

Energy dispersive x-ray (EDX) analyses of the C-S-H gel formed during the first day of hydration indicated that the average Si:Ca ratio increased slightly with increasing temperature. Qualitative compositional analysis of the calcium hydroxide within a given sample indicated a compositional range from almost pure  $\text{Ca(OH)}_2$  to appreciable amounts of Si, Al, and S. In places, large  $\text{Ca(OH)}_2$  crystals were observed engulfing smaller  $\text{Ca(OH)}_2$  grains and partially hydrated cement grains. The solubility of lime in water at 90°C is approximately 1/2 the solubility at 25°C. As temperature was increased from 25°C to the curing temperature, calcium apparently precipitated out of solution and grew to form these large  $\text{Ca(OH)}_2$  crystals.

Secondary deposits of  $\text{Ca(OH)}_2$  resembling small closely spaced platelets have been reported filling open spaces near the interface after about three days for samples cured at 25°C (1-3). This structure was not typical of the interfacial regions formed at higher temperatures and pressures. However, it was observed lining voids presumably formed by air bubbles trapped in the cement.

One effect of pressure on the morphology of the interfacial region is to increase the contact between the cement and rock. Figure 4 shows the interfacial region developed after curing for three days at 90°C and 68.9 MPa. This figure shows the paste half of the sample taken from the unpolished side of the Tuscarora quartzite. After three days, most of the C-S-H gel and  $\text{Ca(OH)}_2$  formed at the interface are attached to the paste. The C-S-H paste forms a blanket-like texture made up of interlocking rosette structures.

Figure 5 again shows the paste half of the sample; the other half is polished quartzite. The sample was cured for seven days at 90°C and 68.9 MPa. The medium-gray, smooth-textured area in the center of the figure is a

portion of the  $\text{Ca(OH)}_2$  film which was deposited on the rock surface shortly after it came in contact with the paste. When the sample was fractured, part of the thin lime film remained attached to the rock, and part to the bulk cement.

Figure 6 shows the aggregate half of a sample cured for seven days at 90°C and 68.9 MPa. The aggregate in this case was unpolished Juniata siltstone. Hexagonal  $\text{Ca(OH)}_2$  crystals, dense C-S-H gel, and partially hydrated clinker grains are attached to the siltstone surface and masks the interfacial morphology after only seven days curing. This was also the case for limestone and quartzite aggregates.

Samples containing Valentine limestone, Tuscarora quartzite and Juniata siltstone, when cured for periods of up to 28 days, showed continued hydration. When samples were broken, fracture occurred through the bulk paste above the interface. Most of the hydration products formed during these studies thus remained attached to the bulk paste. It was therefore difficult to detect changes in and/or characterize the interfacial morphologies of these three relatively non-reactive rock types.

An entirely different type of interfacial morphology was detected in samples containing opaline aggregates cured seven days to six months at 27°, 60° and 90°C over the entire pressure range studied. (Three-day samples showed morphologies similar to those previously discussed.) Fracture was observed to take place typically in layered steps from the aggregate surface upwards through the interfacial region and then the bulk cement paste. The interfacial region between the reactive opaline rock and the low alkali Type I cement was characterized by two zones each of which was made up of a thin film on which semicrystalline or gel particles appeared to be growing. Figure 7 is an SEM stereo image of the two-zoned interfacial region developed on a reactive opaline rock. The opaline substrate is exposed in the upper left of the image. It is overlain by a thin film, from which particles appear to be growing, Interfacial Zone I. Shrinkage cracks were most likely induced in the desiccation necessary for SEM/EDX analysis. An enlargement of the gel particles in Zone I is shown in Figure 8.

Zone II is seen in Figure 7 overlying the particles on Zone I. Interfacial Zone II is also characterized by a film on which particles appear to be growing. Figure 9 is an enlarged view of Zone II which typically consists of a porous film covered with C-S-H gel particles.

An EDX-qualitative chemical analysis from area A, Figure 7, is plotted in Figure 10a. Zone I has a silica-rich potassium-calcium composition. Comparative analyses of the film versus the particles in this interfacial zone indicated a slightly higher Si:Ca ratio for the film. A chemical analysis of Zone II is shown in Figure 10b and can be seen to contain a relatively higher Ca:Si ratio and no potassium, in contrast to the analyses of Zone I.

Bulk cement paste is shown in Figure 7 in the lower right corner and also in the left corner of Figure 9. It appears to be attached to the interfacial region of the C-S-H gel particles growing on the film in Zone II.

Figure 2. Morphology of interfacial region formed between paste and Valentine limestone cured 24h at 60°C and 0.1 MPa is characterized by C-S-H gel particles, partially hydrated clinker, and hexagonal  $(\text{Ca})\text{OH}_2$  crystal attached to the rock surfaces.

Figure 3. Interfacial region formed between paste and Valentine limestone cured for 3d at 60°C and 0.1 MPa is characterized by an increase in the amount of C-S-H gel particles and a decrease in partially hydrated clinker attached to the rock surface.

Figure 4. Intergrowth of C-S-H gel particles attached to the complementary paste half of the fractured sample is characteristic of the interfacial region formed between type I cement and unpolished Tuscarora quartzite surface, cured 3d at 90°C and 68.9 MPa.

Figure 5. A thin patchy film of  $\text{Ca}(\text{OH})_2$  is also characteristic of the interfacial region formed between type I cement and a polished Tuscarora quartzite surface cured 3d at 90°C, 68.9 MPa. The thin  $\text{Ca}(\text{OH})_2$  film is shown attached to the bulk paste by interlocking C-S-H particles.

Figure 6. Hexagonal  $\text{Ca}(\text{OH})_2$  crystals, dense C-S-H gel and partially hydrated clinker grains are attached to the Juniata siltstone surface after 7d curing at 90°C and 68.9 MPa.

#### DISCUSSION AND CONCLUSIONS

The morphology and mode of fracture through the interfacial region formed between portland cement paste and rock are both dependent on the reactivity of the aggregate (solubility in a high-pH solution caused by hydrolysis of uncombined free water in cement pastes to produce hydroxyl ions) and the degree of hydration of the cement paste (sodium and potassium are released into solution by the formation of ettringite which ties up sulfate ions previously combined with alkalies). The net effect of reactive rocks used as aggregates in portland cement has been termed alkali-aggregate reaction. In this study the degree of cement hydration was found to increase with increasing time and temperatures up to 90°C. Aggregates were classified as reactive and unreactive based on morphologies developed in the interfacial region after curing for six months. Valentine limestone (99.0% calcium carbonate), Tuscarora quartzite (95% quartz plus silica cement), and Juniata siltstone (25-30% illite matrix plus 65% quartz) were found to be non-reactive; Beltane opal was reactive.

Figure 7. Stereo image of the interfacial region developed between reactive Beltane opal and type I cement cured 21d at 60°C, 0.1 MPa. The opaline substrate (upper left) is overlain by an S-C-K-H film on which S-C-K-H gel particles appear to be growing (Zone I). These particles are overlain by a C-S-H (C-H) film from which C-S-H gel particles appear to be growing (Zone II). These C-S-H particles attach the interfacial region to the bulk paste shown at the lower right.

Figure 8. Magnification of S-C-K-H gel particles from Interfacial Zone I.

Figure 9. Magnification of C-S-H porous film and C-S-H gel particles making up Interfacial Zone II.

Figure 10. (a) Energy dispersive x-ray analysis of S-C-K-H gel particles within area A, Figure 7. (b) Energy dispersive x-ray analysis of C-S-H gel particles within area B, Figure 7.

Figure 11 is a schematic diagram of the characteristic two-layer zone developed in the interfacial region between a non-reactive aggregate and portland cement paste. The interfacial morphology is characterized by a thin film of C-H (C-S-H) from which C-S-H particles appear to be growing. In addition to C-S-H particles, larger crystals of  $\text{Ca}(\text{OH})_2$  appear to attach the interfacial region to the bulk paste and thereby the aggregate to the bulk paste. As the degree of hydration increased, more bulk paste became attached to the interfacial region, making further characterization of the aggregate-film contact difficult. Where the interfacial region was exposed in six-month runs it still appeared as a two-layer zone.

A schematic diagram of the morphology of the inter-

Figure 11. Schematic diagram of the interfacial region formed between a non-reactive silica substrate and Type I cement paste.

Figure 12. Schematic diagram of the interfacial region formed between a reactive silica substrate and Type I cement paste.

facial region which developed on a reactive aggregate surface is shown in Figure 12. In contrast to the two-layered region formed on an unreactive aggregate and previously reported on reactive surfaces (1-3,6),

four interfacial layers characteristically were present on reactive surfaces. The reactive aggregate surface was typically overlain by a S-C-K-H film from which S-C-K-H particles appeared to be growing. These two layers make up Zone I. S-C-K-H particles on Zone I were attached to an overlying second film containing relatively more calcium than silicon and no alkali, C-S-H (C-H) film. Again, C-S-H particles appeared to be growing from this film and attaching the interfacial region to the bulk paste. Independent sets of shrinkage cracks were observed in both Zones I and II. However, they were much more abundant in Zone I (S-C-K-H Zone). Fracture typically took place in a step-like manner across each layer of the interfacial region.

The effect of elevated pressures was to increase the contact between paste and rock surface, and, when combined with elevated temperature, to increase also the hydration rate. Surface roughness of the rock resulted in no major effect upon the basic structure of the interface.

# Interface phenomena and durability of concrete

## *Phénomènes à l'interface et durabilité du béton*

G.P. TOGNON, Chem. Eng. Italcementi S.p.A. - Laboratorio Chimico Centrale - Bergamo - Italy,  
S. CANGIANO, Chem. Eng. Italcementi S.p.A. - Laboratorio Chimico Centrale - Bergamo - Italy.

**RESUME :** En opérant sur des éprouvettes de mortier de ciment cylindriques, coulées autour d'un cylindre coaxial en calcaire ou en quartz, on a confirmé l'existence d'une porosité particulière (rayons compris entre 150 et 300 Å) à l'interface du mortier et de la pierre; elle semble due à des discontinuités dans les liaisons.

Après autoclavage, cette porosité, déjà réduite dans les éprouvettes à noyau calcaire après une cure normale, semble disparaître complètement, notamment dans les éprouvettes à noyau de quartz. Des mesures conductimétriques ont, en outre, montré que cette zone interfaciale était particulièrement perméable à NaCl. La profondeur de la pénétration du NaCl dans cette zone dépend étroitement de la dimension des pores.

L'addition d'un entraîneur d'air augmente cette perméabilité à 20°; l'augmentation est plus importante avec le noyau calcaire qu'avec le noyau quartz, par suite probablement de l'accroissement des discontinuités de liaison du fait des bulles d'air. Toutefois, des éprouvettes comportant un entraîneur d'air, et soumises à des cycles de gel/dégel ont montré que l'augmentation de la perméabilité de la zone interfaciale était plus faible que celle produite, dans les mêmes conditions, sur des éprouvettes sans entraîneur d'air.

**SUMMARY:** By testing cement mortar specimens with a cylindrical limestone or quartz inclusion in the centre, the existence of a peculiar porosity (radii between 150 and 300 Å) was confirmed at the mortar-aggregate interface, attributable to bond discontinuities. After autoclaving, such a porosity, already reduced in normally cured specimens with calcareous inclusion, appears to be almost suppressed especially in specimens with quartz inclusion. Moreover conductimetric measurements showed that the interface, compared with the mortar, is the site of a preferential penetration of a NaCl solution. The magnitude of this penetration must be related to the volume of pores there existing.

The addition of an air-entraining admixture is liable for an increase in the interface penetration at 20°C. This increase is more marked in the specimens with calcareous aggregate because of the greater extent of the bond discontinuities due to the formation of bubbles at the interface. Nevertheless the lower interface penetration observed after freeze/thaw cycles in air-entrained specimens compared with the plain ones proved that the air-entraining admixture restrains the frost action also at the interface.

## 1. INTRODUCTION

As known, the contact zone between cement matrix and aggregate plays an important role in the development of the mechanical strength of concrete, especially of the very high strength one (1, 2).

For some types of aggregates, having suitable chemical and mineralogical composition, a crystallochemical interaction is added to the interface interaction of physical type (3, 4). The former can be due to an epitaxial intergrowth between carbonated portlandite crystals and calcareous aggregates in concrete cured at ordinary temperature (3) and between quartz aggregate and tobermorite 11 Å in autoclaved mortars (5).

The discontinuities always present at the aggregate-matrix interface, which would appear already reduced in the case of epitaxis with calcareous aggregate (3), ought to be almost absent owing to the hydrothermal lime-silica reaction. In fact, in this case, the formation of a "weld bead" was observed around the aggregate (1).

It is reasonable to think that the durability of concrete is affected by the type of interaction (physical and crystallochemical), as was found for the mechanical strength. In fact the interface layer can be more permeable to water or saline solutions than the matrix or the aggregate itself.

The purpose of this work is to prove the existence of a higher permeability in the interface zone due to a peculiar porosity and to verify whether the substantial strengthening of the interface bond, observed in very high strength concretes (2, 5), yields a decrease in permeability, so improving the durability of concrete to freeze/thaw cycles.

## 2. EXPERIMENTAL

The materials used in the different tests are:

- very high strength portland cement (class 525)
- quartz containing 86.2% quartz silica
- limestone containing 99.4% CaCO<sub>3</sub>
- binder obtained by mixing the cement and the quartz ground to a Blaine specific surface of 4500 cm<sup>2</sup>/g at the 1:1.66 ratio respectively.

Two types of mortar were prepared by using these materials; an ordinary one, with cement, for specimens to be water-cured at 20°C, and another with binder for specimens to be autoclaved. The composition of the two mortars is shown in Table I.

TABLE I: Composition of mortars

Materials and mix ratios	Cement mortar %	Binder mortar %
525 Ptl cement (C)	45.8	28.6
Ground silica (4500 cm <sup>2</sup> /g) (S)	-	17.2
Quartz (fract. 0 + 0.83 mm)	54.2	54.2
W/C ratio	0.4	-
W/C + S ratio	-	0.4
C/Sand ratio	1:1.8	-
C+S/Sand ratio	-	1:1.18

Besides these, mortars containing an air-entraining admixture (saponified VINSOL resin) in the rate of 2% of the binder were made. The air content in the fresh

mixes was about 8%.

The adopted curing conditions are given in Table II.

TABLE II: Curing conditions

Normal	Autoclaved
Immersion in water at 20°C for 28 days	Presteamming about 17 h at 20°C
	Low pressure steam curing 8 h at 60°C
	Rate of temperature rise 0.7°C/min.
	High pressure steam curing 24 h at 190°C
	Rate of temperature rise 0.7°C/min.

## 2.1 Determination of the porosity in the interface zone

To determine the porosity and the pore distribution in the interface zone, porosimetric measurements were carried out by a mercury porosimeter in the range of the pore radii between 75 and 75 000 Å (6).

The measurements were performed on the specimens indicated in the first column of Table III. The specimens 5 to 8 consisted of a cylindrical calcareous or quartz core surrounded by a ring of binder paste.

TABLE III: Porosimetric values concerning the individual materials, the specimens and the interface zone

Materials	Measured volume of pores (cm <sup>3</sup> /g) (a)	Calculated volume of pores (cm <sup>3</sup> /g) (b)	Volume of the interface pores (cm <sup>3</sup> /g) (a-b)
1) Limestone (cylinders: h = 15 g = 8 mm)	0.0070	-	-
2) Quartz (cylinders: h = 15 g = 8 mm)	0.0022	-	-
3) Normally cured binder paste	0.0737	-	-
4) Autoclaved binder paste	0.0072	-	-
5) Normally cured binder paste + limestone	0.0346	0.0252	0.0094
6) Autoclaved binder paste + limestone	0.0098	0.0071	0.0027
7) Normally cured binder paste + quartz	0.0463	0.0360	0.0103
8) Autoclaved binder paste + quartz	0.0061	0.0047	0.0014

The section of the specimens is shown in the detail of figure 2.

The second column of Table III shows the pore volume determined experimentally in the different specimens. The third column lists the porosity values calculated from the porosity values of the individual components (aggregate and binder paste), their weighted ratio considered.

The difference between the measured and the calculated porosimetric values is reasonably attributable to the porosity of the interface zone.

Table III allows the following observations: in the normal curing, the interface porosity of the specimen with calcareous inclusion is lower, even if slightly, than the one of the specimen with quartz aggregate; the difference reverses when the specimens are autoclaved.

Autoclaving reduces the porosity drastically, namely: by about seven times in the specimens with quartz inclusion and by about three times in the ones with calcareous inclusion.

The pore size distribution in the interface zone of the normally cured specimens is shown in figure 1.

As can be seen, there is a peak in the pore range between 150 Å and 300 Å; the peak is more marked and shifted

ed to wider radii for the specimen containing quartz. Since these peaks are not present in the binder paste and in the aggregate, it is reasonable to attribute them to discontinuities in the interface zone.

FIG. 1: Pore size distribution of normally cured specimens (20°C - fog room)

On the contrary, this peak lacks in the autoclaved specimens. Here the two curves take a continuous trend which decreases as the radius increases. Moreover, especially in the above-mentioned range, they show a more marked porosity in the sample containing the calcareous inclusion than the one of the sample with quartz inclusion.

FIG. 2: Pore size distribution of autoclaved specimens

The presence of a certain porosity at the paste-quartz inclusion interface was confirmed experimentally as

follows. Some specimens having the shape shown in the detail of figure 2 were subjected to mercury penetration at increasing pressures. After each treatment, the paste was detached from the quartz cylinder by according to the tensile splitting test. This procedure led to determine the pressure values at which the mercury begins and ends the penetration at the interface.

FIG. 3: Autoclaved specimen with quartz inclusion split after mercury penetration at 250 atm

Figure 3 shows that, at 250 atm pressure necessary for filling the pores having  $r \geq 300 \text{ Å}$ , the contact surfaces of the two components (binder paste and aggregate) are not yet blackened by the metal. This means that the penetration of mercury has not yet occurred. The figure also shows pieces of mortar still strongly bonded to the aggregate core. On the contrary, at 400 atm pressure (pore  $r \geq 150 \text{ Å}$ ), the mercury penetrated the specimen.

FIG. 4: Autoclaved specimen with quartz inclusion split after mercury penetration at 400 atm

As figure 4 shows, the penetration occurred mainly at the interface. In fact the mercury blackens the surfaces in contact with the quartz core and the binder paste, but it does not concern the real mass of the binder paste. This fact confirms that the interface porosity, also by autoclaving, is located in a wider range of radii (150-300 Å) than the one of the binder.

## 2.2 Permeability of the interface and the cementitious matrix

To evaluate the permeability of the interface layer and the mortar, measurements of electrical conductivity were carried out on special specimens subjected to penetration of a NaCl solution.

The electrical conductivity of the hardened and wet

cement pastes was recently (7) described by a model consisting of an equivalent circuit composed of four parallel resistances. In this model, the total conductance of the system is given by the sum of the following conductances:

$y_0$  = inherent conductance of the paste  
 $y_{ad}$  = conductance of the adsorbed water films  
 $y_{elk}$  = conductance depending on the electrokinetic processes  
 $y_{ely}$  = electrolytic conductance.

By considering this model, the Authors tried to maintain the effect of the three first terms constant by always operating in alternating current, at the same frequency and with equal "cells" for all the specimens. Under these conditions, the differences of conductivity among the different specimens were only attributable to the term  $y_{ely}$  which depends on the amount and the number of ionic species participating in the electrolytic conduction.

The conductimetric tests were carried out on mortar prisms (10 x 10 x 4 cm) whose upper part was provided with a cylindrical cavity ( $\phi = 5$  cm,  $h = 2$  cm) suitable for accommodating a 3% NaCl solution (figure 5).

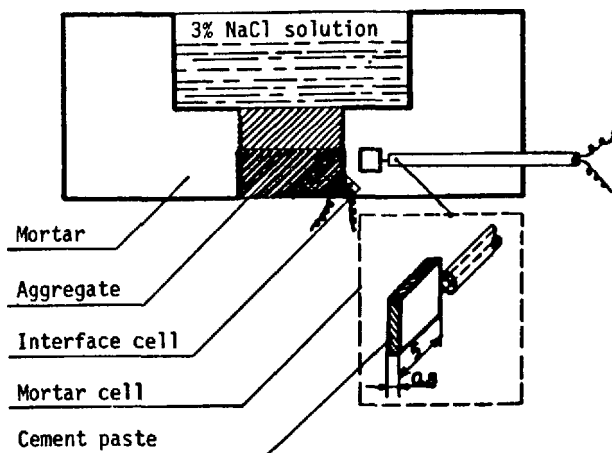

FIG. 5: Specimen and arrangement of conductimetric cells for penetration tests

Before casting the mortar, an aggregate cylinder ( $\phi = 2.2$  cm,  $h = 2$  cm) was placed in the centre of a suitably shaped mould. Moreover, a measurement "cell", represented in the detail of the same figure 5, consisting of two platinum electrodes (5 x 5 mm) 0.8 mm distant from each other and between which a cement paste ( $w/c = 0.5$ ) was previously cast, was carefully introduced into the mould at the distance of 3.5 mm from the aggregate inclusion and at the depth of 1 cm. Another cell (interface cell) adherent to the aggregate cylinder was placed at the same depth as the previous one. Its construction was carried out as follows. The first electrode was drawn on the cylinder by a silver colloidal suspension and immediately covered by a thin layer of cement paste ( $w/c = 0.5$ ) whose thickness was determined by weighing. The second electrode was drawn on this paste again by the silver suspension. The conductimetric tests were performed continuously at 20°C and during freeze/thaw cycles by working with a conductimeter having a 1 kHz operating frequency, judged as optimum for conductimetric tests on cement pastes (8) under a 200 mV tension.

### 2.2.1 Permeability at 20°C

As for the normally cured specimens, the increase in conductivity was always indicated at first by the cell at the interface and then by the one embedded in the mortar. Indeed, the latter did show no significant conductimetric signal since the specimen cracked at varying times but anyhow subsequent to those of appearance of the signal at the interface.

TABLE IV: Times of appearance of the conductimetric signal at the interface

Type of specimen	Hours from the beginning of the permeation
Ordinary mortar + calcareous inclusion	4
Ordinary air-entrained mortar + calcareous inclusion	2.5
Ordinary mortar + quartz inclusion	1
Ordinary air-entrained mortar + quartz inclusion	0.5

Table IV shows the times of appearance of the conductimetric signal at the interface. They were measured from when the NaCl solution was poured into the cavities of the specimens.

FIG. 6: Conductivity curves at the interface (A) and in the mortar (B) of autoclaved specimens stored at 20°C and 50% R.H.

Figure 6 gives the conductivity trend measured on autoclaved specimens. These did never show cracking because of their high strength.

The recorded data show that, for all the specimens, the conductimetric signal appears before at the interface than in the mortar and, at least in the first 48 hours, it takes ever-increasing values at the interface compared with those of the mortar. Obviously this means that the interface zone constitutes a preferential way to permeation.

The permeation in the mortar is affected, owing to the side diffusion, by the rapidity of its occurrence at the interface. In fact more rapid increases in conductivity were noticed in the mortar of the specimens whose interface revealed a quicker permeation. The normally cured specimens (Table IV) with quartz inclusion showed more rapid permeations at the interface than those of specimens with calcareous inclusion.

sion.

The autoclaving of the specimens containing quartz aggregate strongly reduces the permeability and causes a considerable delay in the appearance of the conductimetric signal compared with what observed in the normally cured specimens (see figure 6).

On the contrary the same behaviour is not recorded for the specimens with calcareous aggregate. In this case the autoclaving, compared with the normal curing, does not involve a substantial decrease in permeability. In all cases, the addition of air-entraining admixture causes the appearance of the conductimetric signal in advance and therefore it increases the permeability.

### 2.2.2 Permeability during freeze/thaw cycles

Figure 7 shows the conductivity values measured during freeze/thaw cycles in the air (cooling or heating rate:  $5^{\circ}\text{C/h}$  - storage at extreme temperatures ( $+20^{\circ}$ ,  $-20^{\circ}$ ); 4 h) in the interface zone and in the mortar of autoclaved specimens.

FIG. 7: Conductivity curves at the interface (A) and in the mortar (B) of autoclaved specimens subjected to freeze/thaw cycles

It was not possible to work on the normally cured specimens because of the aforesaid phenomenon of cracking. The curves are affected by the effect of the thermal alternances on the conductivity and the permeation. Both phenomena are progressively reduced by a decrease in temperature until they are partially blocked.

At about  $-8^{\circ}\text{C}$ , a rapid drop in conductivity is observed when the water begins freezing in the pores of the paste placed between the electrodes of the two cells.

Figure 7 shows that, similarly to what occurs in the case of the permeation at  $20^{\circ}\text{C}$ , the specimens with calcareous inclusion have a higher interface conductivity than the one of the specimens with quartz inclusion.

The addition of air-entraining admixture causes a decrease in permeation at the interface for both types of specimens, that is an opposite behaviour to the one occurring at  $20^{\circ}\text{C}$ .

The comparison of the curves of figures 6 and 7 evidences that, at the end of the cycles, the interface shows higher conductivity values than those attained in the same period of time by the analogous specimens stored at  $20^{\circ}\text{C}$ , except for the air-entrained one with calcareous inclusion.

On the contrary an appreciable increase in conductivity is measured in the mortar only after the 3rd cycle.

### 3. DISCUSSION

The normal curing gives the specimens with calcareous inclusion a lower interface porosity by 10% than the one of specimens with quartz inclusion. This fact must be related to the formation of an epitaxial-type additional bond at the mortar-limestone interface (3).

The considerable reduction in the interface porosity occurring in the autoclaved specimens with quartz aggregate must be attributed to the existence of wide surfaces of lime-silica reaction. On the other hand the presence of a residual interface porosity confirms that not all the surface of the aggregate is involved by the reaction.

The reduction in the interface porosity also observed in the autoclaved specimens with calcareous aggregate, even if less marked than in other specimens, is likely due to the fact that the reaction products between ground silica and hydrolysis lime covering the aggregate (9) partially fill the discontinuities at the interface. Actually these discontinuities are still visible under the electron microscope (1).

The autoclaved plain specimens with calcareous aggregate show a considerably higher permeability at the interface than the one of specimens with quartz inclusion, even if the respective interface porosities are of the same order of magnitude ( $0.0027$  and  $0.0014 \text{ cm}^3/\text{g}$ ). This is related to the fact that the NaCl solution by exerting its disjoining action (3, 10), can penetrate only the zones where there is no epitaxial intergrowth. In the case of calcareous inclusion, the interface bond mainly occurs by physical cohesion whereas wider and broader interaction zones of crystalline chemical type form on the quartz one.

Microscopic observations showed that the autoclaved and normally cured air-entrained specimens with calcareous inclusion have a higher concentration of bubbles at the interface than the one found at the quartz-mortar interface (figures 8 and 9).

FIG. 8: Air bubbles present in the mortar (upper left side) and at the calcareous inclusion-mortar interface -  $10\times$

This explains the insignificant difference of permeability between air-entrained and plain specimens when

the inclusion is quartzy and the considerable difference when the inclusion is calcareous.

FIG. 9: Air bubbles present in the mortar (left side) and lacking at the quartz inclusion-mortar interface - 10 X

The bubbles at the interface form discontinuities and determine a higher permeation at 20°C but, in case of freezing, they act as pressure compensation chambers. In this way they prevent or anyhow retard the disaggregating action of frost (figure 7).

#### 4. CONCLUSIONS

The layer at the interface constitutes a zone of higher porosity liable for the experimentally observed preferential permeation.

The obtained results, besides confirming the hypothesis about the higher sensibility to frost of the interface zone, indicate that the bond strengthening owing to the lime-silica reaction involves an appreciable reduction in the permeability of this zone when the specimens are subjected to freeze/thaw cycles. Nevertheless this permeability is always higher than the one observed in the mortar.

# TABLE DES MATIERES CONTENTS

## ALLOCUTIONS

### Séance inaugurale

Allocution de M. R. Poitrat .....	17
Discours de M. A. Giraud .....	19

### Séance de clôture

Conclusions du Congrès par M. F. Le Bel .....	22
Allocution de M. R. Poitrat .....	29
Allocution de M. de Assis Basilio .....	31
Allocution de M. A.S. Boldyrev .....	32

## RAPPORTS GENERAUX

### THEME I - Influence des matières premières, des combustibles et des procédés de fabrication sur la structure et les propriétés des clinkers. Influence of raw materials, fuels and manufacturing processes on clinker structure and properties.

Rapport général par M. R. Bucchi et M. J.P. Méric .....	37
Résumés des débats de la table ronde .....	43
Conclusions .....	47

### THEME II - Hydratation des ciments portland sans constituants secondaires. Hydration of pure Portland Cements.

Rapport général par M. F.W. Locher .....	49
Discussions .....	55
Conclusions de la Table ronde par P. Barret .....	57
Conclusions de F.W. Locher .....	61

### THEME III - Structure des laitiers et hydratation des ciments de laitier. Structure of slags and hydration of slag cements.

Rapport général par M. M. Von Euw .....	63
Discussions .....	71
Conclusions .....	84

### THEME IV - Structure des pouzzolanes et des cendres volantes et hydratation des ciments aux pouzzolanes et aux cendres volantes. Structure of pozzolana and fly-ash and the hydration of pozzolanic and fly-ash cements.

Rapport général par M. F. Massazza .....	85
Table ronde .....	91
Discussions .....	93
Conclusions .....	96

**THEME V - Ciments spéciaux.  
Special cements.**

Rapport général par M. de Assis Basilio .....	97
Discussions .....	107
Conclusions des échanges de la Table ronde par M. Soustelle et B.F. Cottin .....	110

**THEME VI - Les pâtes de ciment : rhéologie, évolution des propriétés et des structures.  
Cement pastes : rheology, evolution of the properties and structures.**

Rapport général par M. S. Diamond .....	113
Discussions .....	124
Conclusions .....	127

**THEME VII - Réactions aux interfaces entre ciment et granulat dans les bétons et mortiers.  
Interface reactions between cement and aggregate in concrete and mortar.**

Rapport général par M. G.M. Idorn .....	129
Discussions .....	148
Conclusions .....	151

## POSTERS

**THEME I**

M. Kouguia (URSS)	Etudes thermochimiques de la formation du clinker. Thermochemical investigations in clinker formation .....	157
R. Trettin and W. Wieker (R.D.A.)	Influence of temperature, grain size and the amount of added water on the development of the porosity and surface size during the hydration of $C_3S$ . Influence de la température, de la granulométrie et du dosage en eau sur le développement de la porosité et de la surface spécifique du $C_3S$ hydraté .....	163
Dr. S. Tsimas, Dr. V. Kasselouris, Dr. Ch. Ftikos, Dr. G. Parissakis (Greece)	Determination of specific surfaces of co-grinded materials with different grindabilities. Détermination des surfaces spécifiques des matériaux de différents broyabilités après leur broyage simultané .....	168
K. Popovic, A. Bezjak (Yougoslavie)	Influence of $MgO$ on Phase Composition of PC-Clinker and on Cement Properties. L'influence de la magnésie sur la composition de phases du clinker Portland et sur les propriétés du ciment .....	172
A. Mituzas, J. Mituzas, L. Ramanauskiene (USSR)	A method for determination of free $CaO$ ( $Ca(OH)_2$ ) in binding materials La détermination de la chaux libre dans des matériaux cimentés .....	178
A. Boikova, A. Esayan, V. Lazukin (URSS)	On the composition of cement minerals. Sur la composition minérale du ciment .....	183
A.M. Dmitriev, M.T. Vlassova, B.E. Youdovitch, S.I. Ivachtchenko (URSS)	Investigation of aluminoferrite calcium crystallization processes. Etude du processus de cristallisation des aluminoferrites de calcium .....	186
Y.I. Sidorovitch (URSS)	Shales and their working-over solid by-products in portland cement production. Schistes et déchets solides de leur transformation dans la production du ciment portland .....	191

**THEME II**

Y.S. Malinine, V.I. Gousseva, N.D. Klichanis (URSS)	On the process of $C_3S$ hydration in initial period. Etude sur le processus d'hydratation de $C_3S$ à la période initiale .....	195
--	---	-----

G. Stadelmann and W. Wieker (RDA)	Influence of organic compounds on the hydration reaction of tricalciumsilicate Influence de certains composés organiques sur l'hydratation du $C_3S$ .....	199
V.V. Timachev, V.G. Akimov	Influence des défauts ponctuels sur l'activité d'hydratation des constituants de clinker. Point defects influence on the hydration activity of clinker minerals .....	203
V.A. Dmitrieva, T.V. Kouznetsova (URSS)	Electron microscope investigation of sulfoaluminate calcium hydration processes at the first stages of solidification Etude microscopique électronique des processus d'hydratation du sulfoaluminate de calcium dans les premiers délais de durcissement .....	208
I.V. Kravtchenko, V.L. Bernstein (URSS)	Utilisation des réactions de formation de l'ettringite pour l'action orientée sur les processus de formation de structure du ciment durci. Use of ettringite formation reaction for directed influence on the structure formation processes of the cement stone .....	212
B. Youdovitch, N.D. Klichanis, O.I. Papiachvili, V.G. Abramova (URSS)	Résistance du ciment portland en fonction des facteurs technologiques et micromécanisme de destruction. Portland cement strength depending on technological factors. Micromechanism of destruction .....	216
S.M. Royak, T.Y. Galperina, Y.N. Perminova, M.G. Doroguina (URSS)	Characteristics of the compositions with low water-demand based on gypsumless portland cement. Propriétés des compositions nécessitant une petite quantité d'eau sur la base du ciment portland sans gypse .....	220

### THEME III

A.T. Souleimenov, T.B. Parchikova (URSS)	Activated phosphorus slag raw material for slag portland cement production. Laitier phosphorique activé - Matière première pour la production du ciment portland de laitier .....	225
S.A. Mironov, I.I. Kurbatova, S.A. Vysotsky (URSS)	Hydratation des ciments portland de laitier à différentes températures. Hydration of blastfurnace cement under different temperatures .....	229
V.A. Beletskaja, I.G. Louginina (URSS)	Nouvelles compositions à base de laitiers. New binding compositions based on slags .....	233

### THEME IV

R. Herr, W. Wieker and G. Priem (DDR)	The use of $SiO_2$ -residues as admixtures for pozzolanic portland cements. Utilisation de résidus siliceux comme pouzzolane des ciments .....	237
V. Korac et V. Ukraincik (Yougoslavie)	Fly ash from Kakanj power plant in cement production. Production du ciment aux cendres volantes de la centrale thermique de Kakanj .....	242
Dr. Ch. Ftikos, Dr. G. Parissakis (Greece)	A study on the mechanism of the reaction of Santorin earth during its hydration with portland cements. Etude sur le mécanisme de la réaction de la terre de Santorin pendant son hydratation avec des ciments portland .....	250
V. Sabatelli, and G.L. Valenti (Italy)	Influence of alkali sulphates on setting and hardening of pozzolanic cements. Influence des sulfates alcalins sur la prise et le durcissement des ciments pouzzolaniques .....	256
L.Y. Goldstein (URSS)	Aspects chimiques et technologiques de l'utilisation des machefers granulés lors de la fabrication du ciment. Physicochemical and technological aspects of application of furnace granulate slags in cement production .....	261
M.B. Svatovskaya, M.M. Sytchev, L.Y. Goldstein (URSS)	Alite composition and structure state of ferrum in high-basic furnace slags. Composition de l'alite et état structural du fer dans les machefers à haute basicité .....	266
L. Kourassova, Z. Larionova (URSS)	Influence des matériaux analogiques aux pouzzolanes sur la formation de la structure du ciment durci. Influence effects of pozzolona-like materials on structure formation of cement stone .....	270

## THEME V

A.N. Kazanskaia, M.M. Sytchev, Spirov I.S. (URSS)	Centres basiques sur la surface des solutions solides du silicate bicalcique. Basic centers on the surface of dicalcium silicate .....	275
S.D. Makachev, V.I. Akounov, T.A. Arbekova, T.V. Kouznetsova, B.E. Youdovitch (URSS)	Mechanical-chemical activation of mixed portland cement with increased content of technogen belite product of alumina industry. Activation mecano-chimique du ciment portland mixte à teneur élevée en produit belitique technogène de la production de l'alumine .....	279
B. Mortureux, E. Revertegat, B. Thuret (France)	Synthèses à basse température de silicates bicalciques actifs. Syntheses at low temperature of active dicalcium silicates .....	283
M. Bikbaou (URSS)	Processus de formation des minéraux et composition de phase du clinker d'alinite. Mineral formation processes and phase composition of alinite clinker .....	285
G. Oliev, W. Wieker (DDR)	Calculation of Strength parameter for hydrated portland cements from hydration heats measured by differential calorimetric analysis (DCA). Prévision des résistances des ciments portland au moyen de leur chaleur d'hydratation .....	291

## THEME VI

G.A. Gamlen, D. Dollimore, P.F. Rodgers (England)	The effect of various admixtures on the surface area and pore structure of portland cement paste prepared in suspension form. Etude de l'effet de divers mélanges sur la surface spécifique et la structure poreuse de la pâte de ciment portland préparée en suspension .....	295
V.B. Tcherniavski, V.Y. Doubnitski (URSS)	Hydration and hardening processes modeling Simulation des processus d'hydratation et de durcissement des ciments ....	299
V.I. Korneev, G.N. Kassianova (URSS)	Sur la composition des produits d'hydratation des hydroaluminates et les hydrogrenats de calcium et de magnésium On the quantity of hydroaluminates and hydrogarnets of calcium and magnesium dehydration products .....	304
G.I. Gortchakov, O.A. Markova, L.P. Orentlikher, O.O. Perebatova (URSS)	Précisions pour la méthode $\alpha$ d'estimation des paramètres de la structure poreuse du ciment durci Method of the cement stone porous structure parameters estimation $\alpha$ improvements .....	308
D.-A. Ugincius (URSS)	Application of physical-chemical and micromechanical formalized models for cement stone pore structure analysis. Application des modèles formalisés physico-chimiques et micromécaniques à l'analyse de la structure poreuse de la pierre de ciment .....	313
G. Teodoru (R.F.A.)	Structures et résistances mécaniques sous des traitements hydrothermiques. Structures and mechanical resistances under hydrothermal treatments .....	318
P.F.G. Banfill, (U.K.)	Rheology of setting portland cement pastes. Rhéologie des pâtes du ciment portland faisant prise .....	324
A. Bajza (Czechoslovakia)	Effects of curing time on the mechanical properties of cement paste. Effets du temps d'étuvage sur les propriétés mécaniques de la pâte de ciment .....	329
S. Ziegeldorf, H.K. Hilsdorf, (R.F.A.)	Early autogeneous shrinkage of cement pastes. Retrait initial des pâtes de ciment .....	333

## THEME VII

G. Royak (URSS)	Etude de l'effet produit sur la déformation des bétons par les alcalis de ciment au cours de leur interaction avec la silice dans les agrégats. Investigation of cement alkalis influence on concrete deformations at interaction of the alkalis and silica in aggregates .....	339
-----------------	--	-----

L. Kourassova, Z. Larionova (URSS)	La formation de la zone de contact à la limite avec un agrégat poreux. Formation of contact zone on the border with porous aggregate .....	344
V.V. Timachev, Y.I. Benstein, L.V. Balkevitch, N.S. Nikonova (URSS)	Investigation of contact zone in cement stone hydrate phases single-crystal concretions and their concretions with aggregates. Etude de la zone de contact dans les agrégats de monocristaux des phases hydratées du ciment durci et dans leurs agrégats avec les matériaux de remplissage .....	347
V.S. Danuchevski, A.P. Tarnavski (URSS)	Corrosion des ciments portland par les gaz contenant du sulfure d'hydrogène. Portland cement hydrosulfide gas corrosion .....	353
Ch. Ftikos, V. Kassalouris, S. Tsimas, G. Parissakis (Greece)	A study on the action of sea water on hydrated cement pastes. Etude de l'action de l'eau de mer sur les pâtes de ciments hydratés .....	357
D.I. Bhatti, D. Dollimore, G.A. Gamlen, R.J. Mangabhai (England)	The mechanical properties of polymer modified cement paste cured under sea and tapwater. Les propriétés mécaniques de la pâte de ciment modifiée par l'addition de polymères, et conservées dans l'eau de mer ou dans l'eau du robinet .....	363

## COMMUNICATIONS

### THEME I

M. Bikbaou (URSS)	Processus de formation des minéraux et la composition de phase du clinker d'alinite. Mineral formation processes and phase composition of alinite clinker .....	371
-------------------	---	-----

### THEME V

J. Bensted (England)	Quantitative determination of the degree of conversion of high alumina cement. La détermination quantitative du degré de la conversion du ciment alumineux .....	377
Deng Jun-an, Ge Wen-min, Su Mu-zhen, Li Xiu-ying (Chine Populaire)	Sulfoaluminate cement series. Ciments sulfoalumineux .....	381

### THEME VI

S. Modry, J. Hejduk (Czechoslovakia)	The limitation of high pressure mercury porosimetry to the study of hardened cement pastes. Mesures de dimension des pores par pénétration de mercure dans l'étude des pâtes de ciment durci .....	387
O.Z. Cebeci (Saudi Arabia)	Ca(OH) <sub>2</sub> formation in air voids of cement pastes. La formation des cristaux de Ca(OH) <sub>2</sub> dans les vides de pâtes de ciment .....	390
Erik J. Sellevold, Dirch H. Bager (Denmark)	Low temperature calorimetry as a pore structure probe. Détermination de la structure des pores, par calorimétrie à basse température .....	394

### THEME VII

J.H.P. Van Aardt, S. Visser (South Africa)	Sulphate expansion of cement products made with aggregates containing Ca- rich feldspars. Gonflement sous l'action des sulfates des ciments en contact avec des granulats calcaires riches en feldspath .....	400
A.F. Chtchourov (URSS)	Microtexture et résistance mécanique du ciment durci. Microtexture and mechanical resistance of hardened cement .....	404

## SEMINAIRES

### SEMINAIRE A – Rôle du $C_3A$ sous toutes ses formes dans l'hydratation des ciments et leur attaque par les sulfates

Introduction par Mme M. Regourd .....	415
<b>THEME 1 - Polymorphism of <math>C_3A</math> and its solid solutions.</b> <b>Polymorphisme de <math>C_3A</math> et de ses solutions solides.</b>	
General report by A.E. Moore (U.K.) .....	417
Rapport général par A.E. Moore (U.K.) .....	419
Communications :	
V.V. Timachev, A.P. Ossokine, E.N. Potapova, E. Nikolski (U.R.S.S.)	La non-stoechiométrie des solutions solides de $C_{11}A_7CaX_2$ et leurs propriétés. Non-stoichiometry of solid solutions $C_{11}A_7CaX_2$ and their properties .....
	421
Y. Takéuchi, F. Nishi, I. Maki, (Japon)	Structural aspect of the $C_3A-Na_2O$ solid solutions. Etude de la structure des solutions solides $C_3A-Na_2O$ .....
	426
B. Tavasci, F. Massazza, U. Costa (Italy)	Anisotropic forms of $C_3A$ : phase relations. Formes anisotropiques de $C_3A$ : relations de phase .....
	432
<b>THEME 2 - The hydration of <math>C_3A</math></b> <b>Hydratation de <math>C_3A</math></b>	
General Report by H.N. Stein (The Netherlands) .....	438
Rapport Général par H.N. Stein (The Netherlands) .....	441
Communications :	
P. Barret, D. Bertrandie, (France)	Hydratation de $C_3A$ en présence d'eau de chaux Hydration of $C_3A$ in lime water .....
	443
H.N. Stein (The Netherlands)	The Colloid Chemistry of calcium aluminate hydrates. La chimie colloïdale des aluminates de calcium hydratés .....
	449

N. Bilanda, P. Fierens, J. Tirlocq, N. Tenoutasse (Belgique)	Hydratation de l'aluminate tricalcique dopé à l'oxyde de sodium. Hydration of tricalcium aluminate doped by sodium oxide	607

## SHORT COMMUNICATION

J. Calleja (Spain)	Some considerations on the present state and future trends of knowledge on calcium aluminates, as a possible basis for discussing the future work in this field	613
--------------------	---	-----

## SEMINAIRE B - Insolubilisation à l'aide de liants hydrauliques des ions métalliques contenus dans les boues industrielles

Introduction par M. J.-P. Méric		616
Exposés généraux :		
P. Longuet, G. Bellina, (France)	Chimie des ciments et traitement des boues minérales. Cement chemistry and mineral sludge processing	617
P.-J. Pichat, (France)	La solidification des déchets : motivations, acquis, perspectives. Solidification techniques motivations, state of the technology, developments	623

Communications :

L. Petit, P.-G. Rouxhet, (Belgique)	Incorporation d'ions métalliques dans la silice. Incorporation of metallic ions in silica .....	629
J.-M. Blanchard, (France)	Caractérisation des boues d'hydroxydes. Characterization of hydroxide sludges .....	635
V. Formanek, (France)	Importance de l'absorption des ions métalliques sur les surfaces minérales dans le procédé de flottation. Importance of metallic ions absorption on the mineral surfaces in the floating process .....	639
J.J. Emery (Canada)	Stabilizing industrial sludge for fill applications. Stabilisation des boues industrielles pour comblement d'excavations .....	644
Tomonitsu Sugi, Koji Kataoka, Shuzo Yamada, Yutaka Ando (Japan)	Solidification of sludges with cement-slag-CaSO <sub>4</sub> . Solidification des boues à l'aide de ciment, de laitier et de gypse .....	649
Takashi Suzuki, Toshiaki Hatsushika, Yasumasa Hayakawa, (Japan)	Removal of valuable but toxic ions from waste water by synthetic hydroxyapatites. Utilisation des hydroxyapatites de synthèse pour la récupération d'ions métalliques toxiques .....	653
E. Rau, (U.S.A.)	The Poz-O-Tec process for fixation of industrial wastes. Le procédé Poz-O-Tec de traitement des cambouis industriels .....	657
J.B. Leroy, (France)	Fixation des boues industrielles avant décharge. Consolidation of industrial sludge before disposal .....	663
Compte rendu général par P. Longuet .....		667
Conclusion du séminaire par J.-P. Méric .....		668

### SEMINAIRE C - Economies d'énergie vues prospectives (Président, M.-A. Guy)

Communications :

G. Urbain (France)	La chimie solaire à température élevée. High temperature solar chemistry .....	669
P. Etoc, (France)	Utilisation d'un sous-produit à très haute teneur en soufre comme combustible dans un four de cimenterie, sans transfert de pollution atmosphérique. Use of a by-product with very high sulphur content as fuel in a cement kiln, without transferring atmospheric pollution .....	674
L. Vorobeichikov, V. Satarin, (U.R.S.S.)	Complex utilization of rotary kiln heat losses. Utilisation complexe des pertes de l'énergie thermique par les fours rotatifs .....	680
G.-R. Gouda, G.-J. Labelle, (U.S.A.)	Opportunities for energy saving in the cement industry. La conservation d'énergie dans l'industrie cimentière .....	685

J. Bouchet (France)	Industrie et électricité dans un proche avenir. Industry and electricity in a near future .....	689
I. Teoreanu, D. Dulamescu, (Roumanie)	Corrélations entre la proportion de laitier, la marque du ciment et les consommations énergétiques à la fabrication des ciments mixtes. Correlation of slag ratio, cement class and power consumptions in mixed cement production .....	693
M. Kondo, S. Fukuda (Japon)	The latest operation performance of the MFC system. Les résultats récents d'opération du système « MFC » .....	699
W. Kurdowski, A. Garbacik (Pologne)	CaCl <sub>2</sub> utilization in clinker burning. Utilisation de CaCl <sub>2</sub> dans le processus de formation du clinker .....	702
N. Musikas, E. Haag, J.P. Henin, P. Garde, (France)	Aptitude à la cuisson des crus de cimenterie en fonction de leur finesse de broyage. Burning ability of cement raw materials in relation with grinding fineness ....	707
E.M. Gartner, (U.S.A.)	Energy savings through better utilization of waste heat. Economie d'énergie par récupération de la chaleur non utilisée .....	713
J.-P. Bombled (France)	Bilan énergétique de l'incorporation d'ajouts et des moyens d'activation de ces liants. Thermal evaluation of binder induction and their induction means .....	719
N. Nakamura, (Japon)	Fuel oil saving by IHI-SF precalciner-kiln process. Economies de combustible pétrolier au moyen du procédé IHI-SF au four de précalcination .....	725
F. Fiala, A. Rival, (Belgique)	L'utilisation des additifs aux différents stades du processus peut apporter une économie importante d'énergie lors de la fabrication du ciment. The use of additives at different stages of the process can bring in an important economy of energy at the time of cement manufacturing .....	731
N.P. Kogan, O.-P. Mchedlov-Petrosyan, (USSR)	Intensification of the burning process by using components with high exergy in the raw mix. Augmentation du processus de cuisson par utilisation des composés à haute énergie dans les matières premières .....	732
O.-I. Avramenko, A.I. Zdorov, V.-M. Kopeliovich, (USSR)	On reduction of fuel consumption during burning of cement clinker. Sur la réduction de la consommation de combustible pendant la cuisson du clinker de ciment .....	737
H. Rechmeier (R.F.A.)	Economie d'énergie lors de la cuisson du ciment par utilisation intégrale de déchets et de combustibles de moindre qualité .....	740
	Saving energy during cement burning by complete utilization of waste material and low-grade fuels .....	744
T.M. Lowes, B. Tettmar, (England)	Utilization of combustible wastes in cement manufacture. Utilisation des déchets combustibles dans la fabrication du ciment .....	748

# SEMINAIRE D – Influence des caractéristiques du ciment sur les propriétés du béton

Introduction par M. J.-P. Mchedlov Petrossyan, et M. J. Baron .....	755
---	-----

## THEME 1 - Influence de la composition minéralogique et de la finesse du ciment sur les propriétés du béton.

Rapport général par M. J.-P. Bombled (France) .....	756
---	-----

### Communications :

# **ALLOCUTIONS**

## Séance inaugurale - 30 Juin 1980

### ALLOCUTION DE M. R. POITRAT

*Président du Syndicat National des Fabricants de Ciments et de Chaux  
Président du 7<sup>e</sup> Congrès International de la Chimie et Ciments*

Nous sommes particulièrement heureux d'accueillir en France le 7<sup>ème</sup> Congrès International de la Chimie des Ciments.

Au nom de l'Industrie Cimentière Française et en mon nom personnel, il m'est agréable d'exprimer à l'ensemble des congressistes mes souhaits cordiaux de bienvenue à Paris, et tout particulièrement à ceux d'entre vous qui sont dans notre capitale pour la première fois.

Les plus hautes autorités françaises ont marqué l'intérêt qu'elles portaient à cette manifestation. Le Chef de l'Etat, M. Valéry Giscard d'Estaing, lui a accordé son Haut Patronage, et le Comité d'Honneur qui a été constitué a reçu l'adhésion de :

- M. Raymond Barre, Premier Ministre,
  - M. Jean-François Poncet, Ministre des Affaires Etrangères,
  - M. Michel d'Ornano, Ministre de l'Environnement et du Cadre de Vie,
  - Mme Alice Saunier-Seïté, Ministre des Universités,
  - M. Joël Le Theule, Ministre des Transports
  - M. Jean-François Deniau, Ministre du Commerce Extérieur,
- et de M. Pierre Aigrain, Secrétaire d'Etat auprès du Premier Ministre - Chargé de la Recherche.

M. André Giraud, Ministre de l'Industrie, nous a fait, pour sa part, le grand honneur d'accepter de prendre la parole au cours de la présente séance inaugurale. Nous aurons le plaisir de l'accueillir dans un instant.

Et nous avons aussi la joie d'avoir parmi nous deux des plus éminentes personnalités du monde scientifique :

- le Professeur André Guinier, Membre de l'Académie des Sciences, qui, dans les laboratoires de la Faculté des Sciences d'Orsay, a su communiquer sa foi à de nombreux chercheurs;
- le Professeur Henri Lafuma, élève et collaborateur d'Henry Le Chatelier, dont il a maintenu la présence permanente et vivante parmi nous en poursuivant au CERILH, Centre de Recherches de l'Industrie Cimentière française, les travaux de l'éminent savant qui avait été son maître.

Je suis sûr d'être l'interprète de l'ensemble des congressistes en exprimant aux Professeurs Guinier et Lafuma la profonde reconnaissance de l'industrie cimentière mondiale.

o  
o o

Six années se sont écoulées depuis le précédent Congrès qui s'était tenu à Moscou; six années qui n'ont pas effacé l'excellent souvenir qu'en ont gardé les participants.

Six années qui ont été marquées par de profondes évolutions dans la quasi totalité des secteurs industriels du monde, et notamment dans ceux dont les activités exigent d'importantes quantités d'énergie. C'est pourquoi nous avons souhaité que l'organisation de cette nouvelle rencontre puisse bénéficier des travaux réalisés dans le monde entier.

Un Comité Scientifique International a été constitué dans cet esprit, auquel ont été appelés à participer les plus éminents spécialistes internationaux.

Présidé par M. François Le Bel, ce Comité s'est attaché, depuis quatre années, à choisir et définir de façon précise les questions à étudier.

Deux de ses membres nous ont malheureusement quittés au cours de ces travaux : le Professeur Kondo et le Docteur Peter.  
Je m'incline ici devant leur mémoire.

o  
o o

L'activité de l'industrie cimentière a connu, entre les années qui ont suivi la seconde guerre mondiale et 1973, un rythme de progression continu, de l'ordre de 6 à 7 % par an en moyenne.

De 102 millions de tonnes en 1948, la production du monde passait à 314 millions de tonnes en 1960, 589 millions de tonnes en 1970 et 717 millions de tonnes en 1973.

Après 1973, cette évolution a subi les à-coups économiques nés de la crise de l'énergie; ainsi, le taux de croissance moyen des cinq dernières années s'est établi à 3 % et la production de 1979, avec 860 millions

de tonnes, n'est que de 20 % supérieure à celle de 1973.

Mais cette moyenne recouvre des situations fort diverses allant de la stagnation, voire de la récession dans certains grands pays producteurs, à un développement considérable dans d'autres pays.

o  
o o

Ainsi donc, cette crise de l'énergie a profondément marqué la période qui s'est écoulée entre le Congrès de Moscou et notre présente Assemblée. Le renchérissement du fuel-oil lourd et celui, bien qu'à un degré moindre, des autres sources d'énergie, ont bien évidemment incité les cimentiers à porter leurs efforts sur l'adoption de dispositions permettant de réduire leur consommation en combustible. Dans tous les pays, la recherche s'est orientée sur les moyens d'économiser l'énergie en général et les produits pétroliers en particulier.

En premier lieu, s'est engagé un mouvement général de reconversion vers le procédé de fabrication par voie sèche, qui permet une économie de thermie à la tonne de ciment appréciable.

Dans la même optique, est apparu l'intérêt d'une utilisation plus large de constituants secondaires dans la composition du ciment. En effet, pendant une longue période, le problème du coût de l'énergie ne se présentait pas avec l'acuité actuelle; les usines étaient conçues essentiellement pour la production de ciments Portland purs et l'on se préoccupait peu de les adapter à l'utilisation d'ajouts réactifs. Il faut cependant souligner que quelques pays, dont la France, produisent depuis des décennies des ciments contenant du laitier de haut-fourneau, des pouzzolanes, ou des cendres volantes de centrales thermiques et l'emploi de ces ajouts, dans des proportions définies par les normes, permet à la fois d'obtenir des produits dont les qualités spécifiques les rendent souvent préférables aux ciments purs tout en réalisant des économies appréciables d'énergie. L'expérience ainsi acquise a conduit d'autres pays à étudier la possibilité d'avoir recours aux types d'ajouts dont ils peuvent disposer, dans des conditions économiques acceptables. Une extension de cette utilisation se manifeste et il est permis de penser que cette tendance se développera dans un très proche avenir.

Enfin, un grand effort a été amorcé pour diminuer la consommation de produits pétroliers en substituant le charbon au fuel-oil lourd. Cette reconversion au charbon est particulièrement indiquée en cimenterie, notre industrie ayant la rare faculté de pouvoir utiliser des charbons de qualité secondaire à forte teneur en cendres, sans que cette utilisation pose, dans le domaine de la chimie des ciments, de problèmes autres que ceux de la

composition du cru, qui peuvent être résolus sans grandes difficultés.

o  
o o

Cette obligation devant laquelle l'industrie cimentière s'est trouvée de consacrer une attention particulière aux problèmes de l'énergie ne l'a pas empêchée de se préoccuper parallèlement, au cours des six dernières années, de l'amélioration de la qualité de ses produits : les résistances mécaniques exigées par les ouvrages modernes, en béton précontraint notamment, les résistances chimiques aux ambiances agressives dues à l'eau de mer ou à certaines pollutions, ont fait l'objet d'études approfondies.

Ce 7ème Congrès va montrer que d'importants progrès ont été réalisés dans le domaine de l'utilisation des constituants secondaires, ainsi que dans celui de la qualité depuis le Congrès de Moscou. Il montrera également que les chercheurs, face à la rapidité de l'évolution des conditions économiques, se sont attachés à dégager les conclusions les plus utiles aux applications technologiques et à réduire ainsi le temps de réponse de la recherche que nous connaissions jusqu'alors.

Dix-neuf rapports principaux, près de trois cents communications individuelles, les exposés et les conclusions de quatre séminaires spécialisés ont fait ou feront l'objet de publications qui constituent incontestablement les meilleures références des connaissances actuelles en matière de recherche sur nos produits.

Nous présenterons dans un instant, sous la forme d'un diaporama et d'un divertissement un bref rappel de l'histoire du ciment et de la construction. Les Congrès de la Chimie des Ciments s'inscrivent dans cette histoire. Et le Septième du nom qui s'ouvre aujourd'hui montrera que notre industrie, bien que traditionnelle par ses origines, est capable d'une adaptation rapide et efficace aux situations nouvelles.

Je vais passer maintenant la parole à M. Raymond Peltier, Ingénieur Général des Ponts et Chaussées, Secrétaire Général du Congrès, qui vous donnera des informations précises sur le déroulement de cette manifestation qu'il a eu la lourde charge d'organiser avec le concours du CERILH.

Mais auparavant, et en terminant, laissez-moi vous exprimer tous les vœux que je forme pour le plein succès de vos travaux, me réjouir des échanges de vues bénéfiques qu'ils vont permettre de réaliser et vous faire part de ma conviction que ce septième Congrès International de la Chimie des Ciments constituera une date importante pour une meilleure connaissance scientifique des produits que nous fabriquons, cette connaissance étant la condition nécessaire du progrès économique ainsi que du développement de l'industrie cimentière mondiale.

## Séance inaugurale - 30 Juin 1980

### DISCOURS DE M. A. GIRAUD

Ministre de l'Industrie

Monsieur le Président, Mesdames, Messieurs,

Permettez-moi tout d'abord de dire combien je suis heureux de me trouver parmi vous et de souhaiter la bienvenue aux nombreux congressistes étrangers, issus d'une cinquantaine de pays, que nous accueillons aujourd'hui pour le 7ème Congrès International de la Chimie des Ciments.

Par une sorte de coïncidence, vos congrès se tiennent dans des années portant des millésimes qui retiennent l'attention : 1968, 1974, 1980. La conjonction de ces réunions avec des événements où sont posées, de façon plus aiguë, des questions économiques et des questions de société qui engagent l'avenir des nations, semble faite pour illustrer que les scientifiques sont pris désormais, eux aussi, dans les urgences, que de leurs trouvailles dépend la solution de problèmes majeurs, et que leurs recherches répondent à des attentes intenses, même si elles sont quelquefois confuses.

Cela est vrai, permettez-moi de le souligner, tout autant dans des industries de base que dans des industries de pointe. Les progrès éblouissants de l'électronique ou de la biologie, qui profitent d'ailleurs aussi aux industries de matériaux de construction, pourraient par instants faire perdre de vue qu'il reste un grand nombre de besoins fondamentaux et simples, exigeants en énergie et incompressibles. Ces consommations fondamentales ne méritent pas moins d'attention que les autres; elles aussi déterminent les formes de notre civilisation et participent à nos réussites comme à nos échecs. Elles sont en outre, pour les pays moins pourvus, parmi celles dont la satisfaction est la plus pressante.

#### Les Thèmes du Congrès :

Les thèmes que vous avez retenus pour le Congrès sont d'une grande diversité; ils se regroupent cependant autour de deux préoccupations centrales qui mon-

trrent bien la continuité de la volonté d'adaptation de ces industries :

- Comment obtenir une meilleure qualité des ciments, c'est à dire obtenir des ciments plus résistants, plus réguliers, donc plus sûrs, mais aussi mieux adaptés à leur emploi,
- Comment économiser au maximum l'énergie nécessaire à leur fabrication.

#### A - La qualité :

Sur le premier point, nous constatons l'importance du progrès technologique et l'interdépendance des différentes branches d'un système technique; ainsi, par exemple, grâce à la puissance des moyens d'investigation modernes, dont le pouvoir séparateur en particulier s'améliore toujours et avoisine maintenant quelquefois la dizaine d'angströms, la connaissance et la maîtrise de la structure des matériaux complexes que sont les ciments peut progresser comme progresse aussi celle des mécanismes de formation de leurs produits d'hydratation dans des ambiances agressives.

Le fabricant pourra ainsi mener sa fabrication de façon à obtenir les meilleures caractéristiques de son produit pour un usage déterminé.

De même, au stade de la fabrication du béton, la liaison granulats-pâte de ciment a fait l'objet de recherches particulières, qui ont conduit à la constatation que les cristaux qui se forment au contact des granulats sont différents de ceux qui se forment dans la pâte de ciment. Une meilleure connaissance de cette zone intermédiaire devrait permettre d'en renforcer la liaison granulats-ciment.

Prolongeant la recherche afin de mieux maîtriser les éléments qui déterminent les qualités du ciment, on trouve l'effort d'optimisation de la gestion de la qualité. C'est naturellement le rôle des normes. Les nouvelles normes françaises de ciment, entrées

en vigueur en 1979, garantissent à l'utilisateur des produits mieux définis, plus réguliers et mieux contrôlés. Elles se définissent essentiellement par référence aux performances, c'est à dire à ce qui est le plus directement utile à la mise en oeuvre du produit, plutôt que par référence à la composition, laquelle est laissée plutôt à la disposition du fabricant pour obtenir les performances prescrites.

Cet effort de modernisation des normes ne se limite pas à la France, mais s'insère dans un mouvement plus vaste, à l'échelon européen.

#### B - Les économies d'énergie.

Le deuxième thème que vous abordez de façon préférentielle est d'une importance manifestement cruciale. La crise énergétique a frappé de plein fouet l'industrie cimentière, grosse consommatrice.

J'ai déjà abordé ce thème par le biais des normes; en effet, la transformation des normes a permis des économies d'énergie considérables, grâce à l'adjonction de produits secondaires. C'est un champ où la recherche française est bien avancée; où chaque point d'ajout de ces constituants secondaires permet une économie de combustible de l'ordre de 1 %. En général il est possible d'aller jusqu'à 30 % de produits secondaires, et pour certains usages même davantage. L'adjonction de produits secondaires au clinker peut permettre de régler des problèmes d'utilisation de sous-produits industriels; plusieurs pays ont pris, de longue date, l'habitude d'utiliser le laitier de haut-fourneau; l'usage des cendres volantes de centrales thermiques, moins ancien, tend à se répandre.

A côté de cette évolution récente et fortement liée à la recherche, citons parmi les choix qui, sur le plan industriel, contribuent à réduire la consommation énergétique, le fait que le procédé de fabrication par voie sèche tend, partout où cela est possible, à remplacer les anciens procédés par voie humide.

En France, dans l'ensemble, les efforts réalisés permettent d'économiser déjà presque 400.000 tonnes de fuel annuelles. Et le Gouvernement français, pour sa part, a tenu à encourager l'industrie dans ce sens par des aides financières.

Enfin, l'industrie du ciment s'oriente vers des sources d'énergie bon marché : bitumes lourds et produits pétroliers difficilement valorisables, et plus encore: charbon.

Si vous me permettez de citer encore le cas de la France, l'industrie cimentière y est une des premières, sinon la seule à être déjà bien engagée dans cette voie, et elle peut espérer que ce combustible représentera 75 % de sa consommation d'énergie en 1985.

Si le recours au charbon ne pose pas aux fabricants de ciment de problème majeur, il impose un effort d'organisation des approvisionnements, qui n'est d'ailleurs que la première étape d'un retour général au charbon dans l'industrie. Il me plaît de souligner que l'industrie cimentière y fait oeuvre de progrès.

D'autres voies encore pourront conduire sans doute à des économies d'énergie : ainsi par exemple l'amélioration des échanges de chaleur dans les fours, la réduction et la récupération des pertes thermiques, la fabrication de clinker à plus faible température, et la réduction de la consommation d'énergie au niveau du broyage.

Je parlais, en commençant, des dates significatives de vos congrès ... On pourrait presque tracer un parallèle entre ces dates et les thèmes choisis : 1968 est une année où est devenue visible à tous l'émergence de la revendication de la qualité de la vie, qui commence par la qualité des produits et la limitation des nuisances. Ces préoccupations ne nous ont plus quittés, et les progrès accomplis ont été considérables.

1974 est pour chacun l'année où le monde a commencé à prendre conscience de la nécessité de réaliser une croissance plus sobre en énergie, et de trouver des alternatives au pétrole. Ici encore, ces préoccupations nous sont demeurées, et à vous aussi dans la profession cimentière elles sont restées un grand souci.

Mais quel sera le thème qui poindra en 1980 ? Je ne me hasarderai pas à en formuler un sur le plan général, mais je prends le risque d'en proposer un pour les cimenteries. Si nous réfléchissons bien, et si nous nous demandons où se trouve l'avenir du ciment, il apparaît que ce n'est pas principalement dans les pays industrialisés avancés. Même si, aujourd'hui en France, quelques mesures sont prises pour soutenir la conjoncture dans le bâtiment, il est clair que ni en France, ni dans l'ensemble du monde industrialisé, ne se trouvera rien de comparable aux immenses besoins

des pays en voie de développement et à démographie à croissance rapide.

Que peut-on envisager afin de faciliter la satisfaction de ces besoins ? Je suis persuadé qu'une orientation d'une partie des recherches vers le développement de technologies spécifiques, qui tiennent compte des gisements, des conditions industrielles, de la nécessité de disposer d'unités de production plus petites et plus dispersées dans certains cas, bref de l'ensemble des différentes caractéristiques rencontrées dans les pays en voie de développement pourrait être un facteur important pour permettre à ces pays

de se donner rapidement les infrastructures et le parc immobilier qui leur sont nécessaires.

L'importance de ces différents thèmes n'échappera à personne; aussi concluerai-je, si vous me le permettez, Mesdames et Messieurs, en souhaitant aux congressistes - j'espère que ce n'est pas contradictoire - à la fois un agréable séjour dans notre capitale et des discussions et des réflexions qui seront fertiles, j'en suis sûr, pour l'ensemble de l'humanité.

## Séance de clôture - 4 Juillet 1980

### CONCLUSIONS DU CONGRES PAR M. F. LE BEL

*Président du Comité Scientifique du Congrès*

Après ces journées passionnantes (le qualificatif n'est pas trop fort), des devoirs m'attendent : l'un est facile et agréable : vous remercier toutes et tous; l'autre, plus difficile et probablement très incomplet ; établir un bilan; bilan qui, heureusement, ne peut être encore que très provisoire.

Si la raison majeure du succès de ces journées a été votre présence vivante, leurs fruits sont l'apport extraordinaire que vous avez fait à l'industrie cimentière mondiale par les textes mis à sa disposition. Ils sont très nombreux : l'ensemble des rapports principaux, l'ensemble des communications, et enfin celui des rapports généraux et les conclusions des tables rondes, ainsi que vos interventions dans les discussions concernant les thèmes de ce Congrès.

Sa préparation matérielle a été élaborée avec beaucoup de minutie, par un Secrétariat Général intelligent et actif, animé par mon ami Raymond PELTIER, Ingénieur Général des Ponts et Chaussées, que je tiens à remercier tout spécialement, sans oublier Mme J. CARDEY, sa fidèle collaboratrice, pour son rôle obscur, mais déterminant. L'aide efficace et bienveillante de notre Syndicat National des Fabricants de Ciments et de Chaux doit être mise en vedette, car sans elle rien n'était possible. Je tiens donc à remercier tout particulièrement son Président, M. Raymond POITRAT, et son Délégué Général, M. Gilbert DENOIX, auprès desquels nous avons toujours trouvé un patronage efficace, une grande compréhension, et enfin des fonds qui, hélas, sont toujours délicats à trouver.

La préparation intellectuelle de ce Congrès doit être également évoquée, car elle fut originale quant à sa conception et efficace quant à ses résultats.

Originale, car elle a été conçue et organisée par un groupe de travail international qui, bénévolement, avec passion et sérieux, a choisi les thèmes, les a précisés, faisant appel, pour en parler, aux sommités internationales les plus compétentes que vous avez pu entendre pendant ce Congrès. Je tiens donc à remercier devant vous tous les membres de ce Comité Scientifique International pour leur collaboration amicale et efficace durant plus de deux ans à la préparation intellectuelle du Congrès.

Je me plais à souligner également l'assistance scientifique de haut niveau que nous ont apportée les Universités françaises, les chercheurs du C.E.R.I.L.H. et ceux des Sociétés cimentières et des Services Officiels français.

#### Un bilan intellectuel.

L'amélioration de nos connaissances sur les clinkers industriels ou de laboratoires et sur leurs composants est indispensable, car l'évolution des technologies de fabrication est permanente avec ses retombées sur les spécificités des produits fabriqués même si les matières premières, c'est à dire les entrées du système, ne changent pas. Par exemple, au cours des dix dernières années, chauffe avec un mazout riche en soufre, four avec échangeurs verticaux à cyclones, dé-

poussiérage rigoureux des fours, recyclage des poussières, sont des raisons suffisantes pour concentrer des éléments mineurs tant et si bien que la composition potentielle des clinkers correspondants s'en est trouvée modifiée; ceci pour le plus grand bien de certains utilisateurs (des sulfates alcalins, donc des ciments rapides), pour le plus grand dommage de certains autres (concentration par recyclage du thallium.

Ce qui prouve d'ailleurs que le contrôle minutieux de ce que l'on produit ne doit échapper ni aux producteurs, ni aux consommateurs; ce mot "contrôle", pris au sens anglo-saxon du terme, implique donc recherches et laboratoires, car il vaut mieux prévoir que subir. C'est là une partie des missions pratiques de nos congrès, qui doivent chercher les messages issus de la recherche, susceptibles d'être appliquées dans l'industrie à délai aussi bref que possible.

Aussi comment établir un bilan de ce Congrès? C'est l'affaire de tous les congressistes, car je pense que chacun y a trouvé de quoi rassasier provisoirement sa faim de savoir et exciter son désir d'en savoir plus.

Je rappellerai ici que les recommandations faites à l'intention des rédacteurs de communications précisaient que les travaux présentés à notre Congrès devaient :

1. autant que possible concerner des produits industriels, sans exclure toutefois les préparations en laboratoire;
2. être orientés dans des directions favorables aux économies d'énergie.

Nous pensons que ces recommandations ont été bien perçues, car les retombées pratiques de ce Congrès sont nombreuses et nous montrent que la recherche de base, orientée, peut déboucher sur le marché plus rapidement qu'on pouvait le penser. Cela est un encouragement solide pour les chercheurs, car, dans bien

des cas, leur efficacité est liée aux dialogues fructueux qu'ils peuvent nouer avec les exploitants et les utilisateurs.

Le nombre des communications écrites a été élevé : 290 pour le congrès, 130 pour les séminaires, plus 155 posters.

Le nombre des participants aussi, si on le compare aux congrès précédents :

Tokyo : 572 - Moscou : 708 - et Paris : 880

Les rapports principaux : 19

Les rapports généraux : 7

Toute cette nourriture intellectuelle est dense et diversifiée; l'assimiler complètement demandera une longue réflexion, donc du temps, c'est à dire une période dormante, à l'issue de laquelle les fruits essentiels de ce Congrès cristalliseront; bilan et vues sur l'avenir suivront.

Quelques faits saillants m'ont particulièrement frappé : c'est un peu de la pêche à la ligne que je fais ici; ce ne sera donc pas un examen complet. Vous m'en excuserez sans doute, et les poissons seront présentés trop en vrac peut-être, d'autant que je suis avant tout industriel et ingénieur, tenté par la science certes, car son pouvoir d'attraction est devenu irrésistible du jour où les chercheurs sont devenus des pédagogues.

Le sujet du Thème 1 est une innovation dans un tel Congrès, qui s'intéressait jadis plus aux structures et propriétés des clinkers qu'à la philosophie de leur genèse.

Or l'évolution des moyens de production, pour obtenir des produits réguliers, nous a conduits à étudier les corrélations multiples qui existent entre matières premières et produits finis, et, de ce fait, à déterminer avec une grande précision les conditions requises pour fabriquer, de façon très régulière, des produits spécifiques déterminés : choix des matières premières et leur traitement, c'est à dire choix optimal des procédés.

Les recherches sur ces corrélations ont alors une portée scientifique et industrielle qui dépasse le stade de la curiosité scientifique.

Les notions de réactivité des minéraux naturels ou artificiels se sont précisées dans les esprits du fait de l'invention et de la mise au point de nouveaux équipements de laboratoire; ils permettent de juger des structures moléculaires, des structures cristallines, et, ainsi, de définir des critères de choix, dont les retombées dans l'art de l'ingénierie cimentière sont très importantes.

Si le séminaire sur les économies d'énergie nous a permis de mieux connaître ce qui se passe dans le domaine des technologies actuelles de fabrication, des idées intéressantes sur leurs prolongements ont été proposées.

D'un point de vue plus fondamental, en se basant sur des théories de la migration ionique en milieu fondu, deux résultats importants ont retenu notre attention :

- la fabrication du silicate tricalcique chloré avec inclusion d'aluminium et de magnésium (bain fondu de  $\text{CaCl}_2$  à 1000/1100°) minéral plus réactif que le silicate tricalcique bien connu;
- la fabrication du  $\beta\text{-C}_2\text{S}$  sulfaté dans un bain fondu me semble très importante et ouvre peut-être de nouvelles voies pour l'utilisation rationnelle des énergies dégradées.

Dans les séances concernant les thèmes 2, 3, 4, un accord presque général est apparu sur les phénomènes de prise; en particulier, celui de la mise en solution de la silice et de sa migration dans le milieu aqueux, expliquant que la formation du silicate monocalcique hydraté CSH ne se forme pas seulement de façon topochimique, mais aussi dans le bain grâce à cette diffusion ionique.

C'est un fait très important, et les hypo-

thèses présentées pour analyser ce phénomène de prise et l'expliquer sont beaucoup plus homogènes que dans le passé.

Une foule de résultats ont été exposés sur la qualité des ciments, en fonction de leurs dosages en clinker, en laitier et en pouzzolanes. Les structures propres de ces éléments se précisent chaque jour davantage, ainsi que leurs réactivités. Aussi les mélanges de ces éléments broyés ensemble ou séparément, à des dosages différents, donnent ils toute une palette de produits hydrauliques dont les thèmes 5 et 6 ont mis en valeur les propriétés, grâce à un arsenal de méthodes d'essais très diverses; ces méthodes d'essais intéressent plus particulièrement les phénomènes de rhéologie des pâtes de ciment, leur mode de durcissement, l'évolution de la porosité au cours de la formation du squelette, les raisons des résistances et le rôle fondamental joué par l'eau liée.

L'étude de la porosité en particulier nous a montré que granulométrie des pores structuraux et granulométrie des pores capillaires ont une incidence fondamentale sur les résistances à la traction des pâtes durcies et sur leur résistance aux eaux agressives.

Je me permettrai de citer à cet égard l'intérêt des études sur les ciments de laitier, qui nous ont montré que, dans les pâtes durcies, la répartition granulométrique des pores capillaires est plus régulière que dans celle des ciments Portland purs, et que c'est probablement une des explications de leurs meilleures résistances à la traction et résistances aux eaux agressives.

Le thème 7 est venu clôturer ce Congrès; et là aussi, ce thème 7 est un peu une nouveauté comme le thème 1, car nous avons pensé que si les pâtes de ciment sont intéressantes à étudier, leur rôle dans les bétons l'est aussi; le ciment est principalement fait pour le béton, et de son bon emploi dépend grandement la qualité de la construction.

Nous mentionnerons en particulier les très intéressantes études présentées sur les liaisons pâtes-agrégats, sur les migrations ioniques dans la pâte pendant la prise, sur la qualité de la structure de contact et la découverte des échanges d'ions entre pâte et agrégat; tout cela est prometteur et demande réflexion néanmoins, car grande résistance et fragilité sont souvent corrélatives; or si le béton, matériau composite par excellence, doit résister à de nombreuses sollicitations sans faillir, il doit aussi avoir une certaine aptitude à la déformation. J'ai eu le plaisir de constater que l'ensemble des rapports rédigés à l'occasion de ce Congrès forme vraiment une chaîne continue, du thème 1 au thème 7, dont les retombées pratiques sont, comme nous venons de le voir, très importantes; des lacunes restent à combler, bien entendu; heureusement elles seront en partie les raisons d'être du prochain Congrès auquel nous souhaitons déjà bonne chance.

#### Conclusion :

Je vous l'ai dit; tout cela n'est qu'un survol très rapide et peut-être peu significatif. La matière est en effet très dense; il nous faut donc digérer ce qui a été écrit ou dit. Pour essayer de faire une bonne synthèse des apports de ce Congrès, si ce n'est pas abuser de la gentillesse de nos Présidents de thèmes, je leur demanderai de résumer en quelques pages, pour la fin de l'année, le bilan de leur intervention et de celles de leurs collaborateurs, que je remercie tous bien vivement pour la qualité très exceptionnelle de leurs prestations. Elles rejoignent, bien que quelquefois apparemment lointaines, nos préoccupations communes au service des pâtes de ciment, des mortiers et des bétons, qui peuvent être résumées en une phrase d'un de nos amis bien connu :

"Il est important de prendre en considération le fait que la morphologie, la porosité, la densité et la composition chimique sont des facteurs interdépendants, qui déterminent

les caractéristiques des résistances."

o  
o o

Avant de terminer, j'aimerais aborder rapidement avec vous quelques données sur l'avenir de l'Industrie Cimentière, dont les retombées sur les programmes de recherche ne sont pas négligeables, loin de là.

Par quelques exemples, on peut imaginer l'échelle des économies d'énergie et des investissements que représente une politique raisonnable des ajouts.

Les prévisions des Nations Unies nous disent que de 1980 à l'An 2000, c'est à dire en 20 ans, la production cimentière dans le monde va croître de 850 MT (195 kg par habitant) à 1 500 MT (238 kg par habitant), c'est à dire s'accroître de 650 MT.

Taux de croissance : 2,88 % par an; c'est à dire que le nombre des usines nécessaires à assurer ce surcroît de production exigé par le marché en 2000 pourrait être de 650 usines de 1 MT/an, ce qui correspond donc à la création annuelle de 33 usines de 1 MT/an.

Chaque année, de 1980 à 2000, ces cimenteries s'implanteront dans des pays les plus divers dans tous les domaines, dont les stades de développement sont différents; il s'agira donc d'usines adaptées à chaque marché et à chaque contexte (dont le contexte géologique), à la cadence figurative de mise en route suivante :

1 usine de 1 MT/an tous les 10 jours  
et cela pendant 20 ans.

Estimation du montant annuel de l'investissement pour 1 T de production annuelle de CPA :

1 000 F :

1 000 x 33 M = 33 milliards de francs

Consommation supplémentaire annuelle de fuel correspondante :

33 x 100.000 T. = 3,3 MT de fuel.

Réaliser ce programme pose des cas de conscience graves; il ne s'agit pas de construire des usines en série, car celles-ci sont dans la généralité des cas mal adaptées aux

contextes locaux; hélas, nous constatons qu'il en est souvent ainsi. Pourquoi ?

L'expérience prouve qu'en général le problème est mal posé, ou insuffisamment précisé; en particulier, les études préalables ne sont pas poussées aussi loin que l'ont recommandé nos amis du thème I. Par ailleurs, les leçons apportées par les thèmes II, III et IV devraient ouvrir les yeux des responsables sur les économies d'investissement et d'énergie, réalisables par une bonne connaissance des ressources géologiques de leurs pays. L'expérience prouve que la nature a été généreuse et qu'aucun pays n'est dépourvu de cette manne. Un énorme effort de formation universitaire appliquée doit être donc entrepris. Voilà un programme passionnant pour les chercheurs qui doivent devenir bons pédagogues, et le sont en fait, comme nous l'avons vu ces jours-ci.

Nous venons de parler du programme de construction de 33 usines de 1 MT/an de ciment Portland

L'expérience prouve que, dans bien des cas, même avec des ajouts peu réactifs, un bon clinker peut supporter 30 % d'ajouts réguliers, et ce d'autant qu'ils sont broyés séparément à une granulométrie appropriée. Il en résulterait une économie annuelle d'investissement de 10 usines de fabrication de clinker, donc de 10 millions de tonnes de clinker. Soit, en se basant sur un coût de construction de 600 frs par tonne de clinker fabriquée annuellement, pour un coût de 1000 frs par tonne de ciment CPA produite, une économie annuelle de :

$$600 \times 10 \text{ M.} = 6 \text{ milliards de francs}$$

L'économie annuelle supplémentaire de fuel serait de  $0,1 \times 10 \text{ M} = 1$  million de tonnes de fuel ou d'équivalent fuel.

Il est intéressant de constater qu'au prix de 1000 frs la tonne de blé, cela correspondrait au prix de 6 millions de tonnes de blé, ce qui permettrait de nourrir, en pain, l'excédent annuel de la population du monde.

Une autre constatation : en l'An 2000, la production mondiale de ciment sera très probablement de 1.500 MT; ajoutons à ce tonnage (en supposant que les clinkers seront de bonne qualité et le broyage bien contrôlé) 5 % d'ajouts, réactifs ou non, broyés très finement; les ciments correspondants ne se porteront pas plus mal, et souvent mieux; cela est certain pour les CPA.

Ce tonnage d'ajouts sera de 75 MT. Il permettrait donc d'arrêter pendant deux ans les investissements-lignes de production de clinker :

$$\text{Economies } 600 \times 75 \text{ MT} = 45 \text{ milliards de frs}$$

Economies de fuel :

$$75 \times 100.000 = 7,5 \text{ MT d'équivalent fuel.}$$

Ne trouvez-vous pas que cela en vaut la peine ?

Une autre constatation :

En l'An 2000, la quantité de carbone envoyée dans l'atmosphère sous forme de  $\text{CO}_2$  sera (en désignant le clinker par K)

300 kg  $\text{CO}_2$  par tonne de clinker

100 kg de C par T de K (part de  $\text{CO}_3\text{Ca}$ )

70 kg de C par T de K (part de fuel)

-----

170 kg de C par T de K, c'est à dire

0,17 T

$$1.500 \text{ MT ciment} \sim 1.000 \text{ MT de K} \rightarrow 0,17 \text{ T} \times 1000 \text{ M} \\ = 170 \text{ MT de C par an}$$

Cette estimation peut donner des idées, nous le verrons plus tard.

Je serais heureux que nations, investisseurs et bureaux d'engineering soient conscients de ces gains possibles. L'adaptation des technologies aux conditions locales devient une nécessité certes, mais encore faut-il bien connaître les buts poursuivis dans l'u-

utilisation des produits hydrauliques. Une connaissance de plus en plus approfondie de leurs comportements est donc une autre nécessité et, dans ce sens, nos Congrès et ceux qui suivront ont rempli et rempliront leurs missions.

Pour conclure, je m'aventurerai dans un domaine un peu plus prospectif et qui tient peut-être du rêve sait-on jamais ? Les combustibles fossiles sont la propriété d'un certain nombre de nations, mais d'autres nations en sont complètement dépourvues, ou le seront avant la fin du siècle. Cela pose, pour ces dernières, un déséquilibre dans leur balance des paiements, soluble quelquefois au prix de lourds sacrifices; s'ils deviennent insupportables, il leur faudra trouver d'autres solutions.

Si nous examinons dès maintenant, en France par exemple, les prix de l'énergie électrique, nous arrivons aux résultats suivants, rapportés au kwh produit en usine :

Origine	Nucléaire	Fuel	Charbon
Investissement	6,70	4,44	5,16
Exploitation	2,55	2,52	2,85
Combustible	4,27	26,56	14,28
Total partiel	13,52	33,52	22,29
Majoration pour désulfuration		2,80	2,50
Total	13,52	36,32	24,79

c'est à dire qu'à court terme :

le kwh-fuel coûtera 3 fois plus cher que le kwh nucléaire,

le kwh-charbon coûtera 2 fois plus cher que le kwh nucléaire.

Nous savons déjà que les réserves de la France en énergies fossiles seront rapidement négligeables, et que d'autre part nos réserves en uranium naturel sont évaluées à 100.000 T, c'est à dire l'équivalent en énergie électrique des réserves de pétrole de la mer du Nord; mais utilisées dans les surgénérateurs, elles représentent trois

fois les réserves de l'Arabie Saoudite; elles représentent donc un atout énergétique puissant, qu'il serait peut-être temps de tester dans le cadre de notre industrie (en l'An 2000, 50 % de l'énergie électrique sera d'origine hydraulique et nucléaire).

Pour le broyage des ajouts, pas de problème, bien entendu, mais dans celui des clinkers c'est une autre histoire. Quelles voies choisir ?

#### 1. La fusion dans le four électrique ?

Des essais ont permis de réaliser des clinkers fondus très réactifs, après trempe très énergique (les cristaux de  $C_3S$  sont très petits).

Mais le bilan est mauvais du fait de la mauvaise récupération de la chaleur sensible des clinkers.

Le frittage serait-il possible par cette voie ? Pourquoi pas.

#### 2. Chauffe avec l'hydrogène (fournie par l'électrolyse ou décomposition catalytique de l'eau dans les piles atomiques) Combustion de cet hydrogène dans l'air ou dans l'oxygène ?

Evidemment, la mise au point d'une telle combustion de l'hydrogène pose des problèmes, mais ils ne sont pas insolubles.

Nous y reviendrons in fine.

#### 3. Fabrication du $C_2S$ à 700°, en utilisant de l'énergie dégradée disponible; par exemple, la combustion hydrogène oxygène, qui permettrait de fabriquer le $C_3S$ et l'énergie dégradée pourrait être utilisée pour ce $C_2S$ dont on nous a montré que la réactivité est assez voisine du $C_3S$ à condition d'en fabriquer dans certaines conditions.

#### 4. Activation des produits d'addition par broyage séparé.

On pourrait multiplier les exemples; ils sont faciles à trouver. Mais les études correspondant à ces souhaits demanderont des efforts financiers importants et de la réflexion. Cela en vaut la peine,

d'autant que du rêve à la réalité le chemin est court quelquefois.

Enfin, l'utilisation de l'hydrogène comme carburant pose des problèmes; on en parle suffisamment dans la presse pour que je ne revienne pas sur le sujet.

Mais il est un produit qui pourrait être intéressant : c'est le gaz carbonique pur,  $\text{CO}_2$  pur, porteur éventuel d'hydrogène, pour lequel MOBIL a pris récemment un brevet.

En présence d'un catalyseur adéquat, on peut passer du  $\text{CO}_2$  au méthanol ou plus directement aux carbures d'hydrogène, qui, par polymérisation, peuvent redonner des produits voisins de l'essence du commerce.

Le problème est donc d'obtenir du  $\text{CO}_2$  pur.

L'industrie cimentière en serait elle capable ? Pourquoi pas ? Si les matières premières sont, d'une part du calcaire pur, d'autre part de la silice pure; tout cela

broyé finement bien entendu.

La fabrication de  $\text{C}_3\text{S}$  ou de  $\text{C}_2\text{S}$   $\beta$  dégage, si la combustion hydrogène-oxygène est bien réglée, uniquement du  $\text{CO}_2$ .

Les cimentiers seraient donc capables, dans des conditions à préciser, de fabriquer un  $\text{CO}_2$  pur, donnant ainsi une nouvelle voie de fabrication d'un combustible utilisable dans les futures automobiles.

Tout cela n'est qu'un schéma, mais pourquoi pas ? Le carbone est encore abondant sur notre globe, mais pas pour tous les pays, et, à terme, à quel prix. Et quelles autres conditions pour ceux qui n'en ont pas ?

Alors pourquoi ne pas réfléchir à cette voie ?

Je m'arrête donc là; peut-être parmi vous existe-t-il le chercheur qui nous dira si cette voie est fiable, mais surtout économique. Merci.

## Séance de clôture - 4 Juillet 1980

### ALLOCUTION DE M. R. POITRAT

*Président du Syndicat National des Fabricants de Ciments et de Chaux  
Président du 7<sup>e</sup> Congrès International de la Chimie des Ciments*

M. LE BEL vient de nous donner des chiffres qui situent bien la place occupée par l'industrie cimentière à l'échelon mondial.

Personnellement je ne vous en donnerai qu'un. J'ai essayé de prévoir à quelle époque la production cimentière mondiale atteindrait le milliard de tonnes. Eh bien, très vraisemblablement, ce chiffre sera atteint en 1986, date de notre prochain Congrès. Une image vous permettra de vous représenter ce qu'est un milliard de tonnes de ciment. Si nous les chargeons sur des bateaux de 100.000 tonnes et que nous mettions ces bateaux les uns derrière les autres, le convoi ainsi formé s'étendrait sur deux mille kilomètres.

De toutes les industries lourdes, l'industrie cimentière est sans conteste la plus développée sur notre planète. Le calcaire et l'argile se rencontrent pratiquement partout et il est peu de pays qui ne possèdent de cimenteries où n'aient des projets pour en implanter. C'est dire la nécessité impérieuse de la recherche en ce domaine et, par là, toute l'importance de nos rencontres.

Aussi, en ouvrant Lundi dernier, ce 7<sup>ème</sup> Congrès International de la Chimie des Ciments, c'est avec beaucoup de conviction que je souhaitais un plein succès à vos travaux, conscient que j'étais de la somme de réflexion et d'expérience dont ils allaient être l'aboutissement.

Après ce que vient de dire M. Le Bel, j'ai la profonde satisfaction de constater que ce souhait a été vraiment exaucé. Non seulement les inscriptions au Congrès ont dépassé nos prévisions, puisque 54 nations ont été ici représentées par près d'un millier de congressistes, mais la fréquentation aux séances a été exceptionnelle aussi bien pour les réunions de travail plénières tenues dans cette salle, que pour les séminaires du premier jour ou les posters qui ont connu toute la semaine une grande affluence.

Par ailleurs, l'exposition a été aussi très fréquentée. Je me suis entretenu avec bon nombre d'exposants et j'ai recueilli chaque fois le même écho, chacun s'estimant satisfait de l'attention que vous avez portée aux matériels exposés.

Sans doute, le soin apporté à la préparation de ce Congrès n'est pas étranger à sa réussite. Le Comité Scientifique International qu'a présidé M. LE BEL a effectué un excellent travail et je suis heureux de le féliciter en votre nom aujourd'hui.

Nous avons tenu à ce que vous receviez avant le Congrès les rapports principaux et vous avons distribué le premier jour deux tomes de communications. Ceci représente, vous vous en doutez, une documentation considérable dont il faudra beaucoup de temps avant d'épuiser la richesse. Vos bagages vont s'en trouver quelque peu alourdis, je le crains, mais vous n'attacherez sûrement qu'une importance mineure à cet inconvénient.

Il a fallu collationner et traduire près de trois cents communications, relancer les retardataires de façon à ce que toutes ces communications soient prêtes en même temps, au moment voulu. Tout cela n'a pas été facile, mais seul le résultat comptait et il est là.

Je suis sûr d'être votre interprète en remerciant M. Raymond Peltier, Secrétaire Général du Congrès, qui n'a ménagé ni son temps, ni sa peine pour mener à bien cette tâche considérable. Il a été secondé avec ardeur dans cet accomplissement par l'équipe du CERILH, tout particulièrement par son Président, M. Charreton, et son Directeur Général, M. Méric, ce dernier cumulant sa participation à la réalisation du Congrès et sa mission de Président de thème. Et personne n'a non plus garde d'oublier, dans tout ceci, le rôle de Mme Cardey qui, depuis deux ans, est la véritable cheville ouvrière de l'organisation de cette semaine de rencontre.

Le rôle des organisateurs n'est d'ailleurs pas terminé. Vous savez que nous avons encore un document à vous faire parvenir; il s'agit des actes les plus importants de cette semaine de travail, et en particulier des rapports généraux et des comptes rendus des séminaires.

Vous allez donc recevoir, dans un délai raisonnable, un quatrième volume, qui viendra ainsi compléter votre documentation. Je ne doute pas que vous ayez ainsi à disposition dans votre bibliothèque une véritable mine de références, dont vous saurez tirer le plus grand profit.

o  
o o

Lundi dernier, je vous avais également souhaité, dans mon allocution inaugurale, la bienvenue à Paris, et j'avais exprimé le désir que ce Congrès soit une occasion fructueuse de rencontres et d'échanges de vues.

C'est à vous qu'il appartient de dire si cet objectif a été atteint.

Nous avons fait de notre mieux pour vous donner un aperçu de notre capitale. Il était bien évidemment impossible, en si peu de soirées, de faire davantage; nous avons opté pour le maximum de diversité dans notre choix, en espérant vous donner le désir de revenir à Paris.

Le précédent Congrès a eu lieu à Moscou en 1974, présidé par M. Boldyrev. Il a rencontré le succès que l'on sait et je tiens encore à dire à M. Boldyrev combien tous les participants ont goûté leur séjour dans sa capitale.

Le prochain Congrès aura lieu en 1986 dans un lieu qui vous sera indiqué tout à l'heure par celui-là même qui nous y invitera.

Devant le progrès de vos recherches et le nombre toujours croissant des résultats dans des domaines diversifiés, la question a été posée de savoir si l'intervalle de six années entre nos rencontres n'était pas un peu trop important. En fait, je pense difficile

de changer nos traditions à cet égard, compte tenu des délais nécessaires à la préparation d'une telle réunion.

Il faut, en effet, laisser aux chercheurs, aux professeurs et aux savants le temps nécessaire pour mener à bien leurs travaux, et nous avons vu, tout au long de ces journées que dans le domaine du ciment plusieurs mois, et parfois plusieurs années, étaient nécessaires pour tirer des conclusions de certaines expériences. Une suggestion a été faite qui méritera sans doute d'être étudiée et approfondie. Il s'agirait de la création d'un noyau permanent qui se réunirait entre les Congrès, à la fois pour faire le point des dernières découvertes et préparer les prochaines rencontres. Il y a là une idée à creuser.

o  
o o

J'arrêterai ici mon propos, mais avant de donner la parole à M. de Assis Basilio qui a une communication importante à vous faire, je voudrais vous remercier tout d'abord en mon nom personnel pour le très grand plaisir que j'ai pris à vous rencontrer au cours de cette semaine, et au nom de l'industrie cimentière française pour être venus si nombreux et vous être montrés si attentifs à ce Congrès.

Si vous emportez le sentiment d'en avoir retiré un enrichissement à la fois sur le plan scientifique, sur le plan culturel, et sur celui de l'amitié, ce sera pour nous la meilleure récompense.

## Séance de clôture - 4 Juillet 1980

### ALLOCUTION DE M. DE ASSIS BASILIO

*Président de l'Association Brésilienne du Ciment Portland*

Monsieur le Président,  
Mesdames, Messieurs,

M. POITRAT a créé un "suspense" en parlant de notre prochain Congrès - le huitième - sans en indiquer le lieu, mais en passant la parole au délégué du Brésil.

Je dois vous dire que depuis deux ou trois ans, au cours des réunions du Comité Scientifique International du Congrès, nous avons, à plusieurs reprises, évoqué cette question. Et sans que l'on sache très bien comment cela s'est produit, un beau jour le Brésil a été pressenti pour organiser ce huitième Congrès.

L'Industrie cimentière brésilienne et M. le Ministre d'Etat de l'Industrie et du Commerce du Gouvernement brésilien ont donné leur accord. Nous sommes conscients de la grande responsabilité que nous prenons, mais nous nous sentons en mesure de l'assumer. Aussi, je propose à votre Assemblée de choisir le Brésil comme lieu du 8ème Congrès International de la Chimie des Ciments (vifs applaudissements dans toute la salle)

Je vous remercie de votre approbation.

Je vous signale que s'il fait parfois très chaud dans le nord et le centre du Brésil, à cette époque de l'année, qui pour nous correspond à l'hiver, il ne fait pas plus chaud à Rio et à São Paulo qu'à Paris actuellement.

São Paulo est le centre industriel du Brésil; c'est une très grande ville, environ douze millions d'habitants, extrêmement active, mais où se posent malheureusement parfois des problèmes de pollution atmosphérique.

Par contre, Rio dispose de kilomètres de

plage et bénéficie d'un air marin très pur et d'un ensoleillement agréable; en outre, il y a à Rio une vie nocturne qui incite à la détente.

L'apport technique des Congrès Internationaux de la Chimie des Ciments est toujours très marquant. Les sessions au cours desquelles sont examinés et discutés les problèmes les plus aigus qui se posent aux cimentiers, aboutissent généralement à des conclusions d'une grande importance pratique, par leurs conséquences sur la technologie des ciments et des bétons. Je citerai par exemple le problème de l'hydratation de l'aluminate tricalcique, sur lequel s'étaient déjà penchés les Congrès précédents, et sur lequel notre présent Congrès a apporté une grande clarté.

Nous espérons que le 8ème Congrès sera dans la ligne de ce 7ème Congrès, et nous apportera de nouveaux progrès. Nous avons demandé à tous ceux qui ont participé à l'organisation, si réussie, de ce 7ème Congrès, en particulier à MM. FELTIER, LE BEL et POITRAT, de nous aider de leurs conseils, dans la préparation du 8ème Congrès.

Nous espérons pouvoir compter sur votre participation à tous, en 1986, au Brésil. Nous espérons aussi voir arriver les jeunes générations de techniciens, qui auront la charge de poursuivre les recherches sur le ciment, ce matériau si largement utilisé, mais qui, malgré tous nos efforts, ne nous a pas encore dévoilé tous ses secrets.

Merci encore à tous; et je vous donne rendez-vous en 1986, au Brésil, pour notre 8ème Congrès.

## Séance de clôture - 4 Juillet 1980

### ALLOCUTION DE M. A.S. BOLDYREV

*Vice-Ministre de l'Industrie des Matériaux de Construction de l'U.R.S.S.*

Mesdames, Messieurs,

Je pense que nous avons tous bien fait de tenir ce congrès en France, et à Paris. Le ciment en profitera sûrement.

Le congrès de Paris laissera une trace profonde dans l'esprit des spécialistes et aura une grande importance pour les praticiens. Ce congrès a été plus représentatif que les précédents puisqu'il a attiré les plus grands spécialistes de 55 pays du monde, s'occupant de tous les aspects des problèmes complexes d'obtention de clinkers de ciments Portlands et d'utilisation rationnelle des ciments dans les bétons.

Nous avons entendu des exposés très intéressants, donnant un éclairage nouveau aux questions de la chimie et de la technologie des ciments.

Il est aussi très important que ce congrès se soit fait l'écho de questions vitales, dont dépend le développement à venir de l'industrie cimentière : on y a discuté des possibilités d'économiser l'énergie et d'utiliser des sous-produits et des déchets industriels.

On a examiné avec soin les questions d'utilisation des laitiers, des cendres, des ajouts hydrauliques naturels pour fabriquer des ciments composés, qui jouent un rôle important dans la diminution des dépenses énergétiques. Une grande attention a été portée aux ciments spéciaux. On a abordé sous un jour nouveau les problèmes théoriques, l'hydratation des ciments et les nouvelles méthodes d'intensification du durcissement et d'amélioration des caractéristiques de résistance mécanique

par emploi d'adjuvants.

Le système des rapports principaux, des séminaires, des affiches commentées et des communications écrites, ainsi qu'un large échange de vues, ont permis aux participants du congrès de prendre connaissance d'une quantité énorme d'informations.

Je pense que les participants seront d'accord avec moi pour dire que l'organisation de ce congrès a été admirable, que l'hospitalité française s'y est manifestée de façon authentique par le soin dont tous les participants ont été entourés, par l'organisation d'une bonne détente, qui leur a permis de découvrir les curiosités de Paris.

Ce congrès aura eu une grande importance scientifique.

Permettez-moi d'exprimer au nom de tous, les remerciements des participants à MM. POITRAT, LE BEL, MERIC, PELTIER et à tous ceux qui les ont aidés dans l'organisation irréprochable du congrès.

o  
o o

Permettez moi de transmettre également au Président du congrès la lettre que l'un des plus vieux spécialistes du monde des ciments, élève et traducteur russe de Henry LE CHATELIER, père de la chimie des ciments, a écrite: je veux parler du Professeur I.F. PONOMAREV, aujourd'hui âgé de 98 ans.

o  
o o

Permettez-moi enfin de souhaiter à tous les participants de ce congrès une bonne santé, beaucoup de bonheur, et un travail fructueux pour le développement de la science des ciments et la préparation du prochain congrès.

Je vous remercie.

Lettre de M. I.F. PONOMAREV, Professeur à l'Institut Polytechnique de Novocherkask (URSS) aux participants du 7ème Congrès International de la Chimie des Ciments, à Paris.

"Chers participants au Congrès,

"Recevez mes cordiales salutations et mes vœux de succès pour les travaux de ce Congrès de portée mondiale.

"Ce Congrès a lieu à Paris, où Henry Le Chatelier a fait ses travaux de recherche scientifique et a écrit son remarquable ouvrage "La silice et les silicates"\*

"Je lui ai toujours été très reconnaissant de m'avoir autorisé à imprimer la traduction russe de cet ouvrage et de m'avoir fait parvenir en plus sa photographie, ainsi que des corrections et des compléments, qui n'ont été publiés que dans l'édition russe.

"Recevez les amicales salutations d'un vieux spécialiste des silicates".

I.F. PONOMAREV  
Professeur

faite à Novocherkask (URSS)  
le 25 Juin 1980

# THEME I

## Influence des matières premières des combustibles et des procédés de fabrication sur la structure et les propriétés des clinkers

par R. BUCCHI et J.-P. MERIC

Quatre rapports principaux (de MM. BUCCHI, SPRUNG, TIMASHEV et MERIC) et près de soixante communications originales de différents Auteurs constituent une mise à jour très complète des connaissances sur les différents sujets de ce thème.

Les principaux sujets traités sont les suivants :

- 1.- La réactivité des crus.
- 2.- La physico-chimie de la phase liquide.
- 3.- L'influence des additions et des composés mineurs sur les réactions de clinkérisation.
- 4.- La structure du clinker en fonction des paramètres de fabrication.
- 5.- La mécanique de la fragmentation et son application aux broyeur industriels.
- 6.- La broyabilité du clinker et des constituants secondaires.

### 1.- LA REACTIVITE DES CRUS

Deux grandeurs distinctes rendent compte de la manière dont le cru se transforme en clinker : l'aptitude à la cuisson et la réactivité. Cette transformation est caractérisée par plusieurs paramètres :

- $\alpha$  qui est le degré de combinaison de la chaux dans les composés formés,
- $\text{CaO}_f$  qui est le pourcentage de  $\text{CaO}$  libre,
- $t$  la température,
- $\theta$  le temps.

L'aptitude à la cuisson est en général représentée dans un espace à trois dimensions par la fonction reliant  $\alpha$  à  $t$  et  $\theta$  ou par la fonction reliant  $\text{CaO}_f$  à  $t$  et  $\theta$ . De cette représentation on peut déduire les relations entre deux variables, la troisième restant constante. Ces différentes relations permettent de quantifier l'aptitude à la cuisson d'un cru.

La réactivité, par ailleurs, est définie comme la vitesse d'une réaction ou d'un ensemble de réactions à une température donnée. Dans le cas d'un cru de cimenterie, on mesure souvent la réactivité moyenne apparente de la cuisson.

Il se révèle que ni la mesure de l'aptitude à la cuisson ainsi qu'elle vient d'être définie, ni celle de la réactivité moyenne, ne sont adaptées à la caractérisation complète d'un cru. Cette caractérisation complète pourrait sans doute être approchée par l'étude de trois valeurs de réactivité moyenne dans trois intervalles de température :

$$\Delta t_1 : 500^\circ\text{C} - 1000^\circ\text{C}$$

$$\Delta t_2 : 1000^\circ\text{C} - 1300^\circ\text{C}$$

$$\Delta t_3 : 1300^\circ\text{C} - 1450^\circ\text{C}$$

Ces trois intervalles sont suggérés par l'identification des différentes réactions qui précèdent ou accompagnent la clinkérisation.

L'aptitude à la cuisson dépend de la saturation en chaux et de la réactivité des matières. La réactivité des matières, c'est-à-dire la vitesse à laquelle elles se combinent, est fonction de SM, TM, de la dimension des grains, de leur nature minéralogique et de leur état d'activité au moment où elles entrent en combinaison. Ce dernier point est capital pour expliquer la différence de réactivité d'une même matière lorsqu'elle se trouve dans des crus différents. L'explication de ces effets est fondée sur les lois de la diffusion solide, notamment sur les relations entre les coefficients de diffusion solide et l'énergie d'activation de la matière. Cette énergie d'activation dépend elle-même des défauts de structure des solides en présence. D'autres paramètres, notamment ceux de la phase liquide comme la viscosité, la mobilité ionique et la tension superficielle jouent également un rôle essentiel.

U. LUDWIG et S.E. IBRAHIM ont établi une relation entre l'aptitude à la cuisson mesurée en termes de durées nécessaires à différentes températures pour atteindre  $\text{CaO}_f \leq 2\%$  et certains de ces paramètres (figure 1).

$$B_{c,t} = \left[ 0,04 \sum_{20}^{300} \text{HE} + 0,043 (K_{st} \text{ III}^2 - 90^2) - 0,114 \text{ SA}^2 \right] - e^{0,0126 (1360-t)}$$

$$r = 0,94$$

- $B_{c,t}$  = Aptitude à la cuisson calculée à  $t^\circ\text{C}$ .
- $\sum \text{HE}$  = Somme des influences de "hétérogénéité",
- $K_{st} \text{ III}$  = Kalkstandard sel. SPHON.
- $\text{SA}$  = Phase liquide sel. DAHL à  $1360^\circ\text{C}$ .
- $t$  = Température.

Fig. 1 Aptitude à la cuisson calculée,  $B_c$  (min)

P. GOMA a établi une fonction qui prend en considération même la présence et la teneur de quelques composés mineurs.

S. CHROMY a mis en évidence l'importance de la granulométrie du calcaire et du quartz pour l'aptitude à la cuisson.

## 2.- LA PHYSICO-CHIMIE DE LA PHASE LIQUIDE

Le rapport de V.V. TIMASHEV présente une théorie unitaire des propriétés de la phase liquide et de la cinétique de formation de  $C_3S$  en s'appuyant sur des connaissances obtenues par les chercheurs russes. Une communication supplémentaire particulièrement remarquable sur la cristallogenèse dans les microzones des grains de clinker est apportée par V.V. TIMASHEV en collaboration avec A.P. OSSOKINE et E.N. POTAPOVA.

Le milieu fondu est l'intermédiaire grâce auquel l'alite peut se former. La température à laquelle la phase liquide se forme, ses propriétés physico-chimiques et la quantité formée déterminent la cinétique de dissolution des grains de  $CaO$  et de bélite en fonction de leur dimension et de leur état d'activation, ainsi que la cinétique de diffusion de  $Ca^{2+}$ ,  $O^{2-}$  et  $Si_2O_7^{4-}$  vers les zones de naissance et de croissance des cristaux d'alite. Les trois paramètres cités contrôlent donc la micro et la macro-structure du clinker.

Le milieu fondu présente un caractère fortement ionique. Il est composé essentiellement d'ions  $Ca^{2+}$ ,  $O^{2-}$ ,  $SiO_4^{4-}$  et de deux groupes  $MeO_x$  d'ions amphotères  $Al$  et  $Fe^{3+}$  : il s'agit d'abord d'ions tétraédriques  $MeO_4^{5-}$  où le métal est fortement lié à l'oxygène et présentant un caractère acide et ensuite d'ions octaédriques  $MeO_6^{3-}$  présentant un caractère basique, facilement dissociables en  $Me^{3+}$  et  $6O^{2-}$  et par conséquent plus mobiles que les ions tétraédriques. Les propriétés du bain sont donc différentes selon le déplacement de l'équilibre acide-base

Ce déplacement est fonction de la nature et de la concentration des ions de composés mineurs. Ces propriétés peuvent être traduites par trois paramètres principaux : la viscosité, les coefficients de diffusion et la tension superficielle.

En principe, la viscosité  $\eta$  diminue lorsque le potentiel ionique  $Z/a$  (et l'énergie de liaison  $Me-O$ ) des éléments dans le bain augmente. Ainsi s'expliquent l'action défavorable de  $K^{1+}$  et  $Na^{1+}$  et celle favorable de  $F^{1-}$ ,  $Cl^{1-}$ ,  $Ti^{4+}$ ,  $S^{6+}$ ,  $P^{5+}$ ,  $Mg^{2+}$ .

La présence simultanée d'éléments différents ne permet pas de cumuler les effets lorsque ceux-ci s'exercent dans le même sens, mais elle peut compenser partiellement des effets opposés ; ainsi les sulfates alcalins rédui-

sent la viscosité qui, par ailleurs, augmente brusquement lorsque  $[K_2O] + [Na_2O] > [SO_3]$ . Il est à noter que  $Mg^{2+}$  compense  $K^{1+}$  et  $Na^{1+}$ . Les effets simultanés des quatre éléments les plus fréquents dans les crûs ( $K^{1+}$ ,  $Na^{1+}$ ,  $S^{6+}$ ,  $Mg^{2+}$ ) sont représentés par les courbes d'isoviscosité de la figure 2.

Fig. 2

Les ordres de grandeur des coefficients de diffusion  $D$  sont :

Ca	: $10^{-9} m^2/s$
Al, Fe	: $10^{-10} m^2/s$
Si	: $10^{-11} m^2/s$

Les dimensions des lacunes dans le bain de l'ordre de  $1.1\text{\AA}$  justifient l'hypothèse suivant laquelle  $Ca^{2+}$ ,  $Al^{3+}$ ,  $Fe^{3+}$  (rayon ionique  $1\text{\AA}$ ) diffusent par trous, tandis que les ions plus grands  $SiO_4^{4-}$ ,  $AlO_4^{5-}$ ,  $FeO_4^{5-}$  diffusent plus lentement par déplacement.

Les grandeurs  $\eta$  et  $D$  agissent sur la vitesse  $I$  de dissolution par diffusion de  $CaO$  et de  $C_2S$  (figure 3), ainsi que sur la vitesse de formation de  $C_3S$ .

On suppose qu'il existe deux mécanismes pour cette formation en raison de l'apparition de phénomènes de liquidation. Dans les zones bilitiques (acides) du bain, ce sont  $I_{C_2S}$  et  $D_{Ca^{2+}}$  qui contrôlent le processus. En conséquence, les cristaux d'alite croissent sur les cristaux de bélite pour se substituer à eux. Dans les zones les plus basiques (surtout en présence de  $K^{1+}$  et  $Na^{1+}$ )  $I_{C_2S}$  est plus élevé et le processus est contrôlé par  $I_{CaO}$  : dans ce cas, la bélite se corrode en se dissolvant dans le bain. L'alite précipite de manière homogène et des vides se forment à la place des grains de chaux.

Fig. 3

La cristallisation et l'agglomération des particules, c'est-à-dire la granulation du clinker, sont essentiellement influencées par la quantité de masse fondue, par sa viscosité et par sa tension superficielle  $\sigma$  (B.S. ALBATS et Coll.). V.V. TIMASHEV démontre que la fonction reliant la dimension moyenne des grains de clinker à la tension superficielle est linéaire (figure 4). Cette relation est vérifiée sur les installations industrielles et elle donne un moyen d'action sur la granularité du clinker en faisant varier la quantité et les propriétés de la phase liquide.

Fig. 4

### 3.- L'INFLUENCE DES ADDITIONS ET DES COMPOSES MINEURS SUR LES REACTIONS DE CLINKERISATION

R. BUCCHI a examiné onze éléments mineurs dans 141 crus industriels. Les plus fréquents sont, par ordre de concentration :  $MgO$ ,  $K_2O$ ,  $SO_3$ ,  $Na_2O$ ,  $TiO_2$ .

En ce qui concerne les alcalis, on vient de voir que lorsqu'ils sont en excès stoechiométrique par rapport à  $SO_3$ , ils dégradent les propriétés de la phase liquide. En outre, ils créent, comme l'a montré SPRUNG, des circulations nuisibles dans le four et des anomalies dans la prise du ciment. Souvent les alcalis semblent donc indésirables.

$MgO$  présente de nombreux aspects positifs qui sont souvent méconnus. En effet, il s'agit d'un minéralisateur et d'un fondant efficace qui peut être admis à des concentrations supérieures à celles qui sont annoncées, à condition cependant qu'il soit finement cristallisé et bien dispersé dans la masse fondue. Ces conditions sont d'autant mieux remplies que le cru est finement broyé et qu'il contient du  $SO_3$  et des fluorures (Y.V. NIKIFOROV et R.A. ZOSOULIA). On retrouve ainsi le rôle bénéfique des sulfates, rôle qui est cependant contesté par les travaux de N.H. CHRISTENSEN et V. JOHANSEN ; W.A. KLEMM et I. JAWED.

Les résultats concernant  $TiO_2$  (D. KNÖFEL, 1977-1979) concluent à un rôle positif.

Le rôle des fluorures déjà connu a été ré-examiné.  $F^{1-}$  favorise la dissociation de  $CaCO_3$  d'une manière plus ou moins marquée selon le cation associé à l'ion  $F^{1-}$  (figure 5 S.N. GHOSH). Dans le système C-A-F-S,  $F^{1-}$  étend le domaine d'existence du  $C_3S$  à des intervalles de composition plus grands. Il élargit le domaine de phase primaire des solutions solides de  $C_{12}A_7$ , mais il restreint celui du  $C_3A$  (A.K. SARKAR et R.M. SMART). Il augmente de 2 à 2,5 fois la vitesse de formation de l'alite par l'intermédiaire d'un accroissement de la phase liquide et des vitesses de diffusion (N.H. CHRISTENSEN et V. JOHANSEN). Plusieurs travaux ont comparé l'efficacité de l'ion  $SiF_6^{2-}$  et de l'ion  $F^{1-}$ , mais sans conclure de manière indiscutable. L'action de  $F^{1-}$  est renforcée par la présence de  $MgO$  et de  $SO_3$ , surtout du point de vue de la cinétique de clinkérisation, de la structure du clinker et des résistances mécaniques qui sont plus élevées même à des échéances brèves, notamment lorsque  $TM = 1,5$  ainsi que W.A. KLEMM et I. JAWED le montrent.

L'ion  $Cl^{1-}$  améliore les propriétés de la phase liquide et comme l'ion  $F^{1-}$ , il est un fondant et un minéralisateur efficace. Le chlore présente un certain nombre d'inconvénients qui proviennent du caractère

Fig. 5

volatil des chlorures alcalins et du fait que sa concentration dans le clinker atteint des niveaux très faibles (0,01%).  $\text{Cl}^-$  catalyse la formation de  $2\text{C}_2\text{S} \cdot \text{CaCO}_3$  (spurrite) et provoque des croûtages, des collages, des anneaux, soit dans le four, soit dans le préchauffeur. S. SPRUNG fixe à 150 ppm la concentration en chlore dans un cru au-delà de laquelle, si  $\text{K}_2\text{O}$  est supérieur à 2%, il est nécessaire de dépasser les fumées des fours avec préchauffeur à suspension. R. BUCCHI constate, qu'en dessous d'une concentration de 50 ppm, le fonctionnement du four est dans tous les cas régulier pour ce type de four. Le remède à ces inconvénients du chlore, préconisé par H.M. SYLLA (1974), est de bloquer  $\text{Cl}^-$  en chloro-apatite à l'aide de phosphate, ce qui a été confirmé par M. KOVACS et K. BENYEI. 0,8% de  $\text{P}_2\text{O}_5$  dans le cru réduit la formation de spurrite, mais son élimination complète ne se fait que vers 1,5%. Cette teneur en  $\text{P}_2\text{O}_5$  peut être dangereuse pour la qualité du produit, même si V. V'IKOV et Coll. (1967) considèrent qu'elle est tout à fait tolérable dans les clinkers ayant une saturation en chaux basse.

#### 4.- LA STRUCTURE DU CLINKER EN FONCTION DES PARAMETRES DE FABRICATION

Les minéraux du clinker sont des solutions solides hors d'équilibre contenant des impuretés dans les différentes phases. L'activité hydraulique plus ou moins élevée provient essentiellement des défauts et distorsions du réseau provoqués par les substitutions isomorphes, soit homo, soit hétérovalentes, ainsi que par le refroidissement. La structure fine des phases est responsable de la concentration et de la répartition des impuretés qu'elles contiennent : grossièrement, l'alite peut en contenir 4%, la bélite 6%, l'aluminoferrite jusqu'à 10% et l'aluminate jusqu'à 13% (A.I. BOIKOVA).

Dans un rapport très important, P. GOURDIN, E. DEMOULIAN, F. HAWTHORN et C. VERNET ont étudié, par une approche statistique, les relations entre l'alite, le  $\text{C}_3\text{A}$ , les résistances mécaniques, les espèces minéralogiques du cru, les composés mineurs et le procédé de fabrication de 60 clinkers industriels. Ils ont trouvé des formes d'alite très diverses :

$\text{M}_{\text{Ib}}$  : 47% des cas

$\text{M}_{\text{IIb}}$  : 35% des cas

R : 18% des cas

Le  $\text{C}_3\text{A}$  est cubique dans 48% des cas et rarement tétragonal (8%) ; dans 43% des cas les deux formes coexistent simultanément.

L'association d'alite R avec du  $\text{C}_3\text{A}$  cubique est fréquente dans les crus quartzeux pauvres en  $\text{MgO}$  et en alcalis mais présentant un excès de  $\text{SO}_3$  sur  $\text{K}_2\text{O}$ . Les résistances de ces clinkers à 7 et à 28 jours sont supérieures à la moyenne.

Les clinkers provenant de crus "illitiques" riches en magnésie et en alcalis non saturés par les sulfates, alcalis qui sont par conséquent disponibles pour entrer dans les réseaux de  $\text{C}_3\text{S}$  et de  $\text{C}_3\text{A}$ , contiennent le plus fréquemment une alite  $\text{M}_{\text{Ib}}$  et un  $\text{C}_3\text{A}$  tétragonal. En outre, si les teneurs en  $\text{Na}_2\text{O}$  sont élevées, on constate également la présence de  $\text{C}_3\text{A}$  cubique. On constate que l'alite R n'est jamais associée avec le  $\text{C}_3\text{A}$  tétragonal.

Les clinkers contenant de l'alite  $\text{M}_{\text{IIb}}$  et de l'aluminate cubique (ou cubique ou tétragonal) donnent les résistances les plus élevées, tandis que les clinkers contenant de l'alite  $\text{M}_{\text{Ib}}$  ont des résistances inférieures à la moyenne.

Les relations entre composition, conditions de cuisson, structure microscopique et résistances mécaniques sont discutées dans trois communications : celles de Y. ONO, de S. TAKAGI et A. KAWASHIMA et de B.V. VOLCONSKI et Coll. La figure 6 donne l'équation de Y. ONO pour l'évaluation de la résistance en fonction des paramètres géométriques et optiques du clinker.

#### 5.- LA MECANIQUE DE LA FRAGMENTATION ET SON APPLICATION AUX BROyeurs INDUSTRIELS

Le rendement énergétique de la fragmentation par rapport à l'énergie de surface libérée est très faible, de l'ordre de 1%.

Si on rapporte le rendement du broyage à l'énergie de fissuration, c'est-à-dire à l'énergie nécessaire au déplacement d'une fissure, on trouve encore des chiffres très modestes inférieurs à 10%.

$$R_{M28} = 253 + 6,4(AS) + 21,9(AB) + 40(BS) + 21,5(BC)$$

(AS) = Dimension alite  
(AB) = Birefringence alite.  
(BS) = Dimension belite.  
(BC) = Couleur belite.

Fig. 6

On peut comparer les rendements des différents modes de broyage entre eux. On constate alors que ces rendements se situent dans un intervalle dont les extrêmes sont dans un rapport dix.

Les pertes énergétiques analysées par J.P. MERIC dans son rapport sont de quatre types :

- celles dues aux déformations plastiques qui entraînent une dissipation énergétique dans la matière même ;
- l'énergie élastique excédentaire communiquée au matériau pour la propagation de la fissure ;
- les pertes dues au manque de sélectivité des corps broyants qui communiquent à la matière plus d'énergie qu'il n'est nécessaire pour créer le champ de contraintes (ce qui se traduit par des réagglomérations) ;
- les pertes mécaniques.

H. HORNAIN et M. REGOURD communiquent des mesures de l'énergie spécifique de fissuration du clinker  $\gamma_f$  comprises entre 12 et 22 J.m<sup>-2</sup>, ce qui signifie que l'énergie théoriquement nécessaire pour libérer une surface de 3500 cm<sup>2</sup>/g est de 1.65 kWh/t, alors que celle des broyeurs industriels est de l'ordre de 40 kWh/t. Le rendement par rapport à l'énergie de fissuration qui est ainsi mis en évidence est de 4%.

En comparant les différents modes de fragmentation, on constate que l'écrasement lent est très sélectif et présente les rendements les plus élevés. Il est réalisé dans les broyeurs à meules, mais d'une manière imparfaite seulement.

La percussion par masse tombante est le mode de broyage le moins sélectif, étant donné que les corps broyants attaquent tous les grains, les plus fins comme les plus gros, avec une énergie égale. Le rendement diminue très rapidement lorsque la finesse augmente. Cette diminution peut être freinée par deux remèdes : l'utilisation de corps broyants de petite dimension (mini pebs) ou des séparateurs à air qui éliminent les grains les plus fins.

La projection de matière sur une enclume pourra donner naissance à une troisième génération de broyeurs très sélectifs avec un rendement amélioré, à condition que l'on sache maîtriser les problèmes technologiques posés par l'utilisation de ciments à spectre granulométrique étroit. Une revue très claire de ce problème est présentée par Y. LE JEAN. La figure 7 illustre la sélectivité du broyeur à projection.

Fig. 7

A première vue, il semble que des progrès considérables peuvent être faits dans le domaine du broyage du cru et du ciment car les outils actuels ont des rendements médiocres et réagglomèrent les grains.

Dans le cas du cru, cette conclusion est indiscutable puisque, comme l'a montré R. BUCCHI, la réactivité du cru est plus élevée lorsque le spectre granulométrique est resserré.

Dans le cas du clinker, on arrive à la même conclusion en ce qui concerne la réactivité vis-à-vis de l'eau. Un spectre granulométrique étroit conduit à d'excellentes performances hydrauliques mesurées sur éprouvettes normalisées. Cependant, l'influence d'un tel spectre sur la rhéologie est négative. Si l'on considère la qualité du béton, qui résulte à la fois des propriétés rhéologiques et hydrauliques, le bilan est loin d'être indiscutablement positif, mais il pourra s'améliorer lorsque l'on saura encadrer le spectre granulométrique du clinker par des compléments fins et grossiers inertes qui amélioreront le comportement rhéologique tout en conservant les bonnes propriétés hydrauliques.

La possibilité de préparer des ciments consistant en fractions presque monogranulaires de matière active (clinker ou laitier) et de particules inertes ayant une granulométrie complémentaire pour un remplissage optimal reste un des thèmes fondamentaux de la science du broyage avec un double objectif : l'économie d'énergie de broyage, l'économie de clinker pour une même qualité du béton.

#### 6.- LA BROYABILITE DU CLINKER ET DES CONSTITUANTS SECONDAIRES

Les clinkers les plus faciles à broyer sont ceux dont la concentration en microfissures est la plus élevée. L'état de fissuration dépend à son tour de la structure, de la composition minérale et de la vitesse de refroidissement du clinker. Le module d'élasticité et le coefficient de dilatation thermique permettent d'expliquer la bonne broyabilité de  $C_3S$  et la mauvaise broyabilité de  $C_2S$  (H. HORNAIN et M. REGOURD). D'autre part, I.F. PETERSEN montre que les clinkers industriels sont d'autant plus broyables que l'aire des pores par unité de volume est plus élevée (figure 8). Celle-ci dépend à son tour de la finesse des cristaux et de la quantité de phase liquide (figure 9).

Pour la préparation de ciments composés, il apparaît que la règle de broyer séparément les composants, que l'on applique si le composant le moins actif du point de vue hydraulique est aussi le plus difficile à broyer, soit à réviser à la lumière de résultats présentés par OPOCZKY et T.K. MRAKOVICS. Le bon choix entre broyage simultané et broyage séparé doit, en effet, tenir compte, non seulement de la broyabilité des composants, mais aussi de leur tendance à la réagglomération (indice d'uniformité de la distribution de ROSIN RAMMLER) de leurs proportions respectives et du type de circuit de broyage, ouvert ou fermé, utilisé.

Fig. 8

Fig. 9

W. KURDOWSKI et Z. WELISZEK rappellent que le broyeur à ciment, dont la fonction première est de libérer des surfaces nouvelles, est également un réacteur chimique alimenté

par l'énergie de broyage presque entièrement dégradée en chaleur qui vient s'ajouter à la chaleur propre du clinker.

Les réactions qui se déroulent dans le broyeur conduisent à la formation de semi-hydrate, de syngénite, d'ettringite. Elles dépendent du type de broyeur et de son régime de fonctionnement. Les auteurs établissent ainsi que la syngénite peut se former à partir de  $K_2SO_4$  et de sulfate de calcium hydraté ou semi-hydraté à condition que la température s'élève au-dessus de  $75^\circ C$  et que la tension de vapeur d'eau passe un certain seuil (figure 10).

Fig. 10

## CONCLUSION

Sur ce dernier sujet, nous terminons cette présentation, malheureusement trop rapide, des progrès les plus récents dans la connaissance des transformations physico-chimiques intervenant dans la fabrication du clinker et du ciment.

L'objectif qui est poursuivi par tous les laboratoires qui travaillent sur ces sujets est double :

d'abord maîtriser les transformations chimiques pour faire face à la très grande variabilité des matières premières ; il s'agit en effet pour le cimentier de passer d'une matière crue, particulièrement et souvent hétérogène, à un produit régulier parfaitement défini et adapté au marché ;

ensuite choisir parmi les transformations qui sont possibles celles qui exigent la dépense d'énergie la plus faible.

En raison de ces deux contraintes, souvent contradictoires, l'on aboutit à des procédés de plus en plus complexes, difficiles à régler et à stabiliser, qui vont exiger, de la part des constructeurs et des exploitants, une analyse approfondie des phénomènes physico-chimiques.

Les communications présentées à ce Congrès démontrent que cette analyse progresse rapidement, grâce à la collaboration très étroite des scientifiques et des industriels.

## RÉSUMES DES DÉBATS DE LA TABLE RONDE

U. LUDWIG

Institut für Gesteinshüttenkunde, RWTH Aachen

Remarks on the burnability of cement raw materials.

I would like to give only a short summary here specially of the latest results of our working groups on the burnability of industrial raw mix for the production of Portland cement clinker.

Together with G. Ruckenstein and S.E. Ibrahim we found that increasing values for the standard lime and for the heterogeneous coarse material,  $> 90$  and  $> 20 \mu m$ , respectively, lead to an increase and increasing values for the molten fraction at sintering temperature to a decrease in the time needed for well burned clinker under otherwise constant conditions.

With respect to the kiln feed we have not been able to decide up to now whether granules or nodules on the one hand or powdered material on the other give the best values for burnability, or whether they have any influence at all. The cause is the formation of active states during dehydration and decarbonization at meal-like feed, and from these results the formation of meal granules and adhesives on the rotating laboratory burning equipment. So, we did not succeed in direct burning of meal feed. But we are of the opinion that these active states of the meal during heating up are the primary cause of the formation of adhesives and meal rings in the kiln and the pre-heater system. Their stabilization by alkalies and others is a secondary effect but of no less importance.

According to the burning temperature it is of little practical interest that A. Wolter

refined the lowest temperature of  $C_3S$  formation to 1264°C instead of 1250°C. Of greater importance for the cement production is the stable formation of alites already at 1200°C and their unstable formation above 1160°C. From our work with additional additives in amounts of 0.5 wt.-% to alite only fluorine leads to a further lowering of the alite formation temperature to 1100°C. Finally, fluorine-alite is already formed at 925°C. From these results one can conclude that the formation of Portland cement clinker should be possible for below 1360°C. Besides we know from the work with D. Bürger that the low temperature alites and alinites have sufficient hydraulic properties. - Our revision on O. Philipp's work with several raw meals together with H. Bomas showed only in some cases a more rapid lime combination by using a high heating rate. - F. Bayer found in his experimental work that rapid heating, slow cooling up to 1250°C and rapid cooling again afterwards result in best mortar strength (DIN 1164).

From the above-mentioned great influence of the coarse and heterogeneous particles of the raw mix one can conclude that cement manufacturers should try to improve the grindability of the raw mix and the effectiveness of the separator by the use of surface active substances. H. Glock found a marked lowering of coarse particles > 90 and > 25  $\mu$ m diameter, with the help of such substances.

A more extensive summary of our work on the influences on burnability of Portland cement raw mixes will be published shortly. I am indebted to C.A. Mulhern for his revision of the English text.

Comportement des mélanges crus à la cuisson

Le comportement à la cuisson d'une matière première ne se réfère pas seulement à l'aptitude à la cuisson, mais comprend tous les facteurs d'une importance technique lors de la cuisson, soit l'aptitude à la cuisson, la formation du croûtage, la volatilité (des alcalis, du soufre et du chlore), la formation de la poussière et la granulométrie du clinker.

Les facteurs les plus importants influençant l'aptitude à la cuisson sont la saturation en chaux, le module silicique et la quantité des grains de quartz et de calcite au-dessus d'un certain diamètre critique des grains. Basé sur un très grand nombre d'essais, nous avons établi un modèle mathématique des effets exercés par ces facteurs sur l'aptitude à la cuisson de tout mélange cru à ciment, modèle qui permet d'optimiser la préparation et la cuisson du cru.

Le comportement du cru à la cuisson aux températures inférieures est aussi important. D'un échauffement trop lent de quelques crus résulte une diminution de la réactivité de la matière cuite.

Pour caractériser la formation du croûtage et la volatilité, nous avons développé des tests spéciaux.

La performance d'un ciment Portland peut être attribuée jusqu'à environ 90% à la chimie du clinker correspondant. Parmi les facteurs chimiques ce sont notamment les sulfates d'alcalis qui influencent surtout le développement de l'hydratation. La performance d'un ciment n'est souvent pas celle qui pourrait être attendue sur la base des propriétés du clinker, parce que non seulement le clinker, mais également le broyage et le stockage influencent sensiblement les propriétés du ciment.

A. BOIKOVA

Institute of Silicate Chemistry of the USSR Academy of Sciences, Leningrad

Remarks on Alinite

Alinite, a high-basic Al-Cl-calcium silicate differs strongly from alite in composition, structure and properties.

The peculiarity of alinite is that aluminium and chlorine, together with the main elements Ca, Si and O, participate in the formation of a specific structure arrangement in the form of mixed anionic network consisting of oxygen and chlorine atoms (1, 2).

Based on the structural analysis the authors propose the idealized formula of alinite as  $Ca_{11}(Si_{10.75}Al_{0.25})_4O_{18}Cl$ ; the tetragonal cell contains two formula units.

However, under real synthesis conditions the alinite single crystals obtained by the authors always contained Mg and Fe.

The X-ray diffraction pattern of alinite is different from either of well-known patterns of triclinic ( $T_I$ ,  $T_{II}$ ,  $T_{III}$ ), monoclinic ( $M_I$ ,  $M_{II}$ ,  $M_{III}$ ) and rhombohedral alites.

The presence of chlorine in the structure provides the lower formation temperature of this mineral compared to alite (1000-1100°C instead of 1400-1500°C).

Alinite is highly reactive with water and shows high long term strength.

Although alinite is the main constituent of alinite clinker (a clinker of the low-temperature synthesis), the problem of alinite cannot solve the clinker problem as a whole due to a number of reasons.

The mineralogical phase composition of alinite clinker is rather complex, and the influence of other phases on the properties of clinker (and cement) should be noticeable.

However, the character of interrelation between these phases and chlorine is unknown.

Some other facts are also unknown such as the real composition of phases in the alinite clinker, isomorphic impurities in them, the distribution of impurities of the raw mixture (mainly of chlorine) among these phases.

Due to imperfect homogenization of the initial raw mixture and to the non-equilibrium conditions of the annealing of clinker the satisfactory combining of chlorine by the clinker constituents may hardly be attained.

Apparently in this case one should not exclude the possibility of obtaining the alinite analogs with more "quiet" elements in structure than chlorine.

It is also important to know the thermal stability of alinite and of the other phases of alinite clinker.

The study of the interaction process of alinite, the other phases and the alinite cement with water is of greatest practical and scientific significance. The main problem of this trend is the behaviour of chlorine during the hydration, in particular the probability of its entering into the structure of hydrates.

The composition, structure and properties of hydrates containing chlorine are also of great interest.

The problems mentioned are only part of the scientific tasks to be solved in the course of production and investigation of the alinite clinker.

Société des Ciments Français, Centre d'Etudes et de Recherches de GUERVILLE

Polymorphisme de l'alite et du  $C_3A$ . Statistiques. Remarques complémentaires.

La question du polymorphisme des composés du clinker est complexe puisque l'alite est soit triclinique, soit monoclinique ou trigonale et que le  $C_3A$  peut être cubique, orthorhombique ou monoclinique. Le Séminaire A a montré que la forme tétragonale du  $C_3A$  n'existe pas, ce qui simplifiera un peu ces remarques.

Notre contribution à ce Congrès a été de montrer que l'alite des clinkers industriels est, le plus souvent, monoclinique et que l'alite trigonale fait plutôt figure d'exception puisque nous ne l'avons rencontrée que 11 fois sur 60 clinkers examinés. Le  $C_3A$  est cubique (29 clinkers) ou orthorhombique (5 clinkers) ou sous les deux formes simultanément (26 clinkers).

Nous voyons donc que :

- l'alite trigonale est plutôt une exception;
- l'alite monoclinique ( $M_I$  et  $M_{II}$ ) est très fréquente ;
- l'alite triclinique est absente, sauf dans un échantillon exceptionnel, ayant séjourné longtemps dans le four rotatif et décrit dans une autre communication.

Nous ajouterons que l'alite trigonale est toujours associée au  $C_3A$  cubique dans nos clinkers industriels.

On peut alors se poser deux questions : pourquoi voit-on telle ou telle forme dans les clinkers industriels ? et quelle est la forme la plus favorable aux meilleures résistances à la compression des ciments portland correspondants ?

Pour répondre à ces questions nous avons dressé des Tables de Fréquence des formes allotropiques observées dans les clinkers en face des principales caractéristiques des mélanges crus, des clinkers et des ciments portland correspondants. Nous sommes arrivés aux trois conclusions suivantes :

1.- Parmi les ciments portland qui développent les plus hautes résistances à la compression se trouvent ceux dont l'alite est de forme trigonale et le  $C_3A$  de forme cubique.

2.- L'alite trigonale et le  $C_3A$  cubique se voient plus fréquemment dans les clinkers où  $SO_3$  est en excès par rapport à  $K_2O$ , après formation de  $K_2SO_4$ .

3.- Les clinkers dans lesquels  $\text{SO}_3$  est en excès par rapport à  $\text{K}_2\text{O}$  proviennent des mélanges crus dont la silice est sous forme de quartz et de kaolinite, c'est-à-dire sans composés alcalins et clinkérisés avec du fuel-oil ordinaire, à 4% de soufre.

De ces conclusions, on peut supposer que l'alite trigonale renferme plus de  $\text{SO}_3$  dans sa structure et moins de  $\text{MgO}$ ,  $\text{K}_2\text{O}$  et  $\text{P}_2\text{O}_5$  que l'alite monoclinique. Cette supposition, à partir de 60 clinkers industriels, confirmerait les analyses que Mme REGOURD a présentées à Copenhague en 1972 et à Moscou en 1974, selon lesquelles "l'alite trigonale contient moins de  $\text{MgO}$  et plus de  $\text{SO}_3$  que l'alite monoclinique". Ainsi comprenons-nous l'importance pratique du polymorphisme de l'alite et du  $\text{C}_3\text{A}$ .

Blue Circle Technical, England

#### 1.- Reactivity of raw mix predicted by its physico-chemical properties.

There can be no question that the reactivity of the individual species present in raw material depends on the size, shape and perfection or imperfection of the crystal forms in which they appear, with special reference to their purity and the regularity of the lattice structure and the fine structure of the boundary surfaces. In other words the lattice energy, occurrence of defects, minor constituents and surface energy are all as important as Prof. BUCCHI has indicated in his Summary Paper on this theme. Also important are the presence of reducing compounds and the homogeneity of the ground and blended raw materials both of which can materially influence the temperature/time/atmosphere regime required in the kiln, i.e. what we call the combinability.

The question is directed at our ability to predict. Immediately, the difference in viewpoints of the academic and the industrial scientist becomes apparent. Of course both can agree that any means of accurate prediction of necessary process parameters must be valuable in principle. But in practice it is also necessary that the procedures leading to a prediction should represent an economy in time and cost over the already existing methods of measuring combinability. In my view, the procedures for determining on a representative scale, as distinct from on a few individually prepared crystals, the lattice energy, defect occurrence and surface energy for the range of materials present in one raw mix would be far more time-consuming and expensive than is the relatively simple combinability test. It could be argued that after the acquisition of sufficient data in an early phase the balance would eventually swing in favour of the predictive method.

This would be more likely if the range of raw materials of interest were restricted. Unfortunately, as Prof. BUCCHI has pointed out, cement has to be made where there is a market for it and we have to use the materials that lie within economic reach. Those of us whose interests are worldwide are constantly encountering new forms of the necessary minerals. For a predictive method to be universal in application, the investigative early phase would in fact prove to be extensive and expensive.

Apart from the case of works with a limited range of mineral and crystal forms, where there should be little difficulty anyway in understanding combinability, I believe that the most useful approach is to continue with intelligent performance, and interpretation, of combinability tests resorting to more refined methods of study only when unusual aspects of the materials are revealed by those tests; in other words what we are already doing.

#### 2.- Influence of grinding on cement properties.

It is well known and has been stated by Dr. MERIC and others that alite and  $\text{C}_3\text{A}$  are more brittle than belite and the ferrite phase. In principle therefore it would not be surprising to find more alite and  $\text{C}_3\text{A}$  in the finer fractions and more belite and ferrite in the coarser fractions of clinker in cement. This simple principle can however be modified, for example, according to the method of preparation of the raw meal and the burning and cooling regimes. These factors influence the sizes of the unground crystals and indeed their brittleness. Rapidly cooled belite, e.g., may contain little or no crystalline ferrite owing to its glassy form. Another important factor is the overall clinker composition with especial reference to silica ratio and liquid content. The whole field of possibilities is obviously enormous. But taking the simple principle already stated as a centre line of thought, it is broadly true that the lower the silica ratio and therefore the higher the liquid content the less obvious are the signs of segregation of the four phases: conversely the higher the silica ratio the more obvious will be those signs of segregation. But of course in real clinkers the impurity of all the phases can again modify the picture.

Heterogeneity at random is bound to occur in clinker nodules unless the distances between unlike particles in the decarbonated nodules are small and closely grouped about their mean. This is why fine grinding and efficient blending of the raw meal are vital for fuel economy and clinker quality. Radial heterogeneity in a nodule can arise in two principal ways. First, as Dr. SPRUNG has said in answering M. VON EUW, if the coal

in a coal-fired kiln is not ground finely enough then quite apart from the important effects on flame characteristics, the molten ash will fall in the burning and decarbonating zones primarily. In cases where the raw material has already nodulised this means that the centre of the nodule is overlimed and the surface of the nodule is underlimed because the Works Chemist has provided in the raw meal an excess of lime intended to react with the acidic coal ash. There are many beautiful photomicrographs of such clinker showing belite concentrations round the surface and free lime in the interior of the nodule. Similar effects can occur as a result of coatings, clinker rings and other anomalous deposits breaking away.

The second form of radial heterogeneity arises in the very hard burning of high silica ratic materials. The clinker nodules tend to be friable and to be surrounded by a sugary deposit of alite crystals alone. The extent to which this is due to kiln and/or cooler conditions varies.

## CONCLUSIONS RESUMEES SUR LE THEME I PAR LES PRESIDENTS

1.- Dans les six années qui se sont écoulées depuis le Congrès de Moscou on a vu apparaître d'importantes et remarquables contributions à la connaissance des propriétés et des mécanismes physicochimiques qui interviennent dans la fabrication du ciment. Les principaux domaines couverts par ces contributions sont les suivants :

- la réactivité des crus et de leurs composants,
- la cinétique de la diffusion solide-solide et solide-liquide,
- la micro et macrostructure du clinker,
- et enfin, la mécanique et mécanochimie du broyage.

Une attention toute particulière a été apportée au rôle d'échange de la phase fondue et plus particulièrement à l'influence de sa composition, notamment en éléments mineurs, sur les principaux paramètres qui la caractérisent.

Bien que tous les aspects de ces problèmes ne soient pas encore éclaircis, l'état actuel des progrès réalisés est tel qu'il est possible d'espérer des retombées rapides sur la technologie et donc sur l'industrie où des changements décisifs sont à attendre.

2.- Les discussions de la table ronde ont démontré que la cuisson en four rotatif, outre qu'elle présente un bilan thermique imparfait, ne permet pas de conserver aux solides originels ou aux néoformations qui proviennent du cru un niveau élevé d'activité susceptible de favoriser la vitesse de combinaison. Le séjour prolongé des matières à des températures inférieures à celles d'apparition de la masse fondue alors que la décarbonatation est déjà accomplie, contribue au "vieillissement" des matières et favorise l'évolution des structures vers des états stables peu réactifs. Il en résulte une diminution des vitesses de toutes les réactions de diffusion qui se produisent avant ou après l'apparition de la phase liquide.

Il est à prévoir que dans un proche avenir, on assistera à des tentatives sans doute nombreuses pour modifier le processus qui se déroule dans "l'intervalle mort" entre 1000° et 1300°C environ ; il s'agira d'utiliser éventuellement des types d'installations différents de ceux actuellement connus.

3.- Un autre domaine dans lequel il faut s'attendre à des progrès techniques d'une importance non négligeable est celui du broyage.

Les procédés de comminution fine par projection constituent un espoir concret d'une grande portée ; ses possibilités sont loin d'avoir été entièrement explorées. Ce type de broyeur porte les matériaux à un niveau de réactivité très élevé, mais ce niveau est tel que les propriétés rhéologiques des ciments s'en trouvent perturbées par des réactions de surface trop précoces. Ce problème devra être maîtrisé avant d'envisager son utilisation pour le broyage du ciment et il s'agit là d'un objectif pour les recherches des années à venir.

Le broyage du cru pourra également être amélioré par l'utilisation du broyeur à projection car il est possible que la très grande réactivité des matériaux préparés dans ce type de broyeur puisse permettre d'élaborer des crus de cimenterie ayant des cinétiques de cuisson nettement plus élevées que celles qui sont couramment obtenues par des broyages dans les broyeurs à boulets ou à meules. Dans ce cas les effets secondaires sur la rhéologie des produits ne présenteront pas la même gêne que pour le ciment.

La sélectivité du broyage par projection permettra de concevoir des ciments composés particulièrement performants. Dans ce cas, le but ne se limite pas seulement à l'économie dérivant du remplacement d'une partie du clinker par des constituants ayant un contenu énergétique plus bas, mais s'étend au con-

traire à un objectif plus ambitieux qui est la réalisation de ciments reconstitués à partir de fractions granulométriques définies, ces ciments permettant de confectionner des bétons présentant des propriétés rhéologiques adéquates pour des rapports E/C faibles.

4.- Il est impossible de ne pas évoquer pour terminer les composés mineurs du clinker. L'influence qu'ils exercent sur les équilibres de phase, sur la cinétique des réactions, sur les propriétés du clinker, ainsi que sur la régularité du fonctionnement du four, est, depuis longtemps, l'objet de recherches actives et approfondies. Ce chapitre de la recherche cimentière est cependant loin d'être terminé. Il reste l'un des domaines d'investigation les plus prometteurs, surtout lorsqu'il s'agit de la possibilité d'obtenir des types d'alite stables à plus basse température ou des types de bélite plus actifs hydrauliquement que ceux qui sont actuellement fabriqués.

## THEME II

### Hydration of Pure Portland Cements

by F.W. LOCHER

#### 1. Synopsis

There are 2 principal reports and 51 basic reports on Theme II "Hydration of Pure Portland cements". The first principal report by J. Skalný and J.F. Young deals with the course of cement hydration, the second principal report by H.F.W. Taylor and D.M. Roy provides a general view of the composition and structure of the compounds which form in cement hydration and can occur as constituents of hardened cement paste. The 51 basic reports can be divided into 7 fields as shown in table 1.

Table 1: Classification of the basic reports of Theme II

#### Theme II: Hydration of pure Portland Cements Basic Reports

A	Theory of Hydration	2
B	Methods of Investigation	4
C	Initial Reactions	18
D	Ettringite	2
E	Hydration of Silicates	12
F	Effect of Admixtures	9
G	Compounds in Hardened Cement Paste	4
		51

This classification shows that more than 3/4 of the basic reports are concerned with the fields of "initial reactions", "hydration of calcium silicates" and "effect of admixtures".

It is the task of the general report to present a summary of the principal and basic reports. On the basis of the congress contributions this report will attempt to describe in particular the processes in hydration which, in our opinion, are of special importance regarding the practical aspects of setting and hardening of cement. If the opinion of our institute is particularly stressed it should be understood as a stimulus for the discussion which will follow.

#### 2. Summary of the course of reaction

A large number of investigations have shown that the course of cement hydration can be divided into 3 stages. The most important connexions are illustrated in figure 1. In both diagrams the division of the abscissa shows the duration of hydration; on the left of the ordinate the content of nonhydrated tricalcium aluminate (top) and tricalcium silicate (bottom) and on the right the content of non-evaporable water (top) and newly-formed calcium hydroxide (bottom) are shown.

Figure 1: Hydration of tricalcium aluminate and tricalcium silicate in Portland cement

The course of the 4 curves illustrates that the initial reaction which starts immediately after the mixing of the cement stops after 15 minutes at the latest. The dormant period, which lasts for a few hours, follows and practically no or only a very weak chemical reaction occurs. Then the actual cement hydration starts in which the hydration prod-

ucts are formed which are essential for the hardening.

Tricalcium aluminate and calcium sulfate added for control of setting are primarily involved in the initial reaction. In the first minutes after mixing the tricalcium silicate mainly only releases calcium hydroxide to the solution. Certain initial reactions can also be expected from calcium aluminate ferrite and dicalcium silicate but the extent of the reaction is very low.

### 3. Reaction of tricalcium aluminate with calcium sulfate

The amount of tricalcium aluminate involved in the initial reaction does not depend on the addition of calcium sulfate. This is shown by studies of the course of hydration of ground cement clinker with and without the addition of gypsum. The results are shown in figure 2.

Figure 2: Hydration of tricalcium aluminate in ground Portland cement clinker with and without addition of gypsum

It shows that the reduction in the content of tricalcium aluminate as a result of hydration is practically the same with and without the addition of gypsum. The addition of gypsum thus influences neither the quantity of tricalcium aluminate, which reacts in the first minutes after the mixing of the cement, nor the start and end of the dormant period. The retarding effect of the calcium sulfate on the setting is thus not due to the inhibition of a chemical reaction.

The calcium sulfate does, however, have a very important influence on the type of reaction products occurring in the first minutes and the structure formed by them. These processes can be followed by studies with the scanning electron microscope. Without the addition of calcium sulfate relatively large crystals of tabular calcium aluminate hydrate form which are responsible for the

rapid setting as they produce a rigid structure shortly after mixing (figure 3).

Figure 3: Structure of paste from ground Portland cement clinker without addition of gypsum 30 minutes after mixing

With the addition of calcium sulfate ettringite forms in the shape of very small particles on the surface of the cement grains (figure 4) which are so fine-grained that they cannot produce a rigid structure.

Figure 4: Structure of paste from ground Portland cement clinker with addition of gypsum 30 minutes after mixing

The orderly retarded setting of the cement paste starts during the dormant period as a consequence of a recrystallization of the ettringite in which the small crystals are dissolved and the larger crystals grow so that they can bridge over the space between the grains of cement and produce a rigid structure (figure 5).

Only that proportion of tricalcium aluminate which goes into solution in the first minutes of hydration until the start of the dormant period is involved in these reactions. The amount varies from cement to cement and is

between 0.3 and 2.0 percent by weight in relation to the total clinker.

Figure 5: Structure of paste from ground Portland cement clinker with addition of gypsum 4 hours after mixing

It does not only depend on the total amount of tricalcium aluminate but to a greater degree on other influences too. It increases, for example, if the cement clinker is burned and slowly cooled in a reducing atmosphere. It grows with decreasing grain size and decreasing width of grain size distribution. Also it is greater the higher the temperature during hydration of the cement. On the other hand, this amount of tricalcium aluminate involved in the initial reaction with calcium sulfate can change during the grinding and storage of the cement. A more or less large share of the tricalcium aluminate available for the initial reaction can react with water vapour without the participation of calcium sulfate and can form very fine-grained calcium aluminate hydrate on the surface of the tricalcium aluminate which only reacts very slowly with sulfate. Consequently the amount of tricalcium aluminate, which can react immediately after the mixing of the cement with the added calcium sulfate, decreases. Such prehydration must be expected if water is improperly injected into the cement mill, if the cement is stored outside, or if cement is stored in a silo and the gypsum still contained in the cement after grinding dehydrates slowly at an increased temperature.

The greatest possible retardation of setting occurs when the share of tricalcium aluminate which goes into solution in the first minutes after the mixing of the cement, i.e. before the start of the dormant period, is combined on the surface of the cement grains completely as fine-grained ettringite.

If the sulfate supply in the solution is not sufficient to bind the amount of tricalcium aluminate going into solution during the initial reaction as ettringite, monosulfate and/or calcium aluminate hydrate also occur,

besides ettringite, in the shape of large tabular crystals (figure 6) which cause quick setting.

Figure 6: Structure of Portland cement paste with a sulfate supply which is too low

If the sulfate supply in the solution during the initial reaction is too great e.g. as a result of too high a content of hemihydrate, so-called secondary gypsum (figure 7) is formed, apart from ettringite, and also generates solidification. If the secondary gypsum forms very quickly and if the amount is so small that it can be consumed before the start of the dormant period by reaction with the tricalcium aluminate still going into solution at this time, so-called false setting occurs.

Figure 7: Structure of Portland cement paste with a sulfate supply which is too high

If the amount of secondary gypsum is so great that it cannot be consumed before the start of the dormant period the early solidification remains, so the formation of secondary gypsum causes quick setting.

For the greatest possible retardation of setting it is thus necessary to adjust the sulfate supply in the solution to the amount of tricalcium aluminate going into solution during the initial reaction. If the amount of tricalcium aluminate is low the addition of gypsum is sufficient for this, but if it is relatively high the cement should contain hemihydrate which goes into solution much faster and in greater quantities than the gypsum. To retard setting it has thus proved useful to add a mixture of gypsum and natural anhydrite whose proportion of gypsum must be adjusted to the reactivity of the tricalcium aluminate and to grind the cement at a temperature that the gypsum is completely dehydrated to hemihydrate. The proportion of natural anhydrite which goes into solution more slowly serves to maintain a certain sulfate supply for a time after the end of the dormant period as it promotes further hydration reactions.

Dehydration of the gypsum in grinding also has the advantage that during the subsequent storage in the silo the formation of coating is avoided and the cement properties remain constant. Coating on the wall of the silo is usually due to the fact that the water contained in the gypsum escapes at a high temperature, diffuses to the colder silo wall, concentrates there and causes chemical reactions which lead to solidification.

As a result of the prehydration described above part of the water expelled from the gypsum reduces the amount of tricalcium aluminate available for the initial reaction with sulfate. On the other hand, the sulfate content of the solution increases, as the hemihydrate forming during the dehydration of the gypsum goes into solution more quickly and in greater amounts. The result can be false or quick setting, usually acceleration of the setting. For this reason it is advisable, as far as possible, not to take any water into the cement silo, especially not with the gypsum, if high temperatures cannot be avoided in the silo. The storage temperature which can cause these reactions to occur is the lower the longer the cement remains in the silo. For 7-day storage it is approximately 60 to 70 °C.

#### 4. Hydration of calcium silicates

The amount of tricalcium silicate reacting in the first minutes after mixing is in the order of 1 % (figure 8). Little is known of the influences on the extent of this reaction. Various results suggest that just as in the case of tricalcium aluminate, the chemical composition, the crystal structure and its degree of disorder are of importance.

The start and end of the dormant period are different with tricalcium silicate and tricalcium aluminate. The addition of calcium sulfate has no effect on the dormant period of the tricalcium aluminate; in the case of tricalcium silicate the dormant period is shortened by the calcium sulfate. This means that the calcium sulfate still contained in the solution after the dormant period accelerates the hydration of tricalcium silicate and as a result increases the initial strength.

Figure 8: Hydration of tricalcium silicate in ground Portland cement clinker with and without addition of gypsum

The dormant period of the tricalcium silicate in the cement is approximately 4 hours with hydration under normal temperature conditions. It can practically not be reduced by finer grinding of the cement. This means that the hardening of the cement only starts after this time and that a certain initial strength can be expected at the earliest only after approximately 6 hours. If greater strengths are desired earlier the hydration products of other compounds must be used, e.g. calcium aluminate hydrates and/or monosulfate or similar compounds as with regulated set cement or jet cement.

A certain initial reaction can also be expected for dicalcium silicate. The dormant period occurring afterwards is much longer than with tricalcium silicate. Thus for the development of the initial strength only the hydration of the tricalcium silicate is important. It practically does not start until after the dormant period when the reaction between tricalcium aluminate and calcium sulfate responsible for setting has been concluded, i.e. when the first structure of ettringite and maybe monosulfate or secondary gypsum has formed which is rigid but has relatively large pores and whose strength is thus very low. The hydration products of the tricalcium silicate gradually fill these

pores. As the degree of filling increases, the strength also grows. In order to achieve a high degree of filling with a low degree of hydration of the tricalcium silicate, the first structure should have as few pores as possible. This happens if before the dormant period only very fine-grained ettringite and no large crystals of monosulfate or secondary gypsum have formed, i.e. if during the initial reaction the sulfate supply in the solution was adjusted to the reactivity of the tricalcium aluminate. But even in the case of ideal adjustment differences in the packing density of the initial structure may occur and it can be assumed that the pore space increases with increasing ettringite content, i.e. with increasing reactivity of the tricalcium aluminate. Also the shape of the ettringite is important which depends on the composition of the solution, especially on its alkali content.

The hydration products which produce the first structure form relatively quickly during the initial reaction before the dormant period. The tendency to form a more or less rigid very porous first structure is thus particularly great during the initial reaction. For this reason it is advisable during this time to mix the cement paste, mortar or concrete very intensely. The first structure then forms during the dormant period because of recrystallization processes which are much slower so that a first structure with fewer pores can form.

Various research results and observations show that the hydration products of tricalcium silicate and dicalcium silicate can only fill the pores which were previously filled with water. This would mean that the hydration of calcium silicates is also a process which at least partly runs via the solution. The conclusion for the practice of cement application results from the fact that during the initial hardening even a short drying out of the concrete should be avoided as with rewetting under normal pressure the water cannot penetrate all pores afterwards. As a result these pores can no longer be filled with hydration products.

##### 5. Effect of admixtures

Even small additions of inorganic or organic compounds can greatly change the course of the hydration reaction. Studies by W. Richartz with a large number of different substances have shown that 3 groups can be distinguished according to the effect on the initial reaction and the length of the dormant period. This is illustrated in figure 9.

In the first group are substances which shorten the dormant period of the tricalcium silicate. They promote the reaction of the tricalcium aluminate during the initial reaction, but do not influence the initial reaction of the tricalcium silicate and the dormant period of the tricalcium aluminate. According to studies made so far, only chlo-

rides, formates and thiocyanides have this effect.

Figure 9: Effect of admixtures on hydration of tricalcium aluminate and tricalcium silicate in Portland cement

As a result of the increased reaction of tricalcium aluminate at the start of hydration more ettringite is formed as long as the sulfate supply in the solution is sufficient; otherwise more monosulfate or other aluminate compounds are formed. As a result of the shortened dormant period of the tricalcium silicate hardening also starts more quickly.

The substances in the second group do not affect the reaction of tricalcium aluminate and tricalcium silicate during the initial reaction but increase the dormant period of both compounds. In this group are, for example, phosphates, tartrates and citrates soluble in water. The result of the longer dormant period of the tricalcium silicate is that hardening starts much later. As the reaction of tricalcium aluminate does not change before the start of the dormant period the amount of ettringite formed during the initial reaction remains the same. Setting is retarded all the same, however. Studies carried out with the scanning electron microscope have shown that the admixtures of this group greatly change the crystallization behaviour of the ettringite. Instead of needle-shaped, very thin crystals, the ettringite forms in the shape of short columns with larger diameters which grow very little also during the dormant period. It can be assumed that the change in the ettringite crystallization causes the retarding effect in the setting.

The substances in the third group increase

the amount of tricalcium aluminate which reacts at the beginning of hydration but do not change the dormant period of the tricalcium aluminate, do, however, increase the dormant period of the tricalcium silicate. In this group are, for example, sugar, triethanolamine and zinc oxide.

With normal composition of the cement clinker, the increased amount of tricalcium aluminate reaction during the initial reaction results in quick setting, which is generally caused by the formation of monosulfate besides ettringite. Due to the increased dormant period of the tricalcium silicate, strength also develops much later.

The effect of all additions depends to a great extent on the amount added. The typical effect of each addition can only be seen when certain minimum concentrations are exceeded. This is particularly important, for example, for triethanolamine which only inhibits hardening if its concentration, related to cement, is more than 0.1 %. With concentrations of 0.02 to 0.05 %, when used as a grinding aid, changes in the setting and hardening are not yet to be expected.

The type of effect is also to a great degree dependent on temperature. The initial reaction of tricalcium aluminate is not changed, for example, by citric acid at a temperature of 20 °C but is greatly increased at 35 °C.

The effect of additions is also greatly influenced by the solution behaviour of the calcium sulfate. Citric acid and citrates retard, for example, to a large degree the dissolution and rehydration of the hemihydrate. As a result the supply of sulfate during the initial reaction decreases. This can either be an advantage or disadvantage depending on the reactivity of the tricalcium aluminate in the cement.

The effects of the additions described so far were chemical processes. The additions change the amount of the substances involved in the chemical reactions and as a result influence the type and amount of the reaction products and their crystallization behaviour. It is, however, possible that surface effects are also involved which promote the dispersion of the cement particles in the mixing water solution. In the case of plasticizers, particularly of super-plasticizers, we assume these effects to prevail or to be the sole effect.

Discussion on the Principal Paper  
of SKALNY and YOUNG

by Prof. H.N. STEIN  
Laboratory for Colloid Science  
Vakgroep Elektrochemie  
University of Technology  
EINDHOVEN, THE NETHERLANDS

C<sub>3</sub>A HYDRATION : FACTS UNEXPLAINED BY THE SKALNY  
MECHANISM :

C<sub>3</sub>A hydration is a complicated process, as well appears from the mechanism proposed by Dr SKALNY and Dr YOUNG, and I feel somewhat guilty in having to drawn the attention of the audience to some facts which cannot easily be understood on the basis of this mechanism, indicating that the truth must be more complicated still.

1. - Addition of Ca(OH)<sub>2</sub> crystals to a C<sub>3</sub>A + water paste does not accelerate the hydration of C<sub>3</sub>S, as should be expected on the basis of SKALNY's mechanism, but rather retards it (1). This is explained by SKALNY and YOUNG through poisoning of the Ca(OH)<sub>2</sub> crystals in their function as nuclei, silicate ions being regarded as a poison in this respect (2). It remains unexplained, however, why this poisoning is more pronounced in the presence of added Ca(OH)<sub>2</sub> than in its absence; Ca(OH)<sub>2</sub> cannot be expected to increase the silicate ion concentration.

2. - Congruent dissolution of C<sub>3</sub>S is found, when precautions are taken against precipitation of calcium silicate hydrates from the solution. The most thorough investigation in this respect is by KOHLSCHUTTER (3), who achieved freedom from precipitation of C-S-H by working either in very dilute suspensions, or by leading a stream of water through a thin C<sub>3</sub>S bed.

It might be argued that these data are not indicative on C<sub>3</sub>A hydration in pastes, because of the different water/C<sub>3</sub>A ratio. However, it should be noted that congruent dissolution of C<sub>3</sub>S is also found in dilute suspensions in which an important parameter, viz. the pH, has been adjusted such as to resemble paste conditions in early hydration stages (e.g., pH = 11.75 or 12) (4). This is not accounted for by the SKALNY mechanism, where, without any interaction with other C<sub>3</sub>S particles, preferential leaching of Ca<sup>2+</sup> and OH<sup>-</sup> ions into the solution is postulated from the start of the hydration onwards.

Both phenomena are consistent, however, with the formation of a first, strongly retarding hydrate, and its conversion into a second, less retarding one; the conversion being stimulated by low initial [Ca<sup>2+</sup>] and [OH<sup>-</sup>]. It should be noted that this hypothesis also provides for a natural explanation of the accelerating effect of amorphous silica on C<sub>3</sub>S hydration (5).

It is not necessary that the first hydrate has a composition C<sub>3</sub>SH<sub>n</sub>, although it would be natural to expect that it has a higher C/S ratio than the second, less retarding hydrate. Neither it is surprising that the first hydrate cannot be seen by electron microscopy (5), since it may originate through penetration of water into the C<sub>3</sub>S.

## INTERVENTION

DU Professeur O.P. MITCHELOV-PETROSSIAN

Je voudrais exprimer ma satisfaction à propos de ce qu'un des fondateurs de la cristallogénie moderne du ciment, le Professeur Taylor, qui enfin, après une discussion de 20 années, a suggéré l'idée que les processus de base relatifs au durcissement de la pierre de ciment sont déterminés, dans les conditions normales par les phénomènes évoluant au stade colloïdale et formant la porosité. La cristallogénie joue ici un rôle secondaire.

En ce qui concerne la discussion des participants de la table ronde au sujet de la nature des forces conditionnant la prise, il convient de dire qu'il n'y a qu'à considérer la caractéristique énergétique (thermodynamique et thermochimique) du processus de prise de ciment portland pour comprendre clairement que tous les processus déterminant la prise se déroulent pendant la période de l'hydratation active des aluminates.

Les études effectuées par le Professeur Roy et le Professeur Sérédà ont montré que les phases de silicate sont également soumises à la prise sous l'influence de température et de pression. Cependant, ce fait n'a aucun rapport avec la prise des ciments portland habituels.

I would like to express satisfaction that Prof. Taylor, one of the founders of modern cement crystal chemistry, at last after our 20-year discussion has said that the main processes of cement stone hardening under normal conditions are determined by the phenomena taking place during colloid phase and forming porosity. Crystal chemistry acts here a secondary part. As to the argument between the participants of the discussion on the nature of the forces motivating hardening, it might be well to point out that one should only look upon energetic (thermodynamic and thermochemical) characteristic of portland cement hardening process to clear up that all the processes determining hardening proceed in the period of aluminates active hydration.

Prof. Roy and Prof. Serada have showed that silicate phases also harden on exposure to temperature and pressure, but this has no relation to the hardening of ordinary portland cements.

## CONCLUSIONS DE LA TABLE RONDE

par le professeur I. BARRET

Ce thème était divisé en deux sous-thèmes et 8 questions essentielles appartenant à ces sous-thèmes ont été abordées :

### Sous-thème 2.1 : Mécanismes d'hydratation

#### Sujet n° 1 :

Un résumé des résultats du Séminaire sur l'aluminate tricalcique est fait par Mme REGOURD d'où il ressort en premier lieu, en ce qui concerne les phénomènes aux interfaces  $C_3A$ /eau et  $C_3A$ /solution de chaux, qu'à la suite de la communication de P. BARRET et D. BERTRANDIE, la dissolution congruente de  $C_3A$  peut être admise, ce qui, d'après H.N. STEIN n'est pas incompatible avec les valeurs positives du potentiel  $\zeta$  qu'il a observées sur les hydrates hexagonaux et cubiques se formant durant l'hydratation de  $C_3A$  et qui correspondent à une extraction préférentielle des ions aluminates favorisée par l'adjonction de NaOH. La plupart des contributions soulignent l'idée que dans la phase liquide, les concentrations locales tout près de  $C_3A$  diffèrent des concentrations loin de  $C_3A$  et que ces concentrations locales jouent un grand rôle dans la formation des hydrates et sur la vitesse d'hydratation de  $C_3A$ .

L'influence de  $Na_2O$  sur la vitesse d'hydratation de  $C_3A$  reste controversée. En fait, deux questions se posent :

- 1°)  $Na_2O$  retarde-t-il ou accélère-t-il l'hydratation de  $C_3A$  ?
- 2°)  $Na_2O$  en solution solide avec  $C_3A$  agit-il de la même façon qu'une quantité équivalente de NaOH ajoutée séparément ? La plupart des publications concluaient à un retard par  $Na_2O$  certaines, comme celles de BUTT, à une accélération.

Les communications au Congrès ne mettent pas fin à ce désaccord puisqu'elles se partagent en nombre à peu près égal entre les deux thèses. Les opinions sont divisées également en ce qui concerne la réponse à donner à la seconde question et de nouvelles expériences devront être imaginées.

Les avis sont également partagés pour attribuer le rôle retardateur à l'hydratation de  $C_3A$  en présence de gypse, soit à la couche d'ettringite elle-même (communications de GHORALE, HEINZ, LUDWIG, MESKENDAHL et WOLTER), soit à une couche de  $C_4AH_{13}$  (CHATTERJI) s'interposant entre la couche d'ettringite et  $C_3A$ .

Dans les discussions ont été évoquées les différentes possibilités de formation de l'ettringite, plus ou moins amorphe autour des grains de  $C_3A$  et cristallisée à plus grande distance, les interactions entre  $C_3A$  et  $C_3S$  pour donner des silicoaluminates.

D'après ODLER, l'adsorption de sulfate sur C-S-H empêcherait l'ettringite de se former. B. COTTIN souligne le rôle retardateur de  $C_3A$  au cours de l'hydratation de  $C_3S$  dans le développement des résistances.

#### Sujet n° 2 :

Après le rapport général exposé par F.W. LOCHER, la discussion porte sur le processus d'hydratation du ciment Portland dans la période initiale et particulièrement sur le point de savoir si la prise est la conséquence, comme le pense F.W. LOCHER, de la présence dans le ciment Portland, d'aluminate tricalcique et de gypse, et s'explique par la constitution d'une structure rigide à base de gros cristaux. Un défaut de gypse entraînerait la prise rapide par formation de gros cristaux tabulaires d'aluminates de calcium hydratés peu de temps après le mélange avec l'eau. Une proportion convenable de gypse, se combinant exactement sous forme de fines particules d'ettringite avec l'aluminate tricalcique dissous durant les premières minutes donnerait la prise retardée, s'expliquant par la recristallisation en gros cristaux, pendant la période dormante des particules d'ettringite initiales incapables, en raison de leur finesse, de donner une structure rigide.

L'attribution de la prise uniquement à la présence d'aluminate tricalcique et de gypse est controversée notamment par F. YOUNG, qui pense que  $C_3S$  contrôle la prise plus que  $C_3A$ , mais que celui-ci est impliqué dans la fausse prise. B. COTTIN demande comment alors expliquer, si la prise est due à la recristallisation de l'ettringite, le mécanisme de la prise de  $C_3S$  pur et parfois des clinkers non gypsés, ainsi que celle des ciments fortement surgypsés dans laquelle l'hydratation de  $C_3A$  peut être bloquée pendant des semaines.

D'autres questions vont dans le même sens. La formation des hydro-silicates dès la période initiale et pendant la période dormante doit donc être impliquée dans la prise, mais il est certain qu'il doit être tenu

compte non seulement de la chimie des hydrates, mais aussi de la structure.

#### Sujet n° 3 :

La discussion engagée sur la "période dormante" révèle l'existence de deux conceptions différentes. La première, qui est celle de F.W. LOCHER et qui est partagée par TAYLOR et par de nombreux auteurs tels que DE JONC, STEIN, STEVELS, ODLER et DORR, TADROS et col., DOUBLE, BIRCHALL, JENNINGS et PRATT, DENT-GLASSER et beaucoup d'autres, admet un véritable arrêt de la réaction. Cet arrêt est attribué à la constitution, dans la période initiale, de barrières de diverses natures laissant seulement diffuser les ions  $\text{Ca}^{2+}_{\text{aq}}$  et  $\text{OH}^{-}_{\text{aq}}$  mais non les ions silicates :

couche protectrice d'hydrate primaire, membrane semi-perméable développant une pression osmotique, couche semi-fluides d'ions silicates riches en protons et de molécules d'eau. Dans cette conception, la nucléation de C-H et de C-S-H n'intervient pas pendant la "période dormante"; c'est pourquoi cette période est aussi appelée "période d'induction"; la nucléation de C-H et de C-S-H n'a lieu qu'au début de la période suivante dite de post-induction ou d'accélération.

La seconde conception soutenue par P. BARRET à partir des expériences faites par ses collaborateurs en coopération avec la Société LAFARGE, et partagée notamment par C. VERNET et col. suppose un processus continu depuis l'instant initial du mélange, les diverses périodes ci-dessus décrites n'étant que le résultat d'une autorégulation du système fermé, sous l'influence des facteurs cinétiques dont les valeurs locales dépendant de sa propre évolution.

Ce processus se décompose en une étape interfaciale liquide-solide d'hydroxylation par protonation des ions  $\text{O}^{2-}$  et  $\text{SiO}_4^{4-}$  qui deviennent des sites superficiels à mesure qu'ils sont découverts par ceux qui, déjà hydroxylés, passent en solution. Cette étape mobilise pratiquement toute l'eau qui entre dans la composition des hydrates C-H et C-S-H. Les concentrations ioniques locales résultent de l'apport congruent des ions  $\text{Ca}^{2+}$ ,  $\text{OH}^{-}$  et silicates en régime établi, de leur diffusion et de leur consommation par précipitation au-delà d'une certaine sursaturation. La sursaturation la plus élevée est atteinte au voisinage immédiat de l'interface  $\text{C}_3\text{S}$ -solution qui est un lieu privilégié de nucléation, toujours accessible aux molécules d'eau auxquelles le dépôt de C-S-H n'oppose pas une barrière étanche. La composition et l'état de condensation de la silice dans ces C-S-H dépend à une température donnée de la concentration de la chaux et de la silice dans la phase liquide, indépendamment du rôle éventuel d'impuretés.

Dans cette conception, la "période dormante" n'est une période d'induction que pour l'hy-

droxyde de calcium puisque le C-S-H se forme depuis la période initiale. La quantité de C-S-H ayant précipité à l'instant  $t$  est étroitement corrélée à la quantité de chaux accumulée dans la phase liquide car  $(3 - \alpha)$  moles de chaux passent en solution lorsque  $\alpha$  moles de C-S-H de rapport molaire C/S =  $\alpha$  ( $\alpha < 3$ ) précipitent.

#### Sujet n° 4 :

F.W. LOCHER amène précisément la discussion sur les causes de la période d'induction : recouvrement protecteur, membrane semi-perméable, zone frontière semi-fluide et sur les facteurs qui contrôlent la nucléation à la fin de la période d'induction.

L'effet ralentisseur d'une concentration élevée dans la phase liquide indépendamment de toute barrière est illustré par P. BARRET en présentant des courbes de taux d'hydratation en fonction du temps établies comparativement à l'aide d'une suspension de  $\text{C}_3\text{S}$  agité soit dans l'eau, soit dans une solution de chaux sursaturée ( $35.10^{-3}$  mole.kg $^{-1}$ ) dans le même rapport  $\ell/s = 10$ .

Alors que le taux d'hydratation croît régulièrement dans le premier cas depuis l'instant initial, il demeure presque nul dans le second cas pendant la même durée (4 heures). Le décalage dans les deux taux d'hydratation se conserve par la suite. Mme DELLA ROY et J. SKALNY objectent que la situation est différente dans une pâte où le rapport  $\ell/s \leq 1$  et dans une suspension de rapport  $\ell/s = 10$ .

Ainsi pour différents rapports  $\ell/s$ , on obtiendrait différents types de C-S-H. Dans un milieu dilué, il ne se formerait pas de C-S-H de type I comme avec  $\text{C}_3\text{S}$  en pâte, mais du C-S-H du type II (en nid d'abeilles).

Bien qu'en outre, dans une pâte, le milieu soit stagnant, il est remarquable que la durée de la "période d'induction" ne varie que de 4 à 6 heures et que la concentration maximale atteinte par la chaux ( $\approx 36.10^{-3}$  mole.kg $^{-1}$ ) reste la même lorsque le rapport  $\ell/s$  passe de 0,5 à 10.

Cela paraît indiquer que les facteurs cinétiques jouant un rôle essentiel dépendent peu des masses des phases en présence et l'on pense tout naturellement que de tels facteurs sont les concentrations ioniques en solution, étant entendu que la réalisation des concentrations locales des diverses espèces dépend du rapport  $\ell/s$  et du fait que le milieu est agité ou stagnant.

#### Sujet n° 5 :

La dissolution de  $\text{C}_3\text{S}$  est elle toujours incongruente ?

C'est la question posée à F. YOUNG par Mme REGOURD. Les partisans de l'incongruence de la dissolution de  $\text{C}_3\text{S}$  prennent comme argu-

ments les mesures de potentiel  $\zeta$  qui dans les suspensions est trouvé  $> 0$ , ce qui est interprété comme un indice du passage préférentiel des ions  $\text{Ca}^{2+}$  en solution et de leur adsorption à la périphérie des grains. Le passage sélectif des ions  $\text{Ca}^{2+}$  et  $\text{OH}^-$  dans la phase liquide est souvent considéré comme l'effet de la présence à la périphérie des grains d'une couche protectrice à propriétés semi-perméables, comme on l'a vu plus haut dans le cas des pâtes. Mais F. YOUNG estime que dans les conditions utilisées par P. BARRET et col., de flux rapide de solvant à travers une couche de  $\text{C}_3\text{S}$ , la dissolution est probablement congruente.

#### Sujet n° 6 :

La discussion vient sur l'effet des sulfates alcalins sur  $\text{C}_3\text{S}$ . J. SKALNY souligne leur effet accélérateur sur l'hydratation de  $\text{C}_3\text{S}$ , dû probablement à leur influence sur la solubilité de  $\text{Ca}(\text{OH})_2$ . D'après Mme REGOURD, les sulfates alcalins augmentent la réactivité des aluminates plutôt en agissant sur la réaction entre sulfate de calcium et  $\text{C}_3\text{A}$  qu'en augmentant la réactivité propre de  $\text{C}_3\text{A}$ . Pour F.W. LOCHER, la présence de sulfates alcalins dans le clinker entraîne la formation d'une solution d'hydroxydes alcalins à pH élevé susceptible de provoquer une modification des premiers hydrates et donc de la résistance finale. J. SKALNY exprime son accord sur le fait que la résistance finale dépend des premiers hydrates produits.

Les questions posées par les intervenants ont été généralement des invitations à préciser certains points restés obscurs ou sans réponses dans les problèmes discutés. Par exemple, il est demandé par M. BAILEY si le panel est d'accord sur le fait que la microscopie électronique montre la formation de C-S-H durant la "période dormante" lorsque la concentration en ions silicates dans la solution est faible; M. BENSTED demande si ce n'est pas une simplification de discuter de la sursaturation des ions  $\text{Ca}^{2+}$  et  $\text{OH}^-$  pendant la période dormante et de ne pas parler des autres cations et anions sûrement impliqués. Pour M. STEIN, le mécanisme d'hydratation de  $\text{C}_3\text{S}$  présenté par J. SKALNY et F. YOUNG se heurte à deux objections : la dissolution congruente initiale de  $\text{C}_3\text{S}$  quand la précipitation à partir de la solution n'intervient pas et le rôle retardateur, plutôt qu'accélérateur de  $\text{Ca}(\text{OH})_2$ .

D'autres questions tendent à faire préciser certains détails des mécanismes proposés par F.W. LOCHER sur l'influence de proportions relatives plus ou moins importantes de  $\text{C}_3\text{A}$  et de gypse. Par exemple, M. WALL demande si une plus grande différence dans le temps de prise entre le ciment Portland ordinaire et les "sulphate resisting cements" ne devrait pas être attendue, tandis que M. HELMUTH s'interroge sur la cause du retard à l'hydratation de  $\text{C}_3\text{A}$  puisqu'il s'observe avec ou sans la présence de gypse ?

Le Professeur FIERENS fait remarquer que l'influence des défauts dans les solides n'a pas été assez rappelée dans les discussions et cite à ce propos les observations par S.E.M. rapportées dans la publication de D. MENETRIER, D.K. Mc NAMARA, I. JAWED et J. SKALNY sur les premières secondes de contact entre  $\beta\text{-C}_2\text{S}$  et l'eau, valables également pour  $\text{C}_3\text{S}$  et mettant en évidence une dissolution préférentielle aux joints de grains ainsi qu'une distribution non uniforme des produits d'hydratation à la périphérie des grains.

#### Sous-thème 2.2. : Structure et composition des hydrates.

#### Sujet n° 1 :

La discussion s'engage sur le problème des structures et des degrés de cristallinité. D'après F.H.W. TAYLOR, le degré de cristallinité du C-S-H est très faible. Alors que l'idée majeure de F.D. TAMAS est que la résistance des ciments est liée au degré de condensation des ions silicates dans le C-S-H, TAYLOR, qui est d'accord sur le fait que les ions silicates subissent une polymérisation au cours du temps, ne voit aucun lien entre la résistance des ciments et le degré de polymérisation. Pour lui, l'organisation des C-S-H repose sur celle de la chaux plus que sur celle de la silice. Ce serait les feuillettes Ca-O qui commanderaient la morphologie. La question actuellement sans réponse certaine est celle de savoir si la polymérisation donne des chaînes de silicates. D'après BERNAL, c'est l'enchevêtrement des matériaux qui confère la résistance.

F.H.W. TAYLOR est d'accord avec F.W. LOCHER sur le point que la structure des C-S-H initiaux influe sur la forme finale des hydrates produits et pense que les hydrates qui se forment tard dans l'évolution sont de type morphologique III dans la nomenclature de DIAMOND (grains formés de particules à peu près équidimensionnelles dans toutes les directions).

#### Sujet n° 2 :

Mme M. REGOURD revient sur les conclusions du Séminaire sur  $\text{C}_3\text{A}$  pour souligner l'influence des adjuvants sur l'hydratation de  $\text{C}_3\text{A}$  et notamment le retard provoqué sur celle-ci par le lignosulfonate de calcium. Il apparaît clairement, à la suite de la communication de V.S. RAMACHANDRAN que ce retard est dû à l'adsorption sur  $\text{C}_3\text{A}$  du lignosulfonate qui s'adsorbe également sur les aluminates hydratés hexagonaux. Cependant, pour F. MASSAZZA qui a étudié l'hydratation de mélanges de  $\text{C}_3\text{A}$  et de gypse en présence de lignosulfonate de sodium et de condensat de naphthalène sulfoné et de formaldéhyde dans le but d'éclaircir les causes de l'action fluidisante exercée par ces substances sur les pâtes de ciment,  $\text{C}_3\text{A}$  non encore hydraté n'adsorbe pas ces adjuvants. Ce sont les sulfoaluminates hydratés qui absorbent des quantités considé-

rables de ces adjuvants et cela cause des modifications morphologiques dans les cristaux d'ettringite qui apparaissent sous forme de petites aiguilles au lieu de gros cristaux fibreux. Cette morphologie différente pourrait expliquer, au moins partiellement, l'action exercée par ces superfluidifiants sur la rhéologie des pâtes de ciment. En outre, ce feutre microcristallin sur les grains de  $C_3A$  empêcherait son hydratation.

D'autre part, le changement de signe du potentiel  $\zeta$  qui passe de + à - en présence de lignosulfonate et de carbonate de sodium ou d'un adjuvant à base de polymère de naphthalène sulfoné, pourrait, d'après les expériences de M. COLLEPARDI contribuer à la fluidisation.

D'autres modes d'action sont évoqués, notamment la formation de complexes en solution, par certains des intervenants.

En conclusion générale, il apparaît que de nombreux progrès ont été accomplis grâce à la mise en oeuvre de méthodes expérimentales nouvelles : ESCA, AUGER, S.E.M. et T.E.M.S.C.A.N., triméthylsilylation, chromatographie en couche mince, spectrométrie de masse et grâce à une meilleure utilisation des moyens analytiques plus traditionnels. Cependant, il faudra encore du temps pour que les nouvelles données soient prises en compte dans les interprétations et leur permettent de triompher des nombreuses idées préconçues, qui retardent le progrès dans les connaissances et leurs possibilités d'application à la technologie du ciment.

## CONCLUDING REMARKS

by F. W. LOCHER

The panel discussion and general discussion dealt with the subjects of

1. Initial reactions,
2. Hydration of calcium silicates and
3. Influence of admixtures.

The summary below contains the main conclusions which can be drawn from the contributions to the congress and the discussion.

### 1. INITIAL REACTIONS

In the first minutes after mixing, the share of tricalcium silicate, dicalcium silicate, tricalcium aluminate and calcium aluminate ferrite decreases slightly by 1 % due to reaction with water. This is followed by the induction period which lasts for several hours during which the share of the 4 clinker compounds is not further reduced or is only reduced very slightly. After the induction period, which can vary in length for the 4 clinker compounds, the hydration reactions occur in which compounds essential for hardening form, in particular calcium silicate hydrates.

Basically two reaction mechanisms are considered the cause of the induction period:

- 1) Blocking of the surface mechanisms of the cement constituents and
- 2) Hindrance of the crystallization of the hydration products.

A blocking of the surface may be caused by various ions or molecules accumulating from the pore solution, by the development of a less permeable cover of metastable hydration products or by the dissolving of certain elements, e.g.  $\text{Ca}^{2+}$ , resulting in a less reactive surface layer richer in  $\text{SiO}_2$ .

A hindrance of crystallization may occur: if at first a certain oversaturation in calcium hydroxide has to be attained so that the nucleus of crystallization with a critical size, necessary for the rapid formation of the hydration products, can form.

The cause of setting appears to be the formation of a more or less rigid network of hydration products which develop during the first reaction before the induction period. The agglomeration of the cement particles and of the first hydration products as a result

of surface forces probably also play a major role here.

Hydration products which are involved in the formation of the first network are primarily calcium aluminate hydrates and/or calcium aluminate sulphate hydrates. Calcium silicate hydrates may also be involved in Portland cement; in pastes of pure tricalcium silicate they are the only cause of setting.

A large number of studies have shown that the setting of Portland cement depends to a large degree on the reaction between tricalcium aluminate and sulphate. The share of tricalcium aluminate which dissolves directly after the cement is mixed until the beginning of the induction period, reacts with the sulphate from the alkali sulphate of the clinker and from the calcium sulphate which is contained in the cement in the form of admixed gypsum, hemihydrate, soluble anhydrite and/or natural anhydrite. Depending on the share of quantities in the solution, ettringite, monosulphate, calcium aluminate hydrate and/or gypsum then forms. The greatest possible retardation always occurs when the share of tricalcium aluminate dissolved before the beginning of the induction period is bound solely as ettringite.

It is generally assumed that the retardation of the setting by the admixture of calcium sulphate is due to a corresponding retardation of the chemical reaction. This is in contrast, however, to the finding that the calcium sulphate admixture does not retard the hydration of the tricalcium aluminate and tricalcium silicate in the period important for setting. This would mean that it is not primarily the quantity of newly-formed hydration products which are important for setting but their tendency to form a rigid structure as a result of recrystallization. Here the agglomeration of the cement particles as a result of surface forces could play a decisive role. The calcium sulphate admixed as a set retarder, would thus prevent the share of tricalcium aluminate dissolved at the beginning of hydration and maybe also the share of calcium aluminate ferrite, crystallizing as coarse-grained, structure-forming calcium aluminate hydrate but it would settle as a thin cover of fine-grained ettringite on the surface of the cement particles. The cause of setting would then be the slow formation of a structure of recrystallized ettringite. On the other hand, it is also possible that the calcium silicate hydrate is involved in the formation of the first structure which is very important for setting. At the time, however, at which setting normally begins, the quantity is much lower than that of the other hydration products. It is thus improbable that in the case of Portland cement the formation of calcium silicate hydrate controls the setting.

## 2. HYDRATION OF THE CALCIUM SILICATES

In the hydration of the calcium silicates, calcium silicate hydrate occurs as a reaction product to which the hardened cement paste owes its strength in particular. Despite extensive research it is not yet possible to give a generally accepted description of the formation of the calcium silicate hydrate, its chemical composition and its structure.

During the initial reaction before the induction period a small share of the calcium silicates are dissolved either congruently if calcium and silicate ions go into solution in the same quantities in which they are originally contained in the silicates or incongruently if more calcium ions are dissolved.

The calcium silicate hydrate which occurs as a reaction product does not have a uniform composition; the ratio of  $\text{CaO}/\text{SiO}_2$  varies in the range of between approx. 1.5 and 3.0. It may contain larger quantities of foreign substances, in particular aluminium, iron, alkalies and sulphate.

During hydration the silicic acid polymerizes. The degree of polymerization appears to be greater the slower the calcium silicates hydrate.

The arrangement of the calcium and silicate ions in the calcium silicate hydrate is closer to the amorphous state than to the regular arrangement in a crystal lattice. There does not appear to be any connexion between the degree of crystallinity and the mechanical properties of hardened cement paste.

## 3. INFLUENCE OF ADMIXTURES

Admixtures of foreign substances soluble in water can retard or accelerate the hydration of the cement compounds, can influence the change of hydration products already formed or can alter the zeta-potential, i.e. the surface charge of the solid particles and their agglomeration behaviour. Chlorides, nitrates and nitrites accelerate hardening because they increase the initial reaction of the tricalcium silicate and tricalcium aluminate and reduce the induction period of both constituents. Compounds of heavy metals soluble in water, e.g. zinc, lead and copper, increase the induction period of the tricalcium silicate and thus retard hardening. As, on the other hand, they increase the initial reaction of the tricalcium aluminate, they increase the amount of ettringite formed at the beginning. The result may be a rapid start of setting and a higher heat of hydration. Glucose and lignosulphonate can have a similar effect.

The effect of all admixtures depends largely on the amount added. It also depends on whether and to what degree the admixtures influence the solution behaviour of the calcium sulphate and  $\text{Ca}^{2+}$  ion concentration of the solution.

Surface-active admixtures reduce, in particular, the viscosity of the cement paste but do not greatly change the setting and hardening. Without admixtures, agglomerates form in the cement paste shortly after mixing as the solid particles attract each other under the effect of surface forces. As a result the viscosity of the cement paste increases. This process is increased by sulphate ions in the mixing water solution. Surface-active substances, e.g. melamine compounds, reduce the viscosity greatly as they change the surface charge of the particles and thus reduce the tendency to agglomerate.

## THEME III

### Structure des laitiers et hydratation des ciments de laitier

par M. VON EUW

Messieurs les Présidents,  
Mesdames,  
Messieurs,

#### 1. PREAMBULE.

Mes éminents collègues du Comité Scientifique ont eu l'extrême indulgence de me confier la Présidence du Thème consacré aux laitiers et ciments de laitier. Je les en remercie et je souhaite ne pas les décevoir par ce trop bref exposé.

Les travaux présentés à ce 7ème Congrès International de la Chimie des Ciments ont soumis à 3 directives émises par le Comité Scientifique :

- présenter essentiellement un caractère scientifique et non pas technologique.
- concerner des produits élaborés industriellement, sans toutefois exclure des préparations en laboratoire.
- orienter les recherches dans des directions favorables aux économies d'énergie.

30 communications, 3 rapports principaux et 8 posters présentés par 13 pays rendent compte des résultats obtenus depuis le Congrès de Moscou dans les études visant à relier les phénomènes d'hydraulicité à la structure des laitiers. Le fait que les travaux exposés concernent des laitiers ou scories industriels aboutit à une diversité d'informations que j'ai essayé de mettre à profit pour établir le lien indispensable entre composition-structure et réactivité. En permettant de mieux comprendre les phénomènes en jeu, tant dans l'élaboration que dans l'utilisation de ces sous-produits industriels, une contribution importante est apportée à l'objectif général des économies d'énergie.

Cette préoccupation de valoriser des sous-produits d'origines diverses en les faisant entrer dans la production des liants, soit dans la Cimenterie, soit en dehors de cette Industrie, conduit à distinguer, d'une part, l'origine des produits, d'autre part, leurs modes d'activation.

Afin d'établir une certaine cohérence entre les communications, je traiterai d'abord des laitiers de haut-fourneau et des ciments correspondants. Les problèmes posés par les laitiers d'aciérie et les scories de métaux non ferreux seront discutés ensuite.

#### 2. LAITIERS DE HAUT FOURNEAU.

##### 2.1. CARACTERISATION.

Les méthodes utilisées se rapportent à l'analyse chimique, à la structure et à l'hydratation.

##### 2.1.1. Méthodes chimiques.

Parmi les diverses méthodes retenues pour caractériser les laitiers, l'analyse chimique est certainement la plus courante. Il existe deux possibilités d'utiliser les résultats de l'analyse élémentaire, soit le calcul d'indices ou modules, soit le calcul de la composition minéralogique potentielle.

Les auteurs qui utilisent les indices chimiques relient la réactivité des laitiers à leur basicité. Les nombreuses formules adoptées expriment le rapport pondéral ou molaire des éléments basiques aux éléments acides; certaines tiennent compte du rôle amphotère de l'alumine.

SMOLCZYK dans son rapport principal, après avoir fait une étude critique de ces indices établit une régression multiple entre les teneurs des constituants et les résistances. Il précise cependant que les coefficients dépendent beaucoup du clinker utilisé.

La critique que nous pouvons faire à l'emploi des indices est que ceux-ci définissent des limites, mais ne permettent pas d'établir une relation réelle. Ceci d'autant plus qu'elles ne prennent en compte qu'une partie de la composition. C'est pourquoi les calculs de corrélation multiple appliqués aux laitiers par SMOLCZYK donnent de meilleurs résultats.

.../...

DEMOULIAN ajoute aux propositions de SMOLCZYK la prise en compte d'autres éléments de l'analyse tels que Cl, Ti, F, S, ainsi que la somme des minéraux dosée par microscopie optique.

Les corrélations multiples de SMOLCZYK et celles de DEMOULIAN montrent que l'appréciation de l'hydraulicité par les nombreux modules chimiques habituels ne concernant que les éléments majeurs sont insuffisants. Ceux qui placent l'alumine au dénominateur comme formateur de réseau donnent de moins bons résultats que ceux qui l'introduisent au numérateur comme modificateur de réseau; c'est probablement la raison qui a fait choisir le rapport  $\frac{\text{Al}_2\text{O}_3}{\text{SiO}_2}$  pour sélectionner les laitiers hydrauliques en URSS, ainsi que l'avait relaté SATARINE au Congrès de Moscou,

Le rôle de MnO a été traité en tant qu'élément mineur respectivement par SMOLCZYK et DEMOULIAN, mais certains laitiers en renferment des proportions importantes, ainsi que le signale TANEJA. Cet auteur a étudié des laitiers indiens renfermant 3 à 7 % de MnO, et il a vérifié que les ciments métallurgiques correspondants font preuve d'une bonne hydraulicité. Un tel résultat pourrait paraître infirmer la règle classique selon laquelle MnO a une influence négative sur la valeur hydraulique des laitiers. En fait SOLACOLU avait montré dans une étude publiée en 1964 que le rôle de MnO pouvait être soit négatif, soit neutre, soit positif selon la basicité du laitier. A l'examen il apparaît que le laitier de ROURKELA, qui a été étudié par TANEJA, se place dans la catégorie peu basique définie par SOLACOLU. Ceci explique que malgré son taux élevé de MnO, les résistances du ciment soient conformes aux normes indiennes.

Une autre façon d'utiliser l'analyse élémentaire est le calcul de la composition minéralogique potentielle proposée par GOURDIN et introduite par DEMOULIAN dans ses corrélations multiples.

Les minéraux qui cristallisent lors de la dévitrification complète des laitiers dans le système  $\text{SiO}_2$ ,  $\text{Al}_2\text{O}_3$ , CaO, MgO ont une structure à base de chaînes  $\text{SiO}_3^{2-}$ , ou de doubles tétraèdres  $\text{Si}_2\text{O}_7^{6-}$ , ou encore de tétraèdres simples  $\text{SiO}_4^{4-}$ . Les auteurs ont observé une relation entre les bonnes résistances développées par certains laitiers et les structures à base de tétraèdres simples dans les minéraux de la composition potentielle.

## 2.1.2. Méthodes basées sur la structure.

Si la composition chimique joue un rôle essentiel dans la valeur hydraulique des laitiers, leur structure est non moins prépondérante. On sait depuis longtemps que l'état vitreux est indispensable, mais des précisions viennent d'être apportées quant aux méthodes basées sur la structure.

FIERENS par la mesure de l'exoémission électronique a pu apprécier les défauts de surface agissant comme centres de formation des germes de sels hydratés. L'auteur a mis les taux d'exoémission en corrélation avec les résistances en compression de microéprouvettes de laitier gâchées à la soude.

HAWTHORN a relié les résistances ISO de ciments à haute teneur en laitier aux dimensions des hétérogénéités du verre mesurées par diffusion centrale des rayons X.

SMOLCZYK examine la répartition des minéraux par microscopie optique; il en déduit que les germes cristallins bien dispersés dans la masse vitreuse, ont une influence favorable à l'hydraulicité.

Mme REGOURD a recristallisé par chauffage à 850° 7 laitiers de compositions différentes. Elle a constaté que la réactivité est fonction du taux de gehlénite dans la mélikite. Il s'agit là d'une méthode rapide d'appréciation de l'hydraulicité qu'il est d'ailleurs possible de recouper par le calcul en utilisant l'analyse chimique.

DRON montre que les taux de dissolution en milieu sodique de la silice, de l'alumine et de la chaux, sont en relation directe avec la basicité et la teneur en alumine du laitier; ceci est en accord avec les résultats d'HAWTHORN opérant sur les mêmes laitiers, et se trouve d'ailleurs illustré par ceux des essais mécaniques ISO.

## 2.1.3. Méthodes basées sur l'hydratation du laitier.

A priori, il semble logique de vouloir relier le taux d'hydratation aux résistances mécaniques mesurées sur éprouvettes.

Mme REGOURD travaillant sur des pâtes pures de ciment CHF, préparées à partir des laitiers retenus par DRON et HAWTHORN, trouve une bonne relation entre le taux de laitier hydraté et les résistances mécaniques.

De même, elle trouve une bonne relation avec la chaleur d'hydratation, et elle conclut avec E. GAUTIER et leurs collaborateurs, que dans la comparaison de la réactivité des laitiers, la calorimétrie se révèle être une méthode très sensible.

.../...

DAIMON préconise de son côté la détermination du degré d'hydratation par l'extraction sélective des phases.

En définitive, quels que soient les procédés d'appréciation de l'hydraulicité, tous doivent se référer aux résultats donnés par les mesures de résistances mécaniques, et ces essais sont effectués sur des mélanges laitier/clinker.

Malheureusement, les résultats obtenus ne sont pas seulement fonction de la qualité du laitier, mais de celle du clinker, du taux de gypsage et de la finesse des constituants ainsi que de l'échéance retenue.

## 2.2. STRUCTURE ET REACTIVITE DES LAITIERS.

2.2.1. SMOLCZYK reprend dans son rapport principal la théorie de ZACHARIASEN selon laquelle le verre de laitier est un réseau à trois dimensions, plus ou moins déformé. Le silicium y forme des tétraèdres  $\text{SiO}_4^{4-}$  plus ou moins polymérisés. Les charges négatives de ces groupes anioniques (Tétraèdres, doubles tétraèdres, chaînes) sont compensées par les charges positives des cations. Ces cations, dont le rayon ionique est plus grand que celui du silicium, sont situés dans les cavités où ils jouent le rôle de modificateur du réseau. Le degré de polymérisation des tétraèdres  $\text{SiO}_4^{4-}$  est alors d'autant plus petit que la part des cations modificateurs est plus grande à l'intérieur du réseau. Il en résulte pour le verre correspondant une plus grande instabilité, donc une plus grande réactivité chimique.

L'ion  $\text{Ca}^{2+}$  avec la coordinance 6 est le modificateur de réseau responsable en majeure partie de l'activité du laitier, ce qui explique l'usage de l'indice  $\text{CaO}/\text{SiO}_2$ . L'aluminium et le magnésium, apparaissent dans le réseau des laitiers avec les coordinances 4 et 6 soit comme formateurs, soit comme modificateurs. Ceci explique la place, qui leur est donnée dans certains indices d'hydraulicité.

2.2.2. ROIKAK considère que les différences existant entre les cations dans le réseau, constituent un facteur essentiel de l'activité du laitier. Selon cet auteur les dépenses en énergie de rupture de la liaison  $\text{Me} - \text{O}$  doivent en effet varier avec la position du cation. Il y a création de conditions favorables au passage du cation en solution aqueuse si l'énergie cinétique des molécules d'eau et l'énergie de liaison  $\text{Me} - \text{O}$ , affaiblie dans le milieu aqueux, sont du même ordre.

De telles conditions sont réalisées avec un optimum de cations modificateurs dont le passage en solution perturbe l'électro-neutralité locale.

Approfondissant sa théorie reliant l'hydraulicité à la structure, ROIKAK fait apparaître par résonnance paramagnétique électronique la présence de centres paramagnétiques sur les tétraèdres  $\text{SiO}_4$  de la structure vitreuse, alors qu'ils sont absents des structures cristallines.

Cet auteur explique que le début du processus d'hydratation est la dissolution du liant, mais que ce processus se poursuit par la polymérisation des radicaux hydratés. Ce phénomène de polymérisation contribue à la formation de particules gélifiantes qui adsorbent à leur surface les cations déjà passés en solution, d'où la formation des hydrosilicates des métaux correspondants.

ROIKAK démontre de cette manière qu'il existe entre la partie non hydratée du laitier vitreux et les hydrosilicates de calcium, une couche intermédiaire gélifiante de faible basicité.

2.2.3. DRON dans sa communication, propose une théorie statistique de la structure. Il assimile la structure du verre de laitier à celle d'un liquide constitué de silicates fondus et il fait ressortir que la longueur des éléments de la structure des silicates fondus n'est pas uniforme comme dans un cristal : elle est distribuée suivant une progression géométrique. La longueur et la ramification de ces éléments, qui dépendent de la quantité d'ions modificateurs de réseau, conditionnent la réactivité.

2.2.4. Il faut ajouter à cela que certains éléments mineurs, tels que Na et K, par leur rôle modificateur de réseau améliorent la réactivité du laitier tel que l'ont montré DEMOULIAN et ses collaborateurs, ainsi que SMOLCZYK.

2.2.5. On peut par ailleurs mettre en évidence dans les laitiers industriels, l'existence de microhétérogénéités correspondant à un degré supérieur d'organisation locale. A la suite d'autres chercheurs, c'est ce qu'ont vu également HAWTHORN et ses collaborateurs par des études de diffusion centrale aux rayons X. Ces auteurs ont montré expérimentalement que les diamètres des microhétérogénéités, compris entre 300 et 900 Å, sont une résultante de la composition chimique et de l'histoire thermique du laitier.

L'hydraulicité des laitiers varie pour les cas étudiés par HAWTHORN en sens inverse du diamètre des microhétérogénéités.

Ces expériences pourraient être interprétées en se rapprochant des théories de SOLACOLU et BUSCH relatées par SATARINE au Congrès de Moscou.

Par ailleurs, on observe dans la plupart des laitiers des cristallisations visibles au microscope optique.

.../...

DEMOULIAN et ses collaborateurs ont identifié les différentes espèces cristallines présentes en utilisant la diffraction des rayons X, l'examen au microscope électronique à balayage, puis, la microsonde de Castaing.

Ces cristaux sont de la merwinite et de la méililite. La présence de ces minéraux influence favorablement la réactivité hydraulique des laitiers. Les auteurs ont dosé, selon les cas examinés, de 0 à 30 % de cristaux. Il semble qu'il existe un optimum de cristallisation qui est fonction de la composition pour chaque type de laitier. Cet optimum est lié en particulier à la composition et au traitement thermique du laitier.

On peut être tenté d'expliquer le rôle positif d'une cristallisation partielle, par la modification de la composition chimique du verre dans un sens favorable à sa réactivité. Ainsi la cristallisation de la merwinite enrichit le verre en alumine et éléments mineurs.

2.2.6. Dans une autre optique ROPER a étudié la morphologie de 8 laitiers d'origines diverses obtenus avec des procédés de trempe différents, tels que la trempe à l'eau, la trempe à l'air et le bouletage. ROPER observe que selon le mode de refroidissement les grains de laitiers sont constitués de verres hétérogènes et de particules aciculaires. Il explique que partant d'un laitier fondu d'une composition globalement basique, les hétérogénéités dues au mode de refroidissement peuvent entraîner la séparation de particules aciculaires plus ou moins développées et de composition acide.

2.2.7. Enfin, une particularité intéressante de la texture des laitiers a été étudiée par COURTAULT. COURTAULT s'intéresse aux gaz dissous et aux gaz occlus. Il a analysé les gaz occlus après extraction par broyage sous vide et il a constaté que l'aptitude au broyage et la réactivité des laitiers sont améliorées par l'existence de ces gaz occlus.

### 2.3. HYDRATATION DU LAITIER.

2.3.1. Les travaux récents communiqués au Congrès relancent la discussion de deux théories en complément des explications développées par ROIAK dans son analyse de la structure et de la réactivité des laitiers vitreux : la réaction dissolution-diffusion-cristallisation appelée par certains "trans-solution", et la réaction topochimique.

#### 2.3.2. Réaction "trans-solution".

DRON interprète la solubilisation initiale du laitier comme le passage sélectif en solution d'entités structurales analogues à celles de la rankinite et de l'aluminate monocalcique.

Les ions Ca et les ions aluminates et silicates en solution s'accumulent jusqu'à sursaturation et précipitation sous forme de C S H et d'aluminates hydratés.

VERNET considère à la fois les comportements simultanés du clinker et du laitier mis ensemble en présence d'eau. Il a étudié pour cela 16 ciments à fortes teneurs en laitier et les a comparés au Portland fait avec le même clinker.

L'auteur analyse en continu l'évolution des concentrations ioniques dans des suspensions de rapport  $\frac{\text{eau}}{\text{ciment}} = 4$ . Il résulte de cette

étude que le laitier et le clinker se dissolvent simultanément, mais à des vitesses différentes. Le clinker agit sur la vitesse de dissolution du laitier, et réciproquement la consommation de chaux par le laitier augmente la vitesse de dissolution de l'alite.

L'auteur désigne ces interactions sous l'appellation de "couplages chimiques". Il trouve une similitude dans les actions réciproques des chaleurs dégagées par les réactions d'hydratation, et par analogie il les nomme "couplages thermiques".

VERNET par ses expériences montre la simultanéité des pics de flux thermiques et des variations de concentration des ions en solution.

L'examen des courbes de concentration ionique fait apparaître pour tous les ciments de laitier l'existence de quatre périodes au cours de l'hydratation.

Il faut en retenir que dès la première période le laitier participe à la saturation de la solution en même temps que le clinker; et ceci est une notion nouvelle que l'auteur prouve en se basant sur les différences de concentration ionique en relation avec les différents laitiers et le clinker correspondant.

Mme REGOURD confirme la participation précoce du laitier aux réactions d'hydratation en s'appuyant sur les résultats de mesure de la chaleur d'hydratation et sur l'identification au microscope à balayage et par diffraction des rayons X des minéraux hydratés formés : en effet, l'abondance de l'ettringite n'est justifiée que par la consommation de l'alumine du laitier. Les travaux de Mme REGOURD et ceux de VERNET, par des voies différentes, viennent à l'appui des conceptions de ROIAK sur la structure des laitiers grâce auxquelles l'auteur explique l'hydraulicité par la réaction de dissolution-diffusion-cristallisation.

.../...

### 2.3.3. Réaction topochimique.

Bien que Mme REGOURD et VERNET démontrent assez clairement par leurs expériences que l'hydratation s'effectue par dissolution et cristallisation, cette conception n'est pas partagée par tous les chercheurs. Ainsi, ABO EL ENEIN écrit que les grains de laitier réagissent topochimiquement avec la solution d'hydroxyde de calcium, et DRON, de son côté, n'exclut pas la possibilité de réactions pouzzolanique et topochimique à partir du squelette laissé par l'attaque hydrolytique préalable.

DAIMON exposant ses propres travaux et ceux de KONDO dans son rapport principal suppose que le laitier s'hydrate topochimiquement et il met d'ailleurs l'accent sur l'inhibition de la réaction d'hydratation par la formation de couches d'hydrates faiblement perméables enrobant les grains. Cette inhibition lui apparaît très rapide avec les activateurs alcalins.

De toute façon, la discussion reste ouverte sur le principe même du processus d'hydratation, lequel d'ailleurs n'est pas propre aux laitiers. Heureusement, la plupart des chercheurs s'accordent sur la nature des hydrates formés.

### 2.3.4. Hydrates formés.

Les travaux de Mme REGOURD, de TEOREANU, de SERSALE, de ABO EL ENEIN, de VERNET, et leurs collaborateurs, montrent tous la formation de  $C_2S \cdot H$ , de portlandite, d'ettringite et de monosulfoaluminate.

Cependant, TEOREANU étudiant le système laitier - chaux - gypse - eau, trouve qu'il se forme transitoirement de la géhlénite hydratée  $C_2S \cdot A \cdot H_8$  qui se transforme à long terme en hydrogrenat. A ce sujet, DRON précise que la géhlénite hydratée ne peut se former qu'après la disparition de la chaux.

VERNET, lui, pense avoir trouvé un sulfuroaluminate de calcium hydraté, ou une solution solide de  $CaS$  dans l'aluminate et qui seraient analogues au monosulfoaluminate. Il a révélé la formation probable de ce nouvel hydrate dans son étude de la cinétique d'hydratation des ciments à fortes teneurs en laitier.

Enfin, MASCOLO a préparé par synthèse des hydroxydes doubles de  $Mg$  et  $Al$  et les produits carbonatés correspondants. Il pense que la résistance aux sulfates s'explique par la formation préférentielle de ces produits carbonatés.

### 2.3.5. Chaleur d'hydratation.

La chaleur d'hydratation ou plutôt la chaleur dégagée à une échéance donnée est liée à la fois à l'enthalpie de chacune des réactions et à la cinétique de l'hydratation.

A ce sujet, les conceptions de "couplages chimiques" et de "couplages thermiques" énoncées par VERNET et ses collaborateurs, selon lesquelles le clinker et le laitier ont des interactions aboutissant à l'augmentation des taux de réaction de chacun de ces constituants, trouve une confirmation dans les travaux de TOTANI. Nous comprenons en effet du travail de TOTANI que la chaleur d'hydratation de l'alite ou du clinker est augmentée dans les ciments au laitier du fait de l'interaction des constituants.

### 2.4. MODES D'ACTIVATION CHIMIQUE.

Nous avons vu que pour être effectives, les réactions d'hydratation exigent que le laitier soit maintenu dans un milieu à pH suffisant quel que soit le processus, dissolution - précipitation ou topochimique.

#### 2.4.1. Activations non calciques.

Selon les utilisations plusieurs modes d'activation sont proposés, autres que l'activation calcique : VOINOVITCH a étudié et préconisé l'emploi des métagélinates de sodium; il a défini le dosage en fonction de la température; il a mis au point un liant qu'il nomme silicociment, lequel est constitué de laitier broyé additionné éventuellement de gypse naturel ou chimique et de filler calcaire.

VOINOVITCH précise que des travaux similaires effectués par des chercheurs Soviétiques et Polonais ont abouti à des résultats analogues.

SATARINE parvient à préparer des bétons armés à plus hautes performances mécaniques que les bétons de Portland en ajoutant un activateur polyminéral sulfoalumine-siliceux. Cette action qui se manifeste sur les résistances à tous les âges est conservée dans le cas d'un traitement thermique humide. Selon l'auteur, ces hautes performances sont dues à la formation précoce d'une carcasse d'ettringite remplie d'hydrosilicates de calcium. SATARINE insiste sur la densité de la structure favorisée par la naissance ultérieure de gels de boehmite et de gypse.

#### 2.4.2. Activation sulfo-calcique par le clinker et le gypse.

Bien sûr, l'activateur le plus étudié et le plus employé à ce jour reste le clinker de portland. La plupart des auteurs étudiant l'hydratation des laitiers utilisent des mélanges laitier/clinker.

SMOLCZYK dans son étude déjà citée sur les corrélations entre composition et résistances, constatait une forte influence de la nature du clinker dans le cas de ciments à 60 et 75 % de laitier.

.../...

HAWTHORN lui, a eu pour objectif de préciser le rôle du type de clinker avec les trois laitiers déjà cités utilisés au dosage de 80 %.

Une expérimentation portant sur 7 clinkers couvrant un large éventail de composition minéralogique a montré que :

1. L'influence de la qualité du clinker n'est pas importante avant 2 jours.
2. De meilleures performances sont obtenues à 28 jours avec les clinkers riches en alite et en  $C_3A$  tétragonal.
3. L'accroissement de résistances jusqu'à un an est essentiellement fonction de la finesse du laitier.

L'étude a aussi montré que le gypse optimal est fonction de la finesse du laitier, du temps de réaction et de la teneur en  $C_3A$  du clinker.

Par ailleurs, le surgypage d'un ciment de laitier du type CLK à finesse peu poussée est très préjudiciable aux résistances.

Enfin, je rappellerai que DRON avait précisé que la chaux et le gypse sont de véritables réactifs, alors que la soude ne joue qu'un rôle de catalyseur.

## 2.5. TRAITEMENTS THERMIQUES.

Mme REGOURD, GAUTIER et leurs collaborateurs ont étudié l'influence de la température sur les courbes de durcissement de ciments CHF.

Après traitement thermique à 50°, les différences entre 7 laitiers de diverses qualités sont pratiquement effacées, mais le niveau des résistances atteint dans tous les cas, reste inférieur à celui que l'on obtient à 20°.

En revanche, un traitement à 80° montre un comportement différent très favorable aux ciments les moins réactifs à 20°, et très défavorable aux ciments les plus réactifs.

Mme REGOURD a montré avec l'aide du microscope électronique à balayage que dans le cas du CHF peu réactif à 20°, un traitement à 80° aboutit à un aspect normal des hydrates, alors que dans le cas du CHF réactif, ce même traitement engendre des amas de monosulfoaluminates provoquant une texture hétérogène, laquelle est peu favorable à la cohésion du mortier.

GOVOROV a voulu étudier le comportement dans un traitement hydrothermal jusqu'à 285° de laitiers synthétiques pour une gamme de composition très large sortant du domaine habituel des laitiers sidérurgiques.

GOVOROV rappelle que dans le traitement hydrothermal à 250° les laitiers dont la structure est faite de tétraèdres isolés ou de groupements limités, c'est-à-dire, les laitiers méliolitiques, donnent des hydrogrenats, alors que ceux dont la structure est faite de chaînes de tétraèdres, donnent de la tobermorite. Ces deux types d'hydrates sont eux-mêmes constitués comme les produits anhydres d'origine, soit de tétraèdres ou de groupements isolés, soit de chaînes.

L'auteur trouve que le passage en solution de la silice est d'autant plus retardé que la structure est compliquée.

La chaux accélère aussi bien le passage de la silice en solution que sa recombinaison en hydro-silicate de calcium; cela a pour effet d'avancer le début du durcissement, mais GOVOROV précise que l'addition optimale de CaO est limitée à une valeur de 0,3 à 0,8 %.

Cette étude trouve une application dans l'utilisation des coulis de laitiers pour puits de forage profonds.

HOOTON a étudié l'autoclavage de laitiers bouletés en mélanges ternaires avec du ciment portland et de la farine de silice, soit en pâte pure, soit en mortier. Il a trouvé que les résistances à la compression sont considérablement augmentées par l'addition de farine de silice.

## 2.6. CONTROLE DE LA COMPOSITION DES CEMENTS DE LAITIER.

Nous venons de voir que les laitiers de haut-fourneau activés de différentes manières peuvent donner des ciments hydrauliques. Ces ciments se caractérisent par des performances mécaniques et chimiques égales ou même supérieures à celles des portlands selon l'échéance considérée. Il est cependant indispensable comme pour tous les types de ciments de garantir la régularité de leur qualité. Cette régularité dépend à la fois de la réactivité des constituants et de leurs proportions.

La surveillance de ces proportions nécessite de disposer de méthodes de contrôle rapides et précises.

DEMOULIAN a apporté une contribution intéressante à la résolution de ce problème en proposant la dissolution sélective du clinker et du gypse dans une solution sodique de EDTA et de triéthanolamine à pH = 11,5 ± 0,1. Dans ces conditions, le laitier est insoluble et son dosage est obtenu directement par filtration.

.../...

## 2.7. UTILISATIONS DIVERSES DES LAITIERS ET SCORIES.

Je voudrais rappeler l'utilisation des laitiers et scories comme matières premières dans la préparation des mélanges crus pour ciment portland, ce qui conduit à une sensible économie d'énergie.

Parmi les utilisations nouvelles des laitiers il faut enfin citer les études de BELETSKAIA et LOUGUININA ainsi que de KLUKHOVSKY pour la production de clinker d'un type nouveau à base de laitier et d'additions alcalines.

Par ailleurs, une proposition originale est faite par SOULEIMENOV pour corriger les laitiers par addition de poussières alcalines de cimenterie dans le laitier fondu au moment de la granulation.

## 3. AUTRES LAITIERS ET SCORIES.

3.0. La période actuelle d'économie amène les industriels du monde entier à valoriser les sous-produits de toutes origines, c'est le cas pour les laitiers de métallurgies diverses, allant des laitiers d'aciéries aux laitiers de la métallurgie du zinc, du nickel, du cuivre, etc...

Alors que les laitiers de hauts fourneaux se caractérisent par une hydraulité latente, les scories d'aciéries ayant une composition chimique riche en chaux combinée, sont directement hydrauliques, les autres au contraire doivent être activées.

Les laitiers de métaux non ferreux ont par contre une structure tout à fait différente et se comportent le plus souvent comme des pouzzolanes.

### 3.1. SCORIES D'ACIERIES.

La plupart des scories d'aciéries n'avaient pas jusqu'à maintenant été employées comme liants hydrauliques étant donné leur composition chimique non adaptée. Cette non-adaptation réside principalement dans l'insuffisance de silice et surtout d'alumine, ainsi que dans un large excès d'oxyde de fer, de chaux libre, et souvent de magnésie.

GEORGES et SORENTINO ont étudié en remplacement du spath fluor un nouveau fondant synthétique désigné CAMFLUX apportant les éléments manquant à la scorie et qu'ils mettent en oeuvre dans le convertisseur B.O.P au début de l'affinage.

Cette opération améliore à la fois la composition et l'homogénéité de la scorie. Elle rend cette dernière hydraulique et supprime le gonflement.

Les auteurs ont étudié l'hydraulité de la scorie améliorée en suivant la fixation de l'eau et le dégagement de chaleur en fonction du temps. Ils en ont conclu que la valeur hydraulique de tels produits est malgré tout insuffisante, et qu'il est nécessaire de les additionner de ciment portland, comme pour les laitiers de haut-fourneau afin d'obtenir des

résistances convenables.

Cependant, il existe des laitiers d'aciéries dont la composition chimique est telle que la teneur en  $C_3S$  en fait des produits directement hydrauliques.

Ce sont des produits de ce type qui ont été étudiés par WANG Yu Ji.

L'étude pétrographique de cet auteur indique comme constituants du  $C_3S$  en quantités variables, du  $C_2S$ , du  $C_2F$  et des solutions solides de  $FeO$  et de  $MgO$  ainsi que de la chaux libre.

L'auteur relie à la teneur en  $C_3S$  les résistances à 28 jours données par de tels laitiers normalement gypsés, mais il élimine ceux qui renferment plus de 3 % de chaux libre, étant donné leur forte tendance à l'expansion.

LUO SHOUSEN étudie également les scories d'aciéries et s'attache particulièrement à définir l'état de la magnésie en vue de remédier au gonflement qu'elle provoque.

LUO a travaillé avec 6 scories d'origine différentes dont la teneur en magnésie varie de 6 à 18.

Cet auteur a montré que la magnésie est inoffensive si elle est combinée à l'état de composés silicatés, ou si elle se trouve en solution solide avec  $FeO$  et  $MnO$ .

L'auteur précise que dans les scories réductrices  $MgO$  est à l'état de périclase et que les ciments qui seraient fabriqués avec de telles scories seraient détruits à l'autoclavage. En revanche, il existe pour les scories oxydantes une teneur optimale en magnésie définie par le rapport 
$$\frac{MgO}{FeO + MnO}$$
 lequel doit rester inférieur à 1.

Pour éviter le gonflement LUO propose d'utiliser par mélange avec du clinker de portland les scories où  $MgO$  est combiné à l'état de silicates et il remédie à l'expansion des laitiers réducteurs riches en périclase en les additionnant, soit de sulfate de magnésium, soit de laitier de haut fourneau granulé, soit de matières siliceuses telles que les cendres volantes. Il propose également un traitement de carbonatation en l'absence de gypse.

Par ailleurs, le problème de l'hydratation de la magnésie a été étudié par MASCOLO et MARINO qui ont synthétisé les hydroxydes doubles de  $Mg$  et  $Al$  identifiés dans les produits d'hydratation des laitiers de haut fourneau en présence de chaux.

Ces auteurs ont montré que des laitiers à forte teneur en  $MgO$  sont capables de résister à l'attaque des sulfates parce que les tétraèdres  $SO_4^{2-}$  pénètrent difficilement dans la structure des hydroxydes doubles.

.../...

Ils constatent accessoirement une carbonatation facile de ces hydroxydes pour former un carboaluminate de magnésium hydraté. Peut-être peut-on trouver là une explication aux bons résultats obtenus par LUO SHOU SUN dans son traitement de carbonatation pour annihiler l'expansion du périclase.

### 3.2. SCORIES DE METAUX NON FERREUX.

CARLES GIBERGUES étudie les scories hydrauliques résultant de la fabrication du magnésium. Ces scories se composent de deux parties distinctes, l'une pulvérulente, composée de  $C_2S$  gamma et d'aluminate  $C_{12}A_7$ , l'autre granulée, renfermant du  $C_2S/\beta$  dans une matrice vitreuse hétérogène; la granulation par trempe à l'eau de cette seconde partie de la scorie hydrate partiellement l'aluminate en  $C_3AH_6$ .

La cinétique d'hydratation est évidemment différente pour la scorie fusante et pour la scorie granulée, ce qui s'explique partiellement par l'état anhydre de l'aluminate dans le premier cas et par sa préhydratation partielle dans le second cas.

Le mélange de ces scories donne d'excellents résultats en technique routière, mais prises séparément elles peuvent trouver leur utilisation dans la préfabrication de matériaux manufacturés.

L'auteur propose de produire des matériaux cellulaires en ajoutant aux scories fusantes de la poudre d'aluminium, et de fabriquer des éléments très résistants par autoclavage du laitier granulé broyé.

Les auteurs qui ont étudié les scories de la métallurgie du cuivre et du nickel, s'accordent à leur trouver une structure et des propriétés pouzzolaniques.

BARAGANO s'attache à montrer les qualités pouzzolaniques des scories de la métallurgie du cuivre.

Ces laitiers vitrifiés et finement granulés à l'eau ont une composition chimique pratiquement exempte de chaux, mais en revanche très riche en silicate ferreux détectable sous forme de cristaux de fayalite en aiguilles.

Il est permis de penser que la présence de silice soluble résultant de la décomposition de la fayalite par la chaux, explique les résultats positifs obtenus par l'auteur dans tous les tests de pouzzolanité qu'il a appliqués.

Il faut cependant remarquer que ces scories utilisées sous forme de ciments à la pouzzolane par mélange avec du portland réagissent plus lentement que les pouzzolanes naturelles, mais que les résistances obtenues après 60 jours sont du même ordre.

Par ailleurs, de tels produits résistent excellemment aux attaques chimiques et aux épreuves climatiques.

Les scories de la métallurgie du nickel ont une composition et des propriétés pouzzolaniques analogues à celles de la métallurgie du cuivre; c'est ainsi que LANEUVILLE, étudiant ces scories, aboutit dans ses recherches aux mêmes résultats que BARAGANO. Il précise que d'autres auteurs, tel que THOMAS, ont également démontré les propriétés pouzzolaniques des scories de la métallurgie du plomb.

Nous voyons donc qu'il y a là des sources importantes de sous-produits utilisables en cimenterie pour la préparation de ces ciments particulièrement appréciés pour leurs propriétés spécifiques que sont les ciments pouzzolaniques.

BOLDYREV met en valeur les tonnages très importants de résidus industriels disponibles en U.R.S.S., et parmi ceux-ci des scories de métaux non ferreux. Les compositions chimiques de ces scories sont voisines de celles annoncées par BARAGANO d'une part, et LANEUVILLE d'autre part, avec en particulier la présence de fayalite.

BOLDYREV développe des explications très approfondies du processus d'hydratation de ces scories. Il ajoute que le verre alumino ferro siliceux de ces scories est responsable de leur comportement pouzzolanique de la même façon que la silice active et le verre alumino-siliceux.

\* \* \*

### THEME III - DISCUSSION DU PANEL

---

Membres du Panel :

M. M. VON EUW, Président de Thème .

Prof. M. DAIMON, Professeur à l'Institut de Technologie de Tokyo, JAPON.

Dr R. DRON, Ingénieur au Laboratoire Central des Ponts et Chaussées, FRANCE.

M. B. ENTINE, NII Cement Department Chief, Cand. Sci. (Techn.) de Moscou, U.R.S.S.

M. le Prof. FIERENS, Doyen de l'Université de l'Etat de Mons, BELGIQUE.

M. LUO SHOUSUN, Ingénieur Cement Research Institute, Beijing, CHINE.

Dr M. REGOURD, Chef du Département Microstructures, C.E.R.I.L.H., FRANCE.

Dr H.G. SMOLCZYK, Forschungsgemeinschaft Eisenhüttenschlacken, Duisburg, R.F.A.

---

## 1. STRUCTURE ET REACTIVITE

M. VON EHW :

- "Je souhaiterais que nous discussions d'abord des recherches liant la structure et la réactivité hydraulique.

J'ai retenu des différents travaux sur la structure des laitiers "dits vitreux" que le verre de laitier est constitué de tétraèdres  $\text{SiO}_4$  plus ou moins polymérisés. Le réseau est déformé par l'insertion d'un certain nombre de cations dont le rayon est plus grand que celui du silicium.

Dès 1932, ZACHARIASEN expliqua que les cations modificateurs de réseau conditionnent le degré de polymérisation. Il résulte de cette conception de la structure, que le nombre de tétraèdres simples est d'autant plus grand que les cations modificateurs de réseau occupent plus de place ; en conséquence, la réactivité chimique est elle-même d'autant plus grande. Cette explication n'apparaît pas suffisante. Elle est maintenant précisée par des travaux récents."

- "M. le Professeur ROIAK a particulièrement étudié la dépolymérisation des ions complexes silicium-oxygène par les cations Aluminium et Magnésium. Prof. ENTINE voulez-vous nous apporter quelques informations sur les travaux de ROIAK ?"

Prof. Z.B. ENTINE :

- "Les travaux scientifiques russes et plus particulièrement ceux du Prof. ROIAK ont montré que l'oxygène joue un rôle déterminant dans l'activité des laitiers fondus. Les ions modificateurs du réseau exercent leur action sur l'état énergétique de l'oxygène, sur la polymérisation ou la dépolymérisation des complexes ions-oxygène, c'est-à-dire sur l'état vitreux. L'état énergétique des ions Al et Mg a aussi une grande influence. Il faut accroître la teneur en aluminium pour obtenir une bonne activité du laitier, liée au fait que Al prend une valence  $6^+$  et contribue à la dépolymérisation des ions dans le laitier. Cette valence  $6^+$  a été confirmée par spectroscopie d'absorption infrarouge et résonance paramagnétique électronique. Le magnésium joue un rôle moins marqué que celui du calcium. Il peut y avoir démixtion de la masse fondue en deux phases et cristallisation partielle. Ces deux phénomènes, démixtion et cristallisation partielle ont, à mon sens, une très grande influence sur la réactivité et n'ont pas été suffisamment étudiés car des laitiers ayant des compositions identiques peuvent avoir une réactivité différente. Ceci permet d'expliquer l'effet des éléments mineurs Ti et Mn et l'hétérogénéité qu'ils entraînent.

- "M. DRON, en étudiant la réactivité du laitier granulé, vous avez été conduit à proposer une théorie statistique de la structure. Votre approche s'écarte-t-elle en cela des conclusions de ROIAK ?"

M. R. DRON

- "La conception du verre à laquelle je me réfère part de la structure du verre de silice. Elle s'appa-

rente à celle du cristal de quartz qui est formé de tétraèdres  $\text{SiO}_4$  dont chaque sommet est commun à deux tétraèdres. La liaison  $\text{SiO}$  a un caractère covalent extrêmement marqué, avec une hybridation  $\text{sp}^3$  qui détermine les directions de valence à  $109^\circ 28'$ , l'angle  $\text{Si-O-Si}$  étant à  $180^\circ$ .

Dans le verre, les angles  $\text{O-Si-O}$  restent proches de  $109^\circ$ , mais les angles  $\text{Si-O-Si}$  s'écartent notablement et de façon aléatoire de  $180^\circ$  de sorte qu'on cesse d'avoir un réseau au sens cristallographique du terme, avec répétition du motif par une opération de translation, mais on conserve un pseudo réseau.

Un verre de silicate peut être considéré comme un verre de silice modifié. Il dérive de celui-ci par une opération de coupure des ponts silicium-oxygène-silicium par suite de la réaction :

Le réseau obtenu diffère du réseau primitif à la façon d'un filet dont on aurait sectionné au hasard une partie des mailles (Fig. 1, Fig. 2),

Fig. 1 - Pseudo réseau du verre de silice.

Fig. 2 - Sectionnement du réseau par  $\text{O}^{2-}$  dans un verre de silicate

Ma conception diffère donc un peu de celle de M. ROIAK, en ce sens que je considère que l'agent modificateur n'est pas le cation ( $\text{Ca}^{2+}$  par exemple) mais l'anion  $\text{O}^{2-}$  apporté par la chaux. Cet anion disparaît en tant que tel dans la réaction de coupure des ponts.

Les tétraèdres, qui initialement étaient tous de même nature puisqu'ils comportaient tous, quatre oxygènes pontants, vont constituer maintenant cinq espèces différentes selon le nombre d'oxygènes pontants qu'ils auront conservé :

Les espèces X avec quatre oxygènes pontants occupent des positions de croisement de chaînes et les espèces Y (trois) des positions de bifurcation de chaînes. Les espèces E (deux) sont des éléments de chaînes et les espèces Z (un seul) des extrémités de chaîne. Il convient d'ajouter à ces quatre espèces l'espèce S qui n'est autre que le tétraèdre  $\text{SiO}_4^{4-}$  isolé.

La statistique permet de dénombrer ces espèces moyennant certaines hypothèses simplificatrices. J'ai pu étendre par ce moyen le dénombrement dans les systèmes à moyenne teneur en silice que constituent les laitiers.

Les agents formateurs du réseau sont bien entendu le silicium mais également l'aluminium qui, dans les milieux basiques, est toujours tétracoordonné. Il semble occuper dans le laitier préférentiellement les sites X (croisement de chaînes).

L'ion calcium se place à proximité des oxygènes porteurs de charges et forme entre eux des ponts de nature électrovalente, facilement détruits par l'eau.

Le magnésium, auquel la plupart des auteurs font jouer un rôle semblable à celui du calcium, a un caractère ionique moins marqué et peut même former, dans des composés cristallisés comme l'akermanite, des structures covalentes. Quoiqu'il en soit, le pont oxygène-magnésium-oxygène est moins facilement hydrolysé que le pont oxygène-calcium-oxygène, de sorte que tout se passe comme si, partiellement du moins, le magnésium jouait un rôle de formateur de réseau."

M. VON EUW :

- "J'ai retenu également que la structure du verre n'est pas seulement hétérogène à l'échelle atomique, mais que plusieurs chercheurs ont observé dans la masse vitreuse des hétérogénéités assimilables à des globules de verre non miscibles.

D'autres auteurs se sont consacrés à l'identification et au dosage des cristaux qui apparaissent en plus ou moins grandes proportions pendant la trempe du laitier.

Enfin, les défauts qui existent à la surface du verre semblent constituer des centres de formation de germes lors de l'hydratation."

- "M. le Professeur FIERENS que pensez-vous de ces aspects différents de la structure des laitiers ?"

Prof. P. FIERENS :

- "Les cristaux "parfaits" qui correspondent à un ordre structural très rigoureux sont très rares. A l'autre bout de l'échelle, les verres "parfaits", caractérisés par un désordre maximum, sont tout aussi peu fréquents.

L'état cristallin et l'état vitreux réels présentent un certain nombre de défauts de structure de

divers types qui constituent souvent des centres actifs jouant un rôle prépondérant dans la réactivité des solides.

C'est la raison pour laquelle il est illusoire de bâtir une théorie de l'hydratation des ciments, des laitiers et des liants pouzzolaniques sans faire intervenir les défauts de structure. Ces défauts sont des lacunes, des interstitiels, des dislocations, des joints de grains, des impuretés, etc ...

Par exemple, dans le verre de laitier, des défauts peuvent se situer à l'interface des microhétérogénéités qui ont été identifiées sous forme de globules vitreux non miscibles par HAWTHORN ou de microcristaux par DEMOULIAN, MORTUREUX, ROIAK et d'autres. Il me paraît évident que l'accroissement de réactivité du laitier n'est pas dû aux cristaux eux-mêmes mais bien, je le répète, aux défauts apparaissant à l'interface avec le substrat vitreux.

La thermoluminescence et l'exoémission électronique sont deux techniques qui permettent de caractériser les défauts de structure à la surface des échantillons et notamment sur le plan énergétique. Ces défauts causent, dans le matériau, des élévations locales de l'énergie libre qui entraînent la diminution de l'énergie d'activation du processus d'hydratation. Les travaux effectués dans mon laboratoire sur l'hydratation de la géhlénite, de laitiers synthétiques et de laitiers industriels montrent que le mode de trempe a une grande répercussion sur les caractéristiques énergétiques et entropiques des défauts de l'état vitreux.

Néanmoins, si l'on veut tirer un enseignement pratique à propos de l'influence de la trempe sur le pouvoir hydraulique des laitiers, il ne faut pas séparer ce paramètre et le facteur relatif à la composition chimique élémentaire quantitative. Pour un laitier de composition chimique donnée, deux modes de trempe différents peuvent conduire à des réactivités variant de 1 à 270, alors que pour un laitier d'une autre composition, les deux modes de trempe n'ont pratiquement aucune influence sur la vitesse d'hydratation. Dans le second cas, il ne sert à rien de tenter d'améliorer le pouvoir hydraulique du laitier en agissant sur le mode de trempe. Au contraire, dans le premier, une telle étude est très bénéfique.

Cette conclusion me paraît avoir un grand intérêt au niveau de la pratique industrielle."

M. VON EUW :

- "J'ajouterai en ce qui concerne les microcristaux dosés par DEMOULIAN et également par MORTUREUX, que la merwinite apparaît comme l'espèce principale:

Je serais tenté d'avancer que la cristallisation de la merwinite aurait pour conséquence l'enrichissement du verre en alumine et éléments mineurs, ce qui est favorable à l'hydraulicité."

- "M. DRON partagez-vous cette hypothèse ?"

M. R. DRON :

- "Je partage cette hypothèse. Si le milieu est enrichi en alumine, il a plus de chance de réagir car Al est l'élément le plus fragile en milieu basique. Le magnésium est par contre renforcé."

## 2. CARACTERISATION

M. VON EUW :

- "Les explications de l'hydraulicité par la structure ne nous suffisent cependant pas. En effet, dans la pratique industrielle, nous avons besoin de caractériser les laitiers et pour cela diverses méthodes sont en concurrence."

- "Dr SMOLCZYK, pouvez-vous nous dire comment vous utilisez les résultats de l'analyse élémentaire, et surtout quelle importance vous donnez aux éléments mineurs ?"

Dr H.G. SMOLCZYK :

- "A lot of most complicated hydraulic formulas for granulated blast-furnace slag are not more precise than very simple formulas of the type  $\text{CaO}/\text{SiO}_2$ . If a precision of more than 90 % ( $r^2$ ) is demanded, then it is necessary to include some minor elements. We introduced only  $\text{MnO}$ , alkali and  $\text{P}_2\text{O}_5$  in our formulas with best results."

In the very interesting formulas of DEMOULIAN, GOURDIN, HAWTHORN and VERNET, all the minor elements are explicitly dealt with. This does not necessarily mean a contradiction to our opinion. The amounts of  $\text{TiO}_2$ , fluor, chloride and crystalline particles in our 24 slags and their range of variation have been far too small for statistical evaluations. We fully agree with the opinion of M. DEMOULIAN that the glass-content has some influence on the hydraulic properties and that the chloride naturally has a very strong positive influence."

M. VON EUW :

- "Mme REGOURD, votre méthode calorimétrique permet-elle de faciliter la sélection des laitiers ?"

Mme REGOURD :

- "La calorimétrie à conduction est une méthode sensible et rapide dans la comparaison de la réactivité des ciments, au laitier. Si les mesures sont effectuées à 40 °C, température à laquelle les hydrates formés sont les mêmes que ceux qui apparaissent à 20 °C, un classement de différents laitiers peut être connu avant la quinzième heure d'hydratation. Les courbes de la Figure 1, relatives à des ciments de haut fourneau CHF (70 % de laitier), montrent que le maximum du flux de chaleur est nettement moins intense et décalé dans le temps avec les CHF 2 et 3 qu'avec le CHF 1, plus encore avec les CHF 4 et 5. Par contre, la courbe du CPA prouve la participation simultanée du laitier et du clinker portland aux premières réactions d'hydratation : le pic le plus intense se place au même moment pour les deux ciments et le rapport entre l'énergie libérée par le CHF 1 et l'énergie libérée par le CPA est très supérieur à la proportion de clinker (28,5 %) dans le ciment au laitier."

Le même classement des laitiers se retrouve dans la comparaison de l'évolution, en fonction du temps, des résistances mécaniques en compression sur mortier ISO. La distinction est particulièrement marquée à 7 jours (Fig. 2) et plus nette, à la même échéance, que lors de l'estimation du degré d'hydratation en pâte pure par la méthode de dissolution. Elle reste toutefois moins rapide que la calorimétrie."

Fig. 1 - Chaleur d'hydratation à 40 °C d'un CPA et de cinq ciments de haut fourneau CHF.

Fig. 2 - Evolution des résistances mécaniques en compression des mortiers ISO du CPA et des CHF 1, 2 et 3.

M. VON EUW :

- "Le regretté Prof. KONDO mesurait le degré d'hydratation par extraction sélective des phases, M. le Professeur DAIMON souhaitez-vous nous parler de cette méthode ?"

Prof. M. DAIMON :

- "When I was asked to prepare a paper on the mechanism and the kinetics of hydration of slag, one question was how to measure the change and degree of slag hydration with hydration time. Obviously, we should find a suitable method for the quantitative analysis of slag in order to determine the degree of slag hydration and the selective method of dissolution"

by Prof. KONDO seems to me the only method which have enough accuracy for this purpose. in this method, hydration products are almost completely dissolved by organic acid solution while unhydrated slag remains undissolved (principal Paper III.2.2). It is necessary to have several independent methods for such fundamental and important measurement. We know that the conduction calorimeter is very useful as mentioned before but we cannot obtain the reaction rate itself. The determination of evaporable water, free lime, free gypsum and so on should also be performed to know the full picture of the slag hydration."

Prof. P. FIERENS :

- "La caractérisation des laitiers, sur le plan de leur pouvoir hydraulique, paraît pouvoir se faire en mesurant la vitesse de progression du degré d'hydratation. En effet, la détermination de l'augmentation du degré d'hydratation en fonction du temps conduit à un classement de différents ciments au laitier conforme à la séquence correspondant aux résistances mécaniques respectives à des échéances données."

C'est ce qui ressort des travaux de Mme REGOURD et de ceux du Prof. DAIMON. C'est également ce que j'ai pu observer moi-même sur des échantillons d'un même laitier trempés selon des modes différents, mettant de plus en évidence le rôle joué par des défauts de structure caractérisés par exoémission électronique.

Ces considérations méritent cependant un commentaire supplémentaire montrant qu'il est nécessaire de distinguer l'usage qui peut être fait d'une part, de la mesure du degré d'hydratation et d'autre part, la détermination de la vitesse de l'augmentation de ce dernier dont il est question plus haut.

S'il est évident que le degré d'hydratation d'un ciment de laitier est un facteur important contribuant aux résistances mécaniques, il est essentiel de souligner que ce n'est pas le seul. Mes travaux ont montré que, pour quatre échantillons d'un même laitier trempés selon des modes différents, pour un même degré d'hydratation, la résistance à la compression prenait les valeurs respectives de 50, 41, 35 et 29 MPa.

Ceci montre sans ambiguïté qu'il n'y a pas de relation quantitative simple entre le degré d'hydratation et les résistances mécaniques et qu'à côté du degré d'hydratation interviennent d'autres paramètres, tels que la texture des hydrates qui dépend notamment des conditions de formation et de croissance des cristaux de ces produits et, en particulier, de la vitesse de cette dernière.

Je crois que beaucoup de progrès restent à accomplir à ce niveau, notamment par l'étude dynamique des microstructures des pâtes en cours de durcissement en relation, d'une part, avec les conditions présidant à la croissance des cristaux d'hydrates formés et, d'autre part, avec le développement des propriétés mécaniques et des caractéristiques rhéologiques.

Enfin, il y a tout lieu de croire que les observations faites dans mon laboratoire à propos de l'hydratation de laitiers industriels, pourraient être étendues aux ciments de laitier et aux ciments portland."

### 3. MECANISME DE L'HYDRATATION

M. VON EUW :

- "Nous avons vu que la structure et la composition chimique conditionnent la réactivité des laitiers. J'aimerais que l'on discute maintenant du mécanisme de l'hydratation."

- "Est-on arrivé à concilier la théorie de LE CHATELIER et celle présentée au Congrès de Londres en 1952 par HANSEN sur la réaction topochimique ? Je ne connais pas l'opinion des chercheurs chinois ; M. LUO SHOUSUN, comment comprend-on en Chine le mécanisme de l'hydratation des ciments de laitier ?"

M. LUO SHOUSUN :

- "We have studied the effect of magnesia in steel slags, so we have not done much work on slag hydration and we do not have anything to comment."

Prof. Z.B. ENTINE - (à la demande de M. VON EUW, point de vue des chercheurs russes) :

- "Le point de vue du Prof. ROIK est relatif à l'influence des valences 6 par rapport à l'oxygène sur la réaction d'hydratation des laitiers. Il y a dans le verre un accroissement des liaisons de type ionique et une diminution des liaisons de type covalent. Les ions modificateurs passent en solution et sont remplacés par des ions qui, de valence 4, prennent la coordination 6. Les liaisons Si-O sont affaiblies et ces radicaux passent en solution. Les ions hydratés calcium s'éloignent de la zone d'influence des grains de laitier alors que les ions hydratés siliciques restent dans cette zone d'influence. Les ions Al et Mg ont une position intermédiaire."

Dans la seconde étape du processus d'hydratation, il y a interaction entre les éléments basiques au voisinage des grains de laitier et les éléments siliciques, avec formation de gel d'hydrosilicate et d'aluminates hydratés. Dans la mesure où la brucite n'a pas été mise en évidence, on peut considérer que Mg entre également dans la composition des hydrosilicates et aluminates hydratés. Les néoformations constituent une couche qui enveloppe les grains anhydres mais est séparée des grains eux-mêmes par des éléments dont la basicité est inférieure à celle des éléments entrant dans les néoformations.

Cette interprétation du Prof. ROIK est vraisemblablement correcte dans son ensemble mais certains éléments de détail ne sont pas admis par tous les spécialistes."

Intervention du Prof. M. SCHULTZ :

- "Je voudrais vous faire part des idées des spécialistes des verres en ce qui concerne les laitiers. La structure du verre peut être envisagée du point de vue de la structure de phase et du point de vue du problème du voisinage. L'expérimentation permet de se faire une idée de la structure de phase, en particulier la démixtion et la cristallisation, mais les verriers sont actuellement très concernés par le problème essentiel du voisinage immédiat. Je suis d'accord avec le Prof. ENTINE, mais dans les problèmes oxydo-basiques, il faut surtout mettre l'accent sur les questions d'échanges électroniques entre atomes. Mes travaux ont montré que la formation des composés de coordination est essentielle dans les

problèmes de structure des verres. Il faut donc absolument aborder les échanges électroniques au niveau de  $Al^{4+}$  et  $Mg^{4+}$ ."

M. VON EUW :

- "Quelle est l'opinion de M. le Prof. DAIMON pour le Japon ?"

Prof. M. DAIMON :

- "Before beginning our discussion, I think we have better to get agreement in the definition of the word topochemical. When I say topochemical reaction, I mean that the reaction product exists at the place where original unhydrate was, when it is observed by electron microscopy. Therefore, the pseudomorphic hydrate which is stated in the Principal Paper by Mme REGOURD, should be identical to the topochemical hydrate in this definition. The topochemical reaction can be dissolution and precipitation process if the precipitation takes place very close to the surface of the unhydrated grains and forms a product layer. Such a product layer surrounding the remaining unhydrate tends to play a very important role in the kinetics of hydration especially when the transportation of a certain species through this layer is the rate determining step in the whole hydration reaction. I am feeling that the discussion of hydrolytic reaction is going to show us the potential hydration reactivity of slag and we will be able to have a better understanding of practical reaction rate in the course of topochemical discussion but we know very well that we have so many things left to be solved yet."

M. VON EUW :

- "Mme REGOURD, votre Rapport principal traite des phénomènes d'hydratation et des hydrates formés. Nous serions très intéressés de connaître votre avis : dissolution-cristallisation ou topochimie ?"

Mme M. REGOURD :

- "La réponse du Prof. ENTINE et celle du Prof. DAIMON effacent, me semble-t-il, les désaccords entre les partisans de la théorie topochimique et ceux de la théorie de la dissolution-cristallisation. Favorable à la théorie de LE CHATELIER, dissolution-diffusion-précipitation, je voudrais illustrer mon propos à l'aide de deux microfractographies prises au microscope à balayage et qui figurent dans le Rapport principal III.2.11.

La première photo représente une lamelle porte-objet sur laquelle a été déposée une goutte de suspension de laitier dans une solution normale de soude. Le grain de laitier est couvert de C-S-H et des cristaux de géhlénite hydratée  $C_2ASH_8$  ont précipité loin du grain anhydre. Mais sur la lamelle elle-même, nous observons clairement des silicates hydratés C-S-H. La présence de silice dans l'hydrosilicate, loin du grain de laitier anhydre, peut être considérée comme une preuve du processus dissolution-diffusion-précipitation.

La seconde photo montre un grain de laitier dans une pâte de 90% laitier + 10% gypse. Le grain de laitier est effectivement entouré d'une couche d'hydrate dont la formation pourrait être interprétée comme le résultat d'une réaction topochimique. Mais, dans ce cas, les forces de liaison entre grain anhydre et

hydrate progressant vers le centre du grain devraient être des liaisons fortes et le C-S-H ne devrait pas se détacher aussi facilement du grain anhydre. Par contre, ce C-S-H pseudomorphique me semble être l'image du caractère limité de la diffusion des ions au travers de la solution dans la pâte de ciment. L'hydrate insoluble précipite en grande partie là où la sursaturation de la phase aqueuse interstitielle est la plus forte c'est-à-dire à proximité de la surface réactive du grain de laitier. Une autre fraction d'hydrate peut précipiter, loin du grain, dans des régions moins saturées et sa composition ne sera pas exactement la même que celle du C-S-H formé à l'interface grain anhydre-solution. Ces notions de distance de diffusion et précipitation ont été clairement mises en évidence par M. VERNET dans une communication à ce Congrès grâce aux observations simultanées de la phase solide et des analyses ioniques des solutions.

Fig. 1 - Activation sodique : C-S-H sur le grain de laitier et sur la lamelle porte-objet, cristaux de  $C_2ASH_8$

Fig. 2 - Activation sulfatique : ettringite et C-S-H compact autour du grain de laitier.

La texture du C-S-H provenant de l'hydratation du laitier est différente de celle formée à partir des silicates du ciment portland. Elle est plus dense et moins bien structurée : elle apparaît amorphe à l'observation microscopique (Fig. 2). Au voisinage immédiat des grains anhydres, le C-S-H du laitier a une composition plus riche en alumine et en magnésie que le C-S-H du clinker. Les analyses à la microsonde

électronique révèlent un enrichissement très net en Mg de la couche d'hydrate entourant les grains de laitier (Fig. 21 (a), Communication principale III. 2/21). La diffusion de Mg apparaît donc très limitée. C'est un point particulier que le Prof. ENTINE a mentionné et qui demande de nouvelles études approfondies bien que la présence de  $Mg(OH)_2$  n'ait pas été décelée.

La faible porosité du G-S-H du laitier joue un rôle important dans la résistance chimique des ciments au laitier, en s'opposant à la diffusion des ions agressifs tels que  $Cl^-$  et  $SO_4^{2-}$  contenus dans l'eau de mer (Fig. 21 (c), Communication principale III. 2/21)."

M. VON EUW :

- "Les travaux communiqués par M. VERNET semblent en effet bien faire une démonstration intéressante de la théorie de la dissolution-cristallisation applicable aux ciments de laitier.

Ce chercheur présente d'ailleurs un poster expliquant sa méthode. Nous pourrions lui demander de nous résumer ses résultats."

M. C. VERNET :

- "Nous avons appliqué les méthodes développées dans le poster à l'étude de nombreux ciments pour lesquels nous avons fait des observations simultanées des phases solides et de la solution correspondante. Ces observations nous conduisent à penser que le mécanisme de dissolution-cristallisation de LE CHATELIER s'applique à l'hydratation des ciments de laitier, comme à celle des ciments portland. En effet, il existe une correspondance permanente entre la composition ionique et les vitesses de réaction des phases solides. Les concentrations résultent de la différence entre les flux ioniques de dissolution et de précipitation : tant que cette différence n'est pas nulle, l'énergie libérable (après hydroxylation superficielle des anhydres) est utilisée à maintenir un certain taux de sursaturation, moteur de la cristallisation et de l'évolution du système vers l'équilibre thermodynamique, qui ne peut être atteint que lorsque les anhydres ont disparu, et que la vitesse de précipitation tend vers zéro.

Cette sursaturation est illustrée par la première figure, où l'on voit le trajet du point figuratif (F) des concentrations en chaux et silice, qui se déplace dans le diagramme chaux-silice eau pendant la lixiviation du ciment portland. Dès les premières minutes, F parvient en  $R_1$  dans le domaine sursaturé qui se trouve au-dessus de la courbe (G - correspondant à l'équilibre du C-S-H). Le trajet  $R_1-R_2$  est de nature cinétique : c'est le résultat d'une compétition entre la vitesse de dissolution et la vitesse de précipitation, qui est ici très grande : en effet, ce trajet est voisin de la courbe (M - correspondant à la nucléation rapide de C-S-H), établie par D. MENETRIER. Malgré la dilution par l'eau de lixiviation, ce qui devrait produire une sous-saturation, le point F continue ensuite un trajet voisin de la courbe G, mais toujours dans le domaine sursaturé.

Voilà bien une preuve expérimentale de l'existence d'un mécanisme de dissolution-précipitation. Mais ceci n'exclut aucunement l'intervention des phénomènes à l'interface réactionnelle, par exemple :

1°) Au premier contact avec l'eau, la formation d'une couche hydroxylée, par chimisorption d'eau, ce qui est prévu par les calculs du Prof. BARRET, et

observé par le Prof. FIERENS, qui a montré l'existence de "défauts" électroniques de la surface où cette réaction est plus intense.

2°) Des phénomènes de chimisorption d'ions calcium libérés par la dissolution et créateurs de barrières de potentiel. Ceci a été observé par la mesure du potentiel  $\zeta$  et plus récemment, par spectroscopie de photo-électrons (mesures de D. MENETRIER et de M. REGOURD).

Fig. 1 - Diagramme d'équilibre de C-S-H.

Le mécanisme de LE CHATELIER, qui implique une composition ionique commandée par des paramètres cinétiques, nous a amené à introduire deux concepts nouveaux qui en sont la conséquence :

- d'une part, le concept de couplage entre phases,
- d'autre part, le concept de distance de précipitation.

Le couplage entre phases permet d'analyser la "personnalité" de chaque ciment, y compris celle des ciments de laitier, ce que nous allons illustrer par la Figure 2. Ce diagramme simplifié montre l'évolution de 5 paramètres durant 3 des 4 périodes de l'hydratation d'un ciment à 75 % de laitier. Pendant la période II ou "période dormante", la solution se sature en chaux. Comme l'a très bien expliqué F. YOUNG, il y a de bonnes raisons expérimentales de penser que la croissance de la portlandite est alors empêchée par un empoisonnement (par la silice dissoute), jusqu'au temps  $t_2$ , où la sursaturation est telle que cette croissance peut s'effectuer. Il y a alors précipitation de la portlandite, annoncée ici par la chute de conductance, au début de la période III (courbe [1]). Toutes les vitesses de réaction augmentent alors : celle du laitier, dont la teneur diminue de manière significative (courbe [2]), celle de  $C_3S$ , qui augmente le flux thermique et celle de  $C_3A$  (qui est ici une solu-

tion-solide orthorhombique, riche en sodium et potassium et dont la vitesse est repérée par l'ion  $\text{Na}^+$  qui sert de traceur) (courbe [3], en bas).

La précipitation de la portlandite a donc produit un couplage des réactions :

- par effet chimique (sur  $\text{C}_3\text{S}$ ) en abaissant la teneur en chaux dissoute,
- par un effet thermique (couplage  $\text{C}_3\text{S}-\text{C}_3\text{A}$ ),
- et par les deux ensemble (effet thermique et chimique sur le laitier).

En conséquence, il se forme du C-S-H et de l'ettringite, plus rapidement que pendant la période précédente. Ceci, d'une part consomme de l'eau libre et, d'autre part, crée dans les mortiers des structures liantes nouvelles, ce qui aboutit à une modification rhéologique qui n'est autre que la prise. Il y a donc coïncidence temporelle entre la vitesse maximale de formation de l'ettringite et la période de la prise, mais ce n'est pas une raison pour affirmer que l'ettringite est la cause du phénomène : les vitesses de formation du C-S-H et de la portlandite passent également par un maximum durant cette période.

Au temps  $t_3$ , la relative accélération des réactions du  $\text{C}_3\text{A}$  et du laitier conduit à la disparition du gypse, qui ne se produit, dans les mélanges riches en laitier, que par une participation du laitier. Cette disparition est suivie d'une chute brutale de la teneur en  $\text{SO}_4^{--}$  de la solution : ceci produit la transformation de l'ettringite en monosulfoaluminate, au temps  $t_4$ , signalé par le minimum de conductance et par un deuxième pic de flux thermique. Il y a, à nouveau, accélération de toutes les réactions, dont celle du  $\text{C}_3\text{A}$  et celle du laitier, qui atteint ici sa vitesse maximale.

Figure 2

Dans le cas des ciments finement broyés, ceci peut même produire la dissolution de la portlandite: la disparition du gypse a donc entraîné un couplage de toutes les réactions, y compris celles des hydrates.

Un autre exemple de couplage est donné dans le Tableau I qui montre la réaction du laitier dès les premières minutes : la consommation de la chaux libérée par le Clinker C7 varie en sens inverse de la basicité des laitiers (donnée par le rapport C/S).

Tableau I - Exemples de couplages chimiques laitier-clinker.  
(Période I :  $t = 10$  min)

Ciments :	Clinker C 7 et			C 7
	Laitier A	Laitier B	Laitier C	CPA
( $\text{Ca}^{++}$ )mM/L	14	1	6	17
C/S des laitiers :	1,33	1,24	1,18	

Le deuxième concept, concept de "distance de précipitation", permet d'interpréter, dans le mécanisme de LE CHATELIER, les variations dans le temps et dans l'espace de la microstructure des hydrates, variations particulièrement importantes dans le cas des ciments de laitier. Notre étude expérimentale de la cinétique de précipitation des C-S-H permet, en effet, de calculer la distance  $d$  parcourue par les ions silicate depuis l'interface de dissolution jusqu'au site de précipitation. Comme le montre la Figure 3, cette distance des écarts ( $X_0 - X$ ) entre concentrations

Figure 3

à l'interface et concentration à l'équilibre et ( $X_d - X$ ), entre concentration à la distance  $d$  et concentration à l'équilibre. Plus le taux de sursaturation est élevé et plus le gradient de diffusion à partir de l'interface est élevé, plus la distance  $d$  devient faible. La Figure 4 montre que la majeure partie des C-S-H va se former à une distance très faible des grains, de l'ordre de l'épaisseur de la couche de diffusion, mais que cependant une certaine proportion d'hydrates peut se former à une distance plus grande, là où la solution est moins sursaturée : on peut donc s'attendre à des différences de structure et de composition entre ces hydrates, formés à des vitesses différentes et dans des zones où les concentrations sont différentes. Et effectivement, la microstructure des ciments de laitiers hydratés correspond bien à ce schéma : on y observe divers types de C-S-H, dont certains cristallisent à grande distance et viennent combler les pores : ceci donne aux ciments riches en laitier une faible porosité et améliore leur résistance en milieu agressifs. De la même façon, le concept de distance de précipitation permet d'expliquer le mode de croissance particulier du C-S-H dans les ciments portland ou le  $C_3S$ .

Figure 4

Ces deux concepts, couplage entre phases et distance de précipitation, qui sont l'aboutissement d'un travail expérimental, sur des ciments industriels, et non pas de considérations théoriques basées sur des interprétations de phénomènes pris isolément, permettent donc de replacer le mécanisme de LE CHATELIER dans le contexte de toutes les observations connues, sans négliger les phénomènes de surface ou de diffusion qui l'accompagnent."

#### 4. PROPRIETES PARTICULIERES DES CEMENTS DE LAITIER

M. VON EUW :

- "Il est connu que les ciments de laitier présentent l'avantage d'une faible chaleur d'hydratation et également la qualité d'une grande résistance aux attaques chimiques.

Une autre propriété spécifique de ces ciments est leur très grande résistance à la diffusion des chlorures. Cette propriété est probablement liée à la faible porosité des pâtes de ciments de laitier signalée par plusieurs auteurs dont SERSALE.

Dr SMOLCZYK nous aimerions vous entendre sur ce sujet."

Dr H.G. SMOLCZYK :

- "The high resistance of BFC against the diffusion of chlorides into the concrete is "State of Knowledge" meanwhile. Another wellknown fact is the very low permeability of BFCs. The reason for this advantageous effect of the blast-furnace slag is not a distinctly lower total porosity of the cement paste. The reason is the distinctly lower amount of bigger pores with ratio of  $> 300 \text{ \AA}$  or  $> 1000 \text{ \AA}$  which decreases with increasing slag content. The result of this favourable pore-size distribution is an elevated resistance against the penetration of salt-solution and ions, for sure.

However, this explanation is not sufficient. We meanwhile know that even the diffusion of sodium-chloride is a much more complicated reaction than the mere moving of the dissolved salt through capillary pores. In our studies on concretes in 3 mol NaCl-solution, we compared the quantitative amounts of penetrated Na- and Cl-ions. It became evident that the molar ratio of chloride to sodium was 2 to 1 instead of 1 to 1. That means that a chemical reaction evidently did occur and hydroxyl-ions had to move out of the concrete."

#### 5. LAITIERS D'ACIERIE

M. VON EUW :

- "Nous avons discuté uniquement jusqu'ici des laitiers de haut fourneau. Il me paraît juste et intéressant d'aborder maintenant les recherches sur les laitiers d'aciérie et ensuite sur les scories de métaux non ferreux.

Plusieurs auteurs proposent de valoriser les propriétés hydrauliques des laitiers d'aciérie.

. WANG YU JI classe ces laitiers en fonction de leur teneur en  $C_3S$  et  $CaO$  libre.

. GEORGES et SORRENTINO modifient la composition en cours d'affinage de la fonte pour donner aux scories BOP des propriétés hydrauliques."

- "M. LUO SHOUSUN vous avez présenté une brillante communication consacrée aux laitiers d'aciérie. Voulez-vous, en particulier, nous faire part de vos conclusions sur l'influence de  $MgO$  ? Vous préconisez aussi un ajout de  $MgSO_4$  pour éviter l'expansion du périclase. Comment expliquez-vous cette action ?"

- "The initial idea of using steel slag to make cement in China dates back to the early seventies. Today, the annual production of steel slag cement amounts to more than 100,000 tons not including the steel slag used directly as binder in the making of concrete products. The gypsum steel slag cement, made at the plant in Pekin, has a 28 day compressive strength of 44N/mm<sup>2</sup>. The mortar brick which is made from this has a cement/sand ratio of 1 to 3 and W/C about 0.3. The slag cement concrete made with cement/aggregate ratio of about 1 to 4 after carbonation treatment has a 28 day compressive strength of 20 to 30 N/mm<sup>2</sup>. Both the cement mortar and concrete specimens have proved to be sound after autoclaved tests. The present contribution deals mainly with the relationship between the form and the content of magnesia (the used steel slag from the open hearth and the electric furnace) and the long term durability or soundness of the cement made thereby. According to the author's investigation with optical microscope and actually diffraction pattern studies, the steel slags were found to exist in three forms : firstly, in the form of combined states mainly as merwinite or monticellite, secondly, in the form of free state as periclase and thirdly, in the form of RO phase.

The long term soundness of the steel slag cements as accesses from results of autoclave tests is related with a form or state of magnesia and the radical contained in the diverted oxide present as RO phase.

The chemically combined magnesia has not, but the free apparently has harmful effect. The effect of magnesia in form of RO phase on soundness of cement is determined by the magnesia to ferrous oxide plus manganese oxide ratio. The cement is sound when the ratio is said to be less than 1, but it is often unsound when the ratio exceeds 1. The long term soundness of the resulting steel slag from the electric furnace can be favorably improved by the addition of magnesium sulfate or a preparation of siliceous materials or granulated blast-furnace slag and further by carbonization treatment."

## 6. SCORIES DE METAUX NON FERREUX

M. VON EUW :

- " Ces produits s'apparentent plus à des pouzzolanes artificielles et je craindrais d'empiéter sur le domaine du Thème IV. En effet, les travaux de LANEUVILLE sur les scories de nickel et ceux de BARAGANO sur les scories de cuivre sont basés sur les méthodes d'essais des pouzzolanes. Ils mériteraient à mes yeux d'être discutés par le Prof. MASSAZZA."

- "Cependant, les scories de la métallurgie du magnésium, étudiées par CARLES-GIBERGUES sont douées de propriétés hydrauliques. Nous serions donc heureux d'entendre M. CARLES-GIBERGUES".

M. A. CARLES-GIBERGUES :

- "Le laitier de magnésium provient de l'Usine de Marignac qui produit du magnésium selon le procédé Magnetherm. On réduit la dolomite, préalablement décarbonatée, par du ferrosilicium additionné de bauxite. Le magnésium se dégage à l'état de vapeur ; le four est alors ouvert puis retourné au-dessus d'une fosse pleine d'eau. On recueille ainsi un laitier granulé, poreux, friable, de granulométrie comprise

entre 0,2 et 10 mm. Par ailleurs, une fraction moins importante du bain (le tiers environ) reste collée aux parois du four : elle se refroidit lentement à l'air et se délite en une poudre qui constitue le laitier fusant (surface spécifique voisine de 1800 cm<sup>2</sup>. g<sup>-1</sup>). Ce laitier est très différent des laitiers de fonte.

a) - Par sa composition chimique tout d'abord :

L'examen du Tableau I montre qu'il est beaucoup plus basique que les laitiers de fonte Thomas français.

Tableau I : Compositions chimiques moyennes des laitiers de :

	Magnésium	Fonte Thomas
SiO <sub>2</sub>	25	31 - 36
Al <sub>2</sub> O <sub>3</sub>	14	11 - 18
CaO	54,2	42,2 - 45,4
MgO	3,9	3,8 - 5
i = CaO/SiO <sub>2</sub>	2,17	1,25 - 1,45

b) - Par sa composition minéralogique ensuite :

Le laitier fusant est presque entièrement cristallisé : à l'état essentiellement de  $\gamma$ -C<sub>2</sub>S et, en faibles quantités, sous forme de périclase et d'aluminate de calcium C<sub>12</sub>A<sub>7</sub>. Le laitier granulé, pour sa part, est largement cristallisé. La Figure 1, qui est une interprétation d'examen à la microsonde électronique montre que les cristaux, pour leur grande majorité, sont de gros individus (30 à 80  $\mu$ m) de silicates bicalciques,  $\alpha'$  et  $\beta$ , au sein d'une matière interstitielle, vitreuse, hétérogène. Cette dernière est globalement caractérisée par un rapport molaire  $\frac{C + M}{S + A}$

proche de 2. La prépondérance de l'aluminium sur le silicium (11 Al pour 2 Si) a amené, localement, des différenciations en petits cristaux d'aluminates de calcium directement hydratés, au cours de la trempe, en C<sub>3</sub>AH<sub>6</sub>. En outre, au contact des cristaux de C<sub>2</sub>S, on note des concentrations en magnésium, qui correspondent soit à du périclase, soit à de la forstérite (M<sub>2</sub>S).

### COMPORTEMENT AU CONTACT DE L'EAU

A la différence des laitiers de fonte, les 2 formes de ce laitier de magnésium, prises séparément ou conjointement, manifestent des propriétés hydrauliques sans qu'il y ait besoin de les activer.

La fraction fusante réagit rapidement au contact de l'eau : les premiers composés hydratés sont décelables moins de 2 heures après le gâchage. L'aluminate C<sub>2</sub>AH<sub>6</sub> est le produit initial de l'hydratation. Par la suite, il disparaît progressivement. A terme, la phase hydratée responsable du durcissement du laitier fusant gâché avec de l'eau est un système ternaire dont le constituant principal C<sub>2</sub>ASH<sub>8</sub> est associé à 2 aluminates de calcium hydratés : C<sub>4</sub>AH<sub>13</sub> et C<sub>3</sub>AH<sub>6</sub>.

Le laitier granulé, même broyé à une finesse comparable à celle de la fraction fusante, est moins réactif : les premiers hydrates ne s'observent qu'à 1 jour. Il s'agit d'aluminate de calcium hydratés et de géhlénite

te hydratée. A long terme  $C_4AH_{13}$  devient prépondérant et  $C_2ASH_8$  est, ici, minoritaire. La formation de C-S-H est probable, mais difficile à mettre en évidence.

Figure 1 - Grain de laitier granulé.

Les deux fractions étant associées, on note l'apparition initiale de  $C_2ASH_8$ . Mais son existence est brève ;  $C_4AH_{13}$  et  $C_2ASH_8$  se développent alors à même vitesse. Là encore, la formation de C-S-H est probable.

#### EMPLOI COMME LIANT, EN PÂTE PURE, DES 2 FORMES ASSOCIÉES

L'élaboration d'un liant optimal conduit donc à associer les deux fractions, après un broyage préalable du laitier granulé. Cette opération est économiquement possible dans un broyeur à barres comme le montre la Figure 2 où la broyabilité du laitier de magnésium de Marignac se révèle bien supérieure à celles de laitiers de fonte.

Nous avons étudié le durcissement de pâtes pures réalisées à partir de mélanges, en proportions variables. Ces essais confirment bien la réaction mutuelle des 2 formes puisque, comme on peut le constater sur la Figure 3, le fuseau correspondant aux mélanges est toujours largement au-dessus des courbes relatives aux deux constituants séparés.

#### CONCLUSIONS : PERSPECTIVES D'EMPLOIS

En conclusion, un liant intéressant peut être obtenu en associant le laitier fusant et le laitier granulé broyé dans des proportions identiques à celles de leur production à savoir, respectivement, 1/3 et 2/3. Ceci n'est pas limitatif et l'on peut, par exemple, envisager 3 autres formes d'emplois.

1) - Mélange utilisé, sans broyage de la phase granulée, en technique routière. L'addition de 10 à

15 % du mélange optimum à une grave siliceuse a permis d'atteindre des résistances à la compression simple de 7,2 MPa.

2) - Fabrication de matériaux cellulaires. En incorporant 1 % de poudre d'aluminium à un mélange, on a obtenu des masses volumiques de  $1 \text{ T/m}^3$  pour une résistance à la compression de 6 MPa et un coefficient de conductivité thermique  $\lambda = 0,15 \text{ W.m}^{-1}.\text{°C}^{-1}$ .

3) - Fabrication de matériaux autoclavés. L'autoclavage du laitier granulé broyé a déjà conduit à des matériaux dont les résistances atteignent 78 MPa."

Figure 2 - Broyabilité du laitier granulé.

Figure 3 - Résistance mécanique en fonction du temps.

## DISCUSSION

by LOU ZONGHAN

It was a great pleasure for us to read Mr. Daimon's paper on the mechanism and kinetics of slag cement hydration; we would like to say something.

Our and other researchers' works in China proved, when only gypsum is added to the acid slag (don't be added any lime or clinker), it has no strength. With the same way, the synthesized  $C_2AS$  or  $CAS_1$  of slag glass will reach the same result too. That is to say, only gypsum can not activate the latent hydraulic property of slag. On the other hand, when a suitable amount of  $Ca(OH)_2$  is added to slag, the slag cement produces strength to some extent, but it is still lower. Granulated blastfurnace slag is an unstable glassphase in the system  $CaO-Al_2O_3-SiO_2$ . The alkaline circumstance in aqueous solution created by lime or clinker, stimulates the activity of slag, brings about the partial disintegration of slag and formation of hydraulic calcium silicate. When the gypsum exists, ettringite will be formed too. The formation of ettringite decreases the concentration of ions  $Ca^{++}$ ,  $SO_4^{--}$  and  $AlO_2^-$  in solution, thus upsets the certain solid-liquid equilibrium established before, and promotes the alkaline stimulation. The fact that the essential function of gypsum to promote the reactivation of alkaline stimulation is generally called "sulphate stimulation". Therefore, we think the alkaline stimulation as a prerequisite for the sulphate stimulation, and the sulphate stimulation further promotes the alkaline stimulation. The continuous activation of the latent hydraulic property of

slag is based on multiply repeated action of the above mentioned two stimulations.

An important problem we should pay attention to is the alkalinity of supersulphate cement. If there were no suitable alkalinity in liquid phase, slag could not be activated and disintegrated. Meanwhile, it is obvious from the phase diagrams of system  $CaO-Al_2O_3-H_2O$  and  $CaO-CaSO_4-H_2O$  that the solution of  $CaSO_4$ , especially of  $Al_2O_3$  is seriously inhibited in saturated solution or nearly saturated with  $CaO$ , this fact shows that the high alkalinity should restrict the formation of ettringite and exertion of latent hydraulic property of slag. Furthermore, the above mentioned conclusions were proved from measuring the reacted slag, the reacted  $CaSO_4$ , the combined water, the heat of hydration, and the strength in the mixture of slag, gypsum and various amount of lime.

In fact, the sulphate stimulation develops fully in supersulphate slag cement with 3-5 % clinker and excessive gypsum, whereas the alkaline stimulation plays an important role in slag Portland cement which consists of 40-60 % clinker and less gypsum. It is clear from above expositions that the two different kinds of slag cement bring out different conditions of hydration, in which hydrated products form in different circumstances and offer different characteristics of properties, for example, ettringite would be different in quantity, growing rate, morphology, transformation, stability and expansion.

Therefore, there are different requirements for the chemical composition of slag for two kinds of slag cement. The requirements for slag portland cement were mentioned in principal reports, as to supersulphate cement, because ettringite is formed much more during hydration and hardening, the suitable amount of  $Al_2O_3$ -content and  $CaO/Al_2O_3$  ratio of slag is necessary. For the most kinds of slag in China, the relation between the strength of supersulphate cement and the

( $2\text{Al}_2\text{O}_3 + \text{CaO}$ ) values is showed as following diagram :

Fig. Relation between chemical composition and compressive strength

We believe, while the researches on mechanism of slag cement hydration and activation of latent hydraulic properties are being carried out deeply, a prospect to make fully effective use of slag in cement industry will appear before us.

## CONCLUSIONS

M. VON EUW :

- " Mesdames et Messieurs,

Au terme de cette matinée, je voudrais tenter de tirer les conclusions de nos travaux.

1. - Les laitiers de haut fourneau et les clinkers de ciment portland sont généralement associés en proportions variables pour constituer différents types de ciments.

On attache couramment aux laitiers ainsi utilisés le terme "d'ajout", c'est-à-dire qu'ils sont considérés comme des auxiliaires du clinker. Cette notion mérite d'être révisée si l'on en juge par les communications consacrées au mécanisme de l'hydratation. Nous avons vu en effet que le laitier et le clinker agissent réciproquement sur leur propre cinétique d'hydratation.

En clair, ceci veut dire qu'il faut optimiser les mélanges en choisissant, si l'on en a les moyens, les "couples de constituants" avec chacun leur finesse propre. La Cimenterie n'est-elle pas la plus apte à réaliser cette opération ?

2. - Nous pouvons grâce aux récentes recherches, faire une analyse de la structure :

- le réseau plus ou moins dépolymérisé de tétraèdres  $\text{SiO}_4$ ,
- les hétérogénéités décelée dans la masse du verre,
- les cristaux ayant germé pendant le refroidissement,
- et les défauts observables en surface, sont autant d'éléments de la structure qui conditionnent la réactivité.

3. - Si nous ajoutons à nos connaissances de la structure, les résultats des recherches sur la cinétique de l'hydratation et sur l'identification des hydrates, nous croyons pouvoir comprendre le mécanisme de l'hydratation.

4. - Ces connaissances étant acquises, il reste à tirer le meilleur parti des propriétés spécifiques de ces sous-produits mis à notre disposition par les diverses métallurgies.

Les chercheurs ont consacré leurs efforts à apprécier la réactivité des laitiers et à optimiser l'utilisation de leur potentiel hydraulique.

Nous avons les moyens de mieux maîtriser l'activation par le clinker et le gypse ; d'autres modes d'activation, étrangers à l'Industrie Cimentière, ont été imaginés.

Enfin, de très récents travaux ont montré que le traitement thermique des bétons de ciment de laitier doit être adapté à chaque ciment, c'est-à-dire à chaque couple laitier-clinker, compte tenu d'un optimum de gypsage.

5. - Les chercheurs qui se sont penchés sur les problèmes posés par l'utilisation des laitiers et scories ont pleinement répondu aux objectifs fixés

pour notre Congrès. Leurs travaux, poursuivis tant dans le domaine de la structure que dans celui des phénomènes d'hydratation, constituent des recherches de base. Ces recherches ouvrent la voie à l'amélioration des produits existants et à la création de produits nouveaux.

Bien sûr, les sidérurgistes et les métallurgistes se soucient d'abord de la production du métal, il n'en reste pas moins que nous pouvons souhaiter et soutenir un effort de recherche et d'adaptation des procédés, afin de réduire cet aspect de "fatalité" appliqué aux laitiers et aux scories.

Ces sous-produits méritent dans les circonstances actuelles une attention particulière si l'on veut bénéficier de leur potentiel énergétique.

### Remerciements :

Je me fais un devoir et un plaisir de féliciter les auteurs de toutes les Communications, des Rapports principaux et des Posters, ainsi que les Membres du Panel pour leur participation hautement compétente à la discussion des sujets traités.

Je renouvelle mes remerciements aux Personnalités qui m'ont confié la Présidence de ce Thème, ainsi qu'à toute l'assistance pour l'attention qu'elle a témoignée à nos exposés et à nos discussions."

## THEME IV

### Structure of pozzolana and fly-ash and the hydration of pozzolanic and fly-ash cements

by F. MASSAZZA

#### 1. NATURE AND CONSTITUTION OF POZZOLANAS

The classification of pozzolanas is a problem still open as they are formed of materials very different from one another in chemical and mineralogical composition, structure and origin.

Actually most of these materials resemble typical Italian pozzolanas, which gave the name to the whole group only in the properties of reacting with lime and of hardening in the presence of water.

The writer made a tentative classification, presented to the Congress of Moscow, which can constitute the base for an useful discussion even if it cannot be considered as perfect (1). Other criteria of classification are contained in Sersale's (2) principal paper and this points out the difficulty of grouping very different materials from one another in a general scheme.

In this report the materials having pozzolanic behaviour will be often called "pozzolana" in the above-mentioned meaning, that is without making any specific reference to the real pozzolanas of the Neapolitan and Latial regions.

##### 1.1 Natural pozzolanas

The great difference in chemical and mineralogical composition and morphology of natural pozzolanas is pointed out in paper (3). It confirms that Rhine trass and Neapolitan tuff contain a small amount of vitreous phase but they are rich in zeolitic phases. In the former chabazite prevails and analcime, feldspar and quartz (10-12%) are present. In the latter herschelite is the major component besides minor amounts of analcime and potassium feldspars. Flegrean (Naples) and Volvic (Puy-de-Dôme) pozzolanas are very rich in glass (50 and 25% respectively). Of course these pozzolanas also contain many crystalline minerals such as, for the flegrean ones, sanidine, analcime, potassic zeolite, quartz, augite and dolomite and, for the Volvic one, abundant anhydrite, quartz, diopside and magnetite. A high silica microcrystalline pozzolana (70.45%  $\text{SiO}_2$ ) essentially consists of opal, traces of quartz and cristobalite, dolomite and phosphates.

A diatomite rich in (~50%) and a gaeze sample poor in (~15%) amorphous silica, used for a study on the hydration of pozzolana-containing cements (4), contain appreciable quantities of quartz and glauconite. The former contains also clayey minerals whereas the latter is particularly rich in calcite (~45%).

##### 1.2 Artificial Pozzolanas

###### 1.2.1 Fly ashes from coal

The chemical and mineralogical composition of coal ashes is less varying than the one of natural pozzolanas: generally silica ranges between 48 and 53%, alumina between 23 and 28%, iron oxide between 7 and 10% whereas lime does not exceed 3% (3)(5)(6)(7)(8). Quartz and sillimanite (5) as well as mullite and magnetite (3) are present besides the predominant vitreous phase. The chemical composition can appreciably vary from the fraction < 40  $\mu\text{m}$  to the one included between 40-80  $\mu\text{m}$  since, if the mineralogical composition is qualitatively the same, the crystallized phases prevail in the fines (5).

Fly ashes can contain considerable amounts of cenospheres which, because of their low apparent density, can be separated in disposal lagoons and used to produce insulating materials (9).

An often neglected constituent of fly ashes is coal. If present in amounts higher than certain levels, it makes fly ashes unusable since it stains the concrete and

adsorbs the admixtures (7). In theory coal can be eliminated by sieving since it is generally concentrated in the coarse fractions (> 100  $\mu\text{m}$ ), or rather by flotation and combustion. However all these procedures have a cost which limits their possibilities of application. In the practice the only valid solution seems to build and to power plants giving fly ashes containing not more than 2-3% of residual coal (7).

###### 1.2.2 Fly ashes from lignite or sub-bituminous coal

The composition of fly ashes from lignite and sub-bituminous coal is different from the one of coal in that they contain considerable amounts of free calcium oxide which can reach 28% (10).

During combustion free lime forms instantaneously, as proved by the very small sizes of its crystals which adhere to the surface of the vitreous particles (5) (17).

The chemical composition of these materials is much more varying than the one of coal fly ashes (11), even within the same deposit, with variations in the silica content also of 13% (12). Obviously this variability has repercussions in the mineralogical composition, as can be noticed in table I.

All these ashes contain considerable amounts of vitreous material and different crystalline minerals. Among these, quartz, mullite, hematite, magnetite,  $\text{CaO}$ ,  $\text{C}_2\text{S}$  ( $\alpha$ ,  $\beta$ ) anhydrite,  $\text{C}_{12}\text{A}_7$ ,  $\text{C}_2\text{F}$  and  $\text{C}_3\text{A}$  besides traces of calcite, periclase and  $\text{C}_4\text{A}_3\text{S}$  were recognized.

The composition of the vitreous mass can be very different from the average one of the sample and the glass can be even richer in alumina than silica (10). The composition of the vitreous particles and therefore their refractive index can considerably vary and this allowed five types of glass to be distinguished (11). The three first types have refractive indexes ranging between 1.620 and 1.640 (vitreous melilite), between 1.670 and 1.720 (glasses perhaps of the system C-F-S since their colour varies from yellow to yellowish brown), between 1.720 and 1.735 (brown or brownish black glasses rich in calcium); the two others are opaque and porous. Glasses of type 2 and 3 have a good hydraulicity because of their high calcium content.

Lignite ashes are richer in glasses of type 2 and 3 than the common coal fly ashes.

###### 1.2.3 Melted ashes

In U.S.S.R. the new thermoelectric power plants produce coal slags, at the liquid state, which are granulated with water (5). Their chemical composition widely varies ( $\text{SiO}_2$  35-65%,  $\text{Al}_2\text{O}_3$  10-25%,  $\text{CaO}$  1-50%,  $\text{FeO}$  up to 20%) and consequently not only the percentage of the vitreous phases but also their composition considerably change.

The recognized crystalline phases, sometimes present in appreciable amounts, are mullite, gehlenite, pseudowollastonite and  $\beta$ - $\text{C}_2\text{S}$ . Of course the presence of glass involves the absence of free lime.

The hydraulic activity of these products increases as the  $\text{CaO}$  content rises but if the  $\text{CaO}+\text{MgO}$  ratio exceeds 1, slags tend to be  $\text{SiO}_2+\text{Al}_2\text{O}_3$  mainly crystalline and the hydraulic activity drops sharply. If however slag has a composition similar to the one of portland cement clinker, its crystallization gives rise to a material containing considerable amounts of alite and belite and having higher hydraulic properties (5).

## 2. EVALUATION OF POZZOLANIC ACTIVITY

The problem relevant to the determination of the pozzolanic activity of a material was the object of thorough studies, clearly summarized in chapter 5 of Sersale's (2) principal paper.

Two reports were presented about the subject which has important technological implications. In the former it is shown that, if the standardization of the method is stricter, Chapelle's test can become more precise. By operating with different cements containing pozzolanas of different origin (natural, melted and fly ashes), a good correlation between amount of lime fixed by pozzolana and amount of vitreous phase determined by X-rays was found (13).

TABLE I

Reference	12	11	10	16	5
Free CaO	X	5-15%	28%	X	7-20%
Glass	X	X	34%	X	X
Quartz	X		5%	X	
Mullite	X				
Hematite	X		4%		
Magnetite	X		4%		
$\beta\text{C}_2\text{S}$	X	X	14%		
$\text{C}_3\text{A}$				X	
$\text{C}_{12}\text{A}_7$	-	X			
$\text{C}_2\text{F}$	-	X			
$\text{CaSO}_4$	-	X	15%	X	X

The decrease with time in the lime present in pastes consisting of one part of lime and four parts of pozzolana can be taken as a measure of the pozzolanic activity of the material. The lime dosage was carried out by X-ray diffraction analysis and it allowed the pozzolanic activity of six studied natural and artificial materials to be clearly differentiated (3). The same study evidenced that the classification of pozzolanas based on the combined lime corresponds to the classification according to the B.E.T. specific surface, so confirming the importance of this parameter on the activity of pozzolanas (3).

Starting from the ascertainment that both chemical and mechanical methods are not able to give an exhaustive evaluation of the pozzolanicity of a material, a new method was proposed. By measuring the mortar strength and the combined lime, four quantities are defined: pozzolanic activity, reactivity, efficiency and relative pozzolanic efficiency.

The overall synthetic characterization is expressed by the index of pozzolanic quality equal to the product of the "pozzolanic reactivity" by the "pozzolanic relative efficiency" (20).

Anyhow the review of the methods to evaluate pozzolanas has once more pointed out the absence of a simple general method valid for all the materials having pozzolanic behaviour (2) (18).

This conclusion depends on that no general correlation

seems to exist between the mechanical strength of pozzolana containing-pastes and the different parameters which, each time, are taken as a measure of the pozzolanic activity (15).

## 3. POZZOLANA-LIME MIXES

### 3.1 Reaction between lime and pozzolana

Sersale's (2) and Takemoto's (18) principal papers examine in detail the mechanism of the lime-pozzolana reaction and the factors affecting the pozzolanic activity. These factors are chemical composition, quantity of active phases, structure, morphology, fineness, specific surface a.s.o.

As regards the compounds forming owing to the lime-pozzolana reaction, the previous results were confirmed, that is most compounds are the same forming during the hydration of portland cement.

The contribution dealing with this subject concern both natural and artificial pozzolanas.

Pozzolanas consisting of lignite or sub-bituminous coal practically behave as an artificial mix of pozzolana and lime since they are formed of vitreous particles accompanied by smaller particles of free lime (4) (11). Therefore these ashes have a good hydraulicity in themselves. In the lime-pozzolana mixes the fixed lime increases as the duration of the reaction prolongs and, at least till 21 days, as the B.E.T. specific surface increases (3). Generally grinding improves the fineness of fly ashes which, being formed of compact microspheres, have a very low B.E.T. surface but it does not appreciably modify the one of natural pozzolanas. Zeolitic pozzolanas react with lime more rapidly than the ones having vitreous structure (3).

The w/s ratio does not affect the mechanism of reaction between the vitreous part of fly ashes and lime but it only acts on the rate of the different reactions (10).

As for lignite fly ashes the pozzolanic reaction occurs naturally after the hydration of free calcium oxide.

By mixing a calcareous lignite ash at w/s = 0.2, free lime decreases linearly as far as to disappear after about 180 days (10), whereas portlandite begins appearing after four hours and ettringite after seven hours. The latter reaches its maximum after about 90 days together with the disappearance of  $\text{CaSO}_4$ . By operating with higher water amounts (w/s=10), free lime disappears after 15 days, portlandite appears after about one hour and ettringite after about one hour and a half (10).

In a lignite ash containing  $\text{C}_3\text{A}$  the X-rays showed that ettringite starts forming before half an hour after the beginning of mixing. Plates of monosulphate hydrate ( $\text{C}_4\text{ASH}_{12}$ ) begin appearing after 4 hours (16). C-S-H gel, probably of type I, is visible under SEM after about 28 days. These gel particles are likely the product of the pozzolanic reaction between glass and lime. The delay in their formation also indicates the slowness of glass to begin the reaction (16). Also in other cases the formation of C-S-H and of other hydrates, such as  $\text{C}_2\text{ASHg}$ , occurs at longer ages, even by operating with diluted suspensions at w/s = 10 (10). Besides participating in the pozzolanic reaction, free lime contained in lignite ashes activates, together with the often present  $\text{CaSO}_4$ , the hydration of glasses,  $\text{C}_2\text{S}$  and other constituents (11). The activating action of free CaO seems to be proved by the fact that lignite ash, melted at 1,350 - 1,450°C and then quenched, loses its hydraulicity since free lime is combined. Indeed it could be maintained that the pozzolanic reaction cannot occur in the absence of free lime.

Nevertheless, it can be assumed that high calcium ashes, similar in composition to metallurgical slags, are activated by  $\text{Ca}(\text{OH})_2$  and  $\text{CaSO}_2$ .

Type I calcium silicate hydrate was also found in fly ashes from sub-bituminous coals. These products form by peeling off the outer surface of the ash particles which would be covered by a coating of calcium compounds (12). The final hydration products would be essentially ettringite wrapped up by tobermorite gel (11). The addition of sodium chloride accelerates the hydration of free lime contained in lignite ashes, the formation of calcium aluminate hydrates and, through the pH decrease, the hydration of silicates. This fact is pointed out by the higher heat of hydration evolved by ashes in the presence of salt (11).

The lime pozzolana reaction can be accelerated by steam curing (3) (5) (10). Interesting results giving a contribution to the interpretation of the variability in the Ca/Si ratio of C-S-H gel were obtained by comparing the reactions of a volcanic glass and a silica glass ( $\text{SiO}_2$  99.97%) mixed with lime at different ratios (17). The tests were performed at temperatures ranging between 70 and 100°C, for reaction times between 2 and 120 days but at a constant water/solid ratio=20. As for the volcanic glass it was found that the initially formed C-S-H and C-S-H(I) transform into 10 Å tobermorite after 20 days and subsequently into 11 Å tobermorite. The microanalysis showed that the former tobermorite has a higher Ca/Si ratio than the latter (about 1.15 compared with 0.93). The same occurs for the Ca/(Si+Al) ratio. On the contrary for the silica glass it was possible to observe the transformation of the initially formed CSH into 14 Å tobermorite having a Ca/Si ratio included between 0.64 (microanalysis) and 0.82 (chemical analysis). The addition of alumina to silica glass tends to decrease the basal spacing and, if the duration of the reaction prolongs, it tends to give Al-substituted 11 Å tobermorite. 12 Å tobermorite or tacharanite and 10 Å tobermorite form as intermediate phases in the presence of alumina. What obtained suggests that each tobermorite having different basal spacing may be a well-crystallized form of C-S-H(I) of different Ca/Si ratio.

As regards the morphology of the hydration products it was observed that, if the hydration products of lignite fly ashes are mostly fibrous after 28 days, hexagonal particles are not lacking (12). These products rich in calcium form on the surface of the spherical ash particles and cause their mutual cementation (12). At first the appearance of the vitreous spheres is unaltered but after seven days the corrosion of their surface and their disaggregation are noticed (16).

### 3.2 Physical and mechanical properties

The presented contributions only considered the physical and mechanical properties of sub-bituminous and lignite ashes. These ashes are used because of self-hydraulic properties suitable to make mortars and concretes (11) and gravel and ash mixes (10).

Lignite fly ashes have a rather rapid set. In fact, depending on the w/s ratio, set begins between 30 and 75 minutes (10) (11) and, in the presence of  $\text{C}_3\text{A}$ , between 15 and 45 minutes (16). Gypsum retards set as it does in cement (11). Below 25°C, a temperature decrease considerably slows down the initial set. The effect is more marked at high w/s ratios (10).

The set of calcareous lignite ashes mixed with water was attributed at first to the formation of portlandite and then to ettringite (10), or directly to the latter (16).

Excellent micrographs show that set is really due to ettringite needles protruding from the individual ash spheres, often perpendicularly, and acting as connection bridges (16).

Generally the presence of free calcium oxide makes the lignite and sub-bituminous coal ashes unsound. The pastes, even if made with different w/s ratios (0.166-0.30), show the same typical behaviour: after an initial volumetric shrinkage the samples swell rapidly and considerably in times ranging between 10 and 40 hours, depending on the water content. Initial shrinkage is attributed to the volume decrease accompanying the water-lime reaction whereas swelling, and therefore cracking and disaggregation of the pastes, are ascribed to the formation and crystallization of ettringite (10).

However it is also reported that the use of lignite ashes containing up to 15% free lime causes no negative effect on the soundness of mortars and concretes (11). Expansive ashes added in small amounts (3-5%) to coarse aggregates (e.g. road gravel), cause no unsoundness and give strengths over 15 N/mm<sup>2</sup> to the mix.

By mixing sub-bituminous coal ashes with water in order to attain the highest density (12-20%), it is possible to obtain materials that, after 28 days' wet curing, have strengths ranging between 0.7 and 6.3 N/mm<sup>2</sup>.

Nevertheless these samples, immersed in water, disintegrate before two weeks (12). The great differences in strength and hardening rate of these samples must be attributed, more than to pozzolanic reactions having different rates, to the different content in promptly reactive calcium silicates and aluminates (12).

Opposite results were obtained with lignite ashes which, in spite of their free lime content, gave strengths of 29.0 and 33.4 N/mm<sup>2</sup> at 7 and 28 days. These values increase to 33.4 and 44.8 N/mm<sup>2</sup> respectively if gypsum is added or to 44 and 56.4 N/mm<sup>2</sup> respectively by addition of NaCl (11).

To conclude, the available information about fly ashes containing free lime is contradictory and insufficient to preconize their use in the field of hydraulic binders. Therefore their knowledge needs to be deepened by studying their chemical and physical properties and their applicative characteristics.

## 4. POZZOLANA-PORTLAND CEMENT MIXES

### 4.1 Reactions in mixes containing cement and pozzolana

In pozzolana-containing cements the hydration reactions of clinker and pozzolana can be considered separately, even if to a certain extent they occur simultaneously. In fact the pozzolanic reaction, which is anyhow slower than the hydration reaction of clinker, can take place only after the hydrolysis of alite and belite has formed  $\text{Ca}(\text{OH})_2$ .

As regards the pozzolanic reaction, since the components mainly involved are  $\text{SiO}_2$ ,  $\text{Al}_2\text{O}_3$ ,  $\text{Fe}_2\text{O}_3$  and  $\text{CaO}$ , it is not surprising if the obtained products are the same forming during the hydration of clinker. The subject is exhaustively treated in the wide and documented chap. 3 of Takemoto's principal paper (18), where the process and the mechanism of hydration of the systems formed by pozzolana with the clinker constituents and portland cement are examined. Here, of course, the main points of the contributions dealing with this subject are recalled.

X-rays showed that cements made with different pozzo-

lanas give the same hydrated phases even if the quantitative ratios can be different (4). The value of B.E.T. specific surface of the hydrated pastes depends on the nature of pozzolanas. In any case it is higher than the one of the control cement and it presents a maximum value at 28 days' curing (4). Also the pore distribution depends on the type of pozzolana and the duration of curing (19).

At 7 days' hydration the pozzolanic reaction has already begun (20) even if the contribution given by the pozzolanic material to the hydraulic properties of clinker would occur only at relatively long ages: 6 months, 1 year and longer (13). Nevertheless it was indicated that the reactions involving pozzolana begin already after 3 days (8), or even after 1 day (19), that is before the time reported by other Authors.

A layer of C-S-H forms on the surface of the ash grains owing to the attack of the solution supersaturated with  $\text{Ca}(\text{OH})_2$ . This layer, which appears in the form of plates and discs, has a lower Ca/Si ratio than the fibrous C-S-H (outer and inner) forming on the clinker grains (20).

Aluminate hydrates and ettringite, forming initially, transform afterwards into monosulphate and the solid solution  $\text{C}_3\text{A}(\text{CaSO}_4, \text{Ca}(\text{OH})_2) \cdot \text{H}_2\text{O}$  (4) (19). After one year, cements containing 20% of different types of pozzolana show the presence of ettringite,  $\text{C}_4\text{AH}_3$ , C-S-H and  $\text{Ca}(\text{OH})_2$  (4) (3). C-S-H forming on the ash and pozzolana grains has a lower Ca/Si ratio than the cement paste (3). At long terms the ash-cement hydration products have morphology similar to the one of type I and III calcium silicates (8). In any case the peculiar morphology depends on the clinker composition, the hydraulic activity of ash, its fineness, its quantity and the degree of hydration reached at a given time (20). The lower early strength of cements containing pozzolanic additions is attributed to the fact that the interaction products between the grains of pozzolana (burnt shale) and the solution supersaturated with  $\text{Ca}(\text{OH})_2$  appear in the form of needle-shaped crystals which are not able to grow continuously in length and have few and weak points of contact. Another cause contributing to decrease early strengths lies in that the additions accelerate the hydrolysis of clinker silicates. This results in the formation of many and short filaments having few points of contact with one another. Subsequently these elements entangle forming a thick skeleton and the cement paste increases in strength (20). Another factor contributing to retard the hardening of fly ash-containing cements is the slowing down of the  $\text{C}_3\text{A}+\text{C}_4\text{AF}$  hydration. In fact by adding fly ashes to  $\text{C}_3\text{A}+\text{C}_4\text{AF}$  separated from the clinker silicates by maleic acid methanolic solution, it was seen that the hydration of the two compounds is much slower than the one observed when an equal amount of ground quartz is added. It was even noticed that fly ashes have a higher retarding effect than gypsum (8). Pozzolanas also decrease the hydration rate of synthetic  $\text{C}_3\text{A}$  but in the presence of  $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$  they cause an acceleration. In this case, the pozzolana accelerates the hydration of tricalcium aluminate since its grains offer the precipitation sites of the formed ettringite. The reaction rate of  $\text{C}_3\text{A}$  also depends on the nature of pozzolanas (composition, specific surface, capacity of ion exchange) (19).

## 4.2 Physical and mechanical properties

### 4.2.1 Influence of the nature and the proportion of constituents

Owing to the relative slowness with which the reaction

between clinker hydrolysis lime and pozzolana proceeds, the pozzolana-containing cements generally have lower early strengths and higher ultimate strengths than control cements.

In any case the strength of the pozzolana-containing cements depends on the nature of pozzolana (3)(8)(10) (13) and its content, at both short and long ages. Similarly, the highest strength obtainable from an ash depends on the composition of clinker (21).

The replacement of 10-35% portland cement with pozzolanas of different nature (9000 Blaine) yield, before 28 days, a lower mechanical strength (in ISO mortar) than the portland cement ground to 3200 Blaine. Till 11 days and at 20°C the strength of mortars decreases proportionally to the increase in the ash content (22). This fact indicates that, till this age, ashes give no contribution to strengths. However after 28 days the strengths at 20°C decrease less than proportionally to the ash content and this shows that the pozzolanic reaction has begun (22).

Also the free calcium hydroxide content of the pastes justifies the mechanical behaviour of mortars. In fact  $\text{Ca}(\text{OH})_2$  is proportional to the clinker content till 11 days' curing at 20°C but it is lower than the proportional value for longer times (or higher temperatures) (22).

In a study extended to six different natural and artificial pozzolanas it was noticed that a correlation between lime fixed in pure pastes and compressive strength in ISO mortars only exists between six months and one year (3).

Tests carried out on mortars made with many cements containing pozzolanas of different origin showed that, as from 180 days, it is possible to correlate the increase in the long term-strength with the amount of fixed lime measured by the modified Chapelle's test (13).

Of course, if the pozzolana is added in excess, a part of it cannot find the lime which to react with. Therefore the addition of 45% pozzolana justifies that the strengths of the blended cements were always lower than those of the control portland cement, till 300 days (4).

By replacing 20% of a portland cement with a fly ash, it was observed that in ISO mortars the strengths of the blended cement exceed those of the control cement after about 150 days' curing (6). However the overtaking moment also depends on the composition of clinker since it was seen that mixes of clinker, containing more than 8%  $\text{C}_3\text{A}$ , and fly or melted ashes exceed the strengths of control cements already between 28 and 90 days, depending on their preparation (13).

The long term-strength increase as the ash content increases (within certain limits) is explained not only by the well-known pozzolanic effect but also by the fact that ashes retard the  $\text{C}_3\text{A}$  and  $\text{C}_4\text{AF}$  hydration. This has, as a counter-effect, the possibility of increasing the volume of calcium silicates (8).

At the same w/c ratio, the ash content increase is accompanied by a slump increase of concretes (8) but it must be reminded that ground ashes demand more water than the original ones (5).

Tests on concretes showed that the replacement of 15% portland cement with fly ashes increases strengths at both 3 days and 91 days' curing, whereas the substitution of 30% improves strengths only after about two months. Higher contents always give lower strengths than the control sample (8).

Chapter 4 of Takemoto's (18) principal paper summarizes the works that, after the Moscow Congress, were carried out to relate the mechanical strength of pozzolana-containing cements to many variables. The

strengths of pozzolanic cements depend, as the one of portland cements, on the texture of the hardened pastes, the composition of the hydrated phases, the capillary and gel porosity, the shape of the gel pores, the pore size distribution and, of course, the nature of pozzolana.

#### 4.2.2 Influence of temperature

The temperature rise accelerates the hardening of pozzolana-containing cements as it does for portland cements. At 80°C it was observed that only 1/25 of the time demanded operating at 20°C is necessary to reach a certain strength (3). At higher temperatures portland cements show a strength decrease whereas those containing 35% ashes indicate a sharp increase which reaches the maximum value at 28 days (22).

Curing temperatures above 20°C (35-80°C) improve the strength of a cement containing 20% fly ashes more than it does for the control portland cement (6). Also by using steam curing, the cements containing fine fractions (<40 µm) of a fly ash show lower strengths than those containing coarser fractions (40-80 µm) (5).

#### 4.2.3 Influence of fineness

The addition of fly ashes to portland cement having the same fineness involves a 28 day strength decrease. A longer grinding time improves the compressive strength but increases the energy consumption (7). From this standpoint it would be suitable to mix portland cement with already very fine ashes.

Anyhow it must be considered that the grindability of ashes and pozzolanas is generally higher than clinker and therefore in the intergrinding the fine fractions are richer in ash and the coarse ones in clinker. Since the latter is the constituent that more contributes to the short and medium-term strengths, it is understood why the early strengths of blended cements are often lower than portland cement (6) (21). Therefore it is clear that the fineness of clinker needs to be increased in order to obviate this inconvenience (6). In fact the pregrinding of clinker, followed by an intergrinding, produces 10-20% ash cements having mechanical strengths practically equal to those of the control cement in the 1-90 day range and higher after 180 days' curing (21). The optimum parameters of this process, such as time and specific surface, depend on the quality of clinker and ash (21).

To find the best conditions of grinding, as regards both mechanical strength and energy consumption, the grinding of fly ash-containing cements can be carried out according to different ways. With 15% fly ash, the best performances were obtained by intergrinding, whereas with a content of 30% the best results were achieved by separated grinding (7). It is obvious that different results can be obtained by using other materials but, as a general rule, this procedure allows the best grinding conditions to be chosen. In any case it was seen that at constant specific consumption (kwh/t), the short term-strengths improve if clinker is ground more finely whereas the 90 day strengths increase if ashes are ground longer.

Till 1-3 months cements containing the finest fractions of two fly ashes (<40 µm) show lower strengths than cements containing the coarser fractions (40 - 80 µm), whereas subsequently this behaviour reverses.

This fact is explained by observing that the fine fractions have a much higher surface than the coarse ones. Therefore the annular volume filled with the liquid

phase forming around the ash grains at the beginning of the hydration is on the whole higher. Subsequently when the pores are filled enough with the newly formed compounds the strength of cements containing the finest fractions become higher (5).

#### 4.3 Heat of hydration

The addition of pozzolana (or limestone) decreases the heat of hydration but accelerates the appearance of the maximum thermal effect. The latter action is attributed to the fact that pozzolanas, since they absorb lime from the solution, accelerate the hydration of clinker whereas limestone reacts, with considerable thermal effect, with C<sub>3</sub>A forming C<sub>3</sub>A.CaCO<sub>3</sub>.12H<sub>2</sub>O. Moreover, all the additions have a dispersing action, which facilitates the contact of water clinker. Simultaneously their grains act as crystallization nuclei during the early hydration (8). This acceleration of the hydration process is confirmed by the fact that a lite disappears more rapidly in the cements containing additions (4).

#### 4.4 Dosage of pozzolana in cements

The dosage of the pozzolana contained in a blended cement constitutes a problem of increasing importance. An interesting attempt was made on this subject by using the quantitative X-ray diffraction analysis (Q X DA) to determine the index of crystallinity of the pozzolanic addition, defined by the ratio:

$$M = \frac{I_{\text{tidi}} - I_A}{I_{\text{tidi}}} \times 100$$

where:

$I_{\text{tidi}}$  = total integrated diffracted intensity

$I_A$  = integrated diffracted intensity of "amorphous halo"

The tests were limited to fly ashes, but also in this case acceptable results are obtained only when the ash used in calibration has an index of crystallinity similar to the one of the unknown mix (23).

#### 4.5 Durability

While it is generally accepted that the resistance to the chemical attack of pozzolana-containing cements is higher than portland cements, doubts arise on the ability of these cements to efficaciously protect the reinforcement. The pozzolanic reaction, as it fixes lime, reduces the alkalinity and therefore it accelerates the neutralization caused by carbon dioxide in the air. However, it is reported that in fly ash-containing mortars not all lime is fixed and the remainder is anyhow sufficient to maintain a pH = 12.5 in the solution and therefore to assure a good protection to the reinforcement (22).

The results of a 10 years' study on the influence of fly ashes on the neutralization of concrete, where the classical method of the colouring by phenolphthalein was used, are given in contribution (24). The test showed that, at the same workability, the depth of neutralization decreases as the cement dosage becomes higher and increases as the ash content rises. The depth of

neutralization results to be proportional to the square root of the time, with a coefficient of proportionality increasing with the w/c ratio. The depth of neutralization results to be inversely proportional to the 28 day strength, regardless of the addition of fly ashes. Anyhow the depth of neutralization of concretes having strengths over 40 N/mm<sup>2</sup> practically tends to zero. It is lower for long cured concretes and, very interesting fact, for the ones in the open. The mechanical strength of cement mortars containing pozzolana (45%) is higher than the one of the control portland cement if they were immersed for three years in solutions containing 2% Na<sub>2</sub>SO<sub>4</sub> and MgSO<sub>4</sub>. It is lower if they have been water-cured for the same period of time. Indeed the strength of pozzolanic mortars cured in water or in the two solutions is the same (4).

To conclude this necessarily short review on pozzolanas and pozzolanic cements it can be noticed that their use is growing and that about this matter studies and research are spreading all over the world. This means on one hand that pozzolana containing cements have excellent performances and on the other they offer economical advantages above all in connection with the energy saving that they allow.

## ROUND TABLE

F. Massazza (Italy) Chairman, K. Takemoto (Japan) and R. Sersale (Italy), principal reporters, Messrs. A.M. Dmitriev (USSR), R. Magnan (France), P. Longuet (France), J. Skalny (USA) participated in the round table on Theme IV.

The round table examined and discussed numerous subjects whose scientific and practical importances were pointed out in the principal papers and the contributions presented to the Congress.

The conclusions reached can be shortly summarized as follows:

### a) Evaluation of the pozzolanic activity

The pozzolanic activity, even if it is the object of many studies, was not yet a simple definition and its evaluation cannot be obtained through an only test. In fact none of the different experimented methods showed to have a general validity since each method generally tends to take, as an index of the pozzolanic activity, a particular property which instead constitutes only one of the numerous parameters characterizing a pozzolanic material. As a consequence, the different methods give good results if a certain family of materials, characterized by the constance of certain parameters, is considered whereas they fail when they are extended to other materials.

### b) Structure and composition of pozzolanas and their reactivity

The reactivity of natural and artificial pozzolanas depends on many chemical, structural and morphological factors. All pozzolanas are characterized by the presence of (vitreous, amorphous or zeolitic) phases rich in silica unstable in the presence of calcium hydroxide. The reactivity of these phases mainly depends on the chemical and mineralogical composition and the BET specific surface. In fact vitreous phases of different composition and pozzolanic activity can be found in certain pozzolanas whereas in others the reactivity can be lowered by reducing their specific surface through thermal treatment and causing the vitreous phases to crystallize.

In some countries, besides the traditional coal fly ashes, also basic fly ashes begin to be used. They result from the combustion on lignites and sub-bituminous coal which can contain up to 28% free lime and therefore be self-hardening.

The negative consequences of the presence of not combined CaO in mortars and concrete were pointed out by different research. Nevertheless it was also reported that lignite ashes containing up to 15% CaO do not cause volume instability probably because the CaO grains are very small and hydrate before

the hardening process starts. The problem of the basic fly ashes, which is already important to day and will be still more in the future, demands other thorough studies to verify the fields and limits of use of these materials.

### c) Relationship between chemical reactivity and mechanical strength

No doubt that there is a relationship nature-reactivity-performances of pozzolanas. Nevertheless it is not yet possible to foresee their performances even if their nature or reactivity is known. In fact the former are conditioned by several factors, sometimes badly known. For example by using a given pozzolana considerably different performances can be obtained by mixing it with different clinkers.

### d) Difference between natural and artificial pozzolanas

The differences between natural and artificial pozzolanas are not deeper than those existing in each group. In this connection it is sufficient to remember the considerable differences findable among natural, vitreous and zeolitic pozzolanas. The most homogeneous group is perhaps represented by coal fly ashes whose genesis and composition are very similar.

### e) Importance of pozzolanas in the energy saving

The importance of pozzolanas in the energy saving is emphasized by the following data relevant to 1979.

About 6 millions of tons of natural and artificial pozzolanas were used to make cements in USSR. Italy used about 5 millions of tons of pozzolanas for the manufacture of about 15 millions of pozzolanic cements. In France, besides natural pozzolanas, one million of tons of fly ashes was used to make different types of cement. These data are obviously partial but give an idea of the importance that pozzolanic materials have in the cement industry, taking into account that natural and artificial pozzolanas are largely used also in many other countries. Considering that substituting ten tons of portland cement for as many of pozzolana involves a saving of about one ton of fuel, it is possible to have a clear idea of the amount of energy saving allowed by the use of pozzolanas.

### f) Performances of cements containing pozzolanic additions

As for the performances of pozzolana-containing cements, the fact that they are used all over the world is the best proof of their excellent characteristics.

Some deficiencies in the performances observed in pozzolanic cements compared with portland cements can sometimes be attributed to unsuitable technological cycles of production rather than to intrinsic quality deficiencies of the former.

As for durability and chemical attack resistance, it is possible once more to refer to the ancient works, especially the ones built by the Romans with mortar and pozzolanic concretes, but also recent studies indubitably prove the favourable action exerted by pozzolanas.

## ORAL CONTRIBUTIONS

### Mechanism of the pozzolanic reaction

The study of the mechanism of reaction of pozzolanas has recently been faced in a new light which could give an important contribution to the knowledge of these materials.

For this reason R. DRON was asked to present the results obtained in the laboratory of Ponts et Chaussées of which we give a short summary.

"Les feldspaths, qui sont les constituants essentiels des pouzzolanes, appartiennent à la classe des tectosilicates. Leur structure cristalline résulte d'un arrangement de tétraèdres  $\text{Si}^{4+}(\text{O}^{2-})_4$  et  $\text{Al}^{3+}(\text{O}^{2-})_4$  dans lequel chaque oxygène est commun à deux tétraèdres et peut donc être considéré comme n'appartenant que pour moitié à un tétraèdre donné. Les tétraèdres s'organisent en un édifice complexe qui laisse des cavités dans lesquelles se logent les cations alcalins et alcalino-terreux. Les verres pouzzolaniques sont constitués des mêmes tétraèdres, mais l'arrangement de ceux-ci est désordonné.

Mécanisme d'attaque alcaline des pouzzolanes

Les silicates et les aluminates de calcium hydratés sont également formés d'un arrangement de tétraèdres, mais ceux-ci sont indépendants, étant constitués d'ions tels que  $\text{AlO}_4\text{H}_4^-$  et  $\text{SiO}_4\text{H}_3^-$ . Le passage de la phase anhydre, où les tétraèdres sont à oxygènes communs aux phases hydratées où ils sont indépendants se fait donc nécessairement par l'intermédiaire d'une individualisation de ces entités sous une forme qui ne peut être que ionique.

Dans l'hypothèse d'un mécanisme suivant le modèle de Le Chatelier, on distinguera trois étapes

#### a) L'étape d'attaque

Considérons un assemblage tétraédrique à oxygènes communs et intéressons-nous à un tétraèdre superficiel. Celui-ci peut comporter, à la différence des tétraèdres "profonds", un sommet libre, occupé par un ion  $\text{OH}^-$ . Ce tétraèdre peut être décroché par une solution basique de la façon suivante:

- un ion  $\text{OH}^-$  est attiré par l'ion central ( $\text{Si}^{4+}$  ou  $\text{Al}^{3+}$ ) de l'un des tétraèdres supports. Il expulse l'oxygène de liaison, provoquant le basculement du tétraèdre superficiel qui n'est plus lié que par une arête autour de laquelle il peut pivoter, et qui présente maintenant un excès de charge égal à  $-1$ , ce qui lui confère une forte affinité pour l'eau (fig.);

- le même processus pourrait provoquer la rupture des liaisons résiduelles, mais la présence d'une charge négative excédentaire tend à éloigner les ions  $\text{OH}^-$ . L'hydrophilie du site ionique créé favorise une coupure par des molécules  $\text{H}_2\text{O}$  libérant ainsi un ion tétraédrique qui sera soit l'ion  $\text{SiO}_4\text{H}_3^-$  soit l'ion  $\text{AlO}_4\text{H}_4^-$ .

#### b) L'étape de diffusion

L'ion libéré par l'attaque diffuse dans la solution, c'est-à-dire que sous l'effet de l'agitation thermique il s'éloigne progressivement de la surface originelle.

#### c) L'étape de cristallisation des hydrates

La présence dans la solution d'ion  $\text{Ca}^{2+}$  provoque, à partir d'une certaine concentration d'ions silicate et aluminate déterminée par les produits de solubilité des hydrates, une instabilité thermodynamique qui entraîne la cristallisation.

Elle conduit à la formation de composés hydrates dont la nature est définie par les règles générales qui gouvernent le système  $\text{CaO-Al}_2\text{O}_3\text{-SiO}_2\text{-H}_2\text{O}$ .

Dans la pratique courante où des quantités importantes de chaux sont utilisées, les produits d'hydratation sont l'aluminate tétracalcique hydraté et le silicate de calcium hydraté".

### Formation of tobermorites from pozzolanic materials

The characterization of calcium silicate hydrates represents a still open problem and was the object of many contributions presented to this Congress. One of these studies, involving the lime-pozzolana reaction, was summarized by N. Hara who, together with N. Inoue obtained different types of tobermorite characterized by different composition and basal planes (10 Å, 11 Å and 14 Å) by starting from mixes containing lime with a natural pozzolana or a silica glass.

The reactions were performed between 70 and 100°C with varying ratios of composition to processing duration. Depending on the starting material and the working conditions, tobermorites of different basal plane form. In any case the formation of tobermorite passes through the formation of CSH.

Starting from volcanic glass, the initially formed CSH transforms into 10 Å tobermorite after 20 days and afterwards into 11 Å tobermorite. Microanalysis show-

ed that the former has a Ca/Si ratio  $\approx 1.5$  and the latter  $\approx 0.93$ . On the contrary starting from silica glass, CSH transforms into 14 Å tobermorite with a Ca/Si ratio ranging between 0.64 (microanalysis) and 0.82 (chemical analysis).

The presence of aluminium tends to decrease the basal plane.

The obtained results suggest that each tobermorite different basal distance is a well crystallized form of CSH having different Ca/Si ratio.

#### How to grind fly ash cements to obtain the best performance and the highest energy saving

A communication particularly interesting for practical purposes was summarized by H.C. Alsted Nielsen who considered the manufacture of fly ash-containing cements as regards both performances and energy consumption.

In particular the different grinding and mixing modes which can be industrially performed were analyzed. The choice of the process depends on the clinker/fly ash ratio but also on the main objects that manufacturers want to obtain, that is low energy consumption or high mechanical strengths.

For instance, for cements containing up to 15% fly ashes, intergrinding gives excellent results, but with higher contents the best results are attained by separate grinding.

This has the advantage of modifying the development of the cement strength according to the requirements of the market. In particular, by distributing the grinding energy suitably between clinker (+ gypsum) and fly ashes, mechanical strengths at short ages can considerably be improved.

The Author only considered one type of fly ashes and one type of clinker, but the arguments and experiences carried out have a general character and therefore they are susceptible of being used as a guide in the preparation of cements containing fly ashes and natural pozzolanas.

#### Influence of pozzolana on the early $C_3A$ hydration

Some Authors mentioned in the synthesis of communications that fly ashes and pozzolanas retard the hydration of  $C_3A + C_4AF$  separated from clinker silicates and synthetic  $C_3A$ . Since Collepardi found rheological changes besides retardation effects, he was asked to summarize his experiences.

When  $C_3A$  hydrates in the presence of pozzolanas, the heat evolution curves are quite lower (see fig.). The influence of pozzolanas is slight when  $C_3A$  hydrates in the presence of lime and gypsum. Moreover, when a volcanic natural pozzolana (Segni) is substituted by a silica rich diatomaceous pozzolana (Sacrofano) the retarding effect becomes more evident. This retarding effect would indicate that some adsorption of pozzolana on  $C_3A$  surface can occur. The adsorption would be lower when both lime and gypsum are present, probably for the presence of "colloidal" ettringite coating the  $C_3A$  grains as stated by Metha (J. Am. Ceram. Soc. 1973) and Collepardi et al. (Cem. Concr. Res. 1978).

In the  $C_3A$  sample containing both calcium hydroxide and the volcanic pozzolana a rheological change from a stiff paste to a flowing one is observed during 10-30 min. of hydration, while the laminar crystals of hexagonal hydroaluminates ( $C_2AH_6$  and  $C_4AH_{13}$ ) are transformed into the cubic crystals of  $C_3AH_6$ .

- Heat evolution curves for  $C_3A$  hydration in the presence of lime (CH), gypsum ( $CSH_2$ ), quartz (Q), Segni pozzolana (Se) or Sacrofano pozzolana (Sa).

Generally the transformation from the hexagonal crystals into the cubic phase occurs after the setting of  $C_3A$  paste. However, when this transformation, for some reasons, is anticipated and the system is still in a plastic state the stiff paste is changed into a flowing one. The change in the morphological character of the hydrated products is caused by the presence of both lime and the volcanic pozzolana but the mechanism is not yet known. A similar phenomenon was pointed out by Traetteberg and Grattan-Bellew (J. Am. Cer. Soc. 1975) on pure  $C_3A$  pastes. However, in this case, the change in the morphology of hydroaluminates and then in the rheological properties was ascribed to high water/solid ratios and high temperatures - caused by large samples liberating remarkable heat of hydration - as both these parameters favour the transformation from hexagonal hydroaluminates into the cubic phase.

#### DISCUSSION

Different participants asked questions most of which received an immediate answer whereas others, for lack of time, were not examined during the session. However all of them are presented here together with the relative short answers.

##### J. BENSTEND's question

There is some evidence in portland cement containing fly ash that alkali hydroxide rather than calcium hydroxide is making the major contribution to pozzolanicity. It thus follows that chemical tests for pozzolanicity need to take full account of this possibility. What are the panel's views on the role of alkali hy-

dioxide as opposed to calcium hydroxide in determining pozzolanicity in such situation?

#### Réponse de P. LONGUET

Sur le plan des principes nous sommes d'accord avec Monsieur Bensted sur le rôle des alcalis dans le développement de l'effet pouzzolanique, et sur l'intérêt qu'il y aurait à en tenir compte pour définir un test chimique d'appréciation de l'activité pouzzolanique. La difficulté serait sans doute de définir le milieu réactionnel convenable assurant une solubilité telle à l'hydroxyde de calcium que la concentration en ions  $\text{Ca}^{2+}$  reste supérieure à celle provenant de l'équilibre de solubilité des composés calciques hydratés susceptibles de se former. Il y a là certainement une série d'études qui seraient très profitables à une connaissance plus complète de l'effet pouzzolanique.

#### Question de E. DEMOULIAN

A quoi peut-on attribuer le retard de prise des ciments qui contiennent des cendres volantes?

#### Réponse de P. LONGUET

Si ce retard n'est pas attribuable à la composition particulière de la cendre: par exemple des impuretés existant naturellement dans le charbon initial (l'exemple du Zn a été signalé) soit provenant de combustibles ajoutés au charbon au niveau du brûleur de la chaudière (huiles usées renfermant des additifs tel le sulfure de molybdène...), la réponse n'est pas évidente. Peut-être faudrait-il vérifier si les propriétés adsorbantes particulières des cendres volantes ne déplacent pas les équilibres ioniques initiaux de la phase aqueuse de la pâte de ciment dans un sens comparable à l'addition d'un retardateur?

#### Question de E. DEMOULIAN

Influence de la réactivité chimique de la pouzzolane sur la structure et la composition des hydrates formés. (Question au Panel).

#### R. SERSALE's reply

The chemical reactivity of pozzolanas does not seem to appreciably affect the structure and composition of the newly formed hydrates. In fact, starting from natural pozzolanas of different eruptive areas, the principal products originating after the reaction with lime and liable for the binding action are constantly: calcium silicate and tricalcium aluminate hydrates. In the light of the experimental research carried out so far, the determining role of the chemical reactivity of pozzolana is likely to be limited to a substantial influence on the formation kinetics of the newly formed phases.

#### S. DIAMOND's question

It has often been thought that reactivity of flyash or pozzolanic glasses may be related in part to the state of strain in the glass, is there any convenient method available to measure this?

#### R. SERSALE's reply

Direct methods for evaluating the state of strain in incoherent glasses, like fly ashes or pozzolanas, probably cannot provide reliable results, even if, no doubt, strain favours reactivity.

By means of physico-chemical techniques, such as evaluation of the heat of solution, dilatometric analysis, high sensitivity thermal differential analysis, a relative and indirect determination of the strain can often be obtained provided glassy samples have the same chemical composition but different thermal history.

#### U. LUDWIG's question

What is your opinion about the maximum replacement of portland cement with pozzolana free of lime with respect to carbonation and:

- influence on ultimate strength
- influence on the carbonation rate

#### F. MASSAZZA's reply

a) Italian pozzolanic cements usually contain around 33% of pozzolana. Practically as much pozzolana is added as much is necessary to combine the hydrolysis lime of clinker (pozzolanicity test ISO R 863). Higher amounts of pozzolana would not react and therefore would reduce mechanical strengths. In pozzolana-containing cements, all the other conditions being equal, the change in mechanical strengths as a function of pozzolana content shows a nearly linear decrease at short ages but presents a maximum after about 28 days. The early and ultimate strengths of a pozzolanic cement depend, of course, on the quality of pozzolanas (active phase content, their nature, BET specific surface, a.s.o.).

b) Latest research by Longuet et al. (Rev. Mat. Constr. 1973, Silicates Ind. 1976) and Diamond (Il Cemento 1977) proved that the solution filling the pores of the cement paste is practically free of calcium hydroxide ( $\text{Ca}^{++} < 10^{-3}\text{M}$ ) and essentially consists of alkali hydroxides.

Therefore the resistance to the carbonation of concrete does not appear to be attributed to the presence or absence of calcium hydroxide in the pore solution, but it must be sought in other factors such as, for instance, the permeability of  $\text{CO}_2$  of the cement paste. Anyhow it must be reminded that appreciable amounts of free calcium hydroxide are always present in the pastes of pozzolanic cements, even when very active pozzolanas rich in silica ( $\text{SiO}_2 > 80\%$ ) and poor in lime ( $\text{CaO} < 0.5\%$ ) are used.

#### G.K. MOIR's question

I would like your reactions to the observation that not only need the pozzolana be assessed by strength test but that clinker rather than  $\text{Ca}(\text{OH})_2$  should be used as factors such as the available alkali and sulphate may influence reactivity. Further, perhaps the most important property of the pozzolana with regard to strength up to 28 days is the influence upon concrete workability (rheology) and consequently w/c ratio.

#### Réponse de R. MAGNAN

Il a été noté par différents auteurs que les connaissances actuelles ne permettaient pas de relier les ca-

caractéristiques chimiques d'une pouzzolane et d'un clinker et la réactivité du mélange.

Il est donc nécessaire pour connaître la qualité d'une pouzzolane de faire des tests mécaniques en utilisant les matériaux réels. C'est-à-dire la pouzzolane et le clinker contenant ses éléments secondaires, sulfates, alcalis, etc....

Il est bon de distinguer deux types de réactivité. La réactivité chimique qui est la vitesse de réaction chimique avec l'eau et la réactivité physicochimique qui est la vitesse d'acquisition des résistances mécaniques. Il est en effet possible d'avoir une réactivité chimique élevée par exemple en augmentant la surface spécifique des produits sans avoir de résistances élevées, car la surface spécifique élevée exigera pour une théologie acceptable un E/C élevé dont on connaît les effets néfastes.

Une bonne pouzzolane correspond au meilleur compromis entre une réactivité chimique la plus élevée possible et une surface ou activité de surface vis à vis de l'eau, la plus faible possible.

#### T. PATZIAS's question

What happens to  $Al_2O_3$  of fly ash with low (or high)  $CaO$  content during the hydration of pozzolanic cements to explain their improved sulphate resistance?

#### F. MASSAZZA's reply

A good portion of  $Al_2O_3$  of pozzolanas and presumably also of fly ashes, enters the lattice of C-S-H. Once the best sulphate resistance of the pozzolanic cement paste was simply attributed to the low  $Ca(OH)_2$  content that made ettringite unstable. Today this fact is ascribed to a lower permeability of the cement pastes toward the  $SO_4^{--}$  ion. In its turn this higher impermeability is attributed to the presence of a higher amount of gel and to differences in its composition and structure.

#### K. POPOVIC's question

Since most pozzolana-containing cements demand more water for a same consistency and therefore a higher cement dosage to obtain the same strength, is it possible to talk about energy saving?

#### F. MASSAZZA's reply

Considering that not all pozzolanic cements, and particularly those containing fly ashes, demand more water than portland cements, it was found that by using Italian pozzolanic cements containing about 1/3 of natural pozzolanas it is necessary to increase the w/c ratio on the average by 0.01-0.02 to have the same slump given by plain portland cements. This difference is slight and therefore also the increase in the cement dosage required to have the same 28 day-strength is small. Needless to say that later on the strength of a pozzolanic cement will increase more than a portland one.

#### E. RAASK's question

I should like to ask for opinion of the Panel if it is further while to investigate further chemical methods of pozzolanic activity tests to supplement the accepted mechanical tests.

#### Réponse de R. MAGNAN

Il a été reconnu par les différents auteurs que seuls les tests mécaniques permettent de mettre en évidence la qualité d'une pouzzolane et son activité.

Les tests mécaniques ont l'inconvénient d'être lents et sont donc peu pratiques pour le contrôle continu d'une fabrication industrielle.

Mais dans ce cas, s'agissant généralement d'un clinker défini et d'un matériau d'addition préalablement testé, il peut être intéressant de faire des tests chimiques qui donnent rapidement une mesure de variations éventuelles de la pouzzolane et qui permettent ainsi de s'assurer de la régularité du produit.

La méthode chimique permet alors de diminuer le nombre de tests mécaniques mais ne peut être considérée que comme une méthode indicatrice.

#### V. RAMACHANDRAN's question

One of the important research problems should concern itself to activate the reaction between lime and a pozzolana for obtaining higher early strength development. Are there any new catalysts being investigated recently?

#### Réponse de P. LONGUET

Il est bien établi que le développement des caractéristiques mécaniques lié à la présence de pouzzolanes dans un ciment est par nature un phénomène lent. Des résistances mécaniques élevées aux premiers âges avec un ciment pouzzolanique ne pourront donc être obtenues qu'indirectement:

- Soit en accélérant les réactions propres au clinker présent en espérant compenser la baisse de résistance à long terme qui en résulte par l'effet pouzzolanique lui-même.

- Soit en ajoutant un système donnant rapidement une résistance initiale (intérêt plus particulier pour le démoulage rapide).

Des résultats intéressants ont été obtenus par addition de ciment alumineux (ciment fondu) ou d'aluminate de sodium, mais à vrai dire il s'agit là d'effets différents de ceux attribués habituellement aux produits accélérateurs dont l'action est plutôt de nature catalytique.

#### A. SAMARIN's question

Is it possible to utilize brown coal fly-ash in concrete? Our experience is that these ashes are high in magnesia and alkalis, have little or no pozzolanic values and cause corrosion of reinforcing steel.

Is it possible, in the opinion of the panel, to overcome these problems?

#### Réponse de P. LONGUET

La réponse est difficile puisque vous décrivez vous-même vos cendres de lignite avec des teneurs élevées en magnésie et en alcalis, avec peu ou prou de propriétés pouzzolaniques et de plus apportant des risques de corrosion des armatures (à cause de la présence de teneurs élevées en sulfates vraisemblablement). Tout au plus, si elles sont assez fines, pourrait-on envisager leur addition comme charge plus ou moins inerte pour compléter la courbe granulométrique du ciment et améliorer les propriétés rhéologiques lors du gâchage. Il conviendrait alors de vérifier les points suivants:

- Extinction complète de la chaux libre et de la magnésie libre présentes dans les cendres.
- Absence de quantités importantes (1 ou 2% au maximum).
- Teneur en sels solubles compatibles avec l'absence d'apparition d'efflorescences à la surface des bétons réalisés.
- Définition des raisons du risque de corrosion des armatures: concentration élevée en sulfates (à compenser par une addition modérée des cendres au ciment), présence éventuelle de chlorures (à proscrire pour les ciments destinés à la précontrainte).

#### Question de W. SCHRÄMLI

Spécifier le ciment aux cendres volantes selon sa performance plutôt que selon sa composition à l'inconvénient que l'aspect durabilité est négligé car il est difficile de la mesurer.  
Est-ce qu'il est fait en France pour attribuer, dans le cadre des normes, à l'aspect durabilité l'importance qu'il mérite?

#### Réponse de P. LONGUET

Nous ne pensons pas que le fait de connaître la composition d'un ciment aux cendres volantes puisse permettre d'établir la durabilité du béton correspondant. En France les normes définissent certes des performances mais indiquent aussi les limites supérieures des teneurs en produits d'addition des différents liants hydrauliques.  
Votre question pose plutôt le problème de la définition d'un béton de référence, à partir duquel des critères de durabilité pourraient être effectivement mieux définis.

#### Question de J. PUIG

Comment pouvez-vous utiliser les cendres à basse teneur en CaO libre (10%) en les séparant des autres, plus grosses, à forte teneur en CaO libre (20%)? Avec 25% de cendres à 10% de chaux libre, avez-vous une bonne stabilité de volume? A quel essai? L'aiguille ou l'autoclave?

#### Réponse de M. DMITRIEV

Les cendres sont directement séparées en fractions aux centrales thermo-électriques où les cendres à dispersion grossière ayant une forte teneur en CaO libre se précipitent aux premiers champs du filtre électrique horizontal, tandis que les cendres à basse teneur en CaO libre et à dispersion fine sont amenées dans le dernier champ de ce filtre. En cas d'utilisation des cendres à fine dispersion, le ciment subit n'importe quels essais concernant la stabilité de volume.

#### B.S. RAUQUEKAR's question

Regarding "Basic Flyashes", is it necessary to add "active or ground silica", when manufacturing portland-pozzolana cement using basic flyashes?  
With such additions is it possible to have a better strength development?

#### Réponse de M. DMITRIEV

La fabrication du ciment pouzzolanique avec l'utilisation des fractions fines de la cendre basique n'exige pas d'additions de la silice active.  
Si l'on utilise les fractions grossières de la cendre ayant une haute teneur en CaO libre, il est possible d'effectuer une certaine quantité d'additions contenant de la silice active. Les meilleurs résultats sont obtenus en cas de 15-25% de cendre, en fonction de sa dispersion.

#### CONCLUSIONS

The conclusions that can be drawn from the principal reports, the written and oral contributions as well as the discussions can be summarized as follows.  
The use of pozzolanic materials shows the following advantages:

- The production of cements that must not only be considered as substitutes of portland cements, but also as cements having some improved characteristics, such as heat of hydration, shrinkage, creep, durability, etc.
- The reduction in the energy consumption and the building costs of the cement factories. In fact the possibility offered by the pozzolanic additions to increase the cement production without a corresponding heat consumption or plant enlargement is doubtless stimulating.
- Finally pozzolanic cements allow the utilization of residues from other processings that, as fly ashes, constitute a serious ecologic problem still today.

The number and the quality of the presented works, both those having an eminently scientific character and those with more practical purposes, are the most convincing proof of the interest that subject "pozzolana" arouses all over the world.

To conclude this general report the Chairman of Theme IV would like to thank the principal reporters, the Authors of the written and oral communications and the participants in the round table and the discussion for the valid contribution they gave to the success of this section.

# THEME V

## Ciments spéciaux

par F. de ASSIS BASILIO

### I - INTRODUCTION -

1. Le Comité Scientifique International a chargé un représentant de l'Amérique Latine de présider le 5ème Thème du Congrès, probablement en hommage aux spécialistes de ce continent lointain, dont la production annuelle de ciment a atteint près de 60 millions de tonnes en 1978.

Le Brésil, mon pays, a produit dans les cinq dernières années les tonnages suivants de ciments de toutes sortes :

1975 -	16.737.458
1976 -	19.146.794
1977 -	21.122.927
1978 -	23.202.867
1979 -	24.873.654

Tableau

Production de ciment Portland en Amérique Latine, en 1978 :

Chiffres en tonnes par année :

Amérique Centrale	3.126.259
Argentine	6.316.129
Bolivie	257.008
Brésil	23.202.867
Colombie	4.140.000
Chili	1.176.698
Equateur	976.060
Mexique	14.055.720
Paraguay	166.777
Pérou	2.047.348
Uruguay	683.300
Vénézuéla	3.349.794

Total: 59.497.960

Source : Asociacion de Fabricantes de Cemento Portland - La industria argentina del cemento Portland : anuario 1978. Buenos Aires, 1979, p.39.

L'item relatif au Brésil fut obtenu par le Syndicat National de l'Industrie du Ciment, Rio de Janeiro.

o  
o o

L'Industrie cimentière au Brésil, comme d'ailleurs dans un grand nombre de pays d'Amérique Latine, a créé, en 1936, l'Association Brésilienne du Ciment Portland, à laquelle appartiennent toutes les cimenteries du pays (actuellement 57 usines).

L'Association du Brésil possède un Centre Technique du ciment, situé à Sao Paulo, et des laboratoires d'essais et de recherches comprenant quatre départements : physico-chimie, chimie,

béton et ciment (essais physiques) et sol-ciment.

Le laboratoire a des techniciens, des ingénieurs chimistes, des géologues et des ingénieurs civils; il travaille avec les équipements normaux d'essais et de recherche (XRD, ATD, microscopie optique, etc...)

2. Le Thème 5 : Ciments spéciaux, a été divisé en trois sous-thèmes :

- Sous-thème 5.1., dont le Rapporteur Principal, M. C.M. GEORGE (U.K.) a présenté un travail intitulé "Ciments alumineux". Une synthèse des récentes publications (1974-1979).
- Sous-Thème 5.2., dont le Rapporteur Principal, M. W. KURDOWSKI (Pologne) a présenté un travail intitulé "Ciments expansifs".
- Sous-Thème 5.3., dont le Rapporteur Principal, M. A.S. BOLDYREV (URSS) a présenté un rapport intitulé "Autres ciments (ciments à haute teneur en  $C_2S$  actif) et leurs utilisations".

3. Le Président du Thème 5 a reçu 41 communications et 3 rapports principaux, qui traitent respectivement :

- du sous-thème 5.1. Ciments alumineux : 16 travaux qui proviennent des pays suivants : France (6), Royaume-Uni (3), Italie, URSS, Roumanie, Inde, Hongrie, Chili et Espagne (1 chacun)
- du sous-thème 5.2. Ciments expansifs : 10 travaux qui proviennent des pays suivants : Chine (2), France, URSS, Roumanie, Pologne, Japon, Bulgarie, Etats-Unis, et Egypte (1 chacun)
- du sous-thème 5.3. Autres ciments : 19 travaux qui proviennent de : URSS (10), Japon (3), Bulgarie (2), France, Etats-Unis, R.F.A. et Tchécoslovaquie (1 chacun)

4. On peut y voir la préoccupation générale d'orienter les recherches sur des bases scientifiques sans oublier :

- a) l'économie du combustible dans la fabrication de ciment, notamment en cherchant des nouveaux types de ciments à température de clinkérisation inférieure à 1200° voire même à des températures inférieures à 1000°C.
- b) l'utilisation des déchets ou sous-produits industriels. L'utilisation des laitiers et des cendres volantes est déjà bien connue, mais il y a d'autres sous-produits qui méritent attention.

Ces deux directives furent traitées en détail dans presque tous les travaux provenant de l'URSS, comme par exemple dans le Rapport Principal du sous-thème 5.3 de M. BOLDYREV, concernant l'utilisation des boues rouges (déchets de la fabrication de l'alumine à partir de la néphéline) dans la fabrication du ciment, car cette boue peut contenir jusqu'à 80 % de  $\beta\text{-C}_2\text{S}$ .

5. On constate aussi qu'il existe un nombre croissant de nouveaux types de ciments alumineux, avec une teneur variable en aluminates, et des ciments alumineux associés aux ciments Portland avec ou sans ajouts.

L'étude de l'influence sur l'hydratation et les propriétés des ciments alumineux des composés mineurs comme  $\text{SO}_2$ , Cl, Ba, Ti, Mn, et d'autres a été présentée dans plusieurs travaux.

Quelques travaux insistent sur l'intérêt d'utiliser l'alunite  $\text{Ca}_{11}(\text{Si},\text{Al})_{18}\text{O}_{48}\text{Cl}$  dans la fabrication des ciments expansifs.

6. Ce rapport général est divisé en trois parties, correspondant chacune à un sous-thème.

o

- 1.14- "Calcul des compositions potentielles théoriquement possibles des ciments alumineux".  
J. CALLEJA - Espagne.

1 - Le rapport principal du sous-thème 5.1 a été présenté par M. G.M. GEORGE, Directeur Technique de Lafarge Fondu International.

Son rapport de 24 pages contient une synthèse des récentes publications (1974-1979) présentées depuis le Congrès de Moscou. Il a examiné ainsi 103 publications récentes.

Examinons les principales questions traitées par les auteurs des travaux présentés dans ce sous-thème 5.1. :

## 2. Conversion (Transformation cristalline des ciments alumineux hydratés).

2.1 - Le rapporteur principal aborde cette question et même prend position de la façon suivante (p.2)

"Les publications les plus importantes concernant les résistances à long terme et la conversion montrent clairement que les ciments alumineux se transforment relativement vite (quelques mois ou années) dans pratiquement toutes les conditions d'utilisation; donc la propriété de durcissement rapide doit être exploitée seulement en considérant les résistances après conversion, et en utilisant un faible rapport eau/ciment".

Et il continue : "CAH<sub>10</sub> est l'hydrate principal formé à 20°C ou moins, à partir de CA; C<sub>3</sub>AH<sub>8</sub> prédomine autour de 30°C et ces deux hydrates se transforment en C<sub>3</sub>AH<sub>6</sub>, d'autant plus rapidement que la température est plus élevée (phénomène de conversion)".

Si la situation se présente comme un fait inévitable, il y a cependant un certain nombre d'études pour trouver une solution de nature physique ou chimique qui puisse empêcher la conversion.

2.2 - Les auteurs de la communication 1.7 affirment que "la conversion du ciment alumineux ... est un fait que l'on doit accepter". Mais ils se préoccupent cependant de trouver une solution pour éviter ou réduire cette conversion par l'addition de β-C<sub>2</sub>S. "En hydratant ensemble du CA et du β-C<sub>2</sub>S on obtient surtout du C<sub>2</sub>ASH<sub>8</sub> (gehlenite hydratée ou strätlingite)".

Et ils arrivent à la conclusion : "Le succès de la technologie d'arrêt de la chute de résistance dépend de l'optimisation des propriétés et de la finesse des aluminates et du β-C<sub>2</sub>S de façon à ne pas accumuler les aluminates de calcium hydratés" (p.7). Malheureusement, ils n'ont présenté de résultats d'essais de résistance à la compression que jusqu'à 85 jours, mais sans réduction de résistance.

MIDGLEY dans sa communication 1.12 présente des résultats de conversion et de récupération; on y voit que le ciment ayant le plus grand pourcentage de β-C<sub>2</sub>S a la plus grande récupération.

Presque toutes les 14 communications ont traité, plus ou moins, de ce problème de la conversion.

2.3 - Dans la communication 1.1. présentée par CURSINO et NEGRO, les auteurs se montrent plus optimistes quant à la possibilité d'éviter la conversion; ils préconisent à ce sujet l'addition de poudre

calcaire broyée à environ 5000 cm<sup>2</sup>/g au ciment alumineux, dans la proportion 20/80. Ils ont réalisé plusieurs essais; les résultats des essais de résistance à la compression de béton, dosé à 350 kg/m<sup>3</sup> avec e/c=0,46 avec agrégats calcaires (courbe F) avec e/c = 0,50 (courbe B), montrent que les résistances à la compression ont toujours augmenté jusqu'à 1800 jours.

L'essai fait avec des agrégats siliceux, mais avec un mélange 25/75 de poudre calcaire et de ciment alumineux, et avec un e/c de 0,51 a présenté aussi des résultats de résistance à la compression toujours croissante jusqu'à 1800 jours (courbe II). Par contre, les effets de la conversion sont visibles dans des essais faits sans poudre calcaire.

Ces conclusions semblent compléter ce qui se trouve dans le rapport principal (p.10) : "En présence de CaCO<sub>3</sub>, le CAH<sub>10</sub> est moins produit à toutes les températures; mais l'apparition de C<sub>3</sub>AH<sub>6</sub> est aussi réduite en faveur de l'apparition de mono-carbo-aluminate hydraté C<sub>3</sub>A.CaCO<sub>3</sub>.11H<sub>2</sub>O. On en conclut que la vitesse de conversion est plus basse en présence de CaCO<sub>3</sub> et que la formation de carbo-aluminates à la place de C<sub>3</sub>AH<sub>6</sub> doit réduire la porosité et donc améliorer la résistance des bétons de ciment alumineux".

En effet, les auteurs du travail 1.1. ont fait des considérations théoriques en se basant sur les réactions connues :

"L'équation (2) montre que C<sub>3</sub>AH<sub>6</sub> et 2 AH<sub>3</sub> occupent ensemble 47,3 % de l'espace occupé par 3 CAH<sub>10</sub> avant sa transformation; il n'y a aucun doute que l'eau constituant 52,7 % du volume total est responsable de la porosité. Sur la base de l'équation (3), le solide occupe 66,5 % et l'eau 33,9 %.

Pour compléter cette étude, les auteurs ont déterminé, à l'aide d'un porosimètre à mercure, la porosité de deux échantillons de mortier après 28 jours et 360 jours, l'un avec du sable siliceux, et l'autre du sable calcaire. Les résultats obtenus sont :

siliceux	28 jours	52,69 %	360 jours	66,61 %
calcaire	28 jours	65,96 %	360 jours	38,36 %

"Ce qui montre une réduction de la porosité du mortier de 42 %".

2.4 - Avec le même objectif, P.K.MEHTA avait présenté au Congrès de Tokyo un travail sous le titre "Prévention de la perte de résistance des bétons de ciments alumineux". Il a employé comme additif 5 % en poids du ciment, du  $C_4A_3S$  et a obtenu des résultats favorables sur un ciment alumineux d'origine américaine.

KONDO cependant a aussi fait des essais avec le même additif et n'a pas obtenu de résultats satisfaisants.

### 3. Composition minéralogique.

Plusieurs travaux traitent de cette question: quels sont effectivement les composés qui se forment dans la production industrielle du ciment alumineux et dans quelles conditions ?

Le rapporteur principal du sous-thème 5.1 fait un tour d'horizon sur les principales recherches faites depuis 1974, en commençant par les aluminates de calcium les plus importants,  $C_{12}A_7$ ,  $CA$  et  $CA_2$ , avec la relation C/A décroissante et les alumino-ferrites de calcium.

Dans le travail 1.14 CALLEJA a considéré comme possible la formation de  $CA$ ,  $C_{12}A_7$ ,  $C_2S$ ,  $C_4AF$ ,  $C_6A_2F$  et  $C_2AS$ , d'après des ciments alumineux produits en Espagne.

Dans le travail 1.3 de KUZNETSOVA, les auteurs montrent que "la composition à teneur en alumine élevée dépend de la température et du caractère du milieu gazeux (oxydant ou réducteur) de la cuisson, ainsi que de la présence d'impuretés ou d'additions de modificateurs dans le mélange cru".

On voit bien l'énorme difficulté de prévoir, en partant de la composition chimique du clinker, sa composition potentielle, comme l'avait fait, il y a une cinquantaine d'années, M. BOGUE, pour le calcul de la composition potentielle du clinker Portland.

C'est pourtant ce que M. CALLEJA a tenté de faire en présentant dans son travail 1.14 les équations, basées sur la stoechiométrie des réactions, pour des ciments alumineux correspondant à la composition suivante :

A entre 39 et 42 %; C de 37 à 42 %, F de 9 à 18 %; S de 1,5 à 6 % et T de 1 à 2 %, qui correspond aux ciments alumineux d'Espagne.

Il a admis trois systèmes en vue de faire les calculs; en partant de la composition chimique du clinker alumineux, il a pu calculer une composition potentielle qui, d'après ses observations, serait en accord avec la composition potentielle mesurée.

### 4. Hydratation.

4.1. Les auteurs du travail 1.2 ont cherché à éclaircir une question relative à la solubilité de la chaux et de l'alumine, du  $CAH_{10}$  déshydraté sous vide à des températures supérieures à 100°C "la solution obtenue laisse à son tour précipiter  $CAH_{10}$ ". C'est une étude assez complexe et qui doit aider à la compréhension de certaines questions relatives à l'hydratation des ciments alumineux.

4.2. Les auteurs du travail 1.5 ont fait une étude théorique minutieuse et sont arrivés à des courbes sur le diagramme C-A-H de supersolubilité du gel d'alumine et du  $C_2AH_8$ , limitée par la courbe "d'instabilité minimale". (p.6)

4.3. L'auteur du travail 1.6 a fait des études sur des mélanges de ciment alumineux (fondu) et ciment Portland, broyés sans gypse (voir le travail 3.11), en proportions variables. Il arrive à établir la composition probable des hydrates pour les mélanges étudiés, dans le domaine du système C-A-H.

4.4. Les auteurs du travail 3.13 ont étudié au microscope électronique à balayage l'évolution de l'hydratation, pendant les premières minutes après l'addition de l'eau, des aluminates synthétisés en laboratoire.

Ils signalent, dans l'hydratation du  $C_{12}A_7$  vitrifié, un mécanisme de "défoliation" (?) et présentent l'explication probable de ce mécanisme (p.3).

### 5. Clinkérisation.

Les travaux 1.8 et 1.9 donnent des renseignements précieux sur les composés du clinker alumineux.

5.1. Les auteurs du travail 1.8 ont présenté une étude remarquable sur les conditions de formation du  $C_{12}A_7$ ,  $CA$  et  $CA_2$  en fonction de la température d'après des minutieuses déterminations faites par XRD. Une conclusion par exemple, le maximum de  $CA$  fut obtenu à la température de 1473° après 2 heures de cuisson au four de laboratoire (p.4).

5.2. Les auteurs du travail 1.9 ont fait une recherche sur la clinkérisation, en laboratoire, de l'alumine et de  $CaCO_3$  calcinées à 1310°C, 1330°C, 1380°C et 1450°C. Par XRD ils présentent au tableau 3 les variations des compositions du clinker obtenu en  $CA_2$ ,  $CA$  et  $C_{12}A_7$ .

## 6. Autres études.

6.1 - Les auteurs du travail 1.10 ont étudié le ciment alumineux : SECAR 71 (contenant 70 % d' $\text{Al}_2\text{O}_3$  additionné de sodium sous la forme de  $(\text{NaPO}_3)_6$  et de dihydrogénophosphate de sodium  $\text{NaH}_2\text{PO}_4$ ).

Comme conclusion "l'étude montre qu'à la température ambiante la prise "phosphate" s'effectue avant la prise hydraulique.... L'intensité de la prise hydraulique est alors affaiblie par rapport à celle du SECAR 71 pur".

6.2 - Le travail 1.4 étudie un ciment réfractaire alumineux avec substitution totale ou partielle du  $\text{CaO}$  par  $\text{BaO}$  et  $\text{MgO}$ . Les auteurs ont fait de nombreuses recherches dans le pseudosystème  $\text{BA-CA-MA-BA-CA}_6$  et arrivent à une composition sans  $\text{CaO}$  ayant une résistance à la compression de 400 da N/cm<sup>2</sup> à 1 jour et 550 da N/cm<sup>2</sup> à 7 jours, et une réfractarité de 1870°C.

6.3 - Le travail 1.11 traite de la résistance chimique du ciment alumineux à l'eau de mer et aux eaux sulfatées. L'auteur attire l'attention sur l'hydrolyse alcaline, c'est à dire celle due à l'action du sodium et du potassium en présence de  $\text{CO}_2$ , et d'humidité, dans un béton assez perméable.

\* 1. Le Rapporteur Principal du sous-thème 5.2 est le Professeur KURDOWSKI, du Centre de Recherches de l'Industrie des Matériaux de Construction, en Pologne. Son rapport présente une appréciation générale sur plusieurs ciments expansifs actuellement utilisés dans la construction et sur ceux qui sont encore en phase d'étude et de recherche. Son travail de 11 pages s'est appuyé sur une bibliographie sélectionnée de 59 publications.

Les ciments expansifs ont normalement deux emplois distincts : produire une expansion qui annule les effets du retrait, ou produire une expansion du béton capable de conduire à la précontrainte des armatures.

Dans le rapport principal ces deux emplois sont étudiés, en indiquant, par exemple, qu'en URSS on fabrique des ciments expansifs capables de produire "un potentiel expansif (pression d'expansion) de 20 kg/cm<sup>2</sup>, 40 kg/cm<sup>2</sup> et 60 kg/cm<sup>2</sup> respectivement". Ces deux derniers sont destinés à la précontrainte.

Les ciments expansifs les plus utilisés au monde sont examinés dans le rapport principal. Les types K et M sont bien connus (1, p.1) ainsi que le M-S; mais on voit croître l'intérêt pour d'autres types de ciments, dont quelques uns sont signalés dans le rapport principal dans les travaux présentés:

- les ciments SCT et SCN ont été étudiés par MICHAILOV ainsi que le ciment WEC. Le ciment SCT doit avoir une cure hydrothermique suivie de cure à l'eau à la température normale : il se produit pendant la cure normale du monosulfoaluminate  $3\text{C}_3\text{A}.\text{CS.H}_{12}$  qui subit une évolution vers l'ettringite (2, p.432).

- des ciments expansifs, utilisant des additifs, largement utilisés au Japon.

2. Nous allons attirer l'attention sur certains aspects, en vue de faire une synthèse des travaux présentés.

### 3. Mécanisme de l'expansion.

L'ettringite est actuellement le composé expansif le plus important, mais comment se forme-t-elle ?

MEHTA, cité dans le rapport principal, a démontré, en se basant sur des observations SEM, que "l'ettringite se forme, en règle générale, par cristallisation dans une solution". Mais dans le rapport principal on trouve aussi que "indépendamment de l'hypothèse de MEHTA, plusieurs auteurs continuent à considérer que l'expansion peut être causée par des transformations locales des phases anhydres en hydrates".

En effet, dans le travail 2.5. de NIKITINA (p.3), on voit que "dans le cas où la réaction de formation de l'ettringite se localise sur la surface des particules d'aluminates de calcium, ces particules se régénèrent peu à peu en un agrégat polycristallin et augmentent de volume comme un cristal unique. De telles particules deviennent alors la source de déformations pour toute la structure dans son ensemble".

On voit aussi, dans le travail 2.6. de MOLDOVAN (p.4) que "l'hydratation du ciment E (expansif) en pâte, est caractérisée par l'apparition de produits d'hydratation du type ettringite à la surface des grains anhydres", comme on peut le voir sur la microphoto (fig.2) de 30.000x.

Mais il signale aussi que "dans le cas du ciment A (Portland), ce qui caractérise l'hydratation c'est l'apparition des produits d'hydratation via la solution dans l'espace intergranulaire" et il conclut "la vraie cause de l'expansion c'est la formation d'ettringite à la surface des grains anhydres en présence d'une solution saturée en  $\text{Ca}(\text{OH})_2$  et en l'absence d' $\text{Al}_2\text{O}_3$  en solution".

### 4. Pression d'expansion et pression de cristallisation.

Dans le rapport principal, on attire l'attention sur les trois niveaux de la pression d'expansion adoptés en URSS (norme ?) soit 20 kg/cm<sup>2</sup>, 40 kg/cm<sup>2</sup> et 60 kg/cm<sup>2</sup>.

On voit que dans le travail 2.5 de NIKITINA (p.5) on s'est préoccupé de mesurer la pression d'expansion et on a envisagé deux méthodes. La deuxième méthode consiste à vérifier "la charge indispensable pour réduire le volume du ciment durci à sa valeur initiale. On détermine ainsi l'effort qui se développe au cours du durcissement de ces ciments (pression d'expansion)".

Les auteurs du travail 2.6 MOLDOVAN et BUTUCESCU considèrent que "des pressions de cristallisation locales déterminent l'augmentation du volume du système déformable". Une explication semblable a été donnée dans la recherche de KROSILNIKOV présentée au Congrès de Moscou.

On voit cependant très peu de données quantitatives au sujet de la pression de cristallisation et de son influence sur la pression d'expansion, depuis que la question a été posée, par exemple, par KALOUSEK et BENTON et a provoqué une contestation de LEVI BROWN (4, p.187 et 5 p.646) en 1970.

### 5. Influence du CaO dans l'hydratation des ciments expansifs.

5.1 - Les auteurs du travail 2.3 présentent des références de plusieurs chercheurs; certains considèrent que la saturation en CaO de la phase liquide est indispensable pour avoir des ciments expansifs; d'autres affirment le contraire, c'est à dire qu'il faut avoir dans la phase liquide une solution sous-saturée en CaO.

Les auteurs ont alors procédé à une expérimentation rigoureuse, en comparant l'hydratation d'une pâte d'aluminates de calcium pour auto-contrainte avec une sous-saturation en CaO dans la phase liquide, et un ciment alumineux du type M. en condition de saturation en CaO dans la phase liquide. Au tableau 3, ils présentent des résultats très favorables à la condition de sous-saturation. Les auteurs ont une large expérience de l'emploi de ce type de ciment auto-contraint dans la fabrication de tuyaux en béton précontraint depuis 20 ans.

5.2 - Les auteurs du travail 2.4. traitent de l'influence de la chaux dans l'hydratation d'un ciment expansif type M. Ils ont étudié le système  $\text{C}_4\text{A}_3\text{S}$  - Gypse-chaux-eau, et les conditions pour la formation du  $\text{C}_3\text{A.CS.H}_{12}$  et du  $\text{C}_3\text{A.CS.H}_{32}$  et la formation intermédiaire de ces deux composés avec en plus du  $\text{C}_4\text{AH}_{13}$  et de l'alumine (p.6).

5.3 - Dans le travail 2.1. les auteurs ont étudié l'effet de l'addition au ciment Portland de la chaux (3 % et 6 % de CaO), du sulfate de chaux (3 % et 6 % de  $\text{CaSO}_4$ ) et de  $\text{C}_4\text{A}_3\text{S}$  (2 % à 5 %). L'addition de 3 % de CaO et 6 % de  $\text{CaSO}_4$  a conduit à une expansion convenable (courbe D de la fig. 2)

## 6. Ciment expansif avec additifs.

6.1 - Le rapport principal traite de la fabrication d'un ciment obtenu par mélange de clinker Portland, d'alumine activée entre 600°C et 800°C, et de gypse; le produit actif de ce ciment est l'ettringite.

6.2 - Le travail 2.2 traite aussi d'un ciment expansif obtenu par mélange d'alumine naturelle (contenant 20 % à 50 % de  $K_2SO_4 \cdot Al_2(SO_4)_3 \cdot 4Al(OH)_3$ ) de clinker Portland, d'anhydrite et de cendres volantes ou de laitiers.

Les auteurs ont utilisé le porosimètre à mercure et ont confirmé par des essais la cristallisation de l'ettringite dans les pores, après sa formation dans la phase liquide.

Ce ciment est employé pour la fabrication de tuyaux précontraints en béton, en Chine (environ 2000 km par an).

6.3 - Le travail 2.8 présente un ciment ayant comme additif  $MgO$ , en envisageant l'emploi de ce ciment à la fabrication du béton expansif pour barrage. Les auteurs montrent que la calcination de  $MgO$  à haute température conduit à un produit d'hydratation très lent ou inerte. Par contre la calcination de  $MgO$  entre 900 et 950°C, avec broyage pour obtenir des grains de 300 à 1180  $\mu m$ , additionnés de 5% de ciment Portland, peut donner un ciment expansif capable de neutraliser le retrait des bétons des barrages.

## 7. Etudes diverses.

7.1 - Le travail 2.9 présente une recherche sur des pâtes de ciments expansifs soumis, après hydratation, à une forte compression de 50 kg/cm<sup>2</sup> jusqu'à 500 kg/cm<sup>2</sup>.

Comme conséquence, on observe une réduction appréciable de la porosité. L'étude comporte des observations morphologiques sur la microstructure des hydrates.

7.2 - Le travail 2.7 traite d'un additif complexe au ciment Portland ou aux laitiers, capable de produire des expansions de 0,1 % à 0,4 %. Le produit est breveté dans plusieurs pays.

I. M. A.S. BOLDYREV, du Ministère de l'Industrie des Matériaux de Construction de l'URSS, a présenté son rapport principal, de 17 pages sous le titre "Autres ciments, ciments à haute teneur en  $\text{C}_2\text{S}$  actif, et leurs utilisations" en s'appuyant sur une bibliographie sélectionnée de 50 textes.

2. Le sous-thème 5,3 peut être commenté d'une façon plus commode en le subdivisant en quatre parties :

a) ciments à  $\text{C}_2\text{S}$  actif

ces ciments ont été étudiés dans le rapport principal et dans les travaux 3.3., 3.4, 3.5 et 3.6.

b) ciments pour colmatage des puits pétroliers.

les travaux 3.7, 3.8 et 3.9 se rattachent à ce type de ciment.

c) ciments à haute résistance initiale

3 travaux : 3.10, 3.11 et 3.13, traitent des ciments à haute résistance initiale.

d) autres ciments.

3. Ciments à  $\text{C}_2\text{S}$  actif.

3.1 - Le rapport principal montre l'intérêt attaché en URSS à l'utilisation, dans la fabrication du ciment, de produits technologiques secondaires comme par exemple la boue rouge : déchet de la fabrication de l'alumine, en partant de la néphéline comme matière première, et qui existe en abondance. "Le procédé fournit, à titre de sous-produit, un schlamm de néphéline à teneur en eau allant jusqu'à 50 %, la matière solide contenant 80 à 90 % de  $\beta\text{-C}_2\text{S}$ " (p.2).

Dans son rapport principal, l'auteur signale aussi l'utilisation du "Schlamm de cendres", des lignites bruns extraits dans la région de Moscou, dont la matière solide est constituée de 70 à 75 % de  $\beta\text{-C}_2\text{S}$ .

Dans les deux cas, le schlamm est considéré comme "un produit de départ très efficace pour la fabrication du clinker et un constituant du ciment portland". En utilisant ce schlamm comme matière première associée au calcaire, trois usines produisent actuellement du ciment. "Dans toutes ces usines le rendement des fours rotatifs est de 30 % plus élevé, et la consommation unitaire de combustible de 20 à 25 % plus basse que dans les fours du même type lors de la cuisson des matières premières traditionnelles" (p.9)

Le rapport principal traite aussi du "Ciment Portland Bélitique (CPB) renfermant plus de 20 % de bélite technogène". La somme de la bélite, additif au clinker Portland, et de la bélite du clinker donne la teneur totale en bélite.

L'expérience a montré qu'avec 45 % de bélite on obtient un ciment Portland bélitique qui atteint des résistances à la compression de l'ordre de 25 à 30 MPa à 28 jours et près de 55 MPa à six mois (fig. 4).

3.2 - Dans le même but, les auteurs du travail 3.3 ont présenté une étude sur l'activation mécano-chimique du  $C_2S$  technogène, en utilisant le broyage par percussion, par vibration et finalement par jet déjà utilisé en Russie.

Un mélange de 70 % de clinker portland avec 30 % de  $\beta$  et de  $\gamma$  -  $C_2S$  et 5 % de gypse a été soumis à un broyage par jet (équipement russe série USU - 300) et "les résultats obtenus sont considérablement plus élevés que ceux obtenus, pour une même composition, dans un broyeur à boulets". Le taux de résistance obtenu "correspond au Portland ordinaire (classe 400, Normes GOST 10178-76) ou bien au ciment type 1 ASTM - 150.

3.3 - Dans le travail présenté par STRUILLON et ARNOULD (3.5) on produit du " $\beta$ - $C_2S$  sulfaté" à partir d'un cru à 6 % de gypse et à spongolithe, en utilisant une phase nitreuse intermédiaire. "L'évolution de la résistance dans le temps du  $\beta$ - $C_2S$  sulfaté est comparable à celle du  $C_3S$  ou du CPA 400. Elle est environ 10 à 15 fois plus rapide que celle du  $\beta$ - $C_2S$  pur, classique, non sulfaté.

L'examen par diffraction RX du  $\beta$ - $C_2S$  avec ou non la phase nitreuse intermédiaire, montre des pics dans le diffractogramme, bien distincts. Les auteurs attirent l'attention sur le fait que les réactions de clinkérisation s'effectuent en 20 minutes à la température de 750°C (beaucoup plus basse que celle de clinkérisation du  $\beta$ - $C_2S$  pur).

3.4 - Des considérations théoriques sont présentées par les auteurs du travail 3.4 sur l'activation chimique du  $\beta$ - $C_2S$ .

#### 4 - Ciments pour des puits pétroliers.

4.1 - Dans son rapport principal, l'auteur signale (p.13) les expériences faites avec "un ciment de colmatage bélitique technogène et siliceux", qui a été préparé à partir d'un mélange d'un produit bélitique technogène et d'un sable quartzeux dans un rapport de 70:30 à 30:70, et broyé jusqu'à l'obtention d'une surface spécifique de 2 à 4 milliers de  $cm^2/g$ . "Ce ciment a bien durci

sans qu'on ait recours à des activateurs tels que le ciment Portland ou le gypse, dans les essais réalisés" à des températures comprises entre 150 et 300°C et avec des pressions allant de 500 à 700 atm."

4.2 - Les auteurs de l'excellent travail 3.7 ont traité des "intensificateurs cristallo-chimiques de durcissement ICD". Dans certaines conditions, les liants additionnés de ces "intensificateurs" en solutions aqueuses saturées de chaux et d'acide silicique, en proportion de 1 à 3 % par rapport à la masse du ciment, accroissent leur résistance d'une valeur allant jusqu'à 60 % (p.5).

Ils ont aussi fait des recherches sur des ciments de colmatage expansif de grande expansion utilisant en tant que constituants des ICD et des oxydes de calcium et de magnésium cuits à des températures différentes avec du sable quartzeux.

4.3 - L'importance de la granulométrie des ciments de colmatage est l'objectif principal des auteurs du travail 3.8. Ils montrent par exemple que "l'augmentation, dans la proportion de 2,5 fois, de la teneur en fractions de 0-5 mm, conduit à un accroissement de 3 fois de la résistance du ciment CCAE-2 (ciment expansif allégé) durant les premiers jours".

4.4 - Enfin, les auteurs du travail 3.9 ont présenté une recherche, encore en cours, sur des ciments pour forages profonds.

Ils ont examiné plusieurs compositions possibles dans les deux systèmes  $CaO-Al_2O_3-SiO_2-H_2O$  et  $CaO-MgO-SiO_2-H_2O$ .

#### 5 - Ciments à haute résistance initiale.

5.1 - Les auteurs du travail 3.10 ont fait des nombreuses recherches dans le système  $CaO-Al_2O_3-SiO_2-SO_3$  et finalement sont arrivés à un ciment ayant la composition potentielle suivante :  $C_4A_3S$ -54%;  $C_2S$ -32%;  $C_4AF$ -5 % et  $CaO$  (libre) 9 %. Ce clinker fut obtenu à température de 1300°C et fut broyé à 5500  $cm^2/g$ . Il est important d'observer que si la température de clinkérisation atteint 1350°C, le  $C_4A_3S$  se décompose et donne  $C_3A$ . Ce ciment a présenté les résistances suivantes dans un béton de 420  $kg/m^3$  de ciment (en  $N/mm^2$ ) : à 6h: 24,7 - à 1 jour: 55,8; à 3 jours: 90,6 et à 28 jours : 96,8.

5.2 - L'auteur du travail 3.11 présente un ciment super-rapide, obtenu par un mélange de 82 % en poids de clinker Portland, et 18 % de ciment alumineux, avec des additifs et du gypse pour le contrôle de la prise. Le mélange est broyé à 5580  $cm^2/g$ . Ce ciment atteint

5 N/mm<sup>2</sup> à 2 heures, selon l'essai normal (DIN 1164).

Les essais sur cubes de 20 cm de côté de ce béton, selon la norme DIN 1048 ont donné, après 2 heures, des résistances de 3 à 6,5 N/mm<sup>2</sup> (rapport e/c de 0,70 et 0,45) à 28 jours, respectivement 30,2 et 46,6 N/mm<sup>2</sup>, et à 360 jours une résistance 20 % plus élevée.

Ce travail contient aussi l'étude d'un ciment pouzzolanique.

5.3 - Les auteurs du travail 3.13 donnent des informations sur un ciment fabriqué avec des laitiers de hauts-fourneaux, des laitiers électrothermo-phosphoreux et d'autres types de laitiers métallurgiques, additionnés de produits basiques contenant des alcalis (sodium, potassium, solutions de silicate de sodium) et de sous-produits industriels (fusion de soude-alcaline, de soude, métasilicate de sodium, etc.).

Ce ciment, en usage en Russie depuis 1960, donne des résistances à la compression (mesurées selon la norme GOST 310.4.76) de :

à 1 jour : 350 kg/cm<sup>2</sup>

à 2 jours : 550 kg/cm<sup>2</sup>

à 3 jours : 750 kg/cm<sup>2</sup>

et à 28 jours : 1000 à 1200 kg/cm<sup>2</sup>

## 6. Autres ciments.

### 6.1 - Ciment blanc - travail 3.1.

Dans cette communication, les auteurs exposent les résultats de recherches sur l'influence des amino-alcools (mono et triétanolamine) et de liquides silico-organiques (éthyl ou méthylsilicate de sodium) sur le processus de blanchiment des clinkers de ciment Portland blanc.

Ils ont obtenu une amélioration sensible du coefficient de réflexion diffuse.

### 6.2 - Ciment à très faible chaleur d'hydratation - travail 3.2

Les auteurs ont fait des recherches en mélangeant un ciment de haute résistance initiale et du laitier de haut-fourneau, et ont obtenu un ciment à dégagement de 55 cal/g de chaleur à 28 jours.

### 6.3 - Béton armé de fibres de verre - travail 3.6.

Les auteurs ont fait des recherches sur un "ciment exempt de C<sub>3</sub>S et de C<sub>4</sub>A. Ses principaux constituants sont : le sulfo-aluminate de calcium 3(CA).CaSO<sub>4</sub> et le sulfosilicate de calcium 2(C<sub>2</sub>S).CaSO<sub>4</sub>". Ce ciment, d'après les auteurs, donne des résistances semblables à celles du ciment Portland et assure

une meilleure durabilité quand il est employé dans le béton armé de fibres de verre.

### 6.4 - Ciment d'alynite - travail 3.12.

Les auteurs traitent d'un ciment breveté en URSS. L'alynite a la formule chimique : Ca<sub>11</sub>(Si,Al)<sub>4</sub>O<sub>18</sub>Cl. Le ciment d'alynite est obtenu à partir des matières premières traditionnelles, avec addition de chlorure de calcium. "L'alynite constitue 60-80 % de la masse du clinker". Les auteurs ont présenté une étude très poussée de la structure atomique de l'alynite.

### 6.5 - Ferrites de baryum - travail 3.14.

Les auteurs ont présenté les résultats d'une recherche du système BaO-Fe<sub>2</sub>O<sub>3</sub> et ont cherché à caractériser les composés suivants : BF, B<sub>3</sub>F<sub>2</sub>, B<sub>5</sub>F<sub>2</sub>, B<sub>3</sub>F et B<sub>7</sub>F<sub>2</sub> (B = BaO et F = Fe<sub>2</sub>O<sub>3</sub>).

L'étude est minutieuse et les auteurs concluent que le B<sub>3</sub>F ne doit pas se former et que le B<sub>7</sub>F<sub>2</sub> a été confirmé pour la première fois dans cette étude.

### 6.6 - Ciment pour emploi aux basses températures - travail 3.15 -

Les auteurs ont étudié un ciment Portland sans gypse, mais avec addition d'un dérivé de lignite et d'un carbonate alcalin (K<sub>2</sub>CO<sub>3</sub>) ou de bicarbonate. Le clinker est broyé très fin (de l'ordre de 10.000 cm<sup>2</sup>/g). Les résistances obtenues à des températures de - 20°C et - 35°C sont de l'ordre de 23 et 12 MPa à 28 jours.

### 6.7 - Ciments thermo-durcissants (CTD) - Le

travail 3.16 traite du CTD qui est composé principalement de C<sub>3</sub>S, de CA et C<sub>4</sub>AF et CaSO<sub>4</sub> (anhydrite avec addition d'acide citrique pour contrôler le temps de prise). Ce ciment est utilisé avec une cure à la température de 80°C pendant 30 minutes à 2 heures. Il présente la propriété de ne pas attaquer les fibres alcalines de verre du béton armé avec ces fibres.

### 6.8 - Adjuvants pour ciment - travail 3.17 -

Les auteurs ont breveté dans plusieurs pays un type d'adjuvant qui peut être additionné au ciment, au malaxeur ou en fabrique. D'après ces auteurs, on peut obtenir une résistance à la compression plus élevée du ciment à l'essai normal ou dans le béton à 28 jours.

### 6.9 - Utilisation de sous-produits minéraux dans la production des liants - travail 3.18

Les auteurs, comme le Rapporteur Principal, attachent une grande importance à l'utilisation de sous-produits et de déchets industriels pour la fabrication des liants.

## DISCUSSION

par T.V. KUZNETSOVA

concernant la communication de J. Calleja "Calcul des compositions potentielles théoriquement possibles des ciments alumineux".

Contrairement au ciment portland, il n'existe pas jusqu'à présent de méthodes fiables pour calculer la composition minéralogique des ciments alumineux à partir des résultats de l'analyse chimique. C'est pourquoi l'approche du professeur J. Calleja mérite une très grande attention et une haute appréciation. Cependant nous voulons souligner les circonstances pouvant conduire aux erreurs dans les calculs:

1. En cas des ciments alumineux fondus, il est nécessaire de maintenir un certain régime de refroidissement, car le refroidissement rapide provoque la formation d'une phase vitreuse qui modifie la composition réelle du clinker par rapport aux calculs.
2. En cas de production du clinker des ciments alumineux par frittage, l'équilibre de phase dans le four industriel est obtenu à grand-peine et dépend considérablement de la température et du milieu gazeux de cuisson, ainsi que de la présence d'impuretés dans les crus. Nos recherches montrent que  $\text{SiO}_2$ ,  $\text{MgO}$ ,  $\text{Fe}_2\text{O}_3$  peuvent former les solutions solides avec  $\text{C}_{12}\text{A}_7$ ,  $\text{CA}$  et  $\text{CA}_2$  en quantité de 2-3%.

Il est nécessaire d'en tenir compte lors des calculs de la composition de phase du clinker.

## DISCUSSION

par T.V. KUZNETSOVA

concernant la communication de U. Yamazaki, H. Kamiaka et S. Kobayashi "Role of expansive additive  $\text{CaO}$  in expansive cement".

La présence de la chaux dans les ciments expansifs influe, en effet, sur la formation de leurs propriétés (expansion, auto-contrainte, résistance). Cependant, de notre point de vue, le rôle de  $\text{CaO}$  consiste en concentrations de la chaux dans le système qui modifie la cinétique et les conditions de formation d'ettringite déterminant l'expansion du ciment. Nos recherches montrent que la cristallisation de l'ettringite primaire à partir de la solution sursaturée conduit à l'étanchéité et à l'amélioration de la pierre de ciment. La formation de l'ettringite secondaire par suite de l'interaction de la solution diffusée contenant  $\text{Ca}^{2+}$  et  $\text{SO}_4^{2-}$  par rapport aux aluminates hydratés de calcium, hydroxyde d'aluminium ou par rapport aux cristallinités d'ettringite mène à l'expansion de la pierre de ciment.

## DISCUSSION

par A. S. BOLDYREV

### I. Activation chimique de $2\text{CaO} \cdot \text{SiO}_2$

Je pense qu'avant de parler de l'activation chimique du  $\beta$ -silicate bicalcique il faut dire quelques mots à propos de sa stabilisation.

La tendance du C.S. au polymorphisme dans la série  $\alpha \rightarrow \alpha' \rightarrow \beta \rightarrow \gamma$  et le changement d'activité d'hydratation du silicate bicalcique, lié à ce fait, ont déterminé la poussée à de nombreuses recherches concernant la stabilisation des formes de haute température du C.S. Du point de vue de l'utilisation industrielle de certains déchets, la conversion  $\beta \rightarrow \gamma$  a une très grande importance, car il n'existe pas jusqu'à présent d'une opinion commune relative à l'activité d'hydratation du  $\gamma$ -C<sub>2</sub>S.

Les principes essentiels de stabilisation cristallochimique consistent en substitution isomorphe cationique et anionique dans la structure du C<sub>2</sub>S. On peut utiliser en qualité des stabilisateurs de nombreux oxydes ( $\text{K}_2\text{O}$ ,  $\text{Na}_2\text{O}$ ,  $\text{MgO}$ ,  $\text{BaO}$ ,  $\text{Al}_2\text{O}_3$ ,  $\text{Cr}_2\text{O}_3$ ,  $\text{P}_2\text{O}_5$ , etc.).

Dans ce cas, on peut également utiliser des additions complexes comprenant les différents cations et anions. En principe,

l'activation du  $\beta$ -C<sub>2</sub>S est obtenue à l'aide de constituants additifs, plus basiques que  $\text{Ca}^{2+}$  et plus acides que  $\text{Si}^{4+}$ .

Dans mon rapport concernant le thème Y j'ai cité les résultats des expériences relatifs à la production d'un grand lot industriel de ciment aluminosilicate aux laitiers obtenus lors de la fonte bauxite. Le laitier se composait de  $\gamma$ -C<sub>2</sub>S et d'aluminates de calcium à faible basicité ce qui a permis d'obtenir le ciment dont l'activité a été de 250-400 kgf/cm<sup>2</sup>.

Il y a des données témoignant que le laitier friable obtenu lors de la production des ferro-alliages et se composant pour 70-80% de  $\gamma$ - $2\text{CaO} \cdot \text{SiO}_2$ , en cas d'utilisation de ses suspensions aqueuses à la température élevée, montre la prise avec du sable (30-50 %) et forme la pierre de ciment possédant une haute thermostabilité. Le  $\gamma$ - $2\text{CaO} \cdot \text{SiO}_2$  actif a été obtenu à NIICiment-1 lors du broyage du ciment contenant 30% de  $\gamma$ - $2\text{CaO} \cdot \text{SiO}_2$  dans le broyeur à projection.

Cependant au niveau de nos connaissances d'aujourd'hui il est plus préférable d'avoir affaire à  $\beta$ - $2\text{CaO} \cdot \text{SiO}_2$ .

### II. Ciments de bélite pour colmatage à base des pâtes néphélines

Grâce au développement en U.R.S.S. de l'industrie du pétrole et du gaz le besoin en ciments pour colmatage a augmenté d'une manière brusque.

L'enfoncement des forages jusqu'à 7-10 M. mètres a mené à l'élévation des températures atteignant 200°C et à l'augmentation de la pression jusqu'à 120 atmosphères techniques absolues.

Les exigences pour la pierre de ciment concernant sa densité, étanchéité à l'eau et, enfin, sa résistance à la corrosion par l'eau minéralisée ont considérablement augmenté.

À présent, l'U.R.S.S. produit environ de 3 millions de tonnes de ciments pour colmatage ayant 8-12 types différents satisfaisant aux conditions spécifiques du colmatage thermostables, on a élaboré et on utilise avec succès le ciment siliceux de bélite "BKC". Il comprend la pâte néphéline ( $\beta$ - $2\text{CaO} \cdot \text{SiO}_2$ ) et le sable quartzueux broyé avec rapport de 3:1 ou 1:1.

Les ciments ci-dessus sont caractérisés par le retardement de la prise aux températures élevées, retardement du durcissement initial, ainsi que par une haute thermostabilité et la stabilité de la composition. Ces ciments sont les meilleurs pour les forages à haute température.

Pour les forages ultraprofonds, où il est nécessaire de monter le mortier de ciment presque jusqu'à la tête du forage, en vue de séparer la rangée de niveaux, on nous a obligé d'élaborer un ciment spécialement allégé ayant un rapport élevé eau/ciment et des additions minérales actives, ainsi qu'une grande surface spécifique. Pour les forages où règnent les températures de 120-180°C on utilise le ciment comprenant 50-60 parties de pâte néphéline, 25-30 parties de sable quartzueux et 10-15 parties d'additions hydrauliques.

### III. Au sujet de la fabrication et de l'utilisation des ciments mixtes à base du ciment portland et du ciment alumineux

On n'utilise pas les mélanges de ciment portland et de ciment alumineux, car ils diminuent brusquement la résistance et montent le temps de prise minimum.

On a élaboré en U.R.S.S. un ciment expansif (RPC) se composant de clinker portland (60-65%), de ciment alumineux (5-7%), de gypse naturel (7-10%) et d'additions hydrauliques (20-25%).

Les études du ciment ont montré que même pendant les premières heures d'hydratation on observait la formation de l'hydrosulfate d'aluminate de calcium ayant la forme de trisulfate qui détermine l'activité et le degré d'expansion du ciment.

# DISCUSSION

by LU CHUN-XUAN

In China, red slime, a by-product consisting mainly of dicalcium silicate and formed in the manufacture of alumina, has been utilized in the cement industry for more than ten years. To date the red slime (dry basis) utilized amounts to 1.5 million tons. More than 5 million tons of various kinds of cement made from red slime, such as ordinary portland cement, oil well cement and red slime-sulfate cement have been manufactured.

The chief constituents of the red slime

are as follows:

$\beta$ -C <sub>2</sub> S	C <sub>3</sub> AS <sub>x</sub> H <sub>y</sub>	NAS <sub>2</sub> H <sub>2</sub>	PH <sub>n</sub>	CaCO <sub>3</sub>	CT
50-60	5-10	5-10	4-7	2-10	2-5

The specific surface of the red slime is about 4200-5000 cm<sup>2</sup>/g. the melting point is about 1250-1270°C. The viscosity of the molten mass is low and its fluidity fair. When the red slime is proportioned with a suitable amount of limestone residue, also an industrial by-product of the alumina works, the resultant raw slurry has good burnability in clinkering.

Table I shows the chemical composition of the clinker made from the red slime and the physical properties of the cement.

Table I

SiO <sub>2</sub>	Al <sub>2</sub> O <sub>3</sub>	Fe <sub>2</sub> O <sub>3</sub>	CaO	MgO	K <sub>2</sub> O+Na <sub>2</sub> O	C <sub>3</sub> S	C <sub>2</sub> S	C <sub>3</sub> A	C <sub>4</sub> AF	sp surf (cm <sup>2</sup> /g)	setting		comp str (N/mm <sup>2</sup> )		
											ini	fin	3d	7d	28d
20.78	5.59	5.58	63.24	1.24	1.13	50.54	21.44	5.45	16.73	3115	2:50	4:41	37.3	47.9	61.7

Since the red slime is low in silica and high in iron oxide content, repeated experiments have been carried out on an industrial scale to produce clinkers of low silica and high iron oxide content. The silica moduli

of the clinkers made are as low as 1.12-1.56 and the iron moduli are from 0.6 to 1.0. The physical properties of the cements made from the clinkers are normal, as shown in Table II.

Table II

No.	L.S.	S.M.	I.M.	C <sub>3</sub> A+C <sub>4</sub> AF	f-CaO	sp surf (cm <sup>2</sup> /g)	setting		comp str (N/mm <sup>2</sup> )		
							ini	fin	3d	7d	28d
1	0.924	1.56	0.98	25.35	1.09	3075	1:52	3:23	46.6	58.1	67.8
2	0.942	1.36	0.80	26.67	1.10	3085	2:16	3:43	46.1	60.0	68.5
3	0.929	1.12	0.95	34.15	0.79	3060	2:08	3:29	41.6	55.2	61.1
4	0.888	1.43	0.84	26.47	0.75	3125	2:19	3:23	40.9	54.3	64.5

If a suitable mineralizer is added to the raw slurry to produce the clinkers shown in Table II, the free lime content in the clinkers may drop down to about 0.5% even if the alkali content of the clinkers is as high as 2%.

The cement made from such clinkers has the following good features, that is,

lower heat of hydration, better resistance to sulfate attack and frost action, and lower permeability as compared with ordinary portland cement. This cement has been used with non-reactive aggregate in hydraulic structures and good results have been obtained.

## Conclusion des échanges de la table ronde

par M. SOUSTELLE et B.F. COTTIN

Ce thème était divisé en trois sous-thèmes et cinq questions essentielles appartenant à ces sous-thèmes ont été abordées.

### Sous-thème V.1: Ciments alumineux

Sujet n° 1 : A la suite de la communication de L. CUSINO et A. NEGRO sur l'hydratation du ciment alumineux en présence d'agréats siliceux et calcaires, il est maintenant bien établi qu'une réaction se déroule entre les aluminates hydratés et le carbonate de calcium pour former des carbo-aluminates. Cette réaction se déroule aux dépens de la conversion de  $CAH_{10}$  en  $C_3AH_6$ . Ce carbo-aluminate formé a une influence favorable sur la liaison pâte-granulat, ce qui provoque une forte augmentation des résistances.

Il est particulièrement intéressant que les auteurs prolongent leur expérience qui a déjà cinq ans, pour prouver que les résistances se maintiennent pour des échéances plus longues. Il est cependant étonnant que les résistances se dégradent aussi vite que l'annoncent les auteurs en présence des agrégats siliceux, et il conviendrait d'examiner avec plus d'attention l'influence du rapport E/C dans les deux cas, et particulièrement en présence de calcite.

Tous les intervenants ont noté l'importance d'une bonne définition de la température aussi bien au moment de l'hydratation que pendant la conservation, car il y a une très grosse influence de ce paramètre sur les résultats obtenus.

Deux problèmes majeurs, auxquels aucune réponse n'est encore apportée, restent posés :

- Quelle est l'influence de la présence d'alcalins ?
- Quelle est la stabilité des carbo-aluminates en présence d'agents agressifs ?

Sujet n° 2 : A la suite de la communication de J. CALLEJA sur le calcul de la composition potentielle des

ciments alumineux, la question est posée pour savoir si ce calcul extrêmement intéressant de l'auteur est applicable dans tous les cas.

Il est évident que prévoir les phases par l'utilisation de formules analogues à celles de BOGUE est du plus haut intérêt pour le fabricant de ciments alumineux fondus. Malheureusement, alors que pour le ciment Portland les formules de BOGUE donnent une bonne approximation des phases en présence, le problème est plus difficile dans le cas des ciments alumineux préparés par fusion.

Parmi les causes de ces difficultés, on peut citer :

- le nombre de phases décelées (par diffraction X, microscopie ...) est toujours supérieur à celui autorisé par la règle de GIBBS (écarts importants à l'équilibre).
- l'existence d'une partie vitreuse dans la masse du ciment,
- l'importance des solutions solides.

Un gros progrès apporté par le calcul du Professeur CALLEJA vient du fait qu'il tient compte d'une manière rigoureuse de certaines solutions solides et notamment des phases alumino-ferrites; mais il est certain que la généralisation de ces formules est limitée par les écarts à l'équilibre, plus ou moins importants selon les cas, et inévitables.

### Sous-thème V.2 : Ciments expansifs.

Sujet n° 1 : Au sujet de la communication de P.K. MEHTA, D. PIETZ et G.J. KOMANDANT sur l'addition d'oxyde de magnésium pour la production de ciment expansif, il est très clairement montré que le maximum de l'expansion est obtenu par une température de calcination de 900°C avec des particules de dimensions comprises entre 380 et 1180 m. Mais il est évident que les résultats sont encore à l'échelle du laboratoire et bien que très prometteurs, ils n'en sont pas encore au stade industriel, et en particulier, le comportement des grandes masses n'a pas été encore étudié.

Sujet n° 2 : Les causes de la pression d'expansion des ciments expansifs : différentes causes de cette pression sont analysées par la table ronde. Sans qu'il soit possible de connaître leurs poids respectifs, on relève :

- les causes liées à la pression de cristallisation qui peut être due, soit à la transformation en travail de la variation d'enthalpie libre de la

transformation, soit à la présence d'une solution sursaturée dans des capillaires, ce qui l'empêche de précipiter,

- les causes liées à la pression osmotique,
- les causes liées au fait que l'ettringite formée est mal cristallisée et se présente sous forme de gel qui provoque le gonflement.

Sujet n° 3 : La formation de l'ettringite est elle favorisée par la sous ou la sursaturation en chaux ? Se forme-t-elle au contact des cristaux d'aluminates ou au contraire loin de ceux-ci dans la solution ?

Le modèle de B. COTTIN répond à l'ensemble de ces questions :

Dès le mélange du ciment avec l'eau, les différents types d'ions suivants passent en solution :

- les ions calcium issus du  $C_3A$ , des sulfates, de la chaux;
- les ions sulfates, issus des sulfates de calcium,
- Les ions aluminiques, issus du  $C_3A$ .

Les ions diffusent, à partir de la surface des constituants, de sorte que, en un point donné de la solution, les concentrations augmentent à des vitesses et jusqu'à des niveaux, fonctions du lieu géographique du point considéré, de la réactivité des phases et de leurs proportions relatives. Le schéma suivant représente les "fronts de dissolution" en fonction des temps croissants 1-2-3, dans un cas où, pour simplifier le dessin, nous avons mis ensemble la chaux et le sulfate de calcium.

La saturation par rapport à l'ettringite (l'hydrate le moins soluble du système  $C-A-S-H$ ) sera donc atteinte en un point (M sur notre schéma) où cet hydrate précipite. Ce point M se situe à une distance d'autant plus petite de la surface de  $C_3A$  que la vitesse de passage en solution de  $C_3A$  sera plus faible par rapport à celle des autres constituants. Lorsque le  $C_3A$  est peu actif, et la chaux libre + semi hydrate très actifs et en grande quantité, la précipitation d'ettringite peut se produire très près de la surface de  $C_3A$  :

Ceci répond à la deuxième partie de la question.

Pour la première partie, il faut considérer que l'apport de chaux en solution par  $C_3S$  et la chaux libre écarte la stoechiométrie de tous les ions en solution de celle de l'ettringite, et diminue la solubilité de l'ettringite. Il en résulte un déplacement du point M vers la gauche, c'est à dire une précipitation plus proche de la surface de  $C_3A$ . La sous-saturation relative en chaux a l'effet inverse (addition de complexants du calcium par exemple). Comme le volume, donc la quantité d'ettringite formée est d'autant plus petit que le point M est plus proche de la surface de  $C_3A$ , il est possible de conclure (et l'expérience le vérifie) que la sursaturation en chaux induit une précipitation d'ettringite en moins grande quantité, et probablement moins bien cristallisée. La sous-saturation a évidemment l'effet inverse.

### Sous-thème V.3 : Autres ciments

#### Sujet n° 1 : Stabilisation et activation du $\beta C_2S$ :

Les différentes interventions mettent en évidence qu'il est possible de préparer une phase  $\beta C_2S$  qui a des propriétés analogues à  $C_3S$ , mais que cette phase doit être stabilisée. Elle peut l'être de trois manières :

- par la présence d'ions de métaux lourds dans le réseau du silicate : ions trivalents (Cr, Fe, Al, B), ion tétravalent (Ti),
- par la présence d'anions divalents ( $SO_4^{2-}$ ) ou trivalents (phosphates) en solution solide dans le réseau du silicate,
- par la présence de cations alcalins dans le réseau du silicate.

Dans les trois cas, on forme de véritables solutions solides.

Examinons ces différents cas et les conséquences qu'entraînent ces adjonctions d'ions au réseau du  $\beta C_2S$  par l'intermédiaire de la neutralité électrique :

- a) la présence de cations trivalents ou tétravalents en substitution d'ions calcium divalents dans un réseau a pour conséquence, comme le montre le schéma, la présence de lacunes de calcium. Par exemple, pour deux ions trivalents on obtient une lacune de calcium.

Schéma 1

#### Introduction de chrome dans un réseau $\beta C_2S$

- b) la présence d'anions divalents ou trivalents en substitution d'ions silicates (tétravalents) a, comme le montre le schéma 2, pour conséquence la présence des mêmes lacunes de calcium (pour un ion sulfate, on obtient une lacune de calcium).

Schéma 2

#### Introduction de $SO_4^{2-}$ dans le $\beta C_2S$

- c) la présence de cations alcalins monovalents de petites dimensions, en insertion dans le réseau a pour conséquence, comme le montre le schéma 3, la présence des mêmes lacunes de calcium.

Schéma 3

#### Introduction d'un alcalin en insertion dans $\beta C_2S$

Il semble donc, en définitive, que l'élément de base qui stabilise cette phase  $\beta C_2S$  et qui sans doute l'active, soit la présence de lacunes de calcium dans le réseau.

Pour introduire dans ce réseau ces différentes impuretés qui induisent ces lacunes, il est clair qu'une méthode qui passe par une phase liquide et une co-précipitation, est plus efficace qu'une méthode de diffusion à l'état solide.

## THEME VI

### Cement pastes : rheology and evolution of properties and structures

by Professor S. DIAMOND

#### I. INTRODUCTION

This general report represents an effort to assess the large body of information submitted to the Congress related in various ways to the characteristics of cement pastes. A total of four principal papers and forty communications are included in this portion of the Congress activity. The topics covered are broken down into four general areas, loosely relating to (a) rheological and other characteristics of fresh cement pastes, (b) the formation and evolution of structure in hardened cement paste, (c) the properties of mature cement paste, and (d) mathematical models attempting to describe structure or strength development. The topics are far from mutually exclusive and are not exactly coincident with the areas covered by the authors of the principal papers, but they serve as a convenient framework for review and analysis.

It should be pointed out at the outset that the opinions expressed in this general report are entirely the personal views of the writer and should be so regarded. The writer apologizes in advance for any statements which misconstrue the results or the interpretations of any of the contributors whose work is mentioned.

#### II. RHEOLOGICAL CHARACTERISTICS OF FRESH CEMENT PASTES Rheology of Plain Pastes and Concrete

It is especially fitting to discuss the rheology of cement paste and concrete at an International Congress to be held in Paris. The accomplishments of what might be loosely termed the French school of cement and concrete rheology certainly deserve special acknowledgement, and the contributions of such workers as LeGrand, Bomblé and other French colleagues are evident in the view provided in the principal paper of Helmuth (1) and in papers contributed to this portion of the Congress.

Strictly speaking, this Congress is concerned with cement and cement paste rather than with concrete *per se*, but it is apparent that the rheological characteristics of fresh paste are of concern primarily because of their influence on the flow behavior and workability of concrete. It has become recognized in recent years that most fresh mortars and concretes behave approximately as Bingham fluids, whose yield stress and plastic viscosity parameters are at least conditioned by the flow characteristics of the cement paste portion. Naturally, concrete flow behaviour also reflects particle interactions between aggregate grains, and the pattern of behavior may be modified by the effects of vibration used in placing the concrete.

Despite efforts by various workers to put testing of flow behavior and "workability" of concrete on a rational basis, nearly all fresh concrete testing continues to be done by arbitrary empirical methods such as the slump, flow, Vebe, compaction factor and Vicat tests. In their contribution to this Congress Maultzsch and Meinhold (2) describe and report on certain proposed improvements in several of these tests, especially the mortar flow test. Such improvements may certainly prove to be helpful, but they do not really address the question of properly characterizing concrete and mortar in rheological terms.

Most of the concern with rheological matters at this Congress is of course not with concrete but with cement paste. Two central questions appear to emerge:

(1) How does one properly characterize and understand the rheological behavior of a given cement paste, and

(2) What are the changes in behavior that follow from changes in cement characteristics, or from incorporation of mineral or chemical admixtures, especially superplasticizers?

Evaluation of the rheological characteristics of cement pastes may be easier than evaluation of concretes because of the reduced level of particle interaction, but even so it is an extremely difficult and demanding field.

Rheological characteristics of suspensions are normally determined in terms of flow curves. For most substances the method of mixing does not seriously affect the flow behavior of the resulting suspension, nor does the suspension change character in response to ongoing chemical reactions while its flow behavior is being determined. Unfortunately, cement paste is uniquely sensitive to details of the mixing procedure for a variety of reasons, and hydration continuously modifies the flow characteristics of the paste, even through the apparent "dormant" period. Both of these features have been discussed in detail by Helmuth (1).

To a reasonable first approximation, the flow characteristics of fresh cement paste are those of Bingham fluids. The behavior is quite obviously the result of the state of flocculation existing in the suspensions, which for pastes not incorporating water-reducing or superplasticizing admixtures is practically complete. As an illustration, sedimentation data for "control" pastes reported in the communication by Palliere and Briquet (3) show no particles sedimenting at effective diameters below about 45  $\mu\text{m}$ , all individual particles below this size being bound in flocs. In ordinary pastes of the usual range of water contents sufficient bonding develops between flocs that some minimal level of shear stress (the Bingham yield stress) must be applied for continuous flow to be initiated. The flow units actively moving at low shear rates are quite obviously flocs and not individual particles. However, if flow is maintained at higher rates by application of shear stresses substantially higher than the yield stress the flocs tend to break down to smaller flow units and the suspension "thins" over some finite period to an equilibrium state characteristic of the particular shear rate. The flowing paste then continues in this state while flow is maintained. If shearing slows or stops the suspension tends to recover its original state of flocculation.

Two complementary descriptive parameters emerge from this picture. The primary parameter is the flow curve, in principle a plot of shear stress-shear rate points, each corresponding to an equilibrium state of the flowing suspension. Of secondary interest but of importance in special situations is a mathematical description of the rate of thinning

and of the rate of recovery of the original structure at each shear rate. The two types of information together constitute an appropriate description of the flow characteristics of a given paste at a given time after mixing (or as close to a given time as the data can reasonably be acquired). Note that the implication is that each measurement at a given shear rate is properly carried out on a separate batch of paste, with the times of mixing of the batches appropriately staggered.

A considerable amount of perhaps avoidable complication has entered the literature on cement paste rheology as a result of flow testing carried out on certain modern coaxial cylinder viscometers. These are highly sophisticated, but in the writer's opinion highly inappropriate instruments for characterizing the flow behavior of cement pastes. Part of the problem is associated with the transient (or sometimes permanent) inhomogeneity in the flow across the gap, referred to by various workers in their communications to this Congress and elsewhere. The other feature is the interaction of the first with the way such instruments are operated. Rather than maintaining a constant shear rate and measuring torque (shear stress) over time until equilibration is established, in these instruments the shear rate is increased continuously according to a program selected by the investigator, and then decreased continuously to zero in a like time period. The torque or shear stress is measured continuously and "up" and "down" flow curves are produced automatically. The paste is never in an equilibrated condition at any shear rate. In such flow curves hysteresis loops, *i.e.* displacements of the down-curve with respect to the up-curve, are commonly observed, and a rounding off toward the origin at low shear rates is a common feature. As indicated by Helmuth (1) these responses are conventionally described as "thixotropic" or "antithixotropic" loops and pseudoplastic behavior, respectively. Much effort and attention has been expended in efforts to provide structural interpretations explaining these observations, even though "thixotropic" and "antithixotropic" behaviour can succeed each other in successive runs with the same paste.

In their communication to this Congress, Nagataki and Kawano (4) suggest that these effects may be manifestations related to the development and breakdown of a somewhat nebulous "secondary structure" relating to gel formation and distinct from the floc structure of the pre-existing paste. This is in contrast to the interpretation in terms of varying rate of breakdown and recovery of the floc structure as outlined by Helmuth (1). The present writer feels that these effects may have more to do with the properties of the different viscometers and shearing schedules selected by the investigators than with the flow behaviour of the cement pastes *per se*. In his view attempts to analyze such transient behavior have not been particularly fruitful and are not likely to be so in the future.

The flow curve determined as a succession of equilibrium states is for most cement pastes approximately that of a Bingham fluid, and as such is adequately characterizable in terms of the simple parameters of yield stress and plastic viscosity. This approach has been taken in most of the relevant contributions to this Congress, and the results stated are at least approximately comparable with each other. One should mention that, as indicated by Helmuth (1), pastes too stiff to be tested in conventional

viscometers may still be characterized in terms of yield stress in specially devised instruments generally called rheographs or plastometers.

Values of yield stress usually recorded for cement pastes may range from a few Pa to several thousand Pa shortly after mixing, and of course these increase drastically with the progressive stiffening that accompanies the approach to set. A number of equations relating yield stress to such factors as water:cement ratio and cement fineness have been cited by Helmuth (1).

Values of plastic viscosity are most appropriately quoted in units of Pa-s, with some workers preferring to use mPa-s ( $\text{Pa-s} \times 10^{-3}$ ) since 1 mPa-s equals 1 centipoise, the traditional unit of viscosity. Cement paste plastic viscosities are normally in the range of tens of Pa-s unless water reducers or superplasticizers have been incorporated, in which case they are much reduced. For comparison, water at room temperature has a (Newtonian) viscosity of 0.001 Pa-s, glycerol 1.7 Pa-s.

As indicated by Helmuth (1) variations in the relative amounts of the different clinker components seem to produce only minor rheological effects, except possibly for augmented  $C_3A$  contents. On the other hand, the amount and form of the calcium sulfate interground with the clinker may have profound influence on the rheological characteristics of the paste. A significant contribution to this Congress is the paper by Bombléd (5) in which the rheological influence of various forms of calcium and other sulfates are sorted out. The effect of the sulfate depends on its solubility, and equally important, on its rate of dissolution. In  $C_3A$ -poor cement pastes, sulfate in solution remains in high concentration and acts as a strong flocculant, as a reducer of the solubility of calcium aluminates, and eventually as an accelerator of silicate hydration. With high  $C_3A$  content cements these effects are modified by rapid precipitation of the calcium aluminate sulfate hydrates and concomitant removal of sulfate from solution.

#### Admixture Effects in Rheology

The influence of mineral and especially of chemical admixtures on the rheology of fresh portland cement pastes may be profound, and a large proportion of the contributed Congress papers on rheology are concerned with this general subject.

One mineral admixture extensively employed in many countries is flyash (pulverised fuel ash). The contribution by Ivanov and Zacharieva (6) is concerned with measurements of the influence of two specific flyashes on cement paste rheology; in fact, the rheology of a complete spectrum of mixes of the two components was examined. The flyash-bearing pastes were found to yield markedly higher yield stress values and somewhat higher plastic viscosities than did the reference cement pastes.

The influence of water-reducing and superplasticizing chemical admixtures is naturally in the opposite direction. These substances function as dispersants, modifying the development of the usual floc structure, or resulting in the partial or even complete dispersion of pre-existing flocs when added after the main mixing step. The result is a marked lowering of both the yield stress and the plastic viscosity, *i.e.* a fluidification of the paste. This translates in concrete practice to a reduced water requirement for the maintenance of normal workability characteristics of the concrete.

Lignosulfonates have been used as water-reducing agents for many years. In the contribution of Tarnaroutski *et al.* (7) the influence of the molecular weight of the lignosulfonate and of the content of various functional groups on the dispersing effectiveness of lignosulfonates are explored. The technically important influences of these variations in molecular structure on air entrainment and on set retardation are also described.

The influence of the dosage rate of several different lignosulfonate water reducers on the flow characteristics of fresh cement paste are described and analyzed in detail in the contribution of Lapasin *et al.* (8). It was found that the general type of transient or "breakdown" behavior between the initial state and the equilibrium state at a given shear rate is not affected by the dosage rate but the amplitude or relative extent of the breakdown effect is concentration dependent, and it goes through a minimum at some critical concentration. Initial viscosity values also show this effect, but equilibrium viscosity values decreased monotonically with concentration. The flow curves exhibit a rounding at low shear rates, and the authors have chosen not to discuss estimates of Bingham yield stresses.

The rheological and the floc-dispersing effects of a number of lignosulfonate-related admixtures (classified as "surfactants" by the authors) and of melamine- and naphthalene-based superplasticizers were studied as functions of time of addition in an interesting contribution by Palliere and Briquet (3). The state of dispersion attained in each instance was followed by measurement of the size distribution of settling particles or flocs using a laser-based particle size measuring device, and comparison of this to the size distribution of the original cement. The superplasticizers were found to be more effective dispersants than the surfactants and were found to be even more effective when added after delays of as much as 2½ hours after mixing. In some of the trials complete dispersion to primary particles was indicated.

Further studies of the mechanism of dispersion were reported in a contribution by Collepardi *et al.* (9), who compared the effects produced by varying concentrations of a sulfonated naphthalene-formaldehyde condensate based superplasticizer with those produced by its monomer. Small addition (*ca.* 0.5 percent by weight of cement) of the superplasticizer increased fluidity markedly, but additional dosage increments to three times this level had comparatively little incremental effect, despite increases in measured zeta potential accompanying these additional dosage increments. It appears from this report that cement paste should be largely dispersed if a zeta potential of the order of -35 mV can be attained. Interestingly, it was found that the sulfonated naphthalene monomer was without effect. In agreement with the results of Palliere and Briquet (3) it was found that delayed addition of the superplasticizer increased its effectiveness, especially in the lower dosage range.

A study of the combined effects of superplasticizer and salt addition on the rheological and other characteristics of cement paste was reported in the contribution of Sheetz *et al.* (10). Such a combination might be found in salt-affected wells cemented with superplasticized portland or oil well cements. Increasing a salt content (up to as much as 35 weight percent NaCl) was found to reduce the viscosity, but the effect was erratic at lower salt concentrations and varied with the type of cement used.

In his principal paper Helmuth (1) briefly describes the results of experiments with cements in which gypsum is replaced by a mixture of a lignosulfonate and an alkali carbonate, the two together acting as a highly efficient dispersant and fluidifier. At high water contents pastes prepared in this manner are thin Newtonian or almost Newtonian fluids. At low water contents (water:cement ratios as low as 0.20) such pastes are peculiar in that they flow without measurable yield stress but only at relatively slow rates: attempts at application of high shear rates produce sudden quasi-dilatant stiffening in a manner not yet adequately described. Concretes formulated with such cements may be of considerable future interest (11).

### III. THE FORMATION AND EVOLUTION OF STRUCTURE IN HARDENED CEMENT PASTES

#### Processes of Structure Formation

Fresh cement paste inevitably becomes stiffer and stiffer, and at some point passes from a system of flocs in concentrated suspension, to a porous viscoelastic skeletal solid capable of supporting applied stresses at least for the short times without significant deformations. This conversion constitutes set. The set paste continues to evolve toward a progressively more rigid porous solid which becomes, roughly speaking, elastic and brittle in character. In this section some of the details of this complex process of structure and strength development will be discussed, with consideration of the properties of the "mature" paste left for the next portion of this report.

What might be called the chemical aspects of this process, that is, the hydration reactions *per se* and the chemical and "nanostructural" characteristics of the hydration products formed, are discussed in the General Report of Theme II by Locher (12), and in the principal papers of Skalny and Young (13) and Taylor and Roy (14), respectively. There is naturally a considerable overlap to be expected between the "hydration" aspects and the "structure formation" aspects of the same basic process.

The structure forming processes in hardening cement paste seem exceedingly difficult to characterize properly, in part perhaps because it is always harder to understand a rapidly changing physical system than a static one. There have been relatively few contributions to this Congress dealing with the structure forming processes *per se*. However, considerable progress seems to have been reported on methods of altering these processes so as to produce superior products.

The rheological behavior of progressively hardening cement pastes almost to the time of set has been followed by a plastographic method by Zacedatelev *et al.* (15), who investigated the effects of varying temperatures and of changing water content. Equations were proposed to describe the stiffening process as influenced by these parameters.

An extremely ingenious new method for indirectly following the change taking place as cement paste hardens is described in the contribution of Balek *et al.* (16). In this so-called "radiometric emission method" the cement is radiolabeled in such a way that radon gas is constantly produced within the cement grains. The gas is emitted from the specimen at a rate which depends on the diffusion coefficient for the gas within the particles, and their surface area.

The evolution of structure as cement paste sets and hardens causes changes in both these characteristics, which result in concomitant changes in the rate of emission of radon from the sample. Changes in the structure by Vicat needle determinations or by hydration measurements are clearly mirrored by corresponding changes in the rate of emission of the gas during and after set. The interpretation is somewhat complicated by the fact that the two governing parameters, diffusion rate and surface area, are changing in opposite directions as the setting and hydration responses proceed.

The processes of structure formation in hardening cement paste may be followed by many different methods, as the foregoing suggest. However, it seems to the writer that perhaps the most informative and satisfying, if non-quantitative, method available today is that of direct examination and description of progressive changes in microstructure as observed in scanning electron microscopy of specimens of progressively increasing age.

As indicated by Sereda, Feldman, and Ramachandran in their principal paper (17), proper interpretation of such investigations depends on an appropriate selection of fields to be examined, since the structure changes at different rates in different parts of even the same specimen, and is never homogeneous. Nevertheless, these problems are not insuperable and the writer is somewhat disappointed at the relative lack of consideration of such results as are already in the literature in the principal papers of both Sereda *et al.* (17) and of Wittmann (18). The relative scarcity of new information of this type in the contributed papers on structure formation is a further disappointment.

To partly remedy this lack, the writer offers the following generalized description of structure development in portland cement paste based on his own scanning microscope observations and those of others. The pastes concerned are ordinary portland cement pastes hydrated under the usual ambient conditions, and not influenced by admixtures.

For such pastes, visible evidence of the earliest hydration can be seen as thin filmy bodies developing on the surfaces of cement grains, at first being rather difficult to distinguish from small chips of ground clinker also often found adhering to such surfaces. Relatively few visible AFT (rod-shaped) particles are seen in the first few hours. As hydration speeds up at the end of the dormant period it can be seen that a thin shell is developed around most of the clinker grains, and clusters of Type I (elongated) C-S-H gel particles and some AFT rods, project outward radially from these "kernals". Thin films of calcium hydroxide become visible in the pore spaces and around other particles, and in some areas Type II (reticulated network) C-S-H gel is observed. As time passes much additional C-S-H gel is produced, and it begins to be clear that a continuous skeleton is being formed by contacts between C-S-H grains and AFT rods projecting from adjacent cement grain kernals. These contacts become reinforced by additional deposits of hydration product, often not of any particular shape. Hexagonal calcium hydroxide crystals appear, and these grow laterally and finally begin to get thicker, in the process invading and engulfing previously deposited C-S-H gel. In occasional and usually isolated areas small clusters of thin hexagonal plates of AFm products are developed,

recognizable by a characteristic edge-to-face contact habit. "Hadley grains" start to appear for higher water:cement pastes; that is, apparent dissolution and removal of cement grain material takes place from within the shells formed earlier around the cement grains, leaving a zone of vacant space between the shell and the reduced cement grain within it. As hydration proceeds further, general deposition of C-S-H gel hydration product seems to take the form of masses of small and indefinite Type III C-S-H grains, and in some areas of infilling material without visible particle structure (at the magnifications available in the SEM). It becomes progressively more difficult to pick out individual particles in many, but not all areas. In some originally highly porous areas, separate and distinct hydration product particles of various types may continue to be distinguished indefinitely. The final "mature" cement paste is an amalgam of these features. Increases in strength may continue long after no further microstructural changes are visible, presumably due to continued infilling and tightening of the existing structure.

Significant changes in the above pattern may be produced by admixtures of various kinds, by heat treatment with or without the use of steam, or by various other physical or chemical treatments that may be imposed.

#### Bond Formation

Among the topics discussed in the principal paper of Sereda *et al.* (17), there is extensive discussion of the nature of the bonds thought to be formed between individual cement hydration particles in the process of hardening, leading to the solid skeletal "xerogel" visualized by Wittmann (18). In following this discussion and others like it, it is not clear to the writer what the "particles" involved are presumed to be. For example, it is uncertain from many of the arguments presented whether discussion postulates bonding between clearly defined individual particles coming into contact across gaps, such as the radial C-S-H Type I particles meeting across the gap between two separate kernels, *i.e.* cement grains, or whether the postulated bonding is within smaller structural units, perhaps thin sheets, within such particles. Also one wonders whether the term "bond" is really being used in a mechanical sense to merely connote adhesion or cohesion between two adjacent particles, or in the more precise chemical sense where electron transfer (or sharing) between closely spaced and precisely-oriented atoms is implied. Certainly one sees little indication of what atom is being bonded to what other atoms across what bond length and what bond energies are involved. Collepardi (19) is quoted by Sereda *et al.* (17) as suggesting that Si-O-Si bonds are formed across contacts of pre-existing C-S-H particles. This may be true, but the indirect evidence adduced for this conclusion is far from convincing. On the other hand, the picture of Ubelhack and Wittmann (20) also cited by Sereda *et al.* suggests that thin water films continue to separate adjacent "bonded" particles, and thus that the attractive forces involved are primarily long range polar forces ("van der Waals' forces") subject to modification with changes in local environmental conditions, especially RH. This would appear to be a completely opposite concept.

In his contribution to the present Congress Chatterji (21) attempts to calculate the probability

of formation of permanent chemical bonds across two intersecting C-S-H needles and concludes that such bonding is exceedingly unlikely. However, it seems to the writer that the arbitrary assumptions made in the calculations render the conclusion open to question.

In their principal paper, Sereda *et al.* (17) also refer to the ideas of Reh binder *et al.* (22) concerning the formation of so-called "crystallization contacts" across particles, as controlled by the level of supersaturation with respect to the substances involved. Certainly dissolution and recrystallization at contacts of such well-defined substances as calcium carbonate is well known to occur and to develop strong bonding in, for example, carbonate rocks. If the writer's understanding of the concept of Reh binder *et al.* is correct, the inference is that particles become bonded by the same kinds of specific, permanent chemical bonds that hold the atoms together within a single particle, and the recrystallization at contacts, once made, should be permanent.

After considerable thought, the writer must admit that it appears to him that in the present state of knowledge, not very much reliable or even useful information concerning the bonds between particles has been adduced.

#### Effects of Admixtures and Altered Conditions of Hydration

It has previously been mentioned that the development of structure in cement pastes can be modified considerably by application of admixtures or by altering the conditions under which the structure formation is taking place. Specific influences of various admixtures, primarily dissolved chemical admixtures, are extensively discussed in the principal paper of Sereda *et al.* (17).

A number of contributions to this Congress record the results of research in which various solid admixtures are used to influence the course of development of the cement paste structure. Changes induced by inclusion of special crystallizing components, so-called "crents", are described in the contribution of Dmitriev *et al.* (23). These substances are blends of aluminum sulfates or hydroxysulfates with silica gel, gypsum, and in some cases dehydroxylated kaolinite. Used in substantial proportions, ca. 10 percent of the cement, they are reported to enhance the early formation of ettringite (resulting in early strength gain), and subsequently to accelerate  $C_3S$  hydration. Ponomarev *et al.* (24) illustrate the effects of such additions on the developing microstructure, and show how variations in content of such admixtures can result in development of a high-strength cement, an expansive cement, or a rapid-hardening expansive cement.

The mode of action of a somewhat different solid admixture has been clearly documented in the interesting contribution of Isogai *et al.* (25). The admixture used in this case was a blend of anhydrite, free lime,  $C_4A_3S$ , and  $C_{12}A_7$ . The expansive effect produced is indicated as being the result of topochemical formation of very fine "non-crystalline ettringite" and of some extra  $Ca(OH)_2$ , both produced over a period of several days after setting. The expansion was definitely not associated with the large, well-formed ettringite particles developed early in the hydration process.

The solid admixtures discussed above are highly reactive chemically. The influence of less reactive solid admixtures on the evolution of structure and strength may also be considerable. In their report Popov *et al.* (26) illustrate the influence of the inclusion of "microaggregate", mostly quartzitic ground rock particles, on the structure produced. A general homogenization and densification is reported. The writer would infer that such effects may be associated with modifications of the gross floc structure that normally develops in the fresh cement paste.

Methods of modifying the evolution of structure by altering the conditions under which hydration is taking place or by post-hydration manipulations have been reported by various contributors. The contribution of Gorianov and Stchastnii (27) illustrates the effects of pressing, hot-pressing, and of exposure to saturated cement pore solution. A somewhat more commercially viable method of altering the development of structure is steam curing, and the contribution of Sauman *et al.* (28) reports on studies in which pastes of 10 different cements, each well characterized chemically and granulometrically, are steam cured for various periods. It appears that differences in the rate of strength development for the different cements is conditioned primarily by differences in alite content, and secondarily by variations in the character of the alite solid solutions. Variations in content of  $C_2S$  or of  $C_3A$ , and differences in alite grain size seem to be unimportant.

A somewhat novel method of influencing the development of structure and strength in cement paste by pretreating the cement with  $CO_2$ -free high humidity air is described in the contribution of Malinine *et al.* (29). Freshly ground cements so exposed are said to develop semipermeable shells of "prehydration product" which accelerate the cement hydration process once water is added. Premature carbonation that would attend the use of moist air not specially purified was said to be counterproductive.

## IV. THE STRUCTURE OF HARDENED CEMENT PASTE

### Structure of the Solid

Having examined (albeit imperfectly) the processes of structure formation we now turn to a consideration of the structure and properties of the "mature" material. There is no sharp dividing line separating paste still in process of formation from "mature" paste, but certainly 28-day old paste is mature for all practical purposes and for some purposes pastes at much earlier ages might well be so designated.

The usual pattern in most modern material science developments is that one studies the structure of a material on the basis that one should be able to understand, predict, and modify its properties most efficiently after its structure is understood. This approach has been quite successful in metallurgy and in ceramics. To date it has not been followed very successfully with respect to cementitious materials, perhaps because the structure is too complicated to be very well understood.

In his principal paper on this subject, Wittman (18) describes the structure of hardened cement paste as comprising a solid "xerogel", water, and pore space. In contrast with most other materials, the solid

part of cement paste is unusually and sensitively linked with the water component, in part because the solid is composed of hydrates, in part because physical characteristics of the solid are unusually sensitive to water content and even to changes in ambient RH. Details of the pore structures seem also intimately bound up to this sensitivity, and it is very difficult indeed to trace through the interrelationships involved.

The chemical and crystallographic characteristics of the several solid phase components normally present have been cogently summarized in the principal paper of Taylor and Roy (14). Hardened portland cement paste prepared under the usual ambient conditions is an assemblage of almost amorphous C-S-H gel of variable chemical composition and morphological type, of calcium hydroxide, of some Aft (red-shaped) and AFm (hexagonal platy) calcium aluminate sulfate hydrates of variable composition, and of whatever unhydrated cement remains. The C-S-H gel is usually considered to be the dominant component, so much so that some workers tend to lose sight of the existence of the other components when interpreting cement paste behavior.

The nature of this C-S-H component has been the subject of much investigation and considerable dispute for many years. The current status of ideas on its internal structure is expertly summarized by Taylor and Roy (14). The structure has only a small degree of order. The well-known Feldman and Sereda model rests primarily on interpretations of measured changes in various characteristics (length change, stiffness, rate of helium penetration, and adsorption-desorption responses) as functions of RH, rather than with structural investigations by the classic tools of structure determination (x-ray diffraction, electron diffraction, infrared spectroscopy, mass spectroscopy, chemical analysis, etc.) This model is discussed at length in the principal paper of Sereda *et al.* (17). The so-called "Munich model" is not really a description of the structure of the C-S-H gel but a mathematical explanation of paste characteristics, based on thermodynamic calculations, water sorption isotherms, and experimental measurements of creep, shrinkage, strength, and other parameters, again primarily as functions of RH. This model is discussed briefly in the principal paper of Wittmann (18).

Recently, the term "xerogel" has been introduced into the cement literature by Wittmann to describe the solid "skeletal" portion of hardened cement paste. In the classical colloid literature a xerogel is a dried gel retaining its original structure after the fluid phase has been removed. Its use to represent the skeletal structure of hardened cement paste is strictly speaking a departure from the older usage. One should also guard against the inference that the solid component is only a small volume fraction of the total colloidal system, as might be implied from the adjective "skeletal" since the solids normally constitute 60 or 70 percent or more of the volume of mature pastes.

Details of the chemical composition of individual particles of this solid as dispersed ultrasonically from specially-prepared hardened cement paste are reported in the contribution of Moore (30). The cement used was ground of unusual fineness (all particles less than 10  $\mu$ m), pressed into pellets, and hydrated by water drawn into the pellets by capillary action. Hydration carried out in this manner was found to be completed in about 3 months.

Individual particles were analyzed in an analytical electron microscope, using thin film calculations which avoid various corrections otherwise necessary. The many C-S-H gel particles examined showed a wide range in chemical composition, with Ca:Si ratio varying from 1.25 to 4.0, and with Al, Fe, and S collectively present within wide limits of 0.1 to 0.9 atoms per atom of silicon. AFm and Aft particles contained large contents of Si, and S and Al were seriously deficient in them, specially in the AFm particles. These compositional ranges and variations from one particle to another particle are similar to those also reported by Lachowski *et al.* (31) for ordinary cement pastes of lesser maturity.

The contribution of Mituzas *et al.* (32) is specifically concerned with the distribution of the silica among the components present in hardened pastes. These workers conclude, apparently from compleximetric measurements, that a very considerable proportion of the silica in cement pastes is bound into unstable "complexes" with the ettringite and monosulfate phases, and that much less C-S-H gel is present than is normally assumed.

#### Pore Structure

Attempts at characterization of the pore structure constitute a surprisingly large portion of the experimental work that has been done on the structure of hardened cement paste. Of interest here are the volume, size distribution, and shape of the pores involved. These range in size over many orders of magnitude, the largest being of the order of millimeters, the smallest of nanometers, or even, by some definitions, of the sizes of spaces left vacant by the removal of individual water molecules on drying. Much of the size range is amenable to investigation by mercury intrusion porosimetry: the finer pores are usually investigated by methods involving gas or vapor adsorption or desorption studies. An extensive review of the subject has been provided in the principal paper by Sereda *et al.* (17), and a brief treatment is given by Wittmann (18). As pointed out by these authors, no method is free from difficulties and uncertainties of interpretation.

A number of papers communicated to this Congress are concerned with pore size measurement and interpretation. The relationship between pore size distributions as measured for a spectrum of cement pastes of varying age and water:cement ratio and the corresponding saturated permeabilities measured for the same pastes is explored in an outstanding contribution by Nyame and Illston (33). A power function relationship of surprising precision was developed between a characteristic radius of the paste determinable from the mercury intrusion curve and the permeability. The radius involved is that of the maximum in the  $dv/dr$  plot set up using divisions of equal volume intrusion, and is considered to be representative of the effective size of the continuous pore system through which most of the water flows. The radius involved is near the upper end of the measured size distribution, and is analogous to the "breakthrough diameter" of Winslow and Diamond (34).

An investigation of cement paste pore structure by mercury porosimetry was reported in the communication by Bozhinov and Borovski (35) and it was again confirmed that the water:cement ratio exercises the major influence in setting the distribution of pore sizes in the resulting paste. A modest supervening

influence ascribable to cement fineness was also detected.

At the other end of the pore size range, inferences about the status of micropores in hardened cement paste were drawn by Lawrence *et al.* (36) from an extensive series of nitrogen and butane adsorption isotherms on pastes that had been dried in several different ways. In this contribution it is suggested that micropores available to nitrogen are present in rapidly dried pastes but not in slowly dried pastes. On the other hand, for the latter the isotherms are interpreted as suggesting the presence of slit-shaped mesopores that appear not to be present if the pastes are dried rapidly.

The alteration of pore structure with drying condition inferred by Lawrence *et al.* is an illustration of the general pattern of reports of the instability of hardened cement paste structure, especially with respect to changes brought about by drying. These changes seem only partly reversible on rewetting. Much of this literature is discussed in the principal papers of Sereda *et al.* (17) and of Wittmann (18). Wittmann suggests that such changes necessarily involve a rearrangement in such a way that the surface area is reduced and the structure coarsened. Measurements of surface area by low-angle x-ray scattering reported some years ago by Winslow and Diamond (37) suggest that dried pastes indeed exhibit only about half the surface area of the same pastes before drying, but that immersion in water restored the original area. Permanent reduction in surface area was found to take place only if the pastes were heated in water.

#### Structure, Creep, and Status of Water

Regardless of the permanence of surface area changes, it is well known that significant shrinkage occurs in cement pastes on drying, and that some of the shrinkage so produced is not recoverable. Shrinkage also occurs in the normal sequence of hydration even in the absence of any drying effects, and one must be careful to distinguish this so-called "autogenous" shrinkage from drying shrinkage.

The separate magnitudes of the two phenomena have been studied by Dorkin and Zaitsev (38) in their contribution to this Congress, as functions of water:cement ratio for several cements of widely varying composition. Typically, autogenous shrinkage was found to amount to about 30 percent of the magnitude of the drying shrinkage. Both were found to be larger in magnitude for pastes made from cements with higher  $C_3A$  contents, and autogenous shrinkage was found to decrease, rather than increase, with water:cement ratio.

Explanations for some of these observations are forthcoming from the detailed study of autogenous shrinkage by Buil and Baron (39). In this contribution the processes were clearly shown to involve a sequence of initial (plastic) shrinkage starting a few hours after mixing, followed by an intermediate stage of expansion, and then a final stage of "hardening shrinkage" after set. The latter was confined to low water:cement ratio pastes ( $w:c$  0.35 and below), and it was considered to be caused by self-desiccation, the water being evolved inward to the interior of the specimen rather than outward to the surrounding atmosphere as in drying shrinkage.

Drying shrinkage is often coupled with creep, a related manifestation of the instability of cement paste. Both are generally thought to be conditioned partly by the pore structure of the paste, partly by the characteristics of its solid component. It appears that both shrinkage and creep may in turn affect the structure, leading to an extremely complex situation. Several of the contributions to this Congress provide some insight into this situation.

The drying shrinkage behavior of a number of thin-walled cylinder specimens of  $C_2S$ ,  $C_3S$ , and cement paste was very carefully determined as the starting point for an interesting set of interpretations provided in the contribution of Bentur *et al.* (40). These workers divide the observed drying shrinkage into "capillary" - and "gel" - related portions on the basis of shrinkage-weight loss curves. The magnitude of the former is related primarily to the content and size distribution of mesopores, *i.e.*, pores in the range of 2.5 to 30 nm radius, which the authors consider to be active in developing capillary shrinkage stresses. The gel-related portion, attributed to drying-induced structural changes in the C-S-H gel component, is related to the volume of micropores (of radius below 2.5 nm), to the surface area, and to the silica polymerization status of the C-S-H gel. An overall effective shrinkage factor is developed which encompassed an empirical combination of the parameters mentioned, and this is shown to be a good linear predictor of total drying shrinkage.

As an illustration of the instability effect, the contribution of Milestone (41) reports the measured effects of drying and of aging at intermediate RH values on the state of polymerization of silica within the C-S-H gel of young  $C_3S$  pastes. Drying (to 11% RH) produces a decrease in monomer content and an increase in polysilicate content, the changes being completed rapidly. Equilibration at higher RH values was found to slowly produce changes in the same directions; Milestone especially noting gradual and progressive increases in polysilicate content at RH values of 75% and to a lesser extent, at 50%. Monomeric silica was shown to exist in the gel portion of fresh C-S-H pastes never exposed to lowered humidities.

The changes found by Milestone to result from drying or from aging seem to be similar in character to those occurring in young cement pastes loaded in creep at 20°C and then subjected to rapid temperature increase to 60°C while under load, as reported in the interesting contribution of Parrott (42). The increase in degree of polymerization was paralleled by a rapid increase in creep rate observed. The enhanced creep component stemming from the change is non-recoverable. Parrott indicates that previous work had indicated that heating of similar pastes not under load had reduced, rather than increased the non-recoverable creep component. Parrott concludes that the enhanced creep rate is due to a structural reorganization involving the enhanced silica polymerization. On the basis of the reasoning of Bentur *et al.* (40), one might expect paste with more highly polymerized C-S-H gel to exhibit reduced, rather than enhanced creep capacity, in view of the stiffening effect thought to be associated with a higher degree of polymerization.

The behavior of hardened portland cement paste is generally considered to be influenced not only by the structure of the solid and by the size distribution and character of the pores present, but also by the varying status of the water present in the pores and within the solid components. Investigations into the status of cement paste water have been reported for many years. Unfortunately, it has proven to be exceedingly difficult to reach any sort of consensus, since the results seem to vary markedly with the method of study.

In his principal paper (18) Wittmann cites a four-fold subdivision of water in cement paste into (a) bulk water in large pores, (b) water of reduced chemical potential in medium-sized pores, (c) "structured" water condensed into pores between 3 and 10 nm in radius, and (d) adsorbed water on surfaces in layers not exceeding  $2\frac{1}{2}$  monolayer thicknesses. The distinctions were made on the basis of freezing behavior.

In their interesting contribution to the present Congress, Sabri and Illston (43) report that a physical separation of two distinct types of water in cement pastes can be effected by a semi-isothermal mode of operation of TGA and differential TGA apparatus, in which heat increase is stopped once a peak start to come off. They were able to consistently separate the water removal process into peaks coming off isothermally at between 47° and 54°C (depending on age of the pastes), and peaks coming off between 78° and 90°C, again as a function of age. Measurements were made of specimens of various ages and water:cement ratios, and of specimens that had been conditioned to various RH values before the investigation. These workers conclude that water removed in the first peak ("type A water") includes all of the pore water and the physically adsorbed water as well, and that water removed in the second peak ("type B water") is structural or hydration product water removed from C-S-H gel or other hydration products. The amount of this "structural" water is reduced on pre-exposure of saturated pastes to even slightly reduced RH conditions, e.g. 94% RH, but most of it is retained against drying at 11% RH.

A somewhat different type of study on the status of water in hardened cement paste is provided in the contribution of Sierra (44), who reports on measurements of IR, broad-band proton spin NMR, and dielectric behavior of C<sub>3</sub>S and portland cement pastes. The results are interpreted as indicating that water in the finest pores and on the surfaces is extensively hydrogen bonded, and a definite picture of the structural location of water molecules and the status of their hydrogen bonding to specific Si-O sites in a postulated C-S-H gel structure was provided. In the opinion of the writer, and of Taylor and Roy (14), the gel structure postulated as the framework, which is the 2- or 3-layer tobermorite sheet structure of Kantro, Brunauer, and Weise (45) is not likely to be an appropriate representation of the actual C-S-H gel structure.

The writer would also suggest that several points be considered by those workers concerning themselves with the status of water in hardened cement paste: (a) results from a number of laboratories in several countries indicate conclusively that at least the "water" in larger pores of cement paste that can be expressed by application of high pressures is not water at all, but is rather a concentrated solution

of sodium and potassium hydroxides, and (b) ordinary "bulk" water is highly structured and at ordinary temperatures is extensively hydrogen bonded. What one must investigate is the change in structure brought about the local environment, both chemical and physical, of the various regions within the hardened cement paste.

#### Crack Formation and Propagation

The various properties and characteristics of hardened cement paste so far discussed are of considerable scientific interest. However, their practical importance rests on whatever bearing they may have on the engineering properties of cementitious materials. Strength is clearly the engineering property of greatest interest in this connection.

In the principal paper of Wittmann (18) strength in hardened cement paste is seen to be limited by crack formation; in the principal paper of Sereda *et al.* (17) it is specifically linked to the pore structure. In the contribution by Zaitsev (46), the influence of pore structure on crack formation and hence on strength in cement paste is explored in a Monte Carlo model of failure in compression. The model assumes a random distribution of pores of the appropriate sizes is present, and that as the system is loaded, cracks extend from the pores along the line normal to the direction of maximum tensile stress. As loading is increased, favorably located cracks from adjacent pores join together, each junction constituting a sudden increase in crack length. This process is followed by computer simulation until a critical crack length is achieved and failure occurs without additional loading.

New methods allowing the study of actual development of cracks in real specimens are described in two contributions to this Congress. Tsilosani *et al.* (47) describe a holographic interferometer method of depicting and studying the state of strain in concrete being subjected to simultaneous mechanical and shrinkage stresses. The onset of cracking is clearly depicted by modifications in the interference bands observed. Thus comparative cracking resistance and measured values to time-to-first-significant-cracking can be compiled for concrete specimens made from various cements or exposed to various preliminary treatments. The results obtained suggest that even modest contents of mineral additions may lower the cracking resistance of concrete but that it is not greatly affected by variations in cement composition.

The prospects for furthering an understanding of the microstructural basis for the cracking and fracture behavior of cement paste would seem to be enhanced by applications of a device described in the contribution of Diamond and Mindess (48). A compact tension fracture mechanics specimen arrangement has been constructed in such a way that it may be included and loaded within the specimen stage of a scanning electron microscope. Thus direct observation of the formation and propagation of cracks produced under controlled conditions can be attained within the scanning electron microscope. Preliminary microscopic observations relating to the geometry, branching characteristics, and displacements of cracks produced in cement pastes are reported.

## V. MATHEMATICAL MODELING OF CEMENT PASTE STRUCTURE AND STRENGTH DEVELOPMENT

The development of mathematical models to describe the evolution of the hydration processes and the development of strength in hardened cement paste and concrete seems not very well advanced. The discrepancy between the possibilities and the practical results so far attained is pointed out in the principal paper of Cheine (49), who considers that a lack of fundamental rigor exists in defining the important characteristics of the starting materials and of the hydration products. This is explainable in view of the inherent complexity of cementitious systems as is obvious from the preceding sections of this report.

Contributions in this area generally attempt to model either the hydration processes in more or less chemical terms or else model strength development, usually empirically or by application of statistical or regression formalisms.

"Chemical"-type treatments are provided in contributions by Rumyantsev (50), and by Pommersheim *et al.* (51).

The former provides a general mathematical treatment of solid-liquid reactions, with application both to high temperature clinker-melt reactions and to cement hydration. A rate process equation in which the surface area is subsumed in the pre-exponential term was suggested to express the temperature dependence of the processes, the Kholmogorov-Erofeev double exponential equation was suggested for fitting to isothermal processes, and an equation developed on the basis of local branched chain reactions was suggested instead of the usual treatment of solid liquid reactions proceeding by slow diffusion through a uniformly-increasing thickness of coating.

A specific mathematical model for the hydration of uniformly-sized  $C_3S$  particles was elegantly developed in the contribution of Pommersheim *et al.* (51). This model assumes progressive development of both "inner" and "outer" hydration product layers, and the temporary development and subsequent disappearance of a barrier layer between them. The essence of the model is contained in a dimensionless parameter expressing the ratio of the rate of diffusion through the expanding layer of hydrate to the rate of chemical reaction at the core-hydrate interface. Based on realistic inputs of particle size, water: cement ratio, and temperature, the model is shown to predict reasonable values of the degree of hydration as a function of time, and to fit the experimental data of Kondo and Ueda (52) for the hydration of closely-sized  $C_3S$  particles.

An extensive mathematical treatment describing both hydration and strength development in hardened cement paste is provided in the contribution of Polak and Babkov (53). In contrast to the paper discussed previously, these authors apparently do not attempt to compare the mathematical formalism developed to actual data for either hydration or strength development processes.

The remaining papers in this area are concerned exclusively with providing mathematical descriptions of strength development, and with its variation under different conditions.

The principal paper of Cheine (49) reports a highly sophisticated time-series analysis of the "activity",

i.e. the strength developing capacity of the product being produced by a particular slag-cement factory. Seasonal fluctuations are shown to occur, loosely correlated with variations in the  $C_3S$  plus  $C_2S$  content of the clinker, but the major factors influencing the strength developing capacity are said to be the specific proportions of slag, gypsum, and clinker, and the fineness of grinding. Equations relating strength at any age to the activity measured in tests at early ages are suggested.

In other contributions, a generalized formula for the estimation of the strengths of concretes and of cement pastes is suggested by Vyrodov and Padalkina (54), a comparison of several equations for the calculation of expected strength from cement compound composition and fineness is provided by Popovics (55), and a set of regression equations relating strengths of concrete to calculated Bogue cement compositions for a range of New Zealand cements is provided by Aldridge (56).

## VI. ACKNOWLEDGEMENTS

This report was written during periods in which the writer was an academic visitor at the University of Aberdeen and at Imperial College. The writer expresses his appreciation for the hospitality provided by Professor H.F.W. Taylor and by Professor P.L. Pratt at their respective institutions, and for travel support by the Science Research Council of the U.K.

par C. LEGRAND

Comme l'a souligné le Professeur DIAMOND dans son rapport général, de nombreuses communications de ce thème donnent des résultats de mesures rhéologiques, effectuées essentiellement à l'aide de viscosimètres coaxiaux. Les auteurs se servent bien entendu de ces résultats pour interpréter les phénomènes observés tout en reconnaissant, pour la plupart d'entre eux, que ces résultats sont différents suivant l'appareil de mesure utilisé. Il y a donc là un problème important et on est en droit de se demander quelle est la confiance que l'on peut accorder à des mesures effectuées sur les pâtes de ciment dans de telles conditions.

Une première source d'erreur réside dans le non respect des hypothèses qui ont servi à établir les formules donnant la contrainte et la vitesse de déformation. On peut rapidement citer quelques exemples :

- le fluide doit être homogène. Or, les mesures sur les pâtes de ciment se poursuivent parfois au-delà de dix minutes et des phénomènes de sédimentation peuvent alors intervenir de façon non négligeable et conduire à des augmentations apparentes de viscosité qu'il ne faudrait pas alors attribuer à autre chose;
- l'écoulement doit être laminaire. On voit trop souvent donner des interprétations abusives à des rhéogrammes qui changent d'allure pour des vitesses angulaires élevées, alors que, tout simplement l'installation d'un régime turbulent rend inapplicables les équations classiques de la viscosimétrie;
- il ne doit pas y avoir de mouvement relatif entre le milieu et les cylindres de l'appareil. Ceci est bien connu et je n'insisterai pas plus sur les dangers qu'il y a à utiliser des cylindres lisses;
- enfin, et ceci est capital, l'écoulement doit être stable; cela signifie notamment que la vitesse de rotation du cylindre mobile doit être constante et égale à celle de l'axe d'entraînement du système. La vitesse de déformation du dynamomètre mesurant le couple résistant doit donc être nulle. Nous savons tous que ceci n'est pas le cas avec les pâtes de ciment qui présentent une structure floculée qui se détruit au fur et à mesure qu'elle est cisailée, provoquant une thixotropie partielle.

Une deuxième source d'erreur réside, en supposant que les hypothèses dont je viens de parler sont respectées, dans l'évaluation du gradient de vitesse à partir des caractéristiques de l'appareillage, de la vitesse de rotation et du couple résistant mesuré sur l'axe.

Ceci ne pose pas de problème particulier lorsque le corps étudié a un comportement linéaire (newtonien ou binghamien). Par contre, de nombreuses difficultés surgissent dans

les autres cas, notamment parce que la détermination du gradient de vitesse dans l'espace annulaire dépend de la loi de comportement que l'on cherche justement à obtenir. Il existe heureusement des solutions plus ou moins précises et plus ou moins lourdes à mettre en oeuvre; je voudrais citer, parmi les communications de ce thème, celle de NAGATAKI et KAWANO, qui ont étudié, par cinémographie directe, la répartition des gradients de vitesse dans l'espace annulaire.

En tout état de cause, déterminer ce gradient à l'aide des formules classiques, qui supposent a priori le comportement linéaire pour trouver, en définitive, un comportement qui ne l'est pas, n'est pas une approximation, mais une erreur.

Je voudrais maintenant revenir sur la destruction de la structure par le cisaillement (structural breakdown) qui conduit à des effets de thixotropie partielle. A mon avis, avec un viscosimètre classique, deux choses seulement sont mesurables. D'une part, le seuil de cisaillement initial, c'est à dire celui de la pâte vierge de tout cisaillement, qui dépend essentiellement des forces de liaison intergranulaires, et, d'autre part, la viscosité finale de la pâte, une fois que la stabilité de l'écoulement est atteinte, c'est à dire après la destruction de toutes les liaisons qui devaient être détruites. Le rapport de ces deux valeurs me paraît être une bonne caractéristique de la thixotropie du milieu. Celle-ci est, toutefois, incomplète puisqu'on ne prend en compte que l'état initial et l'état final. Mais, comme je l'ai signalé tout à l'heure, les mesures intermédiaires ont peu de signification. J'ai déjà montré, il y a quelques années (\*) qu'il existait un couplage important entre le milieu d'essai et l'appareil de mesure et que, suivant la vitesse de rotation et la rigidité du dynamomètre, on pouvait trouver à une même pâte plusieurs comportements rhéologiques.

Mais alors, comment faire pour obtenir des résultats significatifs ?

Peut-être faut-il utiliser des viscosimètres travaillant non plus à vitesse d'entraînement constante, mais à contrainte imposée et tracer ainsi des courbes de fluage en vitesse de déformation.

Peut-être faut-il au contraire tracer des courbes de relaxation en contrainte à vitesse de déformation constante, en utilisant alors des dynamomètres à la fois précis et très rigides ?

Le problème n'est, à ma connaissance, même pas abordé à l'heure actuelle et je souhaitais le poser. Ce n'est, en définitive, qu'en trouvant de vraies caractéristiques mécaniques qu'on arrive à mieux connaître le comportement rhéologique des pâtes, et pas seulement d'ailleurs de ciment.

(\*) C. LEGRAND - Détermination des caractéristiques rhéologiques des corps viscoplastiques à thixotropie partielle - Cahiers du Groupe Français de Rhéologie - III - n° 2 (Avril 1973)

## Intervention

par Yu M. BAZHENOV

L'application de modèles et de méthodes mathématiques à la technologie des ciments et des bétons implique de faire appel à des méthodes d'essais et des caractéristiques nouvelles des matériaux, car les méthodes normalisées, traditionnelles, ne permettent pas de faire les calculs avec la précision nécessaire, compte tenu des possibilités des ordinateurs.

En Union Soviétique, à l'Institut "Ecole des Travaux Publics de Moscou (MISI im Kujbysheva), on a élaboré une méthode d'appréciation des propriétés des pâtes de ciment dans la masse même des bétons, en tenant compte de ce que le comportement d'une pâte est alors différent de celui d'une pâte pure. Les propriétés des matériaux dépendent notablement des granulats, de la composition du béton, et d'autres facteurs.

Par suite de l'influence des forces de surface, les grains du granulat diminuent notablement la maniabilité des bétons frais ainsi que les délais de prise. Pour avoir la même maniabilité que celle de la pâte de ciment, on est conduit à augmenter le rapport eau/ciment des mortiers et des bétons. On peut apprécier l'influence globale d'un granulat en utilisant un coefficient d'influence particulier, qui indique la quantité d'eau supplémentaire à ajouter pour le granulat, afin de ne pas modifier les propriétés du béton frais (sa maniabilité, les délais de prise, etc.)

Par exemple, pour avoir un affaissement du cône sur table vibrante de 17 cm (170 mm), il faut, pour un ciment donné, que  $(e/c)_c = 0,3$ , tandis que pour un mortier 1:2, il faut que  $(e/c)_m = 0,44$ . Le coefficient d'influence du sable sera alors égal en % à :

$$K_s = \frac{(e/c)_m - (e/c)_c}{2} \cdot 100 = 7 \%$$

Les sables courants utilisés dans la construction ont un coefficient  $K_s$  compris entre 4 et 11 % suivant leur grosseur et les propriétés de leur surface.

Pour déterminer les coefficients d'influence d'un sable  $K_s$  ou d'un gravillon  $K_g$  on fait des essais comparatifs sur une pâte de ciment, un mortier et un béton.

Nous utilisons des mortiers 1:2 et des bétons 1:2:3. La consistance d'une gâchée correspond à la consistance normale de la pâte de ciment.

Si l'on connaît les coefficients d'influence du granulat et si l'on sait comment les propriétés de la pâte de ciment varient en fonction de divers facteurs, on peut prévoir les propriétés des mortiers et des bétons avec une grande précision de calcul. Pour cela on fait appel à une nouvelle notion, celle du rapport (eau/ciment) efficace ou effective, qui indique le comportement réel d'une pâte de ciment dans un béton.

Dans ce but, de la quantité totale d'eau on déduit la quantité nécessaire pour compenser l'influence du granulat sur les propriétés du béton frais :

$$(e/c)_{ef} = \frac{e - K_s S - K_g G}{c}$$

où  $S$  et  $G$  sont les teneurs en sable et gravillons concassés respectivement.

Ainsi, par exemple, pour une gâchée de béton 1:2:4, ayant un rapport total de (eau/ciment)  $e/c = 0,6$   $K_s = 0,07$  (7 %) et  $K_g = 0,02$  (2 %), le rapport efficace déterminant le comportement de la pâte de ciment dans le béton sera

$$(e/c)_{ef} = 0,6 - 0,07 \cdot 2 - 0,02 \cdot 4 = 0,38$$

Pour construire des modèles mathématiques définissant la rhéologie des bétons frais, compte tenu de la rhéologie des pâtes de ciment, en plus des valeurs de  $(e/c)_{ef}$ , il faut connaître la teneur en pâte de ciment dans les bétons.

Les meilleurs résultats sont obtenus en introduisant la notion de teneur effective, qui ne tient pas compte de toute l'eau, mais seulement de celle qui détermine le rapport eau/ciment efficace.

$$p_{ef} = \frac{c}{1000} \left[ \frac{1}{\rho} - (e/c)_{ef} \right]$$

où  $c$  désigne le dosage du ciment en kg.  $\rho$  la densité du ciment.

On peut faire des essais comparatifs, déterminer  $(e/c)_{ef}$  et  $p_{ef}$  en utilisant des adjuvants ou en travaillant à des régimes technologiques de fabrication différents, afin d'en déterminer l'efficacité. Ces caractéristiques permettent de prévoir avec suffisamment de précision le temps et les conditions de durcissement d'une pâte de

ciment et d'un béton. Ces facteurs exercent une influence déterminante sur la structuration ultérieure d'un béton et sur ses propriétés finales.

La méthode examinée ci-dessus a permis d'augmenter la précision des calculs faits avec l'aide d'ordinateurs. A l'avenir il nous faut chercher de nouvelles méthodes ou des méthodes semblables permettant d'augmenter la précision des calculs technologiques et économiques.

## REVIEW and CONCLUSIONS

by SIDNEY DIAMOND

The activities/encompassed in Theme VI consisted of the following parts:

- (a) Four principal papers prepared respectively by Helmuth, by Sereda, Feldman, and Ramachandran, by Wittmann, and by Cheine.
- (b) A total of 39 contributed papers by authors from thirteen countries.
- (c) A general report prepared and delivered by the undersigned.
- (d) A total of 29 posters prepared by authors from seven countries.
- (e) A Round Table discussion.
- (f) A final session of questions for the Round Table members.

In conformance with the general regulations of the Congress, the individual principal papers were not delivered by their authors but were summarized by the general reporter.

The principal paper by Helmuth (VI-0) covered structure and rheology of fresh cement paste. Helmuth discussed certain characteristics of cement paste as a disperse particle-fluid system whose particles are flocculated unless an effective dispersant has been incorporated into the mix, and introduced a simplified model in which all the individual particles, of whatever size, have water films of equal thickness surrounding them. The flow characteristics of pastes in terms of Bingham parameters were elucidated, and complications of dilatant, pseudoplastic, thixotropic behavior were discussed. The changing behavior of pastes under repeated shear cycles were attributed to a balance between thixotropic breakdown and recovery, and various cement and solution characteristics that modify flow behavior were reviewed.

The principal paper by Sereda, Feldman, and Ramachandran (VI-1) provided a review of a number of aspects of structure formation and development in hardened cement pastes, particularly those aspects in which major contributions had been made by the NRC Canada group. The paper was subdivided into several independent subsections, the first of which involved

the formation and nature of bonds, bond strength, and bonding as related to material structure and behavior. This was followed by a section on porosity and pore size distributions in hardened cement paste. A third section on physical factors controlling structure and strength development was followed by a final section on the influence of admixtures.

The principal paper by Wittmann (VI-2) reviewed aspects of the characteristics and behavior of hardened cement paste seen as a system comprising a solid skeletal structure with an intrinsic pore system, the latter usually containing water; the presence or absence of the water exerts a profound influence on the mechanical characteristics of the system. A survey of the commonly experienced mechanical behavior features of cement paste and their origins in the nature and microstructure of the system completed this review.

The principal paper by Cheine (VI-3) comprised primarily a treatment of time variation in the strength-producing quality of the output of a particular blended cement plant and an exposition of sophisticated mathematical procedures for the analysis of such variation.

The 39 contributed papers encompassed a wide variety of topics, but may be loosely grouped into (a) nine papers on the rheological and other characteristics of fresh cement paste, with many of them dealing with modifications produced by superplasticizers and other admixtures, (b) ten papers dealing generally with the formation and evolution of structure in hardened cement pastes and the bonding developed therein, (c) fourteen papers relating to the structure and properties of hardened cement pastes; and finally, six papers on mathematical modeling of hydration and strength development. One of the most interesting contributions in this last area, a paper by Knudsen, was perhaps inappropriately assigned to Theme I and is found in that portion of the Contributions volume of the Proceedings.

The general report, prepared and delivered by the undersigned, was an attempt to synthesize as much as possible of the important features of the principal reports and the principal papers. Because of the magnitude of the task and the restrictions on length of report and on time of delivery at the Congress, the general report was necessarily somewhat superficial in character. The writer hopes that the effort was useful to Congress participants and will be of help to later readers of the final Congress volume.

The large set of posters exhibited at the Theme VI session of the Congress was something of a surprise to the writer, who did not have an opportunity to examine their contents prior to the Session. Abstracts of these posters are available in the final volume of the Congress proceedings.

In conformity with the established format of the Congress a Round Table panel was assembled to discuss and answer questions pertaining to this portion of the Congress activity. The panel was chaired by the undersigned and consisted of Messrs LeGrand (France), Helmuth (USA), Sereda (Canada), Ramachandran (Canada), Wittmann (Switzerland), Mchedlov-Petrosyan (USSR), Bomble (France), and Mindess (Canada). A portion of

the round table period was devoted to brief expositions by those of its members who were authors of principal papers of their most significant points and any changed viewpoints since the principal papers were prepared. Several questions were then posed to the panel by the Chair, relating to specific topics of concern that had arisen from prior discussions. The questions posed were in brief form: (1) Is there any experience, or consensus, on what sorts of shear rates might be expected to obtain in the usual run of concrete mixing practices, so that rheological tests might be carried out at such shear rates? (2) What, if anything, happens to the preexisting floc structure of fresh paste on setting and hardening? (3) Whether the usual colloidal concepts in general use are really appropriate to describe the behavior of the set synthetic cement paste or stone, and (4) Whether the brittle failure characteristics associated with high-strength concretes were a necessary and intrinsic feature of high strength portland cement systems, or whether one could expect modification of this sometimes undesirable behavior as a result of future development? Time did not permit discussion of all these questions but the consensus suggested that it is not possible to define a definite range of shear rates for the concrete mixing operation, which varies enormously with equipment and circumstances, and that the floc structure of fresh cement paste is probably carried over intact to the hardened paste, and this

may have important consequences for the behavior of the latter.

In a final session a relatively large number of questions from the floor were handed in for discussion by the panel, but time permitted response to only a few of these. A number of Congress participants requested time to make brief ad hoc presentations, but it was the painful duty of the undersigned to have to refuse all these requests as inconsistent with the format and time available for the session. He regrets this very much and hopes that on future occasions sufficient time might be set aside for such vital and important communications.

As a general conclusion, the undersigned is of the opinion that Theme VI of the Congress was adequately carried out and that the purposes of summarizing progress in the relevant areas since the Moscow Congress in 1974 were in general achieved, despite frustrations due to format and shortage of time. He would like to acknowledge with great thanks, the tremendous efforts of the Congress organizers, the exceedingly fine facilities placed at the disposal of the Congress participants, and the excellent work of the simultaneous translators who were crucial to the successful functioning of this multilingual assembly.

## THEME VII

### Interface reactions between cement and aggregate in concrete and mortar - bond strength and durability

by G.M. IDORN

**SUMMARY:** As introduction is discussed a contrast in the present cement and concrete situation: The cement manufacturing process has reached high industrial efficiency, and civil engineering has proven capable to match the social demands on ever increasing building and construction development, while application of chemical knowledge is too confined to stimulate the creation of contemporary concrete processing technology methods and procedures.

In this context the various aspects of adherence (bond) and durability are discussed on the basis of the contributions to the theme, and selected information from elsewhere.

The advantage is stipulated for application of thermodynamics and reaction-kinetic concepts in studies of the processing of concrete seen as an entirety from the stage of mixing, through placing, curing and performance until ultimate degradation.

Consequently, cement-aggregate reactions and the creation and characteristics of adherence are discussed as primarily dependent upon conversion of "intrinsic" energy, while attack of saline waters is considered as promoted by "intrusive" energy. The adherence between cement paste and reinforcement bars, fibre reinforcement and the effects of pozzolans are dealt with as special issues within this framework.

Contributions on hydrothermally created bond-strength and morphology in cement mortars are treated as elements of future innovative technology development.

Ways and means are suggested for making concrete technology research effective as support to the civil-engineering development of concrete usages.

**RESUME:** Comme introduction, est discuté une contradiction dans la situation actuelle concernant le ciment et le béton:

"Le procédé de fabrication de ciment a atteint une efficacité industrielle élevée et l'art du génie civil s'est montré capable de répondre aux demandes sociales du développement accéléré dans le bâtiment et la construction, tandis que l'application de la connaissance chimique est trop limitée pour stimuler la création contemporaine des méthodes et procédures technologiques".

Dans ce contexte, est discuté les aspects divers concernant l'adhérence et la durabilité, ceci sur la base des contributions au thème et des informations d'ailleurs.

L'avantage est invoqué de l'utilisation des concepts thermo-dynamiques et réaction-kinétiques dans les études de la fabrication du béton dans leur ensemble à partir de la phase de préparation et le coulage, la maturation et performance jusqu'à la dégradation ultime.

Par conséquence, les réactions ciment-agrégats et la création d'adhérence sont considérées comme principalement dépendante de la conversion d l'énergie "intrinsèque", tandis que l'attaque des eaux salines est considérée comme créée par la conversion de l'énergie "intrusive". Dans ce cadre est traité spécialement les problèmes d'adhérence entre la pâte de ciment et les fers de renforcement, les fibres de renforcement et l'influence des pouzzolanes.

Sont traitée à titre d'éléments d'innovation technologique l'influence des conditions hydro-thermiques aux l'adhésion et la morphologie des mortiers de ciment.

Des méthodes et procédures sont suggérées afin d'améliorer l'efficacité de la recherche dans la technologie de béton, comme appui à l'industrie des oeuvres de génie civil.

## INTRODUCTION

The preceding sessions of the 7th International Congress on the Chemistry of Cement have demonstrated that cement manufacture now possesses remarkable abilities for applying cement chemistry knowledge to match the increasing pressures from the depletion of the resources. Also the elaborate evolution of ordinary and special cement characteristics based upon deliberate utilization of chemical knowledge has been convincingly illuminated, and has shown an impressive integration of independent and industrial research, or, if so preferred: of non-mission, basic, and mission-orientated, applied research.

Thus, cement manufacture with its storage tank of cement chemistry knowledge is prepared to serve the needs for vastly increasing uses of cement during the forthcoming decades.

Meanwhile, concrete construction design has pioneered energy conservation throughout the post-war period by enabling considerable increases of imposed loads relative to dead loads of structures and buildings, and also by invention of system and modular building's design etc. Concrete construction execution has concurrently created management of large-scale, mechanized erection operations to earlier unthinkable extents and rates of execution. This synergistic civil engineering development of concrete uses has now made cement a fundamental primary material for the functions and further progress of all human societies.

Therefore, there are obvious reasons why the present congress could have had a concluding session to concentrate on the opportunities for industrial research and development of cement using processes and products, by utilizing the available cement chemistry knowledge. And there are in fact incipient moves in this direction among the contributions to this session.

However, the prevailing feature in actual cement using practice is not industrial innovation, but rather that major constructions, for instance, in the energy producing and the infrastructure sectors, are requested to be designed for higher levels of performance reliability than before, while concurrently repairs and replacements of deteriorated concrete are showing unacceptably increasing consumption of the available resources.

With these trends unfolding: higher performance requirements confronted with increasing deterioration, the established civil engineering concepts for the structural utilization of concrete, relying on simple, empiric specimen-testing and on equally simplified measures of the capabilities of cements, do not suffice. They cannot provide the specified initial and lasting performance qualities of structures and products, let alone stimulate to significant technology progress.

The civil engineering establishments are unable to change this situation, because this requires physico/chemical manipulations in concrete processing beyond the general acceptance systems. This is why it is cement chemistry knowledge which is facing great opportunities and obligations in updating of the technologies for cement uses.

It is the aim of the present general report to assess the potential impact of cement chemistry in counteracting the actually growing concern about insufficient concrete durability. This is to be accomplished by analysing the delivered contributions and other recent acquisitions of relevant knowledge. In this connection the adherence (bond) between matrix and aggregates will be considered as having an important role.

Whilst the attainable assessments from the analyses may prove to be incompatible with several rules and regulations in current engineering practice, the backfire on efforts to develop concrete technology and its research is hoped to be considerable, and in particular with regard to the use of cement-chemistry knowledge in obedience of the conditions under which concrete is made and required to perform.

## SURVEY OF CONTRIBUTIONS

During the Fourth International Symposium on the Chemistry of Cements in 1960 F.M. Lea (1) suggested the adherence between cement paste and aggregate as a subject worth of exploratory research. Since then many studies in this field have appeared, among which the comprehensive survey by Alexander and Gilbert (2) is emphasized. The present principal paper (3) and the adhering contributions (4), (5), (6), (8), (9) bring forward new concepts and methods of investigations regarding the nature of adherence under various circumstances, while (10), (11), (12), (13) in particular deal with hydrothermal reaction conditions.

The principal paper, (14), on the durability of concrete, is a comprehensive, critical review of the complex problems and accumulated knowledge in this field.

The reaction kinetics of cement paste hydration as influencing the characteristics of concrete is discussed in (15) and (16).

An expansive mechanism for porous solids, e.g. hardened cement paste, as a feature in concrete deterioration processes is suggested in (17), while the importance of the pore-size distribution and its measurement is emphasized in (18).

The "intrinsic" reactivity between cement paste and aggregates is treated in (19) and (20), which deal with alkali-silica reactions. These are also mentioned in (5), in relation to adherence, and in (25 - see below) in connection with studies of sea-water attack. Dedolomitization is discussed in (21), and the particular effects of pozzolans upon the chemical resistance of

glass fibre in cement paste are demonstrated in (22).

The "intrusive" reactivity of aggressive solutions on concrete is discussed in (23), the practical basis of which is aggressive, sulphate bearing ground waters, which also is the background for the contribution (24).

In more general, the aggressivity of sulphates, though with emphasis on sea waters is discussed in (25), (26) and (27), in the latter emphasizing the influence of cement manufacture parameters on the C<sub>3</sub>A-content and sulphate resistance of cements.

The special effects of chlorides are treated in (28) and (29).

The discussion in (30) on the influence of the MgO-content on the quality of cements is an interesting example of the "chemical alertness" in research in a developing country, where exploitation of hitherto unknown raw materials must be important. Implicitly the paper also shows, however, that concrete technology research in the "old world" has not contributed sufficient information on the autoclave-test for MgO as a reliable model for the behaviour of concrete, which hardens under atmospheric pressure at temperatures below 100°C.

The above introduced designations: "intrinsic" and "intrusive" reactivity gives a distinction between chemical reactions between the constituents - cement paste and aggregates - of concrete, and reactions by chemically aggressive solutions, primarily attacking cement paste while penetrating into concrete from the environment.

Admittedly, this is a crude distinction which neglects two important things:

(1): Any of the chemical processes concerned involves heat transfer and humidity exchange, i.e. energy conversion in the entire system: concrete and environment.

(2): The reaction kinetics encompass the entire energy conversion in concrete from the commencement, i.e. setting and hardening of the cement paste, until the ultimate stage of thermodynamic equilibrium of the reacting phases of the system is reached.

When these two basic conditions are observed it becomes clear that adherence must be conceived:

- (1) as created during the early hydration of the cement paste
- (2) as subject to continuous transition during concrete performance
- (3) as the seat of migration of substances during any "intrinsic" or "intrusive", deleterious process.

Herewith adherence is "brought in place" as an integral part of the research on concrete durability. At the same time it is implicitly stated that interpretation of experimental or theoretical model studies of durability need clarification of the

"model" thermodynamics and reaction kinetics in relation to those of the intended applications.

#### THE ENERGY CONCEPT

A certain fraction of the chemical energy in cement is converted into bond-forces between the cement-paste components and the surfaces of aggregate particles, fibre and reinforcement bars etc. during the setting-hardening process, see TABLE 1. The creation of these bond-forces is decisive for that the conglomerates of cement, water and aggregates, can become useable building materials.

##### ENERGY INPUT

Available energy in cement:  
1450-1900 kJ/kg cement

##### ENERGY CONVERSION

1. The creation of stable, intrinsic bond-forces and morphological structures of solids, solutions and air in cement paste during the setting and hardening phases of processing.
2. The concurrent creation of bond-forces between cement paste components and aggregate particles, fibre and reinforcement bars.

##### ENERGY CONSUMPTION

3. The development and consumption of heat during hydration as the driving force of the chemical reactions between cement and water.
4. The development and consumption of energy in additional chemical reactions, as e.g. with pozzolans, admixtures.
5. The consumption of energy in rheological deformations, microcracking etc.

##### ENERGY PRESERVATION

6. The preservation of energy in cement particles, at less than complete hydration (available for subsequent hydration during performance).

TABLE 1.

The energy input/output feature in the manufacture of concrete and cement products. The energy-efficiency is represented by the energy conversion into thermodynamic stable hydrates and bond-forces within the cement paste, and gluing the cement paste to the aggregate particles. The energy conversion is decisive for the performance, while the energy consumption as heat is important in modern manufacture economy and efficiency.

#### POWER AND INCINERATION PLANTS

#### WATERWAYS AND DAMS

Natural, acidified waters  
Polluted waters due to urbanisa-  
tion, strip-mining etc.

#### SEWER MAINS AND CLEANING PLANTS

Domestic waste water  
Industrial and agricultural waste  
waters

#### TUNNEL AND MINE SHAFT LININGS

#### DEEP BOREHOLE CASINGS AND PLUGS

#### SWIMMING POOLS

TABLE 2.

Types of structures of importance in modern societies, and exposed to environmental energy, the aggressive effects of which are enhanced by heat, alternate heating/cooling, concentrated aggressive solutions and low pH in waters etc.

During use in practice the materials are exposed to transformations induced by additional available energy, intrinsic and intruding from the environments. The durability depends upon, how the entire system of materials and environments converge towards ultimate thermodynamic equilibrium.

The research associated with cement industry has until recently concentrated upon energy conversion in cement manufacture, which per unit of product is by far the most energy-intensive category of cement/concrete production.

The engineering and construction sector has traditionally been concerned with energy, primarily as (1): potential energy in structural masses, and (2): kinetic energy in mass transport during construction operations, but not with monitoring of the conversion of the available energy in cement in the making of products or concrete.

TABLE 3.

Characteristics of concrete manufacture conditions, encompassing as well neglectance of "good practice" as sophisticated construction operations and precast and product manufacture.

Conceptual research on energy conversion in cement uses - during manufacture and while being used - is therefore rather homeless, yet acquiring increasing impact on both cement industry and engineering practice.

The problems herein are aggravating with the modern development of concrete usages.

Much concrete is now exposed to more severe environmental aggressivity than incorporated in the philosophy of conventional research. TABLE 2 exemplifies some such performance exposures.

Particular references are given in (23) and (24) to aggressive sulphatic ground-waters in East Europe (foundations, tunnel linings etc.). More severe problems with aggressive ground-waters are met in the Middle East, as described for instance by Fooke and Collis (31), and in hot regions elsewhere.

Warm, aggressive waters are also met increasingly in construction work for industrial production, in the infrastructure sector, and in areas with condensed habitation. Acidification of natural waters, due to air-borne pollution, or to strip-mining or agricultural and foresting development etc. is in progress, and in developing countries the increasing accumulation of masses of people in townships with primitive urbanisation facilities may create severe chemical pollution of surface- and ground-waters, often in connection with considerable changes of levels and availability of water for consumption.

In the temperate and cold regions the intensive de-icing practice to facilitate road- and highway utilization in winter seasons is adding chemical energy to the deleterious effects of freezing-thawing. The processes concerned are still not quite satis-

FIGURE 1

Configuration of the "constructive" energy conversion during the making of concrete. The hydration of cement paste results in the creation of inherent strength and cement paste-aggregate bond. Concrete is a material of excellent durability, if adequately cured, whereas "destructive" energy may result in acceleration of deterioration, if the processing does not facilitate efficient energy conversion, as for instance by too rapid release of the heat of hydration during early curing.

factorily explained, yet demanding increasing resources for repair to pavements, sidewalks and bridge-decks. It is unexplored, but likely, that saline run-off melting water may enhance the aggressivity of ground-water towards concrete exposed to capillary suction from beneath.

Severe stress conditions are also to be anticipated for much concrete during the manufacture phase, due to the intensity of the development and transfer of heat of hydration under conditions which are incompatible with the prevailing research methodology. TABLE 3 exemplifies such manufacture conditions, which are in contrast to that most laboratory experiments concerning adherence and durability research are made at "room temperature" conditions  $\sim 20^{\circ}\text{C}$ . However, some researchers do apply supplementary experimental series at higher constant temperatures in order to investigate accelerating effects of heat, see e.g. (5), (19), (22), (25). (Even the use of steam-cured cement mortar specimens are recommended (24) for comparison of the sulphate resistance of different cements).

The traditionally accepted custom to work "isothermic" surely facilitates communication and broad interpretation of findings among researchers. The logical basis is that development and transfer of heat during the setting/hardening process are of no significance in small mortar or paste specimens if dealt with in the temperature/humidity constancy of modern laboratory conditions. Such experiments, therefore, represent adequately homogeneous models of cement paste and mortar behaviour. Correspondingly, adherence and durability studies usually interpretate the behaviour of concrete, as if it is isothermic hardened (mostly at  $20^{\circ}\text{C}$ , 100% RH), and also rely upon comparable, simplified models of aggressive exposures.

The reaction kinetics of cement hydration as decisive for the adhesion within the cement paste and for the cement-aggregate

adherence is discussed on the basis of electro-chemistry in (15) and (16). And in a general way the incompatibility of current experimental and standard-specification practice on the one side, and the actual conditions for the making and uses of cement products and concrete is emphasized in (23), thus sustaining several statements on this issue in the principal paper on durability, (14).

It is characteristic that deleterious energy conversion during concrete performance appears visible as cracking, expansion, distortion, spalling, dissolution etc., and these phenomena are recognizable and empirically comparable when used as measures for durability criteria by laboratory experiments, as e.g. reflected in (19) regarding alkali-silica reactions, (25) regarding sulphate attack, and other contributions.

In contrast, the early damages due to excessive rates of energy conversion and consumption during cement paste hydration - barred further hydration, plastic shrinkage thermal conditioned microcracking - do not appear in the conventional laboratory practice and are therefore in general not experienced by researchers to develop in field scale concrete.

To the studies of adherence and durability are therefore coming to belong, not only initially deleterious effects of modern concrete manufacture, but also synergetic effects in field concrete of invalid processing plus subsequent added "destructive" energy from the environments (or inherently available energy) in contrast to protected experimental models.

FIGURE 1 configures that in principle these problems express the need to introduce energy conversion during cement hydration processing, and during subsequent additional conversion of inherent and environmental available energy, i.e. an overall reaction-kinetic concept, in the research.

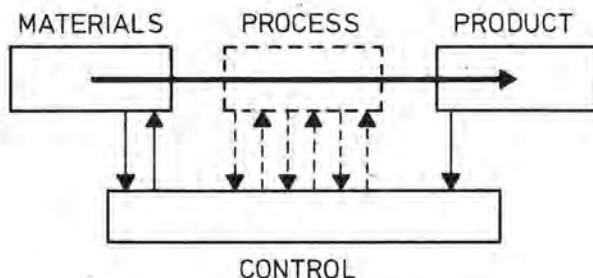

FIGURE 2

Process control in industry consists of check on the primary materials and their entrance in the processing, monitoring of the manufacturing operations with on-line recording of influential process parameters, and final check on the products' compliance with the desired characteristics.

Concrete manufacture is virtually without on-line process control and possibility to monitor that the process results in the required concrete characteristics. And these are largely tested on specially protected test specimens, which do not reflect the impact of the process-parameters on the ultimate characteristics of the concrete as it is placed for permanent performance.

(From Idorn (32)).

The mentioned dialectic "contraposto": the aggravated impact of "destructive" energy on modern concrete behaviour on the one side, and the still prevailing use of simple experimental models, which deliberately eliminate reaction-kinetics from the research on the other side, is also reflected in the principles of concrete control in practice, versus monitoring process-control in high-technology industries, as shown in FIGURE 2, from Idorn (32). It appears: standard concrete control relies exclusively on the testing of the materials and of control specimens, which are not representative of the ultimately attained product, in contrast to the monitoring principle, which continuously records how the processing technology will result in that the specified ultimate characteristics be reached. Also in this context it is apparent that the heat development and consumption during cement hydration is to be considered a valid means of monitoring, and therefore must be taken into consideration in the further progress of research.

The emphasis on cement clinker mineral composition in several contributions notably (24), (25), (27), are demonstrating, how far cement industries have utilized cement chemistry research to conduct their predominant intents for making concrete durable against attack of sulphates in aggressive solutions.

The discussed new aspects in modern cement using technology indicate, that energy additional to that from the cement has commenced to gain relatively more influence than the chemical energy in the cement itself, both on the course of the concrete manufacture processing and on the behaviour during performance. This trend in the background for research, does not degrade the importance of cement chemistry knowledge, but invites to more comprehensive utilization of basic chemistry in the planning and interpretation of technology oriented research.

The contributions (10), (11), (12), (13), (22), are demonstrating the impact of adherence and durability as technology development issues of innovative process and product development with cements, showing that industry exploitation of market potentials have commenced to play a part - glass fibre reinforcement, autoclaved lime/silica technology etc. To complete this picture of a "renaissance dawn" to come for new development of cementitious materials, contributions on superplasticizers and on polymer-impregnation are missed and must be sought elsewhere.

Practically any of the mentioned new developments are closely associated with the energy situation, either as means of savings - as e.g. pozzolans, superplasticizers -, or as means for the attainment of exceptional adherence and durability - e.g. polymer-impregnation - or as enabling less voluminous and lighter products - e.g. glass fibre reinforcement.

A more complete analysis on adherence and durability with respect to the perspectives of the energy situation and to the issues seen in a context of thermodynamics and reaction kinetics is not warranted by the presented contributions, but none the less needed to point towards. This is particularly so, because the frequently met attitude that concrete is an energy extensive building material, does not hold true, when the total quantity of concrete produced - by now about 7000 million tons a year - and the 1980-2000 period's need for increases are considered. The contributions therefore are to be considered forerunners for a decisive orientation of more research to meet these demands, including elimination of unforeseen failure risks and of unreasonable repair needs, as the "defensive" strategy goals, and higher energy efficiency of cement uses as the "offensive" strategy.

#### THE PARTICULAR IMPORTANCE OF HEAT

In a general way it is widely known that heat is a driving force in the chemical process of cement paste hydration, and accelerates the strength development, if not lost to the environments. During many years' evolution of concrete technology the heat

development was, however, so insignificant in practice that it seemed justified to neglect this category of energy consumption as a parameter in research. The post-war need for winter-concreting broke the barrier of this inheritance, and monitoring of concrete making in cold weather which utilized the heat of hydration was developed and implemented in practice, based on combined utilization of works by Powers and introduction of maturity functions, Nerenst (33). The development of steam curing initiated long-term research at the former Concrete Research Laboratory, Karlstrup on the problems of monitoring the concrete processing by high-levels of heat development early during hydration, and Idorn in (34) suggested heat of hydration introduced as a general parameter in research.

Through continued work by Freiesleben-Hansen (35), (36) and others, computerised design/monitoring systems, by which the heat/strength development can be precalculated and continuously controlled, have now been established.

The gist of the concurrent technology development is that cement chemistry and cement production technology jointly with the civil engineering demands on rapid construction and early high strength concrete now often compress the development of heat during the phase of curing in much modern concrete. Consequently, thermal stresses develop, which exceed the mechanical resistance capability of the cement paste at early maturity stages. Invalidity - microfractures - caused this way, are irreparable, and become seats of deterioration, promoted e.g. by too abrupt cooling, and by later "intrinsic" and "intrusive" aggressivity.

This issue is implicitly treated in the contributions underlying the present general report, but deserves, in the opinion of the writer, to be profoundly taken into consideration in research on adherence and durability. This is not only to create means for effective utilisation of the energy converted into heat during hydration, but also because the complex of processes during hydration of cement and performance of concrete are all very sensitive to the time/temperature history of the material. Moreover, calculated development of energy saving requires theoretical and technological elucidation of the role of heat in processing.

#### CEMENT PASTE-AGGREGATE REACTIONS

Alkali-silica reactions are by nature hydration reactions and must be assumed to obey a time/temperature relationship akin to that which is established for the formation of calcium-silica-hydrates and alumina-compounds in cement paste. They depend upon mass-transport of  $(Na, K)^+$  and  $(OH)^-$  ions through the interface-precipitates into the structure of siliceous aggregate particles. While this structure is being disrupted by

FIGURE 3  
Graphic configuration of table 2 in Gutteridge and Hobbs (40) showing the percentage of Beltane Opal dissolved in 3 M NaOH at different temperatures and lengths of time of exposure. From Idorn (41)

the  $OH^-$  ions,  $SiO_2$  is in a gel-phase, migrating back through the interface, or through cracks opened by accumulated pressure in the particles, to precipitation as alkali-silica gel or lime-alkali-silica gel outside the particles. These are diluted as a consequence of the reactions and are left, either fractured due to the created interior pressure, or exceedingly weakened, if not completely converted into a gel or sol.

The rate and extent of alkali-silica reactions depend upon the concentration of  $(Na, K)^+$  in solution relative to the  $Ca^{++}$ -concentration. It is significant that  $(Na, K)^+$  suppress the concentration of  $Ca^{++}$  in the liquid of cement paste, see e.g. Malquori (37) and Lea (38), and increase the pH, thus facilitating the attack on siliceous aggregates.

The course of alkali-silica reactions are also significantly influenced by temperature, inter al because the solubility of  $Ca(OH)_2$  is suppressed at rise of temperature, see e.g. Greenberg and Brunauer (39) who gave the thermodynamic functions for the solution of calcium hydroxide in water.

Also the solubility in alkali-hydroxide of reactive silica increases with temperature, as for instance shown by Gutteridge and

FIGURE 4  
Qualitative comparison of the reaction kinetics of the hydration of cement in the presence of alkalis and pozzolans. At high heat of hydration, alkali-pozzolan reactions may forerun the intended lime-pozzolan reactions, but the developed alkali-silica gel may be metastable and alkali-reactions be renewed at later stages, e.g. at high exposure temperatures.

Hobbs (40) in experiments with finely ground Beltane Opal. Data for North-German opal, referred to in (19) corroborate these findings. Gutteridge and Hobbs' findings were discussed by Idorn (41), see FIGURE 3, emphasizing that the rapid dissolution at temperatures up towards  $80^{\circ}\text{C}$  (>50% dissolved in 1 day at  $80^{\circ}\text{C}$ ) corresponds much more to the circumstances in modern concrete manufacture, than does the common use of  $20^{\circ}\text{C}$  isothermic storage of mortar bar specimens in the research. It must be kept in mind that an exposure of finely ground opal in concrete to  $80^{\circ}\text{C}$  would at the same time suppress the  $\text{Ca}(\text{OH})_2$  concentration considerably, and increase the pH towards 13.5-14.0 dependant upon the available quantities of soluble alkalis.

For several reasons these observations are important to consider in the planning and interpretation of the research.

First, alkali-silica reactions may in our time, due to increased concrete temperatures during early curing (high cement-content, high-strength cements etc.), outfold much faster than corresponding to the con-

ventional concepts. Thus, the reactions may induce early cracking or be completely released while the "green" concrete is still deformable.

Second, in concrete, which is permanently exposed to elevated temperatures, continuous alkali-silica reactions will also continue to suppress the solution of  $\text{Ca}(\text{OH})_2$ . It must also be considered that alkalis may be available from silicate minerals in certain aggregates, see e.g. Lemish(42), Malinowski et al (43), and (25).

Third, the viscosity of the  $\text{C}(\text{N},\text{K})\text{S-H}$  system surely depends upon its composition, as discussed e.g. by Krogh (44) and Struble (45), but must also be expected to depend upon the actual temperature level. This means that penetrability of gel of low viscosity into the surrounding, porous matrix must be considered in reaction kinetic studies as alternative to any pressure building up mechanism. Brown (46), Kennedy and Mather (47), and Idorn (48) have observed evidence of such "gel-impregnation" into ambient cement paste, though in concrete, which probably never experienced temperatures higher than about  $30-35^{\circ}\text{C}$ , and was exposed to cold climate conditions during its performance.

Fourth, the influence of pozzolans on alkali-silica reactions must be evaluated under consideration of

- (1) the contents of soluble alkalis in pozzolans plus cement,
- (2) the solubility of the silicious pozzolanic constituents in the given concentration of the alkaline solvent,
- (3) the time/temperature dependency of the entire reacting system,
- (4) the possible influence upon the reactions of constituents other than soluble silica, in particular alumina-compounds.

A quantitative analysis of these matters would lead the general report into a far too comprehensive investigation of contributions to the preceding sessions, and also to thorough reexamination of many older observations on alkali-silica reactions.

Qualitatively, FIGURE 4 is a summary of the presented, exemplified observations, and stipulates that:

- (a) In modern concrete alkali-silica reactions may be pronounced during the concrete manufacture phase, and their effects may differ from those usually studied by research. Any laboratory study of the reactions should identify its time/temperature characteristics, and implementation for engineering practice must be on such basis.
- (b) In modern concrete with pozzolans, it be natural, fly ash, silica dust etc. alkali-pozzolan reactions may forerun lime-pozzolan reactions, dependant upon temperatures, nature of pozzolans, alkalis in cement etc.

(c) The thermodynamic stability of alkali-silica gel compounds with more or less lime may not be reached in concrete within the phase of manufacture and curing. Observations by Nepper-Christensen and Nielsen (49) on the rise and decline of bond in experiments with glass marbles as aggregates sustain this observation. Also, ion-migration e.g. with external heat or additional chemical energy (e.g. de-icing, aggressive waters) may re-activate alkalies to renewed reactions with available silica. The protective effect of pozzolans is therefore not an a-priori matter of fact, in accordance with an observation referred to in (20).

(d) The development of adherence between any siliceous aggregate and cement paste is a matter of alkali-silica reactions under the conditions outlined above, and the dissolution of the silica-structure by  $\text{OH}^-$  is an essential feature, remarkable even in ancient concrete with high  $\text{Ca}^{++}/(\text{Na},\text{K})^+$  ratio, see e.g. Idorn (50), referring to part-dissolution of the surface-layer in siliceous sand particles in a 600-year old lime-mortar and in Roman concrete from Caesarea.

The results by Gutteridge and Hobbs, (40), and those referred to in (19) showed that even in "highly reactive" silica some 20-40% substance was undissolved in 3M NaOH after 28 days at 20-80°C, and related this to the presence in the opal of sub-microscopic/microscopic crystalline silica. This sustains earlier "reactivity ratings" from opal and pyrex-glass as the "most" reactive, through volcanic glass towards chalcedony, quartzite to crystalline quartz as practically non-reactive in concrete. As appears from the above discussion, such ratings should be re-examined with the entire "reacting concrete system" as the basis.

Turriziani and Rio (51) demonstrate another feature of interest in comparison with the Gutteridge and Hobbs results. They compared the so-called Florentin base-acid attack on two different pozzolans. The highest silica content (88%) gave the highest dissolution (53%  $\text{SiO}_2$  in 28 days), indicating that for low-silica pozzolans, which also encompass some fly-ashes, the preventive effects towards alkali-silica reactions may be much less than for other ones, even if different alkali-contents are not considered.

The presence of calcium-alumina-sulphates in "aureoles", (4), (5), and their precipitation in dependence of the concentration of alkalies, see the solubility study (20), indicate that investigations with time/temperature sequences simulating concrete curing conditions would be rewarding for studies of the behaviour of the alumina compounds of the cements in cement-aggregate reactions.

Extended research on cement-aggregate reactions with slag cements could also be of interest, and it seems natural in this connection to include more work to examine the

hypothesis presented in (17), because expansions within the cement paste itself might also be connected with the migration tendencies for ions in the metastable compounds. Also further studies of the pore-systems, as dealt with in (18), would belong to elucidation of the effects of hydration at higher temperatures than 20°C, since alternate precipitation/dissolution phenomena might profoundly change the pore-systems.

The newer development of cement paste with exceptionally low water-content and high degrees of compaction deserves much research for identification of their behaviour with regard to cement-aggregate reactions. Some of this category of cement paste possess strong alkaline liquids, but only in minute quantities, and this must be assumed in the long run to influence the character of interface reactions and also the stability of created bond forces.

#### THE CREATION OF INTERFACE

Fundamentally, the interface commences to be created when thin films of water are formed on aggregate surfaces during the mixing of concrete. Alkalies from the cement dissolve immediately in the liquid, and lime commences to be released by the hydration reactions. From this outset, with its concurrent creation of strong  $\text{OH}^-$  concentrations, any of the following cement-aggregate reactions may proceed in the interface-zone, dependent upon the available constituents and the conditions for mass-transport and energy-conversion in the system: pore-liquid - interface - interior of aggregate particles.

##### 1. Basic Feature:

$\text{Ca}(\text{OH})_2$  precipitates in the liquid "surface-film" on the aggregate particles during the hydration, and creates a solid "aureole", which in the course of time develops or enhances crystalline orientation and bonding or intergrowth with the matrix and with the aggregate surfaces.

##### 2. Siliceous Aggregate:

Free  $\text{OH}^-$  ions break up the surface layer of the aggregate particles, and therewith the reactions may practically cease. In this case an alkali-(lime)-silica complex inside and outside the original surface becomes a significant element of the "aureole", which may completely intergrow with the outermost surface regions.

If the  $\text{OH}^-$  ions penetrate deeper into the particles the reactions may (1): either entirely transform the siliceous structure into alkali-(lime)-silica gel, which may build up sufficient hydraulic pressure on the surrounding cement paste through the interface-precipitates to impregnate the surrounding cement paste with gel, or to cause it to fracture. Or partial dissolution (low-permeability aggregate) may create local pressure regions within the

particles, and cause fracturing of the particles to proceed out into the cement paste. After fracturing due to swelling of gel in particles, dilute gel will flow out in the cracks and may become a significant constituent of the concrete.

### 3. Silicate Aggregate:

The free  $\text{OH}^-$  ions in the liquid of the paste may break up the structure in low-silica, glassy or crystalline, silicate rocks and release alkalis. These will add to the  $(\text{Na}, \text{K})^+$  and  $\text{OH}^-$  concentration. If such dissolution also releases free  $\text{SiO}_2$ -structures, these may become seats of formation of alkali-(lime)-silica gels.

### 4. Dolomitic Aggregate:

The free  $\text{OH}^-$  ions may break up the Ca-Mg-carbonate bondings, giving  $\text{CaCO}_3$  plus  $\text{Mg}(\text{OH})_2$  plus  $\text{Na}_2\text{CO}_3$ , which in turn may react with  $\text{Ca}(\text{OH})_2$  to form more  $\text{CaCO}_3$ , and regenerate  $\text{Na}^+$  and  $\text{OH}^-$ . The dissolution and migration of ions may encompass silica in aggregates, e.g. as in opaline-magnesium-limestone, or even in quartz, thus establishing a link to alkali-silica reactions. Thorough transformation of the interface precipitates and weakening of the interior of aggregates seem to be characteristic of dedolomitization rather than creation of expansive pressure in the reacting particles.

### 5. Calcium-Carbonate Aggregates:

There is evidence that intergrowth-reactions occur in the initially precipitated  $\text{Ca}(\text{OH})_2$ - "aureole" on the surfaces of calcium-carbonate aggregate, and in the course of time both calcium-carbonate/calcium-hydroxide may exhibit diagenetic inter-layer-growth and the CSH of the paste may develop similar phenomena. However, representative observations are still scarce.

A marked zonality in the composition of interface-layers is demonstrated in (5), and also dealt with in other contributions. Such phenomena were observed early in the history of petrographic examinations of concrete and referred to in numerous publications. The zonality has also frequently been found along internal cracks in concrete, and even on concrete surfaces (D-cracking "deposit cracking" (?)). Poole, in (52) demonstrated remarkable zonality in the interface-layers as a consequence of dedolomitisation. Apparently, one must anticipate that when the cement-aggregate system exhibits intensive migration of ions and substances, then will also variations in the physico/chemical circumstances tend to favour selective dissolution/precipitation phenomena.

It is not a priori possible to evaluate such diagenetic transitions as converging towards increased performance quality and equilibrium, or as contributions to deterioration, and also the position of cracks, for instance in a zonal interface system, ought to be cautiously interpreted at the present stage of knowledge.

There are no contributions which deal with the creation of interface with slag cements, at "natural" concrete curing conditions. The matter of particular interest in this respect is the limited availability of  $\text{Ca}(\text{OH})_2$  without appreciably high  $(\text{Na}, \text{K})^+$  concentration.

Thus, the creation of adherence and the stability of early formed interface compounds with slag cements need further research. It seems likely that in particular with slag cements the inherent reactivity of the cement paste itself should be examined in accordance with Litvan's hypothesis (17).

Some authors (3), (13), refer to the occurrence of air-bubbles in interface zones. One ought to have in mind that compaction of fresh cement paste under some circumstances may cause tiny air-bubbles to adhere to the surface of aggregate particles, a purely physico/mechanical conditioned phenomenon.

## ADHERENCE BETWEEN CONCRETE AND REINFORCEMENT

The adherence between the cement paste in concrete and reinforcement bars is discussed in (8) with zinc and cement paste as special experimental materials, implicitly referring to the possible passivating role of zinc-coating on steel-reinforcement bars. The development of calcium-hydroxyzincate is found as the interface reaction product in lime-solutions, whereas the presence of alkalis promote the formation of zinc-oxides, and soluble zincates are formed in pure alkaline solutions.

The electro-chemistry concepts on hydration, presented in (15) and (16) are also important for further exploration of the reaction-kinetics of the cement paste-metallic adherence and of the reaction products.

It seems likely that in a few years' time more research on the nature of cement paste-reinforcement adherence phenomena will become an important facet of further refinement of concrete construction design. Hitherto, transfer of stresses from concrete to reinforcement bars has been approached empirically with laboratory cast beams, columns, panels etc. as the basis for stress/strain and rupture-measurements and calculations. But effective transfer of stresses through identified interface phases have not been studied as an integral part of civil engineering design. It is therefore indicative of a trend for future research to designate (22) a pioneering study in this field, although with glass-fibre as the reinforcing agent, not ordinary steel bars, and therefore of interest for application in cement-product industries, rather than in civil engineering construction development.

Considering steel reinforcement, even the initial dissolution of alkalis and  $\text{CaO}$  in the liquid of fresh concrete will cause  $\text{Fe}$  to be dissociated and  $\text{Fe}^{++}$  to precipitate in a sequence with  $\text{Ca}^{++}$  as hydroxides

FIGURE 5  
Concrete structure in a Middle East country. The concrete is thoroughly cracked due to severe corrosion of the reinforcement bars with expansive forces developed during the formation of corrosion-products. The corrosion is probably enhanced by capillary suction of salts from the groundwater, and definitely by the temperature-conditioned acceleration of all the involved physico/chemical processes.

creating a passivating layer at pH 12-13.5 as a stable barrier against further corrosion. However, if the pore-liquid of the cement paste is neutralized by access of  $O_2$  or  $CO_2$  or by saline solutions with  $SO_4^{--}$  and  $Cl^-$ , further electrolytic dissociation will be promoted, and more Fe-hydroxides and complex salts will precipitate. This course of reaction (requiring available free energy) is destructive for the adherence and also for the concrete as such.

In hot countries the activation energy level enhances the course and rate of corrosion. FIGURE 5, from Idorn (32) is a typical example of structural failure attained in a course of 5-6 years in an exotic climate. FIGURE 6 is a configuration of the corrosion features which are characteristic of such environments.  $Fe^{+++}$  compounds are precipitated instead of the ferrous-compounds, and this causes pH to decrease to 2-3, see e.g. Bastiansen et al (53), and strong acids to accumulate in pockets created by the expansive pressure which develop because the trivalent, complex hydroxides are 2-3 times more voluminous than are the divalent ferro-hydroxides. Possibly also osmotic pressures and crystallisation pressure exerted by gypsum, see e.g. Dreyer-Jørgensen (54), are involved. As can be seen in FIGURE 5 the release of energy is powerful enough to create deep, longitudinal cracks over reinforcement bars of which there after a few years' time may be only complex  $Fe^{+++}$  hydroxides etc. and no load-bearing capability left.

FIGURE 6  
The sketch outlines the mechanisms of corrosion of reinforcement bars in concrete in warm, saline environments, and also the primary reactants and resulting corrosion products. The configuration is deduced from experienced cases of complete disappearance of metallic iron in a few years' time concurrent with the devastating exertion of expansive pressure from the corrosive "cells".

FIGURE 7  
C<sub>3</sub>A and C<sub>2</sub>(A,F) contents, Bogue-calculated (B) and XRD-measured (X), of eight ordinary portland cements, referred to in (25).

Both in hot and temperate regions the progression of corrosion after the initial formation of passivating Fe- and Ca-hydroxides as the adherence "aureole" around reinforcement bars may be caused either by high cement-content with initial heat-induced microfracturing during the hydration, or by the use of too low cement-content which cannot provide sufficient impermeability and strength to the concrete to prevent access of O<sub>2</sub>, CO<sub>2</sub> or saline waters for reaction with the reinforcement. Also many other factors under the heading "good or bad concrete practice" are involved.

Consequently, the nature and stability of the adherence between cement paste and reinforcement are important, both for the composite, statical function of reinforced concrete, and for the performance reliability of concrete structures. The conditions for the design of optimum concrete composition and of concrete making procedures therefore also depend upon further progress of the research on the nature and characteristics of the adherence phenomena.

#### THE EFFECTS OF SALINE WATERS

Besides the question of different reaction-kinetics in laboratory mortar specimens and in structural concrete, there is one pro-

Criteria	Sample No:							
	1	2	3	4	5	6	7	8
C <sub>3</sub> A < 10% B&X	+	+	+	-	+	+	-	-
C <sub>2</sub> (A,F) < 10% B&X	+	-	-	+	+	+	+	-
B-X ≤ 2.5%	+	-	-	+	-	+	-	-

TABLE 4  
Suitability (+ or -) of the eight ordinary portland cements referred to in FIGURE 4, evaluated according to the criteria: C<sub>3</sub>A < 10% (B&X), for sulphate resistance, C<sub>2</sub>(A,F) < 10% for strength capability, and B-X ≤ 2.5% for reducing ambiguity. Cements Nos 1 and 6 meet the criteria.

blem emanating from the contributions (23), (24), (25), (26) and (27) on sulphate resistance of cements and concrete, which in particular deserves a general discussion. This is the registration and the stipulated influence of the C<sub>3</sub>A-content in cements on the resistance of concrete to the aggressivity of saline sulphate waters.

Schrämli (55) revealed considerable ambiguity among researchers about the net benefit by specifying the use of low C<sub>3</sub>A cements for concrete. He also found a remarkable discrepancy between Bogue-calculated and XRD-measured contents of C<sub>3</sub>A in cement clinkers.

The principal paper (14) discusses these uncertainties, and further information is extractable from (25). FIGURE 7 shows the C<sub>3</sub>A and the C<sub>2</sub>(A,F) contents of eight portland cement samples, Bogue-calculated (B) and XRD-measured (X), respectively (originating from (25), table II). For C<sub>3</sub>A the difference between B and X varies from 0.3% (sample 5) to 6.3% (sample 3). For C<sub>2</sub>(A,F) the difference varies between 1.4% (sample 1) and 3.5% (sample 5). It also appears that a low C<sub>3</sub>A-content may or may not be obtained by a high C<sub>2</sub>(A,F)-content, compare for instance sample 1 and 2. The quality of the eight cements as regards sea water attack is compared in TABLE 4 by introduction of the following three criteria:

- C<sub>3</sub>A < 10%, both by B and X - as a reasonable sulphate resistant limitation.
- C<sub>2</sub>(A,F) < 10%, both by B and X - because the ferrite-compounds are not strength-contributors and thus represent energy waste in concrete.
- B-X ≤ 2.5% both for C<sub>3</sub>A and C<sub>2</sub>(A,F) so as to reduce the ambiguity of the classification of the cement composition for the consumer.

It appears that cement sample No.1 and No.6 comply with these three criteria. However,

FIGURE 8  
Expansion, after 2 years in sea water (Atlantic and Mediterranean), of mortar bars made with the eight ordinary portland cements, referred to in FIGURE 5 and TABLE 4. Cement No.6 which meets the three quality criteria in TABLE 4 shows the highest expansions. Cement No.7 with 14 or 18% C<sub>3</sub>A (B or X) shows much less expansions. Cement No.1 is good according to all four criteria.

when the expansions of mortar bars in sea water, as displayed in FIGURE 8, are added as a fourth criterion, then only cement No.1 can be said to comply, since No.6 has the highest expansions of all samples, while cement No.7 with 14% (B) or 18% (X) C<sub>3</sub>A shows much less expansions.

The results reported in (27) about correlations between the C<sub>3</sub>A-content (Bogue-calculated) and particular burning/cooling cir-

cumstances during the cement manufacture, sustain recent results by Locher (56). It appears that considerable variations in C<sub>3</sub>A-content for one brand of cement may occur in dependence of the cooling conditions, which may well be at variance in cement manufacture under forced changes of fuel, use of mineral admixtures, cost-savings efforts etc. The principal paper (14) does discuss these matters in more detail, and also their influence on the resistance of cements to sulphatic solutions of other clinker components etc.

Thus, altogether a very complex picture exists. This is what the general report must emphasize, because engineering practice in general is served by advisory or compulsory regulations based upon simplifications, which have a weakening basis in the now attained cement chemistry knowledge.

The aggressivity of chlorides under rather specific circumstances are discussed in (28) and (29). There is a broad background for supplementary investigations in serious problems for construction and building:

(1): Continuous progress of deterioration of highways, sidewalks, bridges etc. where de-icing is common practice in winter seasons.

(2): Permanent exposure to temperate saline waters in swimming pools.

(3): Penetration into concrete of saline ground-waters and wind-borne seawater spray in hot countries.

It is characteristic for chloride attack that both concrete and reinforcement are practically defenseless, if the energy activation level is high, and the concrete permeable. This is why quantitative assessments of exposure conditions as germinating the release of the destructive energy conversions have good chances to exhibit big returns on research investments.

#### FIBRE REINFORCEMENT

For many years asbestos fibre have been used as reinforcement in cement based products to provide excellent adherence and durability characteristics attained by empiric, technical development. In recent years glass-fibre have been developed as alternative reinforcing agent. The particular aspects of adherence, and of the stability of the interface structure and constituents, are presented in (22).

It is shown that if the bond is enhanced between fibre and cement matrix there may appear a concurrent decrease of strength of the glass substance, and thus a reduction of durability of the product. It is also shown that the presence of pozzolans in the cement matrix greatly reduces the corrosion of the fibre surfaces. There does not seem to be a correlation between the amount of free alkali in the specimens and the degree of glass corrosion, while curing at high

temperatures (80°C) does aggravate the corrosion, a finding which is in accordance with the results by Gutteridge and Hobbs, referred to above. These observations confirm that a more complete study of the beneficial effects of the various pozzolans might provide additional knowledge of considerable practical interest.

Supplementary investigations of these matters must be anticipated to be important for the further innovation of fibre-reinforced products. The interface phenomena might be found in particular to be sensitive to the processing conditions, to the type and dimensions of fibre materials, to the use of superplasticizers and special pozzolans, to the alkalinity of the matrix etc. A wide range of opportunities are thus awaiting determined industrial exploitation.

#### POZZOLANIC MATERIALS

The effects of pozzolans in glass-fibre reinforced products are discussed in (22) as a deliberate aid against deleterious alkali-silica reactions. Historically, pozzolans have been widely used as a means of cement (energy) saving, to moderate heat development during curing, and to improve sulphate resistance of concrete. The present intensification of the use of pozzolans for the utilization of fly ashes and other types of siliceous materials from dust-collectors raises issues for the research, which have not been much pursued for a number of years. Malquori (37) compiled convincing evidence that pozzolan-granula in cement paste are corroded and surrounded by layers of gel-like, hydrated calcium silicates. Thus, the high specific surface of the pozzolans was found greatly to enhance the kind of reactions which are designated creation of adherence or bond, if the pozzolan material has the size of aggregate particles, instead of cement fineness. Malquori also refers to reactivity of the alumina in pozzolans, which in the presence of sulphates react to give calcium-sulpho-aluminates.

The different quality of pozzolans as means for increasing the sulphate resistance of concrete is mentioned in (25), but the role of alkalies and of the initial reaction kinetics remains to be described.

The various available fineness of pozzolans, from about that of ordinary cement or less (some fly ashes) to more than 15000 cm<sup>2</sup>/g (ferro-silicon dust, or refined fly ash), or even 24000 cm<sup>2</sup>/g (metakaolin) and the influence of particle shape of the pozzolan particles - rounded spheres, partly hollow in case of fly ashes, glass splints in case of volcanic tuff etc., or fragments with high internal surface as the Greek Santorin Earth or the Danish diatomaceous earth, also remain to be examined in depth, and the differentiated effects identified.

Alkalies were found by Malquori (ibid) to combine into the calcium-silicate-gel complex. However, it was noted that the pre-

sence of alkalies has influence on the reaction-kinetics, among other things due to its suppression of the solubility of calcium hydroxide. The observations do not allow conclusions as to whether the fixation of alkalies early during pozzolanic reactions is permanent and stable, or merely loose and liable to transition.

Turriziani and Rio (51) found that the reaction between lime and silica is the initial reactivity, also in cases where alumina takes part in the further reactions, and becomes absorbed in the precipitated gel-complex. (The alkali-content of the pozzolans was not given).

These scattered evidence serves the purpose to stipulate the importance of thorough investigations of the systems N, K - C - S - Al, Fe - H<sub>2</sub>O under real reaction conditions in concrete and in cementitious products, also when siliceous aggregates are used in cement fineness as pozzolan, mineral admixtures to improve adherence or durability or both at the same time.

#### HYDROTHERMAL PROCESSING

Hydrothermal reactions have for many years been utilized on account of the intensive creation of adherence-forces and the high degree of ultimate stability it is possible to attain with mixtures of CaCO<sub>3</sub>, SiO<sub>2</sub> and H<sub>2</sub>O during a brief processing time.

In (10) the synthesis of fibrous CSH crystals by hydrothermal reactions is reported. The solubility of lime was found to decrease in the presence of alkalies, while the solubility of silica increased when the system contained alkalies. Different compositions of the reacting system therefore gave different reaction products: tobermorite, xonotlite, pectolite etc. The influence of the alkalies was conspicuous, the most spectacular result being the manufacture of "rock-wool" fibre of lengths ~200 μm. These were obtained with C/S = 0.8 and treatment in a 2N KOH solution at 180°C for 10 days. In general CaCO<sub>3</sub> dissolved much slower than did SiO<sub>2</sub> and fibre was only obtained when both alkali and calcium sources were carbonates, and K<sup>+</sup> ions were present. There were no reactions observed without alkalies.

Compressive strengths over 150 N/mm<sup>2</sup> have been reached with autoclaved concrete, using quartz aggregates, (11). The high strength is attributed to intense interface reactions resulting in 11 Å crystalline tobermorite intergrowing with silica in the corroded surface of the quartz aggregate. In (12) it is shown that decreasing contents of quartz in the aggregate resulted in less strength. Rapid decrease of elastic yield (ratio of strain energy during unloading to the one during loading) occurred in concrete with non-reactive aggregates for stresses ~60% of failure, whereas the elastic yield was constant and high (90%) up to failure in concrete with quartz aggregates.

Special experiments, referred to in (13)

disclosed that under certain circumstances an air-bubble porosity structure may appear associated with the cement paste aggregate interface. Autoclaving nearly eliminated the pores in the case of quartz aggregates, and this also increased the frost resistance.

Altogether, the mentioned contributions invite to further studies of the interface creation and composition at hydrothermal conditions, and in particular to additional exploratory research on the influence of alkalies on the reaction kinetics and the thermodynamic equilibria of the CSH systems at hydrothermal conditions.

#### THE FUTURE RESEARCH

In 1941 G. Kalousek (57) said:

"---- the mechanism of the expansion of concrete is as complicated as the setting and hardening phenomena. For this reason the need of fundamental research as to the ultimate products of reaction for conditions simulating the normal exposure of concrete is definitely indicated. Phase-equilibria studies will show the end products of reaction".

This statement may be read as an early anticipation that expansion, as a phenomenon of deterioration, is one among the mechanisms of energy conversion and their consequences in concrete, which need to be understood.

Maybe it is today too much of a generalisation to say that cement paste hardening, cement paste-aggregate (and pozzolanic) reactions, corrosion of reinforcement, and saline water attack are merely each their species of hydration reaction. However, this seems closer to the truth, than to consider causes of early deterioration exploitable by means of 20°C isothermic laboratory models. And for some years it has been possible to make on-line recording of the temperature development in concrete during the curing phase, and to connect the thermocouples to a maturity-computer, whereby the early stress/strength development in the concrete can be calculated continuously, and the processing-monitoring can be used to change the course of hardening if need be, according to predesigned criteria and methods.

Practising of this technology can improve the durability of concrete considerably, and, in fact, the attainable benefits do not require more knowledge from chemical research than what Kalousek outlined in 1941: "to understand concrete under the conditions which govern its making".

The problem for research in this respect therefore is primarily in the second category of the R&D entirety: Development. In other words, it is a problem of cohesive technology system approach and instrumentation.

Progress along this line requires that market opportunities can be envisaged. The total concrete production in the world is of the order of magnitude of 60-70.000 million m<sup>3</sup> up till now, and at present are added about 3000 million m<sup>3</sup> a year. The production will converge towards at least 9000

million m<sup>3</sup> of concrete a year at the end of the century (corresponding to a world consumption of 300 kg cement per capita annually at year 2000) if things go unchanged.

With the present development of microprocessors such market potentials are attractive for the monitoring system and equipment industries, also because the market is a mix of innumerable big and small concrete-making customers. The attractiveness also stems from the increasing concern about performance reliability of concrete structures, or in other words: about adherence and durability.

Nuclear Power Agencies are presenting requirements for borehole-plugging materials of 1000 years' trustworthy behaviour, while power plants, and many other kinds of construction must be reliable without repair need for 30-40 years' use.

In contrast USA in 1978 estimated a 6.3 billion \$ budget for repairs alone to Highway Bridge decks, and about 105,000 bridges needing repairs. Comparable data from elsewhere are not easily accessible, but a great part of early concrete construction works - dams, harbours, bridges, tunnels etc. - in many countries are approaching total depreciation or are in fact long overdue, but now very expensive to replace. And concurrently, the real depreciation periods are going short where aggressive environments play a part, while the need for the use of concrete to new construction and building development is increasing and the cost of repair-concrete may exceed that of construction-concrete by a factor of 10. At the same time repairs are unduly contributing to depletion of the materials-, energy- and capital-resources.

These inherent contradictions in the situation:

"Data and methodologies are available to improve the durability of concrete structures. The need to do this is broadly acknowledged as urgent, while the perspectives for growing demands on the materials are equally obvious",

ought to stimulate the research community to launch effective R&D-efforts based upon cement chemistry application in accordance with the conditions for the making and performance of concrete.

An immediate look at the theme-contributions does not indicate, however, that the cement and concrete manufacturers and users are preparing for remarkable upgradings of concrete technology research and development. To advance the utilization of knowledge accumulated by the congress in the prevailing systems will therefore become long-term shoe-horning efforts on the part of the researchers.

But farther away from the research benchmark, certain changes in the environments are appearing, which must be considered - also for the planning of the present scientific priorities in the research.

Steel-, fuel- and power-industries are in the commencement of an era which will make them users and producers of limestone, slag, fly ashes and gypsum etc. in quantities which in several countries will exceed the present cement production - though by far the future needs for inorganic binders.

Chemical industries have only a few years ago commenced to develop powerful, liquid admixtures, not yet more than empirically combined with the above primary materials, and synthetic fibres. And the border-land between inorganic and organic polymers is also in an early phase of exploration.

Electronic industries are awaiting acceptance of processing technology in concrete production, but prepared to implement soft- and hardware.

These categories of industries possess comprehensive R&D-organisations with established knowledge of effective planning and management, and experience with "transfer into technology". Besides, they have elaborate, professional R&D-education, as appears e.g. in the work of EIRMA (European Industrial Research Management Association) and IRI (Industrial Research Institute) etc.

Thus, there is, strategically considered, more capability available for forceful efforts to make concrete durable than as yet called upon for investments.

Although one must realize that the present congress was not requested to outline new research strategies and the present report accordingly only can point towards the new incitements for adjustments of the research, it is timely to say as a terminating statement, that the germination of new advances in concrete durability must have cement chemistry research as the driving force. But also, that fruitful harvesting depends upon more than that.

## CONCLUSIONS

It is in accordance with the principal paper (14) to say that the complexity of the theme: interface reactions, is too comprehensive to make an adequate synthesis possible in one paper. This has, also for the general report, necessitated severe restrictions on the discussions of the individual contributions, and is the reason why the following concluding statements refer both to matters discussed above, and to items, which it has not been possible to deal sufficiently with, despite their importance for research and practice.

There are seven concluding statements, referring both to scientific problems and to those connected with the utilisation of the research in practice.

Herewith an attempt is made to stimulate the researcher in seeing under which circumstances, i.e. chemical and physical conditions, the material concrete is made and used so that dialogues within the research communities may enhance alertness about desirable

adjustments to forthcoming work. At the same time, the general report aims at explaining to the civil-engineer that the rentability of building and construction with concrete can be considerably improved by application of modern chemical knowledge rather than by reliance on mechanistic models of concrete behaviour as the basis for specifications and working procedures.

To promote these views results in the risk that researchers may find the scientific discussion too superficial, while the civil-engineer may still consider the concepts too far from current practice to be of immediate economic advantage.

This risk is accepted, and the seven concluding statements are as follows:

### 1. Adherence and durability are inseparable fields of studies within the framework of diagenetic alterations of concrete in the course of time.

Consequently: research experiments with "static" mechanical disruption must be appreciated as momentary flashlights on the nature of concrete, while development or degradation of characteristics under isothermic laboratory storage must be interpreted as "linearly projected" reflections of the reaction kinetics in real concrete.

### 2. The refinements during recent years, of measurements of cement clinker compositions is a valuable asset for reevaluation of the importance of cement properties for the behaviour of concrete.

The various ways of counting the C<sub>3</sub>A-content of cements is an example of how civil-engineering now needs the service of cement chemistry for more nuanced information on cement characteristics, corresponding to the demands on concrete in widely different environmental and manufacture situations.

### 3. Evaporation during concrete manufacture and performance is a major physical factor influencing the consequences of the energy conversions in concrete.

The omission of physically conditioned aggressivity in the principal papers and the general report was a decided restriction in order to overcome the work and to maintain the cement chemistry as over-all issue of the congress. Admittedly, the physical factors belong to the energy conversion concept, and cannot be neglected. A recent observation is the contribution by Nixon et al (58) on changes of alkali-concentrations through a body of concrete, and the possible influence on partial localization of deleterious alkali-reactivity. Many observations on the validity of mortar-bar "pessimism proportions" as a means of preventive safeguards for practice may need revisions, when alkali-ion migration is acknowledged to be important also in this way. Also in general, the significance of evaporation for salt-concentrations in concrete is known, in particular in hot countries.

4. The swelling mechanisms of cement paste compounds and of substances migrating in the pores of concrete and through the interface regions between cement paste and aggregate, need to be better understood and explained. Their good and bad effects in manufacture and performance of concrete need to be assessed.

Four different issues are in particular calling for the attention of research to the benefit of practice:

(1). Which swelling mechanisms are relevant in the cement paste itself, see (17), with different types of cement and under the processing and performance conditions relevant for concrete in cold, temperate and hot regions, and with/without additional swelling mechanisms in the system?

(2). Which consensus is attainable among chemical researchers regarding the swelling/non-swelling characteristics of alkali-silica gel with/without lime etc.? Reference is made to recent work by L. Dent Glasser (59) and others. In continuation: is swelling gel in cracks in concrete able to exert accumulated hydraulic or hydrostatic pressure on surrounding masses of concrete? And in contrast: May gel-phases in pores of cement-matrix and interfaces have advantageous effects, e.g. as buffers, or by decreasing the permeability?

(3) Can the development of pressure-exerting gel be deliberately prevented by predesign of procedures to give "stable"-gel-compositions which eventually will converge towards crystalline compounds?

(4) Which basic conditions determine the permanent stabilisation-effects of pozzolanic  $\text{SiO}_2$  and/or  $\text{Al}_2\text{O}_3$ ?

5. The availability of a vast storage of chemical knowledge for launching powerful industrial development of cement-based processing technology and creation of new products could be a way to solve durability problems associated with present technique and technology.

Recent years have seen many attempts to promote new products on cement basis, with a higher "end-value" factor than concrete. The research on durability could have untraditional off-springs in this direction. As one example, cement-based, adequately fibre-reinforced boards for permanent shuttering would offer effective protection for less expensive mass-concrete behind.

6. The R&D-systems need to advance the utilization of chemistry in the development of concrete technology for more energy-effective use of concrete.

The powerful development of effective R&D management and planning in industrial environments are exemplifying that the capability exists to restructure cement/concrete research so as to absorb as well market opportunities as social needs. The ever increasing use of concrete and the concurrent concern about performance reliability

strongly point in the direction of more attention to these matters, both from industries, engineering firms, governments, and international organisations.

7. The presented knowledge at the congress contains much information, which could be extracted as guidelines for improvements in practice, and for educational purposes, not least for the benefit of the developing countries.

The formation of a group of researchers and practising professionals is suggested for attaining consensus on urgent issues discussed at the theme session, and to establish cohesive contacts and gain impact on future congresses and on institutions etc. so as to advance fruitful, basic and applied chemical research for concrete technology.

## DISCUSSION

by V.I. BABUSHKIN

In my address I considered it essential to emphasize an important contribution of electrochemical phenomena to the process of hydration and structure formation of the cement, as well as to the cement stone and concrete corrosion processes.

We have experimentally proved that the hydration process, just as any other process producing solution and causing formation of new phases, is accompanied by volumetric separation of electric charges and creation of membrane potentials with values equal to the sum of the Donnan and the diffusion potentials of the inequilibrium type. The inequilibrium state of binder - water systems distorts compensation of the difference of chemical potentials, of tied and free diffusing ions due to interphase electric potentials and the osmotic pressure,

which may amount to 19-54 MPa and can cause deformation and destruction of gel films around hydrating particles, as well as volumetric changes in binder - water systems.

Investigations have revealed that the electrochemical phenomena also play a certain role in contact zone formation along the cement stone - aggregate boundary. But here it is necessary to take into account not only the charge sign and the electrokinetic potential value but also a possibility of the surface hydrophilization.

We applied the above-mentioned notions to explain the mechanism of sulphate and salt corrosion as well as the destructive action of the reinforcing steel rust products upon the protective coating of concrete.

A "pass of potential" experimental procedure for the electrokinetic potential determination in the specified dispersion systems can give the greatest degree of reliability, with allowance for surface conductance.

The investigation of electrochemical characteristics should be conducted simultaneously with determination of construction, of new formation crystallization rate in hardening and corroding, and of pore size distribution. At that a special attention should be paid to the osmotically dangerous pores in which the rate of filling up with new formations particles is higher than in large-size pores and gel pores.

# DISCUSSIONS

## by TANG MING-SHU

Concerning the mechanism of alkali-silica reaction, some aspects seem worthy of consideration.

1. According to revealed observations on the polished surface of mortar containing opal, the expansion is almost always found to have taken place before the reaction product becomes fluid. Besides, the expansion may still increase after cracks have appeared in the mortar. So the water imbibition and swelling theory proposed by Vivian<sup>(1)</sup> and Brown<sup>(2)</sup> seems reasonable.

If we assume that the expansion is caused mainly by water imbibition and swelling, it will be insignificant whether there is a semi-permeable membrane or not, and therefore the expansion will have nothing to do with the composition of a semi-permeable membrane.

2. How to explain the effect of various factors, such as the amount and size of reactive aggregate and alkali content, on the alkali-silica reaction? It should be noted that the expansion is caused by chemical reaction, but at the same time, it is also a physical phenomenon. Therefore, both physical and chemical factors should be taken into consideration. According to Vivian's<sup>(1)</sup> and ourself's investigation, we have mentioned<sup>(3)</sup> that the expansion is related to the following factors: (a) number of active centers, i. e., the number of particles of reactive aggregate per unit volume of mortar; (b) the amount of alkali for unit area of reactive aggregate; (c) the expansive force generated by each particle as a result of alkali-silica reaction. The magnitude of the force depends on the degree of reaction and the total surface area of the particle; (d) the tensile strength of the cement paste. As the overall linear expansion measured includes both the micro and macro cracks formed in the mortar, so factors (c) and (d) should be considered.

According to the above views, the results of the experiments of many authors designed to study the influence of various factors can be explained.

3. It is just what Diamond<sup>(4)</sup> has stated that the competitive reaction theory suggested by Powers<sup>(5)</sup> is only a hypothesis which has not been confirmed by experiments. The theory is not satisfactory in explaining the influence of various factors. For example, Powers calculated by using Woolf's data the  $\text{CaO}_{\text{adsorbed}}/\text{Na}_2\text{O}_{\text{adsorbed}}$  ratios in the reaction process and suggested that no expansion would take place if the ratio attains a certain value. Upon using all the data offered by Woolf and following the same method of calculation, it shows that in case the difference of the ratio of adsorbed  $\text{CaO}$  to adsorbed  $\text{Na}_2\text{O}$  between "safe" and "unsafe" reaction is so small, then it is difficult to explain the reason of expansion.

As to the reason why low alkali cement does not cause expansion, it is probably ascribed to the much less extensive reaction of the reactive aggregate and not to the "safe" reaction. This has been proved by repeated microscopic observations on the degree of reaction of reactive aggregate (opal) in low alkali Portland cement.

Alkali-silica reaction is a complex problem. Mr. J. Calleja had a good proposal. He suggested that further researches in this field should be based on a wide interdisciplinary cooperation.

The authors stated: "There is no essential difference between the hydration in the system pozzolana-cement and that in the system pozzolana- $\text{Ca}(\text{OH})_2$  and pozzolana-cement compound". In a general sense, the above statement is true. However, as portland cement inevitably contains a certain amount of alkali, some sort of alkali-silica reaction might occur at certain stage of cement-pozzolana reaction.

Alkali-silica reaction may be represented by the equation

The  $\text{Ca}(\text{OH})_2$  released in the hydration of portland cement may react with  $\text{Na}_2\text{O} \cdot x\text{SiO}_2$  to liberate alkali. The regenerated alkali can once again penetrate into the particles of the reactive aggregate. As the particles of pozzolanic additives are very small, they will all be eventually transformed into C-S-H and other hydrates while most of the alkali ions will migrate into the solution. It should be noted that at certain stage of the reaction,  $\text{K}^+$  and  $\text{Na}^+$  ions do not necessarily go into pore solutions; on the contrary, they may penetrate into the inner part of the pozzolana particles.

Even though the pozzolana may itself contain alkali, at certain stage of the reaction, it still tends to absorb alkali from the pore solution of cement paste instead of releasing it into the solution. We have made mortar cubes using a high alkali cement and a tuff rock as aggregate which contains 0.88%  $\text{Na}_2\text{O}$  and 2.59%

K<sub>2</sub>O, with a particle size of about 1mm. After one month curing, the tuff particles were observed to have been surrounded by reaction rims which contained much more alkali than the particles themselves as detected with EDAX (Fig.1)

EDAX detection of reaction-rim and unreacted tuff particle.

△ — reaction-rim  
▲ — unreacted particle

Recently, ion-concentrations of pore solution of cement paste were determined with pressing technique (1). The results showed that when portland cement clinker

contains alkalis, the pH value of the pore solution may be greater than 13.0, sometimes as high as 13.7. It is assumed that high concentrations of R<sup>+</sup> and OH<sup>-</sup> ions might affect the reaction process of pozzolana-cement. Diamond (2) in his experiment has shown that the mortar bar expansion may typical alkali-silica reactions. As the particle size of pozzolanic additives is small as compared with aggregates, the amount of alkali for unit surface area will be less. In the mean time, the expansive stress caused by such small particles may be distributed evenly and hence expansion will be inhibited. But in certain stage, the reaction of pozzolana-cement may be likened to alkali-silica reaction. Naturally, further study is needed to determine to what extent the influence of alkali could be.

In the investigation into the reaction mechanism of the system of pozzolana-cement, it might be appropriate to take into consideration the chemical and physical processes of the alkali-silica reaction, especially when the pozzolanas used contain opal or volcanic glass as described in this article.

## CONCLUDING REMARKS

by G.M. IDORN.

Final conclusions regarding achievements and issues requiring further attention and research within the fields of interface reactions in concrete and mortars - based upon the written contributions, including posters, to the theme, the panel contributions and the terminating question and answer part of the session.

The discussions during the session on theme VII underlined that there is now a considerable coherence and progress of ongoing research on sub-theme one: adherence (bond-strength) between aggregates and cement paste, not least based upon comprehensive work in France. Also the adherence between cement paste and metallic reinforcement and glass-fibre, and grout to host rocks in subterranean works, is treated, as well as the enhanced interface reactions created by the high activation energy at hydrothermal treatments.

Contributions are missed about such a "down to earth", but economical important issue as bonding by repairs of new to older concrete, and neither the excessive bond-qualities obtainable with the use of organic polymers as admixtures nor by impregnation have found interested supporters.

Also the more fundamental problems with inherent bonding within cement paste constituents and the binding capability created by pozzolanic reactions remain to be considered in conjunction with the research reported in theme II, III and IV (though principally much governed by the same forces as paste/aggregates adherence).

The difference of the interface-character in dependence of calcareous or siliceous aggregates is now more clear than before (although not applicable in terms of "performance" - value of high or low bond-strength in concrete in practice). It is also obvious that in the case of siliceous aggregates the interface reactions must in any case be considered metastable editions of gel-producing alkali-silica reactions, i.e. bond-creating without expansive pressure formation, but appreciably penetrating into the structural build-up of the aggregates, and not necessarily long-term dependable. With calcareous aggregates the bond-creation seems more restricted to the aggregate surface and the innermost part of the "aureole" zone and the bond-forces to be nearer to, what metallurgists and some authors designate "epitaxial" growth. With dolomitic aggregates a sort of "hybrid" reactivity seems established, since these reactions do release alkalies and do break up the interior  $\text{Ca/MgCO}_3$  structure of the aggregates, but do not produce swelling gel, except probably with siliceous-magnesium lime

stone, which ought to be considered very susceptible to combined dedolomitization and alkali-silica reactions, i.e. to weakening bonding-creation (and gave rise to the pioneer studies of alkali-silica reactions in USA in the forties).

The stage of knowledge now attained seems ripe for systematic application of reaction kinetics and thermodynamics in the further research. This is enhanced by the aim of the American presentation - to gain knowledge on 1000 years or more performance stability of cementitious plug materials for deep boreholes. In this study the long-term geophysical/chemical exposure approaches hydrothermal conditions, which according to the Italian and Japanese contributions on industrial autoclaving processing brings about much more intensive interface reactions than found at ordinary temperature levels.

It is an interesting paradox, that the long-term stability aiming American studies find alkali-silica reactions an identifiable factor in the interface with a siliceous aggregate. This a reminder that even at ordinary temperatures the convertible energy in the high-alkaline environment with soluble silica is sufficient to cause considerable transitions in the entire system beyond those intentionally monitored during the hydration process.

The special bond-creating reactions with glass fibre, metallic reinforcement, and the influence of pozzolans, different cement types and different environments etc. altogether emphasize that the creation, preservation or possible deterioration of adherence as an integral feature of the entire system must be considered dynamically.

The thoroughness of the principal paper on sub-theme 2: durability, makes it easy for students of the individual contributions to find supplementary information within the area of cement-aggregate reactions, the effects of aggressive solutions on concrete and the available counter-measures etc.

There are, however, still many loose ends, for instance, concerning alkali-silica reactions. Even if consensus is approaching that:

1. expansive pressure can develop both within a (compact) partially reacting siliceous aggregate particle, or
2. during complete dissolution of a porous, readily reacting particle, or
3. cause gel to dissipate out into ambient paste while concurrently releasing expansive pressures

it still remains a mystery for the construction engineer, and is untouched by research, how pressure in discrete aggregate particles, usually in the sand fractions, can accumulate so as to crack and displace large parts of concrete masses. No contributions have as yet dealt with the expansive power of dilute

gel in cracks and pores in the concrete - the only medium seemingly available for exertion of a continuum of hydraulic pressure in excess of the strength and weight of concrete masses.

It is another inconclusive situation emerging from the contributions, that beyond excessive limitation of the alkali-content and of the amount of free pore-liquid in concrete there are no safe precautions against deleterious alkali-silica reactions established for application in construction practice, where reactive aggregates are used.

Surely, pozzolanic reactivity is principally an innocuous edition of alkali-silica reactions. But the laboratory examinations have not yet presented reliable models for conversion of the results to match the conditions in engineering practice, among other things with regard to the long-term stability of the pozzolanic reaction products. This seems a prolific field for further research, in particular if thereby the means for the use of high alkali cements without risks could be elucidated.

A possible further step in this direction is indicated by the deliberate utilization of the alkalis in cement as prerequisite for making fibrous CSH by hydrothermal processing as demonstrated in a Japanese contribution, while the advantageous use of alkali-hydroxides as hydration activators jointly with dispersing agents is discussed elsewhere in the congress program. Thus altogether, the historic, monotonous designation of alkalis as primarily deleterious ought to be reviewed, also now in view of the energy expenditure for their removal in much cement manufacture and the presence of soluble alkalis in many natural and synthetic pozzolanic materials.

Concerning the deleterious attack of saline solutions on concrete it is convincingly established that the conventional measurements of the  $C_3A$ -content of cements are qualitatively and quantitatively insufficient. Partly due to this observation but also to the common use of simplified laboratory models in studies of saline aggressivity, it seems reasonable to assume that  $C_3A$  in cements is of relatively minor importance for concrete performance than are many factors which have been less counted with as influential in conventional concrete technology and regulations.

Among the constituents of aggressive saline constituents sulphates are the primary subject of the presented studies. However, modern de-icing practice in the cold regions, and urbanisation in hot countries underline in each their way the implications of more complex salinity and ought to stimulate further studies of their possible synergistic effects, for instance in sea water attack and combined with alkali-silica reactions.

The two mentioned extremes of exposures also underline the urgency of introducing reaction-kinetics in the research. Energy conversion is rapid and violent in both cases, despite

the fact that the available added energy in the one case is chemical, in the second primarily physical.

Preceding the effects of either exposure is, however, the hydration phase during the concrete making. The presentation of the general report exemplified, that by ordinary construction practice about 30 years ago the heat development in concrete during curing slowly caused interior temperatures to rise to about 30-40°C and to descend slowly again towards environmental levels in a temperate region, while modern concrete in an exotic environment jumped beyond 80°C in 12-14 hours, and down to the environment in about 50-80 hours thereafter. This latter time/temperature history is quite common in modern construction and precast works, and may through the overfeed with convertible energy during early curing often cause severe initial microfracturing in the cement paste. Thus, further research must study the physico/chemical aggressivity during performance as possibly superimposed upon initially invalidated structures of the concrete. This requires clarification of the reaction kinetics and thermodynamics in the entire system of concrete making and performance including the environmental energy impact. As pointed out in the principal paper, several contributions inter al from USSR and East-Europe and the general report, such research, operating with concrete as it is made and used in our time, must gain priority over continued work with laboratory experimental specimens, which are kept entirely protected against the effects on an increasing fraction of the energy conversion in concrete in practice.

The contribution from India on the significance of  $MgO$  in cements in conjunction with a discussion during session V brought the issue into focus that developing countries must revise numerous conventional concepts and methods for which the feasibility is questionable, both in view of general advance of knowledge and to their particular conditions. This attitude may in turn become a gift to further advance regarding durability in the old world.

Alertness is also required towards the unfolding impact of new materials in concrete making from industries other than cement, because the technology is to be profoundly influenced hereby, and improvement of durability and adherence under these circumstances require high priority to cement chemistry knowledge in the research and development.

At present it is impossible to analyse in depth the issues dealt with in Theme VII in relation to the achievements in the preceding themes. It is clear, however, that the performance of concrete is a matter of how it was prepared and made as much as of how it is exposed during performance. And all the way through, the cement chemistry knowledge must be applied as an entity and any specialist of the preceding themes must be aware of the performance of concrete in practice as the terminal criterion of reliability.

technology to provide satisfactory durability without profound assistance from cement chemistry.

#### TERMINATING REMARKS

by G.M. IDORN, Chairman

During the congress in Moscow in 1974 I said in the concluding remarks to the presentation of the paper on polymer cement materials, that in advocating more determined industrial R & D to make concrete innovations like in high technology industries - I felt much like the figure in a well-known Danish children's book : "Paul alone in the world".

I was speaking entirely concerning the general pressure of retrogradation of research to come with the economy crises, while at the same time inventors from USA and USSR at that meeting threw light on exciting, quite new opportunities within the field I had reported on.

Today I don't feel nearly as much like such a Paul.

This is because we have been confronted with an enormous capability of cement chemistry knowledge, which is not yet applied to realise the manifold opportunities for making concrete durable, hereunder for the creation of effective and stable bond-forces between the various phases of the composite normally called concrete.

Let me terminate the business of this session - relying not only upon what we have discussed since 9 O'clock this morning, but also upon much more, which we have not yet assimilated effectively from the preceding sessions - in summarizing some among the challenging opportunities we are facing, and thereby also your obligations, because civil engineering cannot anymore develop concrete

- I - Ensure initial quality of concrete to be gained during manufacture in obedience of the governing inherent and environmental conditions. In other words :

Harmonize environmental aggressivity and characteristics of concrete by design of the material composition, the making, and the performance characteristics. Crudely speaking, observe :

Chemical reactions x heat represent energy.

Design and monitor for energy efficiency.

- II. Identify and make use of the advantages of alkalies with :

Pozzolans and fly ashes  
Slags  
Superplasticizers  
etc.

- III. Harmonize the chemical identification of cements for the users with adequate measurement techniques into unambiguous formulae and recommendations.

- IV. Intensify R & D innovations like :

"Sandwich" solutions, i.e. permanent cement-product formwork  
Fibre reinforcement  
High-strength and high-density concrete, etc.

- V. Educate research and practice :

1. Abandon the use of 20°C isothermic storage of cement paste, mortar and concrete as representative for construction conditions.
2. Beware of exaggerated spectacularity of SEM and STEM features.
3. Remember and use research also from the pre-electronic instrument era and continue to utilize the petrographic microscope.
4. Let research gatherings not merely be stimulating sanctuaries occasions for research, but request evaluations of their outcome in terms of development opportunities.

If these guidelines are broadly implemented, then I am confident that the presently increasing lamentations about problems with concrete durability will soon become inferior to significant progress.

This is why I don't hesitate to predict that your aim will be to present remarkable realisation of existing opportunities for development, when your preparation for the 1986-congress on cement chemistry begins on Monday morning, July 7th.

With this challenge, I thank you all for the contributions and attendance realized in such ways that our theme and session hardly at all have needed to have a chairman.

I also want to vote a thank from all of us in attendance to acknowledge the foresight in choice of the subjects, of the panel, and of the principal authors. I do hope that we have injected valid stimuli into the further work on the issues to the satisfaction of the organizers.

And last but not least : many thanks to all those anonymous helpers behind the screen : typist, secretaries, technical staff and interpreters. Your assistance to our performance today has been second to none. Session 7 is terminated.

## Etudes thermochimiques de la formation du clinker *Thermochemical investigations in clinker formation*

M. KOUGUIA, Guiprotsement, Leningrad, URSS.

Les méthodes thermiques telles que la méthode des chaleurs de dissolution et la méthode thermique sous forme traditionnelle et modifiée, ont été utilisées pour l'étude des différences dans le comportement lors du traitement thermique des mélanges crus de ciment sur la base des matières premières provenant des différents gisements de l'Union Soviétique; Ces différences s'expriment par: a) la succession de la formation des minéraux; b) les limites de température de formation des constituants de clinker et de la phase liquide; c) la distribution des dépenses thermiques selon les températures. Les caractéristiques contribuant à un déroulement rapide et complet des réactions à l'état solide ne sont pas toujours favorables pour la formation de l'alite en présence de la phase liquide. Les particularités dégagées du comportement des mélanges crus peuvent servir de base pour l'estimation du comportement des mélanges crus dans les fours rotatifs industriels.

The thermochemical methods of investigations such as thermal and and solution heat methods, both conventional and modified, were used to study distinctions in behaviour of cement raw mixtures, when heated, composed of raw materials from different deposits of the USSR.

These distinctions are expressed in: a) sequence of mineral formation; b) temperature ranges of clinker minerals and liquid phase formation; c) heat distribution with temperature;

Raw mix features contributing to fast and complete proceeding of reactions in the solid state do not always prove to be favourable for alite formation in the liquid phase presence. The revealed particularities of raw mixtures behaviour may serve as a basis when estimating the behaviour of raw mixtures in industrial rotary kilns.

En ce qui concerne les particularités caractéristiques et la présence d'effets thermiques sur les courbes ATD des mélanges bruts, les avis sont partagés [1,2,3,4,5].

Auteur et al. ont effectué un examen des mélanges bruts industriels de plusieurs cimenteries de l'Union Soviétique (plus de 40).

Les charges ont été examinées par la méthode de l'analyse thermique différentielle sous forme traditionnelle et sous forme modifiée, par la méthode thermogravimétrique et par celle des chaleurs de dissolution. Leurs caractéristiques chimiques et granulométriques correspondaient à celles qui sont généralement admises dans la production. Les résultats ont montré que les différences les plus caractéristiques se situent sur les courbes ATD dans le domaine de 1100 à 1450°C. Les données ainsi obtenues, auxquelles s'ajoutent les analyses des matières premières utilisées par les usines, ont permis d'établir une classification des mélanges bruts industriels. Pour le premier groupe de ces mélanges, on a enregistré sur les courbes ATD deux effets exothermiques de formation des minéraux dans le domaine de 1200 à 1350°C et un effet endothermique d'apparition d'une phase liquide dans l'intervalle de 1340 à 1390°C. Pour ce groupe, on utilise le plus souvent des calcaires à gros cristaux, des constituants argileux avec prédominance d'hydromicas et de caolinites, d'argillites et d'aleurolites.

Le second groupe, plus nombreux, est constitué par les mélanges présentant un exo-effet et un endo-effet de fusion. Ici, on utilise essentiellement comme matières premières des calcaires organogènes, la craie, des constituants argileux sous forme de compositions naturelles de divers minéraux argileux, des cendres. Sur les courbes ATD des schlamms du troisième groupe, assez nombreux eux aussi, les effets exothermiques de formation de minéraux étaient absents et on n'a enregistré qu'un maximum endothermique de fusion.

Les usines de cette catégorie utilisent essentiellement des calcaires tendres, des craies, des constituants argileux avec prédominance des variétés mixtes et montmorillonitiques, des schlamms contenant de l'orthosilicate de calcium. La présente communication expose les résultats des recherches effectuées sur les représentants types

des trois groupes précités en vue d'établir les causes des différents comportements des mélanges bruts vis-à-vis du chauffage, traduits par les courbes ATD, et aussi pour élucider l'influence exercée par certains facteurs.

A cet effet, on a exécuté, outre l'ATD, des expériences relatives à la cinétique de l'assimilation de l'oxyde de calcium, on a déterminé les pertes survenant dans les produits de cuisson lors de la calcination, on a opéré des analyses cristallographiques et radioscopiques des phases, déterminé les chaleurs de dissolution.

Les Tableaux 1 et 2 résument les données fournies par les analyses chimiques, des caractéristiques minéralogiques et certaines autres, qui mettent en évidence que les transformations les plus importantes sont intervenues dans le mélange du 3<sup>e</sup> groupe vers 1200°C.

Toutefois, les produits de la cuisson à 1400°C des mélanges du premier et du deuxième groupes ont les pertes par calcination et la teneur en CaO libre inférieures à celles du troisième essai, ce qui prouve que vers 1400°C les processus de formation de minéraux ont été plus marqués dans le mélange du premier groupe par rapport au mélange 2 et surtout au mélange 3.

La chaleur de dissolution du clinker se compose des  $Q_{diss}$  des minéraux individuels qui le constituent et de la phase liquide vitriforme, aussi varie-t-elle d'une façon complexe et non univoque, suivant la température à laquelle est exposée la matière considérée, ce qui ressort à l'évidence du Tableau 2. Dans le but de vérifier, pour avoir plus de certitude, les résultats obtenus, on a aussi effectuées des recherches sur des mélanges bruts synthétiques, présentant les caractéristiques suivantes:  $CS = 0,90 \pm 0,02$ ;  $n = 2,0 \pm 0,2$ ;  $p = 1,2 \pm 0,2$ . Le mélange A contenait, outre le calcaire et les résidus de calcination, de l'argile hydromicacée et caolinitique, le mélange B, de l'argile hydromicacée, le mélange C, de l'argile montmorillonitique, et le mélange D, de l'argile caolinitique. La figure 1 représente les portions à haute température de leurs courbes ATD, obtenues sur l'appareil "Mettler". Les effets thermiques globaux de formation des matières du clinker

et de la phase liquide, calculés à partir des données relatives à l'allure de l'assimilation de la chaux au cours des cuissons des mélanges bruts synthétiques effectuées au laboratoire [6] figurent dans le dessin 2 et sont en assez bon accord avec les effets thermiques observés sur les courbes ATD (fig.1).

L'analyse des phases par diffraction des rayons X à haute température et l'analyse des phases par diffraction des rayons X dans les produits de cuisson des mélanges synthétiques ont montré que dans le domaine de 1000 à 1200°C il y avait, dans la charge C, disparition du quartz, accroissement de la teneur en C<sub>3</sub>A, formation de bélite nette.

Dans le mélange D, la bélite ne s'est formée qu'aux températures supérieures à 110°C (c'est-à-dire que sa formation est décalée de 100 à 150°C par rapport au mélange C); en plus, au-delà de 1200° il y a eu une cristallisation intense de l'alite. Il s'ensuit que dans cette charge la synthèse des princi-

pales matières formant clinker s'est produite à des températures plus élevées et dans un intervalle plus étroit de températures.

Les charges à base des argiles hydromica-cée et mixte occupent une position intermédiaire entre les mélanges C et D quant aux caractéristiques qu'elles manifestent lors du traitement thermique.

L'analyse thermogravimétrique des mélanges bruts industriels et synthétiques a montré (Tableau 2) que la décarbonisation s'y produit selon un mécanisme complexe et s'effectue en deux étapes, les valeurs des énergies d'activation pour la dissociation des carbonates à la seconde étape étant, en règle générale, supérieures à E<sub>a</sub> de la première étape. Les résultats obtenus avec les échantillons synthétiques ont confirmé et complété les données obtenues avec les mélanges bruts industriels, en montrant bien, d'une part, le rôle que joue la nature minéralogique des constituants lors de

la formation du clinker, surtout au stade des réactions intervenant dans la phase solide, et de l'autre, elles donnent lieu à penser que la cause essentielle de l'absence des effets thermiques de formation de minéraux sur les courbes ATD des quelques uns des mélanges bruts au-dessus de 1000°C réside vraisemblablement dans une formation précoce de  $C_2S$ , simultanément avec le processus de décarbonisation, dissimulée sur les courbes thermiques par un endo-effet et la dissociation du carbonate et la coïncidence, selon [7], de l'état actif de l'oxyde de calcium et des minéraux appartenant aux aluminosilicates, modifiés sous l'effet de la chaleur, et la formation d'alite étalée le long de l'échelle de températures, à cause de la combinaison entravée de  $CaO$  avec le silicate dicalcique recristallisé. Il est possible que le ralentissement du dernier stade de formation du clinker est dû lui aussi à la recristallisation de l'oxyde de calcium non entré en réaction. A la lumière des recherches dont il est question, on comprend aisément pourquoi un schlam (E) se prête difficilement à l'agglomération, malgré les bonnes apparences de la matière première (craie et compositions argileuses à partir des minéraux d'hydromicas, de caolinite et de montmorillonite). Dans les expériences que l'auteur a exécutées avec ses collègues [8] dans les conditions industrielles, aux fours mesurant  $5 \times 185$  m, en utilisant des schlams d'une composition plus grossière (le constituant argileux étant représenté

Fig.1. Dérivatogrammes des mélanges bruts des trois groupes: 1 - premier groupe; 2 - deuxième groupe; 3 - troisième groupe

par un limon), en comparaison des schlamms couramment utilisés le constituant carbonaté étant le même (la craie), on a constaté que la consommation spécifique de chaleur a diminué de 3% et les pertes avec les poussières, rapportées aux matières premières sèches, ont diminué de 2%. Ce dernier résultat est dû au décroissement de la teneur de la matière à cuire en granules de petite taille.

C'est ce qui a permis de supposer qu'en cas de schlamms à base de limons un traitement thermique moins intensif est nécessaire dans la zone d'agglomération pour faire entrer la chaux en réaction et pour achever la formation du clinker, par rapport aux matières premières plus tendres.

Compte tenu des résultats obtenus, une circonspection s'impose quant aux recommandations de la communication 9 sur l'utilisation souhaitable des argiles montmorillonitiques dans la fabrication du ciment.

Les données que nous avons obtenues s'accordent avec celles de la communication 10, qui mettent en évidence que l'aptitude de certains mélanges à la formation de la bélite est différente de celle à la formation de l'alite.

Il ressort de ce qui vient d'être dit que la nature minéralogique des matières premières joue un rôle important dans la formation du clinker, en déterminant le stade du processus qui se déroule en phase solide et ayant par là des incidences sur l'agglomération définitive en phase liquide, et que l'analyse thermique conjuguée à d'autres méthodes de la thermochimie permet de pronostiquer les aptitudes réactionnelles des mélanges bruts.

# Influence of temperature, grain size and the amount of added water on the development of the porosity and surface size during the hydration of $C_3S$

## *Influence de la température, de la granulométrie et du dosage en eau sur le développement de la porosité et de la surface spécifique du $C_3S$ hydraté*

R. TRETTIN and W. WIĘKIER, Zentralinstitut für Anorganische Chemie der Akademie der Wissenschaften der DDR - Berlin - RDA

### Summary:

The change of the specific surface areas of hydrated  $C_3S$  was measured by nitrogen adsorption in dependence on the temperature (5-75 °C), the water/solid ratio and the grain size.

After the end of the induction period the specific surface area of the hydrated pastes increases strongly, goes through a maximum after 10 up to 168 hours depending on the reaction conditions. The occurrence of this maximum can be interpreted as a result of the formation of highly dispersed x-ray amorphous calcium hydroxide.

At the end of the induction period the specific surface area of hydration products increases exponentially and gives a maximum at the same time at which the hydration heat evolution has its maximum too. The height of this maximum becomes lower as the temperature of hydration decreases, the grain size and the water/solid ratio increases. The following reduction of surface of hydration products is in high degree dependent on the temperature.

The pore-size distribution was calculated from the nitrogen sorption isotherm data in  $C_3S$  hydrated for 28 days. It was obtained, that with increasing temperature, W/C ratio and particle size the quantity of pores having a radius smaller than 20 Å is larger.

RESUME : Les variations de la surface spécifique du  $C_3S$  hydraté ont été mesurées par adsorption d'azote, en faisant varier la température (5 à 75°C), la granulométrie et le dosage en eau. Après une période de latence, cette surface spécifique augmente fortement, et atteint un maximum au bout de 10 à 168 heures, suivant les conditions opératoires. Le maximum semble résulter de la formation de chaux amorphe.

Après la période de latence, la surface spécifique croît exponentiellement avec le temps et atteint son maximum en même temps que la chaleur d'hydratation. Ce maximum diminue si la température s'abaisse, ou si la dimension des grains et la teneur en eau augmentent. Cette diminution dépend principalement de la température.

La distribution granulométrique des pores a été mesurée, par adsorption d'azote, après 28 jours d'hydratation. La dimension moyenne des pores est de 20 Å ; elle augmente avec la température, la dimension des grains anhydres et le dosage en eau.

## 1. Introduction

From the literature /1,2/ it is known, that the hydration of  $C_3S$  is accompanied with a strong increase of the BET surface, which is attributed to the formation of the CSH-phases. The purpose of our investigations therefore was to look for relationships between the surface size developed and the reaction products formed in the different stages of the hydration process.

## 2. Experimental

Pure  $C_3S$  (free  $CaO = 0,2\%$  by weight, triclinic modification) ground to a Blain fineness of  $3500\text{ cm}^2/\text{g}$  was used. At appropriate times the hydration was stopped and the water was removed by treating with alcohol and ether and then the samples were dried by evacuation. All operations were performed in a  $CO_2$ -free atmosphere. The quantity of nitrogen adsorbed at  $-196^\circ\text{C}$  was determined in a volumetric apparatus. The specific surface areas were obtained from the BET region adsorption isotherms. Pore structure analyses of samples were performed using the method of Brunauer and co-workers /3/. X-ray diffraction was used for quantitative determination of unreacted  $C_3S$  in the hydrated samples. The result obtained were used for the determination of degree of hydration.

The  $Ca(OH)_2$  formed during the hydration was determined by a modified extraction method of Franke /4/ and by x-ray diffraction.

## 3. Results and Discussion

The measured changes in the surface area for  $C_3S$  samples ( $W/C = 0,5$ ) hydrated at  $25^\circ\text{C}$  is shown in Fig. 1.A. Immediately after the contact of the  $C_3S$  with water occurs a first increasing of the surface area. After this it remains nearly constant up to 2 hours. As can be seen from curve 1 in Fig. 1.A, in the further progress of the hydration the surface area is then converted to a increase again up to 56 days. The formation of the maximum of the surface area of the hydrated pastes is remarkable and agrees to the re-

sults reported by Harade et al /5/ and Kondo et al/6/.

Fig.1.(A) Specific surface area of the dried paste (curve 1) and the products of hydration (curve 2) of  $C_3S$  ( $W/C = 0,5$ ) hydrated at  $25^\circ\text{C}$  in function of the time of hydration. (B) Heat evolution measured by differential calorimetry and the calcium hydroxide content determined by the extraction (■) and XRD (□) methods as function of the time of hydration.

If the specific surface area is related to the amount of hydrated  $C_3S$  (Fig.1.A, curve 2) it is seen that at the end of the induction period the surface area increases exponentially which coincides with the period of maximum hydration heat evolution measured by differential calorimetry (DCA). With decreasing heat evolution the surface area of hydration products decreases to (Fig.1.A;

stage III). This decrease is caused by the growth of calcium hydroxide and calcium silicate hydrate. The following maximum of surface areas in the stage IV coincides with the previously mentioned maximum of specific surface area of hydrated pastes (curve 1). To understand why this is formed we investigated the liberation of calcium hydroxide from the  $C_3S$  because there are no indications that in this reaction period a transformation of the C-S-H phases occur. The calcium hydroxide content was determined by the chemical extraction as well as by XRD method. The results of both methods show partially remarkable differences, especially in the reaction time between 8 and 48 hours (Fig. 1.B). This difference can be explained by the assumption that a part of the calcium hydroxide is present in an amorphous form, so that it cannot be determined by XRD-methods, which was previously suggested by Brunauer and Kantro /7/. As can be seen from Fig. 1.A and B, the maximum of surface area (in stage IV) coincides with the maximum amount of amorphous calcium hydroxide. This means that the amorphous part of the  $Ca(OH)_2$  exists in a highly dispersed form.

Additional informations we got by proton spinlattice relaxation time ( $T_1$ ) measurements, the results of which are shown in Fig. 2.

Fig. 2. Course of proton spin-lattice relaxation times ( $T_1$ ) as a function of time of hydration for  $C_3S$  ( $W/C = 0,5$ ;  $25^\circ C$ ).

After 2 hours  $T_1$  begins to decrease lineary. Beginning from nearly 8 hours  $T_1$  increases a little bit and after a small maximum at 10-18 hours is formed the  $T_1$ -values decrease again. Similar results of  $T_1$  measurements, made on  $C_3S$  pastes were reported by Kocuvan and coworker /8/. This maximum of  $T_1$  coincides with the already mentioned maximum of highly dispersed calcium hydroxide content of samples and the maximum of the surface formed in the hydration of  $C_3S$ . Therefore it is assumed that the observed change in the spin-lattice interaction of the protons is connected with the formation and later crystallisation of the highly dispersed practically amorphous calcium hydroxide. The origin of the amorphous  $Ca(OH)_2$  is not quite clear now, but we assume like Tadros et al /9/ that the crystallisation of the calcium hydroxide is poisoned by silicate anions. Additional measurements of specific surface area of the hydrated pastes of  $C_3S$  at  $5^\circ$  and  $75^\circ C$  show as can be seen in Fig. 3.

Fig. 3. Specific surface area of a dried  $C_3S$  paste ( $W/C = 0,5$ ) hydrated at different temperatures in function of the time of hydration

that the maximum are shifted to shorter reaction times with increasing reaction temperature. This effect is in accordance with the heat evolution, the maximum of which is also shifted to shorter reaction times with an increase in temperature.

For the hydration products can be observed besides the shortening of the period up to the rapid surface area development by raising the temperature an increase of the

Fig. 4. Specific surface area of the hydration products of  $C_3S$  ( $W/C = 0,5$ ) hydrated at different temperatures in function of the time of hydration

heights of the surface maximum (Fig. 4.). This increase of the heights of the maximum coincides with an increasing of the hydration rate in the early hydration stages. From the pore-size distribution was obtained, that with increasing temperature the quantity of pores having a radius smaller than  $20 \text{ \AA}$  is larger.

Another factor influencing the surface development in the  $C_3S$  hydration is the grain size of the starting material. Fig. 5. gives the results of surface measurements of  $C_3S$  hydration products in dependence of the grain size.

It shows that the surface developed increases with decreasing grain size. Furthermore the decrease in grain size results in a shortening of the time needed for the beginning of the surface development. The specific surface of the hydration products formed during the acceleration period increases considerably with a decrease in grain size. From the porevolume distribution curves Fig. 6. it is seen that with decreasing

Fig. 5. Specific surface area of a dried  $C_3S$  paste ( $25^\circ C$ ;  $W/C = 0,4$ ) different grain sizes as function of the time of hydration.

Fig. 6. Pore-size distribution of 28-day-old hydrated  $C_3S$  samples ( $25^\circ C$ ;  $W/C = 0,4$ ) for different grain sizes.

grain sizes a strong increase of pores with radii smaller than  $20 \text{ \AA}$  is connected.

The variation of the water/ $C_3S$  ratio gives only small differences in the surface development during the  $C_3S$  hydration. But it is pointed out, that the pore-size distribution is shifted to smaller pore radii with decreasing water/ $C_3S$  ratio.

# Determination of specific surfaces of co-grounded materials with different grindabilities

## *Détermination des surfaces spécifiques des matériaux de différentes broyabilités après leur broyage simultané*

Dr. S. TSIMAS, Dr. V. KASSELOURIS, Dr. CH. FTIKOS, Dr. G. PARISSAKIS,  
HERACLES General Cement Co. - National Technical University of Athens,  
Lab. of Inorg. and Anal. Chemistry, Greece.

**SUMMARY :** It is well known that by co-grinding materials of different grindabilities the desired granulometric curve is not always achieved. The prediction of the granulometry as well as the final specific surfaces becomes more difficult when these materials are co-grounded in different proportions.

The aim of this study is, in the case of co-grinding clinker and Santorin earth, to determine the resulting specific surfaces of each of these materials.

Thus, it has been found that by increasing in the mixture the proportion of Santorin earth (which is easier to grind than clinker) the final values of the specific surfaces of both the materials are decreased. More specifically by grinding clinker and Santorin earth in proportion 70:30 and 60:40 the fraction of 3-30  $\mu\text{m}$  is significantly decreased.

**RESUME :** On sait qu'en broyant ensemble des matériaux de broyabilité différente, la courbe granulométrique obtenue est déficiente.

La prévision de la granulométrie et des surfaces spécifiques finales s'avère plus difficile quand ces matériaux sont broyés ensemble dans des proportions différentes.

L'objet de cette étude, dans le cas du broyage du clinker et de la terre de Santorin, consiste à déterminer les surfaces spécifiques de chacun de ces matériaux dans le mélange.

Aussi on a trouvé qu'en augmentant dans ce mélange la proportion de la terre de Santorin (plus facile à broyer que le clinker) les valeurs finales des surfaces spécifiques de deux matériaux diminuent. Plus particulièrement en broyant du clinker et de la terre de Santorin dans les proportions 70:30 et 60:40 la fraction 3-30  $\mu\text{m}$  diminue d'une façon significative.

## 1. Introduction

From previous works (1,2,3) it has been proved that co-grinding of clinker with a pozzolan leads to the production of cements which show various advantages, especially with respect to their physical properties compared to Portland cements.

Pozzolans are, by nature, easier to grind than clinker, which means that with the same consumption of energy, the finenesses attained from pozzolan are far greater than those from clinker. In addition the co-grinding of these materials which have different grindabilities, results in a great differentiation concerning the final resulting specific surfaces of each one (4,5). The specific surface of each constituent must be known taking into consideration that both the pozzolanic material and clinker demonstrate their beneficial properties over limit values of specific surface. The prediction of the granulometry, as well as the final specific surfaces, becomes more difficult when these materials are co-grounded in different proportions. The aim of this study is in the case of co-grinding clinker and Santorin earth (S.e) to determine the resulting specific surfaces of each of these materials providing a systematic analysis of the weight percentages of the materials to be ground.

## 2. Experimental

### 2.1. Procedure

a) Co-grinding with 10,20,30,40% of Santorin earth. The mixture has been tested at Blaine finenesses of 3350, 3700 and 4150  $\text{cm}^2/\text{g}$ . Thus 12 mixtures have been tested in total. These co-grindings have been worked out in a 510 mm x 340 mm laboratory mill. Both clinker and Santorin earth had previously been ground in the same mill separately, yielding the curves in fig. 1

Fig 1. The effect of grinding time on the specific surfaces of clinker and Santorin earth.

These curves in combination with the Bond Indices (clinker 14Kwh/S.t, S.e 12,1 Kwh/S.t) indicate the difference in grindability between the above materials.

b) Granulometric analysis of each sample, by sieving for the range 90-56  $\mu\text{m}$  and by the use of the Alpine method for the range 56 -11  $\mu\text{m}$ . Apparatuses used in both methods allow for further treatment of separated fractions (5,6).

c) Determination of pozzolanic material in each fraction. This determination is based on the amount of insoluble residue after a suitable chemical treatment.

d) Calculation of the specific surface for both the pozzolanic material and the clinker on the basis of the formula (7,8)

$$S_B = \frac{3}{p} \cdot \frac{x}{r}$$

where  $p$  = density of a constituent  
 $x$  = the percentage of a constituent in each fraction  
 $r$  = the average radius of a fraction

This calculation followed an extension of the granular gradation curves for the range below 11  $\mu\text{m}$ .

### 2.2 Verification of the method

A total of 14 experiments has been conducted in order to secure accuracy of the method. In these experiments clinker and Santorin earth of known specific surfaces were mixed together. The results of the above experiments are presented in the following table I, where the specific surfaces are measured with Blaine apparatus.

TABLE I. Measurements of the accuracy of the method					
CEMENTS			CLINKER		
Spec. surf.	Deviation		Spec. surf.	Deviation	
Meas.	Calc.	%	Meas.	Calc.	%
3360	3356	0,1	3200	3198	0,0
3360	3302	1,7	2890	2931	1,4
3300	3310	0,5	3000	3149	5,0
3350	3419	2,0	SANTORIN EARTH		
3620	3609	0,4			
3350	3399	1,5			
3360	3344	0,4			
3350	3289	1,8			
			4340	4396	1,3
			5800	5783	0,3
			6000	5790	4,7

### 2.3 Results and discussion

The results attained are summarized in Table II.

TABLE II. Specific surface of each constituent						
S.e %	Spec. surf. of the mixture $\text{cm}^2/\text{g}$ (Blaine)					
	3350		3700		4150	
	Cl.	S.e	Cl.	S.e	Cl.	S.e
10	2980	7100	3500	7680	3830	8200
20	2840	5820	3280	6800	3630	6950
30	2680	5650	3170	5600	3380	5900
40	2600	5070	3030	5450	3120	5700

Fig. 2. The specific surfaces of clinker, Santorin earth and their mixture for several percentages of Santorin earth and several finenesses of the mixture.

a. From Table II and the relative Figure 2, it appears that:

- The specific surfaces of each material are considerably differentiated during their co-grinding with decreased specific surface in case of clinker and increased specific in case of Santorin earth.

- An increase in the percentage of Santorin earth results in decreased values of specific surface for both clinker and Santorin earth compared to their respective values when the Santorin earth percentage in the mixture is less.

b. Similar conclusions are derived from the observation of Fig. 3 which depicts the changes in the specific surface of clinker in relation to the mixture's specific surface, for various percentages of Santorin earth. It is noticed that when the Santorin earth percentage is increased, the clinker's specific surface is increased at a more pronounced rate for the range 3350-3700 cm²/g than for that between 3700-4150 cm²/g.

c. On the basis of Fig. 3, the specific surface of the mixture may be calculated by taking into consideration the percentage of Santorin earth in it, so that the specific surface of clinker reaches a certain value. Specifically, if clinker should have a fineness of 3050 ± 50 cm²/g (Blaine), the suggested specific surfaces (Blaine) of the mixture are as follows:

3400 ± 50 cm²/g	for a mixture with 10% Santorin earth
3500 ± 50 cm²/g	" " " " 20% " "
3650 ± 50 cm²/g	" " " " 30% " "
3800 ± 50 cm²/g	" " " " 40% " "

Fig. 3. Relationship between the specific surfaces of clinker and mixture for several percentages of Santorin earth.

d. Table III shows the percentages of mixtute and its constituents in the 3-30 $\mu$ m fraction. As it is clearly seen from this table an increase in S.e. causes a decrease of the % of clinker in the above mentioned fraction.

TABLE III. Percentage of materials for the 3-30 $\mu$ m fraction.									
S.e	3350			3700			4150		
	Cem.	Cl.	S.e	Cem.	Cl.	S.e	Cem.	Cl.	S.e
10	53.0	53.5	46.0	52.5	53.0	40.0	59.0	59.0	49.0
20	50.5	50.0	51.0	47.0	48.0	40.0	50.0	51.0	42.5
30	45.5	44.5	48.5	43.0	44.0	40.0	41.5	44.5	38.0
40	41.0	41.5	40.5	44.5	42.0	45.0	45.0	44.0	48.0

### 3. Problems arising form grinding materials of different grindability and suggested solutions

From the above it is concluded that an increase in the Santorin earth percentage complicates the co-grinding process and leads to smaller specific surfaces both for clinker and Santorin earth. Moreover, the above mentioned increase results in a decrease of the 3-30  $\mu$ m fraction.

This reduced grindability of the constituents may be attributed to the following:

a) The overgrinding of Santorin earth during its co-grinding with clinker is partly due to the latter's behaviour as a grinding medium. Thus, an increase in Santorin earth proportion and a corresponding decrease in clinker make the clinker's role as a grinding medium less significant and therefore, grinding is made more difficult.

b) Due to its smaller bulk density a higher proportion of Santorin earth causes an increase in the loading of the mill. As a consequence, the passing of clinker through the mill is made difficult.

Solutions to these problems which are more pronounced for percentages higher than 20% are suggested below.

As laboratory testings have shown, Santorin earth forms a 75% residue on the 90  $\mu$ m sieve. Thearfore, for the separation of the 25% fine fraction the use of an air-separator is recommended on an industrial scale. In this way the overgrinding of this fraction is eliminated, while operations in the mill's second compartment are facilitated.

A change in the gradation of grinding media inside the mill is necessary, especially in the second compartment, so that the quantity of the grinding media of small diameter is considerably increased.

# Influence of MgO on phase composition of PC-clinker and on cement properties

## *L'influence de la magnésie sur la composition de phases du clinker Portland et sur les propriétés du ciment*

K. POPOVIC, Civil and Construction Engineering Institute, Faculty of Construction Sciences, University of Zagreb,  
A. BEZJAK, Faculty of Pharmacy and Biochemistry, University of Zagreb Yougoslavie.

SUMMARY: According to X-ray diffraction results, the increase from 0 to approx. 2.5% MgO content in clinker (potential composition:  $C_3S$  57,  $C_2S$  23,  $C_3A$  10 and  $C_4AF$  10%) causes considerable lowering of  $C_3A$  and belite, with simultaneous increase in alite and ferrite phase content. Opposite effects are, however, the consequence of MgO additions exceeding 2.5%. The intensities of these phase changes are closely associated with the cooling rate of sintered mixes.

Despite the said differences in phase composition, cements without and those with MgO addition were found to be quite similar in respect to the rate of hardening. The heat of hydration has exhibited the expected changes brought about by various  $C_3A$  contents in clinkers.

X-ray diffraction has also established that the degree of hydration ( $\alpha$ ) of alite does not significantly differ for MgO and MgO-free samples.

RÉSUMÉ: Les résultats de la diffraction des rayons X indiquent que l'augmentation de 0 à environ 2.5 % de la teneur en magnésie dans le clinker (composition potentielle:  $C_3S$  57%,  $C_2S$  23%,  $C_3A$  10% et  $C_4AF$  10%) cause une diminution considérable de  $C_3A$  et de la bélite, avec une augmentation simultanée de la teneur en alite et en phase ferritique. Si toutefois l'addition de MgO dépasse 2.5%, on obtient des effets opposés. Les intensités de ces changements des phases sont étroitement liées à la vitesse de refroidissement des mélanges cuits. Malgré les différences mentionnées dans la composition des phases on a constaté que les ciments avec et ceux sans addition de MgO sont similaires quant à la vitesse de durcissement. La chaleur d'hydratation a montré les changements prévus résultant des teneurs différentes en  $C_3A$  dans les clinkers.

La diffraction des rayons X a aussi confirmé que le degré d'hydratation ( $\alpha$ ) de l'alite ne diffère pas significativement pour les échantillons renfermant la magnésie et les échantillons qui ne la contiennent pas.

## 1. INTRODUCTION

Magnesium oxide is of particular interest in cement manufacture mainly due to the unsoundness of the product that it can bring about if present in greater amounts. When exploring various mineralizers in order to improve the sintering process of white cement, however, the addition of MgO to the raw mix was observed to significantly affect the phase composition of the clinker. Several researchers 1-5) have noticed certain changes in the phase composition of clinker under the influence of MgO, and the present work describes the results of systematic investigations concerning the effect of magnesia on the phase composition and on some cement properties.

## 2. EXPERIMENTAL PROCEDURES

2.1. The influence of MgO on the phase composition of clinker was studied on the  $C_3S$ - $C_2S$ - $C_3A$  system corresponding to white cement, and also on the system of normal portland cement clinker  $C_3S$ - $C_2S$ - $C_3A$ - $C_4AF$ . Table I shows the potential mineral composition of the observed clinkers.

TABLE I Potential mineralogical composition of clinker samples				
Clinker	Phase content (wt %)			
	$C_3S$	$C_2S$	$C_3A$	$C_4AF$
W-1	55	30	15	-
W-2	5	75	20	-
W-3	15	65	20	-
W-4	32	48	20	-
W-5	48	32	20	-
W-6	75	5	20	-
W-7	25	25	50	-
N-1	57.1	24.5	7.6	9.9
N-2	65	15	10	10
N-3	50.6	39.4	10	-
N-4	48.8	38	10	3.3
N-5	47	36.5	10	6.6
N-6	45	35	10	10

Several tests were carried out on the  $C_3S$ - $C_2S$  system too with varying variations in the potential proportion of particular minerals.

The clinkers were synthesized from pure chemicals (W-2 to W-7 and N-3 to N-6) and also from industrial raw materials (W-1, N-1 and N-2) containing practically no magnesia. MgO was added to the raw mix in the amount up to 5% by weight of clinker. The samples were sintered in a laboratory electric furnace of the "Kanthal" type at 1450°C and remained at the sintering temperature for one hour. Cooling was effected in two ways: the majority of samples were subjected to rapid cooling being exposed to room temperature; with the other samples slow cooling was applied from the sintering temperature to the temperature of 1300°C in order to allow the melt to crystallize in equilibrium with the solid phase, and then the samples were cooled rapidly being exposed to room temperature. X-ray diffraction served to establish the phase composition of the clinkers.

2.2. The influence of MgO on cement properties was studied on the system of normal portland cement by comparing MgO-free samples with those containing the amount of MgO that brought about the greatest phase changes. MgO-free industrial raw mixes were used and the sintering was carried out at 1450°C, with rapid cooling.

The potential composition computed according to Bogue's formulas and the actual phase composition of the observed clinkers determined by X-ray diffraction are given in Table II.

TABLE II Composition of clinkers for cement properties examinations (Wt %)				
	MgO free		2.3% MgO	
	Bogue	X-ray	Bogue	X-ray
$C_3S$	57	50	55.6	60
$C_2S$	23	30	22.5	20
$C_3A$	10	10	9.8	3
$C_4AF$	10	5	9.8	9
MgO	-	-	2.3	0

The clinkers were subsequently ground to Blaine fineness of  $3200 \text{ cm}^2/\text{g}$ , with the addition of gypsum ( $2.9\% \text{ SO}_3$ ). In the cements obtained, determinations were performed of the strengths and of the heats of hydration.

X-ray diffraction was applied to determine the degree of hydration of alite over the period of three days.

### 3. RESULTS AND DISCUSSION

3.1. The investigation of the  $\text{C}_3\text{S}-\text{C}_2\text{S}-\text{C}_3\text{A}$  system has established that  $\text{MgO}$ , if added up to the "characteristic" amount of approximately  $2\%$ , brings about lowering of the aluminate and  $\text{C}_2\text{S}$ -phase with a parallel increase in the alite content. The addition of  $\text{MgO}$  in amounts greater than  $2\%$  had the opposite effects e.g., an increase in the  $\text{C}_3\text{A}$  and  $\text{C}_2\text{S}$  contents and a decrease in the alite content. Figure 1 (left) shows such changes in the intensity of diffraction peaks for individual minerals obtained on clinker W-1. In case of raw mixes with very high proportion of alite, there is no increase in alite content; instead free  $\text{CaO}$  appears in the clinker (Fig. 1 - right).

Fig. 1 - Phase changes in system  $\text{C}_3\text{S}-\text{C}_2\text{S}-\text{C}_3\text{A}$  caused by  $\text{MgO}$  (intensities of X-ray peaks)

The "characteristic" magnesia content causing the greatest changes in phase composition is proportional to the potential  $\text{C}_3\text{A}$  content in clinker: it amounts to  $2\%$  for the clinker with  $15\% \text{ C}_3\text{A}$ ,  $2.3\%$  for the clinker with  $20\% \text{ C}_3\text{A}$  and about  $4\%$  if the mix contains  $50\% \text{ C}_3\text{A}$  (Fig. 2). It is also in mix W-7 that the addition of  $\text{MgO}$  causes the appearance of free  $\text{CaO}$ , instead of an increase in alite.

Fig. 2 - Phase changes in system  $\text{C}_3\text{S}-\text{C}_2\text{S}-\text{C}_3\text{A}$  (sample with  $50\% \text{ C}_3\text{A}$ ) caused by  $\text{MgO}$  (intensities of X-ray peaks)

Free  $\text{MgO}$  as periclase appears only if the  $\text{MgO}$  amount in the mix is greater than the "characteristic" one. This is particularly interesting in mix W-7 potentially incorporating  $50\% \text{ C}_3\text{A}$ .

In the  $\text{C}_3\text{S}-\text{C}_2\text{S}-\text{C}_3\text{A}-\text{C}_4\text{AF}$  system the addition of  $\text{MgO}$ , up to its "characteristic" value also reduces the  $\text{C}_3\text{A}$  and  $\text{C}_2\text{S}$  amounts in clinker with a parallel increase in the contents of  $\text{C}_3\text{S}$  and the ferrite phase.  $\text{MgO}$  content exceeding the "characteristic" one will produce opposite effects in that case too. Typical changes in the proportion of clinker minerals determined in clinker N-2 are presented in Figures 3 and 4.

Fig. 3 - Changes in C<sub>3</sub>S- and C<sub>2</sub>S-phase content (system C<sub>3</sub>S-C<sub>2</sub>S-C<sub>3</sub>A-C<sub>4</sub>AF) caused by MgO (quantitative X-ray analysis)

Fig. 4 - Changes in C<sub>3</sub>A- and C<sub>4</sub>AF-phase content (system C<sub>3</sub>S-C<sub>2</sub>S-C<sub>3</sub>A-C<sub>4</sub>AF) caused by MgO (quantitative X-ray analysis).

A further effect of magnesia addition is the change in the composition of the ferrite phase. Based on the position of diffraction peaks it has been established that, depending on the MgO present, the ferrite phase has the composition, shown in Table III.

% MgO	mol % C <sub>2</sub> F	mol % C <sub>2</sub> A
0	45	55
0.7	55	45
1.5	62.5	37.5
2.3	65	35

Free MgO as periclase appears also in this system only if the amount of MgO added is greater than the "characteristic" value.

All the described effects were noticed only, in case of rapid cooling.

The phase changes are the due to differences in the amount and composition of the liquid phase during sintering which result from the different MgO proportions in the raw mix. In the slowly cooled clinkers, where the melt has crystallized in equilibrium, no changes in phase composition have been noticed caused by magnesia. Neither in the C<sub>3</sub>S-C<sub>2</sub>S system where the reaction at 1450°C occurs almost exclusively in the solid phase, the addition of MgO did not affect the phase composition regardless of whether rapid cooling or slow cooling was applied.

3.2. The determination of strengths of cements obtained from MgO-free clinkers and those with MgO added (Table II) has yielded the results shown in Table IV, whereas Table V presents the heats of hydration of the same cements determined by the vacuum flask method.

TABLE IV Compressive strengths of cements with and without MgO (N/mm <sup>2</sup> )				
	1 day	3 days	7 days	28 days
Cement paste (w/c=0.4) 1x1x4 cm				
MgO free	11.8	25.7	48.7	77.2
2.3% MgO	9.6	27.8	43.0	87.2
Cement mortar (1:3) (w/c=0.5) 2x2x20 cm				
MgO free	13.4	30.0	43.4	63.0
2.3% MgO	12.9	27.1	42.0	60.7

TABLE V Heat of hydration of cements with and without MgO (cal/g)		
	3 days	7 days
MgO-free	85.5	92.7
2.3% MgO	74.9	82.3

The results clearly indicate that the determinations of the heat of hydration for cements without and those with MgO exhibit differences that have been expected owing to the different proportion of  $C_3A$  in the clinkers from which the cements were made.

The strengths developed in cements not containing magnesia, however, do not significantly differ, from those in cements with MgO despite the considerably higher alite content in cements with MgO addition. It appears that the proportion of  $C_3A$  in cement has a very important role in strength development, particularly at early ages; as already mentioned  $C_3A$  proportion is much lower if cement contains MgO; thus the higher alite content in the cement with MgO is compensated.

The study of alite hydration over a 3-day period has proved that its degree of hydration is similar in samples with and those without MgO, the hydration rate being, howe-

ver, slightly higher in cements with MgO (Fig.5).

Fig. 5 - Rate of hydration of alite for cements with and without MgO

Because of the great lowering of  $C_3A$  content under the influence of MgO, considerable changes in the sulfate resistance of cement can also be expected. Such investigations are in progress.

#### ACKNOWLEDGEMENT

The assistance of JUCEMA, Association of the Yugoslav Cement Producers, in allowing the authors to use its laboratory equipment during the investigations described is gratefully acknowledged.

J. MITUZAS, Cand. Sc. (chemistry), Head of the Laboratory,  
L. RAMANAUSKIENE, engineer, « Akmenimentas », N. Akmenė, USSR.

RESUME : Nous avons élaboré et vérifié une méthode de détermination à la température ambiante du CaO ou  $\text{Ca}(\text{OH})_2$  libres dans les briques hollandaises et autres matériaux cimentés durcis.

Comme solvant, on peut se servir d'éthylène-glycol déshydraté ou son mélange avec un de ses composés de la classe des alcools en ajoutant  $\text{Ca}(\text{NO}_3)_2$ ,  $\text{Sr}(\text{NO}_3)_2$ ,  $\text{BaCl}_2$  etc. Avant l'analyse, on fait bouillir le solvant avec un des produits ajoutés, puis on le fait refroidir jusqu'à la température ambiante. Le solvant amené au pH nécessaire est prêt à l'utilisation.

L'analyse est faite à un pH constant contrôlé d'une façon potentiométrique. Cela permet de faire la mesure d'une façon automatique suivant le schéma pH-mètre-bloc de titrage automatique -enregistrement des résultats.

SUMMARY: A method for determination of free CaO or  $\text{Ca}(\text{OH})_2$  in clinkers, Portland cements, other binding materials and their hardened products at room temperature has been developed and checked by authors.

Anhydrous ethylene glycol or its mixture with one of compounds from group of alcohols with  $\text{Ca}(\text{NO}_3)_2$ ,  $\text{Sr}(\text{NO}_3)_2$ ,  $\text{BaCl}_2$  or other dehydration agents can be used as solvent. Before the analysis solvent is subjected to boiling and subsequent cooling to room temperature.

The analysis is carried out at constant pH, which is controlled with the help of potentiometer. This allows to carry out the automatic analysis according to the following scheme: pH - meter-block for automatic titration -recording of the results.

## INTRODUCTION

At present determination of free CaO or  $\text{Ca(OH)}_2$  amounts is one of the important problems in chemistry and technology of binding materials. Many scientists are carrying out research work in this field in different countries (1,2).

Among well-known methods for free CaO ( $\text{Ca(OH)}_2$ ) determination the following ones find an extensive use: 1) Emmly modified by Bogue and Lerch (3); 2) Branderburg, s one (4); 3) Franke modified more than once and at present time to be used in the form proposed by Pressler, Brunauer, Kantro and Weise (6) in which either variation of extraction time (TVM) or solution (SVM) amount are assumed.

Methods (3,4,5) are based on selective dissolution of free CaO ( $\text{Ca(OH)}_2$ ) in specimens under investigation in corresponding solvents at their boiling temperature and so according to the method (6) the material to be analyzed can be treated in a certain solvent at boiling temperature and as well at room temperature with the following determination of free CaO transited into solution by voluminous methods.

However the specificity of methods (analyzing at boiling temperature /3,4,5/ or the separation of the material to be analyzed by filtering (5,6) result in some difficulties in the case of automatization and evaluation of experimental results for instrumental methods employment for analysis (potentiometric, coulometric, titration, etc.).

The method developed by the authors of this paper allows to carry out the analysis of free CaO ( $\text{Ca(OH)}_2$ ) content in binding materials and products of their hardening at room temperature and simultaneously solves the problem of automatic system development for a given component analysis.

## I. EXPERIMENTAL PROCEDURE

In the series of experiments it was found that the temperature increase during the treatment of ethylene glycol <sup>x/</sup> with addition of different dehydrating salts of type  $\text{Ca(NO}_3)_2$ ,  $\text{Sr(NO}_3)_2$ ,  $\text{BaCl}_2$ ,  $\text{LiCl}$  etc. with the following cooling of solution to room temperature results in always increasing intensity of CaO ( $\text{Ca(OH)}_2$ ) dissolution. The highest reactivity relative to CaO ( $\text{Ca(OH)}_2$ ) has been attained after boiling with following cooling of pure ethylene glycol (boiling temperature (b.p.)  $197^\circ\text{C}$ ) with  $\text{Ca(NO}_3)_2$  addition. Further in the present work pure ethylene glycol with  $\text{Ca(NO}_3)_2$  addition (60 mg to 1 ml ethylene glycol) boiled in the period of 5 min. and cooled under the stream of water to room temperature was used as solvent. Boiling is carried out in Erlenmeyer flask with reflux condenser supplied with tube filled with soda lime and Bunsen valve not allowing air access to the content in the flask.

After solvent boiling and cooling acetonitrile (1 ml  $\text{CH}_3\text{CN}$  to 5 ml of ethylene glycol) has been added for viscosity decreasing. This aprotic solvent not showing acidity properties possesses of a relatively high dielectric constant ( $\epsilon = 37,5$ ) and plays an important role at the employment of potentiometric analysis methods, which were used by us in the present work.

In reality the analysis was carried out in mixed solvent consisting of polar (ethylene glycol) and aprotic ( $\text{CH}_3\text{CN}$ ) components at the ratio of 5:1.

Thus pH of prepared solvent has attained 9,25<sup>xx/</sup> by addition of 1% KOH solution in ethylene glycol.

Glass electrode with  $\text{H}^+$  function was used as indicator electrode and silver chloride electrode filled with saturated water solution of potassium chloride served as reference one.

After attaining required pH of solvent the material to be analyzed <sup>xxx/</sup> was placed in certain amounts into the cell for titration and after switching on magnetic stirrer automatic titration system was switched on. During the analysis proceeding solvent pH with substance to be analyzed was in the range of 9,20-9,25. pH reducing to 9,20 was caused by cell inertness after addition of next portion of titrant, particularly in the final stage of determination. 0,2N solution of dehydrated benzoic acid in isopropanol has been used as titrant.

The principal scheme of potentiometric titrometer is given in Fig.1.

The final moment of titration is considered achieved when pH variation of solvent does not exceed 0,05 in the period of 20 min.

## 2. EXPERIMENTAL RESULTS

For the evaluation of the suggested method reliability the determinations of CaO ( $\text{Ca(OH)}_2$ ) were carried out on the same specimens by other well-known chemical methods. The following methods developed by different authors were employed: Emmly, s modified by Bogue and Lerch (3); Branderburg (4); Franke modified by Pressler and etc. (6).

Short characteristics of employed materials are given in Table I and experimental results - in Table II.

<sup>x/</sup> Treatment temperature was controlled by addition of corresponding alcohols. In this work the following alcohols were used: isopropanol (b.p.  $-82,5^\circ\text{C}$ ); propyl alcohol (b.p.  $-97^\circ\text{C}$ ); isobutyl alcohol (b.p.  $-108^\circ\text{C}$ ); butyl alcohol (b.p.  $-118^\circ\text{C}$ ); amyl alcohol (b.p.  $-138^\circ\text{C}$ ); cyclohexanol (b.p.  $-161^\circ\text{C}$ ).

<sup>xx/</sup> In some cases pH of the medium was different.

<sup>xxx/</sup> In a given series of experiments all specimens to be analyzed have been ground to fineness of  $40\mu\text{m}$  in jasper mortar. No cautions were taken against action of surrounding atmosphere to specimens during their grinding.

### 3. DISCUSSION OF RESULTS

Data given in Table II show, that CaO content determined by the suggested method in investigated materials are in good correlation with results obtained by Emmly and Franke methods, excluding quantities found in Portland cements hydrated over a long period of time. Amounts of CaO determined by Branderburg's method mainly exceed that obtained in the work carried out by other methods. Most likely this is caused by partly dissolution of other components of binding materials (2).

Considering data on CaO ( $\text{Ca(OH)}_2$ ) in Portland cements hydrated over a long period of time ( $B, B_1, S_1$ ), results obtained by us are as if in "the middle" among the data obtained by Branderburg's method and Emmly and Franke one. X-ray patterns obtained on separate specimens after their treatment at room temperature and also at boiling temperature (Fig. 2) show the absence of  $\text{Ca(OH)}_2$  peaks indicating that really complete dissolution of  $\text{Ca(OH)}_2$  crystals has occurred. Treatment of ethylene glycol with dehydrating salts at elevated temperatures leads to compound formation, composition of which was not determined in this work. Although namely this new compound of solvent favours dissolution of calcium silicate hydrates or calcium aluminate hydrates at  $\text{pH} < 9,0$ , and that of  $\text{Ca(OH)}_2$  only at higher pH.

Fig. 2. X-ray patterns of some investigated specimens.

1 -  $S_1$  after treatment by suggested method; 2 -  $S_1$  after treatment by Franke method (TVM); 3 -  $B_1$  after treatment by suggested method.

Separate experiments showed, that the dissolution even of large single crystals (hexagonal plates  $3-4 \times 0,5-0,6$  mm)  $\text{Ca(OH)}_2$  proceeds with significant rate. The scheme of dissolution rate of  $\text{Ca(OH)}_2$  single crystals in the above mentioned solvent is shown in Fig. 3.

Fig. 3.  $\text{Ca(OH)}_2$  single crystals dissolution rate at room temperature.

The attention is drawn by the fact, that dissolution proceed at constant rate, i.e. reaction rate is proportional to specific area of the material to be dissolved.

Filtrate analysis on the presence of  $\text{SiO}_2$ ,  $\text{Al}_2\text{O}_3$ , etc. after complete  $\text{Ca(OH)}_2$  dissolution was employed for the proposed method verification. After the separation of insoluble part by filtration the obtained filtrate was subjected to vacuum distillation (10 mm Hg column) in which ethylene glycol and acetonitrile were eliminated ~~xxxx~~. The remaining solid substance must consist of the initial  $\text{Ca(NO}_3)_2$  and  $\text{SiO}_2, \text{Al}_2\text{O}_3$ , etc. in the case of their transition into filtrate during the dissolution of the investigated material. Heat treat-

<sup>x/</sup> Wide range diffractometer of the type DPOH - 1,5.  $\text{CuK}_{\alpha}$  radiation; tube current capacity 20 mA; voltage - 32 kV.

<sup>xx/</sup> pH of ethylene glycol with dissolved  $\text{Ca(NO}_3)_2$  (60 mg  $\text{Ca(HO}_2)_2$  in 1 ml of ethylene glycol) before boiling attains  $\sim 7,1$  and after it increases to  $8,5^3-8,6$ .

<sup>xxx/</sup> Single crystals were grown by diffusive method at the temperature of  $52^\circ\text{C}$  in 3 weeks. NaOH and  $\text{CaCl}_2$  served as components of reaction.

<sup>xxxx/</sup> In a given case the analysis proceeding is described after treatment of  $S_1$  (Table II).

ment of the similar system must proceed according to

Free CaO decrease must point to the presence of other components besides to  $\text{Ca(NO}_3)_2$ . However after solid substance firing at the temperature of  $1100^\circ\text{C}$  in the period of 30 min. it was obtained free CaO = 98,93% i.e. really at the purity grade of  $\text{Ca(NO}_3)_2$  used agent. This point to the absence of the components of  $\text{SiO}_2, \text{Al}_2\text{O}_3$  type in filtrate after durable treatment of cement stone in the above mentioned solvent.

x/ In separate experiments it was established that used solvent does not affect separate minerals  $\text{C}_3\text{S}$ ,  $\text{C}_2\text{S}$ ,  $\text{C}_3\text{A}$ ,  $\text{C}_4\text{AF}$ .

# On the composition of cement minerals

## *Sur la composition minérale du ciment*

A. BOIKOVA, Doctor, Institute of Silicate Chem. of the USSR Academy of Sci. Leningrad,  
A. ESAYAN, Engineer, Institute of Silicate Chem. of the USSR Academy of Sci. Leningrad,  
V. LAZUKIN, Engineer, Institute of Silicate Chem. of the USSR Academy of Sci. Leningrad.

RESUME : Les compositions des phases de cinq clinkers industriels du ciment Portland ont été étudiées à l'aide d'un appareil Camebax du type MB-1.

Pour faire un calcul quantitatif des éléments, les produits types suivants ont été synthétisés : des solutions solides de  $C_3S$  avec  $Na_2O$ ,  $K_2O$ ,  $MgO$ ,  $Al_2O_3$ ,  $Fe_2O_3$ ;  $C_3S$  avec  $MnO$ ;  $C_3S$  avec  $TiO_2$ ;  $C_2S$  avec  $P_2O_5$ ;  $C_3A$  avec  $Na_2O$ ;  $C_4AF$  avec  $MgO$ ;  $C_6A_2F$  avec  $Na_2O$ ,  $MgO$ ,  $MnO$ ,  $SiO_2$ ,  $TiO_2$ ; un verre contenant  $SO_3$ .

Les données de l'analyse par microsonde électronique sur les compositions des minéraux du ciment (les phases du clinker) permettent de faire quelques conclusions générales.

Chacune des impuretés de la matière première peut être présente dans tout minéral du ciment.

La composition des cristaux d'une même phase du clinker est différente, par suite des conditions de non-équilibre de leur formation.

La phase aluminatée est l'objet d'une attention spéciale. La quantité la plus grande des impuretés est distribuée dans sa structure.

SUMMARY : The compositions of phases of five commercial Portland cement clinkers were studied using a Camebax apparatus of the type MB-1.

To make a quantitative calculation of the elements, the following standards were synthesized: solid solutions of  $C_3S$  with  $Na_2O$ ,  $K_2O$ ,  $MgO$ ,  $Al_2O_3$ ,  $Fe_2O_3$ ;  $C_3S$  with  $MnO$ ;  $C_3S$  with  $TiO_2$ ;  $C_2S$  with  $P_2O_5$ ;  $C_3A$  with  $Na_2O$ ;  $C_4AF$  with  $MgO$ ;  $C_6A_2F$  with  $Na_2O$ ,  $MgO$ ,  $MnO$ ,  $SiO_2$ ,  $TiO_2$ ; a glass containing  $SO_3$ .

Electron microprobe data on the composition of cement minerals (clinker phases) permit some general conclusions.

Each of the impurities of raw material can be present in any cement mineral.

The composition of crystals of one and the same clinker phase is different due to non-equilibrium conditions of their formation.

The aluminate phase deserves special attention. The greatest amount of impurities is distributed in its structure.

Electron-probe microanalysis of the composition of Portland cement minerals (clinker phases) permits some general conclusions:

1. Inhomogeneous mixing of initial raw materials as well as the non-equilibrium conditions of the clinker burning and of the formation of crystal phases may result in different compositions of crystals of the same clinker phase.

Such phases can exist in clinker in at least two crystal forms (for example belite, alite, aluminite).

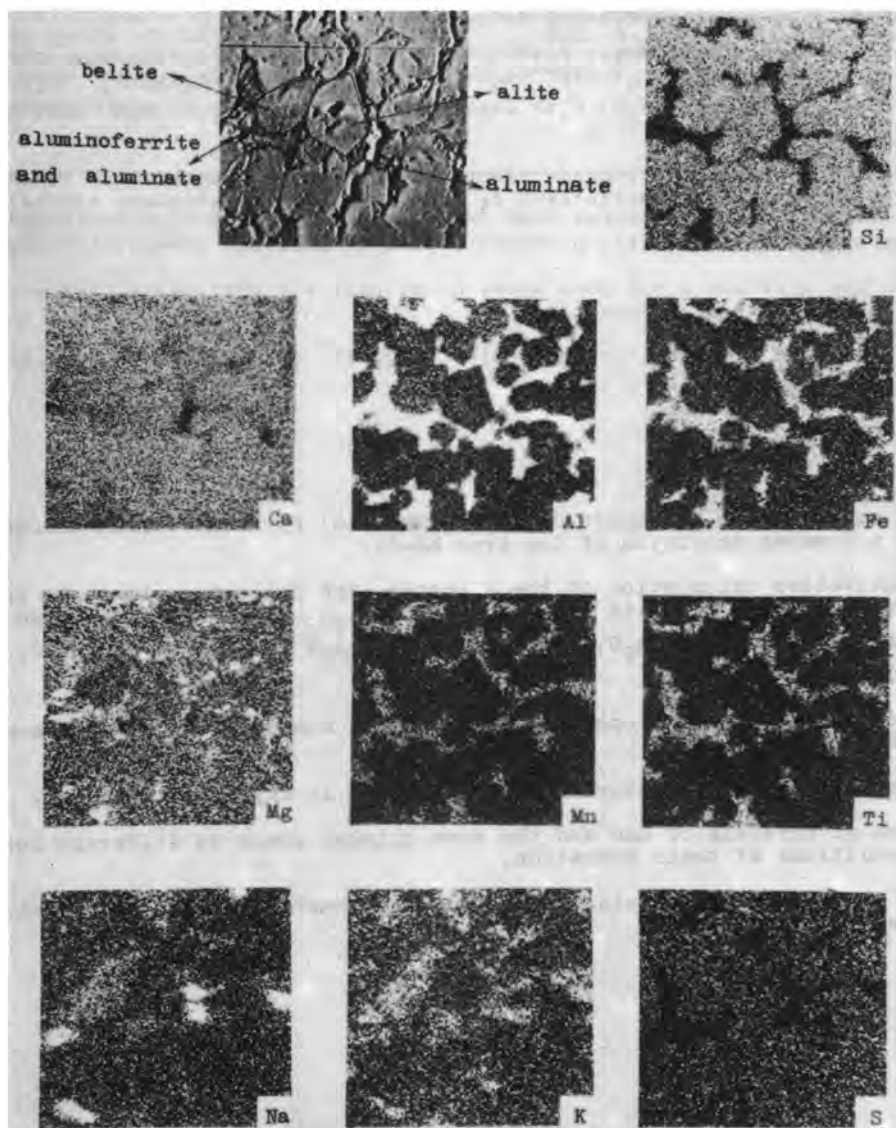

At the same time the different composition of the crystals of one and the same phase

may lie within the composition range of one modification.

It was also observed that the impurity distribution in one crystal is non-uniform. As a rule, the compositions of the center and of the edges of such a crystal are different.

2. Each of the impurities of raw material can be present in any cement mineral.

However, the preferable distribution of impurities among minerals depends on the peculiarities of crystal structure. So the octahedral positions in the aluminoferrites are most convenient for Mg occupancy. Such elements as Ti, Mn, Cr are also distributed

EPMA photograph of clinker

preferentially in the aluminoferrites. The large cations of Na prefer the crystal lattice of  $C_3A$  with large holes.

Owing to the possible substitution  $CaAl = NaSi$  both the aluminate and aluminoferrite contain a considerable amount of Si. P, S, K are preferentially distributed in belite.

For each of the phases there is a most characteristic set of impurities: for alite - Mg, Al, Fe, Na, K (Cr, Ti, P a.o.); for belite - Mg, Al, Fe, K, P, S (Cr a.o.); for aluminate - Na, Si, Fe, Mg, K a.o.; for aluminoferrite - Mg, Si, Ti, Mn, Na (Cr, K a.o.).

Each phase can also form without some impurities (see Table). So the clinker may contain magnesium-free crystals of the aluminate and belite phases.

TABLE  
COMPOSITIONS OF CLINKER PHASES IN OXIDES  
The least and the greatest amount of oxides are given (wt %)

Phases Oxides	Alite	Belite	Aluminate	Aluminoferrite
CaO	69,0 72,7	60,3 64,4	52,3 58,7	45,5 50,7
SiO <sub>2</sub>	23,8 26,4	28,0 33,8	3,5 5,6	2,0 5,5
Al <sub>2</sub> O <sub>3</sub>	1,1 2,7	1,4 3,1	26,4 35,0	17,3 22,9
Fe <sub>2</sub> O <sub>3</sub>	0,4 1,5	0,3 1,8	2,9 7,1	19,4 26,2
MgO	0,5 1,4	0,4 0,8	0,0 2,1	2,3 5,4
Na <sub>2</sub> O	0,1 0,3	0,0 1,1	0,2 4,0	0,0 0,9
K <sub>2</sub> O	0,1 0,3	0,6 1,3	0,3 0,8	0,0 0,3
P <sub>2</sub> O <sub>5</sub>	0,0 0,5	0,2 0,8	0,0 0,1	0,0 0,3
SO <sub>3</sub>	0,0 0,4	0,0 0,8	0,0 0,4	0,0 0,3
Mn <sub>2</sub> O <sub>3</sub>	0,0 0,1	0,0 0,1	0,0 0,1	0,1 0,8
TiO <sub>2</sub>	0,0 0,3	0,0 0,4	0,0 0,4	0,5 1,8

3. The analysis of our results and those of other authors shows that the smallest amount of impurity oxides is present in alite (~4 wt%); belite contains a greater amount of impurities (~6 wt%). The amount of impurities increases sharply in aluminoferrites (~10-11 wt%).

Of special attention is the composition of the aluminate phase. This phase contains the greatest amount of impurities (~13 wt%).

Besides, its composition is most variable because it is greatly influenced by accidental factors, first of all by the presence of the neighbouring phases.

So, as a rule, its Fe<sub>2</sub>O<sub>3</sub> content is overstated due to the influence of aluminoferrite intergrowths. According to the results of the synthesis of the aluminate phases under laboratory conditions the Fe<sub>2</sub>O<sub>3</sub> content does not exceed 4-5 wt %.

4. The CaO:Al<sub>2</sub>O<sub>3</sub>:Fe<sub>2</sub>O<sub>3</sub> ratio in the aluminoferrite phase of the clinkers investigated is close to 6:2:1 but not to 4:1:1.

In alite and belite the CaO:SiO<sub>2</sub> ratio is, as a rule, higher than 3:1 and 2:1 respectively.

5. Inaccuracies in the determination of the compositions of clinker phases can be due to several reasons: to the superimposition of one phase on another, especially if the parts close to the crystal edge are chosen for the analysis; to the intergrowth of one phase with another; to the presence of microinclusions of one phase in another.

Thus the possibility of using EPMA is limited by the size of the crystal analyzed.

# Investigation of aluminoferrite calcium crystallization processes

## *Etude de processus de cristallisation des aluminoferrites de calcium*

A.M. DMITRIEV,  
M.T. VLASSOVA,  
B.E. YUODOVITCH,  
S.I. IVACHTCHENKO, Nitssement, Moscou, U.R.S.S.

On a étudié l'influence des différentes additions catalytiques sur les processus de cristallisation de la phase aluminoferritique du clinker. On a proposé le modèle du mécanisme de la formation des aluminoferrites de calcium de composition différente en fonction de la concentration de l'addition introduite et des conditions thermiques de la cuisson du clinker. Ce modèle est fondé sur la relation établie pour la première fois entre la position d'un élément catalytique dans le tableau périodique des éléments de D.I. Mendéléev et la composition de la phase aluminoferritique en cours de cristallisation. On a révélé la dépendance entre la composition et la structure de la phase aluminoferritique et la broyabilité et l'activité d'hydratation du clinker de ciment portland.

The influence on the aluminoferrite clinker phase crystallization processes of different catalytic additions have been studied. Model mechanism of different composition aluminoferrite calcium formation depending on the concentration of an addition introduced and thermal conditions of clinker burning has been proposed. This model mechanism is based on a first determined interrelationship between catalytic element position in the Periodic Mendeleev's system of elements and crystallizing aluminoferrite phase composition. Dependence between composition and structure of aluminoferrite phase and grindability and hydration activity of portland cement clinker is exposed.

Calcium aluminoferrites represent a series of solid solutions of general formula  $2\text{CaO} \cdot (\text{Al}_2\text{O}_3)_x \cdot (\text{Fe}_2\text{O}_3)_{1-x}$  where x varies from 0 to 0.7 and constitute a considerable part of Portland cement clinker (up to 15%). Their composition and structure have a significant effect on hydraulic activity of cements.

At present many researchers consider that the hydraulic activity of "pure" minerals of calcium aluminoferrites increases with the ratio  $\text{Al}_2\text{O}_3/\text{Fe}_2\text{O}_3$  although some data indicate that the highest hydraulic activity is displayed by  $\text{Fe}_2\text{O}_3$ -enriched aluminoferrite phase.

Possessing considerable isomorphic capacity calcium aluminoferrites may accommodate in their crystal lattice various microimpurities (Mg, Si, Ti, Mn, Cr, Na, K, Ca, Al, Fe, Sr, Ba,  $\text{SO}_3$ ) [1-3] which makes the problem of most hydraulically active aluminoferrite phase more difficult to solve. Analysis of results obtained in NIITSEMENT and in work [1] shows that, despite the complex dependence between hydraulic activity and composition and nature of microimpurities, a general tendency of increase of hydraulic activity of both "pure" and modified calcium aluminoferrites with increase of  $\text{Al}_2\text{O}_3$  content exists. Accordingly in this work we studied means of enhancing hydraulic activity by changing the composition of aluminoferrite phase, introducing various microadditives ( $\text{CuO}$ ,  $\text{ZnO}$ ,  $\text{P}_2\text{O}_5$ ,  $\text{BaO}$ ,  $\text{Ni}_2\text{O}_3$ ,  $\text{Mn}_2\text{O}_3$ ) into raw cement charges.

The synthesis of calcium aluminoferrites modified by the microadditives mentioned above is described in [4]. The amount of the modifying ion in the aluminoferrite phase was monitored by methods of rational chemical analysis and atomabsorption spectroscopy and its composition by petrographic, chemical and X-ray phase methods of analysis. The composition of calcium aluminoferrites was determined from calibrated plots by reflection at  $d=1.92 \text{ \AA}$ , which is the most sensitive characteristic of aluminoferrite phase variation [2].

Roentgenograms of the aluminoferrite phase show that on addition of  $\text{BaO}$  the peak at  $d=1.92 \text{ \AA}$  is shifted to lower values, and in the presence of  $\text{CuO}$ ,  $\text{ZnO}$ ,  $\text{Mn}_2\text{O}_3$ ,  $\text{Ni}_2\text{O}_3$ ,

$\text{P}_2\text{O}_5$  to higher values of the diffraction angle (Table 1). As follows from Table 1, calcium aluminoferrites of composition  $\text{C}_6\text{A}_{1.5}\text{F}$  crystallize from clinker melt without additives. Introduction of a basic oxide ( $\text{BaO}$ ) decreases the amount of aluminoferrite phase and enriches it with iron oxides. The presence of acidic components ( $\text{CuO}$ ,  $\text{ZnO}$ ,  $\text{Ni}_2\text{O}_3$ ,  $\text{Mn}_2\text{O}_3$ ,  $\text{P}_2\text{O}_5$ ) increases the amount of aluminoferrite phase and enriches it with  $\text{Al}_2\text{O}_3$  which was also confirmed by petrographic data. The following general tendency is observed (Table 1, Fig. 1): with increase of the acidic properties of additives, characterized by electronegativity ( $E.N.$ ), ionic potential ( $Z/r$ ) and bonding energy between cation and oxygen ( $E_{\text{Me-O}}$ ), calcium aluminoferrite compositions are shifted to a higher degree towards increasing  $\text{Al}_2\text{O}_3/\text{Fe}_2\text{O}_3$  ration. According to the increasing effect on the composition of crystallizing calcium aluminoferrites (facilitating crystallization of calcium aluminoferrites enriched with  $\text{Al}_2\text{O}_3$ , except for  $\text{BaO}$ ), the elements studied may be arranged in the following sequence (Fig. 1):

Ba   Mn   Ni   Zn   Cu   P

A similar sequence with only slight deviations is formed when arranging these elements according to increasing acidic properties.

Most researchers explain variation of aluminoferrite phase composition by different solubility of  $\text{Al}_2\text{O}_3$  or calcium aluminates in liquid phase of ferrite composition due to reduction of viscosity occurring at higher temperatures of clinker burning or on introduction of mineralizers into the raw mixes. However, this does not explain many experimental facts, e.g. why increase of viscosity of liquid phase caused by addition of  $\text{P}_2\text{O}_5$  is accompanied by shift of aluminoferrite phase composition towards formation of  $\text{C}_8\text{A}_3\text{F}$ .

Since viscosity of the clinker melt is determined by its structure it would be more correct to associate variations in calcium aluminoferrite composition not with viscosity variation, but with restructuring of the clinker liquid phase "structure"

Table 1

B No.	Additive	Characteristics of the cations formed on dissociation of the additives			Position of peak with $d=1.92 \text{ \AA}$	$\text{Al}_2\text{O}_3/\text{Fe}_2\text{O}_3$ ratio (mol.) in aluminoferrite phase
		Electro-negativity (Pauling)	Bonding energy with oxygen kcal; Avogadro number	Ion potential, $Z/r$

Fig. 1a. Composition of aluminoferrite phase depending on the bonding energy between the introduced cation and oxygen.

under the effect of temperature of additives. One should also take into account that only change of structural features of amphoteric elements Al and Fe should effect the composition of the crystallizing aluminoferrite phase, whereas viscosity of the melt is determined by the presence of not only aluminoferrite complexes, but also of other large radicals (e.g.  $\text{PO}_4^{2-}$ ) which frequently have a decisive effect on viscosity of the clinker melt [5], but do not noticeably affect the mechanism aluminoferrite phase formation.

Clinker melts are a highly basic (60% of CaO) aluminoferrite phase in which under certain temperature conditions in the presence of certain amounts and types of microadditives a dynamic equilibrium exists

between various coordination forms of amphoteric elements Al and Fe, and the direction in which this equilibrium is shifted is determined by acid-base properties of the system. The intensity of the shift, which determines the absolute value of viscosity change, depends on the acid-base characteristics of the dissolved ions [5].

$2\text{CaO} \cdot \text{Fe}_2\text{O}_3$ ,  $5\text{CaO} \cdot 3\text{Al}_2\text{O}_3$  or  $12\text{CaO} \cdot 7\text{Al}_2\text{O}_3$  and CaO are usually considered real components of solid solutions and formation of the aluminoferrite phase crystallizing from the melt occurs, in the final analysis, when "populating" octahedral and tetrahedral positions by aluminum and iron ions.

It may be concluded from analysis of the published data [6-9] on the ratio of tetrahedrally and octahedrally coordinated iron and aluminum ions in the structure of aluminoferrite phase (Table 2) that with increase of A/F ratio in the calcium aluminoferrite composition that amount of octahedrally coordinated iron atoms increases, whereas the number of tetrahedrally coordinated  $\text{FeO}_4^{2-}$

complexes decreases. The few studies which point to a similar dependence for Al coordinated ions require additional verification with modern methods of physico-chemical analysis. From the available data on structural arrangement of Al and Fe ions in calcium aluminoferrites the following model of the mechanism of aluminoferrite phase formation depending on the concentration of the additive and the temperature conditions of clinker burning may be proposed. Increase of clinker burning temperature or the presence of additives in the raw mix which exhibit acidic properties in the melt (in our case CuO, ZnO,  $\text{Mn}_2\text{O}_3$ ,  $\text{Ni}_2\text{O}_3$ ,  $\text{P}_2\text{O}_5$ )

shifts the dynamic equilibrium towards increase of the number of Al and Fe atoms in octahedral coordination and decrease of the number of tetrahedral complexes. This was confirmed previously in the study of IR absorption spectra of sharply cooled melts [5]. This will cause fluctuations in the melt with structural similarity to  $\text{Al}_2\text{O}_3$ -enriched calcium aluminoferrites (Table 2).

Table 2

Ratio of tetrahedral and octahedral iron and aluminum ions in the structure of calcium aluminoferrites

No.	Value of x in the formula of calcium aluminoferrites	Composition of aluminoferrite phase	Amount of complexes in aluminoferrite phase, %			
			FeO <sub>4</sub>	FeO <sub>6</sub>	AlO <sub>4</sub>	AlO <sub>6</sub>
1	0.824	C <sub>8</sub> A <sub>3.30</sub> F <sub>0.70</sub>	14.0	84.0	-	-

3	0.750	C <sub>8</sub> A <sub>3</sub> F	100.0	0	33.0	66.0
4	0.747	C <sub>6</sub> A <sub>2.24</sub> F <sub>0.76</sub>	23.0	77.0	-	-
5	0.724	C <sub>6</sub> A <sub>2.17</sub> F <sub>0.83</sub>	23.0	77.0	-	-
6	0.681	C <sub>6</sub> A <sub>2.04</sub> F <sub>0.96</sub>	26.0	74.0	-	-
7	0.667	C <sub>6</sub> A <sub>2</sub> F	26.7	73.3	-	-
8	0.628	C <sub>4</sub> A <sub>1.256</sub> F <sub>0.744</sub>	28.0	72.0	-	-
9	0.500	C <sub>4</sub> AF	24.0	76.0	76.0	24.0
10	0.500	C <sub>4</sub> AF	25.0	75.0	75.0	25.0
11	0.498	C <sub>4</sub> A <sub>0.996</sub> F <sub>1.004</sub>	32.5	76.5	-	-
12	0.344	C <sub>6</sub> A <sub>1.032</sub> F <sub>1.968</sub>	38.0	62.0	-	-
13	0.321	C <sub>6</sub> A <sub>0.963</sub> F <sub>2.037</sub>	38.8	61.2	-	-
14	0.0	C <sub>2</sub> F	50.0	50.0	-	-

This facilitates crystallization of the latter from the clinker liquid phase modified by Cu, Zn, Mn, Ni, P ions. The same occurs on increase of clinker burning temperature. The intensity of variation of Al and Fe ion coordination (i.e. composition of the aluminoferrite phase) is determined by the magnitude of the acid-base properties of the additives: the more acidic the element the greater the Al<sub>2</sub>O<sub>3</sub>-enrichment of the aluminoferrite phase (Fig.1). Addition of BaO into the raw increases basicity of the system resulting in formation of additional AlO<sub>4</sub><sup>5-</sup> and FeO<sub>4</sub><sup>5-</sup> and in reduction of the number of octahedra, thus shifting the aluminoferrite phase composition towards C<sub>6</sub>AF<sub>2</sub> (Fig.1).

It should be noted that variation of aluminoferrite phase composition with temperature conditions or addition of microadditives should presumably be determined by a combination of many factors; solubility of Al<sub>2</sub>O<sub>3</sub> and calcium aluminates in clinker melt, redox properties of the additives, appearance in the system of liquation regions, etc. The determining factor affecting the mechanism of this process is however variation of acid-base properties of the clinker melt.

In order to verify the proposed route of increase of hydraulic activity of cements, clinkers with KH=0.93; n=1.8; p=1.1 with addition of Zn and Cu oxides were synthesized.

X-ray phase and petrographic analyses

showed that the phase composition of the test and dummy clinkers practically coincide (59-62 % of C<sub>2</sub>S; 17-19% of C<sub>2</sub>S; 4-5 % C<sub>3</sub>A and 16-19% of aluminoferrite phase).

Modifications of clinker minerals were the same: monoclinic for alite and -form for dicalcium silicate. The composition of the aluminoferrite phase, isolated by chemical methods, in the clinker modified by Zn and Cu ions was shifted towards Al<sub>2</sub>O<sub>3</sub>-enriched calcium aluminoferrites as compared with dummy clinker.

The clinker was well sintered, showed a more uniform granulometric distribution, better grindability and its hydraulic activity was in average by 50-80 kg/cm<sup>2</sup> higher than of the dummy clinker.

Hence, the proposed model of formation of aluminoferrite phase of various composition based on the established relationship between the position of the added element in the Periodic table and the composition of the crystallizing calcium aluminoferrites makes it possible to carry out a directed search for effective additives which significantly affect the composition of the aluminoferrite phase. This is becoming especially important lately since the traditional means of increasing the grade of cements have been exhausted and directed change of aluminoferrites phase composition of clinkers is an additional method of enhancing hydraulic activity of cements.

## Shales and their working-over solid by-products in portland cement production

### *Schistes et déchets solides de leur transformation dans la production du ciment portland*

Y.I. SIDOROVITCH, Institut de Géologie et de Géochimie des Combustibles Fossiles de l'Académie  
des Sciences de l'Ukraine, U.R.S.S.

La masse inorganique des schistes combustibles est représentée sous forme générale par les carbonates de calcium dans le mélange avec les argiles, rarement par les argiles. La masse organique (kérogène) se compose d'hydrocarbures. Ainsi les schistes sont en même temps les matières premières de ciment et le combustible.

Lors de la combustion dans les foyers des générateurs de vapeur et de la pyrolyse des schistes on obtient les déchets solides ayant dans sa composition le silicate dicalcique en quantité de 20 à 60%. Il est mieux d'utiliser ces déchets lors du broyage du ciment portland ou, s'ils contiennent le kérogène résiduel, en qualité du combustible secondaire. Les schistes mélanitiques possèdent un effet fluidifiant des boues de ciment crues et peuvent être utilisés en général au lieu des argiles.

Inorganic substance of oil shales is represented in general by calcium carbonates mixed with clay, rarely by clay alone. Organic substance (kerogen) consists of hydrocarbons. Thus shales are simultaneously raw material and fuel.

In the process of burning in boiler furnaces and after pyrolysis, solid byproducts are received, that contain dicalcium silicate amounting 20-60%. The best way of using such byproducts is to utilize them during portland cement grinding, or as secondary fuel, on condition they contain residual kerogen.

Melanitic shales have a liquefying capacity when added to raw material cement slimes and can be used, in general, instead of clays.

Shales and solid wastes of their thermal processing may be effectively used in a wide scale as a source of thermal energy and raw materials in the cement industry which is characterized by high heat and mass consumption.

In the Soviet Union promising areas of shale mining, in addition to the Baltic basin, are Carpathians, the Dniester and Volga regions and the basin near river Pripyat, there are also considerable deposits in the Komi ASSR.

An advantage of shales in relation to coals is that their kerogen mainly consists of hydrocarbons close in elementary composition to raw oils.

The inorganic mass of shales, the amount of which varies from 40 to 90%, usually includes readily fusible clays or mixtures of carbonates with clays (marls).

The calorific value of most shales varies from 3600 to 10,000 kJ/kg or even higher.

The presence of minerals of laminate structure (montmorillonite, hydromica) with kerogen of the humus type ensures high absorption capacity towards organic ions, from 90-110 mg-eq/100 g of montmorillonite to 25-40 mg-eq/100 g of hydromica [5]. Such shales are characterized by low yield of fuel products when heated to 480-530 °C. Complete removal of kerogen from shales of fraction 2-3 mm is achieved only at 900°C in the presence of oxygen. All other combinations of clayey minerals and carbonates independently of the kerogen release the organic substance at lower energy expenditure and in higher relative yields of fuel products at lower temperatures.

Shales and solid wastes containing organic substance which is difficult to remove are very convenient as a secondary fuel, the oxidation of which begins intensively at temperatures of clay dehydration and is completed in the region of limestone decarbonization.

For combustion in steam generator furnaces of modern power stations shales characterized by calorific value higher than 5800 kJ/kg are used, the mineral mass melt should have viscosity not higher than 200 poise at 1500°C in order to ensure liquid removal of ashes. Fuel shales containing not less than 30% of calcium carbonate and with low or moderate content of alumina display such characteristics.

Solid wastes in the form of slags and ashes are formed when burning such shales in steam generator furnaces. Slags usually contain up to 60% of glass phase and practically do not contain fuel. They are also characterized by enhanced hardness, abrasiveness and high resistance to grinding. Ashes contain up to 2% of residual fuel, are highly dispersed and do not require additional grinding.

Despite the short period of the combustion process, the high temperature and dispersion of the fuel ensure completion of the clinker formation reaction as a result of which calcium aluminates, ferrites and silicates are formed. Content of the latter mainly in the form of  $C_3S$  reaches even 6%. Such slags and ashes may be considered as low-grade cements. At sufficiently high carbonate content in shales, for example more than 60%, such slags mainly contain  $C_3S$

and are very close in mineralogical composition to Portland cement clinkers [6]. They may be added to Portland cement during grinding. Due to the high content of clinker minerals a significant amount of these slags may be added during grinding without deterioration of cement quality. Ashes are especially effective as a raw material component during burning of clinker.

A characteristic feature of such wastes is high exergy [2] which ensures considerable economy of heat in the production of Portland cement.

Pyrolysis of fuel shales at 480-530°C in most cases does not ensure complete (100%) removal of hydrocarbons. A considerable amount (from 20 up to 50% of initial content) remains in the solid residue, semicoke or ash. Such solid wastes may be effectively used as secondary fuel in clinker burning in units equipped with cyclone heat exchangers.

The raw mix in kilns with cyclone heat exchangers is heated in the first cyclone up to approximately 280°C. When using semicoke or ashes, even in the case of direct contact with oxygen, intensive oxidation of the kerogen does not occur at these temperatures. However since these materials were already subjected to thermal destruction the raw mix as a whole is better prepared. In the second and third cyclones where the temperature is increased to 480 and 650°C, due to direct contact with the oxygen of flue

gases kerogen oxidation is considerably intensified (exothermal effect, Fig.1, curve 2) which facilitates thermal preparation of the material in the kiln.

Fig.1. Differential thermal curves

Raw mixes containing natural shales behave slightly differently. The maximum of exothermal effect is shifted towards lower temperatures (Fig.1, curve 1) due to desorption and oxidation at lower temperatures of the light fractions which have higher calorific values. The exothermal effect for most shales begins at 250-300 °C and continues to 700-800 °C and for some shales up to 900 °C (Fig.1, curve 1);

The amounts of shales and their wastes added depends on the chemical and mineralogical composition. Clayey (carbonate free) shales may be added in amounts of only 20-25% (of calcined mass) in the production of common Portland cements. With increase of the amount of carbonates, addition of shales may be increased in proportion to the carbonate fraction.

The use of untreated shales in raw mixes when the cyclone heat exchangers are not used should be restricted on account of possible contamination of the atmosphere with hydrocarbons. The thermal regime may also be considerably distorted along the kiln, the redox processes destabilized resulting in changes in mineral composition of the cement clinker.

A distinctive feature of shale pyrolysis in units with solid heating medium is the high degree of extraction of fuel products, up to 85-90% in organic mass.

Such ashes may be used without detrimental effects in existing technologies.

Cement-raw material slags of menilite shales and their semicokes exhibit enhanced fluidity. Ultimate shearing stress of shale

slags is 150 mg/cm<sup>2</sup> in contrast to 600mg/cm<sup>2</sup> of clayey slags at average moisture content of 38-40%.

The technology of cement clinker production with addition of shales does not meet with any difficulties.

Energy consumption from grinding of the raw mix and the effectiveness of the main technological equipment is on the same level as for traditional raw materials.

Correction of the slags does not meet with any difficulties.

There was some apprehension about possible sedimentational stratification of the corrective slags, however addition of a certain amount of clay, and sufficiently fine grinding of the shale provide satisfactory sedimentational stability of the slags.

Calcination of cement clinker in rotary kilns (L=150 m, d=3.0-3.4 m) is more stable for the experimental slag than for a common slag; The clinker formed is characterized by grain sizes less than 10 mm (up to 80%).

Petrographic studies of the clinker showed that synthesis of clinker mineral was completed, free CaO is practically absent. Crystals of clinker minerals have mainly submicroscopic sizes.

A trial cement clinker had the following mineral composition: C<sub>3</sub>S - 59.92%, C<sub>2</sub>S - 18.30%, C<sub>3</sub>A - 6.85%, C<sub>4</sub>AF - 14.20% and fully met the requirements for the production of high quality Portland cements.

Physico-mechanical tests of a trial batch of cement clinker and Portland cement established the possibility of stable production of "400" and "500" or even higher grade cements.

Of considerable interest is the scheme of industrial treatment of fuel shales in fluidized state with simultaneous production of cement clinker and generation of steam [5]. Despite relatively low calorific value of the shale used (3832 kJ/kg) the process was very economical.

Some progress has been made in the USSR in the development of the technology of shale combustion with simultaneous production of cement clinker in furnaces of high-power steam generators [6].

As sufficiently high levels of fuel and carbonate content in the shales a high degree of autothermal combustion may presumably be achieved.

In cement clinker calcination according to existing technologies it is recommended to first extract fuel products, which may be recycled (Scheme, Fig.2), and then subject the shales to pyrolysis. The obtained solid residue (semicoke or ashes) may then be used as a raw mix component.

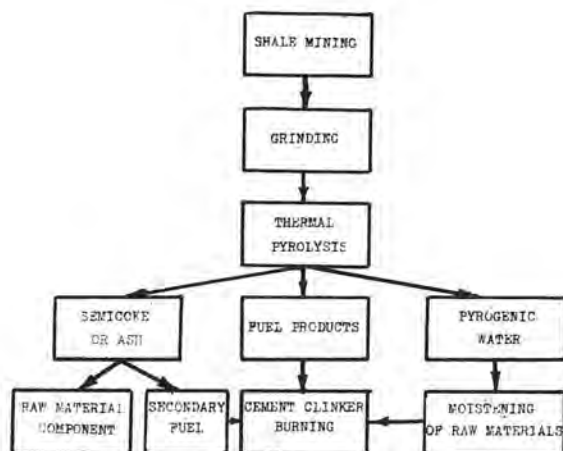

Fig.2. Scheme of complex usage of oil shale

Bearing in mind the increasing cost and decreasing resources of fuel and the abundance of fuel-containing rocks, new plants should be designed for a new type of raw material and fuel basis which will be a guaranteed and stable source of thermal energy and raw materials for many centuries.

## THEME II

### Hydratation des ciments portland sans constituants secondaires

#### *Hydration of pure Portland Cements*

---

#### On the process of $C_3S$ hydration in initial period *Etude sur le processus d'hydratation de $C_3S$ à la période initiale*

Y.S. MALININE,  
V.I. GOUSSEVA,  
N.D. KLICHANIS, niitsement, Moscou, URSS.

On a établi la morphologie identique des produits d'hydratation de  $C_3S$  et de  $CaO$  à la période initiale de l'interaction avec de l'eau. On a également établi que les particules amorphes arrondies, les formations fibreuses et en forme de cigare, les agrégats lamellaires observés dans les microscopes électronique et optique lors de l'hydratation du silicate tricalcique, sont semblables, quant à leurs indices morphologiques, aux produits d'hydratation de  $CaO$  pur dans les memes délais d'hydratation et représentent les différents stades de cristallisation de  $Ca(OH)_2$  et de  $CaCO_3$ . La formation des hydrosilicates de calcium n'est pas en général une fonction primaire (comme l'affirmaient de nombreux chercheurs) mais une fonction secondaire de la surface de la frange de gel formée autour des grains de départ de  $C_3S$  aux points de contact avec  $Ca(OH)_2$  dans les délais d'hydratation plus avancés.

The identity of  $C_3S$  and  $CaO$  hydration products morphology in initial period of interaction with water has been discovered. Spherical amorphous particles, cigar-shaped and fibrous formations, and slaty splices, observable in electron and light microscop during tricalcium silicate hydration have been found to be similar by morphological indications with the products of pure  $CaO$  hydration in the same periods of hydration and represent different stages of  $Ca(OH)_2$  and  $CaSO_3$  crystallization.

In general, calcium hydrosilicate is not the primary, as is claimed by many an investigators, but a secondary function of gel rim surface around  $C_3S$  initial grains in contact points with  $Ca(OH)_2$  at later hydration periods.

The mechanisms of hydration and structure formation of the  $C_3S$  and CaO hardening

grout were studied by the petrographic and electron microscopy methods.

The hydration mechanism was investigated on slides comprising a fine layer of the cement-water mixture placed between the stage and cover glasses which were bonded to each other with a heated paraffin-rosin mixture.

The suspension water-to-cement ratio was 0.8-10.

All the changes taking part in the hydration processes were observed in the slides which constantly contained water without access of air for a prolonged period of time.

To determine the phase composition of the hydration products, the slides were open and their optical constants were found out by the immersion method.

The replicas of the same slides were investigated on an electron microscope.

The morphology of the hydration products at the grain-to-water contact and in the inter-grain space formed in the course of time was traced which was impossible for a conventional microscope.

The structures of hardened  $C_3S$  and CaO samples were studied on transparent polished sections (thinnest slices of hardened samples) by a polarizing microscope and on the replicas of chips of the same samples by the electron microscope.

The contact between the  $C_3S$  crystal surface and water was studied on ground slices of the mineral lumps from the moment of establishing said contact and up to 1 day with the use of the optical and electron microscopes.

As a result of the investigations performed, three morphological forms of the  $C_3S$  hydration products were detected;

- 1 - spherical particles;
- 2 - fibres, cigar- and tree-shaped formations, frequently of the characteristic sheaf-like shape;
- 3 - large crystals and flaked concretions of CH.

These forms of the hydration products are observed both in the suspensions and in the samples with normal W/C ratios. Such products have been frequently disregarded as calcium hydrosilicates.

However, similar morphologic forms of the hydrate phases were also observed when hydrating pure CaO.

For instance, when  $C_3S$  and CaO were hydrated in a suspension, all the above-mentioned forms could be observed on the water surface where first neogenes appeared, obviously owing to surface tension. Initially, there were shapeless isotropic rounded particles, later tight anisotropic spherulites

Fig.1. ( $C_3S$ ). 6h of Hydration. Electron Microscope, X1400

with partial carbonization. While growing, the spherulites disintegrate into separate fibres and "cigars" and get carbonized; Fig.1 ( $C_3S$ ), Fig.2(CaO) - electron microscopy.

The process of formation of the cigar-shaped particles on the surface of the  $C_3S$  grains may be observed by carrying out the following experiment. Pour a freshly crushed  $C_3S$  mineral powder onto a water surface, several minutes of hydration in contact with air will result in needle- and cigar-shaped particles on the grain surface, said particles increasing in size and carbonizing with time. These may be observed through an opti-

Fig.2. (CaO). 6h of Hydration. Electron Microscope, X10000

Fig.3. ( $C_3S$ ). 24h of Hydration. Transmitted Light, without Analyzer, X1200

cal microscope.

The morphological transformations of new formations is also observed in plastic samples with  $W/C=0.5$  on the water surface during water separation.

As regards the internal portions of the samples, the following phenomenon is found there. Water separates ions  $Ca^{++}$  from the surface of the  $C_3S$  crystals and an isotropic border is formed within the initial grains with time. According to its optical constants the border relates to a silica gel (its  $N$  is not below 1.50, whereas the unhydrated core is anisotropic and has refractive indices characteristic of  $C_3S$ ),

Fig.3.

These observations made it possible to suppose that during hydration of  $C_3S$  only calcium transfers to the solution, while silica remains in the solid phase in place of the initial grains.

With time (1 day of hydration) cigar- and tree-shaped particles are still found in the inter-grain space, and later large CH crystals.

In case of samples with a low  $W/C$  ratio, the proportion of the morphological forms changes. Since the solution is more rapidly saturated with lime, there are few spherical particles in the hardened sample; often fibres and cigar-shaped particles grow directly from the  $C_3S$  particle surfaces and large CH concretions are crystallized at oversaturation, Fig.4. The growth of large CH crystals from cigar-shaped and fibrous formations may be also observed at hydration of CaO; This is seen from Fig.5 (the replica of the CaO hardened sample). Hydration of a ground surface of the  $C_3S$  lump slice has revealed that immediately on contacting water spherical particles are formed on the surface of the  $C_3S$  crystals, said particles

Fig.4. (CaO). 24h of Hydration. Electron Microscope, X14000

converting into polygons rapidly and being essentially portlandite.

Intensive migration of calcium ions from the internal areas of the sample assists in rapid formation of large CH crystals without intermediate forms.

Thus, the spherical, fibrous and cigar-shaped particles observed at the initial period of the  $C_3S$  hydration, as well as large crystals and flaked concretions of CH are the products of morphological conversion of CH and  $CaCO_3$ .

The same regularity was detected at hydration of CaO.

In view of the above, it is possible to

conclude that the primary hydrate phase is CH rather than calcium hydrosilicate which is the secondary function of the silica gel border around the initial  $C_3S$  grains at later period of hydration.

# Influence of organic compounds on the hydration reaction of tricalciumsilicate

## *Influence de certains composés organiques sur l'hydratation du $C_3S$ .*

C. STADELMANN and W. WIEKER, Zentralinstitut für Anorganische Chemie der Akademie der Wissenschaften der DDR - Berlin, R.D.A.

### Summary:

The influence of several organic compounds of simple structure on the hydration rate of  $C_3S$  was investigated by means of differential calorimetric analysis (DCA).

The results of these measurements in combination with those of further chemical investigations show that hydration rate of  $C_3S$  is strongly dependent on the calciumionconcentration in the liquid, water containing, phase.

Lowering the dielectric constant of the water by adding alcohols used in the hydration experiments the reaction rate is always decreased in an amount which corresponds to the dielectric constant in the water-alcohol mixture and the solubility of calciumhydroxide in this medium.

Organic compounds, able to form complexes with calciumions, like organic acids and their sodium salts accelerate the hydration reaction because of the lowered calciumion activity in the liquid phase. At higher concentrations of organic acids or of their sodium salts the hydration rate is decreased as a result of an increase of adsorption of these organic molecules at the grainsurfaces of the  $C_3S$ .

The mentioned effect is shown to be dependent on the strength of the complex forming tendency of the added organic compound. To understand fully the influence of organic acids on the  $C_3S$ -hydration we must futher assume the formation of a silicagel like cover at the  $C_3S$  grains that lower the reaction rate drastically.

RESUME : On a étudié, au moyen de l'analyse calorimétrique différentielle (A.C.D.) l'influence de plusieurs composés organiques sur la vitesse d'hydratation du  $C_3S$ . Celle-ci est fortement influencée par la concentration de l'eau en ions calcium.

L'addition d'alcool à l'eau, en abaissant ses constantes dielectriques, diminue cette vitesse d'hydratation, selon la solubilité de la chaux dans cette eau alcoolisée.

Certains composés organiques, susceptibles de former des complexes avec l'ion calcium, peuvent accélérer fortement cette hydratation. Si des gels silicatés se forment autour des grains de  $C_3S$ , la vitesse d'hydratation peut être très fortement abaissée.

## Introduction

Recent investigations on the mechanism of the hydration of  $C_3S$  show that a C-S-H-phase rich in CaO is formed immediately after the beginning of the hydration reaction at the  $C_3S$  surface <sup>1,2,3</sup>). By this, its further reaction is prevented so that an induction- or dormant period appears. After the decomposition of this surface C-S-H-cover by a slow release of calcium ions from it into the liquid a very intensive period of hydration takes place, resulting in the formation of C-S-H-phases and  $Ca(OH)_2$ .

Because the use of admixtures increases in last years very rapidly we tried to investigate the influence of admixtures on the chemical reactions during the first stages of the  $C_3S$ -hydration mentioned above.

The investigations were carried out mainly by means of differential calorimetric analysis (DCA). The hydration temperature was 20 °C and the water/ $C_3S$ -ratio 0.5. Some alcohols, ketones, several organic acids, the corresponding sodium- and calciumsalts and a cation exchange resin were chosen as admixtures.

## Results and Discussion

By adding several aliphatic alcohols to the hydration water (1 mol alcohol/1 hydration water) a retardation of the hydration of  $C_3S$  is noted by means of DCA-measurements (fig. 1).

FIG. 1  
INFLUENCE OF MONOMER ALIPHATIC ALCOHOLS (1 MOL ALCOHOL/1 HYDRATION LIQUID) ON HEAT EVOLUTION RATE IN PASTES OF  $C_3S$  (LIQUID/ $C_3S$ =0.5)

By the determination of the  $Ca(OH)_2$ -concentrations in the liquid phase during the  $C_3S$ -hydration ( $H_2O/C_3S = 10$ ) it is shown, that supersaturated  $Ca(OH)_2$ -solutions are produced as well as in experiments with pure water as in those with water-alcohol-mixtures. But the  $Ca(OH)_2$ -concentrations in the hydration experiments with alcohol-water-mixtures increase much slower and get only smaller values than in the experiments with pure water. These effects are seen in fig. 2 using t- and n-butanol as admixtures.

FIG. 2  
EFFECT OF THE ADMIXTURE OF n- AND t-BUTANOL TO THE HYDRATION WATER (1 MOL ALCOHOL/1 HYDRATION LIQUID) ON THE CALCIUM HYDROXIDE CONCENTRATION OF THE LIQUID PHASE IN DEPENDENCE OF THE HYDRATION TIME (LIQUID/ $C_3S$ =10). STRAIGHT LINES:  $Ca(OH)_2$  - SATURATION LEVELS

From these results we suppose, that the rate of the decomposition of the CaO-rich surface C-S-H-cover is decreased by adding alcohols to the hydration water. That means, that the surface-C-S-H gets stabilized whereby the  $C_3S$ -hydration is retarded.

Similar effects are observed by using some other admixtures listed in table 1.

Table 1

Influence of several alcohols and ketones on the II DCA-peak during the hydration of  $C_3S$  compared with the solubility of calcium hydroxide and the dielectric constants ( $\epsilon_r$ ) of the water-additive mixtures

additive (all 1 mol/l)	II DCA-peak (h)	$Ca(OH)_2$ (mol/l)	$\epsilon_r$
water	10.0	$2.21 \cdot 10^{-2}$	80.4
methanol	13.1	2.04 "	78.6
ethanol	14.9	1.70 "	77.4
n-propanol	15.7	1.44 "	76.2
n-butanol	16.0	1.50 "	75.2
i-butanol	15.7	1.37 "	75.8
t-butanol	18.3	1.25 "	74.9
butane-1,3-diol	15.5	1.70 "	77.3
acetone	20.8	1.36 "	77.4
1,4-dioxane	19.5	1.63 "	73.4

The results in this table show, that the retarding effect of those alcohols and ketones are evidently attributable to the decrease of the  $\text{Ca}(\text{OH})_2$ -solubility in the liquid phase caused by the smaller dielectric constants (dc) of the solution phase with respect to pure water.

In contrast to alcohols and ketones, compounds which are able to bind calcium ions, i.e. by complexing reactions, show a complete different influence on the hydration reaction of  $\text{C}_3\text{S}$ .

A very low concentrations shifts of the maximum of the II. DCA-peak to shorter reaction times are observed (acceleration), while at higher concentrations shifts of the maximum of that peak to longer reaction times are found (retardation).

This is shown in Fig. 3 for propionic acid and the corresponding sodium salt as admixtures.

FIG. 3  
DIFFERENT INFLUENCE OF PROPIONIC ACID, OF CALCIUM AND SODIUM PROPIONATE ON THE II. DCA-PEAK OF THE  $\text{C}_3\text{S}$  HYDRATION IN DEPENDENCE OF THEIR CONCENTRATIONS IN THE HYDRATION LIQUID (LIQUID)  $\text{C}_3\text{S} \cdot 0.5$   
THE DATA ARE RELATED TO THE HYDRATION IN WATER (1:1)

But as can be seen from that figure too, an adding of calcium propionate results at all concentrations only in a retardation of the hydration. The accelerating effect of the acid and the sodium salt we attribute to the formation of complexes with the Ca-ions, resulting in a higher capacity of the aqueous solution for Ca-ions. Therefore the retarding  $\text{CaO}$ -rich cover at the  $\text{C}_3\text{S}$  grains can't be formed to a great extent or it is decom-

posed much more faster than in hydration experiments using only pure water. So the acceleration can be explained.

At higher concentrations of propionic acid and sodium propionate at which we found a retardation, we suppose that the organic anions are adsorbed at the grain surfaces. By it a Ca-propionate cover, which hinders the reaction, is formed.

The same effect, we mean, is responsible for the retardation in the hydration experiments with added Ca-propionate. But in that case we have in addition an increased concentration of Ca-ions in the solution, by which the primarily formed  $\text{CaO}$ -rich  $\text{C-S-H}$ -phase is stabilized already at low concentrations.

Using  $\alpha$ -hydroxyacids (i.e. lactic acid) respectively their salts as admixtures the retarding effect is much stronger. This corresponds to the ability of the lactate-ion to form very stable chelate-complexes with the Ca-ions at the  $\text{C}_3\text{S}$ -surface, resulting in a much more effective blocking of the  $\text{C}_3\text{S}$ -surface.

When adding a cation exchange resin in sodium form to the  $\text{C}_3\text{S}$  hydration experiments there is no possibility that complexforming anions can be adsorbed at the  $\text{C}_3\text{S}$  surface, because they are chemically bound to the solid resin. Therefore the admixture of a cation exchange resin should only result in an acceleration as a consequence of the binding of the Ca-ions to the resin and no retarding should occur even at high quantities of the resin added. That this conception fits in very well is shown in fig. 4. In contrast to the sodium form of the resin the addition of a protonated resin results in a retardation of the  $\text{C}_3\text{S}$  hydration. We assume, that this effect is the result of an acidifying of the aqueous solution by the  $\text{Ca} \rightarrow \text{proton}$  exchange processes, which leads to the formation of a silicagel like cover at the  $\text{C}_3\text{S}$  grains. This envelope we mean is capable for the retarding effect, which we also found by adding several acids to the  $\text{C}_3\text{S}$ -hydration.

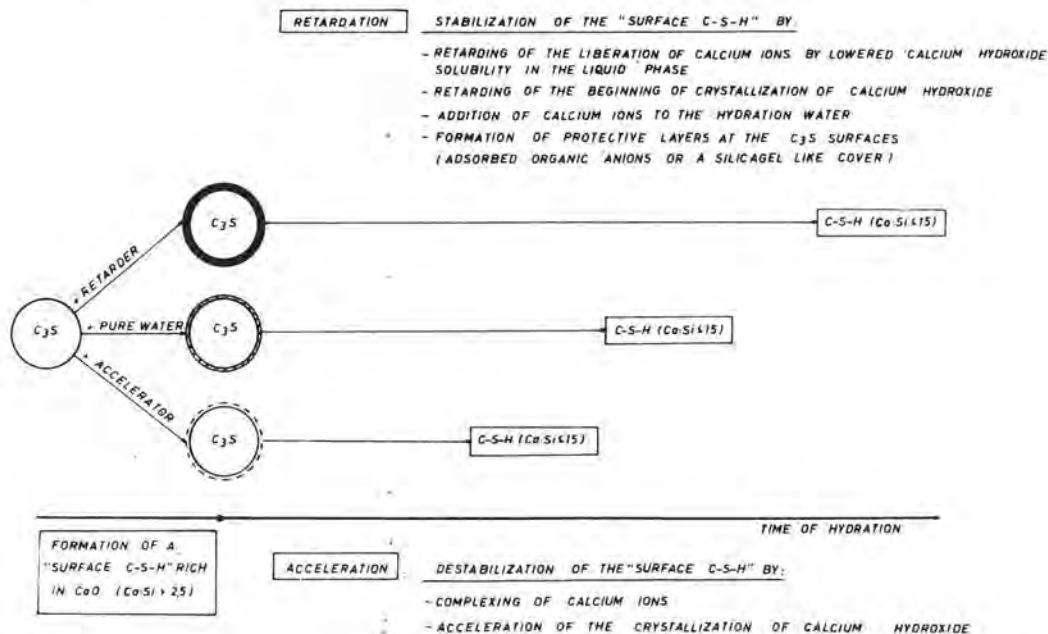

### Conclusions

These investigations show that the effect of admixtures on the hydration rate of  $C_3S$  depends essentially on their influence on the rate of the decomposition of the prima-

rily formed  $CaO$ -rich surface  $C-S-H$ -cover on the  $C_3S$  grains. A stabilization of this  $C-S-H$ -phase gives a retardation of the  $C_3S$ -hydration, and reverse a fast decomposition of this phase accelerates the hydration.

The following scheme shows several possibilities of the influence of admixtures to the  $C_3S$ -hydration. In addition some other effects, which were not discussed in this article in detail are represented at this scheme. A formation of silicate complexes (by adding of pyrocatechol i.e.) or a formation of unsoluble calcium salts (by adding of  $NaF$  i.e.) at the  $C_3S$ -surface also retards the hydration, while an increase of the crystallization rate of  $Ca(OH)_2$  formed during the hydration reaction causes an acceleration of the  $C_3S$ -hydration (by adding of  $CaCl_2$  or  $NaCl$  i.e.).

# Influence des défauts ponctuels sur l'activité d'hydratation des constituants de clinker

## *Point defects influence on the hydration activity of clinker minerals*

V. V. TIMACHEV,

V.G. AKIMOV, Institut Chimico-Technologique Mendéléev, U.R.S.S.

On a étudié le mécanisme de formation des défauts ponctuels de type p-n dans les solutions solides des silicates de calcium et déterminé leur influence sur l'activité d'hydratation des minéraux. Le type, la concentration et la mobilité des porteurs de charge étaient déterminés d'après la mesure des paramètres de l'effet Hall à la température de 25°C. Les caractéristiques d'hydratation sont déterminées par les méthodes de microcalorimétrie et de résonance magnétique nucléaire (écho de spin).

On a établi expérimentalement que la concentration des porteurs de charge libres atteint  $10^{15}$  à  $10^{19}$  T/m<sup>3</sup>, le type de conductibilité par trous dans les minéraux pouvant être changé en conductibilité par électrons par l'introduction dans la composition de la solution solide des ions Fe<sup>3+</sup>, Co<sup>2+</sup>, Ni<sup>2+</sup>. L'augmentation de la concentration des porteurs de charge libres dans les solutions solides du silicate tricalcique de  $2,6 \times 10^{15}$  à  $3,5 \times 10^{18}$  T/m<sup>3</sup> conduit à l'interaction plus efficace des particules de la phase initiale avec l'eau à la période d'hydratation initiale, ce qui fait que la période d'induction commence 18 minutes plus tôt.

The mechanism of electron-hole point defects development in calcium silicates solid solutions has been investigated and their influence on the hydrate activity of minerals has been determined. Type, concentration and mobility of charge carriers were determined by taking measurements of Hall effect parameters at 25°C. Hydration characteristics have been determined by the microcalorimetry method and the nuclear magnetic resonance (spin echo) method.

Experiments ascertained that the concentration of free charge carriers is as great as  $10^{15}$ – $10^{19}$  /m<sup>3</sup>, while hole conductivity in minerals can be changed to electron conductivity by incorporation in the solid solution composition of ions Fe<sup>3+</sup>, Co<sup>2+</sup>, Ni<sup>2+</sup>. Increase of free charge carriers concentration in tricalcium silicate solid solutions from  $2,6 \cdot 10^{15}$  to  $3,5 \cdot 10^{18}$  /m<sup>3</sup> leads to more effective interaction of initial phase particles with water in first hydration period, with the result that induction period sets in 18 minutes earlier.

La défectuosité de la structure cristalline des phases du clinker du ciment portland est un des facteurs déterminant la réactivité du système ciment-eau, les conditions de l'interaction des particules avec l'eau dépendant de la fine structure du constituant pulvérulent (1,2). Les phénomènes qui en résultent se manifestent efficacement sur la surface fortement développée des matières polycristallines et débutent aux centres actifs. L'élucidation des questions liées à une induction artificielle de défauts et au degré de l'influence qu'ils exercent sur l'activité d'hydratation est un problème d'actualité.

Il a été établi (3-8) que dans les solutions solides des phases du ciment il se forme des défauts ponctuels de plusieurs types, dont la concentration est fonction des particularités de la structure du réseau cristallin, du type, de la nature chimique et de la quantité de l'impureté introduite, des conditions de la synthèse, etc. Le présent ouvrage a pour objet la formation des défauts ponctuels à trous électroniques, la détermination de leur influence sur l'activité d'hydratation des minéraux aux premiers stades d'hydratation (ne dépassant pas 180 mn).

Des comprimés d'une charge à composition stoechiométrique ont été cuits sur un support de platine en respectant des conditions de la synthèse identiques pour tous les échantillons. L'identification des solutions solides a été opérée par spectroscopie IR, par analyse thermique différentielle et aux rayons X, par microscopie électronique. Le type, la concentration et la mobilité des porteurs de charge ont été déterminés en mesurant l'effet de Hall à la température de 25 °C. Les études ont été effectuées à une installation pour mesurer la conductibilité électrique, la photoconductibilité et la concentration des porteurs de charge, installation fonctionnant selon le principe de deux champs variables - électrique et magnétique - aux fréquences de 58 et 50 Hz respectivement. Les caractéristiques d'hydratation sont établies par les méthodes de microcalorimétrie et de résonance nucléaire magnétique (écho de spin).

Les recherches effectuées ont confirmé par voie expérimentale l'existence de porteurs de charge libres dans les solutions solides de  $C_3S$ ,  $C_2S$ ,  $C_3A$  (Tableau 1), le type de conduction étant fonction, comme il a été établi, de plusieurs facteurs. Des particularités de la structure cristalline, des défauts, des écarts à la stoechiométrie font apparaître une conduction par trous (type r) dans les échantillons. L'incorporation d'ions étrangers dans le réseau cristallin lors de la formation des solutions solides, ainsi que le remplacement des radicaux principaux de la structure et des ions  $Ca^{2+}$ ,  $Al^{3+}$ ,  $Si^{4+}$  modifient considérablement les paramètres du réseau. On constate des changements du caractère ionique ou covalent des liaisons. En outre, la redistribution de la densité électronique des liaisons de valence soit fait augmenter la concentration des porteurs de charges libres de type r, soit conduit au

remplacement de ce type de conduction par le type contraire (type p).

L'analyse des résultats obtenus a montré un brusque changement des propriétés des solutions solides lors des conversions d'une variété en une autre (fig.1) et, point le plus important, d'une même variété, ou bien dans le cas d'une redistribution continue de plusieurs phases polymorphes dans les échantillons (fig.2,3).

Fig.1. Variation de la concentration des porteurs de charge (N) et de leur mobilité ( $\mu$ ) en fonction de la teneur de  $C_3S$

Ce dernier phénomène se manifeste d'une manière particulièrement prononcée lors de la formation de solutions solides dans lesquelles la concentration de l'impureté varie dans des limites étendues. C'est ainsi que la substitution des ions  $Mn^{3+}$  aux ions  $Ca^{2+}$  et, dans une faible proportion, aux ions  $Si^{4+}$  conduit à la formation de solutions solides de  $\beta$  et  $\alpha'_L-C_2S$  occupent les places des cations  $Ca^{2+}$  de préférence dans les chaînes du type  $-Si-O-Ca-Si-$ , ce qui donne lieu à une variation du paramètre C de la cellule élémentaire, qui passe de 9,19 Å (1% en masse de  $Mn_2O_3$ ) à 8,98 Å (7% en masse de  $Mn_2O_3$ ), les valeurs de a (5,50 Å) et de b (6,77 Å) restant invariées pour toutes les solutions solides synthétisées. Les changements concernant les anions sont peu importants. La formation des solutions solides de  $\alpha'_L-C_2S$  est due au remplacement des ions calcium

b et une augmentation du paramètre C de la cellule élémentaire. La substitution des ions manganèse aux ions calcium par suite de l'incorporation de  $Mn_2O_3$  dans la structure de  $C_2S$  fait apparaître la conduction du type r à l'état de valence, qui s'implifie logiquement avec l'augmentation de la concentration de  $Mn_2O_3$ . Ce phénomène résulte de la redistribution de la densité électronique des liaisons de valence lors de la substitution de  $Mn^{3+}$  à  $Ca^{2+}$  dans les chaînes  $-Ca(Mn)-O-Ca(Mn)-$  et  $-Si-O-Ca(Mn)-Si-$ .

solides de  $C_2S$ . L'activité d'hydratation des minéraux a été étudiée par les méthodes de microcalorimétrie et de résonance nucléaire magnétique à impulsions (écho de spin). Cette dernière méthode ne convient pas quand il s'agit d'étudier la mobilité des molécules d'eau au cours de l'hydratation (9,10). On a déterminé les durées de la relaxation longitudinale ( $T_1$ ) et de la relaxation transversale ( $T_2$ ) des protons par les méthodes à impulsions ( $180^\circ-90^\circ$ ) et on a calculé leurs rapports pour de différentes durées d'hydratation. Une poudre aux grains de tailles uniformes (25 à 30 microns) a été gachée, avant l'expérience, avec de l'eau distillée dont le rapport B/T est égal à 0,5.

Les courbes cinétiques  $T_1$ ,  $T_2$  et  $T_1/T_2$  sont mises en corrélation avec les courbes représentatives du dégagement de chaleur, l'existence d'inflexions sur ces courbes attestant une nette division de l'hydratation de  $C_2S$  en stades (fig.4). Au moment initial de gâchage on observe une brusque diminution des grandeurs  $T_1$  et  $T_2$  des échantillons examinés par rapport à l'eau pure ( $T_1 \approx T_2 \approx 3s$ ); ce qui est dû à un affaiblissement de la mobilité des molécules d'eau par suite de leur adsorption sur les centres actifs de la surface du solide. Etant donné que la grandeur  $T_1$  est fonction de la surface des matières hydratées (11), la décroissement de la durée de relaxation et du rapport  $T_1/T_2$  à la première étape de l'hydratation (jusqu'à 60 mn pour  $C_2S$ ) est dû à la dissolution de  $C_2S$ , au passage, surtout des ions  $Ca^{2+}$ , en solution, à leur hydratation et à la formation de l'hydrate  $3CaO \cdot SiO_2 \cdot nH_2O$  sur la surface du grain initial. Ensuite, l'hydratation se ralentit brutalement et entre dans une période d'induction, dont le début coïncide avec l'accroissement de  $T_1$  et une inflexion sur la courbe  $T_2$ , ce qui peut être dû à la formation d'un hydrate ayant pour formule  $1,6CaO \cdot SiO_2 \cdot nH_2O$ , qui présente un caractère cristallin moins prononcé et une surface unitaire plus développée que l'hydrate  $3CaO \cdot SiO_2 \cdot nH_2O$ . Avec toute nouvelle accélération de l'hydratation, les

Fig.5. Relation entre la vitesse de la variation du temps de relaxation des protons  $T_1$  (ms) et la durée d'hydratation  $\tau$  (mn)

L'influence des défauts ponctuels sur la réactivité du liant est particulièrement manifeste lors de l'hydratation des solutions

Fig.4. Variations de l'intensité du dégagement de chaleur ( $dQ/d\tau$ ), des durées de relaxation des protons ( $T_1$  et  $T_2$ ) et de leur rapport lors de l'hydratation de  $C_3S$

durées des relaxations longitudinale et transversale décroissent régulièrement, mais le rapport  $T_1/T_2$  commence à croître par suite de la formation d'une nouvelle couche extérieure de  $Ca(OH)_2$  et de cristaux hydratés C-S-H dans lesquels les molécules de  $H_2O$  ont une faible mobilité.

L'accroissement de la concentration des porteurs de charge libres par incorporation d'ions étrangers à la composition de la solution solide a pour effet une interaction plus efficace des particules de la phase initiale avec l'eau dans la période initiale d'hydratation. Il en résulte que la période d'induction commence plus tôt qu'en cas de  $C_3S$  pur (fig.5). C'est la conséquence de l'intensification de l'adsorption et de la dissociation des molécules d'eau en ions  $OH^-$  et  $H^+$  avec établissement de liaisons entre les ions  $Ca^{2+}$  et  $OH^-$  et entre

$O^{2-}$  et  $H^+$ . Il se produit un changement dans la structure électronique des ions en réaction, qui s'accompagne d'un passage d'électrons des ions à charge négative aux ions à charge positive, ce qui entraîne un relâchement des liaisons dans le réseau cristallin de la phase initiale. L'accroissement de la concentration des porteurs de charges des types r et p contribue au déroulement de ces processus.

Les défauts ponctuels du type à trous influent également sur l'adsorption des molécules d'eau lors de l'hydratation de  $C_2S$ ,  $C_3A$  et de leurs solutions solides, mais la périodicité est la plus manifeste quand on étudie l'hydratation de  $C_3S$  par la méthode de résonance nucléaire magnétique.

On constate donc que les défauts ponctuels accentuent les aptitudes réactionnelles des minéraux du clinker au début de l'hydratation et exercent par là une influence sur la mise en forme de la structure de solidification aux étapes ultérieures.

# Electron microscope investigation of sulfoaluminate calcium hydration processes at the first stages of solidification

## *Etude microscopique électronique des processus d'hydratation du sulfoaluminate de calcium dans les premiers délais de durcissement*

V.A. DMITRIEVA,  
T.V. KOUZNETSOVA, Niitsement, Moscou, U.R.S.S.

On a étudié les produits d'hydratation des particules minces du sulfoaluminate de calcium qui se forment dans les premiers délais du durcissement dans la suspension.

On a relevé plusieurs types morphologiques de formation des phases hydratées dans un seul microvolume, ce qui témoigne de voies différentes de cristallisation:

- les cristaux croissent directement à partir du minéral de départ;
- les nouvelles formations hydratées se trouvent en contact avec la masse amorphe granuleuse secondaire des produits d'hydratation;
- les composés hydratés cristallisés à partir de la solution.

Dans tous les cas on observe des cristaux aciculaires d'ettringite ayant une structure tubulaire. Les données obtenues peuvent être utilisées pour élucider le mécanisme de l'hydratation et de l'expansion des ciments sulfo-alumineux.

Fine sulfoaluminate calcium particles hydration products generating at the first stages of solidification in suspension have been investigated.

Several morphological models of hydration phases in one microvolume have been revealed, what indicates different ways of crystallization: a) crystals grow up directly from initial mineral; b) hydrate new formations are in contact with secondary granular amorphous substance of hydrate products; c) hydrate combinations, crystallized out of solution.

In all cases needle ettringite crystals with tubular structure are reported. The data obtained can be used for clearing up the mechanism of hydration and widening of sulfoaluminate cements.

**SUMMARY.** IN the last few years much interest has been shown in the study of  $C_3A_3CS-H_2O$  system owing to the development of special cement production. In spite of the intensive investigation of the calcium sulfoaluminate hydration process its early stage of an interaction with water has not been clearly studied so far.

The present paper investigates the hydration products of the calcium sulfoaluminate fine particles formed in suspension at early ages of hardening.

It has been found that several morphological types of hydrate phases are present in one microvolume:

- crystals grow directly from a starting mineral;
- hydrate new formations are in contact with secondary amorphous grainy mass of hydration products;
- hydrate compounds crystallized out in solution.

Acicular crystals of ettringite having tubular structure have been observed in all cases. The data obtained can be used for revealing the mechanism of hydration and expansion of sulfoaluminate cements.

**INTRODUCTION.** Many papers deals with hydration reactions of cement at early stages of hydration. For a long time scientists have considered phase equilibria in the systems:  $CaO-SiO_2-H_2O$  and  $CaO-Al_2O_3-H_2O$  and

then in more complex systems containing  $CaSO_4$ ,  $Fe_2O_3$  along with  $CaO$ ,  $SiO_2$  and  $Al_2O_3$ .

Extensive literature is available on composition of products of a clinker mineral interaction with water (1,2), chemistry of a portland cement hydration process has been studied well (3,4). Scientists are mainly of the same opinion about the composition of hydration products and their studies are reduced to refinement of the ratio of C/S and C/A, the quantity of crystal water in hydrate compounds.

Up till now there are serious differences in the opinions about the mechanism of hydration and structure formation (5-8), since a composition of new formations cannot be used as evidence for topochemical and solution mechanisms of a hydration process. At present intensive investigations using different methods are carried out in the area of origin of a hydrate phase and its morphology. Using a mathematical model

of a cement stone structure, thermodynamic conceptions of origin of new phase nuclei and data on kinetics of a solution process of a starting phase A.F. Polack (5-5) has shown that cement hydration proceeds through solution of anhydrous compounds and hydrate crystallization mainly on the surface of a starting grain of cement. L.G. Shpynov deals with morphology of cement hydration products during long hardening of a cement stone and I. Skalni (10) has recently published the result of investigations of early stages of portland cement hydration with a scanning electron microscope.

The aim of this work was to investigate morphology of the crystals formed at early stages during an interaction with water of calcium sulfoaluminate of  $3CaO \cdot 3Al_2O_3 \cdot CaSO_4$  having great importance in production of rapid-hardening, non-shrink, expansion and tension cements.

**MATERIAL OF THE INVESTIGATION.** Sulfoaluminate was synthesized from  $CaCO_3$ ,  $Al_2O_3$  and  $CaSO_4 \cdot 2H_2O$ , analytical grade, by bur-

Fig.1. Radiogram (1) and ir-spectrum (2) of calcium sulfoaluminate

ning a stoichiometric mixture at  $1350^\circ C$ . The mineral obtained was characterized by the

refraction index of  $N=1.571$ .

The sample radiogram has diffraction lines:  $cd=3.75$ ;  $3.21$ ;  $2.89\text{\AA}$ ;  $2.15\text{\AA}$  and its IR-spectrum shows absorption bands in the area of  $400-500$ ;  $1000-1100$ ;  $3400-3650\text{ cm}^{-1}$  (Fig.1).

The chemical composition of the sulfoaluminate investigated is represented by (%):  $\text{CaO}=36.7$ ;  $\text{Al}_2\text{O}_3=50.2$ ;  $\text{SO}_3=13.1$ .

**EXPERIMENTAL PROCEDURE.** Preparations were made by grinding synthesized calcium sulfoaluminate up to fine particles, with thickness of several tens of angstroms ( $\text{\AA}$ ). Hydration took place in suspension with the ratio of solid; liquid =  $1:50$  and in cement paste with w/c ratio equal to its normal density. After a certain time a liquid phase was filtered and the content of  $\text{CaO}$ ,  $\text{Al}_2\text{O}_3$ ,  $\text{SO}_3$  was determined in it. The filtered solid phase was analyzed with the X-ray diffraction analysis and differential thermal analysis.

In addition, after a certain time a drop was taken from an upper layer of suspension and placed upon the net strengthened with a carbon film. After drying the preparation was investigated with the UEMB - 100K transmission electron microscope having resolving power of  $7\text{\AA}$  at accelerating voltage of electrons of 50 and 75 kW.

**RESULTS OF INVESTIGATION.** At intervals of 10 min, 30 min, 1 hour, 2 hours, 4 hours and 6 days after preparation of suspension or beginning of sample mixing with water it has been found during investigations of the preparations that several types of crystal-hydrates are formed in one microvolume on hydration of  $\text{C}_3\text{A}_2\text{CS}$ .

After 10 minutes one can see submicrocrystals oriented in such a way that there are formed a space lattice with closed cells (Fig.2), transparent plates of calcium sulfoaluminate not effected by hydration, fine

Fig.2. Space lattice from submicrocrystal hydrates (X4000)

whisker crystals and amorphous formations of hydrates.

All four types of hydrate new formations were observed in the subsequent above-mentioned periods.

There are, however, some differences residing in the fact that in the course of time the quantity of submicrocrystals forming fine sieve is decreased, as does the quantity of sulfoaluminate particles not effected by hydration while the quantity of gel-like formations and whisker crystals increases.

The later become thicker and while interweaving form a skeleton (Fig.3). Lack of a

Fig.3. Skeleton from interwoven and intergrown pulled crystals of ettringite (X4000)

starting grain in the places of interweaving and intergrowth of submicrocrystals and pulled crystals can demonstrate crystal growing of hydration products in solution.

At the same time one can also see intergrowth of pulled crystal-hydrates with calcium sulfoaluminate particles (Fig.4) and gel-like mass of alumina hydroxide (Fig.5). Fig. 3, 4 and 5 show a new formation after six days of  $\text{C}_3\text{A}_2\text{CS}$  hydration in suspension.

Of interest, to our opinion, is the structure of ettringite crystals in these figures which have a clear tubular structure. In Fig.4 outer diameter of an ettringite crystal tube is about  $0.6-0.8\text{ k}$  while wall thickness -  $0.01-0.02\text{ k}$  in Fig.5. Ratio of the tube thickness to the outer diameter is  $\frac{1}{6} - \frac{1}{4}$  in both examples.

It has been found that tubular crystals sometimes break down rapidly during preparation drying.

It appears in the fact that pulled crystals become discontinuous, like strokes, and defects develop in a matrix.

Table 1 summarizes the results of chemical analysis of a liquid phase on  $\text{C}_3\text{A}_2\text{CA}$  hydration.

Table 1

Chemical composition of filtrate

Time of hydration, hours	Content, mg/l		
	$\text{Al}_2\text{O}_3$	$\text{CaO}$	$\text{SO}_3$
1	1104	608	432
7	1052	607	175
17	1040	600	137
24	485	308	36

Fig.4. Ettringite crystal intergrown with particle of calcium sulfoaluminate (X75000)

Fig.5. Ettringite crystal intergrown with gel-like mass of aluminum hydroxide (X75000)

The results of the liquid phase chemical analysis show that the ratio of C/A in a liquid phase is close to that in starting  $C_3A_3CS$  while the sulfate quantity in terms of  $SO_3$  is somewhat lesser than in calcium sulfoaluminate. On further hydration (up to 24 hours) the concentration of  $CaO$ ,  $SO_3$  and  $Al_2O_3$  decreases sharply. The C/A ratio remains practically unchanged. X-ray diffraction studies have shown that at the first hours calcium hydrosulfoaluminate of trisulfate form is present in a solid residue after filtration of suspension. The quantity of the calcium hydrosulfate grows rapidly with increase in time of hydration. Calcium hydroaluminates have been also found in the composition of hydration products.
