LA RECRISTALLISATION AU DURCISSEMENT est bien montré dans le travail (6) mais ses calculs théoriques sont vagues. L'analyse énergétique montre qu'elle est causée par le changement d'énergie d'attraction entre les ions des substances dissoutes et les particules des hydrates cristallins dont les tailles et la constante diélectrique sont différentes. Lors de la superposition des sphères d'attraction des particules de l'hydrate cristallins dont la constante diélectrique est différente (par exemple  $Ca(OH)_2$ ,  $\epsilon_2 = 5,39$  et C-S-H  $\epsilon_2 = 14,2$ ) les ions de la substance dissoute ne s'orientent que vers le cristal C-S-H dont l'énergie d'interaction avec ion est plus forte. Le cristal C-S-H grandit plus vite ce qui augmente plus l'énergie d'attraction entre le cristal et les ions. Enfin le moment viendra quand la sphère d'attraction dépasse celle du cristal  $Ca(OH)_2$  et tous les ions ne s'orientent que vers le grain C-S-H (on peut calculer précisément ce schéma). La sortie des ions de substance de la couche diffusée du cristal  $Ca(OH)_2$  conditionnera sa dissolution lors de la croissance ultérieure du cristal C-S-H. Cette régularité conditionne la diminution de la basicité des hydrosilicates lors de la recristallisation et la croissance des gros cristaux en compte de la dissolution des petits.

#### LA FORMATION DE LA STRUCTURE DU DURCISSEMENT

Suivant la croissance des cristaux de l'hydrate la distance entre eux diminue. Ceci conduit à la décroissance de la constante diélectrique d'eau dans l'espace entre les cristaux et à la croissance des forces d'attraction entre eux. Ayant formé à l'intérieur du mortier des germes de tailles critiques quand l'énergie d'attraction entre eux dépasse l'énergie de liaisons intermoléculaires dans la structure d'eau, on note l'augmentation sensible de la solidité structurale du système. A cette période la structure se compose des particules de tailles colloïdales. On peut étudier le processus de rapprochement des particules solides de l'hydrate suivant les relations d'énergie d'interaction données ci-dessus. Lors de la diminution de la cou-

che et de la constante diélectrique d'eau les forces de liaison entre les cristaux augmentent et peuvent être calculées suivant la relation, basant sur la loi de Koulon

$$F_{i-1} = \frac{q_1 q_2}{4\pi \epsilon_0 \epsilon_1 r^2}, \quad (11)$$

où  $q_1$  et  $q_2$  - charges des ions superficiels de ces particules, car on a montré que l'interaction entre les ions peut être représentée comme l'interaction de deux ions proches de la surface de ces particules.

Les lois révélées de la formation de la structure du durcissement donneront la possibilité de déterminer la structure linéaire de la molécule  $Ca(OH)_2$  et la texture feuilletée du plâtre. La même régularité permet d'expliquer la basse solidité de la structure de la chaux, l'extension du composé additionnée par le plâtre et la chaux, les propriétés universelles du ciment.

Analysant les lois énergétiques on déduit la relation de solidité de la structure de pâte de ciment et de la pierre.

$$R_c = \frac{q_1 q_2 N}{4\pi \epsilon_0 \epsilon_1^m \left[ \frac{2(V - V_{l.ch}) V_1}{k S_{s.s.}} + R_1 + R_2 \right]^2}, \quad (12)$$

où  $N$  - nombre des particules et des contacts à l'unité de la surface de section (voir par exemple (8)),  $V_g$  et  $V_{l.ch}$  - volumes d'eau:

de gâchage et liée chimiquement,  $V_1$  - volume relatif de la couche sphérique d'eau entre les particules de l'hydrate (vers la fin de l'hydratation égal à 0,2-0,3),  $K$  - coefficient de la sphéricité (environ 1,02-1,1);  $S_{s.s.}$  - surface spécifique des particules de l'hydrate,  $R_1$  et  $R_2$  - rayons des ions des particules.

Se basant sur la relation (12) on peut prédire la solidité théorique maximale de la structure de la pierre. La solidité sera plus forte si dans la zone du contact des particules de l'hydrate il n'y a pas de couche d'eau. ( $l = 2(V - V_{l.ch}) V_1 / K S_{s.s.} = 0$ ).

Si les tailles des particules sont  $95 \text{ \AA}$  (9) la résistance à la traction sera 64,6 MePa. Notons que la résistance maximale de la pierre obtenue par D.Roy et G.Gouda (10) est égale à 60,3 MePa. La relation donne de bons résultats suivant la cinétique d'augmentation de la résistivité dépendant du contenu d'eau libre. ( $V - V_{l.ch}$ ). L'écart moyen

compose 2% par rapport aux données expérimentales révélées ci-dessus par les auteurs (10) Ainsi, la relation reflète la cinétique du changement de la solidité de la structure, montre la liaison de la solidité dépendant de l'hydratation (à travers  $V_{l.ch}$ ) et donne

des voies pour augmenter la solidité de la pierre cimentée: l'augmentation  $q, N$  et  $S_{s.s.}$  la diminution ( $V - V_{l.ch}$ ) et  $\epsilon_1^{\text{moyen}}$ .

## CONCLUSION

La méthode de la recherche théorique de la direction énergétique des stades à part du processus d'hydratation avec la mise en évidence des forces motrices intérieures permet de révéler la régularité objective et le mécanisme du processus.

Les relations déduites donnent la possibilité de déterminer les caractéristiques du processus (effet énergétique des stades, concentration de la solution saturée, la durée de la période d'influence et d'hydratation etc. et même la solidité de la pâte de ciment et de la pierre). Notons qu'apparaît la possibilité d'influer sur le processus en changeant les paramètres du système contenus dans les formules de calcul, la prévision de la structure des hydrates obtenus et plus tard - la création des substances dont la structure et les propriétés sont données auparavant.

L'avantage de la méthode proposée pose le problème d'approfondir les connaissances sur la structure (compte tenu d'électronique) de la substance initiale sur les propriétés physico-chimiques afin de donner les calculs précis pour les monominéraux du clinker cimenté et du ciment.

RESUME : Plusieurs problèmes fondamentaux sont étudiés : celui de la congruence de la dissolution de  $C_3S$  ; il est suggéré d'abord d'après les données thermodynamiques qu'il ne convient de parler non pas de la dissolution de  $C_3S$ , mais de celle de son état superficiellement hydroxylé ( $C_3S_{Sh}$ ) par protonation interfaciale directe. Les espèces ainsi constamment renouvelées après leur passage en solution sont les vecteurs de l'hydratation, mais la prise et le durcissement résultent de la précipitation de C-S-H de rapport  $[C/S]_s < 3$ . La vérification de la congruence est obtenue expérimentalement aussi bien dans l'eau de chaux que dans l'eau distillée à l'état dynamique stationnaire réalisé par passage du solvant à flux élevé à travers une couche mince de  $C_3S$  sur filtre dans des conditions telles que les concentrations en chaux  $[C]$  et en silice  $[S]$  ne pénètrent pas trop dans le domaine saturé à nucléation rapide de C-S-H. C'est ce qui se produit en doublant l'épaisseur de la couche de  $C_3S$  et qui donne  $[\Delta C/\Delta S]_p > 3$  en raison de la précipitation de C-S-H. Un modèle d'écriture des étapes élémentaires est proposé et celle du transfert en solution des ions  $Ca^{2+}$  superficiels est utilisée pour établir une loi théorique de diminution de la vitesse en fonction de l'augmentation de  $[C]$ . Cette loi est bien vérifiée par la branche ascendante des courbes d'évolution de  $C_3S$  agité dans l'eau dans un rapport pondéral solide/liquide ( $\ell/s$ ) de 10. En ce qui concerne la variation de composition de C-S-H en fonction de la concentration en chaux dans la phase liquide, la comparaison des résultats obtenus d'une part par fixation ou perte de chaux au contact d'eau de chaux ou d'eau distillée d'un C-S-H préparé avec un  $[C/S]_s$  donné, d'autre part, par formation de C-S-H à partir de  $C_3S$  sur filtre sous courant d'eau distillée, conduit à supposer que la fixation de chaux accompagne la précipitation du C-S-H, mais des expériences actuellement en cours avec les techniques utilisées permettront d'apporter une vérification directe. Enfin, des expériences par passage à travers une couche de  $C_3S$  sur filtre, d'eau et d'eau de chaux pulvérisées, réalisant un  $\ell/s$  comparable à celui d'une pâte, donnent des résultats analogues à ceux obtenus par flux de liquide, ce qui est en faveur de l'unicité du mécanisme à ( $\ell/s$ ) grand ou petit.

SUMMARY : Several basic problems are studied : that of the congruence of the  $C_3S$  dissolution ; first it is suggested, from thermodynamic data, that we should not talk about  $C_3S$  dissolution but talk about the dissolution of its superficially hydroxylated state ( $C_3S_{Sh}$ ) by direct interface protonation. Thus the constantly renewed species after passing in solution are the hydration vectors but setting and hardening result from the precipitation of C-S-H with a ratio  $[C/S]_s < 3$ . Congruence is experimentally verified both with lime water and distilled water in the stationary dynamic state achieved by passing the high flow solvent through a their layer of  $C_3S$ , on filter under conditions such that the lime  $[C]$  and silica  $[S]$  concentrations do not penetrate too much in the super-saturated domain of C-S-H rapid nucleation. This is what happens by doubling the thickness of  $C_3S$  and gives  $[\Delta C/\Delta S]_p > 3$  due to the precipitation of C-S-H. A model describing the early stages is proposed and the expression of the transfer in solution of surface  $Ca^{2+}$  ions is used to establish a theoretical law about the rate decrease as a function of the increase of  $[C]$ . This law is verified by the ascending part of the evolution curves of  $C_3S$  stirred in water with a solid/liquid weight ratio ( $\ell/s$ ) equal to 10. As for the composition variation of C-S-H versus lime concentration in the liquid phase the comparison of results obtained on the one hand by fixation or lime loss on contact with the lime or distilled water of a C-S-H prepared with a given  $[C/S]_s$  and on the other hand by formation of C-S-H from filter  $C_3S$  under distilled water flow leads to assume that lime fixation accompanies C-S-H precipitation but experiments that are being made with the techniques used will allow a direct verification. Finally experiments consisting in passing sprayed water and lime water through a  $C_3S$  layer with an  $\ell/s$  ratio comparable to that of a paste give results that are similar to those obtained with liquide flow, which favours the unicity of the mechanism with a high or low ( $\ell/s$ ).

## INTRODUCTION

La dissolution congruente de  $C_3S$  est encore contestée par certains auteurs (1). A notre sens, il convient d'ailleurs de parler non pas de la dissolution de  $C_3S$  anhydre, mais de celle de  $C_3S_{sh}$  (superficiellement hydroxylé) (2). En outre, c'est un état dynamique du système et non un état statique qui doit être considéré. Pour éclaircir ces notions, nous apportons un certain nombre de résultats expérimentaux et de considérations théoriques, d'ordre thermodynamique et cinétique.

Quelles peuvent alors être les causes de l'écart apparent à la congruence qui se manifeste par un rapport chaux/silice  $(C/S) > 3$  ? Notre point de vue est que ces causes sont : 1) La précipitation de C-S-H de rapport  $[C/S]_s < 3$ , 2) L'enrichissement qui en résulte par complément à 3 de la phase liquide en chaux. Or, l'expérience nous a permis d'établir ce fait remarquable du maintien de la dissolution congruente de  $C_3S_{sh}$  dans un milieu enrichi en chaux.

Le ralentissement de la dissolution de  $C_3S_{sh}$  est-il un effet de "couche protectrice" ou un effet cinétique normal ? Nous apportons une réponse en faveur de la seconde interprétation.

Les mécanismes que nous proposons ne sont-ils valables que quand  $C_3S$  se trouve dispersé dans un volume important de solution  $[(\ell/s) \text{ grand}]$  ? Nos expériences d'hydratation de  $C_3S$  par de l'eau et de l'eau de chaux pulvérisées sur filtre suggèrent que les mécanismes sont les mêmes à  $\ell/s$  grand ou petit.

En ce qui concerne enfin le changement de composition de C-S-H avec la concentration  $[C]$  en chaux dans la phase liquide, il semble que la précipitation de C-S-H dans un milieu plus ou moins riche en chaux et la fixation ou la perte de chaux par un C-S-H déjà synthétisé avec un  $[C/S]_s$  donné, lorsqu'il est plongé dans un milieu plus riche ou moins concentré en chaux, ne soient pas exactement superposables. Mais les protocoles expérimentaux que nous avons mis au point et qui permettent en principe d'obtenir un C-S-H pur au contact d'une phase liquide de concentration stationnaire en chaux et silice seront susceptibles d'apporter une réponse plus précise à cette question.

## METHODE EXPERIMENTALE

Nous avons donné, dans une autre communication (3), une classification des techniques que nous avons utilisées. Ici, il s'agira essentiellement d'études en système ouvert du type  $s/f + \ell$ , consistant à faire passer à travers une couche de solide pulvérulent sur filtre un liquide soit versé soit pulvérisé. Dans une autre publication (4), certains d'entre nous avaient donné les résultats obtenus grâce à des essais du même type mais de courte durée (quelques secondes). Ces essais avaient permis notamment de construire sur le diagramme chaux-silice-eau ( $C_3S_{sh}$ ) une courbe I délimitant le domaine sursaturé à nucléation de C-S-H rapide de celui à nucléation lente ; appliqués à C-S-H, ils avaient également permis d'établir que la dissolution de cet hydrate dans l'eau et l'eau de chaux ne conduisait pas à des compositions appartenant au domaine sursaturé et que le C-S-H était capable de fixer de la chaux aux dépens de la phase liquide. Dans cette publication, nous avons en outre défini les notions de temps de contact  $\theta$  concernant le liquide et de temps de passage  $\tau$ , concernant le solide sur filtre. Nous nous sommes efforcés, dans les expériences décrites ici, de réaliser des temps de contact très brefs et pour cela une couche de  $C_3S$

d'épaisseur  $h$  est uniformément étalée sur un disque de papier filtre d'aire  $a = 102 \text{ cm}^2$ , maintenu par un support en polyéthylène poreux dans un appareil à filtration sous pression millipore. L'échantillon est recouvert d'une seconde feuille de papier filtre et maintenu en place par un disque en matériau poreux élastique lui-même comprimé dans le logement cylindrique de l'appareil par un second disque analogue au support poreux du filtre. L'appareil est relié par une canalisation souple à une pompe péristaltique capable de développer jusqu'à une pression de  $0,5 \text{ N.mm}^{-2}$ . Le débit maximum obtenu à travers l'échantillon est de l'ordre de  $250 \text{ l.h}^{-1}$ . Divers essais ont été effectués différant l'un de l'autre par la masse de l'échantillon et donc l'épaisseur de couche  $h$  et par la composition de la phase liquide : eau, eau de chaux, solution de concentrations en chaux  $[C]$  et en silice  $[S]$  données.

Le débit  $q$  est maintenu constant pendant une durée  $\Delta t$  au cours de laquelle il passe un volume  $V$  de liquide ; le temps de contact  $\theta = ah/q$  est celui pendant lequel un plan du liquide traverse la couche d'épaisseur  $h$ . La difficulté de l'expérience, étant donné l'importance du flux, est de maintenir l'épaisseur de la couche uniforme. Au débit maximum, avec  $h = 0,07 \text{ cm}$ ,  $\theta \approx 0,11 \text{ s}$ . Cela signifie que le liquide recueilli n'est resté à l'état stationnaire que  $0,11 \text{ s}$  au contact de  $C_3S$  c'est-à-dire pendant une durée beaucoup plus faible que les temps de contact réalisés à l'instant initial dans des expériences récentes (5, 6). L'expérience montre que des temps de contact aussi brefs et des vitesses linéaires d'un plan du liquide à travers la couche :  $dz/dt = 0,6 \text{ cm.s}^{-1}$  aussi petites sont nécessaires pour que, d'une part  $[C]$  et  $[S]$  n'excèdent pas de beaucoup la saturation par rapport à C-S-H, d'autre part que ces valeurs soient proches de celles atteintes dans la couche limite au contact immédiat des grains et non des valeurs très inférieures obtenues par diffusion. Si ces conditions sont bien réalisées et qu'en particulier la dilution due à des filets liquides qui ne rencontreraient pas de grains est de faible importance, en doublant l'épaisseur de la couche à débit constant, la vitesse linéaire n'est pas changée mais le temps de contact double de sorte que  $[C]$  et  $[S]$  peuvent pénétrer dans le domaine sursaturé où la nucléation de C-S-H devient rapide. Le fait que le flux du liquide à travers la couche soit grand a de plus l'avantage de rendre négligeable la rétrodiffusion en amont de la couche de sorte que le rapport  $(\ell/s)$  effectif est pratiquement limité par la porosité intergranulaire du lit solide pulvérulent.

Néanmoins, nous avons complété ces expériences par des essais de même principe, mais en utilisant une phase liquide pulvérisée au moyen d'un pulvérisateur de spectrométrie d'absorption atomique qui donne un aérosol exempt de grosses gouttelettes. Un filtre millipore est utilisé et le jet est diaphragmé pour éviter le rassemblement de gouttelettes sur le bord du support du filtre. L'aspiration par la trompe à eau est suffisante pour qu'aucune accumulation de liquide n'ait lieu de sorte que le rapport  $\ell/s$  soit comparable à celui qui règne dans une pâte.

En ce qui concerne les études relatives au changement de composition de C-S-H en fonction de la concentration en chaux dans le milieu, nous avons fait appel à plusieurs techniques : 1) Passage à travers une couche de C-S-H sur filtre d'une solution de chaux de diverses concentrations. 2) Agitation en système fermé de C-S-H préparé indépendamment, dans de l'eau de chaux saturée ; dosage de la chaux et de la silice

dans le C-S-H après dissolution dans HF, puis essai de réversibilité de la transformation par agitation dans un grand volume d'eau du C-S-H ayant fixé de la chaux. 3) Evaluation par les équations du bilan analytique de la composition du C-S-H obtenu par un flux d'eau de longue durée à travers une couche de C<sub>3</sub>S sur filtre. 4) Mise en œuvre de notre technique de filtration rapide ci-dessus décrite pour obtenir, dans des conditions de composition stationnaire de la phase liquide, un C-S-H comme seul résidu solide sur filtre. La composition de celui-ci pourra alors être étudiée avec précision en fonction de la composition du milieu dans lequel il aura été formé et l'état de condensation de la silice dans les ions silicates déterminée par la technique de triméthylsilylation. Ce type d'étude est en cours.

## RESULTATS

Les résultats des essais de filtration à grand débit à travers une couche de C<sub>3</sub>S sont consignés dans le tableau (I). Ils font clairement apparaître les conditions dans lesquelles la dissolution congruente est observée : faible épaisseur de la couche de C<sub>3</sub>S et flux de l'ordre de 2,5 l.h<sup>-1</sup>.cm<sup>-2</sup>. Avec l'eau pure comme solvant, on pourrait objecter qu'en cas de formation de C-S-H, une partie de celui-ci aurait pu être redissous. Mais en partant d'une solution de composition  $[C] = 1,20 \cdot 10^{-3}$  mol.kg<sup>-1</sup>,  $[S] = 0,40 \cdot 10^{-3}$  mol.kg<sup>-1</sup>,  $[(C/S)_\ell = 3]$ , correspondant à la saturation de C-S-H, cette objection n'a plus de valeur et, dans les mêmes conditions de flux et d'épaisseur de couche, on trouve encore un  $\Delta C/\Delta S \approx 3$  ce qui laisse supposer que le domaine de forte sursaturation n'a pas été atteint. De la même façon, avec une solution de chaux de  $[C]^0 = 3 \cdot 10^{-3}$  mol.kg<sup>-1</sup>,  $\Delta C/S$  très peu supérieur à 3.

TABLEAU I

TABLEAU I

	"	10			3,72	1,12	3,32
	"	10			3,70	1,14	3,24
	"	11			3,80	1,15	3,29
eau de chaux pul- vérisée [C] <sup>0</sup> = 3,95	"	12			1,40	0,42	3,33
	"	12			1,41	0,40	3,53
	"	9			1,20	0,40	3,22

Il est donc remarquable que la congruence de la dissolution se conserve avec comme solvant, non seulement une phase liquide déjà saturée par rapport à C-S-H, mais aussi de l'eau de chaux. En revanche, lorsque l'épaisseur de la couche de C<sub>3</sub>S est doublée, on obtient  $[C] > 3 \cdot 10^{-3}$  mol.kg<sup>-1</sup> et  $[(\Delta C/\Delta S)_\ell] > 3$  ce qui s'explique simplement par la précipitation d'un C-S-H de rapport  $[C/S]_s < 3$ .

En effet, alors que dans les essais où  $[(\Delta C/\Delta S)_\ell]$  reste très voisin de 3, la fixation d'eau déterminée par perte au feu est négligeable, même pour des temps de passage de 30 à 45 mn, elle devient importante dès lors que  $[(\Delta C/\Delta S)_\ell] > 3$ . Par exemple, dans l'expérience sur une couche de 0,15 cm de C<sub>3</sub>S (T<sub>II</sub>) avec une solution de concentrations initiales  $[C]^0 = 1,20 \cdot 10^{-3}$  mol.kg<sup>-1</sup> et  $[S]^0 = 0,40 \cdot 10^{-3}$  mol.kg<sup>-1</sup> (Tableau I), l'essai de perte au feu donne après un temps de passage  $\tau = 40$  mn sur une masse résiduelle de 8g (masse initiale 20 g) : 9,7 %, ce qui représente une masse d'eau liée de 0,76 g, correspondant à une masse de C-S-H de 3 à 5 g selon le taux d'hydratation et le rapport  $[C/S]_s$ . La microscopie électronique à balayage met en évidence des amas floconneux qui pourront être complètement caractérisés en poussant ce type d'expériences, suivant le protocole 4) ci-dessus défini, jusqu'à la disparition complète de C<sub>3</sub>S ce qui nécessite des échantillons T<sub>I</sub> purs. De tels essais sont en cours de réalisation. Un autre résultat remarquable apparaissant aussi dans le tableau I est l'extension des mêmes conclusions aux essais dans lesquels le solvant (eau ou eau de chaux) est pulvérisé et où le rapport  $\ell/s$  est très comparable à celui d'une pâte.

En attendant les résultats des essais de type 4, ceux de nos expériences sur la variation du rapport  $[C/S]_s$  du C-S-H avec  $[C]$  dans la phase liquide suivant les protocoles 1) 2) et 3) ci-dessus décrits (méthode expérimentale) tendent à montrer : 1°) que la composition d'un C-S-H de rapport  $[C/S]_s$  donné varie dans des limites assez étroites et avec une cinétique lente lorsqu'il est maintenu dans l'eau de chaux saturée ou dans l'eau pure (Tableau II), 2°) qu'un C-S-H obtenu par filtration continue avec une composition stationnaire du filtrat  $[C] = 4,17 \cdot 10^{-3}$  mol.kg<sup>-1</sup>,  $[S] = 1,25 \cdot 10^{-3}$  mol.kg<sup>-1</sup>, a un rapport  $[C/S]_s = 2$ . Ces derniers résultats, portés également dans le tableau II, ont été obtenus à partir de données analytiques comportant l'analyse quantitative par diffraction X de C<sub>3</sub>S résiduel. Les équations établies par certains d'entre nous (7, 8) pour calculer le nombre de moles et la composition du C-S-H, c'est-à-dire : r et ar, respectivement les nombres de moles de silice et de chaux et  $\gamma$  le nombre de moles d'eau, à partir des données analytiques, sont, en posant :

$$B = [n_C^0 - \Delta(Bq)]M_C + (n_S^0 - \Delta q)M_S$$

$$r = n_S^0 - \Delta q - \frac{pB}{100M_{C_3S}} \left(1 + \frac{a}{100}\right) \quad (1)$$

$$ar = n_C^0 - \Delta(Bq) - \frac{3pB}{100M_{C_3S}} \left(1 + \frac{a}{100}\right) \quad (2)$$

$$\gamma = \frac{Ba}{100M_H r} \quad (3)$$

$M_{C_3S}$ ,  $M_C$ ,  $M_S$ ,  $M_H$  : masses molaires de C<sub>3</sub>S, CaO, SiO<sub>2</sub>, H<sub>2</sub>O ;  $n_C^0$  et  $n_S^0$ , nombre de moles de CaO et SiO<sub>2</sub> dans C<sub>3</sub>S initial ;  $\Delta(Bq) = Bq - B_0q_0$  et  $q = q - q_0$  différences entre le nombre de moles respectivement de chaux et de silice dans le volume V de la solution finale et du solvant ; p : pourcentage en masse de C<sub>3</sub>S résiduel par rapport à la masse m de solide restant

sur filtre ; a, pourcentage en masse d'eau liée par rapport à la masse déshydratée de solide restant sur filtre.

## DISCUSSION

### Étapes élémentaires et cinétique de dissolution-précipitation :

Ces étapes ont été formulées par certains d'entre nous ( 9 ) en éléments de structure avec l'écriture de Kröger et Vink (10).

1) Hydroxylation par protonation des ions superficiels de C<sub>3</sub>S :

(n = 0, 1, 2, 3)

2) Transfert interfacial du solide dans la phase liquide

3) Diffusion des ions de l'espèce i de concentration C<sub>i</sub> de l'interface vers l'intérieur de la solution dans des conditions d'agitation données ou en milieu stagnant :

$$\text{div } D_i \text{ grad } C_i = \frac{\partial C_i}{\partial t}$$

4) Nucléation et croissance de germes de C-S-H : Etant donné la variation de composition du C-S-H en fonction de [C] dans la phase liquide, probablement due à l'existence d'une solution solide avec Ca(OH)<sub>2</sub>, C-S-H peut être représenté par une formule telle que : Ca<sub>α</sub>(OH)<sub>(2α-1)</sub>H<sub>3</sub>SiO<sub>4</sub> ou pour α ≥ 1, Ca<sub>α</sub>(OH)<sub>(2α-2)</sub>H<sub>2</sub>SiO<sub>4</sub>.

S'il se produit une condensation des ions silicates, la première de ces formules peut être remplacée par Ca OH H<sub>4</sub>Si<sub>2</sub>O<sub>7</sub>.  
2α 2(2α-1)

5) Lorsque la solution est sursaturée par rapport à Ca(OH)<sub>2</sub>, nucléation et croissance de germes de portlandite.

Ces étapes élémentaires peuvent être regroupées en trois ou seulement en deux réactions stœchiométriquement simples selon que l'on considère ou non l'état d'hydroxylation superficielle comme un état intermédiaire observable. Or, il paraît logique d'admettre qu'il en est bien ainsi étant donné, d'une part l'importance de l'affinité chimique d'une telle réaction, que nous tenterons d'évaluer, d'autre part, les fréquences des chocs des molécules d'eau à l'interface.

Dès qu'un ion superficiel hydroxylé est passé en solution, un autre doit être immédiatement reconstitué sur le site laissé découvert. La répétition de ce même processus jusqu'au passage complet en solution de la totalité de la masse initiale de C<sub>3</sub>S réalise la majeure partie, sinon l'intégralité de l'hydratation de cette phase anhydre.

Cette équation stœchiométriquement simple peut être écrite :

Elle entraîne l'écriture d'une autre réaction stœchiométriquement simple, celle de la dissolution de cet état superficiellement hydroxylé noté C<sub>3</sub>S<sub>sh</sub> :

Cette écriture suppose la dissolution congruente, alors que les étapes élémentaires du groupe 2 (transfert interfacial) sont des réactions parallèles. Elles pourraient avoir des vitesses propres indépendantes et non pas statistiquement égales entre elles comme l'exige la congruence. Mais, l'expérience montre, qu'à condition que le flux de solvant (eau, eau de chaux) soit suffisamment rapide et l'épaisseur du lit solide assez faible, le passage des ions de l'interface à la solution a bien lieu statistiquement dans les proportions stœchiométriques [C/S]<sub>L</sub> = 3. Il faut croire que les effets compensateurs des champs électriques résultant d'accumulations locales de charges, assurent une autorégulation.

Enfin, dans l'état actuel des connaissances, il est difficile de dire si la nucléation donne, dans un premier stade, un C-S-H stœchiométrique (par exemple de [C/S]<sub>s</sub> = 1), suivi d'un second stade au cours duquel celui-ci fixe ou libère de la chaux pour se mettre en équilibre avec la phase liquide, ou si elle aboutit directement à un composé de formule Ca<sub>α</sub>(OH)<sub>(2α-1)</sub>H<sub>3</sub>SiO<sub>4</sub> par exemple. Par raison de simplicité, nous adopterons le second point de vue se traduisant par une équation du type :

Quant à la nucléation de l'hydroxyde de calcium, elle répond à l'équation classique :

Si l'on admet ce regroupement des étapes élémentaires en ces quelques réactions stœchiométriquement sim-

ples, il est alors possible de décrire schématiquement le réseau de telles réactions simultanées (8) comme on l'a fait dans le schéma (figure 1) :

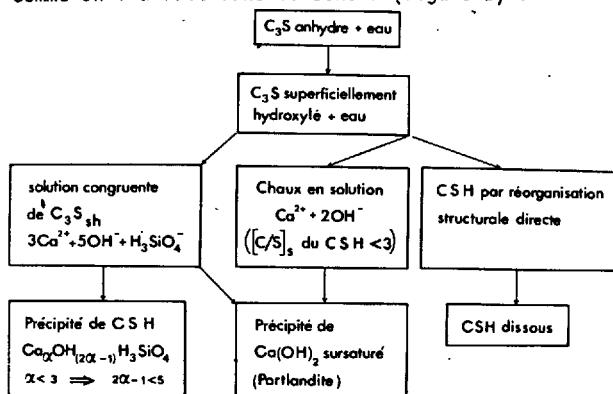

Fig. 1 - Réseau de réactions mises en jeu pour la formation de C-S-H et d'hydroxyde de calcium précipité à partir de C<sub>3</sub>S.

On a fait figurer à droite, en compétition avec le processus de dissolution de C<sub>3</sub>S<sub>sh</sub> - précipitation de C-S-H, le processus hypothétique de réorganisation structurale de C<sub>3</sub>S<sub>sh</sub> en C-S-H sans passage par la solution (hypothèse topo-chimique). Si, comme cela paraît vraisemblable, le rapport stoechiométrique 3 de C<sub>3</sub>S est conservé dans son hydroxylation superficielle, une telle étape de réorganisation structurale en un C-S-H de  $[C/S]_s < 3$  devrait être accompagnée du passage de chaux en solution conformément au schéma réactionnel suivant avec  $[C/S]_s = 2$  par exemple :

Certains d'entre nous ont procédé, dans d'autres publications (4, 7, 8, 9) à une comparaison approfondie d'un tel processus avec le processus de dissolution-précipitation, notamment par une construction graphique sur le diagramme C,S,H.

Il est utile de rappeler que le processus de réorganisation structurale, s'il permet de rendre compte du passage en solution de la chaux, n'autorise pas, en revanche, celui de la silice, du moins, avec une concentration supérieure à la solubilité du C-S-H, de sorte qu'il est nécessaire d'admettre que les états sursaturés de  $[C/S]_s$  de peu supérieurs à 3 (3,3 ; 3,4) observés expérimentalement proviennent de la dissolution de C<sub>3</sub>S<sub>sh</sub> suivie de la précipitation d'un C-S-H de rapport  $[C/S]_s < 3$ .

En outre, nos expériences de dissolution sur filtre à grand débit montrent que la vitesse de transfert interfacial des ions de la surface hydroxylée est très grande puisqu'il faut un temps de passage très court ( $\theta < 0,11s$ ) pour obtenir le rapport exact de congruence  $[C/S]_s = 3$  et cela sans que la compo-

sition n'atteigne le domaine de nucléation rapide. Cette vitesse diminue en fonction de la concentration en chaux dans le solvant, non seulement dans les expériences d'évolution en système fermé, mais aussi dans celles de dissolution sur filtre à grand débit, ce qui montre que ce n'est pas seulement un problème de diffusion, mais que le transfert interfacial est concerné. La vitesse de la dernière étape du groupe 2) peut s'écrire en effet :

$$\frac{d[C]}{dt} = k - k' \frac{c_\ell}{c_r} [C] \quad (4)$$

où  $c_\ell$  et  $c_r$  sont respectivement les concentrations superficielles en lacunes de Ca<sup>2+</sup> et en sites normaux d'ions Ca<sup>2+</sup>. Si pour simplifier, on fait rentrer la probabilité de présence d'une lacune d'ion Ca<sup>2+</sup>,  $W = c_\ell/c_r$  dans la constante K d'équilibre, l'expression (4) devient :

$$\frac{d[C]}{dt} = k \left( 1 - \frac{[C]}{K} \right) \quad (5)$$

Cette équation (5) s'intègre facilement et donne :

$$\text{Log}_e \left[ 1 - \frac{[C]}{K} \right] = - \frac{k}{K} t \quad (6)$$

Or, si l'on considère par exemple, à partir des résultats d'expériences d'évolution de C<sub>3</sub>S agité dans l'eau avec  $\ell/s = 10$ , les valeurs de  $[C]$  aux instants successifs le long de la branche ascendante de la courbe de variation de la concentration en CaO en fonction du temps (voir par exemple les courbes construites indépendamment par D. Bertrandie et D. Ménétrier dans une autre de nos communications (3)) ; ces valeurs de  $[C]$  donnent bien des droites lorsqu'on les porte dans l'expression (6) en prenant arbitrairement  $K = 40$ . Toutefois, comme le montre la figure (2) ces droites ne passent pas tout à fait par l'origine alors que la droite théorique devrait y passer. Comme les phénomènes sont complexes dans de telles expériences puisqu'il y a formation de C-S-H dont le rapport  $[C/S]_s$  peut varier, le résultat obtenu paraît assez satisfaisant. Il montre en tout cas qu'il n'est nul besoin de faire appel à la constitution d'une couche protectrice autour des grains pour expliquer le ralentissement de la dissolution.

Fig. 2 - Transformée linéaire par la loi de vitesse de transfert des ions Ca<sup>2+</sup> en solution en fonction de  $[C]$  de la branche ascendante de la courbe d'évolution de C<sub>3</sub>S agité dans l'eau à  $\ell/s = 10$ , d'après les résultats expérimentaux de : Δ D. Bertrandie (Dijon), o D. Ménétrier (Baltimore).

Mais il attire une autre remarque importante, c'est que, la concentration en silice  $[S]$  diminuant simul-

tanément dans le milieu conformément à la courbe de solubilité de C-S-H, la vitesse de transfert interfacial en solution des ions silicates devrait avoir tendance à augmenter ; en effet les vitesses des étapes correspondantes du groupe 2) conduiraient à des lois semblables à l'équation (4). On devrait donc s'attendre à une distorsion de la dissolution congruente en faveur de la silice par rapport à la chaux. Or, nos expériences montrent qu'il n'en est rien et que le rapport  $[\Delta C/\Delta S]_L$  reste égal ou légèrement supérieur à 3 (en raison de la précipitation de C-S-H) comme dans l'eau. Cela donne une idée des forces de compensation engendrées par les écarts à la stoechiométrie pour imposer l'alignement des vitesses de transfert en solution des différents ions et assurer la congruence de la dissolution. Il se peut que, dans un milieu stagnant, l'uniformité de composition de la solution au voisinage de l'interface soit perturbée par des processus d'adsorption et par une distribution particulière des charges sous l'influence d'un potentiel de surface. Mais cela ne doit pas conduire, en régime dynamique, à une accumulation indéfinie d'un des types d'ions et compromettre à terme la congruence de la dissolution.

#### Etat superficiellement hydroxylé :

La variation d'enthalpie libre  $\Delta G'$  accompagnant l'hydroxylation superficielle est évidemment d'autant plus importante que  $C_3S_{Sh}$  est moins soluble. Sa solubilité doit être suffisante pour expliquer la sursaturation de la solution par rapport au C-S-H. Faute de données expérimentales, du fait de l'absence de période d'induction avant nucléation de C-S-H, on ne peut faire qu'une évaluation reposant sur une valeur hypothétique de la solubilité de  $C_3S_{Sh}$  dans l'eau.

Dans une note précédente (2), l'un de nous avait proposé un mode de calcul en admettant comme résultat d'une dissolution congruente de  $C_3S_{Sh}$  à saturation, une valeur double,  $[C] = 9,78.10^{-3} \text{ mol.kg}^{-1}$  de celle que l'on obtient expérimentalement en faisant passer de l'eau à travers une couche mince ( $\sim 1 \text{ mm}$ ) de  $C_3S$  sur filtre millipore (7,8). Dans ces conditions c'est, non pas une solution saturée de  $C_3S_{Sh}$  qui est obtenue, mais un filtrat dont les germes de C-S-H ont été éliminés et qui, de ce fait, correspond à un domaine de plus faible sursaturation par rapport à C-S-H où la vitesse de nucléation de cet hydrate est petite.

Si l'on considère l'équation globale de passage en solution de  $C_3S$  :

le calcul de la solubilité à l'aide des  $\Delta G_{298}^\circ$  de formation des différentes espèces conduit à une valeur de la solubilité théorique de  $C_3S$  très élevée (11) et qui paraît aberrante. L'hypothèse que nous avons formulée est précisément que l'étape cinétique d'hydroxylation superficielle consomme une grande partie de cette enthalpie libre et que ce sont les ions qui en résultent qui passent en solution réversiblement. Le calcul que nous avons proposé avec l'estimation indiquée ci-dessus de la composition de la solution saturée avec  $C_3S_{Sh}$  conduit aux valeurs suivantes :

Passage de  $C_3S$  anhydre à  $C_3S_{Sh}$  en équilibre avec sa solution :  $\Delta G' = -75,2 \text{ KJ.mol}^{-1}$ .

Passage de  $C_3S_{Sh}$  à la solution en équilibre avec

C-S-H :  $\Delta G'' = -15,38 \text{ KJ.mol}^{-1}$ .

On trouverait une valeur analogue pour  $\Delta G''$  en calcu-

lant l'enthalpie libre de précipitation du C-S-H à partir de la solution en équilibre avec  $C_3S_{Sh}$ .

Ces résultats illustrent l'importance de l'abaissement d'enthalpie libre consécutif à la formation de l'état superficiellement hydroxylé par rapport à celui qui accompagne la précipitation de C-S-H.

#### CONCLUSIONS

Le processus de dissolution congruente des espèces ioniques de l'état superficiellement hydroxylé ayant déjà emmagasiné pratiquement toute l'eau d'hydratation est un stade qui paraît bien établi à la fois expérimentalement et d'un point de vue thermodynamique, dans l'évolution de  $C_3S$  au contact non seulement de l'eau, mais de l'eau de chaux et quel que soit le rapport (L/s). Ce processus rapide conduit, préférentiellement au voisinage immédiat de l'interface, à une sursaturation provoquant une nucléation immédiate de C-S-H de  $[C/S]_S < 3$  dépendant de  $[C]$  locale. Le ralentissement du transfert ionique interfacial en solution en fonction de  $[C]$  paraît pouvoir s'expliquer par un effet cinétique normalement prévisible sans nécessiter l'intervention d'une couche plus ou moins perméable.

# Hardened slag-cement pastes of low porosity

## *Pâtes durcies de ciment de laitier, à faible porosité*

S.A. ABO-EL-ENEIN, Chemistry Department Qatar University Doha State of Qatar,

R.I. ABD-EL-MALEK and R.Sh. MIKHAIL, Department of Chemistry, Faculty of Science, Ain Shams University, Abbasia, Cairo, Egypte.

RESUME : Deux mélanges secs de ciment ont été préparés, contenant un poids égal de laitier et de clinker, broyés, l'un à la finesse de  $5.000 \text{ cm}^2/\text{g} \pm 100$ , l'autre à la finesse de  $3.000 \text{ cm}^2/\text{g} \pm 100$ .

Pour obtenir des pâtes à faible porosité, trois méthodes ont été employées :

- i. Pâtes normales malaxées à une teneur en eau, par rapport au ciment, de 0,20
- ii. Pâtes préparées comme ci-dessus, puis comprimées, après mouillage, à des pressions variant entre 10 et 500 kg/cm<sup>2</sup>.
- iii. Pâtes comprimées, avant hydratation, à des pressions variant entre 100 et 1000 kg/cm<sup>2</sup>, puis hydratées.

Pendant trois ans, on a mesuré l'évolution de la chaux libre, du laitier libre, de l'eau combinée, de la densité et de la résistance à la compression, de ces diverses pâtes. On a observé ainsi la cinétique de l'hydratation des ciments riches en laitier, et montré l'influence de la compression aux premiers âges. Pendant ces premiers âges, la chaux libérée par l'hydratation du clinker, accélère l'hydratation du laitier, et provoque la réaction topochemique. L'augmentation de la pression accélère cette hydratation, grâce à la réduction des trajets de diffusion de la chaux libre entre les grains de clinker et les grains de laitier.

La réactivité du laitier diminue quand la finesse de broyage diminue.

SUMMARY: Two dry cement mixtures were prepared from equal weights of slag and clinker having the same fineness of 6000 or 3000 cm<sup>2</sup>/g,  $\pm 100$ . Low-porosity pastes were prepared by three different methods: (i) normal pastes of initial water/cement ratio of 0.20; (ii) post-hydration compressed pastes prepared by compressing the pastes after mixing the cement with water at a ratio of 0.20, and by applying pressures ranging between 10 and 500 Kg/cm<sup>2</sup>; and (iii) pre-hydration compressed pastes prepared by compressing the dry cement at pressures ranging between 100 and 1000 Kg/cm<sup>2</sup> before mixing with water.

Free lime, free slag, combined (non-evaporable) water content, bulk density and compressive strength were determined for pastes cured up to three years. Hydration kinetics could reveal the mechanism of hydration of the slag-rich cement pastes under investigation, and could show the effect of compression on the hydration mechanism especially during the early stages of hydration. During the early stages the calcium hydroxide released in the hydration of clinker activates the hydration of slag and the reaction proceeds topochemically. Increasing the compaction pressure increases the rate of hydration due to a decrease in the spaces located in between clinker and slag particles leading to a decrease in the diffusion path in which the free lime is proceeding to react with the slag grains.

With increasing particle size of cement constituents, the results obtained indicates the lower hydraulic reactivity of the granulated blastfurnace slag when ground to lower Blaine area.

## INTRODUCTION

Several techniques were used and interesting conclusions have been advanced concerning the production of low-porosity compacted cement pastes. Kamio et al. (1), for example, showed that partially hydrated cement sets instantaneously on pressing to give high compressive strength. Hara et al. (2) were able to obtain light weight building materials, having high strength and good fire-resistance, by mixing blastfurnace slag with lime, gypsum and fibrous materials, heating this mixture at 45°C in water, compression moulding at 30 kg/cm<sup>2</sup>, curing and hardening. Grudemo (3) found that there is a relationship between strength of the cement and the volume of the solid phase of specimens prepared from crushed and compressed high alkali and high Al cement stone. In addition Yoshimoto et al. (4) reported that by pulverizing hardened mortar, then placing it in a vessel and pressing, a remoulded compact of high strength is obtained through adhesion binding; the various factors affecting the compressive strength of the compacted remoulded specimens were also discussed.

On the other hand, Auskern et al. (5) studied the effect of different curing conditions, including hot-pressing, on the capillary porosity of hardened Portland cement pastes using mercury porosimetry; they showed that hot-pressed pastes had essentially no porosity accessible to mercury. Usually high-strength cement pastes, prepared by hot pressing techniques, were investigated at various temperatures, hot pressing times and periods of hydration after hot pressing (6,7). Mikhail, Abo-El-Enein and Oweimreen (8) investigated the low-porosity Portland cement pastes prepared either by reducing the water/cement ratio to 0.20, or by the pre-hydration compression of the dry cement, followed by hydration under water; the changes in degrees of hydration, surface areas and pore structure are reflected on the compressive strength values of the various pastes.

In an earlier investigation (9), kinetics and mechanism of hydration of low-porosity slag-lime pastes were reported and the developed strength was significantly related to the chemical composition and/or the physical state of the formed hydrates. Under hydrothermal conditions, however, the reactivity of granulated slag was also reported (10).

The optimum composition of blastfurnace slag cement made from slag-clinker mixture was specified in order to get more favourable cementing materials (11). By studying the main characteristics of the system as well as the structure of the formed hydrates; the specified composition, obtained for the slag cement produced in Egypt, consists of equal weights of slag and clinker (12).

## EXPERIMENTAL

The granulated blastfurnace slag used in this study has the following oxide composition: CaO, 46.00%; SiO<sub>2</sub>, 35.04%; Al<sub>2</sub>O<sub>3</sub>, 14.58%; MgO, 2.97%; Fe<sub>2</sub>O<sub>3</sub>, 0.52% and SO<sub>3</sub>, 0.14%. The phase composition of the Portland cement clinker used was: C<sub>3</sub>S, 41.81%;  $\beta$ -C<sub>2</sub>S, 27.65%; C<sub>3</sub>A, 15.83% and C<sub>4</sub>AF, 8.51%.

Two dry cement mixtures were prepared from slag and clinker having the same fineness of 6000 or 3000 cm<sup>2</sup>/gm, + 100. Equal weights of slag and clinker, having the same Blaine area, were first mixed in ethanol for one hour; then, ethanol was evaporated completely.

Three methods for the development of low-porosity slag cement pastes were used. These are (i) normal low-porosity pastes prepared with an initial water/cement ratio of 0.20, (ii) post-hydration compressed low-porosity pastes prepared by the compression of the freshly prepared paste, after mixing the cement with water (W/C = 0.20), by the application of various pressures of 10, 20, 50, 100 and 500 kg/cm<sup>2</sup> in cylindrical moulds to produce specimens of 3.14 cm<sup>2</sup> cross-section and 1 cm in height, and (iii) pre-hydration compressed low-porosity pastes prepared by the compression of the dry cement at various pressures of 115, 230, 460 and 1030 kg/cm<sup>2</sup> before hydration under water. The normal low-porosity pastes will receive the notations HN and LN for the high Blaine and low Blaine cement samples, respectively; the post-hydration compressed pastes were designated as H10, H20, H50, H100 and H500 for the high Blaine area cement, and L10, L50 and L100 for the low Blaine area cement according to the pressure used in compression; the pre-hydration compressed specimens will receive the notations H115p, H230p, H460p and H1030p for the high Blaine area cement, and L115p, L230p, L460p and L1030p for the low Blaine area cement, respectively.

The pastes were hydrated under water for ages of 0.25, 1, 3, 7, 28, 90, 180, 365, and 1095 days for the normal and post-hydration compressed pastes; and 1, 3, 6, 9, 12 and 36 months for the pre-hydration compressed specimens, respectively. At the end of each time interval, the fresh specimens were tested for compressive strength, bulk density, and the resulting crushed samples were then dried at 105°C for 24 hours to determine the evaporable water content. The free lime, free slag and combined (non-evaporable) water contents were determined in the crushed dried samples according to the methods described in an earlier publication (9).

## RESULTS AND DISCUSSIONS

## 1. HYDRATION KINETICS AND MECHANISM

The results in Fig. 1 show that for the post-hydration and the pre-hydration compressed specimens, the non-evaporable (combined) water content increases with curing age and that the hydration of these slag cement specimens follows a consecutive reaction as

a result of an indirect activation of the blastfurnace slag with cement clinker.

During the early stages of hydration the combined water content increases with increasing the pressure of compaction (decreasing the initial porosity) after mixing the cement with water. This result is unexpected, since during the hydration of portland cement or slag cement with a lower slag content the increase in the initial porosity of the paste is associated with an increase in the combined water content (degree of hydration) mainly because more spaces are available for hydration products to deposit. However, in the hydration of the present pastes, which contain large amounts of blastfurnace slag (50% by weight), the hydration reaction starts with clinker to give hydration products composed mainly of calcium silicate hydrates and free calcium hydroxide. The free calcium hydroxide released during clinker hydration activates the hydration of granulated blastfurnace slag. Therefore, the slag grains react topochemically with the free calcium hydroxide solution located in the originally water-filled spaces, and consequently, by decreasing the spaces between clinker and slag particles (decreasing the porosity with increasing pressure of compression), the free lime will find a shorter diffusion path to react with slag grains leading to an increase in the rate of hydration of slag during the early stages of hydration. This stage ends after 3-7 days at room temperature for the post-hydration compressed pastes and after 2-3 months for the pre-hydration compressed specimens.

In the later stages of hydration, however, the normal expected behaviour predominates, namely the rate of hydration increases with increasing the porosity (decreasing the pressure of compaction) of the specimen. Higher porosity pastes can accommodate larger amounts of hydration products in their pore system than lower porosity pastes. Nevertheless, in the pre-hydration compressed specimens, the rate of diffusion of water through the partly hydrated sheath of the specimens into the unhydrated middle parts seems to be the rate controlling step in the final stages of hydration; the rate of hydration in the final stages increases with decreasing the compaction pressure used in the preparation of the specimens as a result of the increase in the rate of diffusion.

With increasing particle size of cement constituents, the differences in hydration kinetics diminishes during the early stages of hydration of the post-hydration compressed pastes; this result is associated with the lower hydraulic reactivity of the granulated blastfurnace slag when ground to a lower Blaine area. However, in the pre-hydration compressed specimens, the degree of compaction of coarse cement particles becomes less than that of fine cement particles when compressed at the same pressure leading to higher degree of hydration in the former pastes, especially during the early stages of hydration.

Fig. 1 - Combined water contents as a function of curing age

Fig. 2 - Free lime contents as a function of curing age

The results in Fig. 2 indicate that, for the post-hydration compressed pastes, the free lime content increases during the early stages of hydration up to 7 days. This result is mainly attributed to the fact that the amount of free lime released during clinker hydration exceeds that consumed by slag hydration at the early stages; therefore there appeared a net initial increase in the free lime contents of the specimens. After 7 days, however, the free lime content decreases as a result of its consumption by slag hydration; the acceleration period during slag hydration is then initiated leading to an increased rate of consumption of free lime by slag hydration as compared with the rate of release of free lime by clinker hydration. In the final stages of hydration, the major fraction of slag was already hydrated and a consequent increase in the free lime content was obtained. These results indicate that the rate of hydration of slag during the final stages, which is diffusion controlled, is very small

as compared with the rate of hydration of portland cement clinker.

In the hydration of the normal low-porosity pastes, prepared with an initial water/cement ratio of 0.20, there appeared a continuous increase in the free lime content of the pastes, prepared from the finer cement (Blaine area = 6000 cm<sup>2</sup>/g), up to 28 days hydration; this result is due to the high initial porosity of the normal low-porosity pastes leading to a higher rate of clinker hydration for a longer period as compared with the rate of hydration of slag. By increasing the particle size of the slag and clinker grains, however, the free lime content shows a continuous increase at the various ages of hydration due to the decreased hydraulic reactivity of blast-furnace slag with increasing particle size.

The variations of the free lime contents with duration of hydration of the pre-hydration compressed specimens are similar to those obtained during the hydration of the post-hydration compressed pastes beyond one month hydration. This result indicates that the mechanism of hydration of the pre-hydration compressed specimens is almost similar to that of the post-hydration compressed pastes; the only difference is the diffusion of water into the compacted cement grains in the former specimens.

From free slag determination, the reaction ratio of slag could be derived and the values obtained are shown in Fig. 3.

Fig. 3 - Reaction ratio of slag as a function of curing age

The results in Fig. 3 show that in the post-hydration compressed slag cement pastes, the hydraulic reactivity of granulated blast-furnace slag increases with increasing the pressure used in compression (decreasing the initial porosity) during the early stages of hydration, indicating that the hydration reaction is governed by the rate of dissolution of free lime released by the clinker grains and its subsequent diffusion to activate the slag grains. Apparently, the

hydration of granulated blastfurnace slag during the early stages of hydration is not under normal equilibrium conditions of saturation of the water-filled spaces by calcium hydroxide which needs longer times to attain this condition. Therefore, the early hydration of slag takes place in an unsaturated free lime solution and this leads to an increased rate of hydration with decreasing the distance of contact between clinker and slag grains. In the final stages of hydration, however, the hydration of slag proceeds under equilibrium conditions in the saturated lime solution when most of the clinker grains are consumed by hydration, leading to the accumulation of free lime; this effect leads to an increase in the rate of hydration of slag with decreasing pressure of compression (increasing initial porosity). In addition, higher porosity pastes could accommodate larger amounts of hydration products than the denser low-porosity pastes.

Evidently, the rate of slag hydration in the normal low-porosity pastes, prepared with water/cement ratio of 0.20 without compression, is found to be different than that in the compressed pastes indicating a difference in the mechanism of hydration.

In the pre-hydration compressed specimens, beyond the first month of hydration, the rate of hydration of slag increases with increasing the initial porosity of the specimen (decreasing the compaction pressure). Therefore, the rate of diffusion of water through the porous system of the unhydrous compacted specimens is not the rate controlling step, and the paste which is capable to accommodate larger amounts of hydration products in its pore system should have a higher rate of hydration.

In all pastes investigated, the hydraulic reactivity of the granulated blastfurnace slag was found to diminish markedly by decreasing the Blaine area of slag.

## 2. TOTAL POROSITY

The total porosity of the hardened cement paste could be calculated according to the relation:  $\epsilon = W_e/V_p$ ; where  $W_e$  is the weight of evaporable-water per one gram of the paste, and  $V_p$  is the volume of one gram of the paste.

The results shown in Fig. 4 clearly indicate that for the post-hydration compressed pastes, the total porosity decreases with increasing time of hydration; the fall in the total porosity is sharp during the early stages of hydration and is gradual during the later stages of the hydration process. In addition, the pastes compressed at higher pressures were found to have lower porosities than the pastes compressed at lower pressures when hydrated for the same age. Furthermore there appeared a sharper decrease in the total porosity of the denser (low initial porosity) pastes than that of the lean samples (compressed at lower pressure); this result might be partly attributed to the

Fig. 4 - Total porosity as a function of curing age

Fig. 5 - Compressive strength as a function of curing age

initial porosity as controlled by the pressure of compression, and partly due to the increased hydraulic reactivity of slag with clinker with increase of compression pressure (decreasing initial porosity) of the paste.

The total porosities of the hardened pastes prepared from the coarser slag cement were found to be higher than those of the pastes prepared from the finer cement, a result which is mainly due to the increased degree of compaction in the finely ground cement than in the case of the coarser cement; the hydraulic reactivity of the granulated slag is also diminishing with increasing particle size.

Actually, the total porosity of the pre-hydration compressed specimens could not be derived from the evaporable water contents due to the continuous diffusion of water through the compressed dry specimens.

### 3. COMPRESSIVE STRENGTH

The results in Fig. 5 clearly indicate that the strength of every cement paste increases with increasing age of hydration; this behavior is similar to that reported earlier, and which is normally correlated with the total porosity and degree of hydration. In addition, the compressive strength values are higher for the pastes prepared from the finely ground cement as compared with the values obtained using the coarser cement; this result might be attributed partly to the increased degree of compaction and partly to the increased hydraulic reactivity of the blastfurnace slag with decreasing particle size.

Fig. 6 - Compressive strength versus total porosity of the post-hydration compressed pastes

The relation between compressive strength and total porosity is shown in Fig. 6 for the post-hydration compressed pastes. There appeared a gradual and slight increase in the strength with decreasing porosity at relatively higher porosity values, where the amounts of hydration products deposited in the pores contribute slightly to the strength development. At intermediate total porosities, a distinguishable increase in the compressive strength with decreasing porosity was observed; such notable increase in strength was obtained below a certain porosity value characteristic of the initial porosity of the compressed paste as controlled by the pressure used during the compression. In this range of total porosity, the precipitation of the hydration products within the pore system has a distinct contribution to the strength of the hardened pastes. At lower values of total porosity (longer time of hydration) only a slight increase in strength with decreasing porosity was observed for the pastes compressed at relatively low pressures (10-50 kg/cm²); this result might be associated with the nature of the hydration products to undergo some sort of partial crystallization as a result of the available empty spaces provided by the initial porosity of the paste. At

relatively higher compression, however, (pressures of 100 and 500 kg/cm<sup>2</sup>), the lower porosity values cause a sharp increase in the strength of the paste, and this is mainly attributed to the highly amorphous (ill-crystalline) state of the hydration products as controlled by the extremely limited initial porosity.

# L'hydratation hydrothermale des laitiers

## *The hydrothermal hydration of slags*

A.A. GOVOROV, Institut de chimie colloïdale et de chimie de l'eau, Kiev, U.R.S.S.

**RESUME :** L'on a étudié l'hydratation et le durcissement des coulis de laitiers vitreux synthétiques du système  $\text{CaO-MgO-Al}_2\text{O}_3\text{-SiO}_2$  dans des bombes hydrothermales dont on élevait progressivement la température à la vitesse de  $150^\circ\text{C/h}$  jusqu'à  $285^\circ\text{C}$ .

La diminution du rapport  $\text{CaO:SiO}_2$  dans la composition des laitiers entraîne une réduction de la vitesse du passage en solution de la silice, mais aussi un accroissement des teneurs maximales de silice dissoute ainsi que des températures auxquelles ces maxima sont atteints pour la première fois. Cela peut s'expliquer d'une part par un plus haut degré de condensation des tétraèdres siliciques dans la structure des laitiers, et d'autre part par le déficit croissant en  $\text{CaO}$ .

L'apparition d'hydrosilicates de calcium ainsi que le début du durcissement des coulis succèdent au premier maximum de teneur de silice en solution, et correspondent à un accroissement de leur résistance électrique. Les ajouts de  $\text{CaO}$ , dans certaines proportions, ont pour effet d'abaisser les températures auxquelles ces maxima sont atteints, et font apparaître à des températures moins élevées un accroissement préliminaire de résistance électrique, qui met en évidence un stade plus avancé dans la formation des hydrosilicates de calcium. Il semble qu'à ce stade la part des réactions topochimiques soit importante.

**SUMMARY :** The author investigated the hydration and hardening processes of finely ground synthetic vitreous slags in the system  $\text{CaO-MgO-Al}_2\text{O}_3\text{-SiO}_2$ , which were heated in hydrothermal bombs to  $285^\circ\text{C}$  at the rate of  $150^\circ\text{C/h}$ .

It was found that a decrease of the  $\text{CaO:SiO}_2$  ratio in the slag compositions is slowing down the early dissolution of silica, but at the same time it increases its maximal concentrations in solution, as well as the temperatures they are reached at first. This may be explained by a higher degree of condensation of the  $\text{SiO}_4$  tetrahedra in the structure of the slags, and by the increasing lack of  $\text{CaO}$ .

The appearance of the calcium silicate hydrates, as well as the beginning of hardening are coming next to the first maximum of silica in solution, and correspond to an increase in the electrical resistance of the slag suspensions. Additions of  $\text{CaO}$ , made in certain proportions, lower the temperatures at which this maximum occurs, and cause a preliminary increase in the electrical resistance, indicates an earlier step of formation of the calcium silicate hydrate phase. The role of the topochemical processes seems to be important at this stage.

Le durcissement des liants hydrauliques résulte de la destruction hydrolytique plus ou moins profonde de leurs constituants anhydres et de la formation de phases hydratées en particules extrêmement fines, pratiquement insolubles dans l'eau. La cinétique de cette destruction, ainsi que celle de la formation des produits hydratés joue un rôle de premier plan.

L'intensification de ces réactions en milieu hydrothermal a pour effet de conférer une activité hydraulique et des propriétés liantes à certains matériaux inertes à la température ambiante, tels en particulier les laitiers métallurgiques finement moulus. Du fait de l'accroissement du degré de dissociation de l'eau et de la mobilité des ions  $H^+$  et  $OH^-$  avec la température, ainsi que du nombre de liaisons Si-O-Si rompues (1,2), le passage en solution de la silice se trouve facilité. Cela a pour effet d'intensifier la genèse des phases hydratées, ainsi que le durcissement des pâtes, mais aussi la croissance des cristaux et leurs transformations éventuelles, ce qui peut nuire au durcissement.

L'une des applications intéressantes de l'aptitude au durcissement des suspensions de laitiers en milieu hydrothermal est leur emploi pour la consolidation des puits de pétrole et de gaz naturel profonds. Dans les conditions de température et pression élevées qui y régnent les liants à base de laitiers présentent des avantages incontestables sur ceux à base de ciment portland (3,4), en particulier une meilleure résistance mécanique et à la corrosion, ainsi qu'un prix de revient moindre.

La structure des constituants anhydres des liants hydrauliques est un facteur primordial de leur activité. Dans le cas des liants à base de laitiers son importance est encore accrue du fait de la diversité de composition et de structure des laitiers industriels.

Le problème de la structure de la phase vitreuse des laitiers granulés et du verre en général n'est pas encore résolu. Il est cependant acquis que leur structure contient des éléments ordonnés, dont la forme et les dimensions restent toutefois hypothétiques. Selon (5) la phase vitreuse des laitiers granulés contiendrait des groupements d'ions dénommés "phases quasi cristallines", pouvant être des structures du type Zachariasen, des structures cristallitiques ou de tout autre nature. Selon ces auteurs ces groupements dépendent des sous-systèmes de paragenèse de phases, où la phase primaire joue probablement un rôle prépondérant.

L'on sait d'autre part que les groupements possibles de tétraèdres siliciques  $SiO_4$  dépendent dans leur forme et leurs dimensions de la proportion relative d'atomes de silicium et d'oxygène se trouvant dans le verre. Ainsi dans le cas où Si:O est inférieur à 0,286 les tétraèdres siliciques ne peuvent

théoriquement se grouper que par deux ou qu'être isolés les uns des autres; lorsque Si:O est compris entre 0,286 et 0,333 ces tétraèdres peuvent se grouper par deux ainsi qu'en anneaux ou chaînes séparés; lorsque Si:O est compris entre 0,333 et 0,400 ces groupements de tétraèdres peuvent se réunir dans le plan et dans l'espace par l'intermédiaire de tétraèdres communs; lorsque Si:O est compris entre 0,400 et 0,500 il ne peut plus y avoir de groupements séparés, tous les tétraèdres étant nécessairement réunis par au moins trois des sommets (atomes d'oxygène) en un réseau, dont la densité devient maximale lorsque Si:O atteint la valeur 0,500.

L'existence de tels groupements de tétraèdres siliciques, ainsi que leur accroissement avec la teneur en silice sont confirmés par les études au moyen de spectres infrarouges (6,7,8). Cependant leur interprétation dans le cas des laitiers vitreux est compliquée par la présence de tétraèdres  $AlO_4$  et de liaisons Si-O-Al en proportions difficiles à déterminer avec précision.

D'après nos résultats de recherches (9,10) effectuées sur des laitiers vitreux synthétiques  $CaO-MgO-Al_2O_3-SiO_2$  avec 0 et 5% MgO il semble que l'on puisse distinguer: les laitiers orthosilicatiques, donnant une bande d'absorption IR ayant deux à trois faibles maxima dans l'intervalle 860-950  $cm^{-1}$ ; les laitiers alumineux, donnant une bande avec deux maxima 760-780 et 950-980  $cm^{-1}$ , le premier étant le plus intense; les laitiers méliilitiques, donnant les bandes 700-730 et 950-990  $cm^{-1}$ ; les laitiers wollastonitiques, donnant les bandes 720-810 et 1000-1050  $cm^{-1}$ ; les laitiers anorthitiques donnant les bandes 790-800 et 940-1110  $cm^{-1}$ , cette dernière étant la plus intense et comportant deux maxima à 940-980 et 1090-1110  $cm^{-1}$ .

Compte tenu de la disposition des points figuratifs de ces laitiers sur le diagramme du système  $CaO-MgO-Al_2O_3-SiO_2$  à 5% MgO, et de l'interprétation structurale (6,7,8) des spectres IR des silicates et aluminosilicates, l'on peut admettre l'existence de tétraèdres isolés dans les laitiers orthosilicatiques, de groupements limités et séparés de tétraèdres dans les laitiers méliilitiques, de groupements illimités pouvant être réunis par des tétraèdres communs dans les laitiers wollastonitiques, d'un réseau de tétraèdres tous réunis entre eux dans les laitiers anorthitiques.

Au traitement hydrothermal à 200-250°C les laitiers méliilitiques donnent essentiellement des hydrogrenats, et les laitiers wollastonitiques - de la tobermorite (10-11). Ainsi la disparition des groupements limités et séparés de tétraèdres au profit de leurs groupements polymères illimités dans la structure du laitier correspond à un changement analogue dans celle de leurs produits d'hydratation au cours du traitement hydrothermal.

Le coulis de ciment introduit dans les puits de forage est soumis, au cours de sa descente jusqu'au niveau nécessaire, à un accroissement considérable de température et de pression, et ne doit pas faire prise ni durcir pendant sa mise en place, qui dure en moyenne de une à deux heures et demi. Aussi l'étude de l'hydratation et du durcissement des ciments au cours d'une élévation progressive de température en milieu hydrothermal présente-t-elle un intérêt pratique pour cette application.

De telles recherches ont été effectuées en notre laboratoire sur des coulis de laitiers vitreux synthétiques, moulus jusqu'à la finesse de 3500-4000 cm<sup>2</sup>/g. La pâte à 50% d'eau était introduite dans des moules cylindriques que l'on immergeait aussitôt dans des bombes hydrothermales remplies d'eau distillée à 80% de leur volume intérieur. Celles-ci étaient alors chauffées à la vitesse de 150°/h jusqu'à diverses températures, puis rapidement refroidies par de l'eau froide.

L'on déterminait alors, par la méthode du complexe silicomolybdique, la fraction de silice du laitier se trouvant en solution, exprimée en pourcentage pondéral. Le durcissement de la pâte était exprimé par la résistance à la pénétration d'un cône de durromètre, calculée en N/mm<sup>2</sup>. Par ailleurs l'on enregistrait, dans un autoclave spécialement conçu (10), les variations de résistance électrique du coulis en cours de montée en température.

Les laitiers synthétiques étudiés étaient obtenus par fusion à 1600-1700°C et refroidissement brusque à l'eau froide, de deux séries de mélanges d'oxydes purs, contenant respectivement 5 et 20% en poids de Al<sub>2</sub>O<sub>3</sub> pour 5% de MgO, avec CaO:SiO<sub>2</sub> variable.

TABLEAU DES COMPOSITIONS					
	Teneurs, moles %				Type de laitier
	CaO	MgO	Al <sub>2</sub> O <sub>3</sub>	SiO <sub>2</sub>	
A	51,6	7,2	2,8	38,4	1,34 orthosil.
B	41,5	7,2	2,9	48,4	0,85 wollast.
C	31,4	7,2	2,9	58,5	0,53 wollast.
D	21,0	7,3	2,9	68,8	0,31 anorth.
E	44,2	7,7	12,1	36,0	1,22 méllilit.
F	33,3	7,7	12,2	46,7	0,72 wollast.
G	22,4	7,8	12,3	57,5	0,39 anorth.
H	11,3	7,8	12,4	68,5	0,17 anorth.

L'on voit sur la fig.1 que la fraction de silice des laitiers qui se trouve en solution croît différemment selon leur composition et leur type. Avec la diminution du rapport CaO/SiO<sub>2</sub> l'on observe: a/ un ralentissement du passage en solution de la silice, b/ un accroissement de la fraction de la silice du laitier se trouvant en solution aux teneurs maximales, c/ un décalage de ces maxima vers les températures plus élevées. L'accroissement des teneurs en alumine des laitiers jusqu'à 20% a pour effet d'intensifier légèrement le passage de la silice en solution aux basses températures, mais aussi de réduire ses teneurs maximales en solution.

Fig. 1 - Les variations des teneurs de silice en solution (trait plein) et le durcissement des coulis (pointillé) des laitiers contenant 5% (I) et 20% (II) d'alumine (voir tableau ci-dessus).

Les considérations sur la structure des laitiers vitreux exposées au début de cette communication permettent d'expliquer la lenteur initiale du passage en solution de la silice des laitiers acides par le degré de condensation élevé de leurs tétraèdres  $\text{SiO}_4$ . La légère accélération initiale observée dans le cas des laitiers plus riches en alumine pourrait être due à l'introduction de tétraèdres  $\text{AlO}_4$  parmi les tétraèdres siliciques, entraînant une certaine diminution du degré de condensation de ceux-ci, à teneurs en silice égales (en moles %).

Une contribution intéressante à l'interprétation des maxima de teneurs de silice en solution est fournie par les mesures de résistance électrique des coulis au cours de leur traitement hydrothermal. Afin de mettre en évidence l'influence propre du laitier sur la résistance électrique de l'eau, et d'exclure l'effet de l'échauffement, nous avons comparé les variations de résistance  $R_e$  de l'eau distillée avec celles des coulis de laitiers  $R_s$ , et considéré le rapport  $(R_e - R_s) : R_e$  exprimé en % aux différentes températures.

La fig. 2 montre les variations de ce rapport en fonction de la température dans le cas de trois laitiers synthétiques à 5% d'alumine. L'on voit que l'abaissement de résistance électrique de l'eau par le laitier (ou plus exactement par le passage en solution de ses constituants) croît d'abord avec

Fig. 2 - L'abaissement relatif de la résistance électrique de l'eau par les laitiers A, B, C, au cours de la montée en température hydrothermale des coulis.

la température, passe par un maximum entre 120 et 160°C, puis décroît. La valeur de ce maximum diminue avec le rapport  $\text{CaO}:\text{SiO}_2$  du laitier, tandis que la température correspondante augmente. Cela semble indiquer que ces courbes reflètent essentiellement les variations de teneur de  $\text{CaO}$  en solution.

La comparaison des fig. 1 et 2 permet alors de constater que ces maxima de teneur de  $\text{CaO}$  en solution surviennent en même temps qu'une accélération du passage de la silice du laitier en solution. Ainsi est mise en évidence la recombinaison de la chaux, préalablement lixiviée du laitier, avec la silice passée en solution, avec pour résultat la formation de silicates de calcium hydratés. Des diagrammes de rayons X ont en effet montré l'apparition des raies principales de la tobermorite dès 280°C dans le cas du laitier B dans ces conditions de traitement.

L'accroissement de la teneur maximale de silice en solution avec sa teneur dans les laitiers s'explique par le déficit croissant en  $\text{CaO}$  nécessaire à sa recombinaison en silicates de calcium hydratés, ce qui se confirmera plus loin. La diminution de la teneur maximale de silice en solution dans le cas des laitiers plus riches en alumine correspond à la formation d'une quantité moindre d'hydro-silicate. Nous avons de même observé une réduction de cette teneur maximale dans le cas d'un remplacement partiel de  $\text{CaO}$  par  $\text{MgO}$  dans la composition des laitiers.

Ainsi qu'on le voit sur la fig. 1, la teneur maximale de silice en solution n'est pas atteinte dans le cas des laitiers D, G, H, du type anorthitique. Il est intéressant de constater que si l'on admet qu'en moyenne 2/3 des atomes d'aluminium se trouvent en coordination tétraédrique dans les laitiers vitreux, le degré de condensation des tétraèdres  $\text{SiO}_4$  et  $\text{AlO}_4$  donné par le rapport  $(\text{Si} + 2/3\text{Al}) : \text{O}$ , sera respectivement égal à 0,394, 0,405, 0,439 pour les laitiers D, G, H, c'est à dire sera pratiquement égal ou supérieur à 0,400. Ainsi la limite entre les domaines de composition des laitiers wollastonitiques et anorthitiques, basée sur les données des spectres IR semble s'accorder avec celle basée sur le calcul du degré de condensation des tétraèdres si l'on admet que 2/3 des atomes d'aluminium sont tétra-coordonnés.

La teneur de silice en solution passe par une série de nouveaux maxima lorsqu'on maintient constante pendant quelques heures la température à 285°C, leur amplitude étant la plus élevée dans le cas des laitiers wollastonitiques. La teneur moyenne de silice en solution se stabilise alors pour quelque temps à des niveaux d'autant plus élevés que le degré de condensation des tétraèdres siliciques est plus grand. Cette stabilisation survient dès avant 100°C dans le cas des laitiers orthosilicatiques et entre 150 et 250°C pour les laitiers mélilitiques.

On a vu sur la fig. 1 que les coulis commen-

Fig. 3 - Les variations des teneurs de silice en solution (I) et le durcissement des coulis de laitier B (II), sans ajout (a) et avec ajout de 0,3% CaO (b), et de 3% CaO (c).

cent à durcir lorsque la teneur de silice en solution baisse après avoir atteint sa valeur maximale. Le durcissement le plus intense s'observe dans le cas du laitier B du type wollastonitique, ayant donné de la tobermorite dans ces conditions. Au cours d'un traitement hydrothermal de 48 h à 250°C ce sont également les laitiers wollastonitiques qui donnent les résistances mécaniques les plus élevées (10,11).

L'addition de CaO aux laitiers a pour effet (fig.3) d'abaisser les teneurs maximales de SiO<sub>2</sub> en solution, ainsi que les températures auxquelles elles sont atteintes. En même temps le passage de la silice en solution est sensiblement intensifié aux basses températures. Ainsi la chaux accélère aussi bien le passage de la silice en solution que sa recombinaison en hydrosilicates de calcium. Cela a pour effet d'avancer le début du durcissement, ainsi que le montre la fig.3, cependant le gain de résistance mécanique initiale qui en résulte diminue lorsque la quantité de CaO ajoutée dépasse un certain optimum, en l'occurrence 0,3-0,8%.

Cela se répercute également sur l'allure des courbes de résistance électrique des coulis (fig.4). Dans le cas du laitier B sans ajout la baisse initiale de résistance, due à l'échauffement et au passage en solution des constituants du laitier, se ralentit entre 150 et 170°C, ce qui correspond au maximum de la fig.2, ainsi qu'au début du passage en solution accéléré de la silice (fig.1). L'accroissement ultérieur de la résistance électrique correspond à la baisse de teneur de silice en solution, ainsi qu'au début du durcissement du coulis.

En présence d'ajout de CaO la résistance électrique initiale du coulis se trouve considérablement réduite, mais elle augmente brusquement avant que la température ait atteint 100°C. L'intensité de cet accroissement croît avec la quantité de CaO ajoutée, mais diminue lorsqu'elle dépasse 0,3-0,8%, c'est à dire la quantité qui s'est révélée optimale pour l'intensification du durcissement initial.

Fig.4 - Les variations de résistance électrique du coulis de laitier B sans ajout (a), et avec ajout de 0,3% CaO (b), et 3% CaO (c).

Il est intéressant de constater que cet accroissement de résistance électrique ramène sa valeur à celle du coulis sans ajout, et compense sa chute initiale due à la chaux. En outre cet accroissement de résistance correspond à l'apparition de produits d'hydratation et à un épaississement du coulis.

Etant donné que l'intensification par CaO du passage de la silice en solution aux basses températures est beaucoup plus faible que l'accroissement de résistance électrique mentionné, l'on est amené à admettre que les réactions topochimiques jouent un rôle important à ce stade avancé.

L'on a également étudié le comportement des laitiers réels de haut-fourneau dans les mêmes conditions de traitement hydrothermal, et obtenu des résultats analogues, quant aux variations de teneur en silice en solution et au durcissement des coulis. Les laitiers de haut-fourneau se rapportant au type méli-litique de notre classification, des ajouts de sable siliceux permettent d'obtenir des mélanges correspondant à des valeurs moins élevées du rapport  $\text{CaO}:\text{SiO}_2$  et équivalents aux laitiers du type wollastonitique. De tels mélanges sont utilisés avec succès dans les puits de forage profonds (4).

#### CONCLUSIONS

Au cours de l'hydratation, en milieu hydrothermal à température et pression progressivement croissantes, des laitiers granulés moulus, la teneur de silice en solution croît différemment selon leur composition et le degré de condensation des tétraèdres siliciques dans leur structure.

Il existe un lien entre les premiers maxima de teneur de silice en solution, les variations de résistance électrique des coulis au cours de leur échauffement hydrothermal, l'apparition des produits d'hydratation et le début du durcissement des coulis.

Des ajouts de CaO en certaines proportions abaissent considérablement les températures auxquelles la silice en solution atteint les teneurs maximales, ainsi que ces teneurs elles-mêmes, et accélèrent le durcissement des coulis. Les réactions topochimiques semblent jouer un rôle important au premier stade de l'action du CaO.

Les résultats de ces recherches peuvent contribuer à l'utilisation rationnelle des divers laitiers métallurgiques dans la fabrication des ciments destinés à durcir en milieu hydrothermal, en particulier dans les puits de forage profonds.

L'auteur tient à exprimer sa reconnaissance à ses collaborateurs E.V.Djouss, N.V.Bakouchina et L.I.Khokhlova pour leur participation dans la partie expérimentale de ces recherches.

# Composition, Morphology, Hydration and Bond Characteristics of some Granulated Slags

## *Composition, Morphologie, Hydratation et Propriétés adhésives de quelques laitiers granulés*

H. ROPER, Senior Lecturer, Department of Civil Engineering, The University of Sydney, Australia.

**RESUME :** La technologie de la fabrication du ciment dépend du mode de production du laitier. Une étude de la morphologie d'une série de laitiers granulés a été faite afin d'étudier l'influence de leur composition et de leur mode de trempage. Il est suggéré que certains laitiers ont tendance à présenter les caractéristiques des liquides de Stuart, c'est à dire une grande facilité de formation de particules aciculaires ou en forme d'aiguilles.

Certains résultats d'essais de compression et de traction et des observations au microscope électronique suggèrent que l'adhérence entre la surface des particules de laitier et les produits de l'hydratation du ciment de Portland est inférieure à celle du sable quartzeux. Ceci mène à la suggestion que les surfaces de certains laitiers tendent à être de caractère hydrophobe.

**SUMMARY :** Different methods of producing granulated slags are influencing the technology of cement binder production. A study has been made of the morphology of a series of granulated slags in order to study the influence of composition and quench methods used in their production. It is suggested that certain of the slags tend to show the characteristic of Stuart liquids, viz great ease of acicular or needle-like particle formation.

Some data on compressive and tensile testing combined with electron microscopy suggest that the bond between a slag particle surface and portland cement hydration products is lower than that for quartz sand. This has led to the suggestion that the surfaces of certain slags tend to be hydrophobic in character.

## INTRODUCTION

In Australia, research interest in slags for use in hydraulic cements dates back to 1966, when production of blended cements consisting of an interground mixture of granulated slag and portland cement clinker commenced. The developmental work was described by Ryan (1), who, for the locally produced slag, noted in particular, the retardation of initial set when concrete was cast at low ambient temperatures, and its high susceptibility to the adverse effects of improper curing. Since then such blended cements have been produced from Port Kembla slags in New South Wales where up to 100,000 tonne of granulate is used annually, and, more recently, from Kwinana in Western Australia, where a blended cement containing 30% ground granulated slag is being produced by two companies leading to the use of 50,000 tonne per annum of granulate.

## METHODS OF GRANULATION

In the past slag cements were exclusively produced from high-glass, water quenched granulates. One of the more interesting recent developments in granulated slag technology has been the introduction in several countries of a variety of quenching processes. Kister et al (2) have described a new system for the production of granulated blast furnace slag with a high content of glass and a low content of residual moisture. Special attention was paid to the spray box design in order to break up the slag stream at high flow rates, and to guarantee an effective contact between water and fluid slag and hence the production of a high glass content in the product.

Margesson et al (3) patented a process for air pelletizing of slag. Cotsworth (4) describes the use of such pelletized slag in concrete masonry units and notes that the structure of such pelletized slag is primarily a glass, and that if ground to a size finer than 75  $\mu\text{m}$  the resulting product is cementitious, hydrating in a manner similar to portland cement.

Alderete et al (5) have patented a portland blast-furnace slag cement containing up to 25% air-cooled blast-furnace slag. Unlike granulated slag, the air-cooled slag is generally more than 50% crystalline, representing a marked departure from usual practice where only glassy slags are used. A typical cement composition containing 10% air-cooled slag and 5% gypsum developed compressive strengths of 7.85, 21.2, 25.9 and 36.7 MPa as compared to 7.6, 20.2, 24.0 and 34.0 MPa, respectively, for a normal Type I portland cement.

Although not strictly a slag cement, the production in Japan of granulated slag sand for use as fine aggregate is of considerable interest. Recent work has been described by Fujimoto (6). The slag sand is formed in a similar manner to granulated slag, but cooling water is under a higher pressure than conventionally employed. Slag sand production is being studied in Australia; Ryan et al (7) have discussed the use of such a material in a test road pavement.

## MATERIALS

In order to study how the composition and preparation methods influence the morphology of granulates, eight

slags were selected for study. Two were produced by Australian Iron and Steel at Port Kembla, Australia, the first being a low MgO product, and the second a slag having a somewhat higher percentage of MgO. Both of these products were quenched using sea water. A South African slag produced by I.S.C.O.R. was water quenched as were three European slags from Hoogovens, Ymuiden Plant, Holland; Voest A.G., Linz, Austria; and Hoesch-Westfalenhutte, Dortmund, Germany. Special slags included in the study were a Canadian slag produced by air quenching and a Japanese slag sand.

## CHEMICAL COMPOSITION

The chemical composition of quenched slags can vary in at least three ways, first, bulk differences due to changes in the composition of the tapped slag secondly, differences between individual particles developed as the quenching occurs, and thirdly by the development of different silicate phases within the glass. In order to assess the bulk variations over a period of six months (January to June 1978), twenty-four samples taken from approximately 12,000 tonne of granulated slag from Port Kembla were analysed by usual silicate analysis techniques. The averages of the analyses together with the ranges, standard deviations and coefficients of variation of the data are given in Table I.

	Ave	Range	Standard Deviation	Coefficient of Variation
SiO <sub>2</sub>	35.3	34.3 - 36.3	0.55	1.56
CaO	40.3	39.4 - 41.4	0.66	1.64
Al <sub>2</sub> O <sub>3</sub>	17.6	17.2 - 18.4	0.26	1.48
MgO	3.2	2.9 - 3.7	0.21	6.57
S	0.60	0.54 - 0.66	0.03	5.00
Fe <sub>2</sub> O <sub>3</sub>	0.36	0.32 - 0.43	0.03	8.33
MnO	0.99	0.84 - 1.1	0.07	7.07
Cr <sub>2</sub> O <sub>3</sub>	0.005	0.003 - 0.007	0.001	20.00
TiO <sub>2</sub>	0.98	0.47 - 2.1	0.56	57.14
Na <sub>2</sub> O	0.37	0.24 - 0.50	0.07	18.92
K <sub>2</sub> O	0.43	0.1 - 0.7	0.09	20.93

It is concluded from the data that in a steel works subject to strict quality control, variations over a considerable period of time in the bulk composition of granulated slag, may be held within limits accepted by cement producers. The coefficients of variation of SiO<sub>2</sub>, CaO and Al<sub>2</sub>O<sub>3</sub>, are all below 2.0%. The value rises to 6.57% for MgO and to about 20% for the minor elements such as NaO and K<sub>2</sub>O. Even higher variations are noted for trace elements. As yet it has not been fully established how such variations, particularly those of NaO and K<sub>2</sub>O influence the rate of hydration of the ground granulated products, but judging from high-alkali portland cement clinkers such influences are probably significant.

Grains of granulated slag produced from the Port Kembla

plant were mounted in resin and the chemical composition of a series of grains was determined, this time using an electron probe. Care was taken to vary the position of the scanned area within any single grain so that any possible zonal variation was taken into account. Obvious crystalline materials were avoided in the scans, particularly metallic inclusions but no attempt was made to limit scans to any areas of possible heterogeneity within the glass itself. This procedure was also conducted on all the other slags discussed above, however in the case of the Japanese material, crystalline material could not be avoided. The data obtained for all the slags are presented in Table II.

It must be concluded, since the samples are all from stockpiles and not specifically selected materials, that certain processes lead to glass particles which vary in composition to a greater degree than results from others. It may be concluded from the Canadian slag that air quenching may increase the variability from grain to grain, perhaps due to incipient crystallization. The heterogeneity of the slag glasses in the micro-range by separation of liquid phases has been described by Schröder (8). It is possible that such development of different solid glass phases is reduced in the slags having low coefficients of variation.

TABLE II  
MEAN COMPOSITION AND COEFFICIENT OF VARIATION FOR PARTICLES OF GRANULATED SLAG

	Australian		Australian (high MgO)		German		Austrian		South African		Dutch		Japanese		Canadian	
	Mean	C.V.	Mean	C.V.	Mean	C.V.	Mean	C.V.	Mean	C.V.	Mean	C.V.	Mean	C.V.	Mean	C.V.
SiO <sub>2</sub>	35.83	0.92	34.21	1.05	33.95	0.59	35.74	1.71	34.18	3.45	31.47	4.35	31.23	1.67	35.63	3.65
CaO	41.05	0.51	40.11	1.15	35.85	0.84	33.89	0.65	39.40	5.13	36.84	3.23	37.36	2.86	38.76	2.37
Al <sub>2</sub> O <sub>3</sub>	16.19	1.42	16.87	2.61	13.06	1.38	10.66	2.15	10.35	3.78	16.01	7.37	16.24	8.19	7.76	5.15
MgO	2.65	4.91	5.27	2.66	12.26	1.71	11.56	3.36	11.62	5.65	10.08	4.17	8.46	11.58	11.52	6.51
SO <sub>3</sub>	1.52	4.60	1.53	5.23	2.59	5.02	2.77	6.14	2.09	5.26	2.36	3.39	3.03	19.14	4.36	11.01
FeO	-	-	0.07	28.57	-	-	-	-	-	-	-	-	0.05	40.00	0.11	36.36
MnO	1.33	12.03	0.87	10.34	0.55	12.73	2.76	11.96	1.26	25.40	0.47	21.28	0.65	23.07	0.60	34.62
Cr <sub>2</sub> O <sub>3</sub>	-	-	-	-	-	-	-	-	-	-	-	-	0.01	-	0.01	-
TiO <sub>2</sub>	-	-	-	-	0.55	9.09	0.43	11.63	0.39	12.82	1.08	9.26	1.95	13.33	0.27	29.63
Na <sub>2</sub> O	-	-	0.17	35.29	0.57	8.77	0.47	8.51	0.25	26.09	0.90	35.56	0.64	31.25	0.27	36.11
K <sub>2</sub> O	1.43	11.19	0.92	16.30	0.62	6.45	1.70	14.71	0.50	36.00	0.77	18.18	0.47	14.89	0.43	39.53

Consider firstly the results for the grains of Australian low MgO slag. Although from Port Kembla, they are not strictly of the set used to assess the bulk variability of slag over the six month period, since they are a more recent product and certain of the mean values lie outside the ranges already given for slags from that plant. Nevertheless, the coefficient of variation of all the oxides except MnO are lower for the different grains than for changes in the bulk product over the six month period. These results indicate that a very uniform glass is being produced during granulation at this plant.

Comparable coefficients of variation to those of this Australian slag are noted for the high MgO Australian slag, the German and Austrian products. In all of the other slags at least three coefficients of variation are greater than twice the highest of the above four materials for the compounds in question. For example, the Japanese coefficients of variation are relatively high for CaO, Al<sub>2</sub>O<sub>3</sub>, MgO and SO<sub>3</sub>. The explanation for this is that the Japanese material is in fact crystalline and it would be anticipated that specific points on different grains would have different compositions (figure 1). This does not explain the high values of coefficient of variation for the other materials, in particular for the CaO and SiO<sub>2</sub> of the South African and Canadian slags.

Figure 1 Japanese Slag showing Crystalline Nature (Polished Section)

#### MORPHOLOGY

Stereo-microscopic examination of the slags indicated significant differences in their morphology. Rather than describing in detail each slag the important

Figure 2 Straight and Bent Acicular Particles - Australian Slag

similarities and differences will be discussed. The first important difference between certain of the slags and others is the tendency to form acicular particles. The South African product is a dark buff coloured slag with marked vesicular characteristics. Needle-like particles can be seen macroscopically, and under the microscope it is noted that the finer fractions are almost all made up of either straight or bent acicular particles. The Australian materials (figure 2) show a smaller proportion of acicular particles, the quantity being less in the high MgO Australian slag. The Dutch slag is greyish-buff and is formed of equant grains with relatively few acicular particles, but a fair proportion of material smaller than 330  $\mu\text{m}$  is present. The granulated slag from Austria is dense and either black or brown in colour. The finer fraction appears to be made up of an abundance of shards. A few very long (>20mm) fine individual fibres are present, but there is no significant amount of needle-like particles in the finer fractions. Acicular particles are absent from the Japanese and Canadian slag (figure 3).

Figure 3 Air Quenched Canadian Slag (Polished Section)

There are two possible explanations of the tendency of certain slags to form such acicular particles. The first is that they are formed by the purely mechanical

process of high-speed attenuation of steam jets, converging at a small included angle upon the stream of molten glass. This process may not be smooth, such as to form long uniform fibres of the type developed in fibre glass manufacture, but the melt may be drawn out turbulently in many directions to produce short, fine often bent fibres, together with some small glass particles or shot.

The other possibility is that the glasses which form such acicular products are Stuart liquids, consisting of elongated polymer chains. Schröder (8) suggests that slag melts rich in basic oxides cannot be blown into fibres without increasing their proportion of Stuart liquid by the addition to the melt of fine quartz sand, and this would suggest that the melts should be considered Frenkel liquids. It is tentatively suggested that, under conditions such as that associated with the formation of granulated slags using water-quench spraying techniques, the structural elements of the Frenkel liquid are forced into elongated chain structures by the mechanism of rapid flow. This would explain the development of fibres in certain of the slags and not in others, and for the fact that experiments done on non-mobile melts would indicate that they are essentially Frenkel liquids.

#### ASPECTS OF HYDRATION OF GRANULATE PARTICLES

In order to study some aspects of hydration of slag in the presence of cement paste, a series of 25 mm cube specimens were cast using unground, low MgO, Australian slag mortar, quartz sand mortar and cement paste, all having a water-cement ratio of 0.5. Half of the specimens were cured over water at 21°C; the others were subject to a continuous moist curing regime at 80°C from six hours after casting. The cubes were tested at 21°C in compression at the times indicated in figure 4, care being taken to minimise the effects of thermal shock by slow cooling of the specimens cured at 80°C.

Figure 4 Compressive Strength vs Curing Period

For the normally cured specimens the curves of the paste and sand mortar follow one another closely. The curve for the slag mortar is almost linear on a log-time plot. This mortar appears to continue gaining strength at this rate even between 28 and 60 days, during which period strength gain of the other two materials is increasing at a somewhat lower rate. The strength of the slag mortar is always lower than that of the sand mortar up to an age of 60 days. The two

mortars were designed with the same proportions by weight, even though there is a slight difference in specific gravity between the fine aggregates; the difference in strengths is not however due to this fact.

Elevated temperature curing leads to rapid strength gain in all the specimens, but increments at later ages are low. The sand mortar strengths are again higher than the slag mortar values at all ages.

Mortar bars (500 x 40.5 x 68.5 mm, 2:1 Agg:cement, 0.5 W:C) were subjected to flexural four-point loading in order to determine the tensile strength characteristics of slag and sand mixes. The data obtained are summarised in figure 5.

Figure 5 Tensile Strength vs Curing Period

At all ages the slag mortar has a lower strength than a comparable sand mortar. The ratio of slag mortar strength to sand mortar strength is fairly constant (0.7) at all ages between 1 and 28 days. If figures 4 and 5 are compared it is noted that the linear increment of slag-mortar strength with log-time is true only for the compressive strength; the rate of tensile strength increment with time is always less for slag mortar than for sand mortar.

It can be concluded from electron microscopy conducted on specimens which had been failed by compressive loading, that bonding between the granulated slag and the cement is less well developed than bond between quartz particles and cement. Failure invariably occurred at the aggregate-paste interfaces in slag mortars (figure 6a and b), despite the fact that the high temperature curing allowed hydration to proceed into the slag particles as evidenced by reaction rims (figures 7a and b).

Figures 6a and 6b Paste-Aggregate Interface Failure (21°C, Compressive Strength Specimen)

Figures 7a and 7b Reaction Rims and Failure Plane on Slag Cured at 80°C

In the case of sand aggregate, cracks through sand particles and through the cement matrix were often in evidence. The failures at the cement-slag interfaces were also manifest by the existence of casts left in the paste matrix.

These results suggest the anomaly that although for very fine slag particles hydration reactions do occur and reaction rims do form under high temperature curing, yet bonding of the cement paste hydrates to the slag surfaces appears to be weak. Consideration was given to the possibility that granulated slag may be somewhat hydrophobic. A study was therefore made of the interaction of slag particles with water.

In the presence of air, the contact angles between water and the three solids, slag, cement clinker and quartz sand were measured by placing a water droplet on a clean ground surface of the individual materials and measuring the angle by means of an ocular fitted with cross hairs in a rotatable microscope barrel. The higher contact angle (average 50°) for the slag, as opposed to that of sand and cement clinker (average angle for both being 46°) indicates that the adhesion of water to sand and unground clinker is greater than the adhesion of water to slag. The particular slag therefore shows a reduced affinity for water when compared with sand or portland clinker. This factor could in part lead to the phenomena noted previously in terms of the mechanical strength. The fact that granulated slag generally drains rapidly and has been used for this purpose in road construction projects may also be explained by this lack of affinity between its surface and water.

Whether the somewhat hydrophobic nature of slag is still operative after grinding has not yet been determined, but it may possibly explain some of the observed differences in properties both between slags, and between slag and portland cement behaviour.

#### CONCLUSIONS

Some important granulation techniques have been mentioned which will influence products and procedures in cement use and manufacture. An attempt has been made to assess chemical variability of some slags which have been differently treated under conditions of practice. The morphology of slags treated in such different ways varies significantly. It is believed that certain slag melts show a propensity towards being Stuart liquids under dynamic water quenching and that some may show an hydrophobic tendency which should be further studied.

#### ACKNOWLEDGEMENT

Mr. R. Williams of Australian Iron and Steel Pty Ltd was responsible for the procurement of the slags; both he and D. Campbell-Allen, Professor of Civil Engineering at the University of Sydney are thanked for their interest in this work.

# Research on the Main Mineral Phase and Its cementitious Properties of Oxygen Converter Slag (O.C.S.)

## *Etude des principales phases minérales des laitiers de fours à oxygène et de leur activité*

WANG YU-JI, Lecturer, Department of Construction Materials Engineering, Tong Ji University,  
XIE GONG-XIN, Engineer, Jiang You Cement Research Institute, China.

**RESUME :** Ce rapport décrit spécialement certaines notions importantes sur la fabrication de ciment en employant les laitiers provenant de fours à oxygène. A l'aide de l'analyse chimique et thermodifférentielle, de la technique pétrographique et des essais de diffraction par rayons X, on a réussi à déterminer les compositions chimiques des laitiers, de leurs composants minéraux et leurs propriétés d'hydratation. En outre, on a élaboré une méthode théorique de calcul des principaux éléments des laitiers et de leurs propriétés physiques et mécaniques.

Les éléments principaux de laitiers à four rotatif à oxygène sont : le silicate tricalcique, le silicate bicalcique et sa solution solide contenant du phosphore, la ferrite bicalcique, la phase RO et la chaux libre. En outre, il y existe aussi, en faible quantité, de l'aluminate, de l'alumino-ferrite, de l'apatite, de la fluorine, du métal ferreux etc...

Les qualités de laitiers des fours à oxygène peuvent être déterminées approximativement par les teneurs en silicate tricalcique et chaux libre. D'où leur classement en catégories pour la facilité du contrôle et leur utilisation. Les laitiers contenant plus de 40 % de silicate tricalcique et moins de 3 % de chaux libre sont souvent utilisés pour fabriquer le ciment de laitier, en ajoutant une certaine quantité de plâtre pendant la mouture. Les laitiers contenant 50 à 55 % de silicate tricalcique, ont une résistance à la compression à 28 jours de 50 à 60 N/mm<sup>2</sup>; pour une teneur en C<sub>3</sub>S de 46 à 50 %, une résistance à la compression égale à 40-50 N/mm<sup>2</sup>; et pour une teneur de 40 à 46 %, 30 à 40 N/mm<sup>2</sup>.

**SUMMARY:** This article describes mainly about some problems in the experimental works for making of cement with O.C.S. The chemical composition, mineral component and the properties of hydration of the steel slag were investigated by chemical analysis, petrographic technique, XRD and DTA. Theoretical calculations for chief minerals were carried out and physico-mechanical properties of the steel slag cement were tested.

The main minerals of the O.C.S. are tricalcium silicate, dicalcium silicate and its solid solution containing phosphorous, dicalcium ferrite, RO-phase, free lime and some amount of aluminate, alumino-ferrite, fluor apatite, fluorspar, metallic iron and etc.

The quality of O.C.S. can be approximately discriminated by the content of tricalcium silicate and free lime, so that the slags can be graded accordingly and utilized appropriately. When a steel slag has a content of tricalcium silicate >40% and that of free lime <3%, it can be milled together with a definite amount of gypsum to produce qualified steel slag cement. As the content of tricalcium silicate amounts to 50-55%, the cement made from it will have a compressive strength of 50-60 N/mm<sup>2</sup> at 28 days; a content of C<sub>3</sub>S of 46-50%, a compressive strength of 40-50 N/mm<sup>2</sup>; a content of 40-46%, 30-40 N/mm<sup>2</sup>.

### The Mineral Components and Morphological Structure of O.C.S.

As we all know steel slag is the by-product of steel making, sometimes it was considered as a kind of waste. In fact, it is a cumulative product of many kinds of minerals. During a certain period of time we collected about 30 sample slags from different converters that were producing various kinds of steel and investigated them. We found that the main minerals presented in those slags are tricalcium silicate, dicalcium silicate and its solid solution containing phosphorous, dicalcium ferrite containing some small amount of  $Al_2O_3$ , RO-phase (the solid solution of Fe, Mg and Mn, mainly of FeO), free lime, solid solution containing Fe and in addition, some small amount of fluor apatite, fluorspar, metallic iron and etc.

Under the direct lighting of a microscope the  $C_3S$  in the slags appears to be colorless or unevenly and slightly tinted with yellow-green transparent crystals. According to morphology they have different forms. In the thin section of the sample, they are usually observed to be hexagonal in shape (Fig.1),

Fig.1 Hexagonal section of  $C_3S$   
Direct lighting 100 x

but most of their crystals are columnar, tabular or acicular, their grain size are bigger and they are always encrusted by many cladding substances. Usually we can see RO-phase that grows along the bands of  $C_3S$  with definite orientation (Fig.2), and sometimes we can see also granular  $C_2S$  and fluor apatite co-existing with  $C_3S$  in the notch at the boundary of  $C_3S$  crystal.

$C_3S$  has a refractive index  $n = 1.720-1.725$ , low colour interference, it appears to be first grade grey to greyish white, parallel extinction, positive elongation.

The phosphorous in O.C.S. mostly dissolves into  $C_2S$  in solid state to form solid solution. Due to the differences in the content of phosphorous, alkalinity and metallurgical

Fig.2 RO-phase grown along the bands of  $C_3S$  with definite orientation  
Parallel polarized light 250 x

process of various kinds of steel, the contents of phosphorous in the solid solution of  $C_2S$  of different slags are different. The slags in which the phosphorous is stabilized to form fluor apatite contain  $\beta-C_2S$ .

The solid solution containing phosphorous is usually cladded by  $C_3S$  and appears to be round granular, irregularly granular, cnidoblastic or finger like and other forms. Their optical property is similar to that described by Agrell [1] about the metamorphism of  $C_2S$  containing phosphorous. In the slags with low alkalinity we found what was described by Agrell, the clear rhombic crystal of  $C_2S$  which was grown out from the contaminated type of  $C_2S$  (Fig.3), its optical property is the same as  $C_2S$ . We found: refractive index  $n = 1.75-1.735$ , a colour inter-

Fig.3 Rhombic crystal of  $C_2S$   
Direct lighting 250 x

ference of first grade yellow to bright yellow, inclined extinction, section of parallel extinction has negative elongation, +2v greater.

O.C.S. are the slags produced with the addition of fluorspar during the metallurgical process, but their phosphorous contents are not always stabilized to form fluor apatite

and more often they dissolve into  $C_2S$  in solid state. We carried out petrographic analysis for 22 slag samples picked up during the year of 1973 and 1975. The result of the analysis shows that only one sample contains slender needle shaped fluor apatite. In samples which contain more phosphorous and at the same time the phosphorous is not stabilized to form fluor apatite, in such case even if its alkalinity is very high, it can not be saturated with all the silica it contains to form  $C_3S$ , a part of the silica will form the solid solution of  $C_2S$  containing phosphorous.

Usually we can find solid solution of  $C_2F$  containing a small amount of  $Al_2O_3$  in solid state in the slags. Under the direct lighting of a microscope it appears to be reddish black, no polychromatic property, and under crossed polarized light, to be deep red in colour. Its crystals may be columnar, irregularly columnar, granular or ball like, usually intergrowing with RO-phase and sometimes being cladded by  $C_3S$ . It is characterized by biaxial crystal, parallel extinction with negative elongation and having cracks and incomplete cleavages at the base.

The RO-phases are isotropic homogeneous mass. They are opaque and dark or black in colour and in myrmekitic, granular, dropwise, stripy, hackly or other forms (Fig.2). They are usually cladded by  $C_3S$ , and coexist with the solid solution of  $C_2F$ .

There are two kinds of free lime in the slags, the purer one and the solid solution (Fig.4). The former is f-CaO and the latter is  $CaO+x\% FeO$  ( $0 < x < 10\%$ ). They can be easily distinguished in the XRD patterns, f-CaO has  $d=2.41\pm$  and F-CaO in solid solution state has  $d = 2.38\pm$ .

#### A Study of the Cementitious Properties of O.C.S.

##### 1. Chemical Composition of O.C.S.

From table I, we can see that O.C.S. are alkaline slags. They are characterized by its high c/s ratio and low aluminium and high iron contents.

##### 2. The cementitious Properties of O.C.S.

We tried to add different amount of gypsum to prepare several steel slag cements and the physico-mechanical properties of their pastes were tested. The results are shown in Fig.5. O.C.S. is such a material of having certain hydraulic property. In case, without adding of any additive so long as it has a fineness same as ordinary cement, its 28 days strength is quite high, although its early strength is rather low. The addition

Fig.4 The solid solution of granular f-CaO having dark brown fringe & cross cleavage Direct lighting 100 x

Table I. Average chemical composition of the sample slags of Shanghai Steel Plant

Chemical composition						
year	SiO <sub>2</sub>	CaO	Al <sub>2</sub> O <sub>3</sub>	Fe <sub>2</sub> O <sub>3</sub>	FeO	P <sub>2</sub> O <sub>5</sub>

Fig.5 The influence of gypsum content to the compressive strength of cement prepared with O.C.S.

of gypsum do increase its early strength greatly, but it gives little contribution to the strength at later days. If the gypsum is in excess the strength will tend to decrease. According to the above principle we selected 8% gypsum content to prepare 64 sets of steel slag cement samples with various kinds of slag, and their properties were examined. We obtained an average 28 days compressive strength of  $34.9 N/mm^2$  and higher ones reached  $50 N/mm^2$ , but the fluctuation in quality

appeared evident, the coefficient of variation was 40%. The results of soundness tests also varied in a wide range. Now we put forward several problems and try to discuss them in the following sections.

#### Discussion on Problems for Making Cements from O.C.S.

##### 1. Factors affecting the fluctuation on the strength of steel slag cement.

As slags are the products which have passed through melting at high temperature and then cooled down gradually, the course of their formation may be regarded as an equilibrium process in physical chemistry.

To 64 sets of slag cement samples, basing upon their chemical composition, we carried out theoretical calculations to the amounts of their component minerals. Though such kind of calculation could hardly to be strictly accurate because of the complexities of the states of solid solutions in the slags, yet the components of slags can be generally estimated, thus their cementitious properties can be evaluated.

On the basis of primary investigation on the structures of main mineral constituents in slags, they are divided into two major groups: the one is the type of fluor apatite and the other, solid solution of  $C_2S$  containing phosphorous. The former has  $p/s < 0.1$  and the latter has  $p/s > 0.1$ . [2]

From the calculated results, the correlation between each content of mineral component in slags and the 28 days strength of slag cements were analyzed by Computer, through progressive regression analysis, we found that the correlation between the theoretical content of  $C_3S$  and the 28 days compressive strength was the best one. Thus we took the average values of  $C_3S$  of  $m$  samples with  $\Delta C_3S = 0-1\%$  and their corresponding 28 days compressive strength to make a correlogram as shown in Fig. 6.

From Fig. 6 we can see the correlation curve starts gently; when  $C_3S$  content  $< 20\%$ , the 28 days compressive strength  $< 10 \text{ N/mm}^2$ ; after  $C_3S > 20\%$ , the effect of  $C_3S$  content to the compressive strength increases appreciably; when  $C_3S > 40\%$ , without any exception, all the 28 days compressive strengths exceed  $30 \text{ N/mm}^2$ ; when  $C_3S > 46\%$ , the 28 days compressive strength reaches  $40 \text{ N/mm}^2$ ; when  $C_3S > 50\%$ , the 28 days compressive strength reaches  $50 \text{ N/mm}^2$ .

Certainly, the factors affecting the strength of hardened cement paste are numerous. In addition to the  $C_3S$  content, there are also the effect of crystalline structure, the

Fig. 6 The correlation of 28 days compressive strength of slag cement to its theoretical content of  $C_3S$ .

effect of other minerals, as well as the degree of weathering of the slags, fineness of cement, water cement ratio, and curing conditions, etc.

The early strength of slag cements are generally rather low. The 7 days compressive strength in comparison with that of 28 days is only about 40%; but in later stage, the strength increases more quickly, the 90 days compressive strength will reach 125-140% of 28 days compressive strength. This can be explained by two main reasons: the lack of minerals of aluminates in slag and the  $C_3S$  crystals formed in the melting state are dense and hydrate slowly.

##### 2. Hydration of steel slag cement

We choose two typical samples  $J_3$  and  $J_4$  for analytical study. The chemical constituents and mineral components of the samples are listed in Table II.

Table II. The Chemical Constituents and Mineral Components of Slags  $J_3$  and  $J_4$

sample	Chemical Constituents (%)					
	CaO	SiO <sub>2</sub>	Al <sub>2</sub> O <sub>3</sub>	Fe <sub>2</sub> O <sub>3</sub>	FeO	P <sub>2</sub> O <sub>5</sub>
$J_3$	52.0	12.05	1.33	6.01	13.78	3.04
$J_4$	48.3	7.33	0.82	8.55	19.60	2.39

sample	Mineral Components (%)				
	$C_3S$	$C_2S$	$C_3A$	$C_2F$	f-CaO
$J_3$	46	0	1.3	12	3.9
$J_4$	20	11	0.8	16	16.0

The slags are milled to the fineness of ordinary cement, and the products are the pure

Fig.7 Patterns of XRD and DTA for slag cements at different stages of hydration.

slag cements labeled by J<sub>3-0</sub> and J<sub>4-0</sub>, when with the addition of 8% gypsum, by J<sub>3-8</sub> and J<sub>4-8</sub>. The results of XRD and DTA investigations at different stage of hydration are shown in Fig. 7.

From the analysis to the results of the experiment, we concluded:

(a) solid solution of C<sub>2</sub>S and solid solution of C<sub>2</sub>F are minerals of poor hydration activity or of very low cementitious property. RO-phase, fluor apatite, fluorspar etc. are minerals with very poor hydration activity or without cementitious property.

(b) minerals containing aluminates and aluminoferrites have good hydrating property, and when gypsum is added, their hydration products are ettringite.

(c) C<sub>3</sub>S in slags provide good cementitious property, they are the main minerals for the hardened cement paste to gain strength. With slags of high lime content (J<sub>4-0</sub> and J<sub>4-8</sub>), their hydration products are mainly C<sub>2</sub>SH.

When their lime content are relatively low (J<sub>3-0</sub> and J<sub>3-8</sub>), the main hydration products are C-S-H. In the absence of gypsum the hydration process begins to be evident after 14 days. In the presence of gypsum, the hydration process is greatly accelerated.

(d) Free lime, especially their solid solutions, hydrates slowly, its hydration products are Ca(OH)<sub>2</sub>.

(e) By adding with gypsum, it changes the hydrates from aluminates and aluminoferrites into needlelike polyhydro-complex of polysulfo-aluminates, more over, it accelerates the hydration of C<sub>3</sub>S at the early stage, increases the early strength, but has no distinct effect on the setting time and the soundness of the cements. [3]

### 3. Factors affecting the volumetric soundness of slag cements

Excessive free lime, especially in presence of solid solution with small amount of FeO, is the primary cause of volumetric unsoundness of steel slag cement. When free lime content is above 4%, all samples fail to meet the general requirements; when the contents are above 3%, most of the samples are disqualified, the free lime in the remainder qualified samples (such as J<sub>3</sub>) was determined to be in relatively pure state. Thus we can see, for the cause of unsoundness in slag cements, both the content and the state of free lime have to be concerned.

### CONCLUSIONS

O.C.S. is a kind of material with certain cementitious property. Its hydraulic activity depends primarily upon the C<sub>3</sub>S content. Al-

though the minerals of aluminates and aluminoferrites are of high hydraulic activity, yet their contents in O.C.S. are too low, and the rest minerals are considered to be less active.

In the slags, the presence of excessive free lime, especially in the presence of its solid solutions with rather slow hydraulic activity, is the main cause of unsoundness. They could be milled directly into slag cements only when their free lime contents lie below 3%.

The slags with theoretical amount of C<sub>3</sub>S above 40% and free lime below 3%, by blending with 5-8% of gypsum, can be milled to obtain slag cement. These cements have qualified soundness and normal setting time although early strength are rather low, but increases more rapidly in the later stage, they are also fairly abrasion proof and impermeable.

### ACKNOWLEDGEMENTS

The authors would like to acknowledge comrades FANG QIU-QIN, LING DA-LI and WENG WEI-SONG, Dept. of Construction Materials Engineering, Tong Ji University, for their participating the experimental works for this article.

# Effect of MgO in steel slag on soundness of cement

## *Influence du MgO contenu dans les laitiers sur la stabilité du ciment*

Luo SHOUSUN, Engineer, Cement Research Institute, Chine Populaire.

RESUME : Des études ont été faites sur l'influence de la forme et de la teneur en MgO sur la stabilité à long terme des ciments de laitier. En général, les MgO se présentant en état de combinaison chimique dans les monticellites etc. n'exercent pas d'influence sur la stabilité du ciment. Mais quand les MgO sont libres, c'est à dire en forme de périclase, le ciment sera instable. La stabilité du ciment dépend du rapport  $MgO/FeO+MnO$  lorsque les MgO sont en solution solide dans la phase R0. Le ciment est stable quand ce rapport est  $< 1$  et le ciment est instable quand ce rapport est  $\geq 1$ .

On peut obtenir la stabilité à long terme du ciment de gypse et de laitier, c'est à dire la prévention de l'hydratation du périclase dans le ciment, en prenant une des trois mesures ci-dessous :

- 1) Addition d'un peu de sels de magnésium, par exemple  $MgSO_4 \cdot 7H_2O$ ;
- 2) Addition convenable de laitier expansé ou de matières siliceuses telles que des cendres volantes;
- 3) Carbonisation du ciment hydraté.

SUMMARY: The relationship between the form and content of MgO in steel slag and the long-term soundness of steel slag cement has been studied. When MgO is in the form of combined state, e.g. in monticellite, etc. The cement is usually sound. Whereas if MgO is in free state, i.e. periclase, the cement is liable to be unsound. In the case of R0 phase in which the MgO is formed in solid solution, the soundness of the cement depends upon the ratio of  $MgO/FeO+MnO$ . The cement is sound when the ratio is  $< 1$ , whereas the cement is unsound, when the ratio is  $\geq 1$ .

The long-term soundness of gypsum-steel slag cement or otherwise the prevention of the hydration of periclase in cement have been successfully achieved by one of the three methods, i.e.:

- 1) By adding a small amount of magnesium salt, e.g.  $MgSO_4 \cdot 7H_2O$ ;
- 2) By mixing a pertinent amount of granulated blast furnace slag or siliceous material such as fly ash;
- 3) By carbonization of the hydrated cement products.

## INTRODUCTION

In recent years, the use of steel slag to make cement has aroused interest because of the nuisance created by the volume of the stock-pile and also in view of energy economy. Up to this date, there has been no report outside this country about the production of steel slag cement. Since the early years of the seventies, China has achieved in utilizing steel slag to produce gypsum steel slag cement and carbonized steel slag products with satisfactory result in the construction work (1,2).

## THE PHYSICOCHEMICAL STATE OF MgO

Steel slag of different varieties have been investigated, e.g., the early slag, the refining slag and the tapping slag from open hearth furnace, the oxidizing slag and the reducing slag from electric arc furnace and the Thomas slag from converter. The chemical compositions, ratios of  $\text{CaO/SiO}_2$  and of  $\text{MgO/FeO+MnO}$  of the slags investigated are as shown in table I. The minerals of the slags have been identified by means of XRD (fig. 1) and optical microscope (fig. 2)

No.	Types of Furnace	Kinds of slags	$\text{SiO}_2$	$\text{Al}_2\text{O}_3$	$\text{Fe}_2\text{O}_3$	CaO	FeO	MnO	MgO	$\frac{\text{CaO}}{\text{SiO}_2}$	$\frac{\text{MgO}}{\text{FeO+MnO}}$
1	Open Hearth	Early	12.14	4.35	5.38	50.46	9.33	4.52	6.56	4.16	0.47
2	"	Refining	9.48	4.11	21.18	33.54	10.35	3.11	14.77	3.53	1.10
3	"	Tapping	13.65	4.88	7.44	39.94	11.12	0.62	14.65	2.92	1.25
4	Electric arc furnace	Oxidizing	25.89	4.00	1.36	28.52	15.68	3.44	18.34	1.10	0.95
5	"	Reducing	19.68	13.05	1.04	47.64	-	1.84	14.97	2.42	8.13
6	Converter	Thomas(5)	17.68	2.70	4.75	48.25	12.97	1.46	9.08	2.70	0.63

In the steel refining process, the use of dolomite as flux and the corrosion of magnesia refractory lining often result in the slag to contain MgO exceeding the limit of 6% normally set on portland cement. Question therefore arises, what about the long term soundness of cement and its products that are made from steel slag? J.J. Emery (3) and R. Kondo (4) have recently reported about the undue expansion that might arise from MgO in steel slag. With the view to utilize steel slag with benefit in the making of cement, we have made investigations on the physicochemical states and the relative quantities of MgO in the steel slags in relation to the long term soundness of cement.

MgO in steel slag of basic furnace exists in three states, i.e., chemically combined state, uncombined or free state and solid solution. As it can be seen from fig. 1 and 2, the chemically combined form monticellite is found in the oxidizing slag from the electric arc furnace, the free form periclase is found in the reducing slag also from electric arc furnace and MgO in solid solution form or the RO phase, as named by Mason (6), is found in all slags except the reducing slag.

The RO phase is a solid solution of  $\text{MgO-FeO-MnO}$  series. When the slag has a high content of CaO, e.g., CaO= 52.30%, the RO phase may also contain a small portion of CaO in the solid solution. This

 Transmitted light, 200x

phase are all of regular system, their cell dimensions, lattice spacings and cationic radii are quite approximate (see table II), so that the

Table II Crystalline Characteristics of the Divalent Oxides in RO phases (8)					
Names of Minerals	Molecular formulae	Crystal Systems	Cell dimensions (Å)	Lattice spacings (Å)	Cationic radii (Å)
Periclase	MgO	Regular	4.2	2.106	0.78
Wustite	FeO	"	4.3	2.153	0.83
Manganous oxide	MnO	"	4.35	2.200	0.91

cations are interreplaceable to form solid solution. When Fe and/or Mn cations of larger radii enter into solid solution with periclase crystal, the cell dimension and the lattice spacing become larger; whereas if Mg cations of smaller radius enter into the solid solution with wustite or manganous oxide, the cell dimension and the lattice spacing become smaller. In other words, the variations in cell dimensions and the lattice spacings are related with the compositions of the solid solutions.

As it may be seen from table III, the smaller is the  $MgO/FeO+MnO$  ratio, the larger are the cell dimensions and the lattice spacings. When the ratio is  $\geq 1$ , RO phase is of periclase or ferrous periclase type, the cement made from which is unsound after autoclave treatment. On the contrary, when the ratio is  $< 1$ , the RO phase is of wustite,

Mg-wustite or Mg-Mn-wustite type, the cement made from which is sound after autoclave treatment.

When MgO is in chemically combined state such as it is in monticellite or in merwinite, it is usually nonreactive. So it is not necessary to set limit on its content. The MgO in the oxidizing slag is either contained in monticellite or in Mg-wustite phase so the cement is sound under autoclave treatment, whereas the cement made from the reducing slag, because of the high content of periclase in the slag, collapses under autoclave treatment. Therefore due measures have to be taken in the use of reducing slag.

#### MEASURES TO IMPROVE THE LONG TERM SOUNDNESS OF STEEL SLAGS

Investigations have been carried out to improve the long term soundness of cement made from the

reducing steel slag. The slag that has been studied has the following chemical aspects, i.e.,  $\text{CaO/SiO}_2 = 3.3$ ,  $\text{MgO} = 10.60\%$ ,  $\text{FeO} = 0.59\%$ ,  $\text{MnO} = 0.37\%$ . Experiment shown that the gypsum steel slag cement made from the above reducing slag with slag to gypsum ratio = 92:8 is unsound when it is subjected to autoclave treatment. But when a pertinent amount of any of the following ingredients is incorporated with the slag, e.g., granulated blast furnace slag, siliceous materials or  $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$ , the long term soundness of the cement is improved as proved by autoclave testings (See table IV). Our experiments further shows (See table V) that the reducing slag products having 0.2% syrup added as retarder but with no addition of gypsum, if carbonized prior to autoclave treatment, could be also sound.

The effect of the additives is shown in fig. 3. In XRD spectra 1 and 2 respectively of the reducing slag and its hardened paste, periclase can be recognized by its peak at  $d = 2.10-2.11 \text{ Å}$ . In spectrum 3 of the autoclave treated specimen which collapsed, the peak of periclase vanished while

there appeared instead peaks of prucite at  $d = 4.77$ , 2.7 and 1.58 Å, which fact implies that the collapse of the specimen was due to the hydration of periclase ( $\text{MgO}$ ) to brucite ( $\text{Mg}(\text{OH})_2$ ) which results in destructive expansion. Spectrum 4 represents carbonized paste after autoclave treatment that

has remained intact. There can be seen peak of periclase but none of brucite which implies that carbonation can protect periclase from hydration even under autoclave treatment, thereby keep the specimen sound. The specimen with addition of  $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$  which has also remained intact after autoclave treatment is shown in spectrum 5. In spite of the fact that the height of the peak of periclase has appreciably decreased which could imply that at least part of the periclase has undergone hydrolysis, yet it does not result in undue expansion. The reason thereof might be that the formation of some complex salt like  $m\text{MgO} \cdot n\text{MgSO}_4 \cdot p\text{H}_2\text{O}$  as suggested by Butt(9) accelerated the hydration of periclase before the specimen was subjected to autoclave testing. The specimen that has been incorporated with fly ash but without gypsum and carbonized prior to autoclave treatment has also remained intact. Its XRD spectrum 6 indicates the presence of periclase and calcium carbonate. Likewise it implies that periclase has been protected from hydration. Our experiment has further verified that the incorporation of quartz also helps to improve the soundness of steel slag cement. We notice that similar result has been obtained by Gaze and Smith with high magnesia portland cement (10).

#### CONCLUSION

The long term soundness of steel slag as assessed from results of autoclave testings is related with the form or state of MgO and its content relative to other divalent oxides present as RO phase. The chemically combined MgO has not but the free MgO or periclase has harmful effect. The effect of MgO in form of solid solution on soundness is determined by  $\text{MgO}/\text{FeO}+\text{MnO}$  ratio. It can be detrimental when

the ratio exceeds 1 and vice versa. The long term soundness of the reducing steel slag can be favorably improved by additive of magnesium sulphate, incorporation of siliceous materials or granulated biased furnace slag as well as carbonization treatment.

# Cements along the join $C_4A_3\bar{S}-C_2S$

## *Ciments en fonction de l'ensemble $C_4A_3\bar{S}-C_2S$*

K. IKEDA, Doctor of Science, Department of Mining and Mineral Engineering, Yamaguchi University, Ube, Japan.

RESUME : Une série de nouveaux ciments, utilisant principalement du laitier de haut-fourneau et du plâtre comme matière première, a été étudiée en fonction de l'ensemble  $C_4A_3\bar{S}-C_2S$ . Deux sortes de clinkers ont été préparés à 1200 et 1300°C. Les constituants de ces clinkers ont été identifiés : ce sont principalement  $C_4A_3\bar{S}$  et  $\alpha'-C_2S$ , avec une proportion appréciable de CA et une petite quantité de C $\bar{S}$ . La présence de verres a été décelée dans les clinkers fabriqués à 1300°. Ces clinkers sont très fragiles et se broient très facilement.

Les résistances des pâtes hydratées à E/C = 0,40 ont été mesurées sur micro-éprouvettes à 28 jours. L'alumine augmente les résistances, surtout aux premiers âges. Par exemple, pour des clinkers fabriqués à 1200°C, les résistances étaient respectivement de 16,1, 27,2, 30,9 MPa à un jour, et 34,2, 58,0 et 60,2 MPa à 28 jours, quand la proportion d'alumine croissait.

Bien que le durcissement des ciments fabriqués à 1300°C soit retardé par la présence du verre, de fortes résistances à la compression ont été obtenues à 3 jours. Cette rapide augmentation semble due à l'action des ions calcium provenant de la dissociation du silicate bicalcique; ces ions activent la précipitation de l'ettringite en solution solide, par suite d'un effet de surface entre  $C_4A_3\bar{S}$  et  $C_2S$  dans la solution.

On a observé une baisse de la résistance à la flexion dans certains de ces ciments; mais cette résistance restait au moins égale à celle du ciment Portland; il n'en résultait donc pas en pratique d'inconvénient. Cette baisse de résistance à la flexion peut être combattue par addition de plâtre ou de gypse dans les ciments, de façon à empêcher la transformation du trisulfate en monosulfate.

SUMMARY : A series of newly developed cements called "supersulphated alumina-belite cements" has been studied along the join  $C_4A_3\bar{S}-C_2S$ , using blast furnace slag and gypsum as main raw materials. Limestone and bauxite are needed in the production, but they are replaced by the chemicals of calcium carbonate and alumina in the present experiments. Two series of clinker were prepared at 1200°C and 1300°C. The main constituent minerals were identified to be  $C_4A_3\bar{S}$  and  $\alpha'-C_2S$ , associated with considerable amounts of CA and C $\bar{S}$ . In the 1300°C series presence of glassy phases was noticed. The raw mixtures gave so soft clinkering that no hard grinding was required to make cements. Hydration strength was examined in pastes with W/C 0.40, using small scale test pieces up to 28-day age. With increasing alumina content, compressive strength as well as early strength was increased. For several 1200°C series, for instance, the strength of 16.1, 27.2 and 30.9 MPa at 1-day age increases to 34.2, 58.0 and 60.2 MPa at 28-day age, respectively, when alumina content is increased. Although the hardening of 1300°C series was retarded due to the "coating effect" of glassy phases present, high compressive strength was also reached in 3-day age. This rapid development of hardening may be attributed to the catalizer action of calcium ions derived from the C $\bar{S}$  in solutions, i.e., the calcium ions stimulate the precipitation of ettringite solid solutions by the "cooperative effect" between the  $C_4A_3\bar{S}$  and the  $C_2S$ . Some depression of bending strength was observed in several cements, but the strength after depression is nearly equal to that of Portland cements. Therefore, there will be no trouble in practical use of it. The depression may be improved by admixing gypsum or anhydrite. Since the trisulphate-monosulphate conversion estimated to occur in later age would be the cause of the depression.

## INTRODUCTION

Portland cements mainly consist of four principal clinker minerals,  $C_3S$ ,  $C_2S$ ,  $C_4A$  and  $C_4AF$ . The latter two minerals are present in small amounts and are of minor importance for the strength. Therefore, for simplification, Portland cements may be regarded to be composed of two principal minerals,  $C_3S$  and  $C_2S$ . On the other hand the compound of  $C_4A_3\bar{S}$ , identical with naturally occurring mineral "haüyne" in structure (1), is known to be hydraulic and its hydration strength was tested by Budnikow et al. (2). The compressive strength observed is 18.9 MPa at best at 28-day age. The resulting strength is not so high as that of  $C_3S$ , which is generally 49 MPa at 28-day age. Therefore, replacement of  $C_3S$  with  $C_4A_3\bar{S}$  seems to be disadvantageous in Portland cements and its application has been limited in the field of expansive cements. However, utilization of  $C_4A_3\bar{S}$  replacing  $C_3S$  in Portland cement system will result in saving of energies for burning, since  $C_4A_3\bar{S}$  requires lower temperature for its formation. From this viewpoint "supersulphated aluminabelite cements" burnt along the join  $C_4A_3\bar{S}$  -  $C_2S$ , utilizing blast furnace slag and gypsum as main sources of raw materials have been investigated in the present study.

## EXPERIMENTAL

## Raw materials and mineralogical setting

A water quenched powdered blast furnace slag, "Esment" commercially sold by Shin-nittetsu Chemicals Co. was used as one of the main sources, although both gradually cooled slags and low grade clays will also do for the present purpose. Specifications of the slag are given in Table I. Chemicals of JIS first grade  $CaSO_4 \cdot 2H_2O$ ,  $Al_2O_3$  ( $\alpha$ -alumina) and  $CaCO_3$  were used for present investigation in place of industrially used "gypsum", "bauxite" and "limestone" for the ease of treatment. As the measure of mixing the raw materials A/S wt ratios, 0.4, 1.0, 2.0 and 3.0 were set instead of the mineral ratio  $C_4A_3\bar{S}/C_2S$ , which represents four points of the join  $C_4A_3\bar{S}$ - $C_2S$ , because of the complexity of chemical compositions of the slag. Several test burnings were performed first at 1200°C for 1 hour on the mix 0.4 in order to adjust calculated compositions to get maximum amount of  $C_4A_3\bar{S}$  with varying  $C\bar{S}$  and C components in small amount. Thus, best fitted chemical compositions were determined on the mix 0.4. The other mixes were also prepared on the basis of the mix 0.4, simply blending the chemicals for the formation of  $C_4A_3\bar{S}$  (Tables II and III).

## Burning of cements

Prior to the burning of cements the solidus of present system was determined on the mix 0.4 to be 1268°C. Above this temperature the amount of  $C_4A_3\bar{S}$  begins to decrease abruptly by the formation of liquid and  $C_2AS$  begins to appear as a stable phase as well as  $C_2S$  in  $\alpha'$ -form. Therefore, cements in the present system should be burnt below this temperature. Thus, the burning was made at 1200°C for 1200 °C series, using an electric resistance furnace and a 20-cc platinum crucible. A 20-

minute burning is enough for small amount of charges and longer one for large amount of charges is necessary to avoid unburnt corns in the center of the charges. After 30-minute burning an intermediate grinding was done, followed by 30-minute heating for 1200°C series. Clinkers were also prepared by 30-minute burning at 1300°C without intermediate grinding for 1300°C series. Clinkers thus prepared were ground softly to serve as cements with nearly natural fineness, indicating that cement powders can be made without hard grinding. In the present study, therefore, the cements with nearly natural fineness were used in order to save grinding energies in the practical applications, although the fineness is rather coarse as given in Table VII. X-ray quantitative analyses

Burnt clinkers were analyzed quantitatively by X-ray for each clinker mineral, following the method described by Viswanathan et al. (3) with synthetic minerals,  $C_2AS$ , CA and  $C\bar{S}$  as internal standards. Quantities of  $C_4A_3\bar{S}$  and  $C_2S$  were recalculated on the basis of the chemical compositions represented in Table III, taking the ratios of the three clinker minerals into account. Small amount of liquid phases estimated to be present in 1300°C series was neglected in the calculation owing to the difficulty of detection.

## Hydration strength of pastes and hydration

Small scale test pieces of 1 x 1 x 4 cm dimension were used to examine the hydration strength of the cements in the pastes at W/C 0.40. After cured in humid air for the first day, the test pieces were demoulded and cured in water at 20°C. Laboratory scale setting

times were measured by using small scale testing pastes of 10 gram at W/C 0.40 in plastic vessels of 4.5  $\phi$  x 1.3 cm dimension with wetty covers at 20°C. This is an alteration of the standard method used for Portland cements. Hydrates which appeared during curing were studied by the X-ray powder diffraction technique.

## RESULTS AND DISCUSSION

### Clinkers and clinker minerals

An example of X-ray powder pattern of the present cements is shown in Fig. 1 and the results of designed mineral compositions and resulting mineral compositions are given in Tables IV, V and VI, respectively. In both series the main clinker minerals are  $C_4A_3S$  and  $\alpha'$ - $C_2S$ . The  $\alpha'$ - $C_2S$  may be stabilized mainly by the incorporation of  $S$  component as studied by Sakurai et al. (4), although the effect of other impurities cannot be disregarded. In 1200°C series generally, considerable amount of CA is noticed in addition to the two kinds of clinker minerals. Consequently small amount of  $CS$  component remains and probably some of this may be incorporated to the  $\alpha'$ - $C_2S$  as  $S$  component. Nakamura et al. (5), in their study of silica-rich expansive cements, reported that the volatilization of  $S$  was negligibly small in amount below 1250°C. According to Pliego-Cuervo and Glasser (6), one of the ternary stable assemblages in the system C-A-S-S is  $C_4A_3S$ ,  $C_2S$  and CA. Accordingly, most of the CA encountered in the present study may be stable due to the effect of impurities other than C, A, S and S, included in the slag. Occasionally very small amount of  $C_2S_2S$  was detected. The metastable formation of  $C_2AS$  is suspected, but this was not clearly identified in the product. In 1300°C series anhydrite is present only in trace because of the formation of liquids in small amount that accelerates the clinker formation. Formation of gehlenite is trace and also  $C_2S_2S$  was not detected due to its dissociation into  $C_2S$  and  $CS$  at this temperature (5). Gutt (7) found that the maximum solubility of magnesia in  $\alpha'$ - $C_2S$  is 3.7 wt percent as  $M_2S$  in the join  $C_2S - C_3MS_2$ . The join  $C_2S - CMS$  studied by Schlaudt and Roy (8) indicates that the maximum solubility of  $M_2S$  in  $\alpha'$ - $C_2S$

at 1400°C is about 2.5 wt percent. From these studies it is evident that the solubility of magnesia is very small, i.e., 1.4-2.1 wt percent as  $MgO$ . Considering that present raw mixes have 2.20-5.20 wt percent of magnesia, some of the magnesia should be also dissolved in the clinker minerals other than  $\alpha'$ - $C_2S$ . Present clinkers can be easily pulverized because of soft sintering due to considerably high vapour pressure of  $SO_3$  as well as rather low temperature burning. This feature is remarkable in saving energies for pulverization as well as low temperature required in the practical applications.

### Hydration strength

Both compressive and bending strengths of the present cements are summarized in Figs. 2 - 5 for 1200°C and 1300°C series, respectively. At first sight compressive strength is increasing with increasing A/S ratio for each cement series and markedly high strength is attained by the mixes of 2.0 and 3.0. Development of hydration strength for 1300°C series is extremely retarded owing to the probable presence of glassy phase which has coating effect on clinker minerals. However, the strength of this series gradually increases with prolonged curing time until it exceeds the strength of 1200°C series except for the mix 0.4. It is noted that depression of bending strength of some mixes, especially those of 1300°C series, occurs at later age. It is

Fig. 2. Compressive strength of the cements in hardened paste for 1200°C series. W/C 0.40.

estimated that the depression may be due to the gradual formation of monosulphate hydrates as will be mentioned later. Cements of mixes 0.4, 1.0 and 3.0 in 1200°C series and that of mix 1.0 in 1300°C series have excellent characters both in compressive and bending strengths with no or little depression of bending strength up to about 28-day curing. Generally the present cements have higher bending strength than that of Portland cements because of the formation of ettringite solid solutions as generally seen in high sulphated slag cements. Even after depression the bending strength is nearly equal to that of Portland cements. Besides the depression would be improved by admixing some gypsum or anhydrite in the cements to prevent the trisulphate - monosulphate conversion, which probably occurred during the hydration of the present cements. The bending strength with no depression is nearly twice that of Portland cements.

#### Hydration

Hydration of the present cements seems not so

Fig. 4. Bending strength of cements in hardened paste for 1200°C series. W/C 0.40.

Fig. 3. Compressive strength of the cements in hardened paste for 1300°C series. W/C 0.40.

simple. The hydration process is discussed from the observation of X-ray powder diffraction patterns. The hydration of the present cements is different in the 1200°C series without glassy phase and the 1300°C series with glassy phase. In both cases the hydration process is initiated by the hydration of  $C_4A_3S$  to form ettringite solid solutions accompanied by gibbsite gels, and followed by the formation of hypothetical hydrates given in the dashed box in Fig. 6. These hydrates are estimated to be  $C_6AH_{32}$ ,  $CAH_{10}$ ,  $C_4AH_{13}$ ,  $C_2AH_8$ ,  $C_3AH_6$  and so on, including all calcium aluminates hydrates which exist in the solution. It seems likely that the hydration of  $C_4A_3S$  is accelerated by the action of calcium ions derived from the coexisting  $\alpha'$ - $C_2S$  as will be mentioned in the following section. The ettringite solid solution would contain more  $C_6AH_{32}$  component that is formed by the reaction between portlandite component from the hydration of the  $C_2S$  and the gibbsite gel from  $C_4A_3S$ . The CA forms  $CAH_{10}$ , which may be also incorporated to the ettringite solid

Fig. 5. Bending strength of cements in hardened paste for 1300°C series. W/C 0.40.

solutions in the form of  $C_6AH_3$ , as calcium ions increase in solutions in accordance with the sluggish hydration of the  $\alpha'$ - $C_2S$ . At later age small amount of monosulphate solid solutions appears owing to the reaction between the ettringite solid solution and the  $C_6AH_3$  component, when the solid solution limit of the ettringite is reached, since  $C_6AH_3$  component cannot survive alone (9). This may cause the marked depression of bending strength observed in the cements possessing moderate amount of  $C_2S$  and  $C_4A_3S$  in 1200°C series, i.e., the trisulphate - monosulphate conversion may require more calcium ions. In the mix 3.0, for instance, the content of  $C_2S$  is lower and the conversion may not easily occur. Since the content of  $C_2S$  is high, supplying abundant calcium ions in the mix 0.4, the depression takes place earlier or the conversion effect would be slight because of lower content of  $C_4A_3S$  in this mix. Thus, this conversion phenomenon may be marked in the intermediate mixes 1.0 and 2.0. The hydrate  $CAH_{10}$  is also produced by the hydration of the glassy phase present in 1300°C series cements. Consequently the depression may occur more easily in the cements of this series than in the cements of 1200°C series. The depression, however, may be improved as mentioned in the preceding section. Final hydrates produced comprise ettringite solid solution, gibbsite, monosulphate hydrate solid solution,  $CAH_{10}$  and C-S-H at 28-day age. Monosulphate hydrate solid solution and  $CAH_{10}$  are not always found in the cements and their presence depends on chemical potentials in solutions as described above. At the beginning of initial hydration  $CAH_{10}$ ,  $C_2AH_8$  and monosulphate hydrate appear metastably owing to the presence of CA and  $CS$ , and then disappear soon, incorporated to ettringite solid solution with the progress of hydration. Some  $C_4A_3S$  remains unhydrated at least up to 7-day age or even more than 28-day age in accordance with the initial content of this mineral in the cements. Zakharov (10) stated that no conversion of  $CAH_{10}$  to  $C_3AH_6$  would occur in his "alumina-belite cement" because of low concentration of calcium ions in the solution. The same would be true

in the present cements. However, it is considered that a reversible reaction would take place for the  $CAH_{10}$  phase in the present cements as illustrated in Fig. 6. This would prevent the conversion of the  $CAH_{10}$  into  $C_3AH_6$ , forming ettringite solid solutions or monosulphate hydrate solid solutions. Mehta (11) also stated that no conversion was noticed in his high alumina cements added with  $C_4A_3S$  at 38°C curing.

#### Setting times

Setting times of the laboratory scale are given in Table VII. They depend on the content of  $C_4A_3S$  in the cements. Initial setting times for 1200°C series are quite fast — quick setting, but they are not so fast as the setting time of regulated set cements with no retarders — flash setting. Final setting times are also relatively short especially in the mixes 0.4 and 1.0. Initial setting times of 1300°C series are generally prolonged due to the glass coating effect on clinker minerals, and it is extremely retarded when the mixing ratio reaches 3.0. Final setting times are also delayed with increasing alumina contents in the cements. The clinker mineral  $C_4A_3S$  itself shows not so fast hydration. According to Fukuda (12) the initial setting time is 3 hours, and the final one is 3 hours and 35 minutes at W/C 0.40 for this compound. Judging from the hydration nature of  $C_4A_3S$  and  $C_2S$ , it is quite surprising that present cements set so fast, especially in 1200°C series and some 1300°C series. The mechanism of the faster hardening may be ascribed to relatively high initial concentration of calcium ions dissolved from the  $\alpha'$ - $C_2S$ , though the absolute concentration may be low. It is considered that ettringite solid solutions can be precipitated quickly by this catalyzer action of the calcium ions in solutions, resulting in the fast setting times. The precipitation of ettringite solid solutions may accelerate the formation of calcium ions from the  $\alpha'$ - $C_2S$ , as a consequence of which, hydration of present cements may proceed in this "cooperative mechanism" between the  $\alpha'$ - $C_2S$  and the  $C_4A_3S$ . Near the termination of this cooperation low C/S C-S-H may precipitate. This interpretation is supported by Fukuda's observation (12) that 10 percent blending of portlandite to  $C_4A_3S$  makes flash setting, i.e., 4 minutes and 10 minutes for initial and final setting times, respectively, at W/C 0.45.

#### Comparison with cements previously reported

In 1974 Zakharov (10) reported a new type of cement called "alumina-belite cement" which has peculiar features of rather high early strength, high later strength and high resistance to aggressive media. Desired burning temperature is no higher than 1250-1300°C and the main chemical composition of the new cement is located in the system  $C_2S$ -CA- $C_4A_3S$  with small amount of  $C_4A_3S$ , i.e., between Portland cement and aluminous cement compositions. Some gypsum and other mineralizers were added to stabilize belite as  $\beta$ -form and excess  $CS$  component forms  $C_4A_3S$  and  $C_2S_3S$ . Viswanathan et al. (3) also made cements similar to that of Zakharov at 1300°C from Indian raw materials containing "anorthosites"

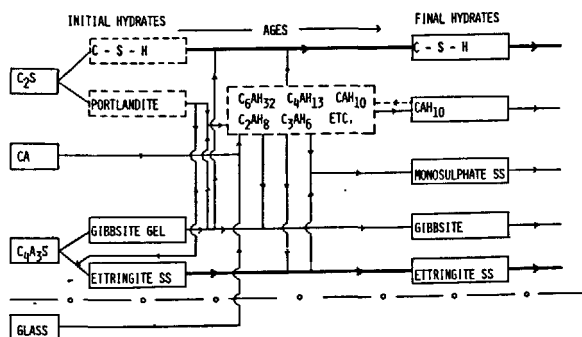

Fig. 6. Schematic hydration courses drawn on the basis of XRD. Thick lines, main hydration courses. Fine lines, subordinate ones. Hydrates outlined by dashed lines are considered to be in solutions, but not as precipitates. Slight  $C_2ASH_8$  was sometimes encountered in later age, but not always.

Setting times and relevant specifications of the present cements. Above for 1200°C series. Below for 1300°C series. See the text for the laboratory scale test.

prevailing in India. Their cements are called "Porsal cement". The present cements are different from these two kinds of cement, since they have more S component and the main compositional system is located along the join  $C_4A_3S - C_2S$ . The author wishes to call the present cements "supersulphated alumina-belite cements".

#### CONCLUSION

From the present experiments the author has a confidence that a series of supersulphated alumina-belite cement can be manufactured from blast furnace slag and gypsum with addition of bauxite and limestone. He also showed that various cements having different strength can be produced, by changing mixing proportions of alumina and silica along the join  $C_4A_3S - C_2S$ . If we intend to obtain superior cements possessing early strength, clinkers should be burnt below the solidus temperature of 1268°C in the present cement system. If liquid forms, initial hydration of cements is retarded more or less, depending on the amount of glassy phases generated. Some depression of bending strength was noticed in several hardened cements in later age of curing. This may be caused by the conversion of ettringite solid solution into monosulphate hydrate solid solution or the trisulphate - monosulphate conversion that occurs gradually in the later age, when cements have moderate amount of  $C_4A_3S$  and  $C_2S$ . This phenomenon becomes clear, when glassy phases are present in the cements. The depression, however, would be no troublesome, because bending strength after depression is nearly equal to the strength of Portland cements. This means that present cements have higher bending strength in early age. Hardened cements with no depression of bending strength give nearly twice the strength of Portland cements as generally seen in high sulphated slag cements owing to the formation of ettringite solid solution, except for alumina-poor cements whose strength does not develop so high at room temperature in the present cement system. The depression phenomenon of bending strength would be improved by admixing some gypsum or anhydrite in the cements. It is very important, however, to study the effect of ferric component replacing

alumina in order to use low grade bauxite containing considerable amount of ferric iron. It is noteworthy that the only one cement ready to be used among the present cements is the one with 0.4 A/S mixing ratio, burnt at 1200°C. This cement requires no bauxite and has relatively high strength that permits demoulding. Further grinding of the clinker into finer powder will increase the initial strength of this mix; recent study shows 12 MPa at 1-day age at 3000 cm<sup>2</sup>/g, and steam curing, autoclaving and reinforcement with fibre glass will bring practical utilization as prefabricated materials. Thus, the present cement system is expected to widen the utilization of "blast furnace slags", "gyphums" of byproduct and low grade "bauxites" with high silica and iron contents, which do not deserve exploitation at present. Strength characteristics of present cements in older ages will be reported elsewhere.

Acknowledgement: The author wishes to express his thanks to Prof. S. Ogino for the facilities of testing apparatus and regulated room.

# The study of a non traditional Pozzolan : Copper Slags

## *Etude d'une Pouzzolane non traditionnelle : Laitier de Cuivre*

J.R. BARAGANO, Dr. Chem. Sc, Asland S.A., Villaluenga de la Sagra (Toledo) Espagne,  
P. Rey, Dr. Chem. Sc., Asland S.A., Villaluenga de la Sagra (Toledo) Espagne.

### RESUME

Dans la métallurgie du cuivre, on obtient un laitier compact, dur, abrasif et à grains fins, se composant essentiellement, dans sa phase cristallisée, de fayalite ( $\text{Fe}_2\text{SiO}_4$ ) et d'oxydes de fer.

Différentes méthodes d'essai démontrent que ce laitier a des propriétés de pouzzolane.

La formation de S-C-H fin et mal cristallisé, à structure alvéolaire et "vermiculée", et l'existence possible d'une ferrite de calcium hydratée, du type  $\text{C}_4\text{FHx}$ , dans sa réaction avec l'hydroxyde de calcium,  $\text{Ca}(\text{OH})_2$ , ont été mises en évidence par l'application des techniques de D.R.X., A.T.D. et M.E.B.

Les ciments préparés avec ce laitier ont des caractéristiques similaires à celles des ciments portland et à la pouzzolane, avec des avantages sous l'angle de la maniabilité.

Les courbes de durcissement indiquent une certaine inertie dans l'augmentation des résistances au jeune âge, avec à la fin un gain très considérable, mais elles réagissent bien avec une activation aux sulfates alcalins.

Il faut en souligner le comportement face aux agents atmosphériques, aux cycles de gel-dégel et aux réactions alcali-silice.

Dans la protection des charpentes, quand les mortiers ne contiennent aucun adjuvant chimique, les ciments de laitier se comportent plus ou moins comme les superciments portland (P-450) qu'ils dépassent en cas de présence de  $\text{CaCl}_2$  avec des aciers normaux, spécialement celui fabriqué avec 45% de laitier.

Lors des essais de durabilité face à des solutions de  $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ ,  $\text{MgSO}_4$  et  $\text{Na}_2\text{SO}_4$ , ils donnent des résultats supérieurs à ceux qu'on obtient avec des portland purs et à la pouzzolane. Il faut faire remarquer leur grande stabilité face à l'eau de mer.

C'est pourquoi le laitier de cuivre convient très bien pour fabriquer des ciments à ajouts, à la pouzzolane ou spéciaux résistants aux agents extérieurs.

L'expérience acquise avec les ciments industriels et les bétons obtenus avec eux le confirme.

### SUMMARY

The slags obtained in copper metallurgy are vitreous, hard, compact, abrasive, of fine granulometry and are principally composed of fayalite ( $\text{Fe}_2\text{SiO}_4$ ) and iron oxides in their crystallized phase.

Different assay methods show that the slags possess pozzolanic properties.

The formation of fine, deficiently crystallized S-C-H with alveolar and vermiculate structure and the possible existence of a  $\text{C}_4\text{FHx}$  type of hydrated calcium ferrite when reacted with calcium hydroxide,  $\text{Ca}(\text{OH})_2$ , was shown in X-R.D., D.T.A. and S.E.M. techniques.

Cements prepared with these slags have similar characteristics to those of Portland and pozzolanic cements with advantages in workability.

The hardening curves show certain inertia in the increase in strength over short periods but with considerable later advantage, though the initial strengths improve well due to activation by alkaline sulphates.

Their behaviour in the presence of atmospheric agents, freezing-thawing cycles, and in alkali-silica reactions is noteworthy.

In the protection of reinforcements, when the mortars do not contain any chemical additives, the behaviour of the slag cements is similar to that of Portland super-cements (P-450) and is superior to these when  $\text{CaCl}_2$  is present with normal steels, especially when 45% slags are used in their manufacture.

The durability tests with solutions of  $\text{MgSO}_4$ ,  $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ , and  $\text{Na}_2\text{SO}_4$  give results which are better than those obtained with pure Portland and pozzolanic cements. They are particularly stable to sea water.

Thus, copper slags are especially suitable for the manufacture of addition and pozzolanic cements and those which are resistant to external agents.

Experience with industrial cements and concrete manufactured with them supports this statement.

### I. INTRODUCTION

There has been an increase in the production of cements based on active constituents to palliate somewhat the high cost of the continuing energy crisis to the cement industry.

Spanish manufacturers have striven to locate traditional additives backed by experience and to study other products which had not previously been used for this purpose.

One such product is copper slag which is produced in copper metallurgy.

### II. PHYSICAL PROPERTIES OF COPPER SLAGS

On removal from the kiln, the slags in their fluid state are subjected to brusque water cooling, vitrifying in relatively fine and compact granulometry.

The shining black slags which are compact and irregular in shape have a humidity of less than 5% when immersed in water.

The specific weight varies from 3,72 to 3,98.

#### II.1. Granulometry

Sieve(mm)	4,76	2,38	1,19	0,59	0,297	0,149	Less
%Retained	0,5	9,3	34,5	32,3	18,2	3,7	11,5

#### II.2. Grindability test

The test were carried out using F.C. Bond's method. The work index was 24 Kwh/Tm equivalent to a theoretical grindability of 40 Kwh/Tm. In identical conditions, clinkers give a value of 23, pozzolan 32 and blast furnace slags 34 Kwh/Tm.

#### II.3. Resistance to abrasion utilising the Los Angeles machine (ASTM-C-535-75 modified)

In view of the high abrasion values of vitreous materials, the Los Angeles test was used for calculation; an abrasion coefficient of 1% being obtained, compared with 10% for clinkers from Lépol kilns, 4% for natural pozzolan and 3% for blast furnace slags. These products were previously ground to correspond with the granulometry of the copper slags.

### III. CHEMICAL AND MINERALOGICAL PROPERTIES

#### III.1. Chemical composition

The chemical composition varies within the range which is usual for this type of subproducts. The limit values found for each element are as follows:

SiO<sub>2</sub>: 30,7-35,9 Al<sub>2</sub>O<sub>3</sub>: 2,4-3,4 FeO: 49,7-54,0  
 Fe<sub>2</sub>O<sub>3</sub>: 0,3-3,6 CaO: 1,1-2,8 Mn<sub>2</sub>O<sub>3</sub>: 0,05-0,10  
 SO<sub>3</sub>: 0,01-0,08 S<sup>2-</sup>: 0,14-0,50 K<sub>2</sub>O: 0,28-0,64  
 Na<sub>2</sub>O: 0,27-0,83 TiO<sub>2</sub>: 0,11-0,30 MgO: 1,8-3,1  
 Cr<sub>2</sub>O<sub>3</sub>: 0,03-0,07 CuO: 0,50-1,25 ZnO: 1,21-3,87  
 Cl<sup>-</sup>: <0,02 Pb: Indicios, IR: 2,8-8,9 LI: (+4)-(+7),  
 SiO<sub>2</sub> soluble (s/Florentin): 12,1-15,9.

#### III.2. Mineralogical composition

##### III.2.1. Microscopy

The presence of crystalline structures in the form of tubular fayalite needles (Photo nº 1) was detected in the samples attacked by HF using the reflected light technique. This was confirmed by electronic transmission microscopy (TEM) (Photo nº 2).

Bands of iron oxides which accompany fayalite crystals with small inclusions of metallic iron spherulites also to be found.

Photo nº 1: Tubular needles of fayalite

Photo nº 2: Partial aspect of the slags (TEM)

#### III.2.2. X-Ray diffraction

An X-ray tube with molybdenum anticathode ( $\lambda$ : 0,71Å) and zirconium filter was used. And increase in background noise was observed between 11° and 19° due to the vitreous state and the principal crystallized component, fayalite (Fe<sub>2</sub>SiO<sub>4</sub>) of the olivine family. When the slags were treated in an oxidising atmosphere for 1 hour at 800°C and allowed to cool very slowly to force the crystallization of the glass, the formation of hematites (Fe<sub>2</sub>O<sub>3</sub>) and magnetite (Fe<sub>3</sub>O<sub>4</sub>) was observed. When the experiment was repeated at 1200°C, cristobalite was observed together with the above mentioned components. In both cases the vitreous phase decreased with the temperature.

#### III.2.3. Differential thermic analysis

A domeshaped exothermic band was observed in an air atmosphere above 400°C, indicating the oxidation of the fayalite.

An exothermic peak, attributed to devitrification was observed in a nitrogen atmosphere at 580°C when the sample was mixed with 50% chemically unreactive periclase to avoid adhesion to the thermocouple.

#### IV. POZZOLANITY TESTS

Due to its chemical composition, this product is considered to belong to the pozzolan family rather than to the hydraulic slags obtained from blast furnaces. Thus, this possible property was tested by various methods.

##### IV.1. $\text{Ca}(\text{OH})_2$ -Copper slag mixtures

##### IV.1.1. Accelerated comparative method

A conglomerate of three parts by weight of the pozzolan ( $20\% > 45\mu$ ) and one part of hydrated lime ( $> 95\%$  in  $\text{Ca}(\text{OH})_2$ ) was prepared.

This mixture was used to make a (1:3) mortar with standardized Spanish sand and  $W/C = 0,5$  in  $4 \times 4 \times 16$  cm specimens.

After remaining at  $21^\circ\text{C}$  for 48 hours, these specimens were placed in a container at  $50^\circ\text{C}$  with saturated humidity for 72 hours.

As resistances were not specifically defined in the methods, a comparison was made with a natural pozzolan of proved characteristics, and standard quartz sand was used as inert matter. The following values were obtained.

Copper slags	Natural pozzolan	Standard sand
17-58 Kp/cm <sup>2</sup>	39-116 Kp/cm <sup>2</sup>	4-10 Kp/cm <sup>2</sup>

##### IV.1.2. DIN 51,043

In this case a minimum of 50 Kp/cm<sup>2</sup> compression after 28 days was required.

Copper slags	Natural pozzolan	Standard sand
30-56 Kp/cm <sup>2</sup>	25-82 Kp/cm <sup>2</sup>	5-6 Kp/cm <sup>2</sup>

##### IV.1.3. Portuguese Method

The method consisted in preparing a paste with 25%  $\text{Ca}(\text{OH})_2$  and 75% pozzolan which was kept in  $4 \times 4 \times 16$  cm moulds in a humid chamber for three days and then in water at  $21^\circ\text{C}$  until breakage date, after 7 and 28 days.

For Type I: 10-20 Kp/cm<sup>2</sup> was required at 7 days and 20-60 Kp/cm<sup>2</sup> at 28 days.

For Type II: 10-30 Kp/cm<sup>2</sup> was required at 28 days.

TABLE I

DAYS	Cu SLAG H <sub>2</sub> O - 26% Kp/cm <sup>2</sup>	POZZOLAN H <sub>2</sub> O - 35% Kp/cm <sup>2</sup>	SAND H <sub>2</sub> O - 36% Kp/cm <sup>2</sup>
7	SOFT	19-62 (100-100)	SOFT
28	11-33 (50-29)	22-112 (100-100)	4-4 (18-4)
60	31-142 (107-93)	29-153 (100-100)	5-9 (17-6)
90	35-192 (117-107)	30-179 (100-100)	7-11 (23-6)
180	37-217 (116-107)	32-202 (100-100)	13-23 (41-11)
270	39-234 (108-113)	36-207 (100-100)	18-33 (50-16)
365	42-252 (111-118)	38-214 (100-100)	21-43 (55-20)

Different analytical techniques such as DTA, X-Ray diffraction, electronic transmission microscopy (TEM) and electronic scanning microscopy (SEM) fitted with a dispersive energy spectrometer were used to study the different components formed in samples of these three types of mixtures (25%  $\text{Ca}(\text{OH})_2$  and 75% additives) after a minimum of 28 days. In the case of the sand, the mixture remained porous and brittle and hydrated lime crystals adhering to the quartz grains but without forming any type of silicate were observed. X-R.D. showed a proportion of 23%  $\text{Ca}(\text{OH})_2$  and a certain amount of  $\text{CaCO}_3$  due to partial carbonation of the sample.

GTA and X-R.D.  $\text{Ca}(\text{OH})_2$  determinations showed no decrease in the course of time, during a period of 300 days.

The natural pozzolan reacted well with the lime, and relatively compact and only slightly brittle hydrated compounds, identified as hydrated calcium silicates, formed after 28 days. These compounds were fine and deficiently crystallized with an alveolar aspect and the exact C/S ratio could not be determined. At this stage, X-R.D. determination showed 11% unreacted  $\text{Ca}(\text{OH})_2$ .

As time passed a better crystallized higher S-C-H content was observed and the presence of hydrated calcium aluminates ( $\text{C}_4\text{AH}_{13}$ ) and hexagonal carbonated calcium aluminate crystals ( $\text{C}_3\text{A} \cdot \text{CaCO}_3 \cdot 12\text{H}_2\text{O}$ ) were identified by SEM, DTA and X-R.D.

4% of unreacted  $\text{Ca}(\text{OH})_2$  remained after 300 days.

After 28 days the copper slag samples showed a hydrated mixture which appeared to be compact and not very brittle but the microporosity was greater than that of the natural pozzolan.

Fine poorly crystallized alveolar and vermiculate C-S-H (Photos nº 3 and 4) which was similar to natural pozzolan was detected and there was 13% non combined  $\text{Ca}(\text{OH})_2$ . This value agrees with the mechanical resistances at the above mentioned age.

Photo nº 3: C-S-H Deposits. Alveolar-vermiculate.

Photo nº 4: C-S-H. Texture examined by TEM

However, after 300 days the non combined  $\text{Ca(OH)}_2$  is 4%, which is equal to that of the natural pozzolan. The presence of a  $(\text{C}_4\text{FHx})$  type hydrated calcium ferrite is also probable. This could be interpreted as corresponding to the  $\text{C}_4\text{AH}_3$ , detected after 28 days in the pozzolan, and could explain the higher resistance of the copper slag mortars after a period of 90 days.

#### IV.2. Portland cement-Copper slag mixtures

##### IV.2.1. English method

The method consists in keeping a series of samples at  $18^\circ\text{C}$  for 7 days, another series at  $18^\circ\text{C}$  for 5 days and the other two at  $50^\circ\text{C}$ . The greatest difference between the two resistances is used to evaluate the pozzolanity of the products studied.

TABLE II			
	MOIST ROOM $18^\circ\text{C}$ $\text{Kp/cm}^2$	WATER BATH $50^\circ\text{C}$ $\text{Kp/cm}^2$	DIFFERENCE ( $50^\circ\text{C}-18^\circ\text{C}$ ) $\text{Kp/cm}^2$

[(B-C):(A-C)] $\times 100 = 324$ (>30) [(D-E):(A-E)] $\times 100 = 185$ (>10)					

##### IV.2.3. ASTM C-618-73

The specimens were kept at  $21^\circ$  for 1 day and at  $39^\circ$  for 27 days. The resistances should be above 75% of the standard cement.

TABLE IV		
	CEMENT PORTLAND(A)	65% CEMENT + 35% SLAG(B)
W/C	0.58	0.54
FLOW%	105	105
28 DAYS	56-370 $\text{Kp/cm}^2$	44-285 $\text{Kp/cm}^2$
(B:A) 100 = 79-77 (>75%)		

##### IV.2.4. N. Fratini

Cements with a total of 3,0%  $\text{SO}_3$  and Blaine S.S. of 2500, 3500 and 4500  $\text{cm}^2/\text{gr}$  were manufactured with the same clinker and gypsum. In each series 25-35 and 45% of this was substituted by ground copper slag, rejecting 20% above 45 m.

The 9 cements prepared were tested after 7, 15 and 28 days (Table V).

TABLE V								
S.S.BLAINE	2500 cm <sup>2</sup> /gr			3500 cm <sup>2</sup> /gr			4500 cm <sup>2</sup> /gr	
millimoles CaO per litre solution								
millimoles OH <sup>-</sup> per litre solution								
DAYS	7	15	28	7	15	28	7	15
75% CEMENT	107	(-) 89	74	103	(-) 89	74	98	(-) 79
25% SLAG	58	567	548	587	564	555	587	555
65% CEMENT	93			93			87	
35% SLAG	51,4			52,4			52,0	
55% CEMENT	74			72			71	
45% SLAG	43,4			44,4			44,4	

It may be deduced from the assays described that copper slags show pozzolanic qualities which are appreciable over a short period but superior to a good quality natural pozzolan over a longer period.

#### V. PHYSICAL TESTS

##### V.1. Setting and rheology

A pure cement of 3500  $\text{cm}^2/\text{gr}$  were taken as a standard and 5-10-25-35 and 45% ground copper slags at 20% rejection above 45 m were substituted. There cements were used for setting determinations in an automatic penetrometer, and the rheological properties of the pastes were measured in CERILH coaxial cylinder viscometer (Table VI). Flow tests (ASTM C-109-77) and bleeding (ASTM C-243-75) in mortars (Table VII) were also performed. The results were as follows:

TABLE VI						
	Time of setting		Coaxial-Cylinder Viscosimeter			
	% H <sub>2</sub> O	INITIAL	FINAL	W/C	Dinasc $\text{cm}^2$	POISES
PORTLAND CEMENT (PC)	25	1h05'	2h05'	0.5	142.0	3.3
95% (PC) + 5% SLAG	25	1h10'	2h10'	0.5	135.7	3.1
90% (PC) + 10% SLAG	24.5	1h20'	2h20'	0.5	116.7	2.7
75% (PC) + 25% SLAG	23.5	1h30'	2h35'	0.5	96.1	1.9
65% (PC) + 35% SLAG	22.5	1h40'	3h00'	0.5	76.6	1.7
55% (PC) + 45% SLAG	22	1h50'	3h15'	0.5	71.6	1.2

TABLE VII					
		MORTAR (1:3)		MORTAR (1:2.5)	
	W/C	FLOW%	BLEEDING	W/C	FLOW%
PORTLAND CEMENT (PC)	0.5	27.3	0.7	0.54	112.8
95% (PC) + 5% SLAG	0.5	34.5	0.7	0.53	110.3
90% (PC) + 10% SLAG	0.5	45.7	1.2	0.52	106.8
75% (PC) + 25% SLAG	0.5	53.4	2.1	0.51	106.5
65% (PC) + 35% SLAG	0.5	58.0	2.5	0.51	106.8
55% (PC) + 45% SLAG	0.5	60.5	2.7	0.49	108.3

There is a substantial increase in plasticity with greater slag addition, and less water is needed than in pure cements.

##### V.2. Hydration heat (ASTM C-186-78)

The results obtained are shown and it may be observed that the presence of 25% slags in the cements complies amply with type IV ASTM.

TABLE VIII		
	7 DAYS (cal/gr)	28 DAYS (cal/gr)
CEMENT PORTLAND (PC)	7.5	9.4
95% (PC) + 5% SLAG	7.2	8.3
90% (PC) + 10% SLAG	6.3	7.3
75% (PC) + 25% SLAG	5.2	6.4
65% (PC) + 35% SLAG	4.7	5.6
55% (PC) + 45% SLAG	4.0	4.8

V.3. Mechanical resistances, Influence of alkalis in the first stages.  
A conglomerate of 65% pure ground cement

(3500 cm<sup>2</sup>/gr), type P-450 and 35% slags with rejection of 20% above 45 $\mu$ m was prepared to compare the increase in resistances of the slag cement as a function of time. The same test conditions were used for the P-450 cement and for the cement which contained 35% ground quartz sand in substitution, at identical rejection with the slags.

Percentages with respect to the pure cement are given in brackets (Table IX)

TABLE IX			
DAYS	CEMENT P-450	(P-450:SLAG) (65:35)	(P-450:SAND)(65:35)
3	63-350	41-194 (65-55)	43-221 (68-63)
7	72-417	48-239 (67-57)	50-262 (69-63)
28	77-494	61-365 (79-74)	52-320 (67-65)
60	82-524	71-422 (87-81)	59-349 (72-67)
90	84-535	74-434 (88-81)	62-351 (74-66)
180	85-537	76-445 (89-83)	64-353 (75-66)
365	87-542	78-462 (90-85)	65-355 (75-66)
450	87-545	79-470 (91-86)	65-360 (75-66)

The cement containing sand showed similar resistances at all ages to the pure cement content (65%), thus demonstrating the inert nature of the sand used.

Low values were obtained after 3 and 7 days for the cements prepared with copper slags. However the difference from the inert standard was evident after 28 days, and values were closer to those obtained for pure cement as time increased ( $\approx 90\%$  at 450 days), showing its pozzolanic character.

Although the low initial resistances may be useful in many aspects, higher values are required for others, and thus the contribution of alkali, in the form of precipitator dust, acting as an activator, improving resistances, was compared.

The chemical composition of the powder was as follows:

I.L. 11,3% SiO<sub>2</sub> 15,5% Al<sub>2</sub>O<sub>3</sub> 3,9% Fe<sub>2</sub>O<sub>3</sub> 2,1% CaO 46,0% MgO 2,4% TiO<sub>2</sub> 0,13% SO<sub>3</sub> 11,9%

K<sub>2</sub>O 5,2% Na<sub>2</sub>O 0,65% S= traces.

Soluble salts: SO<sub>3</sub> 5,1% K<sub>2</sub>O 4,6% Na<sub>2</sub>O 0,44%

An industrial P-350 with 35% of its weight substituted by sand and copper slags ground in the same conditions as above, was used.

It is assumed that the slag cement (n° 3) contains additions of 5 and 10% power (95:5) and (90:10), (cements n° 6 and 7) or that for the same pure cement content (61,75 and 58,50) (cements 4 and 5), the copper slags are partially substituted by electrostatic powder (Table X). Cement n° 8 and 9 are equivalent

to n° 6 and 7 but contain standardized sand and serve as standard.

It may be observed that for equal percentages of pure cement, n° 6 and 7, containing electrostatic powder, give higher resistances in the first 7 days when compared with those not containing the powder (4 and 5). The increase is 25%, and there was a decrease in those which contained sand as a substitution, particularly after 3 days (cements 8 and 9).

All the values were similar after 28 days.

The beneficial effect of alkaline sulphates during the first ages of the mortars is obvious, and thus this factor will not be a problem, even if high percentages of slags are used. A lower slag addition and/or a greater Blaine S.S. will give PUZ-350 type cements, IP of ASTM or similar types.

#### VI. RESISTANCE TO EXTERNAL AGENTS

##### VI.1. Protection of reinforcements against corrosion

Three cements numbered 2, 3 and 4 containing increasing quantities of slags (25, 35 and 45%) were used to study the protective capacity by means of electrochemical techniques and the results were compared with those obtained for pure Portland, P-450 (n° 1) and PUZ-350 (n° 5).

It was necessary to know: a) the response of steel on incorporation in a cement without additives, and b) the regenerating capacity of the passive layer of the said cement when the metal was subjected to a corrosion process with depassivating ions, in order to carry out this study.

A mortar without additives was used to study a) and a mortar with 2% CaCl<sub>2</sub> was prepared to study b).

The progress of corrosion was observed during 28 days which provided approximate criteria on the future behaviour of each steel.

Two types of steel were used for reinforcements: type N of natural hardness and type F, cold twisted, both of 6 mm  $\phi$ .

The following measurements were taken:

- 1) The corrosion rate was followed by determination of polarization resistance  $R_p$  and later calculation of the weight loss using Stern's formula:  $I_{corr} = B/R_p$  and the integration of the  $I_{corr}$ -time curves.
- 2) Gravimetric determination of the weight loss.
- 3) Electrochemical determination of potential of pitting by the galvanostatic method.

TABLE X																
N°	CEMENT	SAND	SLAG	POWDER	900	4900	10000	S.S.B.	H <sub>2</sub> O	INITIAL	FINAL	3 DAYS	7 DAYS	28 DAYS	60 DAYS	90 DAYS
1	100	—	—	—	0,8	4,3	12,0	3670	25	1h 05'	2h 05'	58-301	64-355	74-438	74-493	78-488

7	58,50	—	31,50	10	1,4	5,4	123	3883	24	1h 40'	3h 30'	45-182(125-131)	51-223(119-123)	65-302(105-98)	77-350	76-344
8	61,75	5	33,25	—	12	4,2	110	3478	23,5	2h 05'	3h 50'	36-137(92-91)	46-198(102-105)	61-303(100-103)	67-353	71-376
9	58,50	10	31,50	—	15	5,4	121	3422	23,5	2h 10'	3h 45'	34-118(94-85)	42-178(98-98)	57-289(92-94)	67-354	66-346

The results obtained show the five cements tested give similar protection to the two types of steel if the mortar is made without additives.

In presence of  $\text{CaCl}_2$  the classifications of measurements in decreasing order of protection are:

TABLE XI		
STEEL	TYPE OF MEASUREMENT	CLASSIFICATION
N	Weight loss gravimetric	3>4>2>1>5
	Weight loss electrochemical	3>4>2>5>1
	Breaking potencial	4>1>3>5>2
F	Weight loss gravimetric	1>4>5>3>2
	Weight loss electrochemical	1>4>5>3>2
	Breaking potencial	1>4>5>2>3

In the case of F, cement nº 4 was more protective than nº 5 (PUZ-350) and less than nº 1 (P-450).

In the case of steel N, the Icorr show better behaviour of cements 2, 3 and 4 and indicating the favourable response of rupture potentials of nº 4, and partially nº 3 against the attack of depassivating ions.

#### VI.2. Aggressive action of calcium, magnesium and sodium sulphate solutions and sea water

The accelerated Koch-Steinegger method was used, which defines that a cement is resistant to the action of sulphates when the corrosion coefficient or the ratio between the resistance to flexure of the samples submerged in the potentially aggressive solutions and submerged in filtered tap water is equal to or greater than 0,70 at 56 days.

Four types of cement were used, nº 1 or pure Portland, nº 2 with 35% copper slags, nº 3 with 35% silica sand and nº 4 with 35% natural pozzolan.

The slag cement showed greatest resistance to the three sulphates and was the only one which resisted the attack of sea water (Table XII). This property may be attributed to the formation of iron oxide gels which act as impermeabilizers and resist aggression.

TABLE XII					
COEFFICIENT OF CORROSION					
AGGRESSIVES	DAYS	CEMENTS			
		1	2	3	4
$\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$	28	1,19	1,13	1,11	1,17
	56	1,04	1,31	1,24	1,16
	90	1,09	1,28	1,17	1,24
$\text{Na}_2\text{SO}_4$	28	1,23	1,10	1,11	1,07
	56	1,00	1,24	1,06	1,12
	90	0,96	1,17	0,97	1,13

	56	1,00	1,22	1,14	1,22
	90	1,08	1,23	1,11	1,26
SEA WATER (A.S.T.M.)	28	0,78	0,87	0,88	0,81
	56	0,50	0,75	0,14*	0,53
	90	0,27*	0,64	0,18	0,57

\* DESINTEGRATION

#### VI.3. Alkali-silica reactivity

An accelerated method consisting in preparing

a mortar using Pyrex nº 7740, 30 to 50 mesh, as aggregate was used, and W/C ratio of 0,4 and aggregate/cement ratio of 0,75, kept at 43°C for 14 days and 75 days.

The initial clinker gave a total value of  $\text{K}_2\text{O}=0,88\%$  and  $\text{Na}_2\text{O}=0,32\%$ , equivalent to 0,89% in total  $\text{Na}_2\text{O}$ . Soluble  $\text{K}_2\text{O}$  and  $\text{Na}_2\text{O}$  were 0,62% and 0,10% respectively.

TABLE XIII					
CEMENT	% EXPANSION				ASPECT
	7 DAYS	14 DAYS	75 DAYS		
PORTLAND CEMENT(PC)	0,12	0,30	0,47		WARPED
65%(PC) + 35% SLAG	0,02	0,05	0,06		GOOD
65%(PC) + 35% POZZOLAN	0,01	0,02	0,03		GOOD

The mean value of three samples indicates good behaviour of the cements containing slags and pozzolan and deficient behaviour in the pure Portland cement.

#### VI.4. Behaviour in freezing-thawing cycles

4x4x16 cm mortar prisms were used for this experiment and they were subjected to three hour cycle.

The samples began the first cycle after 7 days in a wet chamber at 21°C and 95% R.H.

The values obtained and your aspect show that they are exceptionally useful for these purposes.

TABLE XIV							
CEMENT	7 DAYS	75 CYCLES	$\Delta$	125 CYCLES	$\Delta$		
	Kp/cm <sup>2</sup>	Kp/cm <sup>2</sup>		Kp/cm <sup>2</sup>			
P-350(PC)	70-347	77-480	213	7-133	73-517	381	3-170
65%(PC) + 35% SLAG	54-211	63-338	344	9-127	59-346	781	5-135
65%(PC) + 35% POZZ	57-284	71-403	238	14-119	69-409	850	12-125

#### VI.5. Effect of atmospheric agents in a warm climate

Similarly, tests were carried out keeping 4x4x16 cm prisms for 16 hours in water and 8 hours in an oven at 40°C and the characteristics were determined after 50 cycles.

TABLE XV				
CEMENT	7 DAYS	50 CYCLES	$\Delta$	ASPECT
	Kp/cm <sup>2</sup>	Kp/cm <sup>2</sup>	Kp/cm <sup>2</sup>	
P-350(PC)	70 - 347	73 - 424	3 - 77	GOOD
65%(PC) + 35% SLAG	54 - 211	58 - 297	4 - 88	GOOD
65%(PC) + 35% POZZOLAN	57 - 284	70 - 410	13 - 126	GOOD

The results obtained confirm the excellent qualities of the cement studied.

#### VII. EXPERIENCE INDUSTRIAL

The industrial cements obtained as yet, and the concretes made with them, support the validity of the stated parameters.

VILLALUENGA (TOLEDO) - SPAIN

# Pelletized slag cement : autoclave reactivity

## *Ciment à base de laitier pelletisé : réactivité à l'autoclave*

R.D. HOOTON, Graduate Student, and J.J. EMERY, Associate Professor, Department of Civil Engineering and Engineering Mechanics, McMaster University, Hamilton, Ontario, Canada, L8S 4L7.

**RESUME :** La pelletisation est un procédé qui a été mis au point récemment pour remplacer la granulation des laitiers de hauts fourneaux. Il communique des propriétés hydrauliques latentes au laitier de haut fourneau, mais les facteurs physico-chimiques influençant ces propriétés n'ont jamais été étudiés en détail. Des ciments à base de différents types de laitier pelletisé provenant de plusieurs pays, dont le Canada, ont été préparés de telle sorte que de grandes variétés de compositions chimiques et de degrés de vitrification et de finesse de broyage soient obtenues. Ces ciments ont été ajoutés comme liants dans des pâtes autoclavées à haute température (185°C).

La résistance, la porosité et la composition (sous la forme hydratée) de ces liants (laitier-ciment portland-silice) ont été déterminées dans le but de trouver des relations entre les propriétés physico-chimiques des ciments et celles des pâtes hydratées. La principale phase hydratée pour la plupart des liants de différentes compositions consiste en de la tobermorite (11.3 Å). Lors de l'analyse quantitative à l'aide d'un diffractomètre à rayons X, des courbes d'étalonnage ont été construites.

Ce travail de recherche est particulièrement orienté vers l'augmentation des résistances et l'étude de l'hydratation des produits formés à partir d'un système à trois composantes (ciment à base de laitier, ciment portland et poudre de silice), traité à l'autoclave.

**SUMMARY:** Pelletizing, a recently developed processing and product alternative to both foaming and granulating, imparts latent hydraulic properties to iron blast furnace slag, but the physical and chemical factors influencing these properties have not been previously studied in detail. Pelletized slag cement from both Canadian and foreign sources, covering a wide range of chemical compositions, degrees of vitrification (i.e. glass contents) and fineness of grinding have been incorporated as the major binder component in high temperature (185°C) autoclaved pastes. The strengths, porosities and hydrated compositions of these slag-Portland cement-silica binders have been determined, and it is intended to establish relationships between the physical and chemical properties of the original slag cements and the hydrated pastes established. Over a wide range of proportions, 11.3 Å Tobermorite has been found to be the major hydrated phase and XRD calibration curves were developed for its quantitative analysis. This contribution is primarily concerned with strength development and the hydration products formed in the ternary system of autoclaved, pelletized slag/Portland cement/silica flour.

## EXPERIMENTAL

**Materials:** Chemical and mineralogical compositions as well as physical properties of the pelletized slag (1,2), Portland cement and silica flour are shown in Table I. The sand used in the mortar cubes was standard ASTM C109 Ottawa quartz sand.

The estimate of the glass content of the slag depends on the method employed. By individual, optical particle analysis under crossed polars (3), the glass content was estimated at 69%. The percent of emission at 590 nano meters, compared to a glass standard on a UV spectrophotofluorometer was found to be >100%. The XRD value of 95% glass shown in Table I, was obtained by comparison of peak intensity ratios of the  $\text{CaF}_2$  internal standard to the mellilite and merwinite peaks in relation to those found for synthetic materials. This method was thought to be the most reliable.

**Methods: Pastes:** After sieving all materials through a 150  $\mu\text{m}$  sieve, and mixing at W/C = 0.32, pastes were vibrated into cylinder molds. After autoclaving, three of the 30mm diameter by 50 mm cylinders were capped and tested in compression and two were subjected to splitting tension.

**Mortars:** Three 51 mm mortar cubes were prepared according to ASTM C109 and C305 (constant workability rather than a constant W/C) and were tested in compression after autoclaving.

**Curing:** After mixing, both pastes and mortars were stored for 16 - 18 h at 23°C and 100% RH in order to develop green (initial) strength. Specimens were demolded then placed

in a Cenco laboratory autoclave. The maximum temperature of 185°C (1.03 N/mm<sup>2</sup> steam pressure) was reached in 1h, held for 4h, then the pressure was released slowly over 1.5h. The specimens were left in the autoclave for a further 16 - 18 h before removal.

**X-Ray Diffraction (XRD):** A Norelco diffractometer and monochromatic  $\text{CuK}\alpha$  radiation (30 KeV, 16 mA) were used for the most part at a scanning speed of 1°2 $\theta$ /minute over the range 6 to 70°2 $\theta$ . Several repeat scans were made to verify the presence of weak peaks and to enable the averaging of intensities. 10% by weight of  $\text{CaF}_2$  was added as an internal standard.

**Differential thermal Analysis (DTA):** Samples were heated in air at 12°C/minute using a Dupont 900 analyser at a sensitivity of  $\Delta T = 0.6^\circ\text{C}/\text{cm}$ .

**Non-Evaporable Water:** While initially gaining weight during ignition at 1050°C, the slag was found to lose weight during continued ignition periods. After 20 to 30h ignition, the weight changes became consistent and levelled off (often at a net loss in weight) parallel to the rate of weight change of the pastes. Therefore the method of Copeland and Hayes (4) for determining non-evaporable water content in pastes was modified to include the three binder components and was based on ignition times of 20 and 30 h.

## OBSERVATIONS

**Mortars:** Mortar cubes were made at 10% intervals over most of the range of the ternary system and compressive strengths are shown in Figure 1. It can be seen that at

TABLE I: PROPERTIES OF BINDER MATERIALS

20% silica flour contents, high strengths were obtained over the whole range of slag cement/Portland cement. Maximum strengths were obtained at high slag contents (60% slag cement/20% Portland cement/20% silica flour, 70%/20%/10%, and 75%/15%/10%).

Fig. 1 - Compressive strengths of autoclaved mortar cubes ( $N/mm^2$ )

**Pastes:** The compressive strengths of paste cylinders, made at 20% intervals in the ternary system, are shown in Figure 2. Comparison of these values with the mortar cube strengths in Figure 1, shows that the region of optimum strengths has shifted over to about 40% silica flour. This would seem to indicate that some of the coarse quartz sand (150-600  $\mu m$ ) in the mortars reacted to form hydration products. Even though pastes initially containing 20% silica flour, had large quantities of unreacted silica (detected by XRD), their strengths were less than the pastes containing 40% silica flour. This hydrothermal reaction of coarse quartz sand is supported by Menzel (5) who noted the reaction of 0.3 to 0.58 mm sand at 177°C.

Fig. 2 - Compressive strengths of autoclaved paste cylinders ( $N/mm^2$ )

**Non-Portland Cement Combinations:** one important observation was that without Portland cement, the silica flour reacted hydrothermally with the slag cement in both mortars and pastes resulting in higher strengths than that obtained by slag cement alone. A further point of interest is observed from Figure 3, which gives tensile to compressive strength ratios for the ternary combinations of pastes. While ratios for binders including any proportion of Portland cement did not exceed 0.15, ratios for slag cement and slag cement/silica flour combinations were at least 0.50. Along the slag cement/silica flour binary, the maximum compressive (56.3  $N/mm^2$ ) and tensile (31.4  $N/mm^2$ ) strengths occurred using 60% slag cement and 40% silica flour. From analysis by XRD, it was found that well crystallized 11.3 Å tobermorite was the only hydrated phase formed at this combination.

Fig. 3 - Ratios of tensile to compressive strengths of pastes

The small quantity of free lime liberated by the slag is unlikely to have produced 11.3 Å tobermorite to the extent it was found. Therefore reactions, as yet unaccounted for, must have occurred between the slag minerals and the silica flour. The mechanism of these reactions must certainly be different than the commonly accepted theory of alkali activation, originally proposed by D'Ans and Eick (6). Although not considering autoclave temperatures, they proposed that hydration-inhibiting, acidic gels initially coated the surfaces of the slag grains and could only be penetrated by a sufficient concentration of externally supplied alkali.

The practicality of these non-Portland cement binders was questioned due to low green strengths obtained in the pastes. However, in a related industrial application study, full scale 200 mm masonry blocks were successfully produced, with a binder of 67% slag cement (285  $m^2/g$  Blaine fineness) and 33% silica flour (7).

**Unreacted Materials:** While Figure 4, shows the molar  $\text{CaO/SiO}_2$  ratio of the starting materials for each binder composition, these values would be different than the C/S ratios of the hydrates due to the presence of unreacted portions of all three materials. Unreacted silica flour could be easily detected, by XRD, at any binder composition having it as a component. The presence of unreacted slag glass was assumed to be responsible for the amorphous halo (hump) in the diffraction traces. Unreacted Portland cement (mainly alite) was found in many of the pastes as shown in Figure 5.

Fig. 4 - Molar C/S ratios of initial paste materials

Fig. 5 - Phase identified in autoclaved pastes PC= unreacted Portland cement, SF = unreacted silica flour, CH =  $\text{Ca}(\text{OH})_2$ ,  $\alpha$  =  $\alpha\text{-C}_2\text{SH}$ , TSH =  $\text{C}_3\text{SH}_2$ , T = tobermorite with 11.3 Å peak, CSH = poorly crystalline tobermorite, ( ) = only trace of phase detected.

**Hydration Products:** The hydration products detected by XRD and DTA are also shown in Figure 5. 11.3 Å tobermorite, in various degrees of crystallinity, was found to be the main hydrated phase in all binders containing silica flour, and for 100% slag cement. Poorly crystalline tobermorite was also found in autoclaved (188°C) slag glass by Midgley and Chopra (8). Using an XRD calibration curve for synthetic 11.3 Å tobermorite (not detailed here), the maximum content of tobermorite (about 10 to 15% by weight) was found along the line of binders containing 40% silica flour, coincident with high strengths.

$\alpha\text{-C}_2\text{SH}$  was detected in all combinations of slag and Portland cement not containing silica flour and silica combinations with at least 60% Portland cement, some of which exhibited high strengths as well.  $\alpha\text{-C}_2\text{SH}$  was not detected readily by XRD but the DTA endotherm at 475°C was easily distinguished. Tricalcium silicate hydrate was only found in small quantities in the 100% Portland cement paste and at 20%/80%/0%. The presence of the 3.03 Å peak of either calcite or scawtite was detected in some pastes but was not included in Figure 5, since it was not known if this phase was formed during autoclaving or if it was due to carbonation during storage afterwards.

**Free Lime:** From Figure 5, it can also be seen that slag and silica flour each consume the free lime liberated by Portland cement, during hydration.

**Non-Evaporable Water:** In Figure 6, estimates of the non-evaporable water, uncorrected for any carbonation of the hydrates, are given. The non-evaporable water content generally increased with increasing Portland cement content, which would seem to indicate more complete hydration of pastes containing large quantities of Portland cement after 4h autoclaving at 185°C. However, the presence of increasing quantities of  $\text{Ca}(\text{OH})_2$  with increasing Portland cement content would account for some of this phenomenon.

Fig. 6 - Non-evaporable water content of pastes (% by weight)

**Effect of Slag Variables:** While the analysis of this work is still in progress, a short summary is in order. Paste prisms containing 18 different industrial and synthetic slags were prepared at W/C = 0.28, 0.32 and 0.40, composed of 60% slag cement/20% Portland cement/20% silica flour. The strength and porosity data obtained were used to extrapolate to zero-porosity strengths from least squares line fits, following the methods of Beaudoin and Feldman (9). Realizing the importance of variations in porosity on strengths, the zero-porosity strength was used to eliminate this effect for comparison of strengths to slag properties. The quantity of hydration products was also found to vary with W/C. The higher the water/cement ratio, the larger was the quantity of hydration products.

From preliminary analysis, the changes in glass contents and chemistry between different pelletized slags, whether from the same blast furnace or not, show no trend with respect to either the non-evaporable water contents, strengths at a constant W/C, or zero-porosity strengths. Of the available empirically derived chemical moduli, commonly found in slag studies (10) and slag cement specifications (e.g., Canada CSA:A363, West Germany - DIN:1164), no correlation has been found with reactivity. As mentioned earlier, different techniques of measuring the degree of vitrification in slags exist and these are being evaluated in relation to reactivity and strength development. In summary, none of the commonly accepted methods of assessing slag quality has proved satisfactory.

## CONCLUSIONS

For autoclaved mortars, higher strengths were obtained with pelletized slag cement as the principal constituent in the ternary system than with any non-slag cement combination.

Paste combinations giving high strengths generally contained more silica flour than in mortars.

Pelletized slag cement was activated by silica flour, forming 11.3 Å tobermorite and resulted in high strengths without the use of Portland cement. These slag-silica binders also showed very high tensile to compressive strength ratios.

Most of the pastes having high strengths also had 11.3 Å tobermorite as the major hydration product. Some pastes also containing  $\text{C}_2\text{SH}$  exhibited high strengths, but  $\text{C}_2\text{SH}$  was only detected either in pastes not containing silica flour or pastes having greater than 60% Portland cement.

Preliminary investigations into the effect of chemistry and glass content on the hydrothermal reactivity of pelletized slag have shown no definite trends.

## High Manganese High Alumina Slag for Cement Manufacture

### *L'utilisation des laitiers alumineux à forte teneur en manganèse, dans la fabrication des ciments*

C.A. TANEJA, S.P. TEHRI and MANJEET SINGH, Scientists, Central Building Research Institute,  
Roorkee (U.P.) India.

RESUME : Le laitier de Rourkela a pour caractéristique d'avoir une teneur en MnO supérieure à 6,75 %. Des études antérieures ont montré l'effet défavorable de cette forte teneur en MnO sur l'hydraulicité de ce laitier. Cependant le laitier de Rourkela diffère des laitiers étrangers par sa plus forte teneur en  $Al_2O_3$  et un plus faible rapport  $CaO/SiO_2$ , bien qu'ayant une forte teneur en MnO. L'activation du clinker par des verres synthétiques de même composition ( $CaO$ ,  $Al_2O_3$ ,  $SiO_2$ , MnO) que le laitier de Rourkela, ont montré que MnO pouvait avoir, dans les conditions optimales, un effet favorable. Cependant ces verres synthétiques ne pourraient avoir, au broyage, la même granulométrie que le laitier. En outre, des recherches ont été entreprises sur des échantillons commerciaux de laitier à haute teneur en manganèse.

Des ciments PBFS ont été préparés par mélange de laitier, de clinker et de gypse. Ils ont été essayés. On a trouvé que les proportions optimales de laitier et de clinker étaient de 50x50 avec addition de 4 % de gypse. Ces ciments PBFS sont conformes aux normes. Le laitier à haute teneur en manganèse est recommandé pour la fabrication du ciment PBFS.

SUMMARY: Rourkela slag is characterised by having MnO content upto 6.75 per cent. Studies abroad have shown adverse effects of MnO in slag on its hydraulicity. However, Rourkela slag is different from foreign slags in having higher  $Al_2O_3$  and lower  $CaO/SiO_2$  besides having high MnO. Clinker activation of synthesized  $CaO-Al_2O_3-SiO_2-MnO$  glasses corresponding to composition of Rourkela slags showed favourable effects of MnO under optimum conditions. However, quenching of synthetic glass composition does not simulate conditions of granulation. Therefore, commercial samples of high manganese slag were investigated.

PBFS cements were prepared by intergrinding slag, clinker and mineral gypsum and tested. Optimum proportions of slag and clinker were found to be 50:50 with 4 per cent of gypsum. PBFS cements were found to comply with the standard requirements. High manganese slag is recommended for manufacture of PBFS cement.

Indian slags are characterised by low lime and high alumina contents. The slag from the blast furnaces of Rourkela Steel Plant, Rourkela (Orissa) which employs L.D. process for steel making and makes addition of pyrolusite in the furnace burden, is different from other slags in having comparatively high MnO content (3.1 to 6.75 per cent). Doubts were expressed about the suitability of this slag for cement manufacture. Laboratory investigations were carried out to study the effect of increasing amount of MnO in water-quenched synthetic slag glasses corresponding to chemical composition of Indian slags on their hydraulic behaviour on activation with portland cement clinker. Results showed that MnO content, upto 2.5 per cent in slags was beneficial but a higher content affected the early strength adversely though the late strengths at 28 days and beyond improved appreciably (1). However, quenching of molten synthetic slag compositions does not simulate the conditions of commercial granulation method. Therefore, it was considered desirable to study the hydraulic properties of commercially produced high manganese granulated slags on clinker activation.

#### EXPERIMENTAL

##### Raw Materials

##### a) Granulated Slags:

##### Chemical Composition:

Four samples of commercial granulated blast furnace slag were received from Rourkela Steel Plant. Their chemical composition is reported in Table 1.

Table 1  
Chemical Composition of Slags

Constituents	Composition Percent			
	Sample No.			
	1	2	3	4
SiO <sub>2</sub>	34.46	34.50	34.00	33.80
Al <sub>2</sub> O <sub>3</sub>	23.35	24.10	24.00	23.30
FeO	0.42	0.30	0.56	0.37
CaO	31.40	30.90	29.90	28.60
MgO	6.00	5.60	5.30	6.00
MnO	3.10	4.00	5.10	6.75
S	0.60	0.65	0.52	0.52
Total	99.30	100.05	99.38	99.34

Hydraulic index employed for evaluating the hydraulicity of high manganese slags as recommended by Keil (2) and computed from chemical composition is reported in Table II.

Table II  
Hydraulic Indices of Slags

Formula	Slag samples			
	1	2	3	4
$\text{CaO} + \text{CaS} + \frac{1}{2}\text{MgO} + \text{Al}_2\text{O}_3$	1.55	1.51	1.45	1.36
$\text{SiO}_2 + \text{MnO}$				

According to Keil (2) slags of index more than 1.5 (samples 1 and 2) are of good hydraulic property whereas those of less than 1.5 (samples 3 and 4) are of moderate hydraulicity. These indices are, however, recommendatory only. Hydraulicity is known to depend more on the conditions of granulation of slags.

Sulphur in slags is known to have greater affinity for Manganese forming Manganese sulphide than for calcium or iron. The amount of MnS formed computed from sulphur content in slags and the balance of MnO percent in glassy phase are reported in Table III.

Table III  
Form of Manganese in Slags

Constituent	Slag Samples			
	1	2	3	4
MnS	1.63	1.77	1.41	1.41
MnO	1.77	2.61	3.95	5.60

#### Physical Properties

Representative samples of slags were oven dried at 105°C and examined for their bulk density, glass content and refractive index. Results are reported in Table IV

Table IV  
Physical Properties of Slags

Sample No.	Bulk Density (kg/m <sup>3</sup> )	Refractive Index	Glass Content (%)
1	1480	1.64	90
2	1240	1.62	95
3	1360	1.64	90
4	1320	1.60	91

Data on bulk density shows that the slag is of medium to hard grindability (3) and is expected to be harder to grind than cement clinker: Glass content is more than the minimum specified limit of 90 per cent.

Table V  
Analysis of Rajgangpur Clinker and Gypsum

Constituents	Clinker Percent	Gypsum Percent
SiO <sub>2</sub>	23.68	18.20
Al <sub>2</sub> O <sub>3</sub>	5.18	3.92
Fe <sub>2</sub> O <sub>3</sub>	2.46	
CaO	64.40	27.18
MgO	3.95	2.21
SO <sub>3</sub>	tr	31.13
Loss on Ignition	1.18	18.00
	<u>100.85</u>	<u>100.64</u>

b) Portland cement clinker was obtained from Orissa Cement Works, Rajgangpur. Chemical Composition is reported in Table V.

c) Gypsum was obtained from the above source. Its chemical composition is reported in Table V.

#### Preparation of Portland Blast Furnace Slag Cement

The four samples of slag were inter-ground with cement clinker in the proportions of 40:60, 50:50 and 60:40 with 4 per cent of gypsum to fineness of about 4000 sq.cm/gm (Blains). As a control sample, the cement clinker was ground with 4 per cent of gypsum to fineness of about 3200 sq.cm/gm (Blains).

#### Results

Portland blast furnace slag cements and portland cement thus produced were tested for physical properties as per Indian standard 4031-1968. Results are reported in Table VI.

Table VI  
Physical Properties of Slag Cements

Slag Sample No.	MnO Per-cent	Slag Cement composition S : C : G			Surface Area cm <sup>2</sup> /g (Blains)	Setting Time (minutes)		Compressive strength (N/mm <sup>2</sup> )			
						Initial	Final	3days	7days	28days	90days
1	3.1	40	60	4	4141	250	300	30.2	41.4	57.2	61.4
		50	50	4	4100	275	315	24.1	33.0	49.2	60.0

Portland Cement	IS 269-1976	0	100	4	3230	285	335	34.5	45.3	52.1	64.7
					2250	30	600	15.7	21.6		

### Discussion

Manganese sulphide content in samples of slag is much below the maximum prescribed limit of 5 per cent reported by Solacolu and Balta (4) to affect the hydraulic activity adversely and hence is not likely to cause deleterious effect.

Since the slag cements produced by intergrinding of granulated slag and clinker in the ratios of 40:60, 50:50 and 60:40 pass the standard specifications, these slags can be recommended for manufacture of cements. However, 3 and 7 days strengths of slag cements are much lower than those of control portland cement. Lowering of strength does not bear any correlation with MnO or CaO or CaO+MgO. It appears that apart from chemical composition, the condition of granulation namely temperature and speed, play an important role in deciphering quality of slag.

### Conclusion

PBFS cements produced by intergrinding granulated slag containing MnO as high as 6.75 per cent and portland cement clinker with 4 per cent gypsum comply with the requirements of standard specifications and hence slags are suitable for manufacture of cement.

# The Hardening of Nickel Slags

## *Le durcissement des laitiers de nickel*

J. LANEUVILLE, Director of Research and Development, St. Lawrence Cement Company,  
Mississauga, Ontario, Canada.

**SUMMARY:** The chemical composition of non-ferrous slags produced in Canada from nickel and copper smelters contains mostly iron oxide and silica, with minor amounts of calcium oxide. This composition is quite distinct from steel blast furnace slags normally used in blended cements.

The Pozzolanic properties of finely ground nickel slags have been investigated in comparison with fly ash and ground quartz by means of the Pozzolanic Activity Test ASTM C 595. A good relationship exists between the lime mortar strengths of the materials investigated and their HCl-soluble  $\text{SiO}_2$  plus  $\text{Al}_2\text{O}_3$  contents after 7 days curing. The granulated slag showed the highest pozzolanic activity.

The hardening properties of granulated nickel slag, in blends of slag and cement, have been investigated in ASTM C 109 modified mortars, cured at  $23^\circ\text{C}$  for periods extending to 1 year or autoclaved at 2 MPa. The contribution of slag to strength is negligible at early ages, but is equivalent to that of cement at later ages, say 90 days to 1 year, provided the slag content of binder does not exceed 45%.

On mortars made with various slag/cement ratios, hydrated for 7, 28 and 90 days at  $23^\circ\text{C}$  and dried at  $105^\circ\text{C}$ , the combined water was calculated from thermogravimetric curves and loss at  $1000^\circ\text{C}$ . A fair relationship was found between the mortar strengths and the combined water contents. The proportions and nature of hydration products was found to vary with slag/cement ratios.

Comparative micrographs of cement paste and cement-slag paste, hydrated for 2 months, have been obtained with a scanning electron microscope and analyses of selected areas made with an X-ray energy dispersive spectrometer.

**RESUME:** La composition chimique des laitiers non-ferreux produits au Canada par les fonderies de nickel et de cuivre contient principalement de l'oxyde de fer et de la silice avec des quantités mineures de chaux. Cette composition diffère fortement de celle des laitiers de haut fourneau qui sont normalement employés dans les ciments métallurgiques.

On a étudié les propriétés pouzzolaniques des laitiers de nickel finement broyés en comparaison de cendres volantes et de quartz moulu en suivant l'essai de pouzzolanité ASTM C595. Une bonne relation existe entre les résistances mécaniques des divers mortiers et les teneurs en silice et alumine solubles dans HCl après 7 jours de durcissement.

On a aussi suivi l'évolution du durcissement d'un laitier de nickel granulé, mélangé au ciment en diverses proportions, en mortiers modifiés ASTM C109, maintenus à  $23^\circ\text{C}$ , pendant des périodes s'étendant jusqu'à 1 an ou autoclavés à 2 MPa. La contribution du laitier à la résistance à la compression est négligeable à de jeunes âges, mais elle équivaut à celle du ciment entre 90 jours et 1 an, pourvu que la teneur en laitier du liant ne dépasse pas 45%.

A partir de courbes thermogravimétriques et de la perte à  $1000^\circ\text{C}$ , on a calculé la teneur en eau combinée de mortiers de divers rapports laitier/ciment, hydratés pendant des périodes de 7, 28 et 90 jours et séchés à  $105^\circ\text{C}$ . On a trouvé une bonne relation entre la teneur en eau combinée des mortiers et leur résistance à la compression. On a trouvé que le rapport laitier/ciment influe sur les proportions et la nature des produits d'hydratation.

A l'aide d'un microscope électronique à balayage, on a pris des photos d'une pâte de ciment et d'une pâte de ciment-laitier durcies pendant 2 mois. Sur des microzones choisies, on a fait l'analyse à l'aide d'un spectromètre en dispersion d'énergie.

## INTRODUCTION

Annual production of non-ferrous slags in Canada is estimated to be 8 million tons and is mostly produced from copper, nickel, zinc or lead smelters (1). These slags contain mainly iron oxide and silica (2).

Recently, research on the cementitious properties of non-ferrous slags have been the subject of a few publications. E. G. Thomas (3,4) studied the influence of ground copper reverberatory furnace slag, dezincized lead smelter slag, copper converter slag and lead blast furnace slag on the hardening properties of cemented hydraulic fill. He found that all these slags when used in a quenched, glassy state and ground to a specific surface of about 300 m<sup>2</sup>/kg act as pozzolans providing glassy silica, which reacts with lime and water to produce stable, cementitious hydrated calcium silicates. Thomas pointed out that the pozzolanic nature of the reaction between cement and slags is verified by the fact that addition of these ground slags to a fixed cement content produces increased strength over long periods.

The present author (5) studied the hardening properties of copper and nickel slags produced in Canadian smelters. Experiments were made in order to study the rate of hardening, over the period of one year, of mortars made with binders containing various proportions of cement and ground slag or cement and ground quartz. In the main series of experiments, the Blaine fineness of cement, slag and quartz was 400 m<sup>2</sup>/kg. The mortars were prepared and tested according to ASTM C109-64, the mass of cement plus slag used for preparing the mortar cubes being the same as the mass of cement prescribed in the test method.

The contribution of the granulated nickel slag to mortar strength compared to Portland Cement was very small at 7 days, but it showed increases with longer curing periods attaining that of the cement at 1 year, at slag/cement ratio less than one. For higher slag to cement ratio, the strength decreased more rapidly at the later ages.

Basic knowledge on the hydration characteristics of nickel slag is still very scanty. The present paper makes an endeavour to narrow this gap.

## MATERIALS

The composition of the materials used is shown in Table I. The quartz sample contained 96.4% SiO<sub>2</sub>. Total iron and sulphur have been calculated as Fe<sub>2</sub>O<sub>3</sub> and SO<sub>3</sub>, although they are predominantly found in a reduced state in slags.

Slag A was an air-cooled nickel slag and slag B a granulated nickel slag. Their crystallinity were qualitatively checked by X-ray diffraction in 1970. The main constituent in both slags was a glass phase of low crystallinity, the glass phase being more abundant in slag B. Both slags also contained fayalite, more abundantly in slag A than

in slag B, but of higher crystallinity. Both slags contained magnetite as a minor constituent.

TABLE I-Percentage composition of materials

	Cement	Fly Ash	Slag A	Slag B
SiO <sub>2</sub>	20.65	49.24	36.77	37.96
Al <sub>2</sub> O <sub>3</sub>	5.81	24.84	5.21	6.30
Fe <sub>2</sub> O <sub>3</sub>	2.14	22.50	53.80	50.89
CaO	62.91	1.84	2.84	3.10
MgO	2.80	0.72	2.32	3.10
K <sub>2</sub> O	1.26	-	0.61	0.71
Na <sub>2</sub> O	0.21	-	-	-
SO <sub>3</sub>	2.78	0.77	3.71	2.83
L.O.I.	1.44	-	-	-

## POZZOLANICITY OF SLAGS

Experimental procedure. Samples of slag A, slag B and quartzite were ground in the dry state in a laboratory ball mill. The Blaine specific surface areas of cement, fly ash, quartz, slag A and slag B were respectively 350, 310, 400, 400 and 380 m<sup>2</sup>/kg.

The pozzolanicity of these materials was studied in lime mortars according to the procedures set out for the Pozzolanic Activity Test in Standard ASTM C595.

The HCl-soluble SiO<sub>2</sub>, Al<sub>2</sub>O<sub>3</sub> and Fe<sub>2</sub>O<sub>3</sub> content of the lime-slag, lime-fly ash, lime quartz mortar specimens was determined immediately before and after the 7-day curing period prescribed in the ASTM Pozzolanic Activity Test. The mortar specimens were dried and ground for 2 minutes in a Shatter Box disc grinder. To 1 g of sample, 100 ml of cold HCl (d=1.12) were added and stirred for 10 minutes with a magnetic stirrer. The solution was filtered and the SiO<sub>2</sub>, Al<sub>2</sub>O<sub>3</sub> and Fe<sub>2</sub>O<sub>3</sub> content was determined in the filtrate, using standard gravimetric methods for SiO<sub>2</sub> and Al<sub>2</sub>O<sub>3</sub>, and titration with K<sub>2</sub>Cr<sub>2</sub>O<sub>7</sub> for Fe<sub>2</sub>O<sub>3</sub>. The loss on ignition was also determined and the amounts of soluble SiO<sub>2</sub>, Al<sub>2</sub>O<sub>3</sub> and Fe<sub>2</sub>O<sub>3</sub> calculated as percent of the original mass of slag, fly ash and quartz.

Results: the amounts of HCl-soluble SiO<sub>2</sub>, Al<sub>2</sub>O<sub>3</sub> and Fe<sub>2</sub>O<sub>3</sub> extracted from the mortar specimens, before and at the end of the curing period are shown in Table II and expressed as percent of the original mass of the tested materials.

The soluble SiO<sub>2</sub> and Al<sub>2</sub>O<sub>3</sub> contents of lime-slag mortars increased during the curing period, whereas the Fe<sub>2</sub>O<sub>3</sub> content showed no definite trend.

TABLE II-HCl-soluble  $\text{SiO}_2$ ,  $\text{Al}_2\text{O}_3$  and  $\text{Fe}_2\text{O}_3$ , as percent of original mass of materials.

Materials	$\text{SiO}_2$		$\text{Al}_2\text{O}_3$		$\text{Fe}_2\text{O}_3$	
	1*	2*	1*	2*	1*	2*
Slag A	13.89	18.37	2.30	3.05	43.96	39.70
Slag B	17.96	22.99	3.63	5.79	46.57	42.51
Fly Ash	0.63	9.68	1.82	4.44	1.59	6.78
Quartz	0.94	4.37	1.51	0.36	1.04	4.52

1\* and 2\* refer to extractions from mortar before and after the curing period (Pozzolanic Activity Test).

No relationship could be established between the compressive strength of the mortars and the increase in soluble  $\text{SiO}_2$  and  $\text{Al}_2\text{O}_3$  during the curing period. However, as shown in Fig.1 a relationship exists between the compressive strength of all lime mortars and their soluble  $\text{SiO}_2 + \text{Al}_2\text{O}_3$  contents after 7 days curing. This confirms the pozzolanicity of the two nickel slags, the granulated slag B being more reactive than the air-cooled slag A.

Fig. 1 - Factor related to pozzolanicity

## HARDENING RATE OF CEMENT-SLAG MORTARS

The hardening rate of mortars made with granulated slag B ( $400 \text{ m}^2/\text{kg}$ ) and a Portland cement ( $400 \text{ m}^2/\text{kg}$ ) has been previously reported (5). The series presently reported made in 1973 deals with the hardening rate of mortars made with the same slag B ( $380 \text{ m}^2/\text{kg}$ ) with a coarser cement ( $350 \text{ m}^2/\text{kg}$ ). Experimental procedure: Mortars were prepared according to Standard ASTM C109-64, except that it will be understood that when references are made to the "cement", they will in this case, be to the binders as described in Table III.

TABLE III - Proportions of constituents of binders, in part per mass.

Binders	Cement	Slag B
A	100	Nil
B	70	30
C	55	45
D	25	75

The amount of mixing water was determined with the flow-table. The water-cement ratio was 0.485 for cement mortar and 0.48 to 0.45 for mortars made with slag containing binders, the ratio showing a tendency to decrease with increasing slag content.

A series of 50-mm mortar cubes were prepared by the same procedure and autoclaved at 2 MPa according to the Standard ASTM C151.

Results: as in the previous series (5), the strength producing properties of granulated slag B (Fig.2) is illustrated by a negligible contribution at early ages and a progressively greater contribution at later ages. The strength of the slag binders is approximately equivalent to that of cement at later ages such as 90 days to 1 year, provided the slag content of binders does not exceed 45%. The slightly higher one year strength of binder B mortar over that of Binder A mortar could be ascribed to the effect of a slight difference in water "cement" ratio, as determined by means of the flow-table. The rapid decrease in mortar strength corresponding to slag content of binders exceeding 45% may be ascribed to a deficiency in lime in this composition range.

These results seem contradictory to the results obtained by E.G. Thomas (4) who proved that mixes of tailings, cement and slag can gain additional strength when the slag content is many times that of the cement. In such a case, when progressively larger amounts of slag are added to a fixed cement content, the water-cementitious material ratio decreases. This could explain the apparent discrepancies between the two sets of results.

Fig. 2 - Effect of slag content of binders on the compressive strength of ASTM C109 mortars cubes.

#### WATER IN SET MORTARS

The combined water in hydrated cement mortars and cement-slag mortars was determined by two test methods. The following samples were used: slag B ground to a Blaine surface area of  $390 \text{ m}^2/\text{kg}$  and a Normal Portland cement ( $350 \text{ m}^2/\text{kg}$ ) similar in composition to cement of Table I.

Experimental procedure: with these materials, binders A, B, C, D were prepared in the proportions shown in Table III. Each of the binders was blended with graded standard sand (ASTM-C778), the proportions being 1 part of binder to 2.75 parts of graded standard sand by mass. Mortars were mixed, using a fixed water to binder ratio of 0.50. Immediately after mixing, the mortars were placed in air-tight plastic capsules and held at  $23^\circ\text{C}$  in a moist closet. At test ages of 7, 28 and 90 days, the hardened mortars were crushed, dried at  $105^\circ\text{C}$ , ground for 90 seconds in a Shatter Box disc grinder and dried again at  $105^\circ\text{C}$ , avoiding prolonged exposure to air.

Results: Thermogravimetric analysis  $5^\circ\text{C}/\text{min.}$  from  $20^\circ\text{C}$  to  $1000^\circ\text{C}$  provided the basic data for calculating the combined water of the following samples: cement and slag (TG, DTG), dry mortar blends (L.O.I.) and each of the 12 hardened mortars (TG, DTG and L.O.I.).

The total TG loss for cement and slag amounted respectively to 1.54% and - 5.6% of the original material. The L.O.I. values from muffle furnace tests were 0.51%, -0.04%, -0.33% and -0.86% respectively for the dry mortar blends A, B, C and D.

The total combined water was calculated by two methods: a) from the total TG loss minus corrections for  $\text{CO}_2$  and oxidation of

slag in TG curves, and b) from muffle furnace values, minus corrections for L.O.I. on dry mortar blends. Table IV is the average calculated by the two methods.

TABLE IV - Percent combined water in set mortars.

Mortars	7 days	28 days	90 days
A	3.71	4.32	5.17
B	3.25	3.64	4.34
C	2.87	3.26	3.97
D	1.69	2.06	2.75

As the main features of the derivative thermograms of set mortars, one sharp peak at  $453^\circ\text{C}$  was ascribed to loss of water from  $\text{Ca}(\text{OH})_2$  and a broad peak at  $630^\circ\text{C}$  ascribed to the loss of  $\text{CO}_2$ . No peak was perceptible at  $453^\circ\text{C}$  on the 90 day-D mortar thermogram.

Curves showing the decrease of combined water per unit mass of binders in mortars made with binders of increasing slag content are shown in Fig. 3.

Fig. 3 - Combined water as a function of slag content of binders in mortars of W/binder ratio of 0.5 by mass.

In comparison with Fig.2, one could have expected that points corresponding to 90 day mortars B and C (30% and 45% slag) be located higher on Fig.3. The slag has recently been re-checked by X-ray diffraction and no basic change in crystallinity seemed to have occurred over the last 9 years. In another experiment, water was expelled from mortars A and C, hydrated for 90 days, by raising the temperature at a constant rate of 5°C/minute between 20°C and 800°C, the water vapour being swept by dry nitrogen into a Beckman Trace Moisture Analyzer. This apparatus works on the principle described by Forrester (6): absorption of water in  $P_2O_5$  and electrolysis of water, the d.c. current used being proportional to the amount of electrolysed water.

Water evolution curves of these two hydrated mortars showed major discrepancies. Both curves showed a broad peak between 100° and 300°C mainly ascribed to the evolution of water from calcium silicates and a much smaller peak between 430° and 480°C ascribed to the evolution of water from calcium hydroxide. The ratio of the latter peak over the former peak was 3.3 times smaller for mortar C comparatively to mortar A, thus showing that the proportions of hydration products were different in the two mortars.

In spite of this, by plotting combined water values calculated from Table IV against compressive strength values of mortars (Fig.2), a fairly good linear relation is obtained in Fig.4.

Fig.4 - Relation between combined water and compressive strength.

#### SEM AND KEVEX ANALYSIS

In order to compare some physical and chemical features of hydrated cement with hydrated cement-slag, pastes of cement and binder C (55% cement plus 45% slag B), W/binder = 0.50, were cured for 2 months at 23°C, in plastic capsules. Surfaces of the broken specimens were examined (Fig.5A and B) with an electron scanning microscope (Cambridge S4-10) and plots of analysis of selected areas were obtained (Fig.6) with a Kevex 5100 X-ray energy spectrometer.

Fig.5 - Scanning electron micrographs of pastes hydrated for 2 months, W/binder = 0.50, A (cement), B (cement 55% / slag 45%)

Characteristic features of hydrated cement paste include the presence of  $Ca(OH)_2$  shown in A<sub>1</sub>, in agreement with plot A<sub>1</sub>, and hydrated calcium silicates in A<sub>2</sub>, as indicated in plot A<sub>2</sub>.

Fig. 6 - Plots of X-ray energy analysis of selected areas of Fig. 5.

Hydration of cement-slag paste is more complex: areas of unreacted slag with typical slag analysis is shown in B<sub>1</sub> and likely magnetite inclusion in slag as indicated in plot B<sub>2</sub>; calcium silicate hydrates possibly with inclusion of iron compound may have been formed by an attack of lime on the slag particle in B<sub>3</sub> and B<sub>4</sub>; slightly farther away from the slag particle, calcium silicate hydrates appear at B<sub>5</sub>. Analysis at B<sub>3</sub> and B<sub>4</sub> may also reveal a mixture of C-S-H produced by cement plus some very fine slag particles.

#### CONCLUSIONS

When tested in lime mortar, ground granulated nickel slag has been shown to possess significant pozzolanic properties. In cement-slag mortar, the contribution of slag to strength is negligible at early ages, but is equivalent to that of cement at later ages, say 90 days to 1 year, provided the slag content of binder does not exceed 45%.

A fair relationship exists between the compressive strength of mortars made with various slag/cement ratios and the combined water content.

Differences found in water evolution patterns upon heating hydrated cement and cement-slag mortars suggest that the proportions of combined water and likely the nature of some hydration products vary with the composition of binders and the hydration period. This points out the need to investigate more thoroughly the most appropriate method for drying the hydrated cement-slag mixes. Compared to hydrated cement mixes, the hydrated cement-slag mixes may contain larger amounts of hydrated products which lose water below 105°C.

## MgO-bearing phases in the hydration products of slag cement

### *Action de composés magnésiens sur l'hydratation des ciments de laitier*

G. MASCOLO and O. MARINO, Istituto di Chimica Applicata, Facoltà d'Ingegneria,  
Università di Napoli, Italy.

RESUME : Des hydroxydes doubles de Mg et de Al, carbonatés ou non, ont été fabriqués synthétiquement à la température ambiante, à partir de gels. Ces composés ont aussi été fabriqués dans une solution saturée de chaux. On a constaté qu'ils étaient semblables à ceux qui se forment au cours de l'hydratation des ciments de laitier, et qu'ils présentaient une bonne résistance aux sulfates.

La présence de composés de MgO, autres que  $Mg(OH)_2$ , explique la stabilité volumétrique des ciments de laitier à haute teneur en MgO.

SUMMARY: Synthetic Mg-Al double hydroxides and corresponding carbonated phases were synthesized from gels at room temperature. These compounds were also synthesized in presence of lime saturated solution and are very similar to those found in the hydration products of slag cements.

They also turned out to be resistant to sulfate attack.

The presence of MgO-bearing hydration products different from  $Mg(OH)_2$  explains the volume stability of slag cements having high MgO content.

## INTRODUCTION

The volume stability of blast-furnace cements made up with slags having a high MgO content, may be explained by the formation of MgO-bearing phases different from  $\text{Mg}(\text{OH})_2$  (1). There is some debate in the literature on the nature of the hydration products containing MgO. In fact, Schwiete *et al.* (2), by hydrating suspensions of vitreous gehlenite and/or akermanite, have found at least two hydration products, consisting of MgO intercalated into both CSH<sup>+</sup> and  $\text{C}_2\text{ASH}_8$ .

Kühle and Ludwig (3) have found in the hydration products of cements made with slags having a high MgO content, the compound  $\text{Mg}_6\text{Al}_2\text{CO}_3(\text{OH})_{16} \cdot 4\text{H}_2\text{O}$ , similar to hydrotalcite. One of us (1), besides, has found a phase near to  $\text{M}_4\text{AH}_x$ , by hydration of synthetic vitreous slags in lime suspension. The latter phase was later identified by Taneja (4) among the hydration products of blast furnace slag cement made from slags with a high MgO and  $\text{Al}_2\text{O}_3$  content.

Recently, the synthesis of pure Mg-Al double hydroxides  $[\text{Mg}_{1-x}\text{Al}_x(\text{OH})_2]^{+x}[\text{xOH} \cdot (0.81-x)\text{H}_2\text{O}]^{-x}$  with  $0.23 \leq x \leq 0.33$ , has been reported (5). Their X-ray patterns are very similar to that of  $\text{M}_4\text{AH}_x$  previously identified in lime-slag suspensions (1).

On the basis of these results it was felt worthwhile preparing Mg-Al hydroxides in presence of lime saturated solutions. This has two purposes: firstly, to investigate on the possibility that some Ca enters in the Mg-Al hydroxides lattice, secondly to verify the resistance of Mg-Al compounds to sulfate attack.

## EXPERIMENTAL

Alumina gel, MgO and CaO from decomposition of magnesium basic carbonate and calcium carbonate, respectively, were employed as raw materials. The Al/(Mg+Al) molar ratio ( $x_{\text{Al}}$ ) in the prepared mixtures ranged between 0 and 1. For each  $x_{\text{Al}}$  value, different mixtures containing increasing quantities of CaO were prepared. The different suspensions, using distilled and boiled water, were kept in sealed teflon containers, rotated for two weeks at room temperature. After filtration under  $\text{CO}_2$ -free conditions the products were dried

over silica gel and characterized.

MgO,  $\text{Al}_2\text{O}_3$  and CaO were determined using atomic absorption spectroscopy after dissolution of the solid in diluted nitric acid. The sulfate was determined as  $\text{BaSO}_4$ .

The reaction products were characterized by X-ray powder diffraction analysis using  $\text{CuK}\alpha$  radiation and a Guinier de Wolff camera. Accurate  $d$ -spacing of selected reflections from specimens were measured by scanning  $1/8^\circ(2\theta)$  per minute using a spacing standard.

Some samples were submitted to sulfate attack using a solution of  $\text{MgSO}_4 0.5\text{M}$ . Every now and then the contact solution was replaced and the height of the sedimented powder measured.

## RESULTS AND DISCUSSION

Fig. 1 summarizes the crystalline phases formed in the whole range of the initial compositions ( $x_{\text{Al}}$  versus percent by weight of CaO in the  $\text{CaO-MgO-Al}_2\text{O}_3$  mixture).

Fig. 1 - Crystallization field in the  $\text{CaO-MgO-Al}_2\text{O}_3\text{-H}_2\text{O}$  system. U=unidentified phase.

The full lines divide three main crystallization fields; Brucite (Br) and Mg-Al hydroxides (DH) at low values of  $x_{\text{Al}}$ , Gibbsite (Gib) and DH by increasing Mg content in the magma and Gib and  $\text{Ca}(\text{OH})_2$  (CH) at highest  $x_{\text{Al}}$  values. The dashed lines represent the boundaries between zones containing a third phase besides those of the above main crystallization fields. The third indicated phase, time by time in the various zones, generally appears at higher CaO content. A wide zone without CH appears in correspondence

\*The following common abbreviations currently used in the chemistry of cement have been adopted: S =  $\text{SiO}_2$ ; C = CaO; A =  $\text{Al}_2\text{O}_3$ ; M = MgO; H =  $\text{H}_2\text{O}$ .

with the compositions favorable to the DH formation ( $0.23 \leq x_{Al} \leq 0.33$ ). This indicates the presence of some calcium in DH lattice; in fact, the  $c$ -axial length of DH phases increases with the CaO-doping in correspondence with each  $x_{Al}$  value, as shown in fig.2. The highest  $c$  value in correspondence with each  $x_{Al}$  has been measured throughout the range of the starting compositions. This appears

Fig. 2 - Ca-doping effect on the  $c$ -lattice parameter of DH samples, obtained with different  $x_{Al}$  compositions.

in the upper curve (b) of fig.3; in the same figure the  $c$  values of undoped  $x_{Al}$  compositions are also reported. On the other hand,

Fig. 3 -  $c$  lattice parameter of Ca-doped (b) and pure DH sample (a), as a function of  $x_{Al}$  composition.

slow diffractometric scanning showed a marked broadening of the reflections of Ca-doped phases for  $x_{Al} < 0.8$ , while for  $x_{Al} > 0.8$  a contrary effect was observed. The former effect is shown in fig.4 in which it is possible to compare the trace of the (002) reflections of two specimens, corresponding to the same  $x_{Al}$  value (0.33), undoped (a) and Ca-doped (b). The Ca-doping of DH phases promotes

Fig. 4 - Traces of (002) reflections of undoped (a) and Ca-doped (b) DH samples with  $x_{Al} = 0.33$ .

strains and distortions in the lattice with consequent line broadening.

The contrary effect at  $x_{Al} > 0.8$  between doped and undoped samples might be attributed to a possible ordering in the structure of DH phases, as Taylor (6) suggested for some analogous Mg, Fe-compounds.

As the  $c$  parameter of pure DH phases was found to vary linearly (5) in the composition range (curve (a) in fig.5), supposing an analogous behaviour for the Ca-doped samples, the corresponding  $c$  parameters were estimated: 22.80 Å for Al-rich and 23.45 for Al-poor phases, respectively (curve (b) in fig.5).

The X-ray patterns of DH phases, doped or not, are very similar to those previously found in lime-slag suspensions (1), that is why there is an obvious analogy between the formation of DH from gels and from vitreous

slags. As the magnesium aluminate hydrate forms in presence of free  $\text{Ca(OH)}_2$ , the upper curve (b) might be utilized as a calibration curve to determine the composition of magnesium aluminate hydrate in the hydration products of slag cements.

Fig. 5 -  $c$  lattice parameter of undoped (a) and Ca-doped (b) Mg-Al hydroxides, as a function of  $x_{Al}$  composition.

The CaO content of DH phases in specimens containing two or more phases can obviously only be estimated at about 4-5% by weight.

Two significant samples with  $x_{Al} = 0.23$  and  $x_{Al} = 0.29$  were submitted to the sulfate attack test. After three months in contact with a  $\text{MgSO}_4$  solution the samples showed no volume expansion, as happens for  $\text{C}_4\text{AH}_x$  used as reference.

The X-ray diffraction analysis on the products of the sulfate attack showed some additional broad  $d$  spacings, together those less intense of DH and those more intense of  $\text{Mg(OH)}_2$ . The significant extra  $d$  values observed were: 10.6, 9.2, 5.38, 4.61 and 3.63 Å. These reflections have been attributed to two sulfate-containing phases. The first (10.6, 5.38 and 3.63 Å) phase has the same pattern as a compound prepared by Cole and Hueber (7), by reacting potassium aluminate and magnesium sulfate. To this compound was assigned the probable formula:  $4\text{MgO} \cdot 2\text{Al}_2\text{O}_3 \cdot \text{MgSO}_4 \cdot x\text{H}_2\text{O}$ .

The second phase (9.2 and 4.61 Å) has a pattern very similar to that of the first phase with a lowering of the values of the  $d$  spacings.

It must be stressed that the Mg-Al hydroxi-

des (DH) show ability for anionic exchange, due to exchangeable  $\text{OH}^-$  in the interlayer sheet (8). The Mg-Al hydroxides quickly trap  $\text{CO}_2$  giving rise to the corresponding carbonated phases:

$[\text{Mg}_{1-x}\text{Al}_x(\text{OH})_2]^{+x} [\text{x}/2\text{CO}_3(0.81-3/2x)\text{H}_2\text{O}]^{-x}$ , according to the  $\text{CO}_3^{2-}$  for  $2\text{OH}^- + \text{H}_2\text{O}$  substitution. In this case X-ray analysis showed no significant variation between Mg-Al hydroxides and related carbonate phases (8).

The fact that, in the products of the sulfate attack, phases characterized by a higher  $c$  axial value are found, indicates the exchange of  $\text{OH}^-$  for  $\text{SO}_4^{2-}$  in the DH phase, as also confirmed by the chemical analyses and by the increased  $\text{Mg(OH)}_2$  content.

The explanation of the different behaviour of  $\text{CO}_3^{2-}$  and  $\text{SO}_4^{2-}$  on the  $c$ -axial value of the layer structure lattice of DH must be attributed to the planar conformation of  $\text{CO}_3^{2-}$  which enters in the structure without strains, while the exchange with  $\text{SO}_4^{2-}$ , having a tetrahedral conformation, promotes strains, consequently a low exchange rate and a noticeable variation in the  $c$ -axial value of the resulting exchanged phases.

## CONCLUSION

The results indicate that Mg-Al hydroxides, synthetically prepared in presence of  $\text{Ca(OH)}_2$  take up some CaO (~5%) as shown by the increase in their  $c$ -parameters, if compared to those of pure Mg-Al compounds. Being the powder patterns of these compounds and related carbonated phases similar to those of magnesium aluminate hydrate found in lime-slag suspensions (1), and keeping in mind the Ca-doping, a calibration curve, using the  $c$  axial length v.s.:

$[\text{Mg}_{1-x}\text{Al}_x(\text{OH})_2]^{+x} [\text{xOH}(0.81-x)\text{H}_2\text{O}]^{-x}$  composition with  $x_{Al}$  ranging from 0.23 to 0.33, is available to determine the composition of MgO-bearing phase. Under  $\text{CO}_2$ -conditions the corresponding compositions must be employed:  $[\text{Mg}_{1-x}\text{Al}_x(\text{OH})_2]^{+x} [\text{x}/2\text{CO}_3(0.81-3/2x)\text{H}_2\text{O}]^{-x}$ .

The MgO bearing phases showed a volume stability after sulfate attack, although sulfate bearing phases have been found. These phases show a low formation rate, depending on the difficulty of the tetrahedral  $\text{SO}_4^{2-}$  entering in the layer structure lattice of Mg, Al compounds.

# Microstructure and properties of hydrated cements with different slag content

## *Microstructure et propriétés de ciments hydratés à différentes teneurs en laitier*

R. SERSALE, Professore, B. MARCHESE, Professore, Istituto di Chimica Applicata, Facoltà di Ingegneria, Università di Napoli,  
G. FRIGIONE, Direttore Laboratorio Ricerca e Controllo, Cementir-Cementerie del Tirreno, Napoli, Italie.

RESUME : Les auteurs rapportent les résultats d'une recherche expérimentale accomplie dans le but d'approfondir nos connaissances sur le comportement des liants à haute teneur en laitier de haut fourneau.

L'ensemble des données recueillies montre une évolution des pâtes préparées avec ces liants vers des textures de plus en plus compactes, au fur et à mesure que la chaux libre disparaît. Aux longs âges, d'environ 120 jours, on a relevé le même degré de compacité aussi bien pour les pâtes en portland, que pour celles préparées avec le ciment de haut fourneau, toutes modalités égales; et on a confirmé ce résultat à l'aide des essais de résistance mécanique sur mortier. Ces essais ont parfois indiqué des valeurs franchement plus hautes pour les mortiers préparés avec les liants de haut fourneau.

L'augmentation du rapport Ca/Si des phases de type C-S-H, qui proviennent de la fraction laitier en vertu d'une adsorption d'ions  $\text{Ca}^{++}$  semble exalter le degré de cohésion entre les grains et se révéler donc décisive pour une texture plus compacte. Cette dernière est favorisée aussi bien par une finesse de mouture plus poussée du liant, que par une maturation à plus haute température.

SUMMARY: Results are given of experiments aimed at contributing to knowledge of the behaviour of cements with a high blast-furnace slag content. In all, the data obtained indicate that pastes made from such cements develop an increasingly more compact texture, with a simultaneous disappearance of free calcium hydroxide. For conveniently long curings, at 120 days, a similarity in compactness has been found for both portland and blast furnace cement pastes, under the same operating conditions, as confirmed by the mechanical strengths of the mortars. Indeed these values are sometimes higher for blast-furnace cements. Increase of the Ca/Si ratio in the C-S-H type of phases, produced by the slag fraction, owing to the absorption of  $\text{Ca}^{++}$  ions, seems to promote adhesion between the grains and is thus a determining factor in obtaining a more compact texture. This result is further favored by a finer initial grinding and curing at higher temperatures.

## INTRODUCTION

The factors favoring an increase in blastfurnace cement production are essentially two: the market demand for cements more and more able to satisfy the multiple requirements of building techniques; and the energy crisis dating from October 1973 (1). In fact it is known that cements made from blast-furnace slags give pastes which, compared to those made from Portland, have: a lower hydration heat; greater resistance to sulfate attack; less expansive due to alkali-aggregate reaction effect; lower permeability; in general, greater mechanical strength after long curing (2).

The experiments referred to in this paper aim at widening our understanding of the part played by basic, granular blast-furnace, with in the clinker, so as to enable us to forecast the operational behaviour of high slag content cements and, consequently, to select them suitably for the work to be undertaken. Such research presupposes the identifying of the newly-formed compounds in hydrated and hardened pastes; their quantitative evaluation in relation to the slag/clinker mixture and curing time; systematic observation of the evolution of the microstructure of the pastes and its correlation to the physical and mechanical properties of the mortars, starting from our present knowledge. As regards the nature of the phases, reliable opinion (3) holds that the initial hydration stage of the slag reveals new-formed sulfate phases, such as ettringite, which may later evolve into monosulfate, to give solid solutions with tetracalcium aluminate. The appearance of calcium hydroxide, produced by hydration of clinker silicates, would then favor considerable formation of C-S-H type hydrate masses containing significant quantities of Mg and Al, and play a decisive part in determining the paste texture. It is also true that C-S-H type phases may be conditioned by the presence of electrolytes in the aqueous solution in contact with the slag, and that the presence of gypsum stabilizes ettringite and aluminium hydroxide. The formation of hydrate gehlenite would be precluded, since CH would be consumed in forming C-S-H phases with Ca/Si ratio close to that characterizing those of the clinker (4). The microstructure plays a well known decisive role in the physical and mechanical properties and is influenced by changes in the morphology of newly formed products during the consolidation of hydrating masses (5).

of slag were investigated. Their characteristics are reported in Table I. Specimens 1x1x6 cm were made from pure pastes obtained by hand mixing with a water:solid ratio of 0.33 and cured for 24 hrs in 100% RH atmosphere and then in water for 3.7, 28 and 120 days. The steam curing cycle was: 2h at room temperature, 2 h from 20° to 80°, 6h at 80°, 6h from 80° to 20° and then in water at 20°C. Slices were cut from each specimen, wet-ground in acetone and held over silica gel for 24 hrs. Different fractions of the dried samples were submitted to thermogravimetric (TG), thermodifferential (DTA) and X-ray diffractometric (XRD) analysis, as described previously (6). XRD was performed on the anhydrous specimens and on the mature pastes, before and after TG, using TiO<sub>2</sub> (anatase, 5%) as an internal standard. The intensities of the diffraction lines at 3.52 Å (25.28 °2θ), at 2.85 Å (31.4 °2θ) and at 4.90 Å (18.08 °2θ) for TiO<sub>2</sub>, for CH and for crystalline slag respectively were utilized for obtaining an approximate percentage of both CH and uncombined slag (7). The matching surfaces of the two halves obtained by a single fracture operation, "twin"

surfaces, were examined with a Scanning Electron Microscope (SEM) (6). Mechanical strenghts were determined on mortars (ISO-Rilem).

## RESULTS

Most of the results reported refer to samples 1 and 4, since sample 2 an intermediate behavior. Sample 3, moreover, has the same composition as 4, but a lower Blaine specific surface.

Fig. 1 shows the original XRD patterns for both anhydrous and hydrate samples. The addition of anatase as internal standard makes it possible to measure the relative amount of the crystalline phases present, with the hydration time. It is seen that the quantity of CH in sample 1, Fig. 1a, increases with the

hydration time, and more so when steam curing is adopted. For slag pastes, Fig. 1b, the hydroxide increases slightly at early ages, decreases considerably at 120 days, and disappears after steam-curing.

The paste fractions, after TG analysis show the disappearance of reflections of all the hydrate phases, as well as of the wide band at 26-36°2θ, characteristic of the vitreous structure, Fig. 1b. Instead, merwinite and gehlenite reflections appear; so indicating devitrification. Moreover, there is an increase of reflections of the anhydrous phases, which is attributable to greater concentration, due to dishydration, and probably, to partial reconstitution of poorly hydrated layers toward the original structure.

The data obtained from the TG and XRD, and also from DTA, of the various samples, have been related to the slag content. Comparison may be considered almost quantitative, given the similarity of the experimental treatments. Fig. 2 shows that the CH content of sample 4 is not only lower, at 28 days, than that corresponding to the initial clinker fraction, but is notably lower after 120 days and even lower after steam-curing.

Fig. 3 gives the DTA curves for anhydrous samples 1 and 4 and their relative pastes cured for differing times. The traces of the anhydrous samples show two very weak endothermic peaks, attributable to slight, incipient hydration. For samples 2, 3 and 4 only, the

Fig.4-SEM's micrographs of fracture surfaces of pastes of samples (no.1 and 4) hydrated at 3 (A and D), 7 (B and E), and 28 days (C and F, respectively).

A1, B1, C1, D1, E1 and F1 are enlargements of areas as marked in A, B, C, D, E and F.

exothermic peaks at  $860^{\circ}\text{C}$ – $900^{\circ}\text{C}$  may be attributed to the devitrification process of the slag fraction. Their intensity diminishes with the hydration time. The endothermic peak attributable to the C-S-H fraction, around  $130^{\circ}\text{C}$ , is common to all the traces. Its intensity increases with the course of hydration, while its base widens notably for steam-cured paste. The endothermic peak attributable to CH, at maximum around  $500^{\circ}\text{C}$  is also common to all. The traces of samples containing slag shows further endothermic peaks at  $170^{\circ}\text{C}$  and  $400^{\circ}\text{C}$ ; and steam cured ones at  $237^{\circ}\text{C}$ , too. These may be attributed to hydrated aluminates (8). Moreover, pastes containing slag seem to have greater carbonation also.

Table II gives analytical data from the TG profiles of the four paste samples. The values for each sample are referred to their final weight at  $900^{\circ}\text{C}$ . This was found to be greater for samples with a higher slag content and diminishes during the hydration time. The highest partial losses recorded are those in the  $50$ – $300^{\circ}\text{C}$  range, and are mainly attributable to decomposition of the C-S-H phases. Losses in the  $350$ – $440^{\circ}\text{C}$  range, characterized

by a constantly inclined profile may also be attributed to C-S-H phases and eventual aluminates. Decomposition of CH and Calcium carbonate is indicated by losses in the  $440$ – $550^{\circ}\text{C}$  and  $550$ – $800^{\circ}\text{C}$  ranges, respectively. A slight increase in weight after  $900^{\circ}\text{C}$  in pastes containing slag disappears after 120 days' hydration.

The SEM images of the fracture surfaces of the hydrated pastes, at 3, 7, 28 and 120 days, for samples 1 and 4, are given in Figs. 4 and 5. Both samples clearly show a mass consolidation which intensifies with the hydration time. Minor compactness is found in slag cement pastes, for early hardening times, Fig. 4D and 4E. This difference tends to disappear when the hardening time is more than 28 days (fig. 4F and 5I).

Resistance to water attack is more or less the same for the two pastes cured for 120 days (fig. 5G and 5I). A high degree of compactness is achievable for steam cured pastes, as may be seen by comparing the "twin" fracture surfaces (fig. 5H and 5L).

In steam-cured concrete, too, the mechanical strength of sample 4, after 28 days, is

Fig.5-SEM's micrographs of "twin" fracture surfaces of sample no.1 (G,G' and H,H') and no.4 (I,I' and L,L'). The areas in G' and I' were etched with water for 30s. H and L represent fracture areas of steam-cured pastes. G1, H1, I1 and L1 are magnifications of areas marked in G, H, I and L.

higher than that of sample 1.

## DISCUSSION

The results obtained from thermal and XRD analyses all indicate that slag, in the presence of clinker, manifests a hydraulic activity even at early reaction times. It is true that the hydration of clinker grains occurs before that for slag grains, the former having phases of different chemical nature. This means that the most rapidly formed new phases are of the C-S-H type, and calcium hydroxide; so that  $\text{Ca}^{++}$  ion concentration abounds in solution. Calcium hydroxide plays a particularly important role in stabilizing the hydrate phase; a role determined by its crystallinity and solubility characteristics. One part is devoted to stabilizing C-S-H phases, originating from the clinker; another, initially smaller, is absorbed by the C-S-H type phases of the slag grains.

With the hydration age, particularly for higher slag content cements, there is a considerably decreasing hydroxide content; so much so that, as may be seen in Fig. 2, after 120 days the crystalline calcium hydroxide is very much reduced. With such pastes (Fig. 5I and 5L), however, the length and type of curing favor the forming of a compact texture, very similar that for portland cement pastes, as observation of the fracture surfaces shows. Steam curing accelerates hydroxide consumption by the hydration products of the slag (Fig. 1b, 3 and Table III). The amount and constitution of the C-S-H type phases, thus, have a determining effect on the cementing action. These phases, as has been stated, originate both from hydration of the clinker grains and from hydration of the slag grains.

In the case of clinker grain hydration, the rapid appearance of hydroxide involves its necessary coexistence with larger volumes of C-S-H phase, and so a more difficult steric accommodation, which only in part improves later. This explains the higher mechanical strengths at early ages and smaller increases at later ones, as well as the lower flexion strengths in portland cement pastes in comparison with cements containing slag.

In the latter case,  $\text{Ca}^{++}$  ion absorption occurs slowly, so that a more compact texture is obtained, due to the more gradual incorporation into the mass. This gives initially lower mechanical strengths, but increased ones with ageing.

In slag cements texture compactness is reached only after a long period of curing, because of the greater quantity of C-S-H produced. High degree of compactness is obtainable earlier, however, both by suitable steam-curing and by finer grinding.

**RESUME :** L'exposé traite des résultats de l'élaboration de nouvelles compositions efficaces des ciments portlands de laitier ayant une teneur élevée en laitier granulé de haut fourneau, de l'étude des particularités des processus de durcissement de ces ciments, conditionnant un accroissement intense de la résistance et la formation de la structure du ciment durci avec les caractéristiques mécaniques et les propriétés de construction techniques élevées.

Les paramètres du ciment portland de laitier à faible teneur en clinker assurent, après l'étuvage, une activité qui est supérieure de 20 à 25 % à celle du ciment portland du type 500.

En introduisant, lors du broyage, une addition spéciale, on arrive à élaborer un ciment portland de laitier dont la résistance précoce est élevée et croît intensément au cours du durcissement dans les conditions normales et après le traitement à la chaleur humide, lorsqu'on utilise des clinkers de composition variée et des laitiers de basicité différente.

**SUMMARY :** The results of development of new and efficient compositions of slag portland cement with increased content of granulated blast furnace slag, and of study of specific features of hardening of the said cements which ensure intensive increase of strength and formation of cement stone structure with high mechanical and construction-technological characteristics are presented.

The parameters of the developed low-clinker slag portland cement ensure activity after steaming which is 20-25 % as higher than of portland cement, grade 500.

By introduction of a special additive during grinding a slag portland cement with improved early strength and intensive strength increase in the course of hardening under normal conditions and after hydrothermal treatment when using clinkers of different compositions and slags of different basicity, was obtained.

Nombre d'études et l'utilisation du ciment portland de laitier dans l'industrie de construction ont permis d'établir son efficacité élevée en comparaison du ciment portland : résistance chimique plus élevée, exothermicité plus basse, coefficient d'utilisation et d'accroissement d'activité élevé à l'aide du traitement à la chaleur humide ainsi que consommation d'énergie et de chaleur moindre pour la production.

Dans notre rapport et des communications au VI-ième Congrès sur la chimie du ciment, on a déjà parlé des propriétés du ciment portland de laitier (1, 2), de l'introduction dans la production de ciments portlands de laitier à durcissement rapide et très rapide (2). En ce qui concerne la cinétique du durcissement dans les conditions normales et les indices de résistance, ces ciments sont équivalents au ciment portland des types 400, 500 et 600.

A l'heure actuelle, un grand accroissement de la production du béton et du béton armé pose devant les constructeurs et les techniciens le problème d'élévation notable de la qualité du béton pour la création des pièces et ouvrages d'une longue durée en béton et en béton armé. Pour résoudre ce problème on a besoin de ciments de haute qualité et rentables, car seul le choix des régimes optimaux du traitement à la chaleur humide des pièces en ciments portlands n'assure pas l'obtention des produits à propriétés voulues.

Après le VI-ième Congrès sur la chimie du ciment on a continué les études visant à améliorer les propriétés techniques du ciment portland de laitier et menées dans deux directions :

1. Changement de la cinétique du durcissement du ciment portland de laitier lors du traitement à la chaleur humide, par variation du rapport entre clinker et laitier dans la composition, de la finesse de leur broyage, et du régime de durcissement des produits lors du traitement à la chaleur humide.

2. Variation de la cinétique du durcissement du ciment portland de laitier à l'aide d'additions - accélérateurs de durcissement.

Pour la production des pièces en béton armé soumises au traitement à la chaleur humide, on a mis au point et essayé une variété du ciment portland de laitier dont la teneur en laitier granulé de haut fourneau est de l'ordre de 70 %. Après le traitement à la chaleur humide ce ciment se caractérisait par une activité supérieure de 20 à 25 % à celle du ciment portland du type 500. Au cours du durcissement prolongé le ciment portland à teneur élevée en laitier granulé de haut fourneau continue à acquérir intensément de la résistance. Dans un régime d'étuvage déterminé, les paramètres choisis de broyage du ciment portland de laitier à faible teneur en clinker avec dosage optimal du gypse augmentent le degré d'hydratation du laitier. Ceci entraîne l'accroissement de la quantité de hydrosi-

licates de calcium faiblement basiques de structure submicroscopique qui augmentent la densité de la composante en gel. Les fissures et les pores qui se forment au cours d'étuvage sont remplis d'une masse gélatineuse à grains fins des nouvelles formations (produits d'hydratation du ciment portland de laitier). C'est pourquoi il se forme une texture plus finement poreuse de la pierre de ciment, des bétons et des mortiers en comparaison de la texture du ciment durci dans les bétons étuvés au ciment portland. La pierre de ciment étuvée à partir du ciment portland de laitier à faible teneur en clinker se caractérise par la réduction du volume des macrocapillaires et l'augmentation du volume des pores de dimension de  $5 \cdot 10^{-7}$  cm à  $1 \cdot 10^{-5}$  cm.

Il est établi qu'au cours du durcissement, la chaux, qui se dégage lors de l'hydratation accélérée et de l'hydrolyse de  $C_3S$ , est continuellement fixée par le laitier. Ceci assure le monolithisme de la pierre de ciment qui procure de hautes propriétés techniques aux bétons et détermine une grande résistance au gel et la stabilité dans un milieu agressif. Les données comparatives sur les propriétés techniques principales du ciment portland et du ciment portland de laitier à peu de clinker sont représentées dans le tableau ci-dessous.

Une autre propriété positive du ciment portland de laitier devant le ciment portland est le rapport entre la résistance à la compression et la tension par flexion. Du point de vue de la construction, l'indice de résistance à la flexion a une grande importance. C'est pourquoi on peut supposer que, sur ce point également, le béton au ciment portland de laitier de cette composition aura un grand avantage devant le béton préparé à base de ciment portland.

Les particularités notées de la structure du ciment durci en combinaison avec la capacité du ciment soumis à l'étuvage d'acquies de façon intense de la résistance au cours du durcissement prolongé permettent d'augmenter la longévité du béton armé préfabriqué. La création des conditions optimales de durcissement avec l'utilisation maximale de l'effet de contraction (fig. 1) prédétermine une grande résistance au gel de la pierre de ciment dans le béton et rend possible une large application des adjuvants plastifiants et entraîneurs d'air.

La méthode de variation de la cinétique du durcissement du ciment à l'aide des additions (accélérateurs du durcissement) n'est pas nouvelle (3, 4). Toutefois cette méthode est étudiée à un moindre degré pour le ciment portland de laitier et nous étions les premiers à étudier sous cet angle le ciment portland de laitier à teneur élevée en laitier.

Sur la base des données expérimentales on a établi la composition d'une addition qui élève la résistance initiale du ciment portland de laitier et intensifie son accroissement au cours de durcissement pro-

TABLEAU					
Propriétés techniques principales des ciments étudiés de composition différente					
Teneur en laitier, %	Résistance, %			Coefficient de résistance au gel après 100 cycles de gel et de dégel	Coefficient de stabilité dans la solution à 5 % de $\text{Na}_2\text{SO}_4$ après 6 mois
	après l'étuvage	par unité de clinker	après 6 mois par rapport à la résistance à l'âge de 28 jours		
-	100	100	126	0,41	0,76
70	120	400	130	1,12	0,82

Fig. 1 - Influence des conditions de durcissement et du type du ciment sur la valeur de contraction : ——— étuvage ; ——— durcissement normal ; 1 - ciment portland ; 2 - ciment portland de laitier à 70 % de laitier granulé de haut fourneau.

longé. Il s'agit de l'addition polyminérale sulfoaluminosiliceuse (SAS). Une combinaison favorable des constituants minéraux de l'addition contribue à la réduction du temps de prise et, avant tout, accélère la prise initiale, augmente la résistance dans les délais précoces (1 à 3 jours) et, à la différence d'une série d'additions connues, à l'âge de 28 jours. L'action accélératrice de l'addition sur les processus de prise et la cinétique de l'accroissement de résistance du ciment portland à teneur en laitier de 60 % est établie lors de l'utilisation des clinkers à teneurs différentes

en  $\text{C}_2\text{S}$  et  $\text{C}_3\text{A}$  et des laitiers basiques, acides et électrothermophosphorique. Le gain de résistance dû à l'introduction de l'addition dépend de la composition et des propriétés des constituants du ciment portland de laitier.

Le gain maximal de résistance à l'âge de 28 jours est obtenu grâce à l'introduction d'une quantité optimale d'addition. C'est pourquoi en fonction de la composition et des propriétés des constituants du ciment portland de laitier, on établit expérimentalement la composition de la charge composée de clinker et de laitier à base de l'addition SAS, qui assure l'élaboration d'un ciment à hauts indices de résistance et à temps de prise normaux. À l'aide de l'addition SAS, en faisant varier la teneur de la charge en clinker de 30 à 60 % sans augmentation de la finesse de broyage du ciment (résidu sur le tamis n° 008 est de  $7 \pm 1$  %), on peut élaborer un ciment dont l'activité va jusqu'à 50 MPa lors de durcissement dans les conditions normales (fig. 2).

La capacité du ciment portland de laitier avec addition SAS d'acquiescer intensément de la résistance se conserve également dans le cas de traitement à la chaleur humide (fig. 3). L'utilisation d'un tel ciment dans la production des pièces en béton et en béton armé permet de réduire la durée de la mise à la température isotherme de 2 ou 3 h.

L'accélération du durcissement initial et l'accroissement de l'activité du ciment à l'âge de 28 jours suivi d'augmentation de la résistance au cours de durcissement prolongé en présence, dans le ciment, de l'addition SAS sont dus à la capacité de l'addition d'accélérer les processus d'hydratation des constituants du ciment portland de laitier et de prendre part aux réactions de durcissement aux stades les plus précoces.

À la différence du ciment portland de laitier ordinaire, dans le ciment portland de laitier hydraté avec addition SAS à l'âge de 1 à 28 jours, on observe une diminution intense des maximums de diffraction des constituants de clinker et en premier lieu

Fig. 2 - Influence de l'addition SAS sur les indices de résistance du ciment portland de laitier ; 1 - ciment portland de laitier ordinaire ; 2 - ciment portland de laitier avec addition SAS

de l'alite ( $d = 1,76 \text{ \AA}$ ), l'accroissement de l'intensité des réflexions à  $3,03 \text{ \AA}$  et  $9,8 \text{ \AA}$  avec diminution simultanée de l'intensité des maximums de diffraction correspondant à la formation de l'hydroxyde de calcium ( $d = 4,91 \text{ \AA}$  ;  $2,63 \text{ \AA}$ ).

En procédant aux études physico-chimiques complexes <sup>\*</sup>, on a établi qu'en présence d'addition la quantité d'hydrates varie grâce à la formation de quantités complémentaires d'ettringite, d'hydrosilicates de calcium et d'alumogel à partir des constituants de l'addition. On a établi ce fait en procédant à l'étude séparée de l'influence de l'addition SAS sur les produits de durcissement du constituant de clinker représenté par  $C_2S$  et  $C_3A$  synthétisés et sur le laitier granulé de haut fourneau. L'accroissement de la quantité d'hydrates lors de l'introduction dans le ciment de l'addition SAS est confirmé également par les données sur la variation de la concentration de volume des nouvelles formations avec l'accroissement de la quantité d'addition.

L'addition contribue à l'accélération des processus d'hydratation des constituants du

<sup>\*</sup> Avec la participation de T.Y. Chtchetkina, L.N. Skrynnyk, V.F. Gribko.

Fig. 3. Influence de l'addition SAS sur les indices de résistance du béton après l'étuvage : 1 - béton du type 100 ; 3 - béton du type 200 ; 5 - béton du type 300 au ciment portland de laitier ordinaire ; 2, 4 et 6 - idem, au ciment portland de laitier avec addition SAS. Teneur du ciment en laitier, 60 %.

ciment portland de laitier, à la fixation de la chaux dégagée par  $Al_2O_3$  et  $SO_2$  hydrosolubles additionnés et par la silice active avec la formation des hydrates. Ceci détermine la formation, dès l'âge de un jour, d'une carcasse d'ettringite remplie d'hydrosilicates de calcium en quantité beaucoup plus grande que dans le ciment portland de laitier ordinaire. Les hydrosilicates de calcium formés se distinguent par leur structure et leurs propriétés des hydrosilicates de calcium dans le ciment portland de laitier ordinaire.

Une activité élevée de l'addition donnée envers l'hydroxyde de calcium, sa capacité de participer aux réactions de durcissement ont conditionné des différences notables dans les processus de durcissement du ciment portland de laitier avec addition SAS. Ces différences consistent également dans la formation de l'alumogel du type de la boehmite et de la gibbsite, la diminution de la quantité de  $Ca(OH)_2$  cristallin et des hydroaluminates de calcium, la formation, à un stade plus précoce de durcissement, des hydrosilicates de calcium de structure secondaire (ecaillieux), qui se distinguent des hydrosilicates de calcium fibreux par une densité et une résistance plus élevées.

Tout cela avait pour résultat la réduction des périodes principales de formation de la structure, conduisant à l'accélération de la prise, à un accroissement intense de la résistance au cours de durcissement prolongé, à la formation d'une structure plus homogène et plus dense avec un autre rapport, entre l'agrégat cristallin et la composante en gel que dans le ciment portland de laitier ordinaire. Ceci a assuré l'accroissement de la résistance du ciment durci, de la résistance au gel, surtout après le durcissement normal, de la stabilité dans des milieux agressifs et la diminution de déformations de retrait de 1,5 à 2 fois.

#### CONCLUSIONS

1. On a déterminé les paramètres de production du ciment portland de laitier contenant jusqu'à 70 % de laitier granulé de haut fourneau et ayant, après le traitement à la chaleur humide, une structure dense et homogène, des indices élevés de résistance et un accroissement intense de la résistance au cours de durcissement de longue durée.

On a étudié le processus de durcissement de ce ciment et les causes de l'accroissement de la densité du ciment durci.

Le ciment portland de laitier à teneur élevée en laitier granulé de haut fourneau est efficace lors de la fabrication des produits en béton armé soumis au traitement à la chaleur humide.

2. En introduisant, lors du broyage du ciment, l'addition SAS on a élaboré un ciment portland de laitier à résistance précoces élevée, qui se caractérise par un accroissement intense des indices de résistance au cours du durcissement dans les conditions normales et après l'étuvage et qui possède des propriétés techniques et de construction améliorées. Ceci est obtenu sans changement du schéma technologique et de la finesse du broyage, lorsqu'on utilise un clinker de composition minéralogique non normalisée et de différents laitiers.

Les études physico-chimiques ont établi les particularités des processus de durcissement, l'ordre de formation des phases, leurs propriétés et élucidé le processus de formation de la structure du ciment durci.

# Influence des particularités physiques et chimiques des laitiers de haut fourneau sur leur activité hydraulique

## *Influence of physical and chemical features of blast furnace slags on their hydraulic activity*

S.M. ROIAK, professeur, chaire de la Technologie des Matériaux Liants et des Bétons de "Vzisi",  
J.Ch. CHKOLNIK, candidat ès sciences techniques, chef de laboratoire de "Ouralniitchermet", U.R.S.S.

**RESUME :** En utilisant la résonance paramagnétique électronique, la spectroscopie infrarouge ainsi que d'autres méthodes on montre que l'activité du laitier est fonction du degré de dépolymérisation des complexes ion-oxygène dans le verre de laitier. Un rôle important est joué par la liaison simple Me-O du cation-dépolymérisateur ainsi que sa coordination. On étudie la fonction de l'aluminium et du magnésium dans la structure de formation du verre de laitier dépolymérisé, en particulier, de périclase; on a établi la teneur admissible en oxyde de magnésium par rapport avec l'alumine présente.

On détermine la teneur en  $Ti^{4+}$  dans le laitier de haut fourneau titanifère, de même qu'en  $Ti^{3+}$  pour des coordinances différentes.

On constate que suivant la teneur en magnésium, en aluminium et en titane dans le laitier de haut fourneau il se produit dans le verre des modifications de coordination, de plus, l'accroissement de l'indice de coordination du cation contribue à l'augmentation de l'activité hydraulique du laitier.

On a étudié de même l'opportunité de la présence dans la structure du laitier d'une petite quantité de phases cristallines présentant une activité hydraulique.

**SUMMARY :** It has been proved by the use of the EPR (electronic paramagnetic resonance), IRS (infra-red spectrography) and other methods that activity of slag depends on the degree of depolymerization of ion-oxygen complexes in the slag glass. The energy of the Me-O cation-depolymerizer single bond and its coordination state is of primary importance. The part played by aluminium and magnesium in the structure of periclase-free slag glass formation has been considered; the permissible rational content of magnesium oxide in accordance with presence of alumina has been found out. Content of  $Ti^{4+}$  in the titanium-containing blast furnace slag and content of  $Ti^{3+}$  in various coordination states have been determined.

It has been detected that depending on aluminum, magnesium and titanium content in the blast furnace slag, their coordination in the glass varies, with increase of the cation coordination number providing for increase of hydraulic activity of slag.

The problem of expediency of introducing small amounts of hydraulically active crystal phases into the slag structure has been considered.

Selon la théorie actuellement admise les laitiers ont une structure ionique, c'est-à-dire que le laitier liquide constitue des fusions microhétérogènes composées de cations simples, d'anions, d'oxygène et de soufre de même que d'anions complexes dont la dimension et la stabilité sont fonction de la nature du cation.

L'expérience de plusieurs années a montré que l'activité du laitier de haut fourneau granulé est fonction de paramètres physico-chimiques des phases vitreuse et cristalline.

Avec un rapide refroidissement il s'établit dans le laitier des groupements structuraux de la fusion. Suivant la température de granulation de la fusion de laitier, à côté de la phase vitreuse, il peut se développer une cristallisation de minéraux du laitier, présents dans la fusion avant le début de la granulation; si, par contre, le refroidissement est rapide, on aboutit à une structure vitreuse du laitier.

La similitude entre les structures des silicates cristallins et vitreux réside, selon A.A. Appen, dans la présence dans les deux états d'un squelette en Si-O continu et dans l'existence du principe de coordination dans l'arrangement mutuel des ions. C'est sous cet angle qu'on peut parler d'une chimie structurale du verre, et de ranger parmi les facteurs régissant les propriétés du verre la coordinance et la valence des cations (1).

Certains métaux entrant dans la structure du verre de silice sont considérés non seulement comme des modificateurs mais aussi comme des formateurs du verre, la position des cations Me étant déterminée par son indice de coordination dont l'accroissement augmente l'apport modificateur du cation. Dans ce cas il se place entre les ions sans pont des complexes Si-O.

On peut considérer que la différence dans l'arrangement des cations dans le verre doit constituer un des facteurs essentiels déterminant l'activité du laitier, vu que les dépenses en énergie de rupture de la liaison Me-O doivent varier avec la position du cation.

Si l'on tient compte de la nature iono-covalente de la liaison entre les ions dans les silicates, on peut, de façon conventionnelle, représenter l'énergie de rupture de la liaison Me-O comme le travail développé pour la rupture de la partie ionique (X) et de la partie covalente (I - X) de la liaison. L'énergie de rupture de la liaison ionique dépend de la constante diélectrique du milieu (en cas d'hydratation, de l'eau), de l'énergie de la liaison simple Me-O et de la coordinance du cation à l'égard de l'oxygène. Au cas où l'énergie de la liaison affaibli (du fait de la constante diélectrique de l'eau) est de l'ordre de grandeur de l'énergie cinétique des molécules de l'eau, il se crée des conditions favorables au passage du cation dans la solution. On peut donc admettre, qu'au cours de l'interaction du verre de laitier avec l'eau, c'est, en premier lieu, les cations modificateurs qui passent dans la solution,

car, par suite du grand indice de coordination, l'énergie de la liaison simple Me-O est relativement plus faible. Il en résulte un déséquilibre du système et pour maintenir l'électroneutralité les cations de coordinance inférieure tendent à occuper la place tenue par les cations modificateurs transférés dans la solution. Cela entraîne la perturbation de stabilité de la structure et de mobilité d'ions  $Si_{x/y}O_2$ .

Le passage de ces derniers dans la solution facilité par l'accroissement de la valeur de pH du milieu, par suite de la présence dans ce dernier de cations hydratés, aboutit à la formation d'hydrosilicates de métaux correspondants.

Selon les conceptions actuelles le début du processus d'hydratation est la dissolution du liant, la réaction chimique à la surface du grain s'accompagnant d'un échange ionique entre les ions se trouvant dans le liquide de gachage et les ions composant la structure du silicate (2).

La nature différente de l'interaction des minéraux et des verres ayant la même composition avec l'eau au cours de l'hydratation s'explique par la modification de la structure du minéral avec son passage à l'état vitreux.

A la différence du cristal, où l'orientation mutuelle d'éléments structuraux est constante et régulière, dans les verres elle est perturbée, ce qui appliqué aux silicates peut entraîner une modification de la symétrie des groupements métal-oxygène.

L'étude par la résonance paramagnétique électronique de la variation de la structure, en particulier, de l'okermanite et de la gehlenite, au cours de leur passage à l'état vitreux, a montré que dans les minéraux cristallins on n'observe pas de centres électroniques paramagnétiques sur les tétraèdres ( $SiO_4$ ), tandis que dans les minéraux vitreux ces centres apparaissent.

L'absence de centres paramagnétiques sur les tétraèdres  $SiO_4$  dans les minéraux cristallins peut signifier un haut degré de liaison des tétraèdres Si-O à l'aide des tétraèdres ( $MgO_4$ ) et ( $AlO_4$ ) respectivement dans l'okermanite et la gehlenite.

Dans les minéraux vitreux le degré de liaison des tétraèdres ( $SiO_4$ ) s'abaisse sous l'effet du passage d'une partie de l'aluminium (de la gehlenite) et du magnésium (de l'okermanite) de la structure anionique, constituant le minéral, à la structure cationique. Evidemment, on peut considérer que le passage du minéral de l'état cristallin à l'état vitreux entraîne un abaissement de la symétrie des groupements anioniques Me-O jouant le rôle de fermateurs du verre, mais, par contre, ce passage accroît la symétrie des groupements cationiques Me-O dont les atomes centraux jouent au sein du verre le rôle de modificateurs.

Les cations de grande énergie de liaison avec l'oxygène, par exemple Si, Al, Ti en se séparant de la surface sous forme de complexes anioniques compliqués demeurent dans

le contour entourant le grain. Au moment du détachement de la surface de la graine les complexes constituent des restes d'ions-radicaux chargés positivement et négativement. On peut admettre qu'avec la perturbation de la coordinance du silicium il se produit dans ce cas une hydratation superficielle des radicaux par adjonction d'ions  $\text{OH}^-$  et formation de la liaison  $\text{Si-OH}$  ainsi qu'une compensation de l'oxygène chargé négativement par le proton  $\text{H}^+$ .

Par suite de la dimension différente des radicaux déterminée par la composition chimique du laitier, essentiellement par le rapport  $\text{O/Si}$ , on voit se former des composés du type  $\text{Si}_x(\text{OH})_y$ . La présence dans la solution d'ions  $\text{OH}^-$ , formés en surplus suivant la réaction  $\text{O}_2 + \text{H}_2\text{O} \rightarrow 2\text{OH}^-$  sous l'effet de la rupture de la liaison  $\text{Me-O}$ , contribue à la polymérisation des radicaux hydratés; l'indice de coordination du silicium monte dans ce cas jusqu'à 6, tandis que dans les composés déshydratés il est en général égal à 4.

Le phénomène de polymérisation contribue à la formation de particules gélifiantes dont la dimension est fonction des complexes initiaux et de la cinétique de polymérisation. A côté des processus de polymérisation des radicaux hydratés, il s'effectue à leur surface une adsorption secondaire d'hydrates de cations de métaux alcalinoterreux déjà passés dans la solution avec formation d'hydrosilicates de métaux correspondants. Etant donné que la mobilité des radicaux hydratés est faible, vu leurs grandes dimensions, ces derniers restent au sein du contour du grain de laitier.

Le mécanisme exposé de la formation de phases hydrosilicacées gélifiantes et calciques, de basicité élevée devant celle du laitier de base, permet d'admettre qu'entre la partie non hydratée du verre de laitier et les produits d'hydratation, par exemple, entre les hydrosilicates du calcium, il existe une couche gélifiante intermédiaire de basse basicité, c'est-à-dire que la basicité du grain hydraté peut être représentée sous forme d'une courbe présentant un minimum.

C'est probablement la raison de la présence dans les substances liantes hydratées de produits d'hydratation extérieurs et intérieurs dont la basicité est différente (3).

Nos études du rôle de différents éléments dans la formation de la structure des laitiers établissent que  $\text{Al}$ ,  $\text{Mg}$ ,  $\text{Ti}$  sont susceptibles dans des conditions déterminées de changer leur rôle structural en influençant fortement le processus d'hydratation.

C'est ainsi que dans les spectres de résonance paramagnétique électronique obtenus au cours de l'étude (4) du rôle structural de l'aluminium dans les verres de laitier à teneur constante en  $\text{CaO} = 50\%$ , la variation de  $\text{Al}_2\text{O}_3$  dans les limites de 10 à 40% entraîne l'apparition de l'étroite raie à facteur  $g = 2,007 \pm 0,001$  engendrée par les

groupements  $(\text{AlO}_6)$ . Avec l'accroissement de la teneur en  $\text{Al}_2\text{O}_3$  dans le verre l'intensité de la raie croît d'abord et atteint un maximum pour une teneur en  $\text{Al}_2\text{O}_3$  de 20%, puis elle chute. Les spectres infrarouge, en particulier, permettent de fixer le groupement triplet aux nombres d'ondes  $\nu = 470, 460$  et  $446 \text{ cm}^{-1}$  qui sont caractéristiques pour les oscillations du groupement  $(\text{AlO}_6)$ .

La confrontation de données sur la variation de la coordinance de l'aluminium avec les propriétés liantes des laitiers en fonction de la teneur en  $\text{Al}_2\text{O}_3$  a permis d'établir que le maximum d'activité des laitiers contenant 18 à 20% d' $\text{Al}_2\text{O}_3$  coïncide avec la teneur maximale en complexe  $(\text{AlO}_6)$  dans le laitier surfondu.

La teneur quantitative en  $\text{Al}_2\text{O}_3$  dans le laitier est étroitement liée au rôle structural joué par  $\text{Mg}$  dans le laitier.

Les études qu'on a mené des propriétés hydratantes des laitiers de synthèse du système  $\text{CaO-MgO-SiO}_2\text{-Al}_2\text{O}_3$  ont montré que la substitution admissible de  $\text{MgO}$  à  $\text{CaO}$  est conditionnée par leur teneur en alumine, avec l'accroissement duquel la teneur tolérée de l'oxyde de magnésium augmente.

L'analyse des spectres infrarouges a permis d'observer des variations engendrées par le fait que pour une teneur en  $\text{Al}_2\text{O}_3$  de 15% la quantité d'aluminium octacoordonné augmente avec la pénétration d'une partie de magnésium dans le squelette anionique du verre. Pour la teneur en alumine de 17%, la teneur tolérée d'oxyde de magnésium dans le laitier n'abaissant pas son activité est également de 17%.

Dans un système à quatre composants ces laitiers ne sont pas soumis à la cristallisation nuisible aux propriétés liantes du periclasite et se trouvent dans le domaine où la phase primaire de cristallisation ne concerne que la monticellite et la spinelle.

La teneur en titane de certains laitiers de haut fourneau a conditionnée l'étude à la résonance paramagnétique électronique des particularités de sa pénétration dans la structure du laitier.

Pour la détermination de la coordinance on a utilisé la méthode consistant à un bombardement préalable du verre par des particules gamma.

On a établi que dans le laitier contenant jusqu'à 11% de titane calculé en  $\text{TiO}_2$ , on observe vu la nature réductrice du processus de haut fourneau, également du  $\text{Ti}_2\text{O}_3$ , où le titane occupe des positions tétraédriques dans la structure en élevant la polymérisation du verre. La formation de complexes compliqués  $\text{Si-Ti-O}$  ainsi que la diminution de la longueur de la liaison  $\text{Ti-O}$  avec le passage du titane à la coordinance 4 (la teneur en  $\text{TiO}_2$  est de 4%) conduisent selon les données des mesures de relaxation spin-

réseau et spin-spin de protons d'hydrogène a la diminution de l'adsorption de molécules d'eau par la surface du grain de laitier.

Peut-être c'est la conséquence du fait que l'ion  $Ti^{4+}$  est un meilleur sorbant de l'eau que les ions de métaux alcalino-terreux de plus, pour de petites teneurs en  $TiO_2$ , ce dernier est partiellement hexacoordonné; la distance Ti-O étant suffisamment grande ce qui permet aux molécules d'eau d'interagir directement avec l'ion  $Ti^{4+}$ .

Avec l'accroissement de la quantité de  $TiO_2$  le titane acquiert la coordination 4 et la distance Ti-O diminue. Cela aboutit à ce que l'adsorption de l'eau par les ions  $Ti^{4+}$  devient moins probable à cause de l'écran d'oxygène par rapport au titane.

On a indiqué plus haut que le facteur déterminant de la structure des laitiers de haut fourneau, ayant rapport à leur activité, est le degré de polymérisation des complexes Si-O, qui à son tour est fonction de la concentration en anions d'oxygène du laitier.

Aussi a-t-on émis l'idée que les propriétés hydratantes du laitier peuvent être élevées par introduction d'adjuvants facilitant la destruction du réseau Si-Ti-O. Nous l'avons montré sur l'exemple des laitiers contenant du titane.

Les études de ces dernières années ont permis d'établir que l'existence de la phase vitreuse ne constitue pas par elle-même un facteur déterminant de l'élévation de l'activité des laitiers. Certains estiment même que les propriétés liantes les plus élevées sont propres aux laitiers dont la teneur en phases cristallines varie entre 5 et 20%.

A notre égard le problème de l'opportunité d'un laitier partiellement cristallisé (5) doit se résoudre dans chaque cas particulier compte tenu de la composition chimique du laitier et, en premier lieu, de sa basicité, car cette dernière détermine l'ordre de précipitation des phases cristallines lors du refroidissement du laitier au-dessous de la température du liquide (Tl). La granulation des laitiers basiques ( $Mo > 1$ ) à la température inférieure à Tl contribue à la fixation de la structure dans laquelle, à côté du verre, est présente la phase minéralogique  $2CaO \cdot SiO_2$ , très active sur le rapport des propriétés liantes, et dont l'activité est supérieure à celle du verre.

Avec le refroidissement des laitiers acides ( $Mo < 1$ ) au-dessous de Tl c'est le méilélite qui cristallise le premier et pour certains laitiers spéciaux (titanifères), le perovskite et le baïkovite dont les propriétés liantes sont dénuées d'activité. Aussi la granulation des laitiers acides au-dessous de Tl doit-elle abaisser leurs propriétés liantes.

## CONCLUSION

En se fondant sur la théorie de la structure ionique des laitiers de haut fourneau on a étudié les problèmes de l'interdépendance de leur structure et de l'activité hydraulique; les conceptions répandues sur la similitude entre les structures des laitiers cristallins et vitreux ainsi que de l'influence de l'arrangement des cations dans le verre de laitier sur son activité.

On a analysé l'explication de la possibilité d'apparition dans les laitiers de haut fourneau hydrates de produits d'hydratation extérieurs et intérieurs différant entre eux par leur basicité.

On a étudié le rôle de l'aluminium, du magnésium et du titane dans la formation de la structure du laitier de haut fourneau et établi la capacité de variation de leur coordination, phénomène agissant fortement sur le mécanisme de l'hydratation.

On a passé en revue les problèmes de l'opportunité de la régulation de la granulation du laitier de haut fourneau en rapport avec sa basicité chimique, vu l'influence positive sur l'activité du laitier d'une faible teneur en phases cristallines à activité hydraulique dans sa structure.

## Utilisation d'un laitier de magnésium comme liant alumineux

### *Using magnesium slag as aluminous cement*

- A. CARLES-GIBERGUES, Département de Génie Civil de l'Institut National des Sciences Appliquées de Toulouse,  
B. THENOZ, Institut de Géotechnique de l'Université Paul Sabatier de Toulouse,  
A. VAQUIER, Institut de Géotechnique de l'Université Paul Sabatier de Toulouse, France.

RESUME : La fabrication du magnésium à partir de dolomites décarbonatées puis réduites par le silicium conduit à la formation d'un laitier récupéré sous deux formes distinctes : un matériau pulvérulent refroidi à l'air et un matériau granulé par trempe à l'eau ; le premier est essentiellement formé de  $C_2S$  et de petites quantités de  $C_{12}A_7$  ; le second renferme d'importantes proportions de  $C_2S\beta$  enrobés dans une matrice hétérogène où l'on distingue une phase vitreuse, et du  $C_3AH_6$ .

Gâché avec de l'eau, chacun des deux constituants fait prise spontanément sans l'aide d'activant. Dans les deux cas, les phases hydratées responsables du durcissement sont associées à de la géhlénite hydratée et des aluminates de calcium.

Par contre, d'importantes différences existent dans les vitesses de formation de ces hydrates : rapide pour le laitier fusant, lente pour le laitier granulé. Corrélativement, on note la même disparité dans l'accroissement des résistances mécaniques. Il est donc intéressant d'utiliser ces deux matériaux conjointement.

Les meilleurs résultats, dans une perspective d'emploi comme liant économique de granulats routiers, sont enregistrés avec des dosages de 40 % de laitier granulé broyé et 60 % de laitier fusant.

En technique routière classique des graves laitiers où les deux matériaux sont employés simultanément sans broyage préalable, de bonnes performances mécaniques ont aussi été atteintes.

Les deux composés peuvent également être utilisés séparément ; ainsi, le laitier fusant peut servir à la confection à froid de matériaux cellulaires par simple ajout de poudre d'aluminium, alors que l'autoclavage du laitier granulé broyé donne des matériaux très résistants.

SUMMARY : The fabrication of magnesium from dolomite, by eliminating carbonate, and then reduced by silicon results the formation of slag in two distinct forms : the powdered material by cooling in the air and the granulated material by soaking with water. This primary is essentially formed  $C_2S$  and a little quantity of  $C_{12}A_7$ . The latter mostly consists of  $C_2S\beta$  covered in the heterogeneous matrix in which we distinguish by the vitreous phase and  $C_3AH_6$ .

By mixing with water, each of these two constituents will set immediately without the aid of active agent. In both cases, the hydrated phases, responsible for hardening, are associated with hydrated gehlenite and aluminated calcium.

Nevertheless, the velocity of hydrated formation is greatly different ; it is quick for powdered slag, slow for granulated slag. Similarly, we observed that the growth of mechanical resistance is different in the same manner. It is therefore interested to use both forms of slags combining together.

Better results, in view of using economic slag as road aggregate, are obtained by proportioning 40 % of crushing granulated slag with 60 % of melted slag.

For graved slag road, the use of the two materials together, without previous crushing, allowed us to obtain the mechanical performances.

The two compositions can also be used separately as followed : the melted slag can serve as the cold production of cellular materials by adding aluminium powder while the autoclave of the crushing granulated slag yields high resistance material.

## I - INTRODUCTION

La récupération des sous-produits industriels est à l'ordre du jour dans le double souci d'économie d'énergie et d'aménagement du cadre de vie menacé par l'entassement anarchique des rebuts.

L'expérience acquise permet de penser que les tonnages importants de laitiers de hauts-fourneaux recyclés dans le génie civil tendent vers une limite difficile à reculer.

Mais les déchets inutilisés des autres branches de l'industrie métallurgique (pour nous en tenir à ce seul domaine de l'activité industrielle) n'ont pas fait -et loin de là- l'objet d'études systématiques de emploi. Sans doute, parce que les quantités en jeu dans chaque unité de production ne sont pas aussi considérables que dans le cas de la production de fonte et d'acier. Il n'empêche que des réutilisations techniques et économiquement intéressantes sont possibles.

Cette note a précisément pour objet l'étude de la valorisation d'un laitier de fabrication du magnésium.

La première partie du travail a trait à l'identification précise des phases constitutives du laitier : pouvait-on, a priori, entrevoir une utilisation analogue à celle des laitiers de hauts-fourneaux avec ou sans traitement physico-chimique complémentaire ?

La réponse ayant été franchement positive : présence de certains des constituants classiques des ciments, il convenait, dans une deuxième partie, de confirmer l'aptitude à la prise hydraulique par l'étude du comportement en présence d'eau.

Des possibilités de prise se manifestant effectivement, il restait à examiner dans une troisième partie les différents emplois possibles en génie civil.

## II - CONSTITUTION DU PRODUIT DE RECUPERATION

## II.1 - Propriétés physico-chimiques

La nature et la structure du laitier que libère la fabrication du magnésium dépendent évidemment de la composition des matières premières et du processus de fabrication. Dans le procédé "Magnetherm", en usage à l'usine de Marignac (Haute-Garonne), d'où provient le laitier étudié (1), on réduit, après décarbonatation de la dolomite, l'oxyde de magnésium par le silicium suivant la réaction théorique

Le magnésium se dégage à l'état de vapeur, puis le four est retourné au-dessus d'une fosse pleine d'eau. La partie du bain liquide qui s'en écoule est ainsi transformée en laitier granulé qui se présente sous l'aspect de granulés poreux et friables de granulométrie comprise entre 0,2 et 10 mm. La masse volumique apparente (tous vides compris) est 1,070 T/m<sup>3</sup>. La masse volumique mesurée sur poudre inférieure à 50 µm et dans un liquide est de 3,00 T/m<sup>3</sup>.

D'autre part, une fraction moins importante du bain (environ le tiers) reste collée aux parois du four et se refroidit lentement à l'air en se délitant en une poudre fine qui constitue le laitier dit fusant.

Cette poudre a une surface spécifique de 1 800 cm<sup>2</sup>/g BLAINE. Sa masse volumique est, soit de 0,950 T/m<sup>3</sup> (vides entre grains inclus), soit de 2,960 T/m<sup>3</sup> (vide entre grains exclus).

La composition chimique moyenne ne dépend évidemment que de la composition du bain et non du mode de refroidissement : elle est la même pour les 2 fractions, granulée et fusante, conformément au tableau ci-après.

SiO <sub>2</sub>	25,0
Al <sub>2</sub> O <sub>3</sub>	14,0
CaO	54,2
MgO	3,9
Na <sub>2</sub> O	0,2
SO <sub>3</sub>	1,3

On constate que ce laitier est plus riche en chaux et plus pauvre en silice que les laitiers de fonte de hauts-fourneaux.

La connaissance de la seule composition chimique n'est pas suffisante pour identifier les espèces cristallines susceptibles de prise hydraulique, d'où la nécessité d'une diagnose minéralogique.

## II.2 - Constitution minéralogique

Le laitier granulé diffère considérablement, par sa structure, des laitiers de fonte ; il est largement cristallisé. Ce fait est, selon toute vraisemblance, explicable par son très fort indice de basicité CaO/SiO<sub>2</sub> = 2,16.

Les cristaux, pour leur quasi-totalité, sont des silicates bicalciques. Ils constituent 50 % du laitier granulé. Leur étude par diffractométrie X - radiation Kα<sub>1</sub> du cobalt, détection par compteur linéaire - montre la présence des deux variétés α' et β et, probablement de α.

Ils s'individualisent en constituants arrondis, d'environ 30 à 80 µm au sein d'une matière interstitielle presque exclusivement vitreuse.

Les examens à la microsonde électronique (figure 1) confirment que le rapport molaire CaO/SiO<sub>2</sub> est très voisin de 2, et que les remplacements du silicium par l'aluminium et du calcium par le magnésium y sont rares : 1,1 % d'Al<sub>2</sub>O<sub>3</sub> et 1,3 % de MgO.

La matière interstitielle est hétérogène. Dans sa masse, elle se définit par un rapport [(CaO, MgO)/(SiO<sub>2</sub> + Al<sub>2</sub>O<sub>3</sub>)] très proche de 2, l'aluminium jouant cette fois un rôle important (environ 11 Al pour 2 Si) : ainsi, on pu se différencier en petites quantités des cristaux d'aluminate de calcium que la trempe a hydratés directement en C<sub>3</sub>AH<sub>6</sub>.

Au contact des silicates bicalciques, existent des zones riches en magnésium. Certaines correspondent à des cristaux de périclase, dont l'existence est bien visible sur les diffractogrammes X ; d'autres, à rapport molaire MgO/SiO<sub>2</sub>, voisin de 2, sont constitués de forsterite Mg<sub>2</sub>SiO<sub>4</sub>, minéral plusieurs fois trouvé dans des laitiers (2).

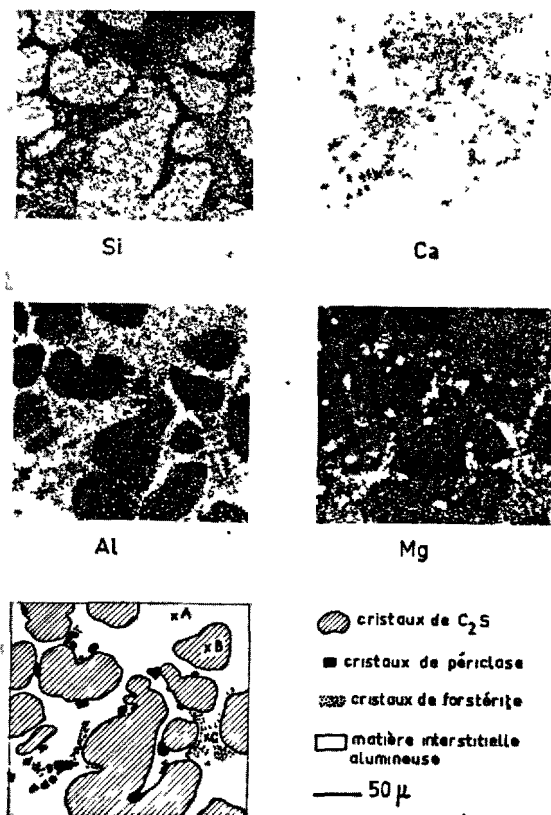

FIGURE 1 : Grain de laitier granulé

Le laitier fusant est largement cristallisé, le constituant majeur étant la variété  $\delta$  du silicate bicalcique (calcio-olivine).

Le refroidissement lent à l'air conduit, vers 500°C, à la transformation de  $C_2S\beta$  en  $C_2S\gamma$ , avec un accroissement de volume d'environ 13 %, ce qui provoque la pulvérisation spontanée du laitier.

À côté de cesilicate, existent de petites quantités de périclase et d'aluminat de calcium  $C_{12}A_7$  qui, comme le montre la figure 2, se concentrent dans les fractions les plus fines.

### III - COMPORTEMENT EN PRESENCE D'EAU ET IDENTIFICATION DES PHASES HYDRATEES

La mise en évidence de constituants connus pour leurs propriétés hydrauliques conduit naturellement à étudier le comportement du laitier en présence d'eau, sous ses deux formes, soit prises séparément, soit associées.

#### III.1 - Comportement dans l'eau pure des constituants séparés

##### III.1.1 - Fraction fusante

La solution se sature rapidement en chaux, puis sa concentration diminue régulièrement avec le temps (figure 3). On note également la présence en faible

quantité du sodium et de l'aluminium. Par contre, pratiquement pas de silice et pas du tout de magnésie. Les premiers composés hydratés sont décelables par diffractométrie X, moins de deux heures après le gâchage. L'aluminat  $C_2AH_8$  est le premier à apparaître et constitue, pendant les trois premiers jours, l'essentiel de la phase hydratée. On détecte également de petites quantités de  $CAH_{10}$  et de  $C_4AH_{13}$ . De la gehlénite hydratée  $C_2ASH_8$  se forme quand la concentration en chaux de la solution diminue (3) et, encore plus tardivement, apparaît l'aluminat  $C_3AH_6$ .

#### III.1.2 - Fraction granulée

Ce matériau, préalablement broyé à la même finesse que le laitier fusant a une nettement moindre réactivité : les diffractogrammes X ne montrent, en effet, l'apparition des premiers hydrates qu'au bout de 1 jour ; il s'agit d'aluminates de calcium et de gehlénite hydratés. On constate simultanément une dissolution beaucoup plus lente du calcium dont la concentration atteint un palier au bout d'une dizaine de jours. Les solutions renferment initialement des concentrations non négligeables de silice dont la teneur s'amenuise ensuite régulièrement avec le temps (figure 3).

### III.2 - Comportement des constituants associés

Les courbes de mise en solution du mélange de 1/3 de la forme fusante et 2/3 de laitier granulé résultent de la superposition des courbes correspondant à chaque forme prise isolément. Les diffractogrammes montrent la formation des mêmes espèces hydratées. Par contre,  $C_2AH_8$  a une existence très courte ;  $C_4AH_{13}$  et  $C_2ASH_8$  se développent à même vitesse.

On peut penser que la libération lente des ions Ca, Al, Si, à partir de la matière vitreuse de la forme granulée devrait favoriser la formation de quantités croissantes de gehlénite et de silicates de calcium hydratés. Pour confirmer cette hypothèse, nous avons étudié la prise (figure 4) et le durcissement (figure 5) de pâtes pures de mélanges en proportions variables des 2 formes granulée et fusante (amenées à la même finesse), gâchées avec des quantités d'eau ajustées pour que la maniabilité reste constante.

On note qu'il y a réaction mutuelle des deux formes, traduite par la forme en cloche des courbes de la résistance mécanique. Le maximum d'activation correspond à une proportion 40-60 de granulée-fusante.

### IV - LES EMPLOIS POSSIBLES

Ainsi, l'étude de la réactivité à l'eau du laitier de magnésium montre qu'il se comporte, sous sa forme fusante (et à un degré moindre, sous sa forme granulée), comme un liant hydraulique à la différence des laitiers de hauts-fourneaux qui ont besoin d'un activant ou d'un catalyseur pour stimuler une hydraulicité latente.

Ce point étant acquis, il restait à étudier les utilisations effectivement possibles du laitier sous ses deux formes combinées, ou sous chacune d'elles séparément. Nous avons retenu les 4 exemples ci-après.

#### IV.1 - Mélange utilisé comme liant

Les résultats de l'étude du comportement en présence

FIGURE 2 : Diffractogrammes X du laitier fusant

FIGURE 3 : Dissolution du laitier dans l'eau pure

FIGURE 4 : Influence de la composition des mélanges sur leur vitesse de prise

FIGURE 5 : Influence de la composition des mélanges sur leur résistance à la compression simple

FIGURE 6 : Broyabilité du laitier granulé

d'eau conduisent à essayer un liant formé de 1/3 de forme fusante et de 2/3 de forme granulée, préalablement broyée jusqu'à une finesse comparable à celle de la forme fusante, ce qui est économiquement possible dans un broyeur à barres, comme le montre la figure 6 qui met en évidence une broyabilité bien supérieure à celle de laitiers sidérurgiques variés.

Les performances obtenues sont loin d'être négligeables et autorisent toute une gamme d'emplois.

#### IV.2 - Mélange utilisé directement sans broyage préalable, en technique routière

L'addition de 10 à 15 % du mélange optimum à une grave siliceuse de granulométrie continue permet de fabriquer des éprouvettes de résistance à la compression simple voisine de 7,2 mPa, soit de l'ordre de grandeur des résistances habituellement admises en technique routière.

#### IV.3 - Matériaux cellulaires à partir de la forme fusante

Le laitier fusant étant un véritable ciment alumineux, on peut l'utiliser pour préparer à froid des matériaux cellulaires en ajoutant seulement de la poudre d'aluminium : on a ainsi obtenu des masses volumiques de 0,850 T/m<sup>3</sup> et des résistances de 6 mPa.

#### IV.4 - Matériaux autoclavés à partir de la forme granulée

L'autoclavage du laitier granulé plus ou moins broyé entraîne son activation par l'hydratation des silicates bicalciques et donne des matériaux très résistants : on a obtenu des résistances atteignant 78 mPa (4).

### V - CONCLUSION

Nous nous étions proposés de rechercher les conditions de valorisation d'un laitier jusqu'ici mal utilisé. Nous avons constaté qu'il contenait des composés hydrauliques en quantité suffisante pour justifier une utilisation pratique, soit directement sous sa forme fusante, soit en mélangeant (dans les proportions de leur production) les formes fusante et granulée (après éventuellement un simple broyage de cette dernière), soit, enfin, en activant la forme granulée par autoclavage. Ce cas particulier illustre tout l'intérêt écologique et énergétique d'études systématiques complètes de matériaux dont les propriétés hydrauliques étaient, jusqu'ici, méconnues.

# Expérience et fondements physico-chimiques de l'utilisation des sous-produits dans l'industrie du ciment

## *Experience and physico-chemical bases of using secondary raw materials in cement industry*

**RESUME :** L'utilisation dans l'industrie du ciment de sous-produits permet d'économiser le combustible, d'abaisser les frais de production et d'établissement, de mettre en valeur les résidus industriels, de contribuer à l'amélioration de l'équilibre écologique.

On utilise chaque année en U.R.S.S. 25 à 27 millions de tonnes de sous-produits dont le rôle d'adjuvant minéral actif est fonction de son interaction acido-basique avec la solution aqueuse de chaux hydratée et formation de sels de calcium hydratés difficiles à dissoudre. Une telle interaction est propre aux laitiers ferro-siliceux composés pour l'essentiel de verre aluomferrosiliceux et de fayalite.

A des fins de contrôle de la prise du ciment on se sert de gypses chimiques aux compositions variées en phases, dont la solubilité est proche de celle du gypse naturel bihydraté.

Les sous-produits et, notamment, les cendres des centrales thermiques sont efficacement utilisés en qualité de constituant de base pour l'obtention du clinker.

**SUMMARY :** Utilization of the secondary raw materials in the cement industry ensures economy of fuel, reduction of production and capital costs, utilization of waste products, improvement of ecology balance.

From 25 to 27 million tons of the secondary raw materials are used in the USSR annually. The suitability of the secondary raw materials for use as an active mineral additive is determined by its ability for acid-base interaction with an aqueous solution of hydrated lime with formation of difficultly soluble hydrates of calcium salts. The ability for such a reaction is offered by ferrosilicate slags consisting mainly of aluomferrosilicate glass and fayalite.

To control the setting time of the cement, use is made of chemical gypsum of different phase compositions whose solubility approaches that of the natural gypsum dihydrate.

The secondary raw materials, especially fly ash of the power plants is also advantageously used as an ingredient of raw mix in the production of cement clinker.

L'utilisation des résidus industriels est un des plus efficaces moyens d'abaisser les besoins en énergie et en investissement d'établissement de cimenteries et d'améliorer le bilan écologique de ces derniers. Dans nombre de pays on observe une tendance permanente à l'accroissement de la mise en oeuvre de matériaux tels que les laitiers de haut fourneau, les cendres de centrales thermiques, les boues béliques (2-6).

En Union Soviétique une grande expérience a été accumulée dans le domaine de l'utilisation en cimenterie de produits technogènes (résidus des productions techniques). Le volume total mis en oeuvre atteint 25 à 27 millions de tonnes par an, ce qui dépasse de beaucoup leur emploi dans les autres pays. Dans le rapport de VI. Satarine, présenté au VI-ième Congrès International de chimie du ciment tenu à Moscou, ont été exposées les conclusions de l'expérience d'utilisation des laitiers granulés de haut fourneau (7).

Dans la présente communication une tentative est faite d'analyser les fondements physico-chimiques de l'élargissement de l'assortiment de produits technogènes utilisés dans la production du ciment, de même que l'expérience acquise dans ces applications.

**EXPLOITATION DE L'EFFET D'ADJUVANTS MINÉRAUX ACTIFS DES PRODUITS TECHNOGENES SECONDAIRES.** Les normes soviétiques autorisent à utiliser en qualité d'adjuvants minéraux actifs des matériaux à effet soit hydraulique, soit, le plus souvent, pouzzolanique.

Le trait commun de ces matériaux est leur aptitude à l'interaction acido-basique dans des solutions aqueuses de l'oxyde calcique hydraté avec formation d'hydrates difficilement solubles.

Selon les conceptions développées pour la première fois par Bernstade l'interaction acido-basique se réduit au transfert du proton de l'acide-donneur à la base-accepteuse. La force thermodynamique active du phénomène est engendrée par la diminution de l'entropie de la substance de basicité intermédiaire par rapport à la somme d'entropies de l'acide et de la base initiaux. Dans les solutions aqueuses de  $\text{Ca(OH)}_2$  le rôle d'acide peut être joué par toute substance capable de transmettre le proton à l'ion hydroxyle. Si le produit des solubilités du composé de la réaction s'avère dans ce cas inférieur au produit des solubilités des substances de base, les cristaux hydratés formés seront alors stables et inattaquables par l'hydrolyse, tandis que la concentration de  $\text{Ca(OH)}_2$  dans la phase liquide du système sera inférieure à celle d'équilibre de la solution pour la température et le pH donnés. Ce dernier phénomène est un indice de la possession par la matière de propriétés pouzzolaniques.

La silice active et le verre alumosiliceux sont des pouzzolanes manifestes. Les donneurs de proton sont dans ce cas les surfaces hydroxylées de particules de ces matières. L'aptitude à l'hydroxylation et aux

manifestations de propriétés acides est également propre au verre aluomferrosiliceux de même qu'aux matériaux de composition essentiellement ferrosiliceuse à teneur importante en  $\text{FeO}$ . Pour une dispersion très fine de ces matériaux, l'oxyde ferreux qu'ils contiennent est oxydé en présence d'alcali jusqu'à l'oxyde ferrique par l'oxygène dissous dans la phase liquide du ciment en voie de durcissement et s'avère capable de s'hydroxyler avec formation subséquente d'hydroferrites ou d'hydroalumoferrites calciques de formule générale  $\text{C}_4(\text{A}_x, \text{F}_{1-x})\text{H}_{13}$  ( $0 < x < 1$ ), et à des conditions déterminées également d'hydrogrenats.

En guise d'exemple examinons les résultats d'études réalisées par I.G. Boun, A.S. Sventaitzki et Z.B. Entine des propriétés des ciments aux laitiers ferrosiliceux dont la composition chimique et la teneur en phases sont communes à de nombreux résidus de la métallurgie de métaux non ferreux. La composition des matières étudiées est donnée au tableau I.

TABLEAU I

Composition chimique des laitiers et du clinker, %						
Dénomination de la matière	$\text{SiO}_2$	$\text{Al}_2\text{O}_3$	$\text{Fe}_2\text{O}_3$	$\text{FeO}$	$\text{CaO}$	$\text{R}_2\text{O}$
Clinker	21,6	4,20	4,32	-	54,6	1,08
Laitier granulé	31,82	6,31	6,95	40,70	5,97	2,47
Laitier non granulé	32,96	5,94	7,88	39,98	7,15	2,42

Une partie des éprouvettes de laitier était granulée, tandis que l'autre était progressivement refroidie à l'air. Les deux types d'éprouvettes se conformaient aux normes soviétiques établies pour les adjuvants minéraux actifs quant aux délais de prise et à la résistance à l'eau, une fois mélangés à de la chaux blanche. La concentration de  $\text{Ca(OH)}_2$  dans la phase liquide du ciment s'est avérée inférieure à celle d'équilibre pour la température donnée. Elle a été pour les laitiers granulés et lentement refroidis respectivement de 2,6 et 6,3 mmole/litre, tandis que celle d'équilibre s'élevait à 8,2 mmole/litre.

Les analyses pétrographique et aux rayons X ont établi que les laitiers se composent pour l'essentiel de fayalite (45 à 55 %), de verre aluomferrosiliceux (35 à 40 %) et de magnétite (12 à 15 %). La teneur en verre était quelque peu élevée dans les laitiers granulés, toutefois cela n'exerçait pas d'influence sensible sur la résistance ainsi que sur les autres caractéristiques des ciments.

La figure 1 représente l'influence de l'addition de laitiers sur la résistance des ciments.

Fig. 1 - Influence des laitiers ferrosiliceux sur la résistance des ciments (laitier granulé) : 1 - à 3 jours ; 2 - à 7 jours ; 3 - à 28 jours ; 4 - à 90 jours ; 5 - à 180 jours

Avec l'addition de laitiers la résistance du ciment diminue au début, toutefois au bout de 28 jours et plus les ciments contenant 15 % de laitier ne cèdent en rien aux ciments de contrôle sans constituants secondaires. L'addition du laitier pour 30 % abaisse la résistance de 10 %, par rapport au ciment de contrôle, également à des délais avancés, mais même dans ce cas l'effet pouzzolanique de l'adjuvant se manifeste de façon évidente. Des résultats similaires ont également été obtenus après étuvage des éprouvettes.

L'étude de la composition en phases de la pierre de ciment durcie a montré qu'il y a fixation de nouvelles formations identifiées sous forme d'hydroferrite de calcium aux cristallisations peu prononcées.

La résistance des ciments aux laitiers aux agents atmosphériques et aux sulfates était supérieure à celle des ciments de contrôle. L'efficacité de l'utilisation des ciments aux laitiers dans les bétons était estimée par comparaison du taux de consommation de contrôle, exigé pour l'obtention du béton de même résistance, non pas du ciment naturel mais du clinker qui y est contenu (8). L'addition de 15 et de 30 % de laitier se solde ainsi par un gain en clinker respectivement de 10-12 et de 20-25 %.

Les résultats obtenus confirment la validité

des principes généraux du choix d'adjuvants minéraux actifs à additionner aux ciments et permettent d'élargir l'assortiment de matériaux utilisés à cette fin.

**GYPSES CHIMIQUES.** Les résidus de nombreuses branches de l'industrie chimique : production de superphosphate, d'acides phosphorique et borique, etc., constituent des matériaux composés pour 60 à 95 % de modifications variées du sulfate de calcium. L'intérêt pour l'exploitation des gypses chimiques en tant que régulateurs de prise du ciment se manifeste dans de nombreux pays. Les résultats obtenus sont encourageants, mais l'utilisation de ces matières demeure toujours assez limitée (9, 10).

Parmi les résidus se présentant en grande masse il faut nommer le phosphogypse contenant pour 95-98 % de gypse bihydraté. Le taux de phosphore calculé en  $P_2O_5$  est de 1,0 à 1,5 %, celui de fluor, jusqu'à 0,3 %.

Le borogypse qui est un résidu de fabrication de l'acide borique contient pour 60 à 70 % de sulfate de calcium. L'impureté principale est la silice qui s'y trouve en quantité allant de 20 à 25 %. La teneur résiduelle en  $B_2O_3$  est de 0,5 à 1,5 %, dont 0,5-1,0 % d'acide orthoborique. Les autres impuretés constituent en masse près de 5 %. D'après les données d'analyses pétrographique et aux rayons X le sulfate de calcium s'y trouve sous forme de gypse bihydraté (40-55 %) et d'anhydrite (20-35 %). La silice se présente en une structure dendritique amorphe (11).

Le fluorogypse contient pour 80 à 95 % de sulfate de calcium. En qualité d'impureté on y trouve de la fluorine (0,5-5,0 %) et de la silice (1,5-4,0 %). Les autres impuretés ne dépassent pas au total 3 à 5 %. Le sulfate de calcium se présente pour l'essentiel sous forme d'anhydrite et de gypse semi-hydraté en étroites coalescences. La quantité de gypse bihydraté est moindre. Vu la présence dans les gypses chimiques d'impuretés sous forme de phosphore, de fluor, de bore, etc., ainsi que de différentes variétés de gypse il s'est avéré intéressant de procéder à l'étude du rôle de ces facteurs dans les délais de prise, la résistance et les caractéristiques techniques de construction du ciment.

L'essentiel de l'action de réglage du gypse sur les délais de prise réside dans son aptitude de former avec  $C_2A$  et  $C_3AF$  des hydrosulfoaluminates et des hydrosulfates de calcium. La forme stable de l'hydrosulfoaluminate de calcium est celle du trisulfate qui en cas de teneur insuffisante en gypse dans la solution et un excès d'autres ions, formant le sel complexe, devient un monosulfate. En outre, la concentration d'ions  $SO_4^{2-}$  dans la phase liquide est un des facteurs essentiels impliquant l'aptitude des ciments à engendrer des réactions de fausse prise (12). Aussi la cinétique de la dissolution des gypses chimiques en phase liquide est-elle

un des principaux facteurs déterminant les possibilités de leur exploitation en qualité d'accélérateurs-retardateurs de prise. Le problème ne se pose pas au cas où le gypse des résidus se trouve sous la forme de sel bihydrique, situation ne se présentant toutefois que pour le phosphogypse.

La figure 2 fournit les données sur la variation de la composition en phases d'une éprouvette industrielle de gypse chimique (fluorogypse) maintenue en contact avec l'eau durant 7 jours. L'anhydrite soluble se transforme progressivement en gypse hemihydraté, tandis que la teneur en gypse bihydraté s'accroît de façon relativement lente (15). La coexistence prolongée de sels bihydraté et hemihydraté implique que la présence du fluor s'oppose à la transformation du gypse hemihydraté en gypse bihydraté, la dissolubilité des deux formes du gypse étant presque la même. A 20 °C la dissolubilité du fluorogypse est de 1,5-1,9 g/l  $\text{CaSO}_4$ , ce qui est quelque peu inférieur à celle du gypse bihydraté, mais dépasse de beaucoup celle de l'anhydrite.

Fig. 2 - Variation de la composition en phases du fluorogypse au contact de l'eau ;  $\Delta$  - anhydrite ;  $\circ$  - gypse hemihydraté ;  $\square$  - gypse bihydraté ;  $\times$  - anhydrite insoluble.

Tous les gypses étudiés garantissent des délais de prise du ciment fixés par les normes pour des dosages à peu près les mêmes que le gypse naturel.

La présence de l'anhydrite dans les gypses chimiques soulevait des doutes que cette forme difficile à rehydrater du sulfate de calcium entraîne la destruction de la pierre de ciment déjà durcie par formation à des délais plus avancés de l'hydrosulfo-aluminate de calcium (destruction gypseuse). Pourtant, des études spéciales ont montré que déjà après trois jours de durcissement tout le sulfate de calcium y compris l'an-

hydrite s'avérait fixé dans l'hydrosulfo-aluminate de calcium, et on ne décelait pas de gypse libre dans la pierre de ciment.

L'étude de l'influence des gypses chimiques sur la résistance des ciments a établi que le remplacement du gypse par l'une quelconque des formes du gypse chimique ne se répercute pratiquement pas sur la résistance du ciment à tous les délais d'essais (11, 13).

Une autre application efficace des gypses chimiques est l'exploitation de leurs qualités minéralisatrices pendant la cuisson du clinker.

L'efficacité du phosphogypse dont l'utilisation par les cimenteries en qualité de minéralisateur date déjà de plusieurs années, est bien connue. Son emploi permet d'améliorer le rendement des fours et d'obtenir un clinker à alite mieux cristallisé et de meilleure qualité (14).

L'utilisation à des fins identiques du fluorogypse se révèle également rentable. La figure 3 montre l'influence du fluorogypse sur la cinétique de la fixation de la chaux dans le mélange cuit comparée à celle du phosphogypse et du gypse naturel (15).

Fig. 3 - Influence des gypses sur la fixation de l'oxyde de calcium dans les mélanges bruts soumis à la cuisson : 1 - sans minéralisateur ; 2 - avec addition de gypse naturel ; 3 - avec addition de phosphogypse ; 4 - avec addition de fluorogypse

Toutes les variétés de gypse accusent un effet minéralisateur sensible dans l'in-

TABLEAU II

Teneur en  $\text{CaO}_{11b}$  et  $\text{C}_3\text{S}$  dans les éprouvettes cuites à des températures variées, %

Composition du mélange brut	1280 °C		1300 °C		1320 °C		1340 °C		1360 °C	
	$\text{CaO}_{11b}$	$\text{C}_3\text{S}$	$\text{CaO}_{11b}$	$\text{C}_3\text{S}$	$\text{CaO}_{11b}$	$\text{C}_3\text{S}$	$\text{CaO}_{11b}$	$\text{C}_3\text{S}$	$\text{CaO}_{11b}$	$\text{C}_3\text{S}$
Mélange avec cendre basique	12,36	n.d.	7,52	17,5	5,05	32,7	2,82	47,9	0,65	62,8
Mélange avec cendre acide	20,99	n.d.	10,24	3,1	5,20	24,4	1,91	55,0	1,03	60,2
Mélange avec argile	12,62	n.d.	10,64	3,0	6,93	25,2	4,01	55,6	0,74	65,5

tervalle de températures allant de 900 à 1300 °C, l'action du fluorogypse se manifestant de façon un peu plus forte dans l'intervalle de 1200 à 1300 °C. Dans les éprouvettes cuites, obtenues avec tous les minéralisateurs essayés, on a observé une quantité élevée de sulfates alcalins. On n'y a pas décelé de phases alcalines siliceuses et alumineuses, quant à la microstructure des éprouvettes elle s'est avérée meilleure. Les essais à l'échelle industrielle du fluorogypse en qualité d'agent minéralisateur de la cuisson du clinker ont montré que son efficacité ne cède en rien à celle du spath fluor (fluorine).

Enfin il existe encore une application possible des gypses chimiques et, surtout, du phosphogypse, celle consistant à obtenir sur sa base de l'acide sulfurique et du ciment.

Sous ce rapport, les nouvelles orientations se concentrent sur l'obtention, en partant du phosphogypse non pas du ciment portland de composition ordinaire, mais du ciment à sulfoaluminosilicates, dont le clinker contient une sensible quantité de sulfoaluminate de calcium anhydre  $3(\text{CA}) \text{CaSO}_4$  (16).

**SCHLamm ROUGE.** Lors de la production de l'alumine à partir des bauxites on obtient pour chaque tonne de produit fini jusqu'à 2 tonnes de résidus sous forme de schlamm rouge. Les schlammes rouges sont des poudres finement dispersées, où plus de 90 % de particules ont des dimensions inférieures à 10  $\mu\text{m}$ . Leur composition chimique varie dans les limites suivantes :  $\text{SiO}_2$  - de 9 à 11 %,  $\text{Al}_2\text{O}_3$  - de 17 à 19 %,  $\text{Fe}_2\text{O}_3$  - de 39 à 43 %,  $\text{TiO}_2$  - de 4 à 6 %,  $\text{CaO}$  - de 7 à 10 %,  $\text{Na}_2\text{O}$  - de 6 à 7 %.

La composition chimique du schlamm rouge autorise son emploi en qualité d'addition complexe ferroalumineuse de correction, ce qui s'avère très important au cas de la nécessité d'obtenir un clinker à partir de matières brutes très siliceuses. Les calculs établis d'après le diagramme d'état C-A-F-S montrent que pour chaque pour cent de schlamm rouge additionné au mélange brut

et dosé en fonction de la substance calcinée la teneur en phase liquide dans la matière cuite s'accroît à la température de 1350 °C de 1,3 % et à la température de 1450 °C de 1,5 %. De manière correspondante s'accroît la réactivité du mélange brut.

La réactivité relevée des mélanges bruts à schlamm rouge s'observe déjà à partir de 360-375 °C. A 900-1000 °C les constituants du schlamm sont aptes à former des bains fondus intermédiaires qui disparaissent ensuite par interaction avec d'autres constituants du mélange brut. Le processus de fixation de la chaux s'intensifie donc sur une large gamme de températures. Toutefois, le facteur essentiel demeure l'influence de l'addition de schlamm sur la quantité et les propriétés de la phase liquide.

**UTILISATION DE PRODUITS TECHNOGENES EN QUALITE DE CONSTITUANTS DE BASE DU MELANGE BRUT.** L'application de sous-produits en qualité de constituants de base du mélange brut s'est révélée très intéressante dans l'optique de l'emploi massif des résidus industriels ainsi que de possibilités s'ouvrant pour des économies en énergie et en combustible de même qu'en investissement d'établissement.

C'est ainsi que l'utilisation des cendres acides de centrales thermiques permet de réduire les frais de séchage et de mouture de la matière première, quant à l'utilisation des cendres basiques elle se solde par un gain résultant de l'élévation du rendement des fours et de l'abaissement des dépenses en combustible brûlé pendant la cuisson.

L'étude de la réactivité des mélanges bruts où les cendres volantes ont remplacé l'argile a été réalisée par G.G. Lepechenkova et Z.B. Entine.

Le tableau II fournit des données sur la cinétique de la fixation de la chaux dans les mélanges bruts à cendres. Les mélanges bruts contenant des cendres et de l'argile étaient amendés jusqu'à une composition

chimique presque identique.

Comme il s'ensuit des données fournies, les cendres des centrales thermiques possèdent une réactivité non inférieure à celles des argiles à montmorillonites dont la réactivité est très grande.

Il est également très intéressant d'utiliser en qualité de matière première les boues béliques et les schlamms et les résidus de wollastonite ainsi que d'autres sous-produits. Il s'ensuit de l'exposé que l'assortiment de résidus industriels utilisés en cimenterie peut être sensiblement élargi.

### RESUME

L'étude commentée dans ce texte porte actuellement sur 27 laitiers de haut fourneau représentatifs des productions françaises et luxembourgeoises.

L'analyse complète de ces laitiers de type hémaitite ou lorrain, granulés ou bouletés, est effectuée par des méthodes physico-chimiques très précises. La reconnaissance des cristaux en microscopie optique a nécessité le concours du microscope électronique à balayage, de la microsonde électronique de Castaing et de la diffraction des rayons X.

Les taux de cristaux sont mesurés par microscopie optique et par diffraction des rayons X.

Les caractéristiques ainsi mesurées sont corrélées avec les résultats d'essais mécaniques sur mortiers ISO ou sur mortiers activés à la soude. Les auteurs montrent que les éléments mineurs des laitiers ont une grande influence sur leur hydraulicité et que les corrélations les plus fortes sont celles qui tiennent compte des compositions chimiques complètes et des taux de cristallinité.

Ils montrent aussi qu'à composition chimique identique, une vitrification parfaite n'est pas le critère d'une réactivité maximale.

### SUMMARY

The study described here considers 27 blast furnace slags representative of the french and luxemburg productions.

A complete analysis of these slags of hematite or lorrain type, granulated or pelletized, has been done with very accurate methods. The recognition of crystals by optical microscopy needed the scanning electron microscopy, the X ray microprobe analysis and X ray diffraction. The percentages of crystals have been measured by optical microscopy and X ray diffraction.

These measured characteristics are correlated with compression strength on ISO mortar or with mortar activated by sodium hydroxide. The authors show that minor elements of the slags have a very important influence on their hydraulicity and the best correlations are the ones which considers the total chemical analysis and the percentage of crystals.

They also show that for the same composition, a perfect vitrification is not the criterion of an optimal reactivity.

## INTRODUCTION

Depuis que TETMAJER a défini les conditions de l'hydraulicité des laitiers par les rapports  $\text{CaO/SiO}_2$  et  $\text{Al}_2\text{O}_3/\text{SiO}_2$ , de nombreux indices chimiques destinés à prévoir leur valeur hydraulique, après activation à la soude, à la chaux ou au clinker, ont été proposés par de nombreux chercheurs que nous ne pouvons tous citer dans la bibliographie restreinte de cette courte communication (références 1 à 7). Parmi les travaux les plus récents, la recherche qui s'apparente le plus à celle qui est développée dans ce texte est celle de SMOLCZYK qui montre, entre autres, l'influence non négligeable des éléments mineurs tels que  $\text{P}_2\text{O}_5$ ,  $\text{MnO}$ ,  $\text{Na}_2\text{O}$  et  $\text{K}_2\text{O}$  sur l'évaluation de l'hydraulicité des laitiers (référence 8).

Les études effectuées depuis de nombreuses années, au CEREG, sur plusieurs centaines de laitiers de provenances diverses ont confirmé la valeur de certains indices chimiques.

Une recherche plus récente a montré que la composition minéralogique potentielle des laitiers vitrifiés, qui fait une distinction entre les structures en chaînes et les structures en doubles ou simples tétraèdres, permettait une bonne appréciation de leur valeur hydraulique.

Dans une troisième étape, les auteurs montrent que la composition chimique complète des laitiers vitrifiés et leur taux de cristallisation sont les paramètres prépondérants de leur réactivité.

## 1/ CARACTERISTIQUES DES LAITIERS

## 1.1 - Compositions chimiques et potentielles

Les compositions chimiques et les compositions potentielles sont mentionnées sur le tableau I qui donne les valeurs moyennes, minimales, maximales et les écarts types.

Tableau I : Compositions des laitiers analysés				
Comp. chimiques	Moyenne	Minimum	Maximum	Ec. type
Perte au feu	0,42	0,00	1,04	0,28
Insoluble	0,41	0,00	1,32	0,30
Silice totale	33,48	31,96	37,29	1,36
$\text{Al}_2\text{O}_3$	13,29	10,26	16,01	1,68
$\text{FeO}$	1,24	0,29	9,32	1,73
$\text{TiO}_2$	0,55	0,49	0,65	0,05
$\text{MnO}$	0,64	0,34	1,31	0,21
$\text{CaO}$	42,24	37,92	44,38	1,71
$\text{MgO}$	5,99	3,63	8,66	2,14
$\text{K}_2\text{O}$	0,70	0,44	0,98	0,17
$\text{Na}_2\text{O}$	0,39	0,25	0,50	0,08
$\text{P}_2\text{O}_5$	0,13	0,00	0,34	0,13
$\text{SO}_3$	0,04	0,00	0,19	0,04
$\text{S}^{--}$	0,94	0,68	1,25	0,25
$\text{F}^-$	0,16	0,06	0,31	0,10
$\text{Cl}^-$	0,019	0,003	0,050	0,019
Comp. potentielles	Moyenne	Minimum	Maximum	Ec. type
Merwinite $\text{C}_3\text{MS}_2$	1,74	0,00	20,2	4,83
Géhénite $\text{C}_2\text{AS}$	35,74	27,6	43,05	4,52
Akermanite $\text{C}_2\text{MS}_2$	40,17	24,50	55,30	10,96
Rankinite $\text{C}_3\text{S}_2$	10,28	0,00	29,50	9,79

Diopside $\text{CMS}_2$	0,48	0,00	12,90	2,44

## 1.2 - Cristallinité des laitiers

Analyses qualitatives. A l'échelle du microscope optique, aucun des laitiers analysés n'est totalement exempt de cristaux. Leur distribution ainsi que celle des gaz occlus est d'une hétérogénéité remarquable. Dans les laitiers qui contiennent de fortes teneurs en cristaux, il subsiste des quantités variables de grains totalement vitreux (photographies 1, 2, 3).

Les aspects des cristaux de merwinite et de méililite sont visualisés sur les photographies 4 à 10. Pour les cristaux de quelques microns, la distinction entre merwinite et méililite est parfois difficile.

Les cryptocristaux contiennent des quantités variables de merwinite et de méililite, qui ne peuvent être différenciées en microscopie optique et même électronique (photographie 11). La diffraction X peut alors donner les renseignements souhaités. Le fer métallique se présente sous la forme de nodules très réfléchissants comme sur la photographie 12 : il est absent dans 70 % des laitiers, mais présent en quantités parfois importantes dans les autres.

Les photographies au microscope électronique à balayage (MEB) montrent des aspects de cristaux de merwinite et de méililite. Les images en électrons absorbés visualisent la distribution des éléments : ces images montrent par exemple que le potassium et le soufre sont principalement localisés dans le verre, que la distribution de l'aluminium et du magnésium est différente dans le verre et dans les cristaux (photographies 13 à 23). A l'échelle de la microsonde électronique de Castaing (MEC), les cristaux de méililite contiennent des proportions variables de géhlénite et d'akermanite. Au centre des gros cristaux, la solution solide  $\text{C}_2\text{AS}-\text{C}_2\text{MS}_2$  est plus proche du terme  $\text{C}_2\text{MS}_2$  qu'en bordure. Dans les dendrites, la composition est plus proche de la géhlénite.

Les minéraux accessoires sont des phases riches en titane, en soufre et potassium, des composés de type spinelle : ces phases sont très localisées et rares. Les photographies 24 à 32 montrent des aspects d'hétérogénéités mises en évidence par microscopie électronique.

Analyses quantitatives. En diffraction X, l'étalement a été réalisé par fusion et recristallisation complète de mélanges synthétiques qui avaient la composition des minéraux à analyser. Les mesures comparatives des hauteurs de pics ont été faites en prenant le silicium comme étalon interne. En microscopie optique, les taux de cristaux sont mesurés par comptages de points sur des échantillons enrobés dans de la résine. Les deux méthodes donnent des résultats identiques mais avec des limites de détection différentes. En diffraction X, les limites sont de 1 % à 100 % pour la géhlénite et de 2 % à 100 % pour la merwinite alors que la microscopie optique permet de déceler des traces de cristallisation mais n'est plus précise au-delà de 50 % de cristaux. Dans les laitiers examinés, les taux de cristaux varient entre 0,01 % et 35 % pour une moyenne de 5,5 % et un écart type de 9,0 %. Les taux de merwinite varient dans les mêmes proportions mais 5 laitiers contiennent aussi 0,01 % à 3 % de méililite.

## 1.3 - Essais mécaniques

Pour les essais à la soude, les laitiers sont broyés à refus constant de 10 % au tamis de 40  $\mu\text{m}$ , mélangés avec 3 parties de sable ISO, gâchés à  $\text{S/L} = 0,5$ , 5 est une solution qui contient 200 g de soude et 1 litre d'eau. Les éprouvettes 4 x 4 x 16 cm sont conservées en armoire humide. Les essais en compression sont ef-

10 MO X300 Melilite

11 MO X200 Cryptocristaux

12 MO X150 Nodule métallique

fectués après 6 h et 24 h de durcissement. Pour les laitiers étudiés, les résistances varient de 2,7 à 8,4 MPa à 6 h et de 6,3 à 14,4 MPa à 24 h avec des écarts types respectifs de 1,5 et 3,0 MPa.

Pour les essais en mortier ISO, les laitiers sont mélangés avec du clinker et du gypse dans les proportions : 76 % de laitier, 19 % de clinker, 5 % de gypse. Pour ces essais, nous utilisons toujours le même clinker et le même gypse et les mélanges sont broyés à refus de 10 % au tamis de 40 µm. Pour les laitiers étudiés, les résistances varient de 3,0 à 13,2 MPa à 2 jours ; 17,3 à 32,4 MPa à 7 jours ; 31,7 à 49,1 MPa à 28 jours avec des écarts types respectifs de 1,8 ; 2,9 ; 2,9 MPa. Les étendues et les écarts types sont suffisamment importants pour que les corrélations calculées ultérieurement soient généralisables pour les types de laitiers étudiés.

## 2/ CORRELATIONS SIMPLES

### 2.1 - Indices d'activité et résistances mécaniques

Les indices d'activité proposés par les chercheurs peuvent être classés en trois groupes. Le premier tient seulement compte des éléments majeurs et place l'alumine soit au numérateur, soit au dénominateur. Le second tient aussi compte des éléments majeurs mais donne un rôle amphotère à l'alumine comme formateur ou modificateur de réseau avec des coefficients variables pour les deux rôles. Le troisième tient aussi compte de certains éléments mineurs.

Pour les laitiers étudiés, 15 indices ont été calculés et corrélés avec les résistances en compression des mortiers ISO (tableau II). Les meilleurs indices sont :  $(C + M + A/S) - (20 + C + A + 0,5 M - 2 S) - (C + 0,56 A + 1,4 M/S) - (C + M + 0,66 A/S + 0,33 A)$ , viennent ensuite le C/S des sidérurgistes qui est mis en relation avec d'autres caractéristiques que l'activité hydraulique (5) (6) et l'indice  $C + A + 0,5 M + Ca S/S + Mn$ . Cette classification est en bon accord avec les résultats de différentes recherches.

Nous constatons que les relations qui accordent trop d'importance au rôle formateur de réseau de l'alumine sont les plus mauvaises.

Tableau II : Corrélations simples			
Relation	Coefficients		
	R 2 J	R 7 J	R 28 J
S/A	0,76	0,65	0,75
C/S	0,85	0,78	0,80
C/A	0,56	0,43	0,58
(C + M)/S	0,82	0,79	0,72
(C + M + A)/S	0,91	0,82	0,84
(C + 0,56 A + 1,4 M)/S	0,85	0,81	0,77
$20 + C + A + 0,5 M - 2 S$	0,88	0,79	0,83
(C + M)/(S + A)	0,09	0,09	0,07
(C + A - 10)/(S + 10)	0,82	0,72	0,78
(C + M + 0,33 A)/(S + 0,66 A)	0,37	0,40	0,20
(C + M + 0,66 A)/(S + 0,33 A)	0,86	0,81	0,76
S/(A + F + T + Mn)	0,57	0,50	0,60
(C + A + 0,5 M + Ca S)/(S + Mn)	0,85	0,77	0,80
(C + A + 0,5 M)/(S + FeO + MnO)	0,79	0,69	0,73
$C + A - 10 + CaS + Na_2O + K_2O$ S + 10 + M + MnO	0,72	0,63	0,72

### 2.2 - Activations à la soude et au clinker

Les essais à la soude donnent de meilleurs corrélations à 6 h qu'à 24 h. A 6 h, tout en restant significatives aux trois périodes, la corrélation est meilleure à 2 jours ( $r_2 = 0,73$  -  $r_7 = 0,53$  -  $r_{28} = 0,59$ ).

A 24 h, seule la corrélation à 2 jours est significative au seuil de 0,05 ( $r_2 = 0,55$  -  $r_7 = 0,39$  -  $r_{28} = 0,39$ ).

### 2.3 - Relations entre essais mécaniques et taux de cristallisation des laitiers

Le graphique de la figure 33 montre que les relations entre résistances en compression et taux de cristaux des laitiers d'une même provenance ne sont pas linéaires. Les pentes des courbes sont positives entre 0 % et 5 % et négatives entre 5 % et 35 % de cristaux. Les pentes sont d'autant plus négatives que les temps de durcissement sont plus longs.

Fig. 33 : Influence du taux de cristaux dans les laitiers

Pour les laitiers qui contiennent 5 à 35 % de cristaux, les baisses de résistances ne sont pas proportionnelles aux taux de cristallisation : dans ce domaine, les courbes peuvent être assimilées à des droites et leurs pentes sont nettement inférieures à l'unité. Les pertes nettement inférieures à 1 pour ces laitiers peuvent être expliquées par des compositions chimiques des verres différentes des compositions chimiques moyennes des laitiers. L'exemple donné sur le tableau III pour un laitier qui contient 35 % de merwinite montre ces différences : le verre est enrichi en alumine et en éléments mineurs. Les photographies 16-17-22-23 confirment ces différences. Les corrélations simples ou multiples confirment aussi que la composition moyenne du verre est plus réactive que la composition moyenne du laitier.

Tableau III : Composition du laitier et du verre qu'il contient						
	SiO <sub>2</sub>	Al <sub>2</sub> O <sub>3</sub>	FeO	MnO	TiO <sub>2</sub>	CaO
Laitier	33,6	11,1	0,89	0,64	0,55	42,1
Verre	32,0	17,0	1,37	0,98	0,85	37,2
	MgO	Na <sub>2</sub> O	K <sub>2</sub> O	S <sup>-</sup>	F <sup>-</sup>	Cl <sup>-</sup>
Laitier	8,7	0,38	0,81	1,10	0,09	0,044
Verre	6,7	0,58	1,25	1,69	0,14	0,068

Les performances accrues des laitiers qui cristallisent jusqu'à 5 % de merwinite ne sont pas expliquées. En microscopie optique, nous observons des attaques préférentielles par les acides suivant une multitude de lignes qui s'élargissent par des attaques plus prononcées. Ces attaques préférentielles mettent en évidence des hétérogénéités submicroscopiques qui peuvent être dues à des germes de cristallisation, à des compositions chimiques différentes, à des tensions internes plus élevées dans les verres qui contiennent des cristaux ...

## 3/ CORRELATIONS MULTIPLES

Les indices de réactivité donnés par les chercheurs négligent partiellement ou totalement l'influence des éléments mineurs qui entrent dans la composition des laitiers industriels. Nous avons calculé plusieurs séries de corrélations multiples linéaires qui tiennent compte de l'analyse chimique complète des laitiers, des variations dans le temps de l'influence des différents éléments, des compositions potentielles, des pourcentages de verre, des résistances en mortiers ISO. Les corrélations multiples qui donnent les coefficients  $r$  les plus élevés sont celles qui prennent en compte les compositions chimiques complètes et les pourcentages de verre.

Variables.	Coefficients		
	2 jours	7 jours	28 jours
Perte au feu	- 0,646	- 2,450	+ 0,029
SiO <sub>2</sub>	- 1,401	- 1,766	- 3,392
Al <sub>2</sub> O <sub>3</sub>	+ 0,158	- 0,578	- 1,479
FeO	- 0,233	- 0,320	- 1,011
TiO <sub>2</sub>	- 10,40	- 25,58	- 16,53
MnO	- 1,206	- 3,308	+ 3,005
CaO	+ 0,117	+ 0,242	- 0,059
MgO	+ 0,375	+ 0,857	+ 0,243
SO <sub>3</sub>	- 1,263	- 1,673	- 1,454
S--	- 3,649	- 0,754	- 0,167
K <sub>2</sub> O	+ 3,948	+ 1,120	- 2,294
Na <sub>2</sub> O	- 0,500	+ 11,87	+ 9,411
P <sub>2</sub> O <sub>5</sub>	+ 1,887	+ 12,24	+ 5,632
F-	+ 0,501	+ 1,739	+ 13,04
Cl-	+ 62,29	+ 126,7	+ 110,5
Insoluble	- 1,145	- 3,922	- 4,173
% Verre	+ 0,041	+ 0,131	+ 0,279
Constante	+ 48,75	+ 74,17	+ 149,92
$r$	0,974	0,944	0,934
$r^2$	0,949	0,891	0,872

Ces coefficients  $r$  sont respectivement 0,97 - 0,94 - 0,93 à 2, 7, 28 jours. Les meilleures corrélations simples obtenues avec l'indice (C + M + A)/S étaient 0,91 - 0,82 - 0,84 pour les mêmes périodes. Ces différences montrent l'influence importante des éléments mineurs.

Les corrélations multiples mentionnées affectent des coefficients élevés à différents éléments mineurs tels que TiO<sub>2</sub>, Na<sub>2</sub>O, F-, Cl-. Ces corrélations ne sont que des formulations mathématiques, mais elles paraissent tout de même mettre l'accentuation sur l'action de différents éléments. Le rôle du titane comme agent nucléant, le rôle du fluor sur la vitesse de cristallisation, les actions différentes de Na<sup>+</sup> et de K<sup>+</sup> sont connus des verriers (9). L'influence accélératrice du chlorure de sodium est utilisée par les cimentiers.

Dans ces corrélations, le rôle des cristaux n'est pas suffisamment mis en valeur car le nombre d'échantillons de chaque provenance est insuffisant pour en tenir compte autrement qu'en relations linéaires. Ces corrélations seront améliorées ultérieurement lorsque notre étude comprendra un nombre d'échantillons plus important.

## CONCLUSIONS

Au cours de cette recherche sur des laitiers de types hématite et lorrain, granulés ou bouletés, nous avons mis en évidence que le procédé de trempe n'était pas un facteur déterminant de leur réactivité. Les facteurs principaux sont la composition chimique compte tenu de tous les éléments mineurs et le taux de cristallinité. La composition chimique qui induit beaucoup

d'autres propriétés telles que viscosité, fusibilité, hétérogénéités microscopiques et submicroscopiques donne de ce fait de très fortes corrélations avec les résistances mécaniques des ciments dans lesquels la quantité de laitier est prépondérante.

Pour des laitiers qui dévitrifient principalement de la merwinite au cours de trempes industrielles, nous avons aussi montré qu'une vitrification totale n'est pas souhaitable pour obtenir une réactivité maximale : la présence de 3 à 5 % de cristaux augmente leurs performances. Pour des taux de cristaux supérieurs, leur précipitation enrichit le verre restant en alumine et en éléments mineurs, ceci améliore leur réactivité, d'où en pourcentages, des baisses de résistances nettement inférieures aux taux de cristaux.

## REMERCIEMENTS

Les auteurs remercient MM. BERTIN, MAES et le personnel du département ECPM pour les travaux effectués au CEREG, en microscopie, diffraction X et essais physiques et mécaniques.

## NOTA

Les analyses au microscope électronique à balayage et à la sonde électronique de Castaing ont été effectuées au CERILH sous la direction de Mme REGOURD par Mme MOINE, M. HORNAIN du CERILH et M. BERTIN du CEREG.

# The hydration of blast furnace slag cement

## *L'hydratation du ciment de laitier de haut fourneau*

Y. TOTANI, Y. SAITO, M. KAGEYAMA and H. TANAKA, Japon.

RESUME : Pour étudier l'activité de divers laitiers granulés, sous-produits de l'industrie métallurgique, on a mesuré, à l'aide d'un calorimètre à conduction, le dégagement de chaleur, lors de leur hydratation, de ciments de laitier fabriqués avec ces laitiers. Il existe de grandes différences entre le mode de dégagement de chaleur des ciments portland et des ciments de laitier; la teneur en laitier et la nature de celui-ci ont une grande influence sur ce dégagement de chaleur.

On a observé, en essayant trois sortes de laitiers industriels, que malgré des basicités et des teneurs en verre très voisines, les dégagements de chaleur pouvaient être très différents.

Pour les ciments à faible teneur en laitier, le dégagement de chaleur cumulé est plus faible, initialement, que celui du ciment Portland de même clinker, mais peut être bien plus élevé en fin d'hydratation. Si le dégagement de chaleur du ciment Portland est bien ralenti, dans la deuxième partie de l'hydratation, il n'en est pas de même du ciment de laitier.

Les phénomènes observés peuvent s'expliquer ainsi :

1. Dans l'hydratation du ciment de laitier, une partie inconnue du dégagement de chaleur provient de l'hydratation du laitier lui-même.
2. Puisque le laitier granulé absorbe le  $\text{Ca(OH)}_2$  dégagé par l'hydratation du clinker, l'hydratation du laitier est accélérée par la baisse de concentration, qui en résulte, de  $\text{Ca(OH)}_2$  dans la phase aqueuse.
3. Pour un même clinker du ciment de laitier, puisque le rapport E/C doit augmenter avec la proportion de laitier, il doit en résulter une augmentation plus importante de la chaleur dégagée.

SUMMARY : To study the activity of slag on the hydration of slag cement with granulated blast-furnace slag by-produced from iron and steel industry, the heat liberation process was measured by conduction calorimeter.

There are essentially large differences between the heat liberation process on the hydration of slag cement and that of portland cement; the content and the kind of slag affect considerably on the difference.

Moreover, it was revealed that, in spite that there aren't appreciable difference in the basicity and the glass content of three kinds of industrial slag used, their undetectable properties give a large effect on the heat liberation process of each slag cement.

The accumulated heat liberation of the slag cement with relatively lower content of slag is slightly less than that of original portland cement during early stage, however in later stage, exceeds. Because, though the rate of heat liberation of original portland cement considerably slow down after middle stage, that of the slag cement doesn't so much.

The abovementioned phenomena would be explained as follows;

- 1) In the hydration of slag cement, an ignorable portion of the heat liberation is occupied by that of hydration reaction of the slag itself.
- 2) Since the granulated slag acts as a consumer for  $\text{Ca(OH)}_2$  which is liberated from portland cement during the hydration, the hydration of clinker portion in the slag cement is accelerated by lowering  $\text{Ca(OH)}_2$  concentration in the aqueous phase.
- 3) Referred to the clinker portion in slag cement, since the w/c-value increases as the slag content increases, the heat liberation becomes proportionally larger.

## INTRODUCTION

The hydration of slag cement is depended largely on the hydration property of clinker and the hydration activity, finess, content of slag, etc.

Alégrel) showed that the heat of hydration of slag cement linearly decreases as the content of slag increases. On the other hand, Schröder<sup>2)</sup> reported that the linear relation between the heat of hydration and the content of slag is not always existed, but the heat of hydration of the slag cement with less content of slag is essentially analogous to that of portland cement and that of the slag cement decreases as the slag content increases.

In many studies, it has been considered that the heat of hydration of slag cement is mainly originated from the hydration of clinker portion.

The authors, in present paper, have shown that the heat of hydration of slag cement is consisted of those of clinker and slag portion, respectively, and beside complex interaction exists between both portions in the hydration.

## EXPERIMENTAL ( Materials and Methods )

Three kinds of industrial granulated blast-furnace slag and a commercial portland cement were used. The chemical composition, the basidity and the glass content of the materials used are shown in Table 1. The three slags have similar basidity and glass content and in any of them the existence of crystalline materials is not detected by XRD. After they were pulverized with gypsum ( $\text{SO}_3$  2%) to Blaine 4000 + 50  $\text{cm}^2/\text{g}$ , mixed with portland cement in definite proportions (slag content 30, 60 and 80%).

Table 1. The chemical composition, basidity and glass content of industrial slag and portland cement.

In measurement of heat of hydration of slag, powdered  $\text{Ca}(\text{OH})_2$  is used as an activator and for examining the effect of w/c, reagent grade powdered  $\text{ZrO}_2$  is used in stead of slag.

A conduction calorimeter with six cells is used for measuring the heat of hydration and each slag cement sample is mixed with water outside the calorimeter, then put into the calorimeter. Therefore, the exact recording of heat liberation is not taken place for one hour after the water added.

The heat liberation for this one hour is corrected by data gotten by other method.

## RESULTS AND DISCUSSIONS

The heat of hydration of the slag cement

Fig. 1, 2 and 3 shows the heat of hydration of the slag cement with each of three slags (A, B and C) at 30°C.

The heat of hydration of slag cement with 30% and 60% slag A contents and 30% slag B content are slightly less than that of only portland cement in early stage, however exceed in later stage.

Fig. 1 The heat of hydration of slag cement with slag A at 30°C. w/c = 0.5 cement paste.

Fig. 2 The heat of hydration of slag cement with slag B at 30°C. w/c = 0.5 cement paste.

On the contrary, the heat of hydration of the slag cement with slag C decreases linearly as the content of slag increases.

Fig. 3 The heat of hydration of slag cement with slag C at 30°C. w/c = 0.5 cement paste.

From above-mentioned, it is apparent that, although there aren't detectable differences among each basicity and glass content of three slag A, B and C, there are unignorable differences among the hydration heat of slag cement with each of them, which hydrate at same temperature.

The heat of hydration of slag in presence of  $\text{Ca}(\text{OH})_2$

As shown in Fig.4, the hydration tendency of slag A, B and C is similar to that of slag cement and their activities in the hydration would be in order of A B C.

There is a large difference in the heat of hydration between slag A and B and slag C; in the former about 40 cal/g after 7 days, in the later about 25 cal/g.

The heat which is liberated from the slag- $\text{H}_2\text{O}$  system in the presence of  $\text{Ca}(\text{OH})_2$  added as an activator can be regarded as the heat of hydration originated from slag predominantly.

Since it is possible to consider that the slag in slag cement hydrates also by activation of  $\text{Ca}(\text{OH})_2$  produced from the hydration of clinker portion, the portion occupied by the hydration of slag in the hydration heat of slag cement is so large that it could hardly ignore.

Fig. 4 The heat of hydration of slag in presence of  $\text{Ca}(\text{OH})_2$  at 30°C.  $w/(\text{slag} + \text{Ca}(\text{OH})_2) = 0.5$ .

The hydration heat of slag increases as the added  $\text{Ca}(\text{OH})_2$  increases.

Furthermore, it was revealed that the hydration heat of slag linearly increases in less addition of  $\text{Ca}(\text{OH})_2$  than 7% and also gradually in the addition from 7% to 15%.

The heat of hydration of portland cement with  $\text{ZrO}_2$  in stead of slag

It has been estimated that referring to clinker portion of slag cement, the W/C-value increases than that of slag cement as the content of slag increases, because the hydration of slag would be generally slower than that of clinker.

To check the effect of W/C to the hydration of clinker portion, the heat of hydration of portland cement with various content of powdered  $\text{ZrO}_2$  was measured ( $\text{ZrO}_2$  content 30, 60 and 80%).

The powdered  $\text{ZrO}_2$  was used for examining the effect of only the W/C-value, because it doesn't has any inter-reaction to clinker.

Fig. 5 The heat of hydration of portland cement with and without  $\text{ZrO}_2$  at 30°C.  $w/(\text{portland cement } \text{ZrO}_2) = 0.5$ .

The heat of hydration shown in Fig.5 is given as per gram of portland cement, not per portland cement which mixed  $\text{ZrO}_2$ . The heat of hydration of clinker portion was larger, though being irregular relation, in all the portland cement mixed with  $\text{ZrO}_2$  than that of portland cement without  $\text{ZrO}_2$ .

It can be suggested that the W/C effect as shown in Fig.5 exists also in the hydration of slag cement. However, it is not apparent how much the W/C effect would be realized in the hydration of slag cement, because there is a great difference in the activity between  $\text{ZrO}_2$  and slag.

The rate of hydration of alite and slag

The rate of hydration of slag and alite in the slag cement with slag B were estimated from the heat of crystallization by means of DTA in the former and the pattern of XRD in the latter. As shown Fig.6, the hydration of alite in the slag cement is faster than that of alite of portland cement without slag, as the content of slag increases.

In the slag cement, the acceleration of alite hydration would be caused by lowering  $\text{Ca}(\text{OH})_2$  concentration in the aqueous solution phase, which is also attributed to consumption of  $\text{Ca}(\text{OH})_2$  liberated from the clinker portion by pozzolanic reaction with slag.

It should seem that the w/c-effect above-mentioned also plays the role of the acceleration of alite hydration.

Fig. 6 The rate of hydration of alite in the slag cement at 30°C.  $w/c = 0.5$  cement paste.

Fig. 7 The rate of hydration of slag in the slag cement at 30°C. w/c = 0.5 cement paste.

On the other hand, the rates of slag hydration in the slag cement with 30% and 60% slag B contents are approximately same.

Being over 80% slag B content, the rate of slag hydration decreases, because  $\text{Ca(OH)}_2$  liberated from the clinker portion becomes less and then, consequently, can not accelerate strongly the hydration.

Fig. 7 shows not only the rate of slag hydration in slag cement, but also that of slag hydration in system of slag B- $\text{Ca(OH)}_2$ - $\text{H}_2\text{O}$ .

The latter's curve is similar to that of slag cement with 80% slag B.

From these results, it can be suggested that the hydration heat of slag portion of slag cement with slag B 80% is analogous to that of the slag with  $\text{Ca(OH)}_2$  7% shown in Fig. 4. It can be approximately calculated, by using the hydration heat of slag portion, that the about 70% of the hydration heat of slag cement with slag B 80% is occupied by that of the slag portion.

Thus, it should be considered that the heat of hydration of slag cement consists of that of the clinker portion and the slag portion, respectively.

The interesting fact obtained from present work is that the slag cement with the slag which has a high activity often shows larger heat of hydration than that of portland cement in later stage.

The slag cement with slag B 30% has larger hydration heat than portland cement, because the rate of hydration of the slag portion is larger and the hydration of the clinker portion is accelerated by the presence of slag.

On the other hand, the slag cement with slag C which has lower hydration heat doesn't show larger hydration heat than portland cement.

#### CONCLUSION

The results obtained as follows;

1) The studies on the hydration heat of slag portion, the W/C-effect and the rate of hydration of slag portion and alite phase of clinker portion in the hydration of slag cement show that the slag cement with the slag which has a high activity often shows larger heat of hydration than portland cement.

2) In spite that there aren't appreciable differences in the basidity and the glass content of three kinds of industrial slag used, the heat liberation processes of the slag cement show that there are large differences among their hydration activities.

The authors, at present time, suggest that the difference is hardly revealed by the present conventional method for defining the hydration activity of slag. Speaking additionally, the definition of glassy state of slag particle would be impossible by the conventional method with optical microscope.

Because the glassy state from the melt to the crystalline widely spreads. Besides, the difference in the glassy state effects largely the hydration activity.

Therefore, in order to know the exact characteristics of the hydration of the slag cement, include the definition of glassy state should be established.

# Hydrated phases in slag-water-activator systems

## *Phases hydratées dans les systèmes laitier-eau-activateur*

I. TEOREANU, Professor Dr.Doc., Polytechnical Institute Bucarest,  
 M. GEORGESCU, Lecturer Dr., Polytechnical Institute Bucarest,  
 A. PURI, Lecturer, Polytechnical Institute Bucarest, Roumanie.

**RESUME:** Les processus de durcissement et la nature des phases hydratées formées dans les systèmes laitier-activateur-eau sont influencés par beaucoup de facteurs, parmi lesquels les plus importants sont: la nature du laitier et de l'activateur, leurs proportions relatives et les conditions de durcissement.

Cette ouvrage est une analyse de la nature des phases hydratées formées pendant le durcissement des systèmes laitier-chaux-gypse-eau et laitier-chaux-silicate de sodium - eau, dans conditions normales et par traitement à la vapeur, à 60° et 95° C.

L'analyse thermique différentielle, la diffractometrie et la microscopie électronique nous ont montré que dans les systèmes mentionnés, les plus importantes phases hydratées sont des hydrosilicates de calcium de type tobermoritique; auprès d'eux sont décelés, dans certaines conditions, l'ettringite (pour les systèmes que contiennent du gypse) et des hydrosilicates où le  $\text{Ca}^{2+}$  est partiellement remplacé par le  $\text{Na}^+$  (pour les systèmes activées à  $\text{Na}_2\text{O} \cdot n\text{SiO}_2$ ).

**SUMMARY:** The hardening processes and the nature of the hydrated phases formed in slag-water-activator systems are influenced by some factors, as: the nature of the slag and of the activator, the relative amounts of these substances in the system, and the conditions under which the hardening process take place.

The present work deals with a study of the hydrated phases formed in the hardening process of the slag-lime-gypsum-water and slag-lime-sodium silicate-water systems, under normal conditions and steam-cured at 60° and 95° C, respectively.

The DTA curves and the results of the diffractometry and electronic microscopy (EM) analysis revealed that in the above mentioned systems, the main hydrated phases are tobermorite-type calcium hydrosilicates, there are also noted, under certain conditions, hydrated gehlenite, ettringite (in the case of the systems containing gypsum) and hydrosilicates in which  $\text{Ca}^{2+}$  is partly replaced by  $\text{Na}^+$  (in the case of the systems activated by  $\text{Na}_2\text{O} \cdot n\text{SiO}_2$ ).

An increased use of slags as binders requires a deeper investigation of their behaviour in the hardening processes, especially in complex systems, as, e.g., slag-water-activator. This investigation is primarily aimed at discovering new means for the decrease of the amount of portland cement clinker in hydraulic binders exhibiting satisfactory qualities.

#### EXPERIMENTAL

In order to get informations concerning the nature of the new hydrated phases, two classes of systems were examined: slag-lime-gypsum-water and slag-lime-sodium silicate-water. The characteristics of the used slags are given in table I. Considering the main oxidic components, the slags belong to the  $CS-C_3S_2$ -mellilite subsystem.

Type of slag	CaO	SiO <sub>2</sub>	Al <sub>2</sub> O <sub>3</sub>	MgO	Fe <sub>2</sub> O <sub>3</sub>	Mn <sub>2</sub> O <sub>4</sub>	TiO <sub>2</sub>	R <sub>2</sub> O	sulfides	loss on ignition
Galati, type G	43,49	34,31	8,48	5,20	0,60	0,61	0,24	0,88	1,45	0,39
Hunedoara, type H	44,25	38,03	7,24	5,39	0,50	1,12	0,26	1,06	1,23	0,15

The X-ray analysis of the slags (figure 1) shows a nonequilibrium composition, as expected, and a low degree of crystallisation. The crystalline phases identified are the high-temperature forms of the dicalciumsilicate (interferences at 2,70-2,74 Å, 2,21 Å, 2,03 Å), merwinite (2,65-2,66 Å, 2,86 Å, 2,70-2,74 Å, 2,25-2,28 Å, 2,17 Å, 1,91-1,92 Å) and mellilite (2,86 Å, 2,03 Å, 2,50 Å, 1,91-1,92 Å).

Fig.1 - X-ray patterns of the anhydrous slags:

a - G-type slag; b - H-type slag.

The DTA curves show specific crystallization effects (1), thus indicating the presence of a mellilite-type solid solution, mainly gehlenitic (effects at 930°C, in figure 2) and of a vitreous component, containing mainly calcium metasilicate (effects at 840°C).

The water/binder ratio of the investigated pastes was 0,4.

#### HYDRATED PHASES IN SLAG-LIME-GYPSUM-WATER SYSTEMS

There were investigated masses with slag/lime ratios of 90/10 and 95/5, respectively, and containing 3-5 wt% gypsum, hardened in a water-saturated atmosphere, working both at ambient (20-22°C) and higher (90-95°C) temperatures.

The diffraction patterns in figure 3 show that in slag-lime-gypsum-water systems, hardened under normal conditions, the main products are calcium silicates of the tobermorite type (interferences at 3,3,04 Å, 2,9-2,98 Å, 2,83-2,87 Å, 3,33-3,38 Å, 3,70-3,78 Å). The low intensity of the characteristic peaks, mainly for samples hardened for 7 days only, indicates a relatively weak hydration of the slags and a low degree of crystallinity of the resulting compounds. The increase in the intensity of the X-ray peaks after 28 days of hardening signifies a more complete hydration and a higher degree of crystallinity of the formed hydrosilicates. The progress in the hydration degree is also pointed out by the DTA curves given in figure 4. There are noted an increase on the endothermal peak at 140-150°C (prior to the measurement the samples were dried at 110°C), corresponding to the decomposition of the calcium hydrosilicates, and a lowering of the free  $Ca(OH)_2$  amount in the system because it is bound by hydrocompounds (the endothermal peaks at 480°C consecvently decrease).

Fig.2 - DTA curves of the anhydrous slags: a - G-type slag; b - H-type slag.

The active CaO amount in the lime used was of 90-94 wt% and the  $CaSO_4 \cdot 2H_2O$  amount in gypsum was of 98 wt%. There were used two types of sodium silicate ( $Na_2O \cdot nSiO_2$ ), namely  $n=1,5$  - type L and  $n=2,6$  - type G.

Fig. 3 - X-ray patterns of the slag-lime-gypsum binder:

A - G-type slag/lime ratio = 90/10, hardened under normal conditions; B - G-type slag/lime ratio = 95/5, hardened under normal conditions; C - H-type slag/lime ratio = 90/10, 3 wt% gypsum, hardened for 28 days under normal conditions; D - G-type slag/lime ratio = 90/10, 5 wt% gypsum, steam-cured at 95°C for 8 hours; a - 5 wt% gypsum; b - 3 wt% gypsum; 1 - hardened for 7 days; 2 - hardened for 28 days.

The presence of ettringite is noted by the X-ray interferences at 5,4-5,5 Å, 3,83-3,89 Å, 2,54 Å, 3,24-3,29 Å, even after 7 days of hardening. On the thermal analysis curves, the presence of ettringite is mainly seen on the DTC curves, which show overlapped weight losses up to 300°C, resulting from the decomposition of some hydrocompounds; in the 160-270°C temperature range, ettringite undergoes a complete dehydration (2-4).

The interferences at 4,17-4,3 Å, 3,0 Å, 6-6,08 Å, 2,59-2,62 Å (figure 3) indicate that, after 7 days of hardening, there might be present a gehlenite hydrate ( $C_2ASH_6$ ). For longer hardening periods, there is possible that this low-stability compound (5-6) undergoes a gradual transformation into compounds in the hydrogarnets series. This supposition is supported by the X-ray analysis: there are seen interferences specific to hydrogarnets (at 5,02-5,14 Å, 3,17-3,19 Å); there is noted that the intensity of the interferences at 2,70-2,78 Å, characteristic both of the dicalcium silicate and of the  $C_2A(SH_2)_2$ -type hydrogarnets (2) increases, in the case of the samples hardened for 28 days as compared to the anhydrous slag or the systems hardened for 7 days only (figure 3).

Fig.4 - Thermal analysis of the binder with a G-type slag/lime ratio of 90/10, gypsum 5 wt%, hardened under normal conditions: a - after 7 days; b - after 28 days.

#### HYDRATED PHASES IN SLAG - LIME - SODIUM SILICATE - WATER SYSTEMS

The nature of the hydration products in G-type slag-lime-sodium silicate-water systems hardened under normal conditions and steam-cured at 60° and 95°C, respectively, was investigated. The slag/lime ratio in the studied masses was 95/5 and the sodium silicate amount was 8 wt% (calculated as solid material).

The X-ray patterns taken on the masses hardened under normal conditions show interferences characteristic to the anhydrous slag even after 28 days; their intensity decreases gradually, as the hydration proceeds (see interferences at 2,65 Å and 2,71 Å in figure 5). They are suggesting a low participation in the hydration-hydrolysis processes of the crystalline phases in slag: this is supported by the EM images of the hardened masses, which show the hydrated products and the contours of some crystalline products, namely anhydrous slag (figure 6).

the modulus of the sodium silicate decreases and the hydration proceeds. Thus, in the mass containing C-type sodium silicate there is identified a tobermorite gel (the interferences at 3,01 Å, 2,76 Å, 1,82 Å) while in the mass with L-type sodium silicate there are found more basic hydrosilicates of the CSH(II)-type (3,09 Å, 2,80 Å, 2,84 Å, 1,84 Å - figure 5).

The EM images of the masses hardened under normal conditions for 28 days and steam-cured (figure 6 and 7) show that the surfaces of the slag grains are corroded because hydration products are formed at the interface, determining a cementation of the slag grains; this process is more advanced in the case of the masses with L-type sodium silicate and of the steam-cured masses.

Fig.7 - EM pattern (x5000) of the binder with a G-type slag/lime ratio = 95/5:  
a - with 8 wt% L-type sodium silicate, hardened under normal conditions for 28 days;  
b - with 8 wt% L-type sodium silicate, steam-cured at 95°C for 6 hours;  
c - with 8 wt% C-type sodium silicate, steam-cured at 95°C for 6 hours.

The steam-curing determines a remarkable acceleration of the formation and crystallization processes of the hydration products. On the X-ray pattern of the sample with C-type sodium silicate, steam-cured at 60°C for 2 hours, the interferences characteristic to the weakly basic calcium hydrosilicates of the CSH(I)-type (3,01 Å, 2,78 Å, 2,40 Å, 2,06 Å, 1,80-1,82 Å) are clearly visible. A longer thermal treatment intensifies the hydration-hydrolysis processes and leads to an increase of the degree of crystallinity of the hydromonomers, without modifying their nature (see figure 8).

Fig.8 - X-ray patterns of the binder with a G-type slag/lime ratio = 95/5, with 8 wt% C-type sodium silicate, steam-cured at 60°C:  
a - after 2 hours; b - after 6 hours.

In the masses with L-type sodium silicate, steam-cured at 60°C, there are formed more basic hydrosilicates, whose degree of crystallinity markedly increases as the thermal treatment period gets longer; after 6 hours of steam-curing, some crystalline tobermorite appear (at 3,85 Å, 3,33 Å, 3,02 Å, 2,90 Å, 2,80 Å, 1,82 Å - see figure 9); the peaks at 4,27 Å, 3,0 Å, 2,64 Å, 2,57 Å, 2,26 Å might show that gehlenite hydrate is formed (this was also reported by (7) for an alkaline activated slag). The increase of the steam-curing temperature to 95°C determines the intensification of the crystallization processes of the hydrocompounds; after only two hours of steam-curing there are identified crystalline tobermorite and well-crystallized CSH(II); after 6 hours, the interferences of tobermorite became more intense and gehlenite hydrate formation is noted (see figure 9).

tallized CSH(II); after 6 hours, the interferences of tobermorite became more intense and gehlenite hydrate formation is noted (see figure 9).

In this study no crystalline alkaline hydroaluminosilicates were identified, even in the case of the masses with L-type sodium silicate. It is still possible that such compounds (reported by Constantinov and Puzhanov (8), may result as gels, their identification by X-ray techniques being impossible. It is possible, too, that in the crystalline hydrocompounds identified, a fraction of the  $\text{Ca}^{2+}$  ions might be replaced by  $\text{Na}^+$  ions, but this replacement does not determine changes in the lattice parameters. This affirmation is supported by the exothermal effect at 750-780°C, recorded on the DTA curves (figure 10), which might be generated by the crystallization of some hydrosilicates in whose composition the  $\text{Ca}^{2+}$  ions might

be replaced by  $\text{Na}^+$  ions. This might determine a certain labilization of the lattice of these hydrosilicates and might explain the decrease of the temperature of the exothermal effect characterising the crystallization of the weakly basic hydrosilicates, from 800-850°C to 750-780°C (9).

Fig. 9 - X-ray patterns of the binder with a G-type slag/lime ratio = 95/5, with 8 wt% L-type sodium silicate, steam-cured: a - at 60°C, after 6 hours; b - at 95°C, after 2 hours; c - at 95°C, after 6 hours.

Fig. 10 - DTA curves of the binder with a G-type slag/lime ratio = 95/5, with 8 wt% L-type sodium silicate, steam-cured for 6 hours, at: a - 60°C; b - 95°C.

#### CONCLUSIONS

In the investigated systems, the most important hydrocompounds are tobermorite-type calcium hydrosilicates. Under given hardening conditions, the amount and nature of the activator may modify the amount of the hydrosilicates formed and their basicity and crystallinity.

In both investigated systems there was noted the formation of the gehlenite hydrate, which may eventually transform into hydrogarnets.

In the system slag-lime-gypsum-water there is also noted the formation of ettringite, while in the system slag-lime-sodium silicate-water it is suggested that solid solutions of calcium and sodium hydrosilicates, which might have an important role in cementing the binder system, are formed.

# Caractérisation et activation thermique des ciments au laitier

## *Characterization and thermal activation of slag cements*

M. REGOURD, B. MORTUREUX, E. GAUTIER, H. HORNAIN, J. VOLANT, Département Microstructures, C.E.R.I.L.H. - Paris, France.

### RESUME :

Sept laitiers industriels ont été caractérisés à l'aide de la microsonde électronique, de la diffraction des rayons X, de la microscopie électronique à balayage et de l'analyse thermique différentielle dans le but de relier leur hydraulicité à leur composition chimique élémentaire, à leur composition de phases (phase vitreuse et phases cristallisées) et à la constitution de leurs mélanges de recristallisation.

L'hydratation des laitiers dans des ciments de haut fourneau (66,5 % laitier, 28,5 % clinker, 5 % gypse) a été suivie :

- à la température ambiante, par la méthode de dissolution sélective et par diffraction des rayons X,
- à 20, 40, 50 et 80 °C par calorimétrie à conduction et mesure des résistances mécaniques en compression.

La méthode la plus rapide d'évaluation de la réactivité hydraulique d'un laitier dans un ciment est la mesure de la chaleur d'hydratation en pâte pure à 40 °C.

L'énergie d'activation d'un ciment au laitier peut être déterminée au moyen de courbes d'évolution isotherme, soit de chaleur d'hydratation, soit de résistances mécaniques en compression. Elle permet de prévoir la cinétique du durcissement lorsque la température varie au cours de l'hydratation. Des essais de courte durée permettraient ainsi d'estimer la résistance mécanique du ciment au jeune âge et à long terme.

### SUMMARY :

Seven industrial slags have been characterized with the aid of electron microprobe, X-ray diffraction, scanning electron microscopy and differential thermal analysis in order to link their hydraulicity to their elemental chemical composition, their phases composition (glassy phase and crystalline phases) and the constitution of their recrystallized melilites.

The slag hydration in blastfurnace cement (66,5 % slag, 28,5 % clinker, 5 % gypsum) was followed :

- at room temperature by selective extraction analysis and X-ray diffraction,
- at 20, 40, 50 and 80 °C by conduction calorimetry and measures of mechanical compressive strengths.

The quickest method to evaluate the hydraulic reactivity of the slag in a cement is the measure of the heat of hydration in pure paste at 40 °C.

The activation energy of a slag cement can be determined by using isothermal evolution curves either of the heat of hydration or of the mechanical compressive strengths. It permits the prediction of the hardening kinetics when the temperature varies during the course of hydration. Thus, short term tests could permit to estimate the mechanical strength of a cement at early age and at long term.

## 1. INTRODUCTION

Il n'est pas aisé de relier la réactivité hydraulique des laitiers granulés à des paramètres tels que l'état de vitrification et la composition chimique (1). Deux laitiers vitreux de même composition chimique peuvent présenter des propriétés hydrauliques différentes (2).

Dans ce travail, nous avons cherché à différencier sept laitiers industriels, à l'état anhydre et au cours de leur hydratation à 20 °C et 80 °C, à l'aide de plusieurs méthodes d'analyse : microsonde électronique (MSE), diffraction des rayons X (DRX), analyse thermique différentielle (ATD), microscopie électronique à balayage (MEB), calorimétrie à conduction.

## 2. CARACTERISATION DES LAITIERS ANHYDRES

## 2.1 Analyse élémentaire

L'analyse élémentaire des sept laitiers granulés, obtenue grâce à la MSE, est reportée dans le Tableau I.

Tableau I : Composition chimique des sept laitiers

Laitier	1	2	3	4	5	6	7
MgO	4,7	8,4	8,2	9,6	8,6	5,5	4,3

La composition élémentaire est assez homogène d'un grain de laitier à l'autre. Toutefois, certaines hétérogénéités peuvent exister localement, notamment sous forme de sulfures et de sulfates.

Les points figuratifs des compositions chimiques du Tableau I, dans le diagramme ternaire CaO-Al<sub>2</sub>O<sub>3</sub>-SiO<sub>2</sub> (fig. 1) sont relativement proches les uns des autres ; les laitiers 4 et 5 sont les plus acides. Trois indices d'hydraulicité ont été calculés (Tableau II). Ils montrent, pour les deux premiers et pour les laitiers 4 et 5, des valeurs plus faibles qui devraient correspondre à une moindre réactivité.

Tableau II : Indices d'hydraulicité des 7 laitiers

## 2.2 Analyse de phases

• D'après la DRX, les sept laitiers, vitreux, sont caractérisés par un "anneau" centré à 3,0 Å qui définit la distance moyenne entre atomes plus proches voisins (fig. 2). Un enregistrement pas-à-pas n'a révélé aucune différence significative quant à la position et au profil du halo. La position du second anneau (1,9 Å) varie légèrement d'un laitier à l'autre mais ces faibles variations ne semblent pas pouvoir caractériser

aisément un produit industriel. A l'anneau principal se superposent, dans certains cas, des raies de phases cristallisées : merwinite pour les laitiers 2 et 3, mëlilite pour les laitiers 3, 4 et 6. Avec 5 % de merwinite, le laitier 2 apparaît le plus cristallisé de la série (fig. 2).

Fig. 1 : Position des sept laitiers dans le diagramme ternaire chaux-silice-alumine.

Fig. 2 : Le laitier 2 est caractérisé par un anneau de corps amorphe et par les raies de la merwinite cristallisée (5 %).

Après un recuit d'une heure à 850 °C, on trouve une mëlilite plus ou moins bien cristallisée dans tous les laitiers et de la merwinite dans les laitiers 2, 3 et 6. Toutes les cinétiques étudiées ont montré qu'au cours du recuit, la merwinite cristallise d'abord, puis décroît et peut même disparaître (laitier 1 traité à 1000 °C). Les laitiers 4 et 5 se comportent différemment des autres : le diopside CMS<sub>2</sub> apparaît dans le laitier 4 et la mëlilite recristallisée, détectée dans le laitier 5, est proche de l'akermanite.

Les mëlilités de recristallisation diffèrent par leurs paramètres cristallins, intermédiaires entre ceux de la gehlénite et de l'akermanite (fig. 3) et par la largeur de leurs raies DRX que l'on peut considérer comme un paramètre d'ordre. Les laitiers 1, 4, 5 et 7 donnent par recuit une mëlilite très bien cristallisée. Au contraire, la mëlilite des laitiers 2 et 3 présente des raies larges.

• En ATD, la dévitrification du laitier se manifeste par un ou plusieurs signaux exothermiques, entre 800 et 1000 °C. Ces pics, plus ou moins complexes, sont, en général, précédés d'un pic endothermique dû à une

certaine réorganisation du verre (3).

Fig. 3 : Paramètres cristallins a et c de la mélinite après recuit des 7 laitiers.

Fig. 4 : Thermogrammes des laitiers 1, 2 et 3 (sonde semi-micro).

La figure 4 montre les thermogrammes comparés des laitiers 1, 2 et 3. Les laitiers 2 et 3 ont un comportement assez proche : deux signaux respectivement à 870 et 940 °C et un pic intermédiaire vers 900 °C. Des diagrammes DRX, effectués après trempe du produit à différentes températures, ont confirmé que le premier pic doit être attribué à la merwinite (4). L'effet thermique, vers 950 °C, serait le pic de cristallisation de la mélinite bien cristallisée mais la formation de cette phase commence, dans tous les cas, vers 800 °C. La merwinite, apparue au cours du recuit, est très importante dans les laitiers 3 et 6, elle l'est moins dans le laitier 2 et elle est très faible dans les laitiers 1 et 7 où la cristallisation de la mélinite s'étale sur une grande plage de température.

• Au MEB, l'examen de sections polies montre que certains grains contiennent des domaines orientés de microcristaux, le plus souvent sous forme dendritique (fig. 5). Ces domaines correspondent à un stade précoce de cristallisation. Leur analyse élémentaire ponctuelle n'est pas aisée en raison de leurs très faibles dimensions. Des dosages répétés ont montré que les zones dévitrifiées étaient systématiquement plus riches

en MgO mais plus pauvres en  $Al_2O_3$  que le verre environnant : dans cet échantillon (laitier 2), seule la merwinite  $C_3MS_2$  avait été détectée par DRX.

Fig. 5 (MEB) : Cristallisation dendritique de la merwinite (M) dans le laitier vitreux (V) n° 2 (section polie attaquée par  $NH_4Cl$ ).

### 3. HYDRATATION DES CEMENTS AU LAITIER

Les laitiers broyés à une surface spécifique Blaine de  $3500 \text{ cm}^2 \cdot \text{g}^{-1}$  ont été ajoutés à un clinker de ciment Portland (63 %  $C_3S$ , 17 %  $C_2S$ , 14,5 %  $C_3A$ , 4,5 %  $C_4AF$ ) dans les proportions 66,5 % laitier, 28,5 % clinker, 5 % gypse. Les éprouvettes de pâte pure de ce ciment de haut fourneau CHF, ( $e/c = 0,4$ , cubes  $2 \times 2 \times 2 \text{ cm}$ ) ont été conservées 1, 3, 6 et 12 mois dans l'eau à 20 °C. A chaque échéance, le degré d'hydratation du laitier a été mesuré et la microstructure du matériau durci, examinée au MEB.

#### 3.1 Mesure du degré d'hydratation des laitiers

Le degré d'hydratation du laitier a été déterminé par dissolution des constituants hydratés et du ciment Portland anhydre dans une solution d'acide salicylique dans le méthanol et l'acétone (5). L'analyse quantitative par DRX (méthode de l'étalon interne silicium) a permis de suivre les variations de la concentration en  $Ca(OH)_2$  et la diminution de l'intensité de l'anneau d'amorphe du laitier anhydre.

Les résultats obtenus par ces deux méthodes font nettement apparaître, dès la première échéance (28 jours), des différences de réactivité entre les laitiers étudiés (fig. 6).

Fig. 6 : Décroissance du laitier anhydre, en fonction du temps, dans les CHF- (méthode de dissolution KONDO-OHSAWA).

A 3 mois, la quantité de  $\text{Ca(OH)}_2$ , présente dans les pâtes, varie du simple au double entre les laitiers 1 et 3 par exemple. On note, par ailleurs, une nette diminution de l'anneau des laitiers 1 et 7, entre 28 jours et 3 mois. A 6 mois, les CHF 1 et 3 se différencient de la même manière qu'à 28 jours, en ce qui concerne le taux de  $\text{Ca(OH)}_2$ .

La fraction de laitier n'ayant pas encore réagi, déterminée par la méthode de dissolution, a été reliée à la composition de la méililite cristallisée au cours du recuit (Tableau III), composition estimée à partir des paramètres cristallins représentés sur la figure 3.

Tableau III : Pourcentage de laitier n'ayant pas encore réagi à 6 mois dans les CHF et composition minéralogique de la méililite recristallisée.

Laitier	1	2	3	4	5	6	7
résidu (%)	48	51	51	52	56	50	48
gehlénite (%)	80	59	59		42	68	80
akermanite (%)	20	41	41		58	32	20

Les résultats du Tableau III montrent que la réactivité d'un laitier pourrait être reliée à la teneur en gehlénite (ou en akermanite) de la méililite recristallisée. Les laitiers 1 et 7 ont le mieux réagi, leur méililite était formée de 80 % de gehlénite et de 20 % d'akermanite. Le laitier 5 est le moins réactif, sa méililite contenait 58 % d'akermanite. Le laitier 4 est une exception, la composition de sa méililite ne correspondait pas à une solution solide gehlénite-akermanite mais à une phase plus complexe contenant des éléments mineurs, du potassium en particulier.

L'autre caractéristique des méililites, à savoir le degré d'ordre de la solution solide (raies DRX élargies), ne semble pas pouvoir être corrélée à la réactivité du laitier.

A un an, les CHF 1, 2 et 3 contiennent sensiblement la même quantité de  $\text{Ca(OH)}_2$  mais les fractions hydratées, déterminées par voie chimique, ne sont pas égales. Le taux de chaux donne donc une indication de la réactivité d'un laitier mais cette estimation ne peut être suffisante car l'activation calcique n'est pas seule en cause. Il s'y ajoute l'activation sulfatique due au gypse du ciment Portland et une auto-activation par les sulfates provenant de l'oxydation des sulfures présents dans les laitiers. Le laitier 2 contient le pourcentage le plus élevé de l'élément S (1,79 %), presque cinq fois plus que celui des laitiers 1 et 3 (Tableau I). D'après les résultats à 1 an, le laitier 3 a réagi plus lentement que les laitiers 1 et 2 ; les essais mécaniques sur mortier confirment cette observation.

Dans nos conditions expérimentales, les laitiers les plus réactifs ne se sont pas hydratés à plus de 30 % à un an, en pâte pure. Des taux d'hydratation plus élevés ont été atteints avec une mouture très fine du laitier (6).

### 3.2 Mesure de la chaleur d'hydratation

La réactivité des laitiers 6 et 7 étant respectivement proche de celle des laitiers 3 et 1, la mesure du dégagement de chaleur au cours de l'hydratation des CHF en pâte pure a été effectuée sur les cinq premiers ciments de haut fourneau, à 40 °C, à l'aide d'un calorimètre à conduction. Les courbes de flux de chaleur mettent en évidence, avant 24 heures, des différences très importantes entre les laitiers (fig. 7). Le maximum du flux est retardé dans le temps et nettement moins intense avec les laitiers 2 et 3 qu'avec le laitier 1, plus encore avec les laitiers 4 et 5.

Ces observations sont à rapprocher des estimations du taux d'hydratation par voie chimique.

Fig. 7 : Chaleur d'hydratation à 40 °C du CPA et des cinq premiers CHF.

L'interprétation des courbes de chaleur d'hydratation paraît plus délicate que la comparaison des flux de chaleur.

L'étude au MEB et par DRX du CHF n° 1, avant et après le pic le plus intense (fig. 7) montre que :

1) l'hydratation des silicates du clinker est déjà commencée avant la partie ascendante du pic : présence de  $\text{Ca(OH)}_2$  et diminution de  $\text{C}_3\text{S}$ . Le gypse a très peu réagi.

2) au-delà du pic, le gypse est entièrement consommé. L'ettringite, abondante, n'a pu se former qu'avec l'alumine du laitier, compte tenu de la faible teneur en  $\text{C}_3\text{A}$  du CHF. La concentration en C-S-H a nettement augmenté. Il s'agit donc bien d'une activation du laitier par la chaux et le sulfate.

Par ailleurs, pour un laitier très réactif tel que le laitier 1, le pic survient au même moment que celui du CPA témoin et le rapport entre l'énergie libérée par le CHF et celle libérée par le CPA est très supérieur à la proportion de clinker (28,5 %). Ces résultats (Tableau IV) prouvent la participation du laitier au dégagement de chaleur.

Dans la comparaison de la réactivité des laitiers, la calorimétrie se révèle donc une méthode très sensible.

Tableau IV : Valeur de l'énergie totale libérée à 40 °C par les 5 CHF et le CPA à 108 heures.

CHF	1	2	3	4	5	CPA
J.g <sup>-1</sup>	241	242	223	174	180	341

### 3.3 Mesure des résistances mécaniques des mortiers ISO

Les résistances mécaniques ont été mesurées sur les mortiers ISO de CHF 1, 2 et 3 et comparées à celles du CPA. La variation de la résistance à la compression en fonction du temps sépare bien les quatre ciments dès les brèves échéances (fig. 8) et la distinction est particulièrement nette à 7 jours. A 90 jours, le CHF contenant le laitier le plus réactif est aussi résistant que le CPA entrant dans sa composition. Le développement des résistances mécaniques est lié à l'hydratation des constituants du ciment. La différenciation des laitiers est plus nette dans le cas de la mesure des résistances mécaniques sur mortier que lors de l'estimation du degré d'hydratation en pâte pure par la méthode de dissolution. Elle reste toutefois moins rapide que le classement des CHF par la calorimétrie à conduction à 40 °C.

Fig. 8 : Evolution des  $R_c$  en fonction du temps.

Fig. 9 : Grains de laitier entourés de C-S-H.

Fig. 10 : Cristallisation de l'ettringite en fines aiguilles disséminées.

### 3.4 Examen de la microstructure des pâtes et mortiers

L'examen au MEB de sections polies et de surfaces de fracture d'éprouvettes de pâte pure révèle que le clinker s'hydrate en premier. Les grains de laitier couverts par le C-S-H du clinker s'entourent ensuite d'une zone hydratée qui devient très compacte à un an (fig. 9). L'analyse élémentaire ponctuelle montre que le C-S-H est plus riche en MgO et Al<sub>2</sub>O<sub>3</sub> que celui du clinker, mais il est moins calcique. A ce C-S-H se mêlent des aiguilles d'ettringite, plus courtes et plus fines que celles données par le clinker (fig. 10). L'ettringite est encore détectée par DRX à un an, elle coexiste alors avec le monosulfate aluminé, elle est probablement due à l'auto-activation sulfatique du laitier.

Il est difficile d'apprécier par ces examens une différence de réactivité entre plusieurs laitiers. Tout au plus peut-on séparer les laitiers 1 et 3 par exemple, les zones hydratées autour des grains de laitier étant à 28 jours plus larges dans le premier échantillon que dans le second.

Les différences sont plus marquées dans les mortiers que dans les pâtes pures de ciment. A 14 et 28 jours, les mortiers de CHF contiennent beaucoup moins de Ca(OH)<sub>2</sub> en plaquettes massives mais plus de sulfates aluminés que le CPA. Le monosulfate aluminé est plus abondant, dès 14 jours, dans le CHF 1 que dans les CHF 2 et 3 qui, par contre, contiennent plus d'ettringite.

### 4. ETUVAGE DES CEMENTS AU LAITIER

A l'activation alcaline et sulfatique des laitiers peut s'ajouter une activation thermique lors d'un étuvage. Nous avons étudié l'évolution des chaleurs d'hydratation et des résistances mécaniques au cours de différents traitements thermiques.

#### 4.1 Chaleurs d'hydratation et résistances mécaniques

Les mesures de chaleur d'hydratation ont été effectuées sur pâte pure (e/c = 0,40) à 20, 40 et 80 °C (Tableau V). La variation du dégagement de chaleur en fonction du temps (fig. 11) montre que l'évolution du phénomène est la même à 20 et 40 °C. L'élévation de température de 20 °C accélère les réactions d'hydratation mais les hydrates formés sont les mêmes qu'à température ambiante, d'où l'intérêt de classer les laitiers par leurs courbes calorimétriques à 40 °C (fig. 7).

Les résistances mécaniques ont été mesurées sur des mortiers ISO conservés en moules métalliques dans l'eau jusqu'à leur rupture. Le cycle d'étuvage n'a débuté que 4 heures après le gâchage. La vitesse d'échauffement était de 20 °C.h<sup>-1</sup>, celle du refroidissement de 30 °C.h<sup>-1</sup>. Afin d'englober la majeure partie de la période d'accroissement des résistances, les mesures ont été poursuivies jusqu'à 180 jours à 20 °C, 21 jours à 50 °C et 6 jours à 80 °C (Tableau V). Après un cycle d'étuvage, certaines éprouvettes ont été replacées dans l'eau à 20 °C jusqu'à ce que la durée totale d'hydratation atteigne 28 et 90 jours.

Pour chaque ciment étudié, les courbes d'évolution des résistances mécaniques en fonction du temps, à 50 et 80 °C, croisent plus ou moins rapidement la courbe d'évolution à 20 °C (fig. 12 et 13). Si l'on exclut du durcissement les réactions initiales d'hydratation jusqu'à la fin de la période dormante et si l'on donne à  $\alpha$ , degré d'avancement, la valeur 1 quand la résistance ne varie plus de manière significative (variation

CHF 3	3	10	20	30	39	51	56	17	21	31	27	32	32	22	27	34	35	36	36	36	36	36	36	36	36

inférieure à 5 % quand le temps double), les courbes d'évolution du phénomène, pour chaque température, sont affines. Les rapports d'affinité suivent la relation d'ARRHENIUS :

$$\gamma = \exp. \left[ \frac{E}{R} \left( \frac{T_2 - T_1}{T_1 T_2} \right) \right] = \frac{t_1}{t_2}$$

$t_1, t_2$  = temps d'hydratation,  $T_1, T_2$  = température en °K.

Les essais à 20, 50 et 80 °C permettent ainsi de déterminer une valeur moyenne de l'énergie d'activation  $E$  du ciment pendant la durée du durcissement considérée. Les valeurs finales sont supposées correspondre à des systèmes de même nature et de même degré d'avancement.

L'énergie d'activation  $E$  déterminée dans ces conditions est pour les trois premiers CHF étudiés de 56 kJ.mol<sup>-1</sup>. La même valeur est obtenue à partir des mesures de dégagement de chaleur. Les rapports d'affinité entre la courbe à 20 °C et les courbes à 40, 50 et 80 °C sont respectivement de 4,4, 8,5 et 50. L'énergie  $E$  du CPA entrant dans la composition des CHF est de 42 kJ.mol<sup>-1</sup> et les rapports d'affinité respectivement de 3, 5 et 19 à 40, 50 et 80 °C. La température a donc un effet plus important sur les CHF que sur le CPA.

Dans nos conditions expérimentales à 50 et 80 °C, les formules de NURSE-SAUL, ou leurs variantes, ne peuvent pas représenter la cinétique du durcissement au-delà des premières heures d'étuvage. En effet, dans ces formules, le rapport des temps d'hydratation  $t_1/t_2$ , pour deux températures différentes  $\theta_1$  et  $\theta_2$ , reste constant quelles que soient les valeurs de  $t_1$  et  $t_2$ . Or nos courbes d'évolution des résistances à 50 et 80 °C coupent la courbe à 20 °C (fig. 12 et 13).

Les courbes de l'évolution isotherme à 50 et 80 °C (fig. 11, 12 et 13) tendent vers des valeurs asymptotiques plus faibles que celles des courbes à 20 °C. Un traitement thermique prolongé réduit donc l'accroissement de la résistance (Tableau VII).

Tableau VII : Coefficients d'amortissement

Mortier	Rc			Q		
	50 °C/20 °C	80 °C/20 °C	80 °C/40 °C	50 °C/20 °C	80 °C/20 °C	80 °C/40 °C
CPA	0,75	0,60	0,90			
CHF 1	0,50	0,40	0,70			
CHF 2	0,60	0,60	0,80			
CHF 3	0,60	0,75	0,75			

L'affaiblissement de la valeur asymptotique de la chaleur d'hydratation  $Q$  à 80 °C est moindre que celui des résistances  $R_c$ . Il peut être négligé au-dessous de 40 °C.

Par ailleurs, l'accroissement de la résistance des éprouvettes étuvées puis conservées à 20 °C pendant 28 et 90 jours (Tableau VI) suit, après étuvage, la courbe d'évolution relative du ciment à 20 °C.

A partir de ces observations, l'influence de la température sur le durcissement d'un ciment peut être caractérisée par l'énergie d'activation et l'amortissement. Le durcissement peut alors être considéré comme un système à variables séparées : température et temps. Son évolution à température variable dans le temps est déduite d'essais isothermes.

#### 4.2 Comportement des CHF à l'étuvage

L'étuvage est très favorable aux ciments peu réactifs comme les CHF 4 et 5 ou réagissant lentement comme le CHF 3. Après un traitement à 80 °C, tous trois acquièrent des propriétés mécaniques voisines de celles du CHF 2. Les grains de laitier et de sable s'entourent d'une épaisse couche hydratée, preuve que le laitier a beaucoup plus réagi qu'à la température ambiante (fig. 14).

Des cinq ciments, le CHF 1 est celui qui se comporte le moins bien à l'étuvage. Ses résistances n'atteignent que la moitié de leur valeur après 7 heures à 80 °C puis 28 jours à 20 °C (Tableau VI). A 80 °C, leur amortissement est de 40 % par rapport à 20 °C (Tableau VII). Après 7 heures à 80 °C, des amas de monosulfoaluminate en cristaux massifs forment une texture hétérogène peu favorable à la cohésion du mortier (fig. 15).

Fig. 14 : CHF 5 (13 h à 80 °C). Grandes zones de C-S-H (x) autour des grains de laitier (L).

Fig. 15 : CHF 1 (7 h à 80 °C). Monosulfoaluminate (M) en cristaux massifs.

#### 5. CONCLUSION

L'analyse, par différentes méthodes, de sept laitiers industriels à l'état anhydre et en cours d'hydratation a permis de confirmer et de préciser certains points tels que :

- 1) L'insuffisance des indices d'hydraulicité ne tenant compte que des éléments principaux Ca, Si, Al, Mg.
- 2) L'importance du degré de vitrification du laitier, de la composition minéralogique des mélanites de recristallisation, de la teneur en merwinite.
- 3) L'intérêt de la méthode de dissolution de KONDO et OHSAWA pour apprécier l'hydratation du laitier dans un ciment.
- 4) La facilité de classement des ciments au laitier par la mesure de leurs résistances mécaniques en compression sur mortier ISO.

La méthode la plus rapide d'évaluation de la réactivité hydraulique d'un laitier, dans un ciment, nous semble la mesure de la chaleur d'hydratation en pâte pure à 40 °C. Cette réactivité est révélée en quelques heures. Toutefois, au-delà de 40 °C, les comportements peuvent être différents de ceux observés à 20 °C (formation importante de monosulfoaluminates à 80 °C).

Dans un large domaine de température, la cinétique d'hydratation et les résistances mécaniques des ciments au laitier peuvent être connues après détermination de leur énergie d'activation et de leur coefficient d'amortissement. Des essais de courte durée devraient ainsi permettre d'estimer la résistance mécanique du ciment au jeune âge et à long terme.

*Remerciements : Nous remercions vivement de leur participation à cette étude Martine BADEYAN, Félix SAINZ, Claude TISSIER et Eddy ZWIANZEK.*

# Nouveaux aspects de l'hydratation de laitiers industriels

## *New aspects of industrial slags hydration*

P. FIERENS et P. POSWICK, Université de Mons (Belgique).

RESUME : L'hydratation d'un laitier vitreux industriel a été étudiée par exoémission électronique et thermogravimétrie. Les résultats obtenus permettent de penser que, comme pour la géhlénite et des laitiers synthétiques, la vitesse d'hydratation est liée notamment aux caractéristiques de centres correspondant à des défauts de structure de l'état vitreux et le mécanisme semble comporter au moins deux étapes : germination croissance autoinhibée et diffusion.

Il est également montré que, pour différentes durées d'hydratation, la résistance à la compression de microéprouvettes standard est d'autant plus grande que le nombre d'exoelectrons émis par le laitier non hydraté est élevé.

Enfin, il n'existe pas de relation simple entre la résistance à la compression et le degré d'hydratation d'un laitier industriel donné trempé dans différents milieux.

SUMMARY : Hydration of a glassy industrial slag has been studied by electronic exoemission and thermogravimetry. The results show that as in the case of gehlenite and synthetic slags, the hydration velocity depends among others on characteristics of centres corresponding to structure defects of the glassy state and the mechanism seems to include at least two steps : autoinhibited nucleation and diffusion controlled processes.

It is also showed that, for different hydration durations, the highest the number of exoelectrons emitted by the unhydrated slag, the highest the compressive strength of the hydrated one.

At last, there is no single relationship between compressive strength and degree of hydration of a given industrial slag quenched into different media.

## 1. Introduction

Une étude (1) de l'hydratation de la géhlé-nite et de laitiers synthétiques vitreux en présence d'hydroxyde de sodium a permis les conclusions suivantes.

Le mécanisme de la réaction comporte au moins deux étapes. L'hydratation commence au niveau des centres actifs de la surface du matériau selon un processus de germination autoinhibé ; lorsque les grains sont recouverts d'une couche continue d'hydrates, l'hydratation est cinétiquement contrôlée par un processus de diffusion jusqu'à la fin de la réaction.

La "qualité" de l'état vitreux de la géhlé-nite et des laitiers synthétiques est caractérisée par la probabilité  $p$  de sortie d'électrons piégés mesurée par thermoluminescence ou par le nombre  $n$  d'exoélectrons émis par le matériau dans des conditions standard. Il a été montré expérimentalement (1) que pour un matériau donné ces deux grandeurs sont liées par une relation linéaire  $\log n / \log p$ .

La probabilité  $p$  et le nombre d'exoélectrons  $n$  sont en rapport, l'une et l'autre, avec les défauts de structure de l'état vitreux du matériau et dépendent notamment des conditions de trempe du matériau fondu.

Le présent travail constitue l'extension de cette étude au domaine des laitiers industriels.

## 2. Préparation et caractérisation des échantillons

Le laitier industriel utilisé dans cette recherche provient de la Société Métallurgique Hainaut-Sambre (Belgique) et présente la composition chimique élémentaire donnée dans le tableau I.

TABLEAU I

Composition chimique élémentaire du laitier industriel étudié (poids %)

SiO <sub>2</sub> = 35,57 %	TiO <sub>2</sub> = 1,10 %
CaO = 39,74 %	MnO = 1,09 %
Al <sub>2</sub> O <sub>3</sub> = 12,39 %	Cr <sub>2</sub> O <sub>3</sub> = 0,10 %
MgO = 6,20 %	SrO = 0,11 %
FeO = 0,17 %	SO <sub>3</sub> = 0,23 %
Na <sub>2</sub> O = 0,64 %	Sulfures = 0,79 %
K <sub>2</sub> O = 1,30 %	P <sub>2</sub> O <sub>5</sub> = 0,15 %

Total = 99,58 %

Résidu insoluble dans les acides : 0,35 %

Le laitier fondu s'écoulant du haut fourneau a été trempé dans quatre milieux différents comme l'indique le tableau II.

TABLEAU II

Mode de trempe

Echantillon n°	Milieux de trempe
1	Azote liquide (-192°C)
2	Méthanol fondant (-80°C)
3	Eau glacée (8°C)
4	Air ambiant (20°C)

Les quatre échantillons ont été broyés et leur surface spécifique BET a été déterminée (Tableau III).

TABLEAU III

Surface spécifique BET

Echantillon	Surface spécifique (m <sup>2</sup> /g)
1	0.60
2	0.72
3	0.82
4	0.75

Les quatre échantillons sont entièrement vitreux : leur pic de dévitrification ATD s'est révélé identique.

Une tentative de les différencier par thermoluminescence a échoué. En effet, le laitier industriel contient des éléments mineurs tels que le fer, le manganèse, le chrome qui absorbent la lumière émise et rendent la mesure inopérante.

Les échantillons ont été caractérisés par exoémission électronique photostimulée.

Le tableau IV donne le nombre  $n$  d'exoélectrons émis dans des conditions standard.

TABLEAU IV

Exoémission électronique photostimulée ( $n$  = nombre d'exoélectrons)

Echantillon	$n$
1	202.10 <sup>3</sup>
2	738.10 <sup>3</sup>
3	481.10 <sup>3</sup>
4	595.10 <sup>3</sup>

Les quatre échantillons, de même composition chimique, présentent donc des différences de défauts de structure de l'état vitreux dues aux conditions de trempes.

De plus, on observe la séquence décroissante du nombre d'exoelectrons émis :

$$2 > 4 > 3 > 1$$

### 3. Cinétique de l'hydratation

Les quatre échantillons du laitier industriel ont été hydratés à 20°C par une solution aqueuse molaire d'hydroxyde de sodium, dans les mêmes conditions que la géhlénite et les laitiers synthétiques des travaux précédents.

La cinétique de la réaction a été suivie par thermogravimétrie. La perte d'eau chimiquement liée a été déterminée en fonction de la durée du contact laitier - solution d'hydroxyde de sodium.

Nos observations font l'objet du tableau V. On y trouve la perte d'eau observée et, en regard, la perte d'eau corrigée tenant compte de la surface spécifique de chaque échantillon.

Voir Tableau V

p.III - 11 6

La figure 1 illustre l'évolution des pertes de poids corrigées en fonction de la durée de l'hydratation.

La forme de ces courbes est analogue à celles obtenues, dans les mêmes conditions, avec la géhlénite et des laitiers synthétiques pour lesquels il a été montré qu'elles correspondaient sur le plan cinétique à un processus de diffusion. Cette conclusion paraît pouvoir être étendue au cas présent.

On observe que la vitesse d'hydratation des échantillons contrôlée par ce processus de diffusion suit la séquence :

$$2 > 4 > 3 > 1$$

C'est la même que celle des nombres d'exoelectrons émis par les laitiers non hydratés.

Il semble donc bien que pour le laitier industriel étudié, les défauts de structure de l'état vitreux aient une nette influence sur la vitesse de l'étape "diffusion" de l'hydratation, comme on peut l'observer dans le cas de la géhlénite et de laitiers

Fig. 1 : Perte d'eau chimiquement liée en fonction du temps : thermogravimétrie (gr. par 100 gr. de laitier)

synthétiques.

### 4. Résistance à la compression

Dans le but de réaliser une meilleur approche de la pratique, nous avons mesuré la résistance à la compression sur microéprouvettes. Celles-ci ont été fabriquées en gâchant 2,25 gr de laitier anhydre avec 0,25 gr d'une solution aqueuse d'hydroxyde de sodium normale (E/C = 0.11). Avec ce mélange, pétri pendant 3 minutes, on confectionne des microéprouvettes selon le procédé bien connu.

Les résultats des résistances à la compression après 3, 7, 15 et 28 jours sont donnés dans le tableau VI et la figure 2.

Les résultats montrent que, pour les quatre échantillons, la vitesse de croissance de la résistance à la compression suit la séquence :

$$2 > 4 > 3 > 1$$

c'est-à-dire la même que celle observée dans les mesures d'exoémission électronique photostimulée et de thermogravimétrie.

TABLEAU VI  
Résistance à la compression (MPa)

Durée (jours)	Echantillon			
	1	2	3	4
3	16	33	20	21
7	24	59	36	41
15	26	71	37	47
28	34	77	43	57

Fig. 2 : Résistance à la compression (MPa)

#### 5. Résistance à la compression et degré d'hydratation

Dans le graphique de la figure 3, nous avons indiqué la perte en eau chimiquement liée non corrigée (c'est-à-dire une expression du degré d'hydratation) en regard de la valeur correspondante, pour une même durée, de la résistance à la compression.

Fig. 3 : Relation entre le degré d'hydratation et la résistance à la compression.

Pour chaque échantillon, on observe une courbe distincte.

Cela signifie que, pour l'ensemble des quatre échantillons, il n'existe pas de relation simple entre la résistance à la compression et le degré d'hydratation du laitier, en dépit du fait que la composition chimique de celui-ci est constante.

L'examen du graphique montre qu'un degré d'hydratation déterminé (par exemple représenté par 10 gr/100 gr) correspond à différentes valeurs de la résistance à la compression d'un échantillon à l'autre :

échantillon	2	50 MPa
1	41 MPa	
4	35 MPa	
3	29 MPa	

La séquence décroissante est :

$$2 > 1 > 4 > 3$$

De plus, pour développer une résistance à la compression donnée (par exemple 40 MPa) il faut atteindre des degrés d'hydratation différents, obtenus d'ailleurs après des durées de conservation très variées :

échantillon	2	perte 9.0gr/100g	après 4 j.
1	perte 9.8gr/100g	"	28 j.
4	" 10.7gr/100g	"	7 j.
3	" 11.8gr/100g	"	18 j.

Ici la séquence décroissante est :

$$3 > 4 > 1 > 2$$

Ce résultat montre que la relation entre la résistance à la compression et le degré d'hydratation est complexe même pour un

laitier de composition chimique déterminé.

Les défauts de structure jouent un rôle à côté d'autres facteurs comme la texture des hydrates formés.

Cette conclusion est probablement valable également pour le ciment Portland et les ciments de laitier, systèmes pour lesquels il est beaucoup plus difficile de la mettre en évidence par l'expérience.

# Etude des Gaz des laitiers granulés de haut fourneau

## *Gases study of granulated blastfurnace slags*

B. COURTAULT - C.E.R.I.L.H. - Paris, France.

Les gaz des laitiers sont extraits par broyage sous vide. Ils sont identifiés et dosés par spectrométrie de masse quadripolaire.

Après une description du dispositif de broyage, les résultats obtenus avec huit laitiers sont présentés, les gaz rencontrés sont par ordre décroissant :  $H_2$ ,  $N_2$ , CO,  $H_2O$ , A,  $CO_2$ . Une dépendance est observée entre la broyabilité du laitier et la quantité d'hydrogène libéré.

The gases are extracted by grinding under vacuum. They are identified and determined by means quadrupole mass spectrometry. After a description of grinding device, the results obtained with eight slags are presented, the gases found are by decreasing order :  $H_2$ ,  $N_2$ , CO,  $H_2O$ , A,  $CO_2$ . A dependence is observed between the slag grindability and the quantity of the released hydrogen.

## 1. INTRODUCTION

La présence de gaz occlus et dissous intéresse à divers titres les silicates naturels et artificiels. Certaines laves basaltiques présentent des teneurs pondérales en gaz de 0,5 % à 1 % et voient leur dynamique d'éjection en dépendre largement. Des teneurs beaucoup plus faibles (<0,1 %) sont rencontrées dans les verres industriels et affectent leur propriétés.

La présence de gaz dissous dans les laitiers fondus de haut fourneau a retenu l'attention sur deux points : le rôle possible sur l'expansion du laitier solidifié de la désorption durant le refroidissement, l'influence de la vapeur d'eau solubilisée sur la teneur en hydrogène de l'acier.

Les teneurs en gaz généralement faibles des silicates conditionnent le choix des méthodes analytiques qui distinguent les gaz dissous et les inclusions gazeuses. Les premiers sont extraits par fusion sous vide et analysés en combinant les techniques de condensation fractionnée, de combustion, d'absorption et de micromanométrie ou plus directement de chromatographie. Les gaz des bulles du verre sont recueillis par bris de l'échantillon sous vide ou par fonction de la paroi. Enfin, il faut signaler l'emploi possible, en relation avec la morphologie du matériau, de méthodes microanalytiques non destructives utilisant les réactions nucléaires de basse énergie pour doser les gaz dissous et la microthermométrie ou la microsonde MOLE à effet Raman pour étudier les inclusions fluides des minéraux.

Le présent travail concerne l'étude des gaz des laitiers granulé de haut fourneau et fait appel à la spectrométrie de masse.

## 2. METHODES EXPERIMENTALES

### 2.1 Principe

Le laitier granulé, pris dans son état originel, est broyé sous vide jusqu'à différents stades de fragmentation, caractérisés par une courbe de distribution granulométrique, et les gaz libérés analysés par spectrométrie de masse.

### 2.2 Caractéristiques des matériaux étudiés

Un ensemble de huit laitiers de provenance française est examiné dont les analyses chimiques, limitées aux quatre constituants principaux sont données dans le TABLEAU I.

L'analyse radiocristallographique révèle pour deux laitiers (n° 3 et 7) l'absence de phases cristallines, le diagramme de diffraction X présente seulement un halo large et diffus de corps amorphe entre 0,1 et 0,2 en  $\sin \theta/\lambda$ . La présence de faibles quantités de merwinite est observée dans les autres laitiers qui présentent tous un rapport molaire  $Al_2O_3 / Al_2O_3 + MgO$  inférieur à 0,42 (1).

TABLEAU I

	SiO <sub>2</sub>	Al <sub>2</sub> O <sub>3</sub>	CaO	MgO
1	32,61	12,20	42,91	7,70
2	34,82	12,17	42,35	7,00
3	32,62	14,70	45,00	4,33
4	32,95	11,96	43,28	7,39
5	33,09	11,35	38,94	7,11
6	32,54	11,97	41,76	7,85
7	35,71	10,10	39,45	7,50
8	33,69	11,98	41,38	8,09

## 2.2 Appareillage

Le pot broyeur étanche est un cylindre de 35 mm de diamètre intérieur et 65 mm de longueur, muni d'une vanne latérale, dont les extrémités sont obturées par des plaquettes appuyées sur des joints toriques par des bouchons vissés. (Fig. 1)

Fig. 1 : Pot de broyage sous vide

La mise sous vide du pot est réalisée dans une enceinte annexe permettant successivement le dégazage dans de bonnes conditions de "conductance" - bouchon supérieur non vissé - puis la mise en place de cederrier. Une pompe turbomoléculaire produisant un vide très propre, exempt d'hydrocarbures, est utilisée. Le dégazage, contrôlé par jauge de Penning et jugé satisfaisant à pression inférieure à  $10^{-2}$  Pa, nécessite, en absence ou non d'échantillon de laitier (15g.), des temps respectifs de 20 et 90 minutes. Le broyage est réalisé au moyen d'un dispositif d'agitation du pot provoquant un mouvement violent, à trois composantes orthogonales, se répétant 1200 fois par minute (Mixer Mill 8000 SPEX).

Après broyage, le pot est mis en communication, par l'intermédiaire de sa vanne, avec une réserve de volume connu dans laquelle l'atmosphère gazeuse est détendue avant l'introduction, en régime moléculaire, dans le spectromètre de masse quadripolaire Q M M 17 RIBER, dont les procédés d'étalonnage ont été indiqués (2).

Le choix du matériau constitutif du pot broyeur, conduisant à un dégazage minimum en fonctionnement, est d'une importance primordiale. Dans la forme actuelle, le pot et les plaquettes sont usinés dans un acier élaboré sous vide E 40 CDV 20 AFNOR, contenant moins de 5 ppm de gaz résiduels. Les billes de broyage de 10 mm, au nombre de six, sont constituées d'un alliage chrome, tungstène, cobalt... (Alacrite 505). Le dégagement gazeux par minute de broyage est le suivant : hydrogène  $1 \cdot 10^{-3} \text{ cm}^3$ , méthane  $0,3 \cdot 10^{-3} \text{ cm}^3$  TNP (l'utilisation d'un acier inoxydable austénitique Z 2 CN 18-10 conduit à un dégagement global dix fois plus important, comportant des hydrocarbures à nombre de carbone plus élevé, accentué encore par l'emploi de carbure de tungstène).

## 3. RESULTATS EXPERIMENTAUX

Les gaz libérés d'échantillons de laitier (15g.) broyés respectivement 30 secondes, 1, 2 et 3 minutes sont caractérisés par leur spectre ionique et dosés par étalonnage de l'analyseur quadripolaire pour chaque constituant. Dans tous les laitiers, les gaz observés sont par ordre de décroissance en volume : H<sub>2</sub>, N<sub>2</sub>, CO, H<sub>2</sub>O, A, CO<sub>2</sub>. Les rapports masse/charge identiques des pics moléculaires N<sub>2</sub> et CO - 28 - conduisent à tenir compte, pour l'analyse,

de la contribution différente des ions  $N^+$  et  $CO^{++}$  à la masse 14.

Les distributions granulométriques déterminées par tamisage et au moyen du granulomètre à laser permettent de calculer les surfaces spécifiques des échantillons broyés. La relation entre celles-ci et le temps de broyage caractérise la broyabilité du laitier (Fig. 2).

La Fig. 3 présente l'évolution des dégagements gazeux du laitier N° 1.

La concentration en volume du gaz, supposée uniforme,  $c$ , dans le laitier est déduite du dégagement gazeux au moyen du modèle suivant. Le volume de gaz extractible d'un échantillon de masse  $M$ , constitué de grains de rayon  $r$  pour lesquels l'épaisseur de la couche d'extraction est  $y$ , est donné par :

$$v = \frac{M}{\rho} \left[ 1 - \frac{(r-y)^3}{r^3} \right] c \quad (1) \text{ avec } \rho \text{ masse volumique}$$

ou, en appelant  $S$  la surface totale de l'échantillon et  $V$  son volume :

$$v = V \left[ 3 \frac{S y}{3M} - 3 \left( \frac{S y}{3M} \right)^2 + \left( \frac{S y}{3M} \right)^3 \right] c \quad (2)$$

qui permet d'écrire en première approximation :

$$\left[ 1 - \frac{v}{V} \right] = \exp \left[ - \frac{S y}{M} c \right] \quad (3)$$

$$\text{et } \ln \left[ 1 - \frac{v}{V} \right] = - \frac{S y c}{M} \quad (4)$$

Fig. 2 : Distributions granulométriques et broyabilité (laitier N° 1)

Fig. 3 : Dégagements gazeux (laitier N° 1)

La relation (4) fournit une valeur de  $yc$ , par ailleurs une expression de  $c/y$  est obtenue par le tracé de  $v$  (relation (2)) en fonction de  $\sqrt{S}$ .

Les concentrations en volume ainsi calculées sont converties et rapportées à la masse de laitier, elles sont indiquées  $C_i$  - Concentration interne - dans le TABLEAU II. Le premier dégagement gazeux, observé après 30 secondes de broyage, est exprimé séparément en Concentration superficielle -  $C_s$  - par suite de l'application délicate du modèle à la morphologie d'origine des laitiers. Les profondeurs d'extraction,  $y$ , trouvées dans les différents cas sont de l'ordre de grandeur du micron.

TABLEAU II

Laitiers	1	2	3	4	5	6	7	8
Broyabilité $cm^2 g^{-1} min^{-1}$	290	200	270	125	175	260	284	250
$H_2$ $C_s$	3,2	9,6	2,1	4,3	5,0	4,5	1,3	5,5
$H_2$ $C_i$	20,7	18,6	5,6	3,0	3,2	7,6	9,7	13,5
$N_2$ $C_s$	1,6	1,4	0,9	1,5	2,0	2,5	0,6	2,1
$N_2$ $C_i$	6,3	2,0	2,6	2,5	2,8	2,4	1,8	-
$CO$ $C_s$	0,29	0,53	0,14	0,34	0,47	0,39	0,11	0,48
$CO$ $C_i$	1,13	0,75	0,39	0,58	0,44	0,38	0,24	-
$H_2O$ $C_s$	0,07	0,23	0,10	0,12	0,20	0,11	0,07	0,14
$A/N_2$ $X$	1,06	0,96	0,96	0,93	0,88	0,92	0,93	0,93

Ces résultats appellent les remarques générales suivantes :

- Les quantités totales de gaz des laitiers granulés ( $10$  à  $35 \cdot 10^{-3} cm^3 TPN g^{-1}$ ) sont inférieures d'un facteur 10 environ à celles mentionnées pour les laitiers fondus (3). Le dégazage lors de la trempe peut en être la cause ainsi que l'absence de réactions secondaires dans le procédé utilisé, contrairement à la méthode thermique d'extraction.

- L'oxygène n'est jamais rencontré contrairement à certaines données (4), de même le  $CO_2$  est présent en quantités limitées, toujours inférieures à  $3 \cdot 10^{-6} cm^3 TPN g^{-1}$  ( $6 \cdot 10^{-3} ppm$ ).

- L'hydrogène sulfuré est absent des laitiers granulés, alors qu'il est présent dans les laitiers cristallisés ainsi que de petites quantités d'hydrazine ( $N_2H_4$ ).

Par ailleurs, les concentrations des différents gaz conduisent aux observations suivantes :

- Le rapport  $\text{CO}/\text{N}_2$  est très variable - 0,15 à 0,37- et toujours inférieur à celui de l'atmosphère du haut fourneau - 0,4 environ -. Pour un laitier donné, il est identique dans la couche superficielle et dans la masse, cette homogénéité semble indiquer l'absence d'occlusion d'air durant la trempe.

- Le rapport  $\text{A}/\text{N}_2$ , voisin de celui de l'air atmosphérique, paraît résulter d'une dissolution physique de l'air dans le laitier fondu, avec absorption de l'oxygène. Les concentrations en azote, voisines de la solubilité physique dans les verres (5) présentent une décroissance avec l'augmentation de la viscosité du laitier fondu (Fig. 4) et, partant, la diminution de la basicité qui va à l'encontre des observations pour les verres. Toutefois la solubilité chimique qui est considérée pour ces derniers et la solubilité physique peuvent présenter une complémentarité (6)

Fig. 4 : Concentration en azote et viscosité du laitier fondu (valeur calculée)

- La présence d'hydrogène mérite une attention particulière. Sa solubilité dans les laitiers industriels et synthétiques est faible, 4-7 ppm (45-78  $10^{-3}\text{cm}^3 \text{TPN g}^{-1}$ ) (7), mais néanmoins supérieure aux concentrations observées. Sa présence, dans les gaz extraits par voie thermique des verres et des laitiers est due à la solubilité de la vapeur d'eau dans les silicates fondus où elle s'incorpore suivant des mécanismes variables avec la basicité du milieu (8).

Devant cette conjoncture, la possibilité de dégagement d'hydrogène par broyage d'un matériau hydroxylé, est examinée avec deux échantillons de verre de silice présentant une granulométrie originelle analogue aux laitiers et des teneurs en ions OH respectives de 950 et 100 ppm environ, déterminées par absorption du rayonnement infrarouge à  $2,72 \mu\text{m}$ .

Le comportement des verres de silice est plus complexe que celui des laitiers puisque, parallèlement à sa libération, l'hydrogène est adsorbé sur le matériau broyé. Deux modes de broyage et d'extraction permettent de départager les deux processus : un broyage continu avec extraction finale du gaz, un broyage discontinu avec extraction intermédiaire du gaz et accumulation Fig. 5. Ces deux types de données permettent, tenant compte d'une adsorption dans le modèle de Langmuir, avec dissociation de la molécule d'hydrogène et occupation de deux sites, de calculer le dégagement réel de gaz à chaque stade.

Fig. 5 : Dégagements d'hydrogène des verres de silice en fonction du temps de broyage

L'application à ce dernier du modèle analytique déjà présenté conduit aux concentrations. Les concentrations apparentes en hydrogène ainsi déterminées et les concentrations réelles sous forme d'ions OH sont données dans le TABLEAU III.

TABLEAU III

Verre de silice ppm OH	950	100
Concentrations $\text{H}_2$		
(a) apparente $10^{-3}\text{cm}^3 \text{TPN g}^{-1}$	8,31	1,41
(b) réelle $10^{-1}\text{cm}^3 \text{TPN g}^{-1}$	6,26	0,66
a/b %	1,3	2,1

Le rapport moyen des concentrations apparentes et réelles en hydrogène des verres de silice (1,7 %) conduit, par transposition aux laitiers, à des concentrations réelles en hydrogène allant de 0,18 à 1,22  $\text{cm}^3 \text{TPN g}^{-1}$  (270-1836 ppm OH). Celles-ci sont parfaitement compatibles avec les données sur la solubilité de la vapeur d'eau dans les silicates fondus, dans le domaine pratique de température de la granulation industrielle (9).

L'intérêt que suscite cette solubilisation apparaît plus certain, dans la mesure où la broyabilité du laitier semble en dépendre (Fig. 6).

Fig. 6 : Broyabilité des laitiers en fonction de la concentration en hydrogène

L'augmentation de la fragilisation avec l'incorporation d'ions OH ne peut dans le cas des laitiers, compte tenu de leur composition, s'expliquer par une rupture du réseau silicique comme l'indique la réaction (1). On peut toutefois penser que la réaction (2) concourt à cette action. En effet, la teneur importante en ions modificateurs permet de considérer les laitiers comme des verres inversés au sens donné par TRAP et SEVELS, c'est-à-dire possédant un réseau très fragmenté et une cohésion assurée de façon non négligeable par les liaisons cation-oxygène autres que Si-O.

#### 4. CONCLUSION

Le broyage sous vide du laitier permet d'extraire les gaz dissous physiquement et pour certains chimiquement. Les gaz rencontrés dans les laitiers granulés - H<sub>2</sub>, N<sub>2</sub>, CO, H<sub>2</sub>O, A, CO<sub>2</sub> - sont en concentration relativement faible (0,1 à 25 10<sup>-3</sup> cm<sup>3</sup> TPN g<sup>-1</sup>) eu égard aux teneurs mentionnées pour les laitiers liquides au sortir du haut fourneau.

La spectrométrie de masse est bien adaptée à la mesure de ces faibles quantités et conduit à des seuils de détection très faibles, de l'ordre de 10<sup>-3</sup> ppm.

La broyabilité apparaît en relation avec le dégagement d'hydrogène, lié à la solubilisation de la vapeur d'eau dans le laitier fondu ; une fragilisation du matériau par incorporation d'ions OH pourrait en être la cause.

## Ciment de laitier granulé sans clinker

### *Slag cement without clinker*

I. VOINOVITCH, chef du Service de Chimie,

M. RAVERDY, chef du Groupe des Liants Hydrauliques, Département Bétons et Métaux,

R DRON, chargé de recherche, Service de Chimie,

Laboratoire Central des Ponts et Chaussées, France.

RESUME : On a étudié la possibilité de réaliser un nouveau ciment à faible coût énergétique, composé de laitier granulé broyé, additionné de métasilicates alcalins qui jouent le rôle d'activants de prise. Le maximum de simplicité et de sécurité d'emploi est obtenu par incorporation de l'activant en poudre sous sa forme hydratée. La bonne maniabilité des mortiers obtenus avec ces ciments permet une réduction appréciable du rapport E/C. On a pu montrer également que l'addition de gypse, y compris sous forme de phosphogypse, améliore les résistances et permet de réduire à des teneurs économiquement valables les additions de métasilicate. Les résistances en compression et en flexion des mortiers et des bétons, classiques et allégés, sont comparables à celles obtenues avec des ciments Portland.

SUMMARY : The possibility of realizing a new cement, at a low energetic cost, composed of crushed granulated slag with addition of alkaline metasilicates as setting activators has been studied.

The best simplicity and utilization safety has been reached by incorporation of the activator under the powder hydrated form. The good workability of mortars obtained with these cements allows the ratio W/C to be greatly reduced. We have been able to point out that the addition of gypsum and also phosphogypsum (industrial waste) improves the strength and allows to cut down metasilicate additions : this procedure is the most economic. Compression and flexion resistances of mortars and concretes with standard and light aggregates are similar to those obtained with Portland cements.

## INTRODUCTION

Les études en vue de réaliser un nouveau liant par association du "verre liquide" (jldkoie steklo) et du laitier granulé de hauts fourneaux remontent aux années 1950 et sont à mettre à l'actif de P.P. Boudnikov et al. (1).

Ces chercheurs ont mis à profit l'observation faite en 1939 par A.I. Jilin (2) selon laquelle "le laitier granulé ajouté au verre liquide" en tant que charge inerte accélèrerait le durcissement du silicate de soude". V.I. Outkin (3), puis G.T. Poujanov (4) ont développé ces études dans les années 1955-1960 en examinant plus en détail différents paramètres tels que : - la finesse de broyage du laitier, - le module silicique du silicate de sodium, - les rapports de ces deux constituants, - la température.

Ces auteurs se sont également penchés sur l'aspect théorique du durcissement du liant ainsi activé. En bref, ils aboutissaient à la conclusion que cette prise était très accélérée par les activateurs alcalins (soude, silicate de sodium) ou sulfatiques (gypse) et l'élévation de la température du traitement hydrothermal (autoclavage).

En ce qui concerne le mécanisme d'action du silicate de sodium, ils retenaient l'hypothèse formulée par L.M. Rosenfeld (5) suivant laquelle l'action de l'eau sur le laitier commence par la dissolution et l'hydrolyse du sulfure de calcium avec transformation de ce dernier en  $\text{CaSO}_4$  et formation en fin de réaction de silicate de calcium hydraté (CSH) à partir d'autres formes de calcium et de silicium passant en solution. Ils estimaient également, en accord avec P.P. Boudnikov (6) que la prise des laitiers granulés pouvait être due à la formation de silicates, aluminates et sulfoaluminates hydratés. Procédant plutôt par déduction que par mise en évidence expérimentale, ces chercheurs ont eu le mérite d'adopter la théorie de Le Chatelier de : dissolution - cristallisation des hydrates et de faciliter ainsi les recherches ultérieures.

En se basant sur ces travaux, dans la période 1964-1966, V.I. Outkin (7), M.A. Matveev et G.T. Poujanov (8) ont développé les études sur la préparation des bétons à partir de tels liants à base de laitiers activés.

Conscients du rôle joué par l'eau dans la prise du laitier granulé, nous avons étudié ce facteur dans la période 1968-1970 en tenant compte des travaux de J. D'Ans et H. Eick (9), de G. Malquori et al. (10) et de Schwiete et al. (11), en aboutissant à la conclusion que l'eau a un double rôle

- elle dissout les éléments du laitier, à partir de la surface des grains, et c'est au sein de la phase aqueuse que prennent naissance les composés très peu solubles qui cristallisent ensuite. Le pouvoir dissolvant de l'eau est modifié par une élévation de pH qui assure le passage en solution de l'alumine;

- elle participe à la réaction de la prise, les composés qui prennent naissance étant des hydrates.

Le rôle de l'activant a été partiellement élucidé : il agit de façon certaine sur la solubilisation de la chaux, de la silice et surtout de l'alumine par élévation du pH. Ainsi, l'hydroxyde d'aluminium précipite en milieu ammoniacal (pH 11,5), mais il se redissout vers pH 12,5 par formation de l'ion  $\text{Al}(\text{OH})_4$ . Cette valeur est atteinte avec la chaux (pH 12,6) et a fortiori avec la soude ou le métagélat de sodium. Cela explique, sans doute, que l'activation puisse se faire indifféremment avec la soude, la chaux ou un silicate alcalin à la dose requise (pH du milieu > 12,6). Leur présence permet de passer d'un état métastable (phase vitreuse + eau) à un état stable (phase cristalline hydratée), par l'intermédiaire de l'état dissout, sans être obligatoirement consommé par la réaction. Enfin, toute action hydrophobante exercée au niveau des grains de laitier granulé inhibe la réactivité de ce dernier (12).

Les travaux approfondis que nous avons entamés en 1970 sur l'étude de la cohésion dans une pâte de laitier granulé (13) et le mécanisme de la prise du laitier granulé sous activation alcaline (14) nous ont permis d'aboutir à un procédé de préparation de ce type de ciment au laitier exempt de clinker pour lequel des brevets français ont été déposés en 1970 et 1971 (15, 16), antérieurement à un brevet japonais (17).

## 1 - PARTIE EXPERIMENTALE

Dans ce qui suit, nous relaterons brièvement les études effectuées sur pâtes pures de laitier granulé activé par différents silicates alcalins, puis sur des mortiers de différentes compositions, enfin sur deux types de béton, l'un à base de granulats classiques et le second avec des granulats allégés.

## 1.1 Essais sur pâtes pures

Ces essais préliminaires avaient pour but d'examiner sur un type de laitier granulé donné, broyé à une finesse voisine de 3 500 Blaine, les paramètres suivants :

- le module silicique (environ : 2,0 - 2,8 et 3,8) du silicate de sodium,
- les dosages en silicate, ajouté à l'eau de gâchage,

- les teneurs en eau,
- la température

et leur influence sur les caractéristiques telles que :

- l'allure de la prise (début et fin de prise),
- la maniabilité,
- les résistances mécaniques.

Le début et la fin de prise étaient suivis par l'aiguille Vicat, la maniabilité des pâtes sur le maniabilimètre Lesage-L.C.L., enfin les essais en flexion et en compression ont été effectués sur trois éprouvettes 4 x 4 x 16 cm à : 1, 2, 7, 28 et 90 jours.

Il ressort de ces essais :

- que le module silicique voisin de 2,0 conduit aux meilleurs résultats, à dosage égal, ce qui recoupe les observations faites par plusieurs auteurs (6, 7, 17),
- qu'en variant le dosage en silicate de sodium, au module silicique cité, de 2 à 10 % par rapport au poids du laitier on modulait la vitesse de la prise. Ainsi, pour des teneurs extrêmes (> à 9 %) on observait une véritable prise en masse de la pâte au bout de 5 minutes de mälaxage ....,
- que le début et la fin de la prise (testés à l'aiguille de Vicat) étaient fonction de l'activant employé. Ainsi, pour un dosage moyen de 4 à 6 %, ces caractéristiques sont voisines de celles observées avec le témoin,
- que la maniabilité était très améliorée, même pour des faibles dosages en activant, par rapport aux témoins (CPA 400). Les pâtes obtenues ont une consistance d'une "crème onctueuse". Les mesures faites au maniabilimètre Lesage-L.C.L. donnent des valeurs de 30 à 50 % supérieures à celles des témoins à mêmes teneurs en eau. On peut évoquer à cet égard les phénomènes de thixotropie pour expliquer ce comportement des pâtes : laitier - silicates de sodium à bas module silicique,
- que les teneurs en eau pour des dosages moyens en activant (4 à 6 %) peuvent être réduites de 12 à 15 % par rapport aux essais témoins effectués avec le ciment Portland, CPA 400 dans l'ancienne nomenclature française, par augmentation de la maniabilité des pâtes de laitier activé au silicate de sodium,

- que les retraites, par contre, étaient très supérieurs à ceux des témoins, de l'ordre de 15 à 20 %,

- qu'aux températures de  $+ 5, 20 \pm 1$  et  $70^{\circ}\text{C}$  le comportement des pâtes de laitier variaient en fonction du dosage en activant. Ainsi, pour un dosage élevé (8 %), le durcissement à  $+ 5^{\circ}\text{C}$  était plus rapide que celui des témoins. Pour une température élevée ( $70^{\circ}\text{C}$ ) et un dosage moyen en activant (4 - 5 %) les forces obtenues sont similaires à celles des témoins. Si l'on tient compte qu'une élévation de  $+ 10^{\circ}\text{C}$  double grosso modo la vitesse de prise, on peut moduler cette dernière par des dosages appropriés d'activant en fonction des forces que l'on désire obtenir.

## 1.2 Essais sur mortiers

De nombreux essais ont été effectués en vue de cerner la formulation optimale pour la confection ultérieure des bétons. On travaillait dans ce cas également sur des séries de 3 éprouvettes de 4 x 4 x 16, soumises aux essais de flexion (3) et compression (6).

En plus des paramètres et caractéristiques étudiés sur pâtes pures (1.1), on a examiné sur des mortiers du type Afnor (sable 1350 g, liant 450 g, eau 225 ml pour le témoin CPA 400) l'influence de :

- la nature du laitier (Hématite et Thomas),
- la finesse des laitiers (environ 3000 et 4000  $\text{cm}^2/\text{g}$  Blaine),
- la nature des silicates, à modules siliciques voisins, et leur forme : liquide, anhydre ou cristallisé,
- l'ajout des fillers : calcaires et siliceux.

Il ressort de ces essais que :

- La différence est à peine significative (5 % environ), lorsque l'on passe d'un laitier Thomas à un laitier Hématite,
- La finesse de broyage accroît nettement les performances, aussi bien en compression qu'en flexion. Une série d'essais effectuée avec du laitier granulé ultra fin (> à 5000  $\text{cm}^2/\text{g}$ ) a permis d'obtenir des performances de l'ordre de 20 % supérieures à celles obtenues avec les témoins (CPA 400), en ajustant les quantités d'eau compte tenu de la grande surface spécifique du laitier ultra fin.
- La nature chimique des silicates (de sodium ou de potassium) ou du silicate de potassium plastifié par une macromolécule

organique (brevet Rhône Poulenc), influe moins sur les performances mécaniques, surtout aux jeunes âges, que le module silicique de ces mêmes molécules, dont l'optimum se place également entre 1,9 et 2,2 dans cette série d'essais. Toutefois, des essais ultérieurs effectués avec du métasilicate de sodium au module voisin de 1,0 ayant donné les meilleurs résultats, c'est ce rapport que l'on a retenu pour les formulations des bétons.

De plus, le métasilicate de sodium anhydre (difficile à manipuler), ou cristallisé (hydrate à 5 H<sub>2</sub>O) peuvent être utilisés par simple incorporation dans le laitier en cours de malaxage.

- L'ajout de fillers à raison de 15 à 20 % en substitution au sable peut conférer des résistances améliorées. C'est le filler calcaire micronisé à grande surface spécifique qui se place en tête de ces essais.

Les caractéristiques étudiées en 1.1. : tenneurs en eau et maniabilité sont confirmées sur les mortiers et celles ayant trait aux retraits paraissent atténuées dans ce cas.

### 1.3 Essais sur bétons

Les études systématiques effectuées sur les mortiers (1.2) ont permis d'établir des formules de bétons avec du métasilicate de sodium utilisé à des concentrations de 4,5 à 9 % par rapport au poids du laitier broyé à la finesse de 3 000 cm<sup>2</sup>/g Blaine seulement. En plus du granulats classique, on a fait des essais avec des granulats légers. Dans ce dernier cas, on a pu réduire les quantités d'eau de gâchage (20 % environ) par rapport aux témoins (CPA). A 1 et à 5 ans d'âge les résistances sont, dans certains cas, légèrement supérieures à celles des témoins.

Dans ces essais sur béton avec des granulats légers, on a tenté également une activation mixte en ajoutant à du métasilicate de sodium (5,5 %), du gypse (4,5 %) employé sous forme de phosphogypse (déchet industriel). L'expérience montre que ce procédé est très valable puisqu'on trouve encore des résistances très voisines de celle des témoins (CPA). En outre, ce dernier procédé est plus économique.

Nous donnons, à titre d'exemple, la composition des formules employées ainsi que les résistances obtenues à : 7, 28, 90 jours et à 1, 3 et 5 ans.

Dans tous les cas, le métasilicate et le gypse exprimés en % sont rapportés au total "liant" (laitier + métasilicate + gypse).

## 2 - DISCUSSION DES RESULTATS

La plupart de nos mesures étaient déjà faites sur mortiers et bétons, y compris celles à 5 ans lorsque nous avons eu connaissance en 1977 des travaux similaires effectués en Pologne par A. Derdacka et J. Malolepszy (18). Ces auteurs activent le laitier par le carbonate de sodium, la soude ou le silicate de sodium au module silicique de 1,5. Ils constatent comme nous : "que la surface spécifique (S.sp) du laitier et la nature de l'activant utilisé ont une influence déterminante sur la résistance du liant. Si l'activant est la soude, avec une S.sp du laitier de 3 200 cm<sup>2</sup>/g, on obtient un liant dont la résistance est de 32 à 38 M Pa à 28 jours. Par contre, une élévation de la S.sp jusqu'à 4 200 cm<sup>2</sup>/g entraîne un accroissement de la résistance jusqu'à 44 M Pa. En utilisant comme activant du silicate de sodium, on obtient avec des degrés de broyage analogue du laitier, des résistances de l'ordre de 60 à 70 M Pa. Ces résultats ont été obtenus après traitement des mortiers par la vapeur à basse pression". Les résultats obtenus par les auteurs polonais recoupent les nôtres, à cette différence près qu'à la finesse > à 5 000 Blaine, on atteint à la température ambiante ce qu'ils obtiennent par autoclavage.

En ce qui concerne le mécanisme d'action, ils estiment, rejoignant en cela nos observations (12, 13, 14), que sous l'effet des activateurs alcalins cités, il y a passage en solution des oxydes donateurs de cristaux, tels que la gehlénite hydratée, l'aluminate tétracalcique et le silicate de calcium faiblement basique (CSH). Il y a tout lieu de croire que l'activation mixte employée dans nos essais sur bétons conduit en outre à la formation de l'ettringite qui contribue à une meilleure structuration de l'édifice. Enfin, un récent travail japonais fait mention de l'emploi du silicate de lithium dont l'efficacité serait supérieure à celle du silicate de sodium pour de telles activations, ce qui montre que cette voie continue à être explorée.

## RESISTANCE A LA COMPRESSION (C) ET A LA TRACTION PAR FENDAGE (F)

## SILICOCIMENT avec et sans gypse sur béton de granulats légers

	<u>7 jours</u>		<u>28 jours</u>		<u>90 jours</u>		<u>1 an</u>		<u>3 ans</u>

eau	( 19,35 l pour 4,5 % métasilicate 21,90 l pour 9 % métasilicate et témoin	eau	( 37,6 l ( (témoin) 49,5 l

## CONCLUSIONS

L'étude sur pâtes pures et mortiers de ciments de laitiers activés aux silicates alcalins à différents modules siliciques a permis d'établir que les meilleurs résultats sont obtenus avec le métasilicate de sodium (module silicique 1,0).

Cet activant augmente la maniabilité des pâtes de sorte que le rapport : E/C peut être réduit. Son emploi est compatible avec une augmentation de la finesse du laitier, qui améliore considérablement les propriétés mécaniques.

A partir de ces données, on a préparé des bétons (classiques et allégés) dont le liant était constitué par du laitier broyé à 3 000 cm<sup>2</sup>/g, additionné de métasilicate pentahydraté à des doses variant de 5 à 9 % par rapport au laitier. Les mesures de résistance à la compression et à la traction par fendage montrent que ces bétons sont comparables à ceux à base de ciment Portland. Un gypse modéré, par le phosphogypse, améliore les résistances et permet de réduire les doses de métasilicate.

Ce liant, à faible coût énergétique, pourrait être utilisé en construction routière et pour la production d'éléments préfabriqués.

# Cinetique de l'hydratation des ciments au laitier

## *Kinetics of slag cements hydration*

C. VERNET, E. DEMOULIAN, P. GOURDIN, F. HAWTHORN, Société des Ciments Français, CEREG, France.

### RESUME :

Après avoir étudié par ailleurs les mécanismes et la cinétique de l'hydratation des ciments portland, les auteurs appliquent ici la même méthode globale d'étude des suspensions concentrées, à l'analyse des phénomènes particuliers aux ciments à haute teneur en laitier.

Après une description rapide de la méthodologie et du choix des échantillons, ils montrent pour chaque étape réactionnelle, les particularités cinétiques des ciments considérés en fonction des différences minéralogiques et chimiques des clinkers et des laitiers utilisés.

L'interprétation des phénomènes est donnée dans le contexte des mécanismes généraux de dissolution-cristallisation, en utilisant les concepts de couplage chimique et de distance de précipitation. Les variations de  $S^{--}$  en solution laissent supposer la présence d'hydrates sulfurés. De même, l'observation des courbes de concentration en  $Cl^-$  permet d'étudier la séquence de précipitation des chloroaluminates.

Enfin, une comparaison est établie entre les réactions en suspension et en pâte pure, liant la cinétique aux résistances mécaniques et à l'évolution de la microstructure.

### SUMMARY :

Following another study of the mechanism and kinetics of portland cement hydration in concentrated suspension, the authors apply here the same method to the cements with high content of blast-furnace slag.

The method and the samples are shortly described. They show for each reaction period the differences observed between portland and slag cement according to chemical and mineralogical composition of clinkers and slags.

The phenomena are explained in relation with the general dissolution-crystallization mechanisms and using the concept of chemical couplings and precipitation distance. The evolution of  $S^{--}$  concentration let suppose the presence of sulphide hydrates. In the same way, the  $Cl^-$  evolution allows the study of chloroaluminates precipitation.

Then a comparison is established between suspension and cement pastes which connect kinetics with compressive strengths and microstructure developments.

## INTRODUCTION

Cette communication vise à étudier la cinétique de l'hydratation des ciments de laitier, avec la même méthode que celle appliquée à l'étude du CPA (3). Nous avons montré par des mesures cinétiques que pendant l'hydratation des clinkers, les mécanismes réactionnels sont essentiellement du type dissolution-cristallisation, selon l'hypothèse formulée dès 1887 par LE CHATELIER (1).

La composition ionique de la solution résulte donc à chaque instant de la différence entre vitesse de dissolution de l'anhydre et vitesse de précipitation de l'hydrate correspondant. L'énergie libérable par les anhydres permet de maintenir en permanence la sursaturation de la solution, produisant un déséquilibre thermodynamique, moteur de l'avancement des réactions.

Introduisant le concept de distance de précipitation des hydrates, nous avons expliqué le mode particulier de cristallisation du CSH et proposé une explication cinétique de ses changements de structure (2).

A l'aide d'un appareillage original, nous avons ensuite mis en pratique la mesure indirecte de la cinétique et de la séquence de l'hydratation des suspensions de ciments portland, avec un rapport eau/ciment (E/C) de 4. Cette étude (3) montre que  $K^+$  et surtout  $Na^+$ , sont d'excellents traceurs de l'hydratation du  $C_3A$  et que l'on peut repérer à l'aide des courbes de conductance, de pH et d'évolution ionique de la solution toutes les étapes de l'hydratation. Ceci nous a permis de mettre en évidence l'interdépendance étroite entre vitesses de réaction des constituants du ciment, causée par des couplages de nature thermique et chimique. D'autre part, les conditions opératoires à E/C = 4 conservent la séquence de l'hydratation par rapport aux mortiers, par contre l'échelle des temps est modifiée de manière telle qu'on obtient en une semaine des taux de réaction correspondant à plusieurs mois sur mortier. Ceci constitue un avantage précieux, lorsqu'on cherche à mesurer la vitesse d'hydratation du laitier, activé par le clinker, les réactions des laitiers étant toujours très lentes (5). Nous avons donc appliqué notre méthode à des suspensions de ciments au laitier, fabriquées à partir des clinkers étudiés précédemment (3) et de 3 laitiers représentatifs de la production française.

## 1/ METHODOLOGIE

## 1.1 - Choix des échantillons

Les 7 clinkers utilisés ont des compositions minéralogiques différentes (tableau I), aussi bien par la forme de l'alite que par la forme et la quantité de  $C_3A$  et par la teneur en sulfates alcalins. Leur comportement hydraulique en CPA (évolution de résistances en fonction du temps) est très variable.

Les 3 laitiers sont de provenances différentes et montrent des comportements hydrauliques différents, que nous avons étudiés par ailleurs (6). Leurs compositions chimiques, ainsi que les données minéralogiques et de structure que nous avons réunies, figurent aux tableaux II et III.

A l'aide des clinkers C1 à C7, broyés à 3500  $cm^2/g$  et des laitiers A, B et C, nous avons préparé deux séries de ciments au laitier dont nous avons étudié par ailleurs l'évolution des résistances mécaniques (6) ; une première série de caractéristiques suivantes :

- rapport laitier/clinker L/C = 4
- surface spécifique du laitier : 3500  $cm^2/g$
- gypsage : 3 % en  $SO_3$

et une deuxième série avec broyage séparé du laitier :

- L/C = 4
- surface spécifique du laitier : 6000  $cm^2/g$
- gypsage : 5 % en  $SO_3$ .

## 1.2 - Méthodes

Nous décrivons par ailleurs la méthodologie complète des mesures cinétiques (4). Son originalité réside dans l'utilisation du maximum de capteurs électrochimiques, de manière à ne laisser échapper aucun phénomène transitoire dans l'évolution ionique de la suspension. Des dosages chimiques séquentiels permettent de réétalonner périodiquement les capteurs, et de compléter l'investigation lorsqu'on ne dispose pas de capteur pour un ion donné ( $SO_4^{2-}$ ,  $H_2SiO_4^{2-}$ ). Des dosages de phases sont effectués par des méthodes physiques classiques (diffraction X, ATG, ATD) sur des fractions de solide, prélevées en cours de réaction. Des mesures thermiques sont réalisées simultanément et permettent ainsi d'obtenir une description complète des paramètres cinétiques, sous forme d'un diagramme d'évolution de la phase liquide, de la phase solide, et du flux thermique. Dans le cas présent, nous avons utilisé les capteurs électrochimiques suivants : conductance, pH,  $pK^+$ ,  $pNa^+$ ,  $pS^{--}$ ,  $pCl^-$ .

Les dosages chimiques séquentiels ont porté sur les ions  $Ca^{++}$ ,  $SO_4^{2-}$ ,  $H_2SiO_4^{2-}$ ,  $OH^-$ ,  $S^{--}$ ,  $Na^+$ ,  $K^+$ ,  $Cl^-$ .

Aux dosages de phases classiques, nous avons ajouté ici le dosage chimique du laitier résiduel non hydraté, par notre nouvelle méthode de séparation sélective (7).

### 1.3 - Mesures

De grandes précautions ont été prises pour assurer la validité des dosages : travail sous atmosphère d'azote, essais répétés, prélèvements et filtration par 2 méthodes de séchage (lyophilisation et lavage au méthanol), circuit d'analyse automatique de faible volume mort et exempt d'interférences entre capteurs.

Trois séries d'essais ont été effectuées :

- mélanges à 3500 cm<sup>2</sup>/g avec laitier A et chacun des 7 clinkers
- mélanges à 3500 cm<sup>2</sup>/g avec clinker C7 et chacun des 3 laitiers
- et 5 mélanges avec laitier à 6000 cm<sup>2</sup>/g soit 16 au total.

### 2/ RESULTATS

En comparant les diagrammes des 16 ciments au laitier et des CPA correspondants, nous avons constaté une différence beaucoup plus importante entre les CPA et les ciments au laitier, qu'entre ces derniers. Cependant l'examen des courbes fait apparaître dans tous les cas l'existence de 4 périodes au cours de l'hydratation.

A titre d'exemple, nous avons choisi ici 3 diagrammes, dont le premier rappelle l'allure obtenue pour les CPA (fig. 1) et les suivants montrent les particularités de deux ciments au laitier (fig. 2 et 3). En s'aidant de ces diagrammes, nous nous proposons maintenant d'étudier successivement chacune des périodes.

1ère période : (temps 0 à t<sub>1</sub>)

Nos observations nous conduisent à penser que le laitier participe aux réactions dès les premiers instants. Ces réactions sont initialement rapides, puis très vite ralenties, ce qui conduit à un taux de réaction très faible :

- la chute de SiO<sub>2</sub> en solution montre la précipitation de CSH ;
- l'aspect de la courbe des sulfures, en relation avec des mesures faites par ailleurs sur les laitiers seuls en suspension dans l'eau où dans une solution de chaux + gypse, peut être expliquée par une légère réaction du laitier. Cette dernière est cependant suffisante pour modifier les concentrations en Ca<sup>++</sup> en fin de période. En effet, au bout de 10 minutes on observe pour un même clinker, (C7) et 3 laitiers différents, les concentrations suivantes (à 3500 cm<sup>2</sup>/g)

C7 + Laitier	A	B	C	CPA C7
(Ca <sup>++</sup> ) mM/l t = 10 mn.	14	9	6	17

Ces valeurs varient comme le C/S du laitier : nous pensons que les différences observées sont dues à la fois aux variations de composition chimique et aux variations de vitesse de réaction de chaque laitier.

Pendant la 2ème période dite "période dormante", (temps t<sub>1</sub> à t<sub>2</sub>),

- la concentration en S<sup>2-</sup> reste constante et très faible, de même que le taux de réaction du laitier, inférieur à 2 % en fin de période ;
- le flux thermique est faible, mais, rapporté à la quantité de clinker, plus élevé que le CPA corres-

Fig. 1 : CPA C4

Fig. 2 : Ciment au laitier (A + C6)

Fig. 3 : Ciment au laitier (A + C4) + C1

pendant ;

les pentes des courbes de conductance sont plus élevées. Pour un même laitier, les différences d'allure des courbes de divers clinkers sont atténuées et ce, d'autant plus que le laitier est finement broyé. Le tableau IV donne, pour un même clinker, les valeurs des pentes des courbes de teneur en chaux, calculées à partir des courbes de conductance au temps  $t_2/2$ .

Tableau IV : Vitesses de sursaturation en chaux				
$\frac{dC}{dt}$ ( $t/2$ ) en $mM.l^{-1}.mn^{-1}$ Mélanges AC7, BC7, CC7				
Laitiers		A	B	C
3500 $cm^2/g$	dCa/dt	$4.10^{-2}$	$8.10^{-2}$	$9.10^{-2}$
	(Ca <sup>++</sup> ) temps $t_1$	14 mM/l	9 mM/l	6 mM/l
6000 $cm^2/g$	dCa/dt	$7.10^{-2}$		$8.10^{-2}$
	(Ca <sup>++</sup> ) temps $t_1$	9 mM/l		6 mM/l
C/S laitiers		1,33	1,24	1,18

On remarque les variations en sens inverse de  $dC/dt$  et de  $(Ca^{++})t_1$ .

A partir des teneurs en  $Ca^{++}$  variables au temps  $t_1$ , l'alite des 7 clinkers parvient donc, par une adaptation de sa vitesse de réaction, à créer au temps  $t_2$  un état de sursaturation en chaux du même ordre de grandeur que pour les CPA. Ceci nécessite une vitesse de réaction plus élevée du clinker pendant cette période, qui se traduit par un flux thermique plus élevé. Ce comportement s'interprète bien par le mécanisme de dissolution précipitation : la dissolution de l'alite est ici déplacée et accélérée par la réaction initiale du laitier, et par le rapport eau/clinker élevé conduisant à des concentrations en chaux plus faibles au temps  $t_1$ . La faible réaction du laitier entre  $t_1$  et  $t_2$  peut éventuellement participer à cette accélération.

### 3ème période (temps $t_2$ à $t_4$ )

Nous avons divisé cette période en deux étapes :

#### 1ère étape (temps $t_2$ à $t_3$ )

De même que pour les CPA, nous remarquons au temps  $t_2$  une chute de sursaturation en chaux, accompagnant la précipitation de la portlandite, mais nous n'observons plus ici de palier de concentration en chaux. La teneur en chaux diminue d'autant plus vite que la finesse du laitier est grande et pour un même clinker la pente est plus forte avec le laitier A qu'avec B et C. Le taux de réaction du laitier augmente significativement, de même que la teneur en  $S^{--}$ . Cependant, cette teneur ne correspond qu'au dixième de la quantité calculable d'après la consommation de laitier. Simultanément, les réactions des clinkers s'accélèrent. Le flux thermique augmente, de même que les concentrations en  $K^+$  et  $Na^+$ , indiquant la réaction du  $C_3A$ .

La 2ème étape (temps  $t_3$  à  $t_4$ ) se caractérise par la chute de concentration en  $SO_4^{--}$  qui fait suite à la disparition du gypse. A l'épuisement de  $SO_4^{--}$  succède la transformation ettringite - monosulfate, que nous avons observée en diffraction X, et qui s'accompagne d'une augmentation significative du flux thermique et des teneurs en  $Al_2O_3$  et  $SiO_2$  en solution. C'est pendant cette deuxième étape que nous observons

la réaction la plus rapide du laitier. De même, dans le CPA, on observe à ce moment, un maximum de vitesse d'hydratation des aluminates, suivi d'une reprise de l'hydratation de l'alite.

A ces remarques de caractère général s'ajoutent les particularités suivantes :

- le mélange A + C2 montre une chute de concentration en  $SO_4^{--}$  en deux étapes rapprochées, ce qui peut signifier que le  $C_3A$  cubique de C2 est totalement consommé avant la disparition complète de  $SO_4^{--}$ , qui est alors achevée par la réaction du laitier ;
- pour un certain nombre de mélanges, la solution passe dans le domaine sous-saturé en chaux, ce qui produit la dissolution de la portlandite, en particulier dans le cas des laitiers broyés à 6000  $cm^2/g$  ;
- les courbes d'évolution de  $S^{--}$  sont différentes selon le clinker et le laitier, mais nous observons pour tous les mélanges des variations brutales de la pente de ces courbes, indiquant une discontinuité des réactions produisant la disparition du sulfure. Parmi ces réactions, la formation d'hydrates analogues aux sulfoaluminates nous ayant semblé probable, nous avons tenté d'en faire la synthèse à partir de produits purs. Par réaction directe du  $C_3A$  avec un sulfure de sodium dans le rapport molaire :

en milieu tamponné à pH 12,55 par de la chaux saturée sous atmosphère d'azote, nous avons observé une diminution du sulfure en solution d'un tiers et la précipitation d'un composé de couleur verdâtre. Le diagramme de diffraction X du composé synthétisé est très proche de celui du  $C_4AHx$  et les raies du  $C_3A$  ont presque totalement disparu. D'après la littérature,  $x$  peut varier de 7 à 19 et dans les conditions opératoires, l'examen de la raie principale à 8,05 Å fait penser que le composé hydraté est proche de  $C_4AH_8$ . Compte tenu de la disparition d'un tiers des sulfures, on peut penser à la formation d'un hydrate qui fixe  $S^{--}$ .

Une recherche ultérieure sera consacrée à l'étude de la précipitation des aluminates hydratés en présence de  $SO_4^{--}$  et de  $S^{--}$  car nous pensons que la rétention des sulfures est due à un composé de type sulfuroaluminate hydraté.

Pendant la quatrième période (temps  $t_4$  à  $t_5$ ), les réactions sont ralenties par la diffusion à travers les hydrates. La teneur en chaux de la solution diminue progressivement et passe en général au-dessous de la saturation en fin d'essai ( $\approx 100$  h). Lorsque la vitesse de réaction a été suffisante dans les étapes précédentes, on peut observer une ou plusieurs transformations successives des sulfoaluminates, décelables par les variations simultanées du % de laitier, de la conductance, des teneurs en  $K^+$ ,  $Na^+$  et  $S^{--}$ , et de petits pics de flux thermique.

#### Influence de $Cl^-$

De faibles quantités de chlorures (0,2 % NaCl) modifient la cinétique de l'hydratation des ciments de laitier : l'évolution des résistances mécaniques est significativement plus rapide aux premiers âges.

En suspension à  $E/C = 4$ , nous observons les particularités suivantes des courbes d'évolution (fig. 3).

- La chute plus brutale de  $SO_4^{--}$ , annonçant l'épuisement du gypse en fin de 3ème période ( $t_3-t_4$ ) aboutit non plus à une valeur presque nulle de la concentration, mais à un palier intermédiaire voisin de 1 mM/l.
- La teneur en  $Cl^-$  varie très peu jusqu'en fin de 3e période.
- La chute de  $(Cl^-)$ , annonçant la formation bien connue de chloroaluminate, intervient aussitôt après la chute de  $SO_4^{--}$ .  $(Cl^-)$  ne s'annule pas complètement et atteint un palier au bout de quelques dizaines d'heures. A ce moment ( $SO_4^{--}$ ) diminue à nouveau jusqu'à une valeur très faible,  $(Cl^-)$  augmente,  $(S^{--})$  chute très rapidement,  $(Na^+)$  et  $(K^+)$  augmentant, chacune des variations brutales de concentration étant accompagnée d'un pic thermique. Ceci montre un mécanisme complexe où coexistent des effets antagonistes de solubilité et de vitesse de précipitation des chloro, sulfo et sulfuroaluminates, qu'il faudrait étudier plus en détail.

### 3/ INTERPRETATION - COMPARAISON AVEC LES OBSERVATIONS SUR MORTIERS

#### 3.1 - Correspondance entre cinétique et microstructure des hydrates

Mme. REGOURD (5) a montré que dans les ciments au laitier, le CSH peut se déposer loin des grains de clinker : par exemple sur les grains de laitier ou sur une lame porte-objet. Ses observations faites au MEB s'interprètent parfaitement dans le modèle cinétique théorique basé sur le mécanisme du type LE CHATELIER. Les variations de la taille des particules de CSH en fonction du temps correspondent bien aux distances de précipitation que nous avons définies : peu après la prise, la solution reste suffisamment sursaturée et l'on obtient des fibres courtes, puis, la teneur en calcium diminuant, la distance de précipitation augmente et les CSH forment alors une texture alvéolaire, en cristallisant loin de l'interface, en reliant les CSH précédents et en comblant peu à peu les pores.

La cristallisation des "CSH du laitier" dans une zone compacte autour des grains de laitier s'explique par la formation d'une partie des CSH, de composition très différente, dans la zone de diffusion entourant le grain.

D'autres CSH se forment simultanément dans les pores lointains et leur formation contribue d'ailleurs à la corrosion de la portlandite.

Nous n'observons pas systématiquement la disparition de la portlandite : à 3500  $cm^2/g$ , seul le mélange CIA parvient dans le domaine sous-saturé (à 18 h). Les autres montrent une très faible teneur en portlandite. Par contre, avec les laitiers broyés à 6000  $cm^2/g$ , tous les mélanges passent dans le domaine sous-saturé en chaux lorsqu'ils approchent du minimum de conductance signalant la chute de  $SO_4^{--}$  (entre 15 et 30 h selon le cas) et la reprise des réactions du laitier. D'après les observations de Mme. REGOURD, on peut donc faire la correspondance des échelles des temps pour cette période : 28 jours en pâte pure correspondant à environ 20 h en suspension : l'ettringite atteint alors sa teneur maximum. Nous situons de même la période de fortes teneurs en monosulfoaluminates à 50 - 60 h en suspension et à 3 mois - 6 mois en

pâte pure.

#### 3.2 - Cinétique et évolution des résistances

Dans l'hypothèse de dissolution-cristallisation, les taux de réaction obtenus après le maximum de sursaturation sont reliés à la vitesse de chute de la teneur en calcium en solution. Nous avons donc cherché à mettre en relation la chute de conductance correspondante, directement mesurable sur l'enregistrement, avec les résistances mécaniques mesurées sur mortiers. Pour le laitier A, associé à divers clinkers, on constate une corrélation assez bonne, entre le rapport  $X_m/X_M$  des conductances au minimum et au maximum de la courbe, et les résistances sur mortier ISO à 7j, 28j, 3 mois et 6 mois. Les écarts par rapport aux droites de régression s'expliquent bien en tenant compte dans la corrélation des variables supplémentaires  $C_3A$  tétragonal et  $K_2SO_4$ , dont les alcalins perturbent à la fois la conductance et les résistances. C'est ainsi par exemple qu'à 3500  $cm^2/g$ , à l'échéance de 6 mois :

- 93 % des variations de R sont expliquées par la chute de conductance seule,
- 96,6 % des variations sont expliquées par la chute de conductance et le  $C_3A$  tétragonal,
- 98 % des variations sont expliquées par la chute de conductance, le  $C_3A$  tétragonal et la teneur en  $K_2SO_4$ .

De même, pour la série à laitier variable et clinker C7, on obtient une variation de résistance sensiblement linéaire en fonction de  $X_m/X_M$ .

Il n'est évidemment pas question d'utiliser de telles relations pour faire des prévisions de résistance : le nombre d'essais n'est pas assez élevé ici pour que l'on puisse généraliser les relations obtenues. Mais ces relations montrent que lorsqu'on opère dans des conditions standardisées, on peut mettre en évidence l'influence de la cinétique chimique sur les résistances : les paramètres de porosité et de mise en oeuvre étant rendus sensiblement constants.

Par ailleurs, les coefficients obtenus dans la relation résistances =  $A + B (X_m/X_M) + C(K_2SO_4) + D(C_3A)$  nous fournissent des indications sur les influences de chacune des variables.

Le coefficient D est positif et faible par rapport à B. Effectivement, le rôle bénéfique de  $C_3A$  tétragonal n'apparaît pas clairement dans nos mesures cinétiques. Tout au plus peut-on supposer que les alcalins libérés au cours de son hydratation contribuent à diminuer la solubilité de la portlandite, en élevant le pH. Ceci peut diminuer la vitesse de redissolution de la portlandite lorsqu'on atteint le domaine de sous-saturation en chaux.

Le coefficient C est faible par rapport à B et négatif à long terme. L'action de  $K_2SO_4$  du clinker n'est en effet pas évidente, dans des mélanges où le clinker est dilué par 4 parties de laitier. Dans les CPA, nous avons dégagé les mécanismes accélérateurs de l'hydratation de  $C_3A$  par  $K_2SO_4$  : celui-ci déplace au départ les réactions de l'alite en consommant le calcium pour former de l'ettringite. Il en résulte une accélération de la dissolution de l'alite, et par couplage thermique, une accélération de l'hydratation du  $C_3A$  (2). D'autre part,  $K_2SO_4$  agit sur la structure des CSH, ce qui peut s'expliquer en utilisant le concept de distance de précipitation : l'abaissement de la concentration en chaux ci-dessus diminue la sursaturation en CSH et sa vitesse de précipitation : il cristallise plus loin de l'interface, ce qui retentit sur les résistances.

On conçoit donc que, dans les ciments au laitier,  $K_2SO_4$  puisse avoir deux effets antagonistes sur les résistances, l'ettringite y étant au départ relativement abondante par rapport au CSH.

### 3.3 - Correspondance des échelles des temps sur mortier et en suspension

Ne disposant actuellement que de peu de renseignements sur les taux de réaction du laitier des ciments en pâte ou mortier, nous pouvons faire les remarques suivantes :

- dans l'établissement de la correspondance des temps, il faut prendre comme origine commune le "début de prise chimique" situé sur mortier peu avant le temps de "prise rhéologique" mesuré à la soude de VICAT.
- les observations du paragraphe 3.1 confirment l'hypothèse faite par ailleurs pour les CPA (3), d'une loi non linéaire de correspondance.

### CONCLUSION

Notre méthode d'étude globale des suspensions concentrées est donc riche d'informations.

Elle permet de montrer qu'au cours de l'hydratation des ciments au laitier, il existe des périodes caractéristiques où laitier et aluminates réagissent simultanément mais à des vitesses différentes. La séquence de l'hydratation des ciments au laitier est donc la même que celle des CPA. Ce comportement commun est lié à l'existence de phénomènes de couplage chimique et thermique des vitesses de réaction que nous avons mis en évidence.

La présence de sulfures solubles dans les laitiers, et l'intervention d'un mécanisme de dissolution-précipitation associant le laitier et des hydrates sulfurés, ajoutent quelques particularités au comportement des ciments au laitier. Ces phénomènes rendent difficile l'utilisation directe de  $S^{2-}$  comme traceur de l'hydratation du laitier. Les variations brutales de  $S^{2-}$  sont cependant liées à la séquence des réactions et peuvent servir de points de repère.

Nous montrons également que le laitier, par sa consommation de chaux, augmente la vitesse de dissolution de l'alite pendant toute l'hydratation, ce qui conduit en général à une sous-saturation et une consommation de la portlandite dans l'étape finale.

L'influence des éléments mineurs et des aluminates du clinker est fortement atténuée dans les mélanges riches en laitier. Par contre, des adjuvants comme  $Cl^-$ , en faible teneur, en formant des hydrates intermédiaires parviennent à modifier la séquence et les vitesses des réactions, ce qui produit des effets importants relativement à leur quantité.

Enfin, nous avons relié les échelles des temps en suspension et en pâte pure, la cinétique aux résistances mécaniques et à l'évolution de la microstructure. Cette évolution est en parfait accord avec les mécanismes de dissolution-précipitation, dont l'importance pendant l'hydratation devient évidente.

### REMERCIEMENTS

Les auteurs tiennent à remercier Mme CAULLIER et M. MAES, techniciens au CEREG, pour les nombreux dosages chimiques et diffractométriques effectués.

## Approche du problème de la réactivité du laitier granulé

### *Approach to the problem of the reactivity of granulated slag*

R. DRON, docteur-ingénieur,  
F. BRIVOT, chimiste,  
Laboratoire Central des Ponts et Chaussées, Service de Chimie, France.

RESUME : Les rapports des flux de dissolution des éléments du laitier (Ca, Al, Si) dans une liqueur de soude à pH 12,6 sont constants dans l'étape qui précède l'apparition de la sursaturation par rapport au C-S-H. Ils tendent ensuite vers les valeurs correspondant à la dissolution congruente du laitier.

Pour un élément donné, la concentration instantanée varie comme le logarithme du produit temps x surface spécifique x rapport laitier/eau.

En fixant ces trois facteurs à des valeurs arbitraires choisies de façon à rester dans le domaine de dissolution pure, c'est-à-dire avant toute précipitation d'hydrates, on peut caractériser de façon comparative la réactivité des différents laitiers par simple détermination des concentrations des éléments en solution.

SUMMARY : The ratio of the dissolution fluxes of the elements of slag (Ca, Al, Si) in a soda liquor with a pH of 12.6 are constant at the stage which precedes the onset of supersaturation with respect to C-S-H. They then tend to move towards the values corresponding to the congruent dissolution of the slag.

For a given element, instant concentration is a logarithmic function of the product time x specific area x slag/water ratio.

By fixing these three factors arbitrarily so as to remain in the pure dissolution area, that is, before precipitation of hydrates takes place, the comparative reactivity of various slags can be characterized simply by determining the concentrations of the elements in solution.

Par contact prolongé avec une solution alcaline, le laitier granulé donne naissance à des composés hydratés qui sont à l'origine des phénomènes de prise et de durcissement. Nous avons montré (1, 2) que le nombre et la nature de ces phases hydratées sont conformes aux conclusions d'ordre thermodynamique tirées de l'étude des équilibres hétérogènes qui régissent le système  $\text{CaO}$ ,  $\text{Al}_2\text{O}_3$ ,  $\text{SiO}_2$ ,  $\text{H}_2\text{O}$ , le laitier anhydre restant hors équilibre. Ces conclusions tendent à prouver que les échanges de matière se font par l'intermédiaire de la solution, selon le schéma de Le Chatelier.

La nature des hydrates étant indépendante du laitier d'origine, leur précipitation ne dépend que de facteurs extérieurs à celui-ci et seule l'étape initiale de dissolution peut être mise en relation avec la réactivité intrinsèque du laitier.

Des informations sur la réactivité peuvent donc être recueillies par l'étude de l'évolution de la solution. Le problème a été abordé par Kondo (3) qui a étudié la solubilisation par l'eau pure et par l'eau de chaux de verres ayant la composition de la gehlenite. Il a montré que par des extractions répétées par l'eau pure, on dissout des quantités décroissantes de chaux, de silice et d'alumine dans des rapports qui restent voisins de 6, 2 et 1. En mettant ce verre en présence d'eau de chaux, il a constaté que les concentrations en alumine ou en silice de la solution croissent et passent par un maximum au bout de 24 heures environ, et que la chaux suit une évolution inverse. Seule la seconde expérimentation est à l'image de ce qui se passe dans la réalité. Il est toutefois difficile d'en tirer des enseignements sur le plan de la réactivité car la décroissance de la concentration en chaux, puis en silice et en alumine, ne peut s'expliquer que par des précipitations. Cet écueil est lié au haut niveau initial de la concentration en calcium, qui fait que le produit de solubilité des hydrates est atteint pratiquement dès le début de l'expérience.

Pour surmonter la difficulté, nous avons remplacé l'eau de chaux par une solution de soude de même pH et nous avons cherché des conditions opératoires permettant d'explorer l'étape précédant la précipitation des premiers hydrates. Il faut pour cela utiliser un échantillon de faible surface spécifique et adopter un rapport de masse eau/laitier maximal.

#### METHODOLOGIE ET APPAREILLAGE

L'étude comparative de différents laitiers exige que l'on fixe avec précision la surface de contact. On y parvient en travaillant sur un échantillon constitué par des grains isodimensionnels, obtenus par calibrage entre deux tamis consécutifs (80 et 100  $\mu$ ) et rebroyage du refus jusqu'à épuisement de la fraction supérieure à 100  $\mu$ .

Le contact statique de cet échantillon avec l'eau intergranulaire confinerait le rapport des masses au dessous de l'unité. Or des essais préliminaires nous ont montré que pour étaler suffisamment la phase initiale de dissolution pure, il convenait de porter ce rapport à des valeurs de l'ordre de 100.

Ayant exclu la mise en suspension par brassage, qui provoque une attrition des grains se traduisant par une augmentation considérable de la surface spécifique, nous avons été amenés à retenir le principe de la lixiviation en circuit fermé.

On utilise le montage de la figure 1.

Figure 1 - Appareil de lixiviation en circuit fermé.

La solution est forcée par une pompe péristaltique à travers un lit de 2 g de grains contenus dans une colonne de verre de 13 mm de diamètre intérieur. La hauteur du lit est de 17 mm, le volume de la solution de 260 ml et le débit de 360 m/min. Le temps de rotation de la solution est donc de :  $260/360 = 0,72$  minutes, soit 43 secondes. Le rapport massique eau/laitier est égal à 130.

Nous avons vérifié que la solubilisation de la verrerie était négligeable.

## EXPERIMENTATION

Nous avons utilisé trois laitiers caractéristiques de la production française :

Laitier n° 1 : laitier de fonte Thomas, granulation ordinaire.

Laitier n° 2 : laitier de fonte hématite, granulation ordinaire.

Laitier n° 3 : laitier de fonte hématite, granulation spéciale, dit "bouleté" ou "pellétisé".

Les compositions chimiques sont les suivantes :

	CaO	Al <sub>2</sub> O <sub>3</sub>	SiO <sub>2</sub>	MgO
n° 1	43,7	14,8	33,0	4,4
n° 2	40,5	12,5	34,8	7,7
n° 3	41,0	12,1	34,7	7,0

La solution est préparée par dissolution de 1,6 g de soude pure dans 1 litre d'eau distillée fraîchement bouillie et refroidie à l'abri du CO<sub>2</sub> atmosphérique.

On remplit la colonne avec la solution et on introduit le laitier de façon à ce qu'il sédimente en un lit homogène. On établit alors la circulation de la solution pendant le laps de temps voulu, au terme duquel on soutire la liqueur et on la soumet à l'analyse. Chaque essai est répété 6 fois pour les temps courts et 2 fois seulement pour les temps longs. Chaque série correspondant à un temps donné est faite sur le même échantillon de laitier, après deux cycles de 20 minutes, destinés au nettoyage de la surface, et qui ne sont pas pris en compte.

La silice est dosée par colorimétrie du complexe silico molybdique bleu, l'alumine par complexométrie à l'EDTA et le calcium par complexométrie à l'EGTA.

## RESULTATS ET COMMENTAIRES

Le tableau I donne les concentrations exprimées en mg/l de SiO<sub>2</sub>, Al<sub>2</sub>O<sub>3</sub> et CaO des li-  
queurs d'extraction après des cycles de différentes durées.

Le résultat le plus frappant est la forte diminution de la vitesse de solubilisation au fur et à mesure que la solution se charge ce qui rend caduc notre espoir de caractériser la réactivité par le flux de dissolution, puisque ce dernier n'est pas constant. On voit toutefois que pour des temps égaux, les quantités dissoutes sont significativement supérieures d'environ 30 % dans le cas du laitier n° 1, par rapport aux deux autres, qui donnent des valeurs sensiblement voisines.

TABLEAU I

temps (minutes)	10	20	40	80
laitier n° 1				
SiO <sub>2</sub>	8,4	13,6	18,2	23,4
Al <sub>2</sub> O <sub>3</sub>	4,4	7,1	9,6	11,6
CaO	13,8	21,1	30,0	37,0
laitier n° 2				
SiO <sub>2</sub>	6,9	10,3	13,4	16,2
Al <sub>2</sub> O <sub>3</sub>	3,0	4,4	5,9	7,2
CaO	10,7	16,3	21,5	26,8
laitier n° 3				
SiO <sub>2</sub>	6,0	9,0	14,7	17,9
Al <sub>2</sub> O <sub>3</sub>	2,5	3,8	6,1	7,2
CaO	9,2	14,2	20,7	27,2

Un examen plus attentif des chiffres trouvés révèle un fait assez remarquable : la constance aux écarts analytiques près, des rapports des concentrations en silice, alumine et chaux (tableau II).

TABLEAU II

temps (minutes)	10	20	40	80	laitier d'origine
laitier n° 1					
CaO/SiO <sub>2</sub>	1,65	1,55	1,64	1,58	1,32
Al <sub>2</sub> O <sub>3</sub> /SiO <sub>2</sub>	0,527	0,523	0,526	0,498	0,45
CaO/Al <sub>2</sub> O <sub>3</sub>	3,12	3,19	3,12	3,17	2,95
laitier n° 2					
CaO/SiO <sub>2</sub>	1,55	1,58	1,60	1,65	1,16
Al <sub>2</sub> O <sub>3</sub> /SiO <sub>2</sub>	0,43	0,43	0,44	0,44	0,36
CaO/Al <sub>2</sub> O <sub>3</sub>	3,56	3,68	3,63	3,75	3,24
laitier n° 3					
CaO/SiO <sub>2</sub>	1,53	1,58	1,40	1,52	1,18
Al <sub>2</sub> O <sub>3</sub> /SiO <sub>2</sub>	0,42	0,42	0,413	0,402	0,35
CaO/Al <sub>2</sub> O <sub>3</sub>	3,68	3,63	3,55	3,77	3,39

Le rapport CaO/SiO<sub>2</sub> est sensiblement le même pour les trois laitiers et voisin de 1,6. Par contre, le rapport Al<sub>2</sub>O<sub>3</sub>/SiO<sub>2</sub> est significativement différent dans le cas du laitier n° 1 (0,52) comparativement aux laitiers n° 2 (0,44) et n° 3 (0,41).

Les valeurs de ce rapport sont à rapprocher des rapports correspondants dans les laitiers eux-mêmes (dernière colonne du tableau II). La comparaison montre que le laitier ne se dissout pas de façon globale : parmi les éléments structuraux de la phase vitreuse, ce sont les plus riches en calcium et en aluminium qui passent préférentiellement en solution.

#### SIGNIFICATION STRUCTURALE DES RAPPORTS CONSTANTS

Il résulte de la théorie statistique que nous avons proposée (4), en généralisant la théorie thermodynamique de Masson (5), que les verres à moyenne teneur en silice sont formés de chaînes silicatées droites et ramifiées (fig. 2). La longueur de ces chaînes n'est pas uniforme comme dans un cristal mais elle est distribuée suivant une progression géométrique.

Figure 2 - Structure des verres à moyenne teneur en silice.

Par ailleurs, les éléments structuraux :

sont distribués de part et d'autre de la basicité moyenne suivant une loi binomiale. Cela signifie qu'un verre contient des éléments structuraux plus basiques et des éléments structuraux moins basiques que le cristal de même composition.

Les rapports trouvés sont assez proches des rapports théoriques  $\text{CaO}/\text{SiO}_2 = 1,633$  et  $\text{Al}_2\text{O}_3/\text{SiO}_2 = 0,425$  qui correspondraient au composé fictif  $\text{C}_7\text{S}_4\text{A}$ , ou encore  $2\text{C}_3\text{S}_2, \text{CA}$ . On peut donc interpréter la solubilisation initiale du laitier comme le passage sélectif

en solution des éléments structuraux de la rankinite, soit  $\text{SiO}_3^{3-}$  et de l'aluminat monocalcique, soit  $\text{AlO}_2^-$ .

L'écriture des réactions d'hydratation de ces éléments :

et

montre que l'ion  $\text{OH}^-$  n'intervient pas dans le premier membre que par conséquent l'attaque est hydrolytique et non hydroxylique. La première des deux réactions montre même que des ions hydroxyle sont formés au cours de ce processus, ce qui explique la réaction alcaline du laitier.

La mobilisation de ces éléments "hydrauliques" doit laisser en place un squelette spongieux formé par les éléments moins basiques ( $\text{SiO}_3^{2-}$ ) et acides ( $\text{SiO}_2$ ) qui restent disponibles pour une mobilisation du type pouzzolanique, mais sur lequel, entre temps, des fixations topochimiques (d'ion  $\text{Ca}^{2+}$  et  $\text{OH}^-$ ) ne sont pas à exclure.

#### EXPERIMENTATION COMPLEMENTAIRE

Par suite du ralentissement progressif du flux de dissolution, il est difficile, dans les conditions opératoires décrites plus haut, d'explorer l'étape de sursaturation, dont la mise en évidence est fondamentale dans la démonstration du processus dissolution-précipitation, et à plus forte raison, l'étape de précipitation des hydrates. L'avancement de la réaction variant approximativement comme le logarithme du produit  $t\text{Sm}/e$ , l'étude de ces étapes n'est possible, dans des temps compatibles avec l'expérimentation qu'en augmentant le rapport laitier/solution (m/e) ou la surface spécifique S. Dans les essais à 80 minutes, le produit  $t\text{Sm}/e$  atteint la valeur de  $160 \text{ minutes} \cdot \text{cm}^2$ . Il est possible, sur le même montage, de travailler sur 50 g de grains calibrés de même surface spécifique ( $250 \text{ cm}^2/\text{g}$ ), de sorte que pour 60 minutes, le produit  $t\text{Sm}/e$  est de l'ordre de 3 000.

On obtient alors les résultats suivants sur le laitier n° 1 :

$\text{SiO}_2$	33,5 mg/l	C/S = 1,50
$\text{Al}_2\text{O}_3$	16,5 "	A/S = 0,49
CaO	50,0 "	C/A = 3,03

On constate que les rapports commencent à s'infléchir pour se rapprocher de ceux du laitier.

A ce stade, la solution est déjà sursaturée par rapport au C-S-H. En effet, d'après Greenberg et al. (6), le produit de solubilité de C-S-H est de  $10^{-7}$ , c'est-à-dire que :

$$[Ca^{2+}] [SiO_4H_2] = 10^{-7}$$

Le pK de la deuxième acidité de  $SiO_4H_4$  étant voisin de 12,6, à pH 12,6, qui est précisément celui des solutions que nous employons, la moitié de la silice est sous forme  $SiO_4H_2^-$ , l'autre moitié étant sous forme  $SiO_4H_2$ .

Le produit des concentrations en chaux et silice, exprimées en g/l, est donc :

$$CaO \times SiO_2 = 2.10^{-7} \cdot 56.60 = 672.10^{-6}$$

soit 672 si elles sont exprimées en mg/l.

Nos propres déterminations nous conduisent à une valeur plus élevée, de l'ordre de 1 000 à 1 200. En tout état de cause, pour 33,5 mg/l de silice et 50 mg/l de chaux, le produit est égal à 1 675 et dépasse nettement le produit de solubilité. Nous sommes bien dans le domaine de sursaturation, ce que confirme la précipitation de ces solutions lorsqu'on les conserve 24 heures.

L'étape de précipitation du C-S-H peut être atteinte par mise en contact prolongé de laitier broyé à 3 000 cm<sup>2</sup>/g, avec un rapport m/e = 0,1. Le procédé de lixiviation n'est plus utilisable et on se contente d'une simple mise en suspension par brassage. Au bout de 7 jours, sur le laitier n° 1, on obtient les résultats suivants :

SiO <sub>2</sub>	6 mg/l
CaO	203 mg/l
Al <sub>2</sub> O <sub>3</sub>	55 mg/l

Le produit SiO<sub>2</sub>, CaO a alors pour valeur 1 218, ce qui montre que l'équilibre dynamique est atteint. L'accumulation de la chaux en solution montre que l'on précipite un C-S-H dont le rapport C/S est inférieur à celui des fractions du laitier qui se dissolvent.

Une dernière série d'essais, dont les conditions opératoires pourraient servir de base à la définition d'un essai de réactivité, montre que l'on passe, avant le début de la précipitation du C-S-H, par un stade de dissolution quasi congruente. On opère avec 2,5 g de laitier broyé à 3 000 cm<sup>2</sup>/g, mis en suspension pendant 10 minutes avec 250 ml de solution de soude à 1,60 g/l. On laisse décanter 5 minutes, on filtre sur millipore et on dose les trois éléments. Les résultats sont les suivants :

TABLEAU III

Laitier n° 1		Solution		Laitier
SiO <sub>2</sub>	35 mg/l	C/S	1,34	1,32
Al <sub>2</sub> O <sub>3</sub>	16 "	A/S	0,46	0,45
CaO	47 "	C/A	2,94	2,95
Laitier n° 2				
SiO <sub>2</sub>	29 mg/l	C/S	1,38	1,16
Al <sub>2</sub> O <sub>3</sub>	10 "	A/S	0,36	0,36
CaO	40 "	C/A	3,81	3,24
Laitier n° 3				
SiO <sub>2</sub>	26 mg/l	C/S	1,31	1,18
Al <sub>2</sub> O <sub>3</sub>	10 "	A/S	0,38	0,35
CaO	34 "	C/A	3,40	3,39

## CONCLUSION

La réactivité des laitiers peut être définie comme le taux de dissolution dans une solution sodique de même pH que l'eau de chaux, pour une surface spécifique, un rapport e/c et un temps standardisés, avant que n'interviennent les précipitations d'hydrates.

Notre expérimentation montre que les réactivités se classent de la même façon que l'on opère au stade initial de dissolution non congruente ou au stade plus tardif de dissolution quasi congruente.

La réactivité semble être en relation directe avec la richesse du laitier en éléments structuraux silicatés basiques SiO<sub>3</sub><sup>2-</sup> (et donc avec la basicité) d'une part et avec celle des éléments alumineux AlO<sub>2</sub><sup>-</sup> (et donc avec la teneur en alumine) d'autre part, ce que confirme l'expérience pratique.

## Valorization of basic oxygen steel slags

### *Valorisation des scories d'aciéries BOP*

C.M. GEORGE, Technical Manager, Lafarge Fondu International,  
F.P. SORRENTINO, Research, Scientist, Lafarge S.A., France.

RESUME : Les problèmes posés par les scories d'aciéries BOP,

- instabilité dimensionnelle due à une teneur en chaux libre, haute et variable,
- manque d'activité hydraulique

ont pu être résolus par l'utilisation en cours d'affinage de la fonte, d'un nouveau fondant synthétique à base de  $\text{CaO}$ ,  $\text{MgO}$ ,  $\text{Al}_2\text{O}_3$  et oxyde de fer. Les nouvelles scories ainsi produites présentent une activité hydraulique intéressante avec une teneur en chaux libre basse tout en permettant l'élaboration d'acier de qualité choisie.

La préparation de telles scories est brièvement évoquée dans cette communication, suivie de la présentation de l'étude sur leurs propriétés minéralogiques et hydrauliques.

SUMMARY : The problems of dimensional instability due to a high and variable free lime content in BOP slags as well as their lack of hydraulic activity have been overcome by the use of a new slag forming agent. This synthetic material, combining  $\text{CaO}$ ,  $\text{MgO}$ ,  $\text{Al}_2\text{O}_3$  and iron oxide in specific proportions when added to the converter during refining leads to final slags with a consistently low free lime content and useful hydraulic properties, without prejudice to the conversion of iron into steel.

This paper deals briefly with the preparation of such slags and then reports the study of their mineralogy and hydraulic behaviour.

## INTRODUCTION

An important method of reducing energy consumption in the production of cement consists of adding to the clinker, natural pozzolanes, fly ash, etc., Blast Furnace Slags in particular, principally in granulated or pelletised form are now quite widely used. By contrast, steel making slags arising from the BOP find little application, (1).

The potential interest in BOP (or LD) slags stems from the large quantities arising (50 M tonnes per year, world wide) and their chemical and mineralogical composition which is similar to that of cement, (Table I).

Amongst many attempts to find outlets for steel slag in the construction industry may be cited :

- use as an aggregate, for road foundations and in road surfaces (2, 3, 4, 5) ; the high density and free lime content of the slag hinders this application ;
- use as an addition to Portland cement in a manner analogous to that of Blast Furnace Slag. For this purpose it is necessary to eliminate reactive free lime in steel slags chemically (carbonation) or by long term weathering (5, 6) which is neither cheap nor convenient ;
- use as a raw material for manufacture of Portland cement clinker, as a source of lime and silica (7) ; this offers little if any savings in energy.

The use of steel slags is thus limited by the following main technical factors :

- heterogeneity,
- free lime content,
- absence of hydraulic activity.

The first two factors result from incomplete reaction during the simultaneous production of steel and slag in the refining process - a method of overcoming this should thus open uses for such slags while also improving the refining of iron into steel.

The research and development described in this paper provide a method of achieving this result, producing homogeneous low free lime slags and also imparting hydraulic activity without prejudice to the manufacture of good quality steel by the conventional BOP route.

## PRINCIPLE FOR THE PRODUCTION OF HYDRAULIC STEEL SLAG FOR THE CEMENT INDUSTRY

This development is based on introducing into the BOP converter at the beginning of the refining process a prefired flux (\*) of chosen composition :  $\text{CaO} - \text{Al}_2\text{O}_3 - \text{MgO} - \text{Fe}_2\text{O}_3$ . The effect on the physico-chemical interactions between metal and slag which result have been described previously (8, 9, 10). The resulting steel making process compares with traditional practice as follows :

Classical process	Modified process
Raw materials	Iron + Scrap
Oxygen	Oxygen
Iron oxide	Iron oxide
$\text{CaO} - \text{MgO}$	$\text{CaO}$
Flux (fluorspar)	Prefired flux (CAMFlux) $\left\{ \begin{array}{l} \text{CaO} \\ \text{Al}_2\text{O}_3 \\ \text{MgO} \\ \text{Fe}_2\text{O}_3 \end{array} \right.$

(\*) In cement technology,  $\text{CaO}$ ,  $\text{Al}_2\text{O}_3$ ,  $\text{MgO}$ ,  $\text{Fe}_2\text{O}_3$  is abbreviated to C, A, M, F. Hence the name CAMFlux has been chosen for this new material.

Table I : Compositions of slags, fly ash and cements %

Chemical Composition	Blast Furnace Slag	BOP steel slag	Fly ash		Portland cement	Aluminous cement
CaO	45	47	3.5	45	64	40
$\text{SiO}_2$	33	13	54	18	20	5
$\text{Al}_2\text{O}_3$	15	1	30	12	6	40
Iron oxide	1-2	25	10	7	2	15
MgO	5	6	2.0	1.8	2	
MnO	0.5	5			0	
$\text{P}_2\text{O}_5$		2			0	
$\text{S} + \text{SO}_3$	1.0	0.1	0.5	6	2.5	0.1
Mineralogical Composition						
	glass	$\text{C}_2\text{F}$	glass	glass	$\text{C}_3\text{S}$	glass
	$\text{C}_2\text{AS} - \text{CS}$	$\text{C}_2\text{S}$	AS	$\text{C}_2\text{AS}$	$\text{C}_2\text{S}$	CA
			S		$\text{C}_4\text{AF}$	$\text{C}_4\text{AF}$
	$\text{C}_2\text{S}$	(Mn.Mg.Fe.Ca)O			$\text{C}_3\text{A}$	$\text{C}_2\text{S}$

Products	Steel	Steel
	Classical slag	Modified slag
CaO	40 - 50	40 - 50
SiO <sub>2</sub>	8 - 20	8 - 20
FeO	20 - 30	15 - 20
MgO	2 - 12	2 - 12
Al <sub>2</sub> O <sub>3</sub>	0 - 2	5 - 15
MnO	3 - 6	3 - 6
P <sub>2</sub> O <sub>5</sub>	1 - 2.5	1 - 2.5
Free CaO	5 - 15	1 - 5

The new slag thus differs from classical BOP slag in having a higher alumina content and a lower iron oxide content.

#### STUDY OF NEW HYDRAULIC STEEL SLAG

##### Preparation

Semi-industrial trials, in a 5 tonne converter were carried out to produce two types of slag, one based on conventional materials, the other obtained with the aluminous flux (CAMFlux), of average composition: CaO = 50 %, Al<sub>2</sub>O<sub>3</sub> = 25 %, MgO = 5 %, FeO + Fe<sub>2</sub>O<sub>3</sub> = 15 %, SiO<sub>2</sub> = 5 %.

Table II shows the typical compositions of the slags obtained.

Table II

	Classical Slag	Aluminous Slag
SiO <sub>2</sub>	9.61	9.0
CaO	44.1	45.8
Al <sub>2</sub> O <sub>3</sub>	0.9	11.4
MgO	10.4	7.2
MnO	4.4	3.8
P <sub>2</sub> O <sub>5</sub>	2.4	2.2
Fe <sup>++</sup>	19.7	12.6
Fe <sup>+++</sup>	8.6	8.7
Free CaO	10.8	3.8

##### Mineralogy

The calculated phase compositions of the standard and modified slags, assuming the aluminoferrite phase to have the formula C<sub>4</sub>AF, are shown in table III.

Table III : Calculated phase compositions of slags

	Classical Slag	New Slag
Solid solution C <sub>2</sub> S - C <sub>3</sub> P	31 - 6	22 - 5
Ferrite phase	16	32
(Mn-Mg-Fe-Ca)O solid solution	36	20
Free CaO	11	4
C <sub>3</sub> A	0	17

The actual phase compositions were studied by X-ray diffraction, optical microscopy and electron microprobe analysis.

X-ray diffraction and optical microscopy confirmed the presence of C<sub>2</sub>S - C<sub>3</sub>P, calcium ferrite or calcium aluminoferrite and the (Mn, Mg, Fe, Ca)O solid solution. C<sub>3</sub>A could not be positively identified however and this implies that the calcium aluminoferrite has an A/F ratio greater than unity. This was confirmed by the microprobe which showed the presence of the following phases :

##### Classical slag :

- Periclase, average composition  
Mg<sub>0.7</sub> Ca<sub>0.03</sub> Mn<sub>0.03</sub> Fe<sub>0.2</sub> O  
The composition varied widely from the centre of grains to their surfaces.
- Magnesio wustite, solid solution  
Mg<sub>x</sub> Ca<sub>y</sub> Mn<sub>0.11</sub> Fe<sub>0.6</sub> O  
with 0.12 < x < 0.21 and 0 < y < 0.14
- Lime solid solution  
Ca<sub>0.83</sub> Mg<sub>0.08</sub> Mn<sub>0.04</sub> Fe<sub>0.05</sub> O
- Dicalcium silicate  
Ca<sub>2</sub> Si<sub>0.91</sub> P<sub>0.1</sub> Fe<sub>0.01</sub> O<sub>4</sub>
- Calcium aluminoferrite, average  
Ca<sub>2.2</sub> Si<sub>0.03</sub> Al<sub>0.4</sub> Fe<sub>1.4</sub> O<sub>5</sub>  
with variable composition within grains suggesting that equilibrium had not been reached.

##### New slag :

- Magnesio wustite, solid solution  
Mg<sub>0.47</sub> Ca<sub>0.05</sub> Mn<sub>0.07</sub> Fe<sub>0.45</sub> O
- Dicalcium silicate  
Ca<sub>2</sub> Si<sub>0.89</sub> P<sub>0.1</sub> Al<sub>0.02</sub> Fe<sub>0.01</sub> O<sub>4</sub>
- Calcium aluminoferrite  
(Ca<sub>1.8</sub> Fe<sub>0.2</sub>) Al<sub>1.32</sub> Fe<sub>0.59</sub> O<sub>5</sub>  
all of very homogeneous composition.

##### Hydraulic activity

This aspect of the study is concerned with three points :

- the hydraulic activity of the phases formed in the new aluminous slags,
- the durability of cements containing these slags as a function of their free lime and magnesia contents,
- the influence of the MnO and P<sub>2</sub>O<sub>5</sub> contents of these slags on their suitability for cementitious applications (a factor for which very little information has yet been reported).

Samples of the slags, ground to cement fineness (3600 cm<sup>2</sup> g<sup>-1</sup>, Blaine) were made into neat pastes with a water/slag ratio of 1. The hydration kinetics were followed by calorimetry and measurement of bound water, free water being eliminated at each age of measurement, by washing with acetone and drying with ether.

Reaction with water appears to take place in 2 stages as shown in figure 1.

Fig. 1 - Hydration of classical and aluminous slags measured as bound water

Short term hydration rates increased with the alumina content of the slags due to reaction of the calcium aluminoferrite phase. Very little hydration occurred with the classical slag in which the ferrite phase contained only minor quantities of alumina. Quite a significant degree of early hydration occurred with the new, alumina-rich slags. This result is in agreement with the work of Carlson (11) on pure aluminoferrites.

A second, later hydration, common to both slag types, corresponds to the reaction of dicalcium silicate.

X-ray diffraction of the reacted slags showed that the product of ferrite hydration in the classical slag was  $\text{C}_4(\text{A},\text{F})\text{H}_x$  whereas that of calcium aluminoferrite hydration in the new slag was  $\text{C}_3(\text{A},\text{F})\text{H}_6$ . In both cases these hydrates are transformed into monocarbo calcium aluminoferrite hydrate, in contact with air.

Neither slag is sufficiently hydraulic to be used alone as a cementitious alternative to normal Portland cement, so that studies of strength development were made by mixing them with Portland cement. Mortars were prepared with the composition, in parts by weight :

Sand, 6 ; Slag, 1 ; Portland cement, 1 ; Water, 1.

The chemical composition of the slag/cement portion of the mix were thus :

Table IV

	Portland cement + classical slag	Portland cement + aluminous slag
CaO	54.9	54.4
SiO <sub>2</sub>	15.3	16.4
Al <sub>2</sub> O <sub>3</sub>	2.62	7.30
MgO	5.6	3.3
Fe oxide	15.6	15.0
Free CaO	6.1	2.8
MnO	2.2	1.6
P <sub>2</sub> O <sub>5</sub>	1.2	1.05

The quantities of free lime and magnesia in the mix based on classical slag are high and the test specimens disintegrated by cracking after a few days storage under water. The specimens containing the new aluminous slag remained intact. Some compressive strength test results are given in table V.

Table V : Compressive strengths (MPa) of slag - Portland cement - Sand mortars (AFNOR P 15-403)

Age (days)	2	7	28	90
Portland cement + classical LD slag	7	19	disintegration by cracking	
Portland cement + aluminous LD slag	12	25	42	49
Portland cement + Blast Furnace Slag	16	30	45	53

In order to check on later age effects due to free MgO, similar mortar specimens based on the new aluminous slags, were subjected to the standard autoclave test (ASTM C 151) with fully satisfactory results.

#### CONCLUSIONS

1. A slag forming flux based on a prereacted composition containing  $\text{CaO-Al}_2\text{O}_3\text{-MgO-Fe}_2\text{O}_3$  has been developed for use in BOP steel making converters.
2. This flux produces an end slag which is alumina rich by comparison with traditional BOP-slugs.
3. The fluxing action of this new material (CAMflux) leads to a more homogeneous end slag and hence a low free lime content.
4. The alumina in the flux is retained in the end slag as calcium aluminoferrite, which induces early hydraulic activity not displayed by conventional slags. This enables such slags to be added to Portland cement with results at least as beneficial as those normally achieved with good quality Blast Furnace Slags.

5. The hydraulic activity of calcium aluminoferrite in BOP slags increases with alumina content, in agreement with previous observations on pure materials.
6. The MnO and P<sub>2</sub>O<sub>5</sub> contents (normal) of the aluminous slag do not inhibit its hydraulic activity.
7. The low free lime and free MgO contents of the new slags containing alumina results in freedom from cracking or long term swelling when these slags are used in concrete mixed with Portland cement.
8. Use of the new flux does not affect steel quality and provides for the first time a viable route to the utilisation of BOP steel slags in the construction industry. Since very little of the large quantities of steel slags of conventional composition are utilisable at present, this development offers considerable potential savings in energy.

# Laitiers et clinkers - influences réciproques

## *Blast-Furnace slags and clinkers - mutual influences*

F. HAWTHORN, E. DEMOULIAN, P. GOURDIN, C. VERNET, Société des Ciments Français, CEREG, France.

### RESUME

Les auteurs ont étudié des mélanges à 80 % de laitier vitrifié de haut fourneau et 20 % de clinker avec ajout de gypse réalisés à partir des combinaisons deux à deux de 7 clinkers et 3 laitiers broyés à deux finesses différentes, représentatifs de la production française. Ils ont montré par analyse de la variance, la prépondérance de la qualité et de la finesse du laitier sur les performances de ce type de ciment.

La minéralogie des clinkers a plus d'influence quand les laitiers sont broyés normalement que quand ils sont surbroyés.

La courbe d'évolution des résistances de ces mélanges est très différente de celle des ciments portland réalisés avec les mêmes clinkers. L'influence de la teneur en sulfate de calcium et d'une faible augmentation de la teneur en clinker ont aussi été étudiées.

### SUMMARY

The authors have studied mixes containing 80 % blast-furnace vitrified slag and 20 % clinker with an add of gypsum, prepared with combinations two by two of 7 clinkers and 3 blast-furnace slags ground to two different degrees of fineness, representative of french production. They showed, with the help of the analysis of variance the preponderance of type and fineness of slags in the performances of these cements.

The clinker mineralogy has more influence with the normally ground than with the finely ground slag.

The evolution curve of compressive strength of these mixes is generally different from that of portland cement made with the same clinkers. They also studied the influence of the sulphate content and of a slight increase in clinker.

## INTRODUCTION

Quand on fabrique des ciments qui contiennent 80 % de laitier, 20 % de clinker et du gypse, la qualité principale recherchée est la résistance chimique des bétons à l'eau de mer et aux eaux séléniteuses. Dans le passé, ces ciments développaient des résistances moyennes jusqu'à 28 jours et fortes à long terme.

Depuis quelques années, on demande à ce type de ciments des performances mécaniques plus importantes. Industriellement, il est connu que la qualité du laitier a un rôle important sur les performances mécaniques, mais l'influence du type de clinker n'a pas été aussi clairement mise en évidence.

Nous présentons ici les résultats d'une étude où nous avons utilisé 7 clinkers de compositions minéralogiques différentes et 3 types de laitier. Nous avons déterminé l'influence, sur les résistances, de la minéralogie du clinker, en relation avec la finesse et le type du laitier, et, sur quelques exemples, celle du taux de sulfate et de petites augmentations de la proportion de clinker.

## ECHANTILLONS ETUDIES - RESULTATS

Nous avons sélectionné trois laitiers français représentatifs de trois types de production dont la composition chimique et le procédé de vitrification diffèrent, ainsi que sept clinkers de la SOCIÉTÉ DES CEMENTS FRANÇAIS dont les compositions minéralogiques couvrent l'ensemble des valeurs habituellement rencontrées.

Les caractéristiques des laitiers sont données au tableau I.

Dans celui-ci,  $\phi$  représente le diamètre moyen des hétérogénéités de densité, déterminé par diffusion centrale des rayons X.

Tableau I : Composition chimique des laitiers

K <sub>2</sub> SO <sub>4</sub>	0,0	0,0	0,0	0,8	2,3	0,6	0,0

Nous avons broyé séparément les clinkers à 3500 cm<sup>2</sup>/g, les laitiers à 3500 et 6000 cm<sup>2</sup>/g (Blaine) et le gypse à 0 % de refus au tamis de 40  $\mu$ m. Nous avons ensuite effectué 42 mélanges à 80 % de laitier et 20 % de clinker en réalisant tous les couples laitier-clinker possibles. Le gypse a été ajouté à raison de SO<sub>3</sub> = 3 % pour les laitiers à 3500 cm<sup>2</sup>/g et SO<sub>3</sub> = 5 % pour les laitiers à 6000 cm<sup>2</sup>/g. Les résistances à la compression à 1, 2, 7, 28, 90, 180 et 360 jours ont été déterminées et les résultats figurent au tableau III.

Tableau III : Résistances à la compression en MPa des 42 mélanges

## INFLUENCE DU CLINKER ET DU LAITIER

Nous avons testé l'influence du clinker sur les résistances de ce type de mélange d'une part, et d'autre part, l'existence de couples, type de laitier-type de clinker, conduisant à des résistances significativement différentes de celles des autres couples. Pour cela, nous avons préalablement dépouillé les résultats par analyse de la variance, nous les avons ensuite mis en relation avec les caractéristiques des laitiers et des clinkers, puis nous avons recherché les associations laitier-clinker favorables ou défavorables.

## 1 - Etude par analyse de la variance de l'influence du laitier, du clinker et de la finesse

L'analyse de la variance est une technique statistique qui permet, grâce à un plan d'expérience, d'étudier avec un minimum de mesures, l'influence sur une grandeur de plusieurs facteurs variant simultanément. L'analyse des résultats permet de conclure à l'influence ou non d'un paramètre ou d'un couple de paramètres. Les paramètres sont, dans notre cas, le type de laitier, la finesse du laitier et le type de clinker, les variables sont les résistances aux différentes périodes de durcissement.

## 1.1 - Analyse à 2 dimensions

Pour étudier l'influence du clinker et du laitier, nous avons préalablement effectué des calculs d'analyse de la variance à deux dimensions.

Nous posons symboliquement :

V = variance ; L = laitier ; C = clinker ; F = finesse  
R = résiduelle.

Pour une même finesse de laitier, nous obtenons les résultats suivants :

Tableau IV		$V_L/V_R$	$V_C/V_R$
Laitier 3500	$R_2$ $R_{28}$	24,57 15,56	1,39 5,09
Laitier 6000	$R_1$ $R_2$ $R_{28}$	68,3 243 23,5	4,68 10,36 9,81

L'influence du paramètre étant significative au seuil de 1 %, si  $V_L/V_R > 6,93$  ou si  $V_C/V_R > 4,82$  et au seuil de 5 % si  $V_L/V_R > 3,88$  ou si  $V_C/V_R > 3,00$ , on remarque que l'influence du type de laitier est prépondérante dans tous les cas. A 3500  $\text{cm}^2/\text{g}$ , l'influence du type de clinker n'est pas significative à 2 jours, elle l'est à 28 jours. A 6000  $\text{cm}^2/\text{g}$ , elle est à peine significative à un jour, le devient à 2 jours et à 28 jours. On observe que les caractéristiques propres des clinkers interviennent plus rapidement lorsque la finesse du laitier augmente.

## 1.2 - Analyse à 3 dimensions

Pour étudier ensuite l'existence de couples laitier-clinker, nous avons effectué des analyses à trois dimensions : laitier-clinker-finesse du laitier. Nous avons porté au tableau V les quotients des rapports des variances par la valeur F du test de SNEDECOR au seuil de 5 % par le nombre de degrés de liberté de chaque rapport. Une valeur supérieure à 1 permet de conclure que la valeur est significative au seuil de 5 %.

Tableau V	$\frac{1}{F} \frac{V_L}{V_R}$	$\frac{1}{F} \frac{V_C}{V_R}$	$\frac{1}{F} \frac{V_L \cdot F}{V_R}$	$\frac{1}{F} \frac{V_C \cdot F}{V_R}$	$\frac{1}{F} \frac{V_L \cdot C}{V_R}$
$R_2$	2,1	12,2	0,1	0,3	0,02
$R_7$	3,2	274,3	3,1	4,9	0,40
$R_{28}$	9,7	130,7	5,2	3,9	1,18
$R_{180}$	24,2	71,1	11,6	7,2	2,29
$R_{360}$	20,8	39,2	5,3	3,3	1,43
					0,93

L'examen de ce tableau montre qu'à 2 jours, la finesse et le type de laitier sont prépondérants, le type de clinker n'a pas d'influence significative. A 7 jours et au-delà, l'influence du type de clinker est significative ainsi que le terme  $V_C/V_R$  : le type de clinker a donc une influence qui est fonction de la finesse du laitier. Par contre, l'interaction type de laitier-type de clinker n'est pratiquement pas significative. On remarque aussi que l'influence relative de la finesse du laitier décroît avec le temps.

## 2 - Influence de la minéralogie des clinkers

Pour expliquer et quantifier l'influence du type de clinker, nous avons caractérisé les clinkers par leurs compositions minéralogiques et les laitiers, soit par leur rapport  $\text{CaO/SiO}_2$ , soit par le diamètre en Å des microhétérogénéités déterminé par diffusion centrale des rayons X. On peut penser que ce diamètre est une résultante de la composition chimique et de l'histoire thermique du laitier car il représente une estimation du volume moyen des particules organisées du laitier, il peut donc être utilisé comme variable caractéristique. D'autres paramètres de caractérisation des laitiers que nous décrivons par ailleurs (1), comme par exemple  $(C + M + A)/S$  ont été testés. Ils sont nécessaires pour déterminer l'influence de la qualité propre d'un laitier mais, dans le cas présent, nous utilisons trois laitiers représentatifs de trois productions différentes et les paramètres simples que nous avons choisis devraient être suffisants pour la caractérisation de chaque laitier.

Nous avons testé un grand nombre de corrélations multiples entre les résistances des mélanges à divers âges prises comme fonction et, comme variable, les différents paramètres ci-dessus définis. Pour les laitiers à 3500  $\text{cm}^2/\text{g}$ , les meilleurs résultats sont obtenus en définissant le laitier par le rapport  $\text{CaO/SiO}_2$  et les clinkers par  $\text{C}_3\text{S}$ ,  $\text{C}_3\text{A}$  cubique,  $\text{C}_3\text{A}$  tétragonal,  $\text{C}_4\text{AF}$  et  $\text{K}_2\text{SO}_4$ . A finesse élevée, nous utilisons pour les laitiers le rapport  $\text{CaO/SiO}_2$  à 1 et 2 jours et le diamètre  $\phi$  à plus long terme : nous conservons les mêmes paramètres pour les clinkers. Les tableaux VI et VII donnent les coefficients des équations obtenues et r de la corrélation multiple.

Tableau VI : Coefficient des équations de régression multiple pour les laitiers broyés à 3500 $\text{cm}^2/\text{g}$	$R_2$	$R_7$	$R_{28}$	$R_{90}$	$R_{180}$

Coef. corr. multiple r	0,96	0,97	0,74	0,95	0,79	0,83

La corrélation multiple est très significative à 2 jours, comme le laissait prévoir l'analyse de la variance, en effet, la corrélation simple avec le seul paramètre du laitier est déjà égale à 0,90, l'introduction des paramètres du clinker n'améliore pas sensiblement la corrélation : la faible plage de variation des clinkers industriels et l'incertitude relative sur les résistances à 2 jours ne permettent pas de quantifier l'influence du clinker avec les méthodes statistiques utilisées. A 7 jours, les corrélations sont les moins significatives pour les 2 finesses. A partir de 28 jours, les effets positifs de l'alite et du C<sub>3</sub>A tétragonal et négatifs du C<sub>4</sub>AF deviennent plus importants. Le K<sub>2</sub>SO<sub>4</sub> a toujours une influence positive sur les laitiers broyés à 3500 cm<sup>2</sup>/g mais dans le cas des laitiers à 6000 cm<sup>2</sup>/g, l'action est moins nette et l'incertitude de connaissance du coefficient est importante. L'élimination de ce paramètre modifie très peu le coefficient de corrélation multiple.

L'ensemble de ces corrélations nous permet donc de définir les paramètres principaux d'action des clinkers : taux d'alite et C<sub>3</sub>A tétragonal élevé, taux de C<sub>4</sub>AF faible. A 6000 cm<sup>2</sup>/g, la diminution du coefficient de l'alite après 28 jours, contrairement au cas à 3500 cm<sup>2</sup>/g, peut être mis en correspondance avec la désaturation en chaux de la solution (2). L'activation devenant alors plus alcaline que calcique.

Nous allons maintenant étudier l'interaction clinker-laitier en fonction de la finesse du laitier.

### 3 - Recherche des associations laitier-clinker

Pour mettre en évidence les associations favorables laitier-clinker, nous classons à chaque échéance et pour chaque type de laitier les mélanges par ordre décroissant de résistance et, à titre de comparaison, les ciments portland obtenus avec les mêmes clinkers. S'il n'y a pas d'associations préférentielles laitier-clinker, le classement sera indépendant du type de laitier. Bien entendu, nous avons pris en compte la précision des mesures pour examiner ces classements. Les résultats pour les laitiers à 6000 cm<sup>2</sup>/g sont présentés au tableau VIII.

Ce tableau nous montre qu'à 1 jour, le classement n'est significatif que pour le laitier A ; pour le laitier C, les écarts sont de l'ordre de la précision des mesures. Le laitier A, qui est très réactif, différencie mieux les clinkers que les autres laitiers, ce phénomène disparaît avec le temps. A 1 et 2 jours, le classement des CPA est différent de ceux des mélanges à base de laitier, particulièrement dans le cas du clinker C5 très riche en K<sub>2</sub>SO<sub>4</sub>. Les ciments les plus performants sans K<sub>2</sub>SO<sub>4</sub> donnent sensiblement les meilleurs mélanges mais les clinkers très riches en K<sub>2</sub>SO<sub>4</sub> s'associent moins bien aux laitiers. La comparaison des laitiers A et C à 1 jour nous montre que le laitier A réagit très rapidement car les résistances se développent beaucoup plus vite que si le laitier est remplacé par un inerte ; dans le cas du laitier C, le taux de réaction est très faible à 24 heures et les résistances sont pratiquement identiques avec tous les clinkers. A 2 jours, ce n'est plus le cas, le laitier C participe plus activement au développement des résistances.

Nous en déduisons que le laitier réagit aux premiers temps de l'hydratation, dès que l'alite libère de la chaux et, très vite, les résistances ne sont pas seulement dues aux hydrates des clinkers car, dans ce cas, les classements devraient être les mêmes pour les CPA et les ciments au laitier.

Nous avons, par ailleurs, examiné les mélanges à 20 % de clinker et 80 %, soit de laitier entièrement cristallisé, soit de sable de Fontainebleau broyé en présence de gypse, à une granulométrie équivalente, les résistances sont mentionnées au tableau IX.

Tableau VIII: Classement par résistance décroissante des mélanges pour les laitiers à 6000 cm<sup>2</sup>/g

	Laitier A	Laitier B	Laitier C	CPA
1 jour	C2 9,7	C1 5,5	C1 2,9	C5 20,6
	C1 9,0	C2 5,2	C2 2,9	C4 17,6
	C4 6,9	C4 4,4	C4 2,8	C2 17,4

Tableau IX : Résistances en MPa

	R <sub>2</sub>	R <sub>7</sub>	R <sub>28</sub>
Clinker + Laitier cristallisé	1,5	2,3	3,5
Clinker + Sable	1,5	2,0	2,2

Ceci, associé avec nos études de l'hydraulicité des ciments à haute teneur en laitier (3) nous confirme que le laitier réagit dès les premiers âges et que les résistances observées sont bien dues à l'association laitier-clinker.

Nous constatons aussi que les différences entre les classements CPA et mélanges croissent avec le temps. Nous n'avons remarqué qu'un seul couple laitier-clinker singulier : C5 + Laitier B à 28 et 360 jours.

Si l'on tient compte des faibles différences entre les résistances, on peut dire que dans le cas des laitiers broyés très finement, il n'existe pas d'associations laitier-clinker préférentielles dans ce type de mélanges à très forte teneur en laitier.

Etudions maintenant les classements établis dans le cas des laitiers broyés à 3500 cm<sup>2</sup>/g et décrits au tableau X.

Tableau X : Classement par résistances décroissantes des mélanges pour les laitiers à 3500 cm <sup>2</sup> /g

	C6 27,6	C6 28,4	C2 26,6	C6 46,5
360 jours	C4 54,2	C1 47,8	C4 47,4	C3 76,5
	C3 53,4	C4 47,4	C1 43,5	C1 76,3
	C1 51,7	C3 46,0	C5 42,3	C7 76,2
	C5 49,8	C2 45,7	C2 40,7	C2 68,6
	C2 49,2	C5 45,6	C7 40,4	C6 68,5
	C7 45,1	C7 41,9	C3 39,5	C5 56,0
	C6 43,3	C6 41,8	C6 38,6	C4 53,1

Comme à finesse élevée, on constate que le laitier A réagit très vite alors que le laitier C commence à peine à réagir à 2 jours, les phénomènes sont identiques mais avec un décalage dans le temps. A toutes les périodes, le clinker C3 riche en alite et à faible teneur en K<sub>2</sub>SO<sub>4</sub> et C<sub>3</sub>A tétragonal se situe parmi les meilleurs clinkers avec le laitier A, est moyen avec le laitier B et parmi les moins bons avec le laitier C. Le clinker C7, de composition chimique voisine, mais moins riche en alite et en C<sub>3</sub>A est un des moins bons activants des trois laitiers de 28 à 360 jours. Les clinkers à fort taux d'alite activeront donc très bien à long terme les laitiers de C/S élevés de type fonte Thomas et moins bien les laitiers de type hématite. D'autre part, l'examen des résultats avec le clinker C4 nous montre que les clinkers à teneur en alite moyenne mais à fort taux de C<sub>3</sub>A tétragonal seront parmi les meilleurs, quel que soit le type de laitier.

On peut donc conclure que dans le cas de nos mélanges à très haute teneur en laitier, le rendement de l'association laitier-clinker est une fonction de la finesse du laitier. L'activité des clinkers sera équivalente vis-à-vis de tous les laitiers très finement broyés. Par contre, l'action des clinkers à fort taux d'alite ou à fort C<sub>3</sub>A tétragonal sera différente suivant le type de laitier dans le cas des finesesses peu poussées. Pour obtenir les mêmes résistances mécaniques, les laitiers hématite devront être broyés finement avec des clinkers riches en alite et faibles en C<sub>3</sub>A qu'avec des clinkers à fort taux de C<sub>3</sub>A tétragonal.

A l'aide des tableaux VI et VIII, nous avons déterminé les rapports R<sub>360 jours</sub>/R<sub>28 jours</sub> pour tous les mélanges. On remarque que pour les laitiers à 3500 cm<sup>2</sup>/g, il est en moyenne de 1,51, indépendant du clinker utilisé et varie de 1,46 à 1,57 selon le laitier. Par contre, pour les laitiers à 6000 cm<sup>2</sup>/g, il est de 1,31 en moyenne, indépendant du laitier, et varie légèrement de 1,28 à 1,35 avec le type de clinker.

Ce rapport est donc principalement une fonction de la finesse du laitier.

#### INFLUENCE DE LA TENEUR EN SULFATE ET DE LA FINESSE DU CLINKER

Dans une série d'expériences complémentaires, nous avons fait varier la teneur en sulfate pour des mélanges réalisés avec le laitier A et les clinkers C4 et C6 qui conduisent aux résistances les plus différentes au tableau III.

Nous avons obtenu les résultats suivants portés au tableau XI.

Tableau XI : Influence de la teneur en sulfate et de la finesse du clinker sur le laitier A								
Finesses	SO <sub>3</sub> %	R1		R2		R7		R28
		C4	C6	C4	C6	C4	C6	C6
L : 3500	0,5	1,5	1,6	4,9	5	26,9	25,3	46,0
	1	2,0	1,9	6,2	6,1	27,1	26,0	44,5
	2	2,2	2,7	8,8	7,2	29,6	22,6	45,2
	4	1,7	2,0	4,2	5,6	25,7	20,1	39
	6	1,6	1,8	3,5	4,2	6,0	8,2	32,7
	6	1,6	1,8	3,5	4,2	6,0	8,2	32,7
L : 6000	0,5	2,9	2,9	10,1	9,6	37,8	33,7	53,3
	1	3,5	3,9	11,6	11,0	38,1	33,5	51,0
	2	5,5	4,8	13,6	11,9	36,2	30,9	51,5
	4	7,5	7,2	15,9	14,4	35,2	28,5	48,8
	6	6,1	5,1	9,6	15,7	32,6	28,5	45,6
	6	6,1	5,1	9,6	15,7	32,6	28,5	45,6
C : 6000	2	2,2		10,1		27,1		41,7
	4	2,8		11,0		24,0		35,7
	6	3,1		7,5		22,9		35,9
L : 3500	2	6,1		14,5		34,0		48,0
	4	10,3		17,2		31,1		43,2
	6	6,9		21,8		34,9		45,3

L'examen de ce tableau montre que les résistances à tous les âges sont influencées par la teneur en SO<sub>3</sub>. La teneur optimum varie avec la période et la finesse du laitier.

A 1 et 2 jours, l'optimum se situe vers 2 % pour une finesse de 3500 cm<sup>2</sup>/g et 4 % à 6000 cm<sup>2</sup>/g. A 7 jours, on remarque qu'une teneur élevée en SO<sub>3</sub> (6 %) perturbe le développement des résistances et avec le laitier à 3500 cm<sup>2</sup>/g, elles sont diminuées d'un facteur 5. Par contre, à 6000 cm<sup>2</sup>/g, le laitier tolère une teneur en SO<sub>3</sub> élevée du fait de la dissolution plus importante d'ions Al. A 28 jours, les résistances sont inversement proportionnelles à la teneur en sulfate. On pourrait se demander s'il ne s'agit pas d'un simple effet de dilution. Avec le laitier à 6000 cm<sup>2</sup>/g, pour le clinker C4, très riche en aluminates, la baisse est proportionnelle à la dilution, mais plus forte que la dilution dans le cas du clinker C6 à faible teneur en aluminates. Tout ceci montre que, malgré la faible teneur en laitier, la teneur en C<sub>3</sub>A du clinker doit être considérée pour déterminer l'optimum en SO<sub>3</sub>.

On constate aussi qu'une plus grande finesse du clinker permet d'élever les résistances à court terme, mais les diminue à long terme. Il faut donc adapter la finesse du clinker pour qu'il active le laitier au moment où il en a besoin pour développer les résistances maximales à long terme.

#### INFLUENCE D'UNE PETITE AUGMENTATION DE LA TENEUR EN CLINKER

Cet essai a été réalisé avec le clinker C4 à différentes finesesses et teneurs en sulfates. Le mélange A est à 75 % de laitier et 25 % de clinker et le mélange B à 80 % de laitier et 20 % de clinker.

Tableau XII : Influence de la teneur en clinker									
Finesses SO <sub>3</sub> %		R1		R2		R7		R28	
		A	B	A	B	A	B	A	B
C : 3500	2	5,6	5,5	18,2	13,6	46,1	36,2	60,8	51,5
	4	8,8	7,5	24,2	15,9	44,5	35,2	61,7	48,8
L : 6000	6	6,6	6,1	22,2	9,6	42,2	32,6	55,3	45,6
C : 6000	2	7,3	6,1	23,9	14,5	44,6	34,0	56,3	48,0
	4	10,3	10,3	25,2	17,2	44,4	31,1	54,9	43,2
L : 6000	6	10,0	6,9	28,3	21,8	42,5	34,9	55,1	45,3

L'augmentation de la teneur en clinker de 5 % a peu d'influence à 1 jour, mais elle se fait très fortement sentir à 2 jours, dès que le laitier réagit rapidement, pour atteindre environ 10 MPa à 28 jours. Si le seul but était les performances mécaniques maximales, on aurait intérêt à augmenter légèrement la teneur en clinker. L'augmentation de la quantité de chaux disponible permettrait de maintenir une saturation constante de la solution interstitielle : ce qui ne serait pas favorable à la résistance des bétons aux attaques chimiques.

Cet essai nous montre aussi les limites des conclusions de cette étude sur l'influence du clinker qui n'a été testée que sur les mélanges de rapport laitier/clinker = 4, soit plus de 76 % de laitier dans des ciments où SO<sub>3</sub> = 3 %. Nous sommes à une limite imposée par la résistance chimique. Une faible augmentation de la teneur en clinker peut faire passer dans une autre catégorie de ciments et les conclusions sur l'influence du clinker seraient différentes.

#### CONCLUSIONS

Nous précisons que l'objet de cette étude était de comparer divers types de laitiers et de clinkers de compositions minéralogiques différentes et non pas d'étudier les variations de qualité d'un même laitier. Dans cette étude de laboratoire, nous n'avons pas pris en compte la broyabilité relative du clinker et du laitier, puisque nous avons broyé séparément chaque constituant à une finesse prédéterminée.

L'ensemble des essais réalisés avec 42 mélanges de clinker et de laitier nous permet de tirer les conclusions suivantes.

Contrairement aux idées reçues, les résistances à 1 jour des ciments à très haute teneur en laitier (laitier > 76 % dans le ciment) sont principalement fonction de la qualité du laitier. Il réagit dès les premiers instants et les résistances mesurées aux premiers âges sont celles de l'association laitier-clinker et non pas celles du clinker seul. La qualité du clinker ainsi qu'une légère augmentation de sa teneur n'ont pas d'influence notable avant deux jours. Les meilleures résistances à 28 jours sont obtenues avec les clinkers riches en alite et en C<sub>3</sub>A tétragonal. L'influence de ces deux minéraux sur les résistances est équivalente vis-à-vis de tous les laitiers broyés très finement, mais dans le cas des laitiers à 3500 cm<sup>2</sup>/g, l'action des clinkers à fort C<sub>3</sub>A tétragonal est indépendante du type de laitier alors que les clinkers riches en alite et à faible C<sub>3</sub>A activent mieux les laitiers les plus basiques. On constate aussi qu'il existe un rapport entre les résistances à 1 an et celles à 28 jours qui est principalement fonction de la finesse du laitier.

Les courbes d'évolution des résistances dépendent principalement de la qualité du laitier. Le clinker n'intervient qu'au deuxième ordre et les classements

résistances ciment portland et résistances des mélanges étudiés sont différentes.

L'influence du sulfate de calcium est modulée par deux facteurs : le temps et la teneur en C<sub>3</sub>A du clinker. Comme dans le cas des ciments portland, il existe une teneur optimale en sulfate de calcium variable en fonction de l'objectif recherché mais toujours relativement faible. La contribution de l'activation calcique est donc plus importante pour le développement des performances mécaniques que celle de l'activation sulfatique. Par ailleurs, dans le cas des laitiers à 6000 cm<sup>2</sup>/g, nous avons montré l'influence de l'activation alcaline à long terme.

En définitive, dans le cas que nous avons étudié, tous les laitiers ne permettent pas d'obtenir des ciments à hautes performances mécaniques. Par contre, une faible augmentation de la teneur en clinker et une optimisation de la finesse et du taux de sulfate de calcium permettent d'améliorer significativement les résistances mécaniques.

#### REMERCIEMENTS

Les auteurs remercient le personnel des départements ECPM et ECPC du CEREG qui a effectué l'ensemble des broyages, des mélanges et des essais mécaniques des produits.

#### AVERTISSEMENT

Les analyses par diffusion centrale des rayons X ont été réalisées par M. LACHAUD au CEBTP à SAINT-REMY-LES-CHEVREUSE.

# Détermination de la teneur en laitier dans les ciments par dissolutions sélectives

## *Slag content determination in cements by selective dissolutions*

E. DEMOULIAN, C. VERNET, F. HAWTHORN, P. GOURDIN, Société des Ciments Français, CEREG, France.

### RESUME :

L'étude des différences de pH et de vitesses de dissolution des constituants des ciments à l'aide d'un titrateur automatique a conduit à la mise au point d'une méthode de séparation chimique quantitative du laitier.

Dans des conditions opératoires bien déterminées, une solution qui contient de l'EDTA, de la triéthanolamine et de la soude dissout totalement, à pH 11,5, les minéraux du clinker et le sulfate de calcium sans attaque notable du laitier. La soude évite la précipitation de la silice et des hydroxydes.

Dans les ciments hydratés, la méthode permet de déterminer la quantité de laitier qui n'a pas réagi. Pour les ciments ternaires, elle doit être complétée par les méthodes préalablement mises au point pour doser les cendres volantes et les pouzzolanes.

### SUMMARY

The study of pH and dissolution speeds of cement constituents with an automatic titrator had led to a quantitative chemical method for the separation of the slag in cements.

In well determined operational conditions, an EDTA, triethanolamine and sodium hydroxide solution, dissolves the clinker minerals and calcium sulphate, at pH 11,5, without a notable dissolution of the slag. The silica and hydroxides precipitating is avoided by sodium hydroxide.

In the hydrated cements, the method allows the quantitative determination of the non hydrated slag. In the case of ternary cements, it can be completed by supplementary methods, already perfected for determining fly ashes and pozzolanas contents.

## INTRODUCTION

Depuis plusieurs années, nous étudions au CEREG la dissolution sélective des phases anhydres ou hydratées des clinkers et ciments. Nous avons expérimenté de nombreux réactifs en milieu aqueux ou organique. Ces recherches ont abouti à la mise au point de deux méthodes de détermination des teneurs en cendres et en pouzzolanes dans les ciments. Ces méthodes, mises à l'épreuve par les nombreux participants du CEN GT 4 TC 51 ont été testées avec succès et proposées comme méthodes de référence en projets de normes européennes (1)(2). Le problème de la séparation sélective du laitier restait à résoudre.

L'apparition d'appareillages très élaborés de titration automatique qui permettent des ajouts incrémentiels du réactif, asservis soit aux dérivées du signal, soit à l'écart par rapport à un point de consigne, nous a permis d'étudier les cinétiques de dissolution des laitiers et des phases des clinkers dans différents milieux.

A la suite de cette étude, nous avons mis au point une attaque sélective rapide du clinker et du gypse qui permet de séparer quantitativement le laitier et les autres ajouts que l'on peut identifier par un examen complémentaire de l'insoluble.

## 1/ CINÉTIQUE DE DISSOLUTION DES MINÉRAUX ANHYDRES OU HYDRATES DES CEMENTS

L'étude des différences de vitesses et de pH de dissolution des clinkers et ciments a été réalisée à l'aide du titrateur automatique représenté sur la photographie n° 1.

Photographie n° 1 - Ensemble de titrage automatique

Les fonctions d'asservissement du titrateur ont été utilisées pour ajouter le réactif, par incréments, à une vitesse continuellement égale à la vitesse de réaction de la phase étudiée, qui peut ainsi être mesurée. Nous avons choisi le pH comme variable indicatrice.

Le mode opératoire suivant a permis d'étudier les phases anhydres et hydratées des ciments : alites, bélites,  $C_3A$  cubique et tétragonal,  $C_4AF$ , silicates hydratés, ettringite, monosulfate de calcium et différents laitiers.

Dans une cellule thermostatée à 20°C contenant 500 ml d'eau, on introduit 200 mg de la phase à étudier. Un acide 0,2 N est ajouté par incréments de 100 microlitres. L'asservissement obéit aux principes suivants :

- 1) l'ajout d'un incrément supplémentaire est déclenché lorsque la vitesse de variation du signal (pH) est inférieure à une valeur seuil (en mV/minute) correspondant à la fin de réaction de l'incrément précédent;
- 2) pour prendre en compte le temps de réponse du capteur, un délai supplémentaire constant mais ajustable, fixé ici à 20 secondes, est imposé par le titrateur.

Les courbes obtenues pour les phases étudiées sont représentées sur les figures 2 à 12.

Fig. 12 - Courbe de dissolution d'un mélange laitier + clinker

Elles montrent les différences de vitesses et de pH de dissolution ainsi que l'existence de plusieurs étapes dans le mécanisme de dissolution. Pour les minéraux anhydres ou hydratés, les pH de fin de réaction sont compris entre 7 et 8, dans cet intervalle le laitier n'a pas réagi de manière significative. Lorsque l'acide utilisé est un acide fort comme HCl, la dissolution des aluminates et même des silicates est fortement ralentie, soit par précipitation d'hydroxydes d'aluminium et de fer, soit par précipitation de silice et les dissolutions sont incomplètes à pH7. A ce pH, l'utilisation d'un acide complexant tel que l'acide citrique, comme pour les exemples des figures 2 à 12, n'évite que partiellement ces précipitations, les aluminates du clinker ne sont pas totalement dissous, de la silice reprécipite. Les séparations ne sont pas quantitatives, ce qui a été confirmé sur des mélanges de laitier, de clinker et de gypse en différentes proportions.

Cependant, les différences de vitesses et de pH de dissolution mises en évidence doivent permettre une séparation quantitative du laitier en utilisant des réactifs formant des complexes solubles plus stables que les hydroxydes d'aluminium et de fer. Pour éviter la précipitation de la silice, il faudra opérer à un pH plus élevé, ce qui aura pour inconvénient de diminuer les vitesses de dissolution. Il faudra donc les accélérer en déplaçant les équilibres par complexation du calcium.

## 2/ METHODE DE DOSAGE RAPIDE DE LA TENEUR EN LAITIER DANS LES CEMENTS

Compte tenu des études et observations précédentes, nous avons mis au point une méthode rapide de séparation quantitative du laitier qui ne nécessite que l'utilisation d'un appareillage courant. L'acide citrique ne convenant pas pour séparer sélectivement le laitier du clinker à pH7, après de nombreux essais, nous avons utilisé le sel disodique de l'acide éthylènediaminetétraacétique ou EDTA de formule :

et la triéthanolamine  $(\text{CH}_2\text{OHCH}_2)_3\text{N}$  comme complexants du calcium, de l'aluminium, du fer et l'hydroxyde de sodium pour éviter la précipitation de la silice entre pH 11,0 et 12,0.

### 2.1 - Etude de la méthode

**Influence du pH du réactif :** Sur un mélange constitué de 50 % de laitier, 45 % de clinker, 5 % de gypse, l'influence du pH de dissolution a été mise en évidence par différentes solubilisations à des pH prédéterminés entre 11,0 et 12,0.

Les résultats mentionnés sur le tableau I montrent que la quantité d'insoluble est pratiquement identique entre pH 11,4 et 11,8. La moyenne de  $48,6 \pm 0,2$  met en évidence une faible solubilisation du laitier. Cet effet est un peu plus important aux pH 11,0 et 12,0. Pour les autres vérifications et pour la méthode définitive, le pH de solubilisation du clinker et du sulfate de calcium sera fixé à  $\text{pH } 11,6 \pm 0,1$ .

Tableau I : Influence du pH du réactif							
pH	11,0	11,4	11,5	11,6	11,7	11,8	12,0
Insoluble %	47,5	48,5	48,8	48,5	48,6	48,4	47,5

Analyse de l'insoluble séparé : Nous avons reporté sur le tableau II, la composition chimique du laitier et celle de l'insoluble séparé à pH  $11,6 \pm 0,1$ . Ces résultats montrent que les compositions chimiques sont très voisines et que l'insoluble séparé est principalement constitué de laitier.

L'absence de sulfate montre que le gypse a été totalement dissous. La solubilisation du clinker semble quantitative. Nous notons toutefois un très léger enrichissement en silice et en FeO.

Tableau II : Composition chimique du laitier et de l'insoluble séparé à pH  $11,6 \pm 0,1$

	SiO <sub>2</sub>	Al <sub>2</sub> O <sub>3</sub>	FeO	CaO	MgO	SO <sub>3</sub>	S <sup>++</sup>
Laitier	32,91	14,95	0,54	43,74	4,53	0,04	0,88
Insoluble	33,40	14,77	0,70	43,74	4,60	0,00	0,89

Examen de l'insoluble au microscope optique : Après enrobage dans de la résine, l'insoluble obtenu à pH  $11,6 \pm 0,1$  a été examiné au microscope optique. Cet examen a confirmé la solubilisation complète du clinker et du gypse. D'autre part, les grains de laitier à angles vifs ne semblent pas avoir été corrodés par le réactif au cours de l'attaque sélective (photographie n° 13).

Photographie n° 13 - Aspect de l'insoluble séparé à pH  $11,6 \pm 0,1$

Essais de répétabilité : Ces essais ont aussi été effectués sur le mélange à 50 % de laitier.

Pour 20 essais effectués par un même opérateur, la quantité d'insoluble varie entre 47,8 % et 50,6 % avec une moyenne de 48,8 % et un écart type de 0,7 %.

Les résultats obtenus sont mentionnés sur le tableau III.

Tableau III : Essais de répétabilité sur un mélange constitué de 50 % de laitier, 45 % de clinker, 5 % de gypse

N° Essai	1	2	3	4	5	6	7
Insoluble %	48,6	48,1	48,1	48,5	48,7	48,6	49,9
N° Essai	8	9	10	11	12	13	14
Insoluble %	49,5	49,1	49,1	48,7	48,4	47,8	50,0
N° Essai	15	16	17	18	19	20	
Insoluble %	48,6	48,2	48,3	48,4	49,2	50,6	

Étalonnage de la méthode : Les essais de répétabilité ayant montré une solubilisation non négligeable du laitier, l'exactitude de la méthode préconisée peut être améliorée par un étalonnage préalable.

L'étalonnage a été réalisé sur des mélanges synthétiques qui contiennent 5 % de gypse et des proportions variables de 3 laitiers référencés A, B, C et de 2 clinkers C2 et C4, comme dans une autre de nos communications qui donne leurs compositions chimiques et minéralogiques (3).

Les laitiers sont des laitiers vitrifiés de fontes hématite et de fonte Thomas représentatifs de la production française, les clinkers ont été choisis pour leurs grandes différences minéralogiques.

Les résultats obtenus, mentionnés sur le tableau IV, conduisent à la relation :  $y = 1,024 x - 0,05$ , où  $x$  est le pourcentage d'insoluble,  $y$  le pourcentage de laitier calculé et dans laquelle, l'ordonnée à l'origine peut être négligée.

L'application de la relation  $y = 1,024 x$  au pourcentage moyen d'insoluble trouvé au cours des essais de répétabilité donne 49,97 % de laitier pour un mélange qui en contient 50 %. Ceci montre la validité de l'étalonnage dans le cas des laitiers considérés.

Tableau IV : Etalonnage avec des mélanges synthétiques

Pourcentage de laitier dans le mélange	Pourcentage d'insoluble
0	0,0 - 0,8
20	19,6 - 18,0
35	34,0 - 33,0 - 35,0 - 35,2
45	44,9 - 44,2
50	48,4
55	53,3
65	64,6 - 62,4
75	73,1 - 75,4 - 73,8 - 73,1
85	82,4 - 82,7
95	92,2 - 92,6

## 2.2 - Mode opératoire préconisé

Dans un bécher de 600 ml, introduire successivement :

- 250 ml d'une solution d'EDTA 0,05 M dans de la soude 0,1 N,
- 25 ml de triéthanolamine à dilution 1-1 avec de l'eau distillée,
- ajuster à pH  $11,6 \pm 0,1$  avec NaOH N,
- après broyage à refus nul au tamis de 40  $\mu$ m, ajouter progressivement pendant l'agitation de la solution 500 mg (P1) du ciment à doser (l'ajout doit être progressif pendant l'agitation pour éviter la formation d'amas difficilement délayables),
- continuer l'agitation pendant 20 minutes,
- filtrer sur verre fritté n° 4 préalablement taré (P2),
- rincer 7 fois à l'eau distillée,
- rincer 3 fois à l'alcool éthylique,
- sécher à l'étuve à 105°C pendant 30 minutes,
- laisser refroidir en dessiccateur et peser (P3).

Pourcentage de laitier :

$$\% L = \frac{P3 - P2}{P1} \times 100 \times K \quad (I)$$

K est le coefficient obtenu par étalonnage, il est destiné à tenir compte de la faible dissolution du laitier. Il est de 1,024 dans le cas présent.

## 3/ CONCLUSIONS

Cette recherche nous a conduit à mettre au point une méthode applicable aux ciments contenant du laitier vitrifié. Elle peut, avantageusement, remplacer les méthodes de séparation par liqueurs denses et les mesures par microscopie optique, qui sont des méthodes à temps de réponse longs et de mises en oeuvre délicates.

Elle permet, de plus, l'étude des produits hydratés des ciments qui contiennent du laitier.

Pour déterminer les quantités de chaque ajout, dans les ciments ternaires, elle peut être complétée par les méthodes de détermination des teneurs en cendres et en pouzzolanes dans les ciments (1) (2).

## REMERCIEMENTS

Les auteurs remercient Mme CAULLIER, technicienne au CEREG, qui a effectué les très nombreux essais de mise au point de la méthode.

# Utilization of Pozzolan and Cenospheric Ashes,

## *L'utilisation des cendres volantes pouzzolaniques et cénoosphériques*

E. RAASK, Senior Research Officer, Fuel Ash Sciences, Central Electricity Research Laboratories, Leatherhead, U.K.

**RESUME :** Les cendres volantes sont largement utilisées comme additifs des mortiers et bétons, mais présentent une capacité variable de remplacement du ciment Portland. Il est donc important de disposer d'un test permettant d'évaluer rapidement leur pouvoir pouzzolanique. Le laboratoire du CEGB a mis au point une méthode de détermination de l'activité pouzzolanique des cendres volantes dans laquelle le taux de dissolution de la silice des particules de cendre est mesuré dans une solution d'acide fluorhydrique à 0.1 mole. Le taux d'extraction de la silice suit une loi logarithmique; la constante représente l'indice d'activité pouzzolanique de la cendre.

L'addition de cendres présentant une activité aux mélanges pour béton peut améliorer la stabilité thermique et chimique de la structure en béton. C'est ainsi que la réaction entre la fraction  $MgCO_3$  d'un agrégat de calcaire dolomitique et le  $Ca(OH)_2$  formé lors de l'hydratation du ciment Portland peut être évitée par l'addition de cendres volantes. La réaction du  $Ca(OH)_2$  se faisant de préférence avec la silice des cendres, l'agrégat n'est pas affecté.

Une caractéristique intéressante des cendres volantes est constituée par la présence d'une certaine quantité de micro-sphères creuses, d'un diamètre de 25 à 250  $\mu m$ . Ces cénoosphères sont formées par le dégagement de gaz au sein des particules de silicate à demi-fondues, à une température d'environ 1400°C. Les cendres légères sont récupérées dans les décharges de cendres, et sont maintenant disponibles en Grande Bretagne pour livraison en vrac (cendres non calibrées) ou en quantités moindres, mais calibrées selon des tailles spécifiées. Les cénoosphères de cendres sont utilisées dans les ciments hydrauliques et les liants à résine organique pour la fabrication de matériaux composites pour l'isolation thermique, et celle de matériaux imperméables pour constructions nouvelles.

**SUMMARY:** P.f ash is widely used as a cement-extender in concretes and groutings, but the ash can vary in its ability to replace Portland cement. It is important therefore to have a rapid test of this pozzolanic quality. A method has been developed at the Central Electricity Research Laboratories where the pozzolanic activity of p.f. ash is determined by measuring the rate of dissolution of silica from the ash particles dispersed in 0.1 molar hydrofluoric acid. The rate of extraction of silica follows a logarithmic law and the rate constant is an index of the pozzolanic activity of the ash.

Addition of the pozzolanic quality p.f. ash to concrete mixes can enhance the chemical and thermal stability of the concrete structures. For example, the reaction between the  $MgCO_3$  fraction of a dolomitic limestone aggregate and  $Ca(OH)_2$  formed on hydration of Portland cement can be prevented by addition of p.f. ash. Preferential reaction of  $Ca(OH)_2$  with silica in ash leaves the aggregate unscathed.

An interesting feature of p.f. ash is that it contains a proportion of hollow micro-spheres, 25 to 250  $\mu m$  in diameter. The cenospheres are formed by the evolution of gases inside the semi-molten silicate particles at about 1400°C. The lightweight ash material is being recovered from the ash disposal lagoons and it is now available in Britain for delivery in bulk as ungraded material or in smaller quantities of specified size ranges. The ash cenospheres are used with hydraulic cements and organic resin binders to manufacture heat insulating composites and non-absorbent buoyancy materials.

## INTRODUCTION

For the next two or three decades coal is likely to remain the most important primary fuel for electricity generation in this country and also in many other countries. The Central Electricity Generating Board (C.E.G.B.) in Britain utilizes at present about 70 million tonnes of coal a year. The fuel contains on average between 16 and 18 per cent by weight of uncombustible mineral matter, therefore the total ash products from the C.E.G.B. power stations boilers amount to about 12 million tonnes a year.

At present the majority of large coal-fired boilers in operation and to be constructed, are based on the system of pulverized fuel firing. This mode of firing produces between 15 to 25 per cent ash clinker which is discharged from the bottom of the combustion chamber in the form of crushed pieces of sintered or fused ash, usually 2 to 20 mm in size. The bulk of the incombustible material in a pulverized-coal fired boiler is transported through the combustion chamber and heat exchange ducts and it is captured in the electrical precipitators. The catching efficiency of the modern ash collectors is high, so that only 0.5 per cent weight or less fraction of the total solids escapes the ash collecting system.

The ash captured in the electrical precipitators is known in Britain as pulverized fuel ash, or p.f. ash, or PFA. Historically the term "pulverized fuel ash" was chosen to include the ash residue from pulverized coke. In the U.S.A. and in some other countries it is known as fly ash. This paper describes some of the research work on p.f. ash carried out at the Central Electricity Research Laboratories.

Raask (1) has shown that an interesting feature of p.f. ash is that it contains a proportion of hollow microspheres (or cenospheres) which are formed by internal evolution of gases at about 1400°C. This paper describes the properties of ash cenospheres and some of the lightweight composite materials made with hydraulic cements and resin binders.

## POZZOLANIC ACTIVITY

Lea and Desch (2) have stated that for a material to be pozzolanic it should be capable of combining with calcium hydroxide liberated on hydration of Portland cement to form calcium silicates at room temperature. The definition implies that a pozzolanic material or pozzolana contains a "reactive" form of silica which is capable of reacting with calcium hydroxide at significant rates relative to the rate of hydration of cement. Volcanic ashes and some diatomitic deposits to varying degrees are pozzolanic in behaviour; so is p.f. ash as discussed by Turriziani (3). The ash acquires the pozzolanic activity by the high temperature when the particulate mineral matter of the coal is dispersed in the coal flame.

P.f. ash is being increasingly used in concrete and grouting mixes for partial replacement of Portland cement as described by Barber et al. (4). There is a need for a rapid method of assessing the extent of pozzolanic activity of a given supply of ash. A search was made for a method for the determination of pozzolanic activity based on previous work on the formation and properties of p.f. ash by Raask (5).

The "classical" method of assessing pozzolanic materials is that proposed by Fratini (6) and modified by Rio (7). A mixture of the test material and Portland cement is kept in water at 40°C for eight days and the amount of soluble calcium hydroxide left in the solution determined. A low Ca<sup>++</sup>-ion concentration is a qualitative sign of a reactive material. The method is slow and errors can be introduced by variations in the quality of cement used.

Engineers designing concrete mixes with p.f. ash prefer to use the cementing efficiency factor ( $\kappa$ ) of the ash proposed by Smith (8). He suggested that the weight of p.f. ash (W) in a concrete could be considered as equivalent to a weight  $\kappa W$  of cement in its contribution to the strength of the mix. Usually, the  $\kappa$  values are obtained from the strength measurements of ash, cement and water mixes after 28 days. A value of 0.15 or higher indicates an ash with a useful pozzolanic activity. The method has the same shortcomings as the chemical test of Fratini and Rio, but it is more readily acceptable and in this work it has been used as a standard for comparison.

A rapid test of pozzolanic property was proposed by Jambour (9). In his method the rate of heat evolution is measured when a pozzolana dissolves in a solution of hydrofluoric and nitric acid in a calorimeter. The test takes one hour to complete. Peck (10) applied the method to a selection of ashes but found a poor correlation with the method of Smith (8). The solvent medium, a mixture of 2 molar nitric acid (HNO<sub>3</sub>) and 0.6 molar hydrofluoric acid (HF) was too aggressive, and masked differences in the reactivity of the ashes. By omitting HNO<sub>3</sub>, the HF-solution reacts more selectively with silica and the reaction results in an increase in H<sup>+</sup>-ion concentration of the solution. HF is largely associated in water, whereas the reaction product, hydrofluosilicic acid is dissociated in water as shown by Palmer (11)

This suggests the possibility of following the reaction by measurement of the electrical conductance of the solution. A conductivity cell was constructed from PTFE which is resistant to chemical attack by hydrofluoric acid, as described by Raask and Bhaskar (12)

The conductance measurements were made at 27°C by an a.c. bridge, and the cell was calibrated with pure silica in the form of condensed fume. This material reacts rapidly and quantitatively with 0.1 molar hydrofluoric acid because of its very small particle size (0.01  $\mu\text{m}$  to 0.15  $\mu\text{m}$ ) as described by Raask and Wilkins (13). The conductance of the solution was found to be proportional to the amount of silica dissolved according to equation (1).

Ash samples of known cementing efficient ( $\kappa$ -values as defined by Smith (8)) were used in these experiments. The ash dispersion in HF-solution contained one milligramme of solid per one cubic centimetre of acid, and the increase in conductance was monitored over a period of two hours.

The plots in Fig. 1 show the results for an initial reaction period between 15 minutes and one hour. The results fitted an exponential decay equation of the form,

$$W_r = W_0(1 - b e^{-ct}) \quad \dots (2)$$

where  $W_r$  is the amount of silica reacted at time  $t$  and  $W_0$  is the initial amount of silica;  $b$  is a numerical constant and  $c$  can be defined as the reaction constant.

Fig. 1 - Dissolution of Silica of P.F. Ash in 0.1 Molar Hydrofluoric Acid.

The rate of silica dissolution deviates (it slows down) from the diffusion law prediction after about 50 per cent of the total silica in ash has been dissolved. Kiss et al. (14) have shown that the majority of ash particles are made up from an inhomogeneous mixture of glassy material and crystalline species. The latter are resistant to acid attack and the dissolution rate of  $\text{SiO}_2$  will decrease. The inhomogeneity characteristics of p.f. ash particles are evident in Fig. 2 which shows the acid dissolution residue on the surface of ash particles after HF-treatment.

Fig. 2 - P.F. Ash Particles, Left - before the HF-Treatment, Right - after the Treatment.

The  $c$ -values for different ashes obtained by computer iteration were between  $0.4 \times 10^{-3} \text{ s}^{-1}$  and  $1.25 \times 10^{-3} \text{ s}^{-1}$ . The pozzolanic index ( $P_z$ ) is defined in units of reciprocal kiloseconds, i.e.

$$P_z = 1000 C \quad \dots (3)$$

The plot on Fig. 3 shows that there was a reasonably good correlation between the pozzolanic index (the acid dissolution test) and the cementing efficiency (crushing strength of p.f. ash mortars).

Fig. 3 - The Relationship Between the Pozzolanic Index ( $P_z$ ) and Cementing Efficiency ( $K$ ).

Of the ten samples tested seven passed the pozzolanity tests and three failed. That is, the ashes which have a pozzolanic index value, as defined by equations (2) and (3), below 0.5 should not be used as a pozzolanic material in concrete or grouting mixtures. A simplified method of HF-dissolution test can be applied for routine checks of the pozzolanic quality of p.f. ashes as described by Raask and Bhaskar (12).

#### UTILIZATION OF POZZOLANIC P.F. ASH

The majority of limestone aggregates are stable in concretes at room temperature. However, in the U.S.A. and Canada there have been occurrences of aggregate failure caused by chemical attack as described by Hadley (15), and by Swenson and Gillott (16).

The thermal stability of a concrete made with Portland cement is influenced by the type of aggregate used in the mix. Hannant (17) and Imlach and Taylor (18) have shown that concretes made with limestones lost strength to a much greater degree than those made with siliceous aggregates. The strength loss could be caused by chemical reactions between limestone and the calcium hydroxide,  $\text{Ca(OH)}_2$ , liberated on hydration of Portland cement. Limestones quarried for use as aggregates in concretes contain some magnesium carbonate,  $\text{MgCO}_3$ , which would be the species first to be attacked in the alkaline media of hydrated cement paste.

The rate of decomposition of the  $\text{MgCO}_3$  fraction of dolomitic limestone in a calcium hydroxide solution can be determined by measuring the electrical conductance of the solution. After the solubility limit of  $\text{Mg(OH)}_2$  is reached, the amount of  $\text{MgCO}_3$  reacted is proportional to the decrease in conductance due to the removal of  $\text{OH}^-$  and  $\text{Ca}^{++}$  ions from the solution,

Experimental results suggest that the rate of conversion of  $\text{MgCO}_3$  fraction limestone to  $\text{Mg(OH)}_2$  in

#### IV.4

$\text{Ca(OH)}_2$  solution is governed by diffusion inside the solid particle. Glover and Raask (19) have suggested that a test for a diffusion-controlled mechanism is to

plot the rate of change of conductivity  $\left(\frac{d\Omega}{dt}\right)$  against the inverse of the square root of time as in Fig. 4. The rate of dissolution of the  $\text{MgCO}_3$  expressed as

$\frac{dw}{dt}$  is given by

$$\frac{dw}{dt} = 3w_0 \left( \frac{D}{a^2} - \frac{D^{\frac{1}{2}}}{\pi^{\frac{1}{2}} a t^{\frac{1}{2}}} \right) \quad \dots (4)$$

where  $w_0$  is the original molar fraction of  $\text{MgCO}_3$  in the sample and  $w$  that at times  $t$ ,  $a$  is the radius of particles,  $D$  is the diffusion constant. Since the conductivity change  $\left(\frac{d\Omega}{dt}\right)$  is proportional to the amount of  $\text{MgCO}_3$  reacted, equation (14) can be changed to,

$$\frac{d\Omega}{dt} = 3\Omega_0 \left( \frac{D}{a^2} - \frac{D^{\frac{1}{2}}}{\pi^{\frac{1}{2}} a t^{\frac{1}{2}}} \right) \quad \dots (5)$$

The above results fit the above diffusion equation as shown on Fig. 4 where the values of  $\frac{d\Omega}{dt}$  are plotted against  $t^{-\frac{1}{2}}$  values.

Fig. 4 - Conductance Changes of  $\text{Ca(OH)}_2$ /Dolomitic Limestone Dispersion (A) Particle size  $< 53 \mu\text{m}$  (B) Particle size  $53 \mu\text{m}$  to  $76 \mu\text{m}$ .

In order to demonstrate the beneficial effect of p.f. ash in stabilizing the dolomitic limestone aggregate in concretes the mortar specimens were made with and without the ash. The test mortars were cured at room temperature for six months, followed by another six months in the autoclave at  $150^\circ\text{C}$ .

The results of the differential thermal analysis (DTA) in Fig. 5 show that the preferential reaction of  $\text{Ca(OH)}_2$  in the hydrated cement mortar with ash leaves the aggregate unscathed.

Fig. 5 - Stabilizing Effect of P.F. Ash on Dolomitic Limestone Concrete (A) Limestone concrete (B) Limestone concrete with p.f. ash.

Fig. 6 shows that the spherical particles of p.f. ash were well embedded in the cement matrix. The interface between the surface of the ash particles and the hydrated cement paste was diffused and no micro-cracking was observed in this locality.

Fig. 6 - Embedded P.F. Ash Particles in Hydrated Cement Paste (Left) - Crack Propagation at Limestone Aggregate/Cement Paste Interface (Right).

On the other hand, the sharp-edged particles of crushed limestone were less intimately bonded in the cement matrix. On drying the cement paste had shrunk away from one of the faces of the aggregate particles, thus initiating a crack propagation in the cement paste matrix. It was therefore concluded by Raask (20) that addition of p.f. ash to the concrete mixes with certain aggregates can enhance the chemical, thermal and mechanical stability of the concrete structures.

#### FORMATION AND PROPERTIES OF ASH CENOSPHERES

The large boilers at modern power stations burn coal in the form of powder of particle size about 1 to  $100 \mu\text{m}$ . During the process of milling, the minerals in coal are also ground approximately to the same fineness. In the flame the mineral particles fuse as discrete entities and the irregular shapes are changed to spherical forms by the force of surface tension as described by Raask (5). At the same time gases are generated inside those mineral particles which contain some carbonaceous matter, thus internal combustion takes place on the micro-scale. A vigorous

evolution of gas explodes the particles but a steady rate of expansion followed by a rapid cooling results in the formation of a stable cenosphere.

Raask (1) has found that the process of gas evolution is catalysed by iron oxides present in the molten glass. The formation of the ash cenospheres is governed also by the viscosity and surface tension of fused silicate glass. In view of the complexity of the formation process, and since the boiler furnace is not designed to produce "freak" ash, it is not surprising that the number of cenospheres produced in the flame is small - a few particles in every hundred. However, a number of large stations each produce several thousands of tons of the cenospheres each year.

The unique property of the cenospheres follows from the enclosed single void in each particle which is much larger than that of the shell. Low apparent density and the impervious shell permit the particles to separate from the dense ash in the disposal lagoons. This incidental separation process is fortunate, otherwise the recovery of the material would be uneconomical.

When the particles are viewed under the Stereoscan electron microscope the striking feature (Fig. 7) is that they are almost perfect spheres although there are a few particles with surface blemishes.

Fig. 7 - Ash Cenospheres and Close-up of a Particle

The characteristic properties of a typical sample of ash cenospheres are summarized in Table 1.

Table 1 - Properties of Ash Cenospheres

Particle size	- 20 to 300 $\mu\text{m}$
Apparent density	- 500 $\text{kg m}^{-3}$
Bulk density	- 300 $\text{kg m}^{-3}$
Thermal conductivity	- 0.1 $\text{W m}^{-1} \text{ }^{\circ}\text{C}$
Thermal stability limit	- 1300 $^{\circ}\text{C}$

#### LIGHTWEIGHT COMPOSITES MADE WITH ASH CENOSPHERES

Composite lightweight materials can be made with the cenospheres using a variety of binders. The choice of binders and the amount used depends on the strength, density and working temperature requirements as shown in Table 2. Further data on the properties of ash cenospheres and on the composites can be found in the previous work of Raask (21 to 23).

Table 2 - Properties of Cenosphere Composites

Binder	Binder to Ash ratio Vol:Vol	Density $\text{kg m}^{-3}$	Crushing Strength $\text{MN m}^{-2}$
Portland Cement	1:8	470	2.4
Ciment Fondu	1:8	440	2.5
Polyester resin	1:12	380	2.6
Phenol Formaldehyde	1:12	400	3.1

The above experiments were made with the view of using a minimum of binder to give a product of crushing strength above 2  $\text{MN m}^{-2}$ . These composites have sufficient strength for use as heat insulation materials.

An alternative to the approach of using a minimum of binder is to dispense the lightweight ash particles in a continuous matrix of the binder. The correct ratio of binder, including the fine clay for lightweight bricks, can be calculated from the density values given in Table 1. The bulk density of the fired product (870  $\text{kg m}^{-3}$ ) is about the same as that of Moler bricks made of diatomaceous earth. As the thermal conductivity of lightweight materials is proportional to the bulk density the cenospheres/clay brick should have approximately the same heat insulating properties as that of Moler brick of equal density. However, the advantages of the experimental material are that it has a higher crushing strength than that of the Moler brick, and a low absorptive capacity for liquids. In fact, the amount of  $\text{H}_2\text{SO}_4$  absorbed was found to be less than that taken up by a dense acid resistant brick. This makes it possible to use the material for lining chimneys and ducts where condensation of water or acids may take place.

Lightweight materials, impervious to liquids, can be made from ash cenospheres bound by resins. For example, the specimens made with phenol formaldehyde absorbed less than 0.1% by volume of water.

The lightweight cenosphere ash is now available in Britain for the home market and the material is shipped to a number of overseas countries. The lightweight ash is supplied in bulk as an ungraded material for the manufacture of heat insulating materials of a low liquid absorption capacity. These are usually made with high alumina cements or with sodium and potassium silicate cements. For the manufacture of high quality epoxy resin composites the graded and cleaned material is supplied. The epoxy composites are used as buoyant materials and in other marine applications.

#### ACKNOWLEDGEMENT

The work was carried out at the Central Electricity Research Laboratories and the paper is published by permission of the Central Electricity Generating Board.

# Composition and hydration of high calcium fly ash

## *Composition et hydratation de cendres volantes à haute teneur en calcium*

LIU HUAKUN, Engineer, LU ZHONGYAN, Engineer and LIN SHENGJIE, Engineer Cement Research Institute, Chine Populaire.

RESUME : Les cendres volantes à haute teneur en calcium, provenant de charbons pulvérisés à haute teneur en calcium ont une bonne hydraulité et par des traitements simples peuvent devenir un ciment. Il y a dix ans que ce ciment est produit et utilisé en Chine, à petite échelle.

On a fait des études générales sur la composition des phases et sur l'hydraulité de ces cendres volantes par diffraction à rayons X, microscopie à balayage, ATD, etc. Ces études montrent que les cendres volantes à haute teneur en calcium se composent principalement de verre, d'un peu de cristaux de  $\beta\text{-C}_2\text{S}$  et de  $\text{CaSO}_4$ , et de beaucoup d'oxydes de calcium libres. Durcies, elles comportent essentiellement des gels de tobermorite incrustés de cristaux à haute teneur en aluminosulfate de calcium. Ainsi les cendres volantes à haute teneur en calcium étant différentes des cendres volantes ordinaires, possèdent une bonne hydraulité.

Les oxydes de calcium libres dans ces cendres volantes sont formés presque instantanément; leurs cristaux sont très petits et souvent ils adhèrent sur les surfaces des grains de verre. L'hydratation et la formation d'hydrates s'accroissent mutuellement. Les oxydes de calcium libres n'ayant pas d'influence défavorable sur la stabilité, sont d'importants composants actifs dans les cendres volantes à haute teneur en calcium.

SUMMARY: The high calcium fly ash produced from the pulverized coal boiler possesses good hydraulicity. By simple treatment, it can be made into cement which has been manufactured and used in small scale in China for ten years.

The phase compositions of the ash and the hardened cement paste have been investigated by means of optical microscope, X-ray diffraction, scanning electron microscope and differential thermal analysis. The high calcium fly ash mainly consists of high calcium glass and a small amount of crystals --  $\beta\text{-C}_2\text{S}$ ,  $\text{CaSO}_4$ , etc. Besides, it contains a considerable amount of free lime. The hardened cement paste consists of ettringite and other crystals embedded in tobermorite gel. So the high calcium fly ash is different from ordinary fly ash. It possesses hydraulic property by itself. The free lime contained in the high calcium fly ash is formed almost instantaneously, its crystal size being very small. It usually adheres on the surface of the glass. The slaking of lime and the forming of hydration products work out to mutual advantage. The free lime in the high calcium fly ash does no harm to soundness and is rather an useful ingredient of the ash.

## INTRODUCTION

The pulverized coal, which contains a relatively high content of lime that is inherent in coal itself as in the case of lignite or is deliberately added to the coal either to improve the hydraulicity of fly ash or for sulphur removal, is transformed into high calcium fly ash (HCFA) when the coal dust burns away in the boiler. The phase composition of HCFA and so also its properties are different from those of ordinary fly ash which contains lime no more than 5%. HCFA possesses hydraulicity by itself. After grinding and mixing with a few per cent of salt (NaCl) or gypsum etc., HCFA can be made into cement with 28 days compressive strength (mortar) of 30-50 N/mm<sup>2</sup>. It expands slightly during hardening, but otherwise has similar performance characteristics as slag cement. It has been made and used in small scale in China for some ten years.

## CONSTITUTION OF HCFA

When pulverized coal is injected into the boiler, it burns at a rate of 10<sup>6</sup>°C/min, and is heated up to over 1200°C in 0.05 sec. (1). Due to the impact of the high temperature, the immediate product of fly ash essentially becomes glass embedded with 10-25% of crystalline minerals.

In the case with ordinary fly ash, the major crystals are quartz and mullite, while in the case

with HCFA, the crystalline substances are usually  $\beta$ -C<sub>2</sub>S, C<sub>12</sub>A<sub>7</sub>, C<sub>2</sub>F, CaSO<sub>4</sub>, free CaO etc., the content of free CaO can be as high as 5-15%. The X-ray diffraction patterns of some of the HCFA investigated are illustrated in figure 1. Their chemical compositions are given in Table I. As indicated, the constitutions of the crystalline substances of the HCFA are almost alike.

Fig. 1 XRD of HCFA

A=CaO B= $\beta$ -C<sub>2</sub>S C=C<sub>12</sub>A<sub>7</sub> D=C<sub>2</sub>F E=CaSO<sub>4</sub>

The circumstances of formation of HCFA are quite different from those of portland cement clinker though both are products of high temperature. The high calcium coal dust burns in suspension state at very high temperature rising rate in an extremely short period and is then rapidly quenched. So the crystals are poor in form and very small in size. The minute crystals appear to disperse in the glasses or adhere to the surface of the glasses as

NO.	Ig.loss	SiO <sub>2</sub>	Al <sub>2</sub> O <sub>3</sub>	Fe <sub>2</sub> O <sub>3</sub>	CaO	MgO	SO <sub>3</sub>	Free Lime	Total
1	1.66	26.76	16.22	11.42	33.11	5.21	3.11	6.42	97.49
2	2.12	21.07	10.87	10.01	47.08	5.88	1.90	9.51	98.93
3	0.92	13.61	9.79	8.75	55.29	4.77	2.95	13.08	96.48
4	2.54	25.15	14.46	8.99	39.72	2.76	5.54		98.76
5	4.90	25.49	13.94	6.59	36.31	4.15	3.48	10.30	94.96

discrete particles. The spherical particles of free lime adhering to the surface of glass are illustrated in figure 2. Their sizes are 1-5  $\mu$  or even smaller. The electron microprobe shows that a small amount of ferrous oxide can be dissolved in the free lime, which can be also discerned by the small shift of the 2.41  $\text{\AA}$  value ( $28-37.31^\circ$ ) of  $\text{CaO}$ .

Investigation of the glass components have been made by means of polarizing microscope. They may be differentiated by their optical properties as according to H.A. Popov and E.A. Ivanov (2) (see figure 3):

Fig. 2 Free lime adhering to glass  
SEM 1000X

Fig. 3 Types of glasses in HCFA,  
polarizing microscope, 430X

1. Pink or greenish transparent glass, with refractive indices 1.620-1.640. They can be glassy melilite or gehlenite.
2. Yellow or yellowish brown translucent glass, with refractive indices 1.670-1.720. They are probably related to system C-F-S.
3. Brown or brownish black translucent glass, with refractive indices 1.720-1.735. They can be high calcium glasses.
4. Black opaque glass, their refractive indices being very high, often appear in chain form due to their mutual attraction. They are glassy magnetite.
5. Agglomerates of fused particles, mostly spherical, the larger particles can be porous. Some of the smaller spherical particles adhere to the surface of the larger particles or enter into the latter's cavities as shown in figure 4.

Fig. 4 Agglomerates of glass  
SEM 2600X

As can be seen from the electron microprobe, the compositions of different spherical particles could be quite different. This is because the compositions of coal dust particles of different sizes are different, and the frequencies of collision between particles of argillaceous materials and the

CaO particles are also different. The interreaction during collision of the particles results in the formation of eutectic mixtures which tend to contract into spherical particles due to surface tension.

In the mean time, particles that are less liable to melt become porous when the combustibles burn away. In comparison with ordinary fly ash, there are in HCFA much more glasses of types 2 and 3 which possess good hydraulicity. the higher the content of CaO, the more are the types 2 and 3 and the less glass of type 5 in HCFA. Up to the limit of 45%, the higher the content of total CaO in HCFA, the higher is the strength of the HCFA mortar, whereas the strength of the mortar decreases when the CaO content exceeds 45% because the free CaO then also becomes too high. The reason, that HCFA possesses hydraulicity by itself in comparing with slag that has as high content of CaO, lies in the fact that the free CaO in HCFA acts as activator of hydration. When HCFA is reheated to a temperature of 1350-1450°C and then rapidly cooled, it loses its hydraulic property because all the free lime become absorbed, so is the constitution of the product also changed. This has been confirmed by our experiments.

#### HYDRAULIC PROPERTY

When HCFA is mixed with water, it starts hydration almost instantly. Free lime slakes to form  $\text{Ca(OH)}_2$  which together with  $\text{CaSO}_4$  dissolves in water. They act as activators in the hydration of glasses,  $\beta\text{-C}_2\text{S}$  and some of the other minerals also hydrate. The final hydration product of the hardened paste then consists essentially of calcium trisulphoaluminate embedded in tobermorite gel.

Gypsum, salt (NaCl) and other additives improve the strength of the hardened paste as shown in table II. the HCFA cement used for the test has its composition marked NO. 5 in table I.

If 6% of gypsum were mixed with HCFA, the content of  $\text{SO}_3$  in the mixture as calculated increases to 5.44%, from which considerable amount of ettringite could have been formed in the hardened paste. If, instead, 2% salt were mixed with HCFA, in addition to calcium trisulphoaluminate and  $\text{CSH}$ , there would be also calcium chloroaluminate in the hydration product. The X-ray diffraction patterns of the hydrating pastes at different ages are illustrated in figure V. Ettringite forms largely during the first day of hydration, the height of its peaks

TABLE II							
Weight proportion HCFA : Additives	Specific surface $\text{cm}^2/\text{g}$	Initial set hr. min.	Final set hr. min.	Tensile strength $\text{N/mm}^2$		Compressive strength $\text{N/mm}^2$	
				7 days	28 days	7 days	28 days
100 : 0	6250	0 36	1 40	2.8	2.9	29.6	33.4
94 : 6 (gypsum)	6620	0 58	2 58	2.8	2.7	33.4	44.6
98 : 2 (salt)	6100	0 35	1 39	3.1	3.7	44.0	56.4

Note: Tests made on 1:3 mortar (GB 177-62)

risers no longer from the second day of hydration, but, instead, calcium chloroaluminate is being formed. This is analogous to the experimental result by Nemat Tenoutasse (3). He described that when  $C_3A$  is hydrated in the presence of  $CaCl_2$  and  $CaSO_4 \cdot 2H_2O$ , the  $SO_4^{2-}$  ions react first to give tri-sulphoaluminate, the formation of monochloroaluminate begins only after the  $SO_4^{2-}$  ions have been depleted. As reaction proceeds further,  $C_4AH_{19}$

Fig. 5 XRD of hydration pastes of HCFA with addition of 2% salt

1,2,3,4,5-- 1 day, 2,3,7,28 days respectively

The DTA curve of the hardened HCFA cement paste steam cured at  $100^\circ C$  for 4 hours after 7 days wet curing is illustrated in figure 6. The  $130^\circ C$  and  $170^\circ C$  endothermic peaks correspond to the dehydration of CSH and ettringite respectively, the  $465^\circ C$  exothermic peak indicates the combustion of the residual carbon in HCFA, the  $830^\circ C$  endothermic peak indicates the decarbonization of  $CaCO_3$  and lastly  $890^\circ C$  exothermic peak indicates the formation of  $\beta-C_2S$  from dehydrated CSH.

Fig. 6 DTA curve of the hardened HCFA cement paste

The addition of salt accelerates the hydration of free lime and the formation of calcium aluminate hydrate (4) while it depresses the pH value of the hydrating solution, so that the rate of hydration of the silicate is also accelerated (5). This can be verified by the increase of heat of hydration at early ages as is shown in table III. It should be pointed out, so is it well known, that salt promotes corrosion of the reinforcing steel.

TABLE III			
Common salt %	heat of hydration Cal/g		
	1 day	2 days	3 days
0	58.2	62.6	69.7
1.5	68.1	73.3	79.4

The morphology of HCFA hydration products is shown in figure 7.

Fig. 7 Morphology of HCFA cement (added with 2% salt) hydration products. SEM 2100X

Unlike the dead burned free lime in portland cement clinker, the free lime in HCFA serves only as an alkaline activator of hydration and causes no undue expansion after hardening of the paste, even though its content could be sometimes as high as 15%. This can be readily understood from the circumstance of formation of HCFA which has already been described.

As it is shown in Fig. 5, from the second day of hydration, the peaks of CaO decrease appreciably and after the seventh day, no CaO can be detected any more. The coefficient of expansion of the testing prism is less than 0.8% for HCFA neat paste steamed at 100°C for 4 hours after 7 days wet curing. There has not been record to this day unsoundness of concrete made from HCFA cement since its first use some ten years ago.

#### CONCLUSIONS

1. High calcium fly ash is composed of 15-25% of crystalline substances i.e.,  $\beta$ - $C_2S$ ,  $C_{12}A_7$ ,  $C_2F$ ,  $CaSO_4$ , free CaO, etc. and heterogeneous glasses of different varieties.
2. The hydration products of HCFA without additive essentially consist of calcium trisulphoaluminate embedded in tobermorite gel.
3. The free CaO acts as an important activator in the hydration of HCFA and causes no harmful effect on the soundness of mortar or concrete inspite of its high content.
4. Common salt (NaCl) as an additive, accelerates the hydration of free lime, the formation of calcium sulphoaluminate and silicate, and reacts with excess hydrous aluminate to form calcium chloroaluminate.

5. The utilization of HCFA does not only contribute to the betterment of the environment in removal of  $SO_2$  from the exit gases of coal fired boilers, but also provides cement as a by-product of power plants.

# Formation of 10 Å and 14 Å tobermorite from pozzolanic glassy silica

## *Les tobermorites de 10 Å à 14 Å formés à partir de pouzzolane siliceuse vitreuse*

N. HARA and N. INOUE, Government Industrial Research Institute, Kyushu, Japon.

RESUME : On a étudié la réactivité hydrothermique, en présence de chaux, de deux sortes de pouzzolanes siliceuses vitreuses :

- 1) le verre volcanique (perte au rouge 2.7,  $\text{SiO}_2$  74.3,  $\text{Al}_2\text{O}_3$  12.7,  $\text{Fe}_2\text{O}_3$  1.3,  $\text{CaO}$  1.5,  $\text{MgO}$  0.2,  $\text{Na}_2\text{O}$  4.4,  $\text{K}_2\text{O}$  3.0 %; 5,950 et 3,460  $\text{cm}^2/\text{g}$ ) d'une sorte déposée au midi de Kyushu; et
- 2) la silice vitreuse de quartz fondu ( $\text{SiO}_2$  99.97 %; 1,550  $\text{cm}^2/\text{g}$ )

Dans le premier cas le rapport Ca/Si est de 0.6 à 0.9, et eau/solide 20 en poids. Les expériences ont été réalisées à des températures de 70 à 100°C, avec une durée de réaction de 2 à 120 jours.

A partir du verre volcanique, la tobermorite 10 Å est formée par une réaction à 80°C d'une durée de 20 à 30 jours. Les cristaux sont constitués de plaquettes ou de fibres allongées parallèlement à *b* avec clivage (100). La tobermorite 10 Å est remplacée par la tobermorite 11 Å si la réaction dure plus de 40 jours.

La tobermorite 14 Å est formée directement à partir de la silice vitreuse. Par chauffage dans l'air, celui-ci se convertit en tobermorite 11 Å à 60-400°C. Cependant celui-ci ne se transforme pas en tobermorite 9 Å par chauffage jusqu'à 800°C, contrairement à ce qui se passe avec la tobermorite naturelle.

La longueur des mailles de la tobermorite 14 Å est diminuée par l'addition de  $\text{Al}_2\text{O}_3$ . L'addition de  $\text{Al}_2\text{O}_3$  0.5-5% mélangée de silice vitreuse et de CaO a réalisé des longueurs de maille de 14 Å et 12 Å, 2 % 11 Å et 5 % 10 Å. L'addition de  $\text{Al}_2\text{O}_3$  2 % et de NaOH 0.5 % donnait la longueur de 10 Å. L'addition de NaOH seule à 0.5 à 1 % pourrait améliorer la cristallisation de la tobermorite 14 Å.

Ces résultats permettent de comprendre le mécanisme de synthèse des tobermorites de longueurs de maille diverses ainsi que la similitude des tobermorites aux C-S-H (I) pour des rapports Ca/Si variés.

SUMMARY : Hydrothermal reactivities with lime of two kinds of pozzolanic glassy silica ; i) volcanic glass (ig loss 2.7,  $\text{SiO}_2$  74.3,  $\text{Al}_2\text{O}_3$  12.7,  $\text{Fe}_2\text{O}_3$  1.3,  $\text{CaO}$  1.5,  $\text{MgO}$  0.2,  $\text{Na}_2\text{O}$  4.4,  $\text{K}_2\text{O}$  3.0 % ; 5,950 and 3,460  $\text{cm}^2/\text{g}$ ), a kind of pozzolana deposited in South Kyushu, and ii) silica glass made from fused quartz ( $\text{SiO}_2$  99.97 % ; 1,550  $\text{cm}^2/\text{g}$ ), were studied at starting Ca/Si mole ratios of 0.6-0.9 and water/solid ratio of 20 by weight under various combinations between reaction temperatures (70-100°C) and periods of reaction time (2-120 days).

From volcanic glass, 10Å tobermorite formed by the reaction at 80°C for 20-30 days. The crystals were lath-like, or fibrous elongated parallel to *b* with (100) cleavage. The 10Å tobermorite was replaced by 11Å tobermorite for more than 40 days' reaction.

From silica glass, 14Å tobermorite formed reproducibly. By heating in the air it transformed into 11Å tobermorite at 60-400°C. But this 11Å tobermorite did not transform into 9Å tobermorite during heating up to 800°C in contrast to natural 14Å tobermorites.

The basal spacing of 14Å tobermorite decreased by addition of  $\text{Al}_2\text{O}_3$ . Addition of 0.5-1.5% of  $\text{Al}_2\text{O}_3$  to the mixture of silica glass and CaO gave the basal spacings of 14Å and 12Å, 2% 11Å, and 5% 10Å. Addition of 2% of  $\text{Al}_2\text{O}_3$  and 0.5% of NaOH gave that of 10Å. Addition of 0.5-1% of NaOH improved the crystallinity of 14Å tobermorite.

These results suggest well how to synthesise tobermorites of different basal spacings, and similarities of these tobermorites to C-S-H(I) of different Ca/Si mole ratios.

## INTRODUCTION

Reactions of pozzolanas with lime at ordinary temperatures have been well investigated due to the practical standpoint, where hydration products are usually poorly crystalline. When autoclaving is applied, the hydration products become well crystalline but are very often dominated by the formation of 11Å tobermorite.

By applying the temperatures of steam curing to the reactions of pozzolanas, the present authors (1, 2, 3) could synthesise 10Å and 14Å tobermorites reproducibly. There have been many reports on synthetic 11Å tobermorite, but very few or none on synthetic 10Å and 14Å tobermorites. These 10Å and 14Å tobermorites showed not only some interesting characteristics which have not been reported so far, but also close relationships to C-S-H(I) of various Ca/Si. Besides, effects of Al and Na ions investigated in the syntheses at around these temperatures seem to give some clues to clarify how various tobermorites of different basal spacings could occur including 12Å tobermorite and tacharanite.

These results are reported in this paper.

## METHODS

Two kinds of pozzolanic glassy silica were chosen as a starting material, i.e. i) volcanic glass (ig loss 2.7, SiO<sub>2</sub> 74.3, Al<sub>2</sub>O<sub>3</sub> 12.7, Fe<sub>2</sub>O<sub>3</sub> 1.3, CaO 1.5, MgO 0.2, Na<sub>2</sub>O 4.4, K<sub>2</sub>O 3.0% ; 5,950 and 3,460 cm<sup>2</sup>/g), separated hydraulically from volcanic ash deposited abundantly in South Kyushu, and ii) silica glass (SiO<sub>2</sub> 99.97% ; 1,550 cm<sup>2</sup>/g), made from fused quartz. CaO was obtained by calcining precipitated CaCO<sub>3</sub> at 1,000-1,100°C.

Each siliceous material was mixed with CaO at starting Ca/Si of 0.6-0.9 and with water at water/solids ratio by weight of 20. For some preparations, 0.5-5% of γ-Al<sub>2</sub>O<sub>3</sub> (<0.05 μm) or 0.5-1% of NaOH were added to the mixture of silica glass and CaO by weight. Each mixture was kept in a stoppered polyethylene bottle and cured at 70-90°C for 2-120 days. For reactions at 100°C a stainless autoclave with a stirrer was used instead of the polyethylene bottle.

At intervals of 3-10 days, a portion of preparation was pipetted from the bottle, filtered and dried in a vacuum desiccator at room temperature.

All the preparations were examined by x-ray powder diffractometry and DTA-TG. Besides, some of them were examined by electron microscopy, energy dispersive x-ray microanalysis, selected area electron diffraction (SED) and chemical analysis of unreacted siliceous material. Changes of the basal spacing on heating in the air from 60°C to 900°C for 20 hrs at each temperature were measured by x-ray powder diffractometry to identify a type of tobermorite according to its thermal behaviour.

## RESULTS

## 1. Reaction of Volcanic Glass

Hydration products obtained by starting from volcanic glass are summarised in Table I. 10Å tobermorite formed at 80°C for 20-30 days.

TABLE I

X-ray diffraction data of 10Å tobermorite.

\* : ASTM diffraction data card 6-0020.

\*\* : Starting Ca/Si=0.7, 80°C, 30 days.

s : This line was detected as a shoulder on 2.96Å peak.

X-ray powder diffraction data of the synthetic 10Å tobermorite which showed the highest crystallinity among the preparations are listed in Table II compared with those of a natural specimen from Crestmore. The lattice parameters of the synthetic 10Å tobermorite computed by the least square method from the indexed data in Table 2 are  $a_0=11.24\text{\AA}$ ,  $b_0=7.31\text{\AA}$  and  $c_0=20.26\text{\AA}$ . These agreed well with those of Crestmore specimen, i.e.  $a_0=11.2\text{\AA}$ ,  $b_0=7.3\text{\AA}$  and  $c_0=20.5\text{\AA}$ .

The crystals of 10Å tobermorite were lath-like [A] or fibrous [B] elongated parallel to  $b$  with (100) cleavage (figure 1, A & B). In the SED pattern of a lath-like crystal lying on (100), diffraction spots were indexed to  $0kl$  where  $k$  and  $l$  were even (figure 2). When  $k$  was odd, reflections became continuous streaks parallel to  $c^*$  due to disorder. Some of the fibrous crystals showed a similar pattern to figure 2, but the diffraction spots disappeared very often during observation, and others gave diffraction rings similar to those of C-S-H(I). These results suggest that the lath-like crystals were the higher in crystallinity than the fibrous ones. Figure 3 is a high resolution electron micrograph of the synthetic 10Å tobermorite lying on (100). Lattice planes 10Å apart are resolved.

On prolonging the reaction time, 10Å tobermorite was gradually replaced by 11Å tobermorite, but a trace of 10Å tobermorite was detected even after 60-70 days. The basal spacing of these 11Å tobermorite was 11.8Å, a little longer compared with 11.3Å of ordinary ones. This is characteristic of Al-bearing 11Å tobermorite (4, 5).

The crystals of 11Å tobermorite were platy elongated parallel to  $b$  with (001) cleavage.

11Å tobermorite formed also by the reaction at 100°C for more than six days.

Moreover in almost all the runs, the formation of hydrogarnet,  $C_3ASH_4$ , was observed. Its yield was higher at 100°C than 80°C.  $C_3A \cdot CaCO_3 \cdot 12H_2O$  was also obtained at 100°C for one day.

Chemical compositions were determined by energy dispersive x-ray microanalysis on each crystal of 10Å and 11Å tobermorites using  $\beta$ -wollastonite and kaolinite for calibration (Table III). 10Å tobermorite gave the higher Ca/Si and Ca/(Si+Al) than 11Å tobermorite.

On heating in the air, 10Å tobermorite deteriorated to an amorphous form at around 300°C, which transformed into  $\beta$ -wollastonite at 800°C. 11Å tobermorite proved to be an anomalous type since it kept the basal spacing at about 11Å until the transformation into  $\beta$ -wollastonite occurred at 800-900°C.

## 2. Reaction of Silica Glass

14Å tobermorite was reproducibly obtained from mixtures of silica glass and CaO over a wide range of temperatures from 70°C to 100°C (Table IV). The lower the reaction temperature and the higher the starting Ca/Si were, the longer the period of reaction time was necessary to obtain 14Å tobermorite. At the reaction temperatures less than 80°C 14Å tobermorite was stable, but a tendency was observed that it might transform to 11Å tobermorite at temperatures higher than 90°C. X-ray powder diffraction data of the synthetic 14Å tobermorite agreed well with those of a natural specimen from Crestmore (6). Lattice parameters of the synthetic 14Å tobermorite were  $a_0=11.26\text{\AA}$ ,  $b_0=7.33\text{\AA}$  and  $c_0=27.88\text{\AA}$ .

The crystals of 14Å tobermorite were lath-like or platy elongated parallel to  $b$  with (001) cleavage (figure 4). In the SED pattern of the lath-like crystal lying on (001), diffraction spots were indexed to  $hko$  where  $h$  and  $k$  were even (figure 5). When  $h$  and  $k$  were odd, streaks parallel to  $a^*$  were observed, which show the presence of disorder.

Ca/Si and H<sub>2</sub>O/Si of 14Å tobermorite prepared at 80°C determined by chemical analysis converged to 0.74-0.82 and 1.35-1.42 respectively for more than 40 days. Ca/Si of the crystals determined by energy dispersive x-ray microanalysis are summarised in Table V.

On heating in the air, the synthetic 14Å tobermorite transformed to 11Å tobermorite at 60-400°C. These kept their basal spacing at about 11Å or reduced it to about 10Å during heating up to temperatures where the transformation to  $\beta$ -wollastonite occurred. The former should be designated as an anomalous type and the latter a mixed type (= an intermediate of normal and anomalous types) in the same way as shown in the classification of 11Å tobermorite (7).

Effects of addition of  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> and NaOH are summarised in Table VI as the hydration products prepared at 80°C.

Addition of alumina decreased the basal spacing and finally gave Al-substituted 11Å tobermorite.

C-S-H : C-S-H and C-S-H(I). CH : Ca(OH)<sub>2</sub>.

T : Tobermorite. Numerals in front of 'T' show the basal spacing (Å) of the tobermorite.

s : The basal spacing suffixed by 's' was observed at a shoulder of the neighbouring basal reflection in x-ray diffractometry.

When 2% of alumina to solids by weight was added, 11Å tobermorite formed in all the preparations of starting Ca/Si 0.6-0.9. The 11Å tobermorite was platy with (001) cleavage. Besides, addition of alumina decreased SiO<sub>2</sub> reactivity and H<sub>2</sub>O/Si, increased Ca/Si and improved normality in thermal behaviours of 11Å tobermorite.

The results in Table VI may suggest the formation of 12Å tobermorite or tacharanite during a decrease of the basal spacing according to an increase of alumina from 0.5 to 5%.

Addition of 5% of alumina retarded the reaction and gave 10Å tobermorite of poor crystallinity as an intermediate phase.

The crystallinity of 14Å tobermorite was improved with addition of 0.5-1% of NaOH.

The reaction with addition of alumina and NaOH showed a certain similarity to that of volcanic ash.

#### DISCUSSION

As crystalline tobermorites, the phases having the basal spacing of 14Å, 12Å, 11Å, 10Å and 9Å are known so far. Since 9Å tobermorite is obtained as a dehydrated form of the other tobermorites, its hydrothermal synthesis at low temperatures seems to be impossible.

14Å tobermorite has been found in several places (8), but its synthesis was only once reported by Kalousek and Roy (9). The synthetic 14Å phase seems to be poorly crystalline judging from their brief description on it. 14Å tobermorite prepared in the present study was well crystalline, and showed different thermal behaviours from the natural specimens. The synthetic ones were an anomalous type or a mixed type. On the other hand, all the natural specimens have been reported to transform to 11Å tobermorite at about 60°C on heating in the air, and then to 9Å tobermorite at about 300°C. Namely, these are a normal type. Anomaly of the synthetic specimens seem to be caused by its low Ca/Si due to high solubility of silica glass (10).

12 Å tobermorite is recently thought to be possibly the same as tacharanite (11). The fact that tacharanite, Ca<sub>4</sub>(Si<sub>6</sub>O<sub>18</sub>H<sub>2</sub>)·2/3Al<sub>2</sub>O<sub>3</sub>·5H<sub>2</sub>O (12), contains Al ions in its composition may suggest the similarity of the 12Å phase prepared with addition of alumina (Table VI) to tacharanite. 12Å phase was also observed in the preparations without addition of alumina at 90-100°C (Table IV), and during heating the synthetic 14Å tobermorite in the air. Further investigations are still continuing

to clarify relationships among them.

The lowest temperature ever reported where the formation of 11Å tobermorite was possible was 90°C by Mitsuda et al (13) who could succeed by using clinoptilolite, a natural zeolite. The present results suggest the possibility to lower it even below 80°C, when suitable siliceous materials of high solubility are selected and sufficient periods of reaction time are allowed. The presence of alumina was confirmed to function well for this purpose.

The synthesis of 10Å tobermorite has been unknown so far. However, by starting from volcanic glass, or silica glass with addition of 5% of alumina 10Å tobermorite could be obtained reproducibly. A decrease of silica solubility caused by the presence of Al ions may be suitable for the formation of 10Å tobermorite which is thought to be richer in Ca and deficient in Si compared to 11Å tobermorite (11). The synthetic 10Å tobermorite was peculiar in its crystal habit to show (100) cleavage. Almost all tobermorites have been known to be (001) cleavage except 11Å tobermorite from Loch Eynort (14). Further study is still necessary to clarify these reasons.

A rough correlation has been reported on C-S-H(I) between the basal spacing and Ca/Si; the basal spacing falls from 13-14Å for Ca/Si of 0.8, 12-12.5Å for Ca/Si of about 1.0, to about 10Å for Ca/Si of 1.5 (15). In the present study, 14Å tobermorite showed the lowest Ca/Si; 10Å tobermorite the highest Ca/Si and 11Å tobermorite an intermediate Ca/Si between 14Å and 10Å phases. It seems therefore reasonable to consider that each tobermorite of different basal spacing is a well crystalline form of each C-S-H(I) of different Ca/Si respectively. Temperatures around 80°C are thought to be effective to crystallise these C-S-H(I) especially to semi-stable 14Å tobermorite, or less stable 10Å and 12Å tobermorite.

#### CONCLUSIONS

Reproducible syntheses of 10Å and 14Å tobermorite were possible by hydrothermal reactions of volcanic glass or silica glass with lime at temperatures about 80°C.

The 10Å tobermorite was lath-like or fibrous elongated parallel to *b* with (100) cleavage. The 14Å tobermorite was stable hydrothermally at temperatures less than 80°C in the absence of Al ions, and was confirmed to be an anomalous or a mixed type in its thermal behaviour.

Addition of alumina to the mixture of silica glass and lime functioned to decrease the basal spacing of tobermorite from 14Å to 11Å, the latter of which was the most stable under the present reaction conditions. 12Å phase, which might be 12Å tobermorite or tacharanite, and 10Å tobermorite formed on the way of crystallisation to 11Å tobermorite with addition of alumina. These were less stable than 11Å or 14Å tobermorite.

It is suggested from these results that each tobermorite of different basal spacing may be a well crystalline form of C-S-H(I) of different Ca/Si.

# Hydration Reactions of $C_3A$ Contained in an Unusual Flyash

## *Réactions d'hydratation d'une cendre volante particulière contenant du $C_3A$*

SIDNEY DIAMOND, U.S.A.

### SUMMARY :

Flyashes produced from certain lignite and sub-bituminous coals have high contents of analytical  $CaO$ , presumably derived from limestone within the coal deposits. In the U.S. a special category, "Class C" flyash has been designated for these materials. The mineralogy of the non-glassy portions of some of these flyashes is different from conventional flyashes, and in the material described  $C_3A$ , free lime, and anhydrite are all present. The flyash sets rapidly when mixed with water, and produces ettringite and  $C_4ASH_{12}$ . The unique spherical morphology of the flyash grains makes the morphological relationships between the hydration products and the unhydrated material unusually clear. The early reactions are similar to those of  $C_3A$  in portland cement, and the ash might serve as a useful model system for the study of the influence of various admixtures and other substances on  $C_3A$  reactions and setting behavior. Presumably ettringite and  $C_4ASH_{12}$  are also produced when flyashes similar to the one studied are incorporated in concrete, and their production should enhance early strength development.

### RESUME :

Les cendres volantes produites par certains lignites et par des charbons bitumineux ont une teneur élevée en ions  $CaO$ , provenant probablement des calcaires incorporés à ces dépôts géologiques. Aux Etats-Unis, une catégorie spéciale de cendres volantes "la classe C" a été définie pour ces matériaux. La minéralogie des phases vitreuses de quelques unes de ces cendres volantes est différente de celle des cendres volantes habituelles, et dans ces matériaux on trouve du  $C_3A$ , de la chaux libre et de l'anhydrite. Ces cendres volantes font prise rapidement lorsque malaxées avec de l'eau; il se produit de l'ettringite et du  $C_4ASH_{12}$ . La forme, uniquement sphérique, des grains de cendres volantes, rend particulièrement nettes les relations morphologiques entre le matériau anhydre et les produits de son hydratation. Les réactions initiales sont analogues à celles du  $C_3A$  dans le ciment portland, et ces cendres ont pu servir de modèle courant, pour l'étude de l'action de divers additifs et autres substances, sur les réactions du  $C_3A$  et le comportement durant la prise. Il est probable que de l'ettringite et du  $C_4ASH_{12}$  sont aussi produits quand des cendres volantes analogues à celles étudiées ci-dessus sont incorporées au béton; leur utilisation pourrait apporter une augmentation des résistances initiales.

## INTRODUCTION

The chemical and mineralogical composition of flyashes largely reflect the nature of the inorganic portions of the coal being burned, and to a lesser degree the burning conditions involved. Most flyashes typically contain glass and such minerals as quartz, mullite, magnetite, hematite, periclase, etc. The reactive component is primarily the glass, and reaction in concrete occurs only slowly.

In recent years lignite and sub-bituminous coals have become major sources of fuel for electric power plants in the western part of the U.S. Many of these coals include significant contents of limestone, thus generating flyashes much richer in CaO than conventional flyashes. With large volumes of such flyashes now available, their use in concrete is becoming widespread. Committee C-9 on Concrete of ASTM now recognizes such flyashes as constituting a special and separate category of admixture, distinguishing them as "Class C" flyashes (1).

The mineralogy of the crystalline portions of Class C flyashes tends to be somewhat different from that of conventional flyashes. In addition to quartz, some of these materials contain significant contents of  $C_3A$ . Free CaO is often present, as might be expected. Sometimes some, or most of the limited content of  $SO_3$  present occurs as anhydrite. The major component remains glass, however.

With the presence of  $C_3A$  and a source of available sulfate, the obvious expectation is that ettringite and the calcium monosulfate hydrate  $C_4ASH_{12}$  might be produced when such flyashes are mixed with water, especially since free CaO should insure a relatively high pH. Thus responses similar to some of the early hydration reactions occurring in portland cement might take place in flyash-water pastes.

The present work describes such a response with a particular Class C flyash from Muskogee, Oklahoma. This material has a CaO content of approximately 26% and a relatively high  $SO_3$  content, approximately 3%. X-ray diffraction peaks are weak, indicating that glass is the major constituent as expected, but significant contents of quartz,  $C_3A$ , anhydrite, and uncombined CaO are detected. In addition, a little calcite (presumably due to secondary carbonation of the free lime), some periclase, and even a trace of  $C_4A_3S$  appear to be present.

## FLYASH MORPHOLOGY

The morphology of this flyash is similar to those of a number of Class C flyashes examined by the writer, and significantly different from many conventional flyashes. Essentially all of the particles seem to be solid spheres, mostly of diameters between 1 and 15  $\mu m$ . A few larger spheres are occasionally found, but carbonaceous residues and other evidences of incomplete burning and melting are generally absent, as are very coarse particles of any kind. Also almost completely absent are hollow-shell spheres and complex sphere-within-sphere structures so prominent in scanning electron microscope (SEM) photographs of conventional flyashes.

A typical field showing a reasonably representative size distribution for this material is given as Fig. 1. In this figure the largest sphere, in the

lower central portion of the field, is approximately 25  $\mu m$  in diameter.

Fig. 1. Morphology and Size Distribution of Flyash Particles. Original Magnification 1,000 x.

## REACTIONS WITH WATER

Pastes were prepared by mixing flyash and deionized water and the resulting responses were recorded by various techniques. The water:solids (w:s) ratios used varied from 0.2 to 0.5.

It was noted that there was a distinct but short-lived induction period before any temperature elevation was observed, typically about 15 minutes. Rapid and continuous temperature elevation then took place in the small exposed paste specimens, reaching to as high as 36° C from the initial 22° C laboratory temperature for the w:s 0.2 paste. The temperature rise terminated in about 30 minutes or less after mixing.

Setting, as measured by Vicat needle, took place with exceeding suddenness, at times between 15 minutes for the w:s 0.2 paste and 45 minutes for the w:s 0.5 paste.

X-ray diffraction examination of the hardened pastes immediately after set revealed the presence of significant contents of ettringite.

The pastes were maintained in sealed containers after set, and sampled periodically for x-ray and SEM examination.

After about 4 hours a small peak for calcium monosulfoaluminate hydrate ( $C_4ASH_{12}$ ) at approximately 9Å was detected in most of the pastes, and this increased somewhat with further curing. In contrast, the ettringite pattern was initially quite strong and a large number of peaks of this compound were recorded, even at the earliest period examined. Both components seemed to be retained indefinitely, without too much apparent change in the relative proportions as judged by XRD.

## MICROSTRUCTURE OF REACTED PASTES

Fig. 2 shows a characteristic field taken of the w:s 0.3 paste shortly after set, at approximately  $\frac{1}{2}$  hour after initial mixing. It is immediately obvious that in these pastes set is due to formation of ettringite, rod-shaped particles of which are seen to protrude from individual flyash spheres and act as bridges. In the lower right portion of the micrograph a considerable cluster of ettringite rods seems to have developed, presumably from a grain that is rapidly decomposing.

Fig. 2. Flyash Paste, W:S 0.3,  $\frac{1}{2}$  Hour, Showing Development of Ettringite Rods.

In Fig. 2 and subsequent figures the scale is indicated by the length of the separated right-hand portion of the white marker bar, which is in all cases 5  $\mu$ m in length. The gap between the two portions is 0.5  $\mu$ m wide.

The appearance of the pastes after 4 hours is indicated in Fig. 3, where again the ettringite rods are clearly defined, and the newly-developing  $C_4ASH_{12}$  plates are visible for the first time. It is apparent how a rigid three dimensional structure developed initially through the growth of ettringite rods can be reinforced through the subsequent development of platy particles of the  $C_4ASH_{12}$ , which tend to build up a characteristic "edge to face" or "cardhouse" structure. This has previously been observed by the present writer to be characteristic of this compound in portland cement pastes as well (2).

Further details of the intimacy of the connection between the flyash spheres giving rise to the ettringite and  $C_4ASH_{12}$  products and the products themselves can be seen in Fig. 4, which shows the central area observed in Fig. 3 at higher magnification. Attention is called to growth of the large ettringite rods almost perpendicular to the surface of the host sphere in the large sphere in the upper central portion of the figure and in the smaller sphere in the lower right portion; to the bridging action effected by the platy particle cluster between the large sphere previously mentioned and the small sphere at the center of the micrograph, and to the many connections visible between the

Fig. 3. Flyash Paste, W:S 0.4, 4 Hours, Showing Initial Development of  $C_4ASH_{12}$  Plate Structure Reinforcing Ettringite.

ettringite rods and the  $C_4ASH_{12}$  plates, which thus constitute a single, combined, continuous reinforcing system.

Fig. 4. Higher Magnification View of Area of Fig. 3 Showing Details of Connections Between Particles.

Fig. 5 for a paste taken at 8 hours shows at a somewhat reduced scale how such a structure apparently can bridge quite wide gaps between residual flyash spheres and maintain a rigid, reinforced, but not very dense structure. Also, here for the first time in a few areas some nondescript small products which appear to be neither ettringite nor  $C_4ASH_{12}$  start to appear.

It is noteworthy that the residual flyash spheres in the figures so far displayed mostly do not show any significant change in character of surface texture arising as a result of the reactions. The large sphere in the lower right portion of Fig. 5 is not significantly rougher in surface character than some of the spheres present in the original flyash, even

though it does appear rougher than the large sphere in Fig. 1.

A typical view of the appearance of the pastes after 7 days is shown in Fig. 6. There has been comparatively little change after the first few hours, except that an increasing proportion of nondescript particles seems to be present in many areas. Some of the flyash spheres have lost their earlier almost pristine appearance and are visibly corroding and disintegrating, as can be seen near the left margin and also in the upper left portion of the micrograph.

Fig. 5. Flyash Paste, W:S 0.4, 8 Hours, Showing Effects of Reaction Products in Bridging Wide Gaps Between Flyash Spheres.

Fig. 6. Flyash Paste, W:S 0.4, 7 Days, Showing Accumulation of Nondescript Particles and Fragments of Decomposing Spheres.

Comparatively little further change takes place in the period between 7 and 28 days. The general appearance remains roughly the same. However, especially at low w:s ratios, here and there one can detect individual particles and occasionally clusters of small rods which the writer takes to be C-S-H gel

of the Type I variety (2). The appearance of this material is indicated in Fig. 7. Presumably this represents the product of the reaction of the glassy siliceous component in the flyash with dissolved  $\text{Ca(OH)}_2$ , i.e. the conventional, slow "pozzolanic" reaction. If this interpretation is correct, this system is unusual in that the "pozzolan", that is, the flyash, is supplying its own lime.

Fig 7. Flyash Paste, W:C 0.2, 28 Days, Showing Late Development of Occasional C-S-H Gel Particles

#### DISCUSSION

It is apparent from the preceding descriptions that  $\text{C}_3\text{A}$  in the present flyash reacts in a manner entirely analogous to the way it does in portland cement. However, the unique spherical morphology of the flyash particles provides an unusually clear opportunity for visualization of the spatial relationships between the newly formed hydration products and the starting material, and for studying the details of the structure that develops.

Possibly useful information concerning the effects of various parameters, set modifying chemicals, and other influences on the early reactions in concrete can be obtained using such flyash pastes as model systems. Of course due allowance must be made for the differences between flyash pastes and the more complex portland cement pastes in concrete.

Perhaps of more significance, it is clear that the contribution of flyashes like the present one to early strength gain when they are used in concrete stems from formation of additional ettringite and  $\text{C}_4\text{ASH}_{12}$  hydration product particles, of the same type as formed from the  $\text{C}_3\text{A}$  within the portland cement. This action is thus completely different in character from the conventional pozzolanic response associated generally with flyashes, and involving the formation of C-S-H gel from reaction of the glassy component. The latter response occurs in the present flyash as well, but at a much different and later time.

#### ACKNOWLEDGEMENTS

The courtesy of Mr. William F. Scriminger of the Muskogee Environmental Conservation Co. in supplying the flyash and chemical analyses is much appreciated.

# Influence of pozzolana on the hydration of $C_3A$

## *Influence de la pouzzolane sur l'hydratation du $C_3A$*

H. UCHIKAWA, Doctor of Engineering, Onoda Cement Co., Ltd. and S. UCHIDA, Onoda Cement Co., Ltd, Japon.

**RESUME :** Des échantillons primaires de  $C_3A$ , de  $CaSO_4 \cdot 2H_2O$ , de  $C_3A$ ,  $CaSO_4 \cdot 2H_2O$ , ou de  $Ca(OH)_2$  ont été mélangés à de la pouzzolane (40% pouzzolane en poids). Les mélanges ont alors été hydratés à  $20^\circ C$  ( $\pm 1^\circ C$ ) dans le rapport eau/solide de 0.6. Cette expérimentation est destinée à étudier l'influence de la pouzzolane sur l'hydratation du  $C_3A$ , la réaction "pouzzolanique", et le mécanisme de l'hydratation du système: - pouzzolane- $C_3A$ - $CaSO_4 \cdot 2H_2O$ - $Ca(OH)_2$ .

Le taux d'hydratation initial du  $C_3A$  est ordinairement accéléré, mais on note un retard en début de réaction. Dans la phase moyenne et finale de la réaction, le taux d'hydratation est quasiment identique à celui observé sans pouzzolane.

Bien qu'il n'y ait pas de différence notable entre les deux sortes d'hydrates formés, avec ou sans pouzzolane dans le début de la réaction, dans les phases moyennes et finales, on observe la formation de C-S-H lorsque de la pouzzolane riche en silicium est utilisée, alors que l'on obtient un composé  $C_3AH_6$  par utilisation de pouzzolane alcaline.

Un changement dans la phase liquide lors du début de la réaction conduit à la formation d'ettringite. Contrairement à la pouzzolane placée en milieu aqueux pur, on a pu noter également un changement des concentrations en ions  $Na^+$  et  $K^+$  augmentant avec le temps; Ceci suggère une attaque de la surface des grains de pouzzolane. Cette assertion est confirmée par l'observation "MET" et "MES", au microscope électronique à transmission et à balayage.

Le début de la réaction, variable selon de type de pouzzolane utilisé, prend place en 1 à 28 jours.

Malgré la grande différence entre la vitesse de réaction du  $C_3A$  avec la pouzzolane observée suivant les cas, la réaction semble avoir lieu par diffusion d'ions  $Ca^{2+}$ , d'ions alcalins, ou des deux ensemble - suit un gonflement, puis la destruction du films superficiel par la pression osmotique; la précipitation en surface de l'hydrate ainsi formé, termine cette réaction. L'alcalinité intrinsèque des pouzzolanes joue un grand rôle non seulement lors de l'hydratation, mais aussi dans la formation de la texture solide de la forme pâteuse durcie; Ce rôle est aussi primordial dans la constitution de l'espace entre les grains de pouzzolane et leur hydrate superficiel.

**SUMMARY :** The preliminary samples containing  $C_3A$  and  $CaSO_4 \cdot 2H_2O$  or  $C_3A$ ,  $CaSO_4 \cdot 2H_2O$  and  $Ca(OH)_2$  were mixed with 40% by weight of pozzolana and the mixtures were hydrated at  $20 \pm 1^\circ C$  with W/S ratio of 0.6 in order to study the influence of pozzolana on the hydration of  $C_3A$ , the pozzolanic reaction and the mechanism of the hydration in the system pozzolana- $C_3A$ - $CaSO_4 \cdot 2H_2O$ - $Ca(OH)_2$ .

The rate of the initial hydration of  $C_3A$  was generally accelerated by the addition of pozzolana. But it was depressed in the early stage. The rate of the hydration of  $C_3A$  in middle and later stage recovered almost the same level as without pozzolana.

Though there were no remarkable difference of the kinds of hydrates with or without pozzolana in early stage, C-S-H was formed when Si rich pozzolana was used and  $C_3AH_6$  was observed when alkali rich pozzolana was used in middle and later stage.

Compositional change of liquid phase in initial stage corresponded to the change in ettringite formation. The change in  $Na^+$  and  $K^+$  concentration, quite different from the case of pozzolana's immersing in pure water, increased with age which suggests the destruction of the surface structure of pozzolana grain. This speculation was confirmed by TEM and SEM observation.

The starting time of pozzolanic reaction varied with the character of pozzolana from one day to 28 days.

In spite of large difference between the rate of reaction of  $C_3A$  and pozzolana, the reaction proceeds through the formation of amorphous surface layer by leaching out of  $Ca^{2+}$  and/or alkalies ions, swelling and destruction of surface film by osmotic pressure and precipitation of hydrate on the surface of the film. The alkalies in pozzolana play an important role not only in the hydration reaction but also in the formation of the texture of hardened paste especially the clearance between pozzolana grain and hydrate.

# 1. PREPARATION OF SAMPLE AND EXPERIMENTAL PROCEDURE

1 mole of synthesized  $C_3A$  from stoichiometrical mixture of guaranteed reagent having 3000  $cm^2/g$  of Blaine specific surface area was mixed with 0.5 mol of  $CaSO_4 \cdot 2H_2O$  and/or 0.5 mole of  $Ca(OH)_2$ . Then 40% by weight of pozzolanas and the fly ash were added and blended sufficiently to prepare the samples.

The samples were hydrated at  $20 \pm 1^\circ C$  with  $W/S = 0.6$  except for the case of conduction calorimetry ( $W/S = 0.8$ ) and the measurement of liquid phase composition ( $W/S = 10$ ).

Powder X-ray diffraction (XRD) and simultaneous differential thermal analysis (DTA)-differential scanning calorimetry (DSC)-thermogravimetry (TG) under argon atmosphere (1) were used for the identification and quantitative analysis of crystalline phase. Conduction calorimetry was applied to study the initial hydration. Scanning electron microscope (SEM) and high resolution transmission electron microscope (TEM) were used to observe the microfeature and microstructure of pozzolana,  $C_3A$ , hydrate and hardened paste.

Mercury penetration porosimetry was used to know the macrostructure of hardened paste and pore size distribution in the paste above  $75 \text{ \AA}$ .

To determine the degree of reaction of pozzolana, separation of  $C_3A$ ,  $CaSO_4 \cdot 2H_2O$ ,  $Ca(OH)_2$  and hydrate from hardened paste was effectively performed by 3% HCl-methanol solution.

# 2. RATE OF HYDRATION OF $C_3A$ IN THE SYSTEM CONTAINING POZZOLANA

Initial hydration of  $C_3A$  was pursued by conduction calorimetry. First peak within an hour is the formation of Ca-Al hydrate and ettringite when gypsum is present. The second peak usually appears in a couple of hours after mixing with water corresponds to the formation of monosulfate hydrate.

The effect of  $CaSO_4 \cdot 2H_2O$  and  $Ca(OH)_2$  on the initial hydration of  $C_3A$  was the same as in the case without pozzolana and the effect of pozzolana varied with their own character.

The rate of the hydration of  $C_3A$  in the initial stage within one day was the order of

$C_3A$ , pozzolana- $C_3A$ , pozzolana- $C_3A$ - $CaSO_4 \cdot 2H_2O$ ,  $C_3A$ - $CaSO_4 \cdot 2H_2O$ , pozzolana- $C_3A$ - $CaSO_4 \cdot 2H_2O$ - $Ca(OH)_2$  and  $C_3A$ - $CaSO_4 \cdot 2H_2O$ - $Ca(OH)_2$ . Generally speaking, pozzolana accelerate the initial rate of hydration of  $C_3A$  in the presence of  $CaSO_4 \cdot 2H_2O$  and  $Ca(OH)_2$ . Among pozzolanas, Kanto loam which has large specific surface area, high content of aluminum and high cation exchange capacity (CEC) value showed the most remarkable acceleration proportional to the added quantity as shown in Fig. 1. This effect is more clearly recognized in the second peak than in the first peak. One exception was observed in the second peak of Furue shirasu mixed sample containing much alkalies.

The degree of hydration estimated by the measurement of unhydrated  $C_3A$  with XRD in Fig. 2 shows that  $C_3A$  in the sample mixed with Kanto loam attained to about 65% at one day while the others were remained about 25%. The degree of hydration other than Kanto loam at 28 days attained to about 95% but it remained below 90% in Kanto loam mixed sample.

# 3. CHANGE IN ION CONCENTRATION OF LIQUID PHASE

The change in concentration of several kinds of ions in the liquid phase separated from

Note:

\*, 100°C dry base, \*\*, measuring time, \*\*\*, pH:12.2

Fig. 2-Degree of hydration of  $C_3A$  in the paste [pozzolana- $C_3A$ - $CaSO_4 \cdot 2H_2O$ - $Ca(OH)_2$ ]

the sample of suspension hydration indicates that the degree of hydration of  $C_3A$  is closely related to the concentration of  $Ca^{2+}$ ,  $AlO_2^-$  and  $SO_4^{4-}$ . In Kanto loam mixed sample  $Ca^{2+}$  consumed rapidly by the precipitation of ettringite. High  $AlO_2^-$  concentration in initial stage is favourable to the formation of ettringite. On lowering the concentration of  $Ca^{2+}$ ,  $AlO_2^-$  and  $SO_4^{4-}$  by the precipitation of ettringite,  $C_3A$ ,  $CaSO_4 \cdot 2H_2O$  and  $Ca(OH)_2$  dissolve into liquid phase which brings high degree of hydration of  $C_3A$ . When  $CaSO_4 \cdot 2H_2O$  is completely consumed,  $AlO_2^-$  begin to increase and the hydration of  $C_3A$  is slow down.

Alkalies were not released from Beppu white clay and Kanto loam in pozzolana-water system. Only from Furue shirasu and fly ash, Alkalies were dissolved into pure water and they show fairly high level from initial and kept constant. On the contrary, in the present system pozzolana- $C_3A$ - $CaSO_4 \cdot 2H_2O$ - $Ca(OH)_2$  alkali concentration increased with age. The fact indicates the destruction of the surface structure of pozzolana grain through the leaching out of alkalies by the protonic attack of dissociated water under caustic circumstance.

#### 4. PROCESS OF HYDRATION

Hydrates produced during the hydration were identified by XRD, DTA and TEM observation as shown in Table II.

Initially formed Ca-Al hydrate and ettringite changed to monosulfate hydrate, hexagonal solid solution of monosulfate hydrate-tetrahedral calcium aluminate hydrate, Ca-Al hydrate with low C/A ratio and C-S-H in later age through monosulfate hydrate. Though there were no remarkable difference of the kind of hydrate with or without pozzolana in early age, C-S-H was formed when Si rich pozzolana was used and  $C_3AH_6$  was observed when alkali rich pozzolana was used in later age. The existence of  $C_3AH_6$  in fairly early age is considered to be responsible to alkali concentration of liquid phase as the stability of hexagonal Ca-Al hydrate decreases under coexistence of alkali (2) (3).

#### 5. MICRO STRUCTURE OF HYDRATE AND HARDENED PASTE

The Al rich amorphous layer caused by the elution of  $Ca^{2+}$  from the surface of  $C_3A$  grain and the thin Ca-Al hydrate precipitated on the outer side of amorphous film were observed by

high resolution TEM as shown in Fig. 4. The similar figure of surface layer on pozzolana grain brought by the dissolving-out of alkali ions and  $Ca^{2+}$  and precipitated hydrate on the surface of the layer were also recognized by TEM as shown in Fig. 4.

By SEM observation, precipitated hexagonal Ca-Al hydrate, short rod shaped ettringite of the surface of  $C_3A$  grain, rectangular ettringite just outside them and large monosulfate hydrate grown towards the capillary space were clearly seen at the neighbour of  $C_3A$  grain. While small hexagonal Ca-Al hydrate, rectangular ettringite and type II C-S-H were observed on the surface of pozzolana grain as shown in Fig. 5.

#### 6. POZZOLANIC REACTION

The pore size distribution above 75Å measured by mercury penetration method is shown in Fig. 6. In Beppu white clay mixed sample, pore size distribution shifted towards small radius with age. The densification of hardened paste in this case is considered to be due to the formation of C-S-H. In Kanto loam mixed sample, added  $Ca(OH)_2$  was completely consumed to form aluminate hydrate and built paste structure in early age maintained for long time without changing the pore size distribution. Furue shirasu mixed sample showed similar behavior to Takehara fly ash mixed sample in the change of pore size distribution but the densification was delayed owing to the conversion of hexagonal solid solution to  $C_3AH_6$ .  $Ca(OH)_2$  in hardened paste determin-

ed by DSC-TG are shown in Fig. 7. In Kanto loam mixed sample  $Ca(OH)_2$  was completely consumed within one day by vigorous formation of ettringite.

The degree of reaction of Kanto loam attained to 16% even at one day (Fig. 8.). In the other samples, consumption of  $Ca(OH)_2$  attributed to the formation of  $C_4AH_{13}$  and solid solution of  $C_3A \cdot (CaSO_4, Ca(OH)_2) \cdot H_{12}$ . The solid solution tends to decompose to monosulfate hydrate and  $C_3AH_6$  when the concentration of  $Ca(OH)_2$  is lowered. In Beppu white clay mixed sample, C-S-H was formed by pozzolanic reaction in fairly early stage and decomposition of hexagonal solid solution to monosulfate hydrate and  $C_3AH_6$  was retarded as it contained much reactive opal and less alkalis. In Furue shirasu mixed sample containing much alkali, conversion of  $C_3A \cdot (CaSO_4, Ca(OH)_2) \cdot H_{12}$  to monosulfate hydrate and  $C_3AH_6$  occurred at 28 days in spite of coexisting large amount of  $Ca(OH)_2$ . The pozzolanic reaction started at 28 days as in Fig. 7., C-S-H, however, was not observed until 91 days.

#### 7. MECHANISM OF THE HYDRATION IN THE SYSTEM POZZOLANA- $C_3A$ - $CaSO_4 \cdot 2H_2O$ - $Ca(OH)_2$

Referring the before-mentioned experimental results and the idea of Skalny, Jawed and Taylor (4) on the hydration of  $C_3A$ , the mechanism of the hydration in the system pozzolana- $C_3A$ - $CaSO_4 \cdot 2H_2O$ - $Ca(OH)_2$  is considered to be as follows:

On contact with water,  $C_3A$  is protonially attacked by  $H_3O^+$  formed by the dissociation of water releasing  $Ca^{2+}$  and leaving amorphous Al rich layer on  $C_3A$  grain surface. Amorphous layer is expanded by osmotic pressure and forms slight clearance between hydrated  $C_3A$  grain and itself. This clearance is filled with  $AlO_2^-$  rich solution. There exists  $Ca^{2+}$ ,  $SO_4^{2-}$  rich solution near at the outside of the layer brought by the coproceeding dissolution of calcium sulfate and calcium hydroxide.  $Ca^{2+}$  is adsorbed on the amorphous Al rich layer on the surface of  $C_3A$ . The grain charges positively and the active sites on the surface of  $C_3A$  decreases. Therefore, hydration of  $C_3A$  is stopped temporarily.  $SO_4^{2-}$  is adsorbed on the surface of positively charged grain and play a part of blocking against protonic attack of hydronium ion. Amorphous Al rich film is broken at the weakest point by osmotic pressure. From the openings  $Ca^{2+}$  and  $SO_4^{2-}$  introduced into inner side of film.

Fig. 9-Schematic explanation of the mechanism of hydration in the system pozzolana- $C_3A$  under the existence of  $Ca(OH)_2$  and  $CaSO_4 \cdot 2H_2O$

$AlO_2^-$  moves towards outer side of film and ettringite precipitates on both sides of film. On inner side of film, monosulfate hydrate often precipitates as  $SO_4^{2-}$  is apt to be in shortage. Monosulfate hydrate on the inner side is generally small in size because of the narrow precipitation space. Precipitated hydrates have high crystallinity, so it is easy for  $Ca^{2+}$ ,  $AlO_2^-$ ,  $SO_4^{2-}$  etc. to diffuse through the hydrate layer covering on the  $C_3A$  grain. The porous ettringite layer is broken by the expansion of itself to make the contact of water to  $C_3A$  easy.

Hydration of  $C_3A$  proceeds repeating above mentioned process as one cycle. When solid  $CaSO_4 \cdot 2H_2O$  consumed completely and concentration of  $SO_4^{2-}$  lowers, monosulfate hydrate or solid solution of monosulfate hydrate and  $C_4AH_{13}$  precipitates on the outside of film. Void in the paste outside the grain is usually large so hexagonal monosulfate hydrate or its solid solution precipitate as large crystal towards large void to build the well-known card house structure.

Ettringite once formed convert to monosulfate hydrate or its hexagonal solid solution. The time of conversion of hexagonal solid solution to cubic  $C_3AH_6$  depends upon the concentration of alkali ion.

Negatively charged grains of pozzolana, on the other hand, adsorb  $Ca^{2+}$  formed by the hydration of  $C_3A$ ,  $CaSO_4 \cdot 2H_2O$  and  $Ca(OH)_2$  on its surface. By presenting the sites of precipi-

tation of ettringite formed by the hydration of  $C_3A$ , pozzolana accelerates the hydration of  $C_3A$ .

Protonic attack of water against pozzolana grain proceeds gradually and  $Na^+$  and  $K^+$  begin to dissolve into water from several minutes to one day after mixing with water. According to the dissolution of  $Na^+$  and  $K^+$  into water, solubility of  $Ca^{2+}$  decreases and  $Ca^{2+}$  precipitates as  $Ca(OH)_2$  to lower  $OH^-$  concentration in liquid. As solubility products in liquid are constant, water dissociate to compensate the decrease of  $OH^-$  concentration and produce hydronium ion which result in accelerating the protonic attack.

Si and Al rich amorphous layer swell gradually and makes slight clearance between pozzolana grain and itself. The clearance filled with Si, Al and alkalies rich solution. Thereafter the film is broken by the osmotic pressure,  $SiO_4^{4-}$  and  $AlO_2^-$  in clearance diffuse through the openings.  $SiO_4^{4-}$  and  $AlO_2^-$  near at the outside of film precipitate as ettringite, monosulfate hydrate, Ca-Al hydrate and C-S-H on the surface film of the outside of pozzolana grain or on the surface hydrate layer of  $C_3A$  grains according to the concentration of  $Ca^{2+}$  and  $SO_4^{2-}$  in the liquid. As the rate of diffusion of  $SiO_4^{4-}$  is slow and the concentration of  $Ca^{2+}$  is rather high even at the neighbour of pozzolana grain, C-S-H precipitates restrictively on the outside surface of the amorphous film enveloping pozzolana grain. C-S-H is observed in the paste containing negatively charged acidic pozzolana with low alkali and high  $SiO_2$ .

Concentration of  $SO_4^{2-}$  in the liquid near the pozzolana grain is low, so the nearest hydrate to the pozzolana grain consists mainly of Ca-Al hydrate and towards outside the solid solution of Ca-Al hydrate and monosulfate hydrate and monosulfate hydrate precipitate in this order. Ettringite, precipitated in the early stage of hydration, is not observed in the later stage.

When alkalies do not exist, destruction of amorphous Si, Al rich film enable  $Ca^{2+}$  to move into inside of the film from the openings and to precipitate C-S-H, Ca-Al hydrate on pozzolana grain and filled the clearance. Therefore no void is observed between pozzolana grain and hydrates in this case.

Pozzolana is a mixture composed of alkali containing minerals and glasses and those without alkali. In paste hydration, some places become rich in alkali and others are poor. Therefore, the hydrates produced in alkali rich region tend to be stripped off from pozzolana surface and the hydrates produced in alkali poor region attached closely to pozzolana grain. The glass such as in fly ash contains homogeneously much alkali, so the typical stripping off of the hydrates from pozzolana grain is often clearly observed.

#### 8. CONCLUSION

(1) In the system pozzolana- $C_3A$ - $CaSO_4 \cdot 2H_2O$ , regardless of the presence of  $Ca(OH)_2$ , initial hydration of  $C_3A$ , formation of ettringite and

monosulfate hydrate were accelerated by the addition of pozzolana.

In the system pozzolana- $C_3A$ , initial hydration corresponding to the formation of Ca-Al hydrate was retarded by the addition of pozzolana.

$Ca(OH)_2$  acted as retarder in above-mentioned system.

Pozzolana tend to lower the degree of hydration of  $C_3A$  in later age.

(2) Alkalies in liquid phase from pozzolana, quite different from the case of pozzolana-water suspension, increased in concentration with age. Alkalies accelerated the conversion of hexagonal  $C_3A \cdot (CaSO_4, Ca(OH)_2) \cdot H_{12}$  to cubic  $C_3AH_6$  by decreasing the stability of hexagonal solid solution.

(3) There were no essential difference of the kind of hydrate and process of hydration with or without pozzolana. Besides Ca-Al hydrate, ettringite, monosulfate hydrate, hexagonal solid solution; type II C-S-H and  $C_3AH_6$  were produced according to the composition of used pozzolana.

(4) Structure of hardened paste was more porous than that of pozzolanic cement and pozzolana- $C_3S$ . Formation of C-S-H contributed to the densification of hardened paste, while aluminate hydrates showed less contribution.

(5) TEM and SEM observation give us valuable information to understand the mechanism of the hydration in the system pozzolana- $C_3A$ - $CaSO_4 \cdot 2H_2O$ - $Ca(OH)_2$ . The hydration of this system proceed through the formation of amorphous surface layer by leaching out of  $Ca^{2+}$  and/or alkalies ions, swelling and destruction of surface film by osmotic pressure and precipitation of hydrate on the surface of the film. The alkalies in pozzolana play an important role not only in the hydration reaction but also in the formation of the texture of hardened paste.

## Long-term experiments on the neutralisation of concrete mixed with fly ash and the corrosion of reinforcement

*Experiences à long-terme sur la neutralisation du béton avec des cendres volantes, ainsi que sur la corrosion de l'armature.*

R. TSUKAYAMA, Dr. Director, Division of Clean Set, Nihon Cement Co., Ltd.

H. ABE, Dr. Head, Concrete Structural Section, Central Research Institute of Electric Power Industry and

S. NAGATAKI, Dr., Associate Professor, Dept. of Civil Eng. Faculty of Eng. Tokyo Institute of Technology, Japon.

RESUME : Il est évident que beaucoup d'avantages peuvent être tirés des cendres volantes quand elles sont employées comme ajouts dans le béton. Cependant, il est aussi signalé que la réaction pouzzolanique des cendres volantes produit une réduction de l'alcalinité et par conséquent accélère la neutralisation du béton et par conséquent la corrosion des armatures du béton.

Cette étude rend compte des résultats des expériences faites depuis 1963 pour confirmer ces phénomènes. Ces expériences ont porté sur le comportement à long terme de bétons confectionnés avec ou sans cendres volantes.

Ces expériences ont été faites en faisant varier les proportions de ciment et de cendres volantes, la nature du ciment, le dosage en eau, la valeur du slump et les conditions de conservation des éprouvettes. Des expériences ont aussi été faites à l'extérieur, dans dix emplacements répartis dans tout le Japon, et même dans des sites marins, ou des sites exposés aux embruns ou aux courants marins.

SUMMARY : It is clear that numerous advantages may be obtained when fly ash is being used as an admixture in concretes. However, it is also pointed out that the pozzolanic reaction of fly ash leads to a reduction in alkalinity and hence accelerates the neutralization of the concrete as well as the corrosion of the reinforcing bar embeded in the concrete.

This paper reports the results of experiments carried out since 1963 to confirm these phenomena of concretes with and without fly ash in the long term.

The experiments were carried out for different mix proportions by changing the cement factor, replacement ratio of fly ash, water-cement ratio and the value of slump and under different conditions of curing indoors and outdoors. The outdoor experiments were performed at 10 selected places over the whole country of Japan including places under the sea and places affected by winds and currents.

## INTRODUCTION

Fly ash demonstrates a so-called finely-divided powder effect and a pozzolanic effect to improve workability of concrete, reduce heat of hydration, improve watertightness and increase long-term strength [1], [2], and has a proven record of use as a concrete admixture for approximately 40 years.

While there are many advantages, it has been pointed out on the other hand that when fly ash is used the alkalinity of concrete is lowered due to reduction through pozzolanic reaction of free  $\text{Ca}(\text{OH})_2$ , because of which neutralization of concrete is accelerated and reinforcing steel embedded is corroded [3], [4], [5].

In order to solve this problem, the Committee on Concrete of the Japan Society of Civil Engineers organized a Sub-Committee on Fly Ash and embarked on long-term research and testing in regard to neutralization of concrete mixed with fly ash. It has already been concluded and reported for the intermediate ages of 2 and 5 years that (i) water-cement ratio is the factor predominantly governing depth of neutralization, and (ii) a constant relationship exists between 28-days compressive strength and depth of neutralization regardless of whether or not fly ash is added [6], [7]. In the present report, a comprehensive examination is made of the influence of fly ash on neutralization of concrete based on results at the age of ten years.

## TEST PROGRAM

Tests were performed divided into the 3 series described below and neutralization depths and rusting of reinforcing bars were measured at the ages of 2 years, 5 years and 10 years.

### Series I

Unit cement-fly ash content, slump, fly ash replacement ratio and type of cement were selected as factors and tests in common were performed at 13 laboratories on the influences of mix proportions. Cement and fly ash used were the same at seven laboratories and at other six laboratories, fly ash were supplied by each six manufactures while cement were the same.

Unit cement-fly ash content	: 250, 290, 330 $\text{kg/m}^3$
Slump	: 5, 15 cm
Fly ash replacement ratio	: 0, 15, 30 %
Cement	: normal cement, moderate heat cement

### Series II

Series II and III were tests planned with the purpose of supplementing points which could not be clarified with Series I. In Series I, after casting specimens, testing was done with the period of curing in water prior to exposure in air 14 days, but in Series II,

curing periods were varied between 1 and 91 days before exposure outdoors and indoors to find the influence of the period of curing in water in neutralization.

Period cured in water	: 1, 7, 28, 91 days
Exposure conditions	: indoors, outdoors
Unit cement-fly ash content	: 250, 290, 330 $\text{kg/m}^3$
Fly ash replacement ratio	: 0, 30 %

### Series III

In this series, specimens cast at the same place were exposed to outdoor conditions scattered at various locations throughout Japan to examine regional influences on neutralization. At one region, specimens were submerged in seawater and the effects on neutralization and rusting were examined.

### Specimens

The specimens for neutralization tests were cylinders of 15-cm diameter by 30 cm height, with 3 reinforcing bars of 9-mm diameter embedded at the locations indicated in Fig. 1 for depths of cover of 2, 3 and 5 cm.

### Measurement of Neutralization Depth

The cross sections at which neutralization was measured were the transverse cross sections 7 cm and 23 cm from the top surface, and the longitudinal cross section at the diameter of the middle portion obtained as a result of cutting at 7 and 23 cm. The specimens were dried after cutting, immediately sprayed with phenolphthalein, and colored (unneutralized) and neutralized portions were identified. The average neutralization depths at the various cross sections were calculated by the equations below [6], [7].

Fig. 1 - Specimen for Neutralization

Transverse Cross Section  
Average Neutralization Depth  
 $= R - \sqrt{B/\pi} \dots\dots(A)$   
Longitudinal Cross Section  
Average Neutralization Depth  
 $= (A-B)/2h \dots\dots(B)$

where

B : area of colored portion  
A : total cross-sectional area  
R : diameter of specimen  
h : height of specimen

Reinforcing bars were removed from concrete after measurement of neutralization depth, inspected for rusting, and rusted areas were measured.

#### TEST RESULTS

The average of the average neutralization depth of the two transverse cross sections, determined by Eq. (A) and the neutralization depth determined by Eq. (B) was taken as the average neutralization depth of that specimen, and the examinations made by factor were as described below.

#### Concrete Mix Proportions

On examination of the relationships of unit cement-fly ash contents and fly ash replacement ratio with neutralization depths for the case of 15-cm slump in Series I, the results were as shown in Fig. 2. Depth of neutralization was increased with decreased unit cement-fly ash content and increased fly ash replacement ratio, and especially, in case of such a lean mix as unit cement-fly ash content of 250 kg and replacement ratio 30%, depth of neutralization was large and the progress of neutralization was great at advanced age also. This was due, as previously said [8], to lowering of the quality of concrete, in effect, the increase in water-cement ratio, and the same thinking may be applied to the influence of slump.

When moderate heat cement was used depths of neutralization were slightly larger or equal compared with normal cement. Other conditions being equal, unit water content is reduced when moderate heat cement is used, but

Fig. 2 - Relation between Mix Proportions and Depth of Neutralization

probably, due in part to slower initial strength gain, the result was that neutralization depths were roughly equal.

#### Relation Between Water-Cement Ratio and Depth of Neutralization

That depth of neutralization has a correlation with water-cement ratio has been suggested by many researchers [9], and here, determining water-cement ratios from cement contents excluding fly ash and indicating the relationships with depth of neutralization for Series I and II together, the results were as shown in Fig. 3, and linear relationships were recognized. However, similarly to a previous report [6], the relationships were different depending on whether or not fly ash was admixed. And in case of water-cement ratio of about 0.60 to 0.70, the depth of neutralization of concrete with fly ash was approximately 0.1 cm smaller at the age of two years and approximately 0.3 cm smaller at the age of ten years than that of concrete without fly ash. The main reasons for this probably are the pozzolanic reaction with free  $\text{Ca(OH)}_2$  of particles of fly ash added resulting in densifying the constitution and the acceleration of hydration due to the finely-divided powder effect.

Fig. 3 - Relation between Water-Cement Ratio and Depth of Neutralization

#### Relation Between Compressive Strength and Depth of Neutralization

Since compressive strength has a correlation with water-cement ratio, and water-cement ratio and depth of neutralization have a linear relationship as described in the preceding section, it is thought the same thinking would apply regarding compressive strength also. Therefore, the depths of neutralization at a certain age were arranged according to the relationship with compressive strength at identical age of specimens cured under identical conditions. An example for 2-year age is shown in Fig. 4. Here, similarly to the case of water-cement ratio, the relationship is expressed by two roughly parallel straight lines with and without fly ash, and at identical compressive strengths the depth

of neutralization is 0.1 to 0.2 cm greater in case of admixture of fly ash. The reasons for this are that alkalinity of concrete is lower and initial strength gain smaller, and the result was the view that much of the neutralization occurs at a comparatively early stage [8] was substantiated.

On expressing depth of neutralization be the relationship with strength gained, as can be seen in the figure, it was possible to arrange the data with the same straight line even in cases of types of cement and exposure conditions being different.

The relationship between compressive strength at 28-day age and depth of neutralization is as shown in Fig. 5, and similarly to the previous report [6] the expression may be made by a straight line irrespective of the admixture of fly ash. However, in the case of using moderate heat cement where quality cannot be evaluated at 28 days, a straight line different from the one for normal cement is indicated, while in the case also of exposure conditions being different the relation cannot be expressed with the same straight line.

Fig. 4 - Relation between Compressive Strength and Depth of Neutralization

Fig. 5 - Relation between compressive Strength and Depth of Neutralization

#### Curing Condition

The influences of the period of curing in water on depths of neutralization in outdoor and indoor exposure were as shown in Fig. 6. In outdoor exposure, depth of neutralization was great in the case of curing period of 1 day, while the results for 7 to 91 days were of about the same degree. In effect, it is thought that if curing in water is performed at the initial stage for about 7 days, there will subsequently be supply of water from rainfall and other sources so that hydration of cement and pozzolanic reaction continue to progress to densify the constitution. However, when curing in water is not performed, it is thought that since the supply of water is insufficient the hydration of cement is slow and neutralization progresses greatly at the initial stage.

In indoor exposure, since there is no supply of water, hydration of cement mainly occurs only during the period of curing in water, and even if some amount of pozzolanic reaction were to occur subsequently, it will be accompanied by reduction in alkalinity, and it is thought that the degree to which the constitution is made dense during the period of curing in water will greatly affect the subsequent progress of neutralization. However, for both outdoor and indoor exposure, the influence on depth of neutralization was seen during the earlier stage of up to 2-year age, with the progress of neutralization after 2 years being constant regardless of the period of curing in water.

Comparing indoor exposure with outdoor depths of neutralization of specimen cured indoor were considerably larger than that of outdoor, because there are many conditions disadvantageous indoor for preventing progress of neutralization such as the moisture condition (humidity) of concrete and concentration of carbon dioxide.

Fig. 6 - Relation between Period of Cruing in Water and Depth of Neutralization

### Relation Between Age and Depth of Neutralization

With regard to the influence of age on depth of neutralization, there is a formula proposed that neutralization is proportional to the root of age [10], and a report that neutralization has a linear relation with the logarithm of age [9]. On arranging the depths of neutralization obtained in the present tests based on root of age and water-cement ratio, the equations below were respectively obtained for fly ash replacement ratio of 0% ( $w/c=0.45-0.6$ ) and replacement ratio of 30% ( $w/c=0.6-0.95$ ).

$$\text{Neutralization Depth (cm)} = (1.187w/c - 0.493)\sqrt{t} \dots (F/C+F=0\%)$$

$$\text{Neutralization Depth (cm)} = (1.241w/c - 0.597)\sqrt{t} \dots (F/C+F=30\%)$$

where

$t$  : age

$w/c$  : water-cement ratio

### Regional Influence on Depth of Neutralization

The depths of neutralization of the same concrete exposed outdoors at various locations in Japan at ages of 2, 5 and 10 years shown in the form of a bar graph is Fig. 7. The differences in the climatic conditions of these locations are mainly in temperature and precipitation, and distinct differences according to region were not seen. The results at the one region where specimens were submerged in seawater showed neutralization to be very small.

### Rusting of Reinforcing Bars

In outdoor exposure in Series II, at 2-year age there was no rusting of reinforcing bars at all, and rusting was produced at 5 and 10 years when neutralization had progressed. With the proportion of the specimens in which rusting of reinforcing bars occurred to the total number of specimens as the rusting rate the relation with water-cement ratio was found to be as shown in Fig. 8. The relation between degree of cover and rusting was distinct, and whenever neutralization had progressed to the vicinity of a reinforcing bar, rusting occurred in practically all cases.

Rusting of reinforcing bars in the specimens submerged in seawater was peculiar, where even at the age of 2 years when neutralization had hardly progressed, considerable rusting was seen on reinforcing bars with small depth of cover in lean mixes concrete specimen. The rusting was concentrated at the sides toward specimen surfaces in all cases, indicating that rusting of reinforcement is accelerated regardless of neutralization when there is infiltration of chloride ions.

### Scanning Electron Microscope Examination of Fractured Surfaces of Concrete

In Series II, scanning electron microscope examinations were made of fractured surfaces of neutralized and unneutralized portions of concrete exposed for 10 years after curing in water for 91 days. The photographs are of fly ash particles scanned. For cases of exposure both outdoors and indoors, when curing in water had been adequately performed, and at the center portions of specimens where neutralization had not been produced, it may be seen that pozzolanic reaction had occurred between the free  $\text{Ca(OH)}_2$  and fly ash particles and crystals were formed at the surfaces of the fly ash particles. On the other hand, at neutralized portions at the surface of concrete specimen there are no traces seen of reaction at the surfaces of fly ash particles, and particularly, the tendency for this was seen to be prominent for indoor conditions.

Indoor, Unneutralized. Outdoor, Unneutralized.

Indoor, Neutralized. Outdoor, Neutralized.

#### CONCLUSIONS

Neutralization tests were carried out under various conditions on concretes containing fly ash as an admixture, and from the results obtained up to 10-year age, the following remarks may be concluded.

- (1) Depth of neutralization has a relation with the quality of concrete, and a linear relationship is found to exist with water-cement ratio excluding fly ash. However, at identical water-cement ratio, neutralization is slightly decreased when fly ash is added. Further, it is possible to estimate depth of neutralization by the root of age and water-cement ratio.
- (2) There is a given linear relationship between compressive strength at 28-day age and depth of neutralization regardless of fly ash addition when type of cement and exposure conditions are identical. On the other hand, there is a constant linear relationship irrespective of other conditions between compressive strength at the time of measurement of neutralization and depth of neutralization for fly ash replacement ratios of 0% and 30%.
- (3) The period of curing in water after casting specimens has a great influence in case of indoor exposure, and neutralization is increased unless adequate curing is performed. In the case of outdoor exposure, if curing in water of about one week is performed, this appears to be adequate against neutralization. However, in all cases, the period of curing in water has no influence on the progress of neutralization after 2-year age.
- (4) In ordinary outdoor air in Japan, there is little regional difference in the influence on depth of neutralization. There is a distinct cause-and-effect

relationship seen between progress of neutralization in air and rusting of reinforcing bars.

#### ACKNOWLEDGEMENTS

These tests were performed under the direction of the Sub-Committee on Fly Ash of the Japan Society of Civil Engineers, and the authors wish to express their deepest gratitude to the Chairman, Dr. Masatane Kokubu, and members of the committee for their untiring guidance during the testing.

F. BRIVOT, Chimiste au L.C.P.C., Paris,

A.M. PAILLERE, Docteur es Sciences, Chef de Section "Produits Nouveaux" L.C.P.C., Paris, et

R. DRON, Docteur Ingénieur, L.C.P.C. Paris, France.

RESUME : Le taux de réaction pouzzolanique peut être déterminé par un essai accéléré consistant en un contact pendant une nuit, au voisinage de l'ébullition, de matière pouzzolanique et de chaux en suspension dans l'eau (essai Chapelle). La dispersion des résultats inhérente à cette méthode est réduite de façon décisive par emploi du chauffage au bain marie et de l'agitation magnétique. Les résultats sont corrélés à la teneur en phase vitreuse.

L'étude approfondie des principales caractéristiques des mortiers confectionnés avec des ciments à la pouzzolane permet de montrer le bien fondé de cette méthode.

SUMMARY : The rate of pozzuolanic reaction can be determined by an accelerated test consisting in having bath pozzuolanic materials and lime suspended in water which is nearly boiling (Chapelle test). The result dispersion inherent in this method is considerably reduced by water-bath heating and magnetic stirring the results are correlated with the ratio of vitreous phase.

The elaborated study of principal characteristics of mortars obtained with cements containing pozzuolanic materials shows that this method is well-founded.

## INTRODUCTION

L'existence en France de ciments CPJ composés de Portland et de constituants secondaires, à effet plus ou moins pouzzolanique, dont le dosage peut atteindre jusqu'à 35 % pose le problème de leur réactivité ou propriétés hydrauliques dont va dépendre l'activité réelle du ciment dont ils constituent les ajouts au clinker.

Les matériaux pouzzolaniques français peuvent provenir de trois origines différentes :

- volcanique ou éruptive,
- naturelle,
- artificielle.

Ces matériaux sont désignés généralement par le terme pouzzolane. Terme qui englobe les cendres volantes ou fondues.

Selon la nature et provenance du matériau pouzzolanique les deux caractéristiques essentielles des pouzzolanes qui sont, la fixation de la chaux en présence d'eau et l'aptitude à constituer des produits à propriétés liantes, sont plus ou moins marquées. Il importe donc à l'utilisateur de connaître avec le maximum d'exactitude la réactivité du matériau utilisé afin de déduire les performances que le ciment CPJ, constitué avec lui, pourra atteindre à une échéance donnée.

En effet, le supplément apporté par le matériau pouzzolanique aux qualités hydrauliques du clinker ne survient qu'à des échéances relativement longues 6 mois, 1 an ou plus. Dès lors, il est souhaitable de connaître de la façon la plus certaine possible, et ceci avant utilisation, les possibilités offertes par le ciment à la pouzzolane.

Le problème étant posé au niveau du ciment, il s'agissait de pouvoir déterminer à partir d'un ciment contenant une pouzzolane, au sens français du terme, l'activité pouzzolanique du constituant secondaire introduit dans le ciment CPJ et de trouver la relation existante entre cette "activité" et les caractéristiques à long terme du mortier ou béton hydraulique correspondant.

La recherche a donc été menée d'une part du point de vue analytique sur la mise au point d'une méthode visant à déterminer l'activité pouzzolanique du constituant secondaire présent dans les ciments CPJ et d'autre part du point de vue physique sur l'étude des caractéristiques mécaniques à long terme des mortiers confectionnés avec ces ciments.

Essais chimiques

Parmi les méthodes chimiques proposées pour estimer l'activité des matières pouzzolaniques, celle qui fut imaginée en 1958 par J. CHAPPELLE (1) est particulièrement séduisante par son principe et sa rapidité de réponse. Elle permet théoriquement de caractériser une pouzzolane à sa finesse d'utilisation par le taux de réaction de la chaux, au terme d'un temps de contact standardisé (généralement 16 heures), la réaction étant accélérée par élévation de la température (100°C).

On a parfois opposé au principe même de cette détermination l'argument selon lequel les hydrates qui se forment dans ces conditions n'ont ni la même nature,

ni la même solubilité que ceux qui se forment à température ordinaire. Cette objection serait valable si la cinétique de la réaction était gouvernée par la précipitation des hydrates. Or, l'étape limitante de la réaction pouzzolanique est en réalité l'attaque hydroxylique de la matière, et le flux de dissolution, c'est-à-dire la quantité d'éléments acides passant en solutions par unité de surface et par unité de temps et le reflet direct de la réactivité de la pouzzolane. L'étape suivante de précipitation des hydrates, quels qu'ils soient, est un processus rapide, qui en tout état de cause ne peut que suivre le rythme de la dissolution.

Le mode opératoire d'origine de la méthode Chapelle est le suivant :

Dans un erlenmeyer contenant 200 ml d'eau distillée débarrassée de CO<sub>2</sub>, on met 1 g de matériau présumé à action pouzzolanique, broyé à la finesse du ciment et 1 g de chaux. On porte à ébullition pendant 16 h. Pour éviter que l'eau ne se perde par évaporation, on dispose au dessus de l'erlenmeyer un tube réfrigérant surmonté d'une garde à CO<sub>2</sub>, (solution de soude ou chaux sodée). Après refroidissement, on dose la chaux qui n'a pas réagi, en présence de sucre.

Contrastant avec l'élégance du principe, la dispersion des résultats est assez décevante et, dans ces conditions opératoires, ne peut être réduite que par une standardisation fastidieuse de tous les facteurs : mode de chauffage, réglage de celui-ci, forme et matière du récipient, corrections de blanc, etc...

Les causes de cette variabilité sont de trois ordres :

- L'agitation de la suspension résulte de la seule ébullition et n'est par conséquent pas reproductible. Si elle est trop faible, la matière sédimente. Si elle est trop forte, il se produit des projections qui forment un dépôt en anneau sur les parois situées au dessus de la surface.

- Il existe un gradient de température au niveau de l'interface paroi-suspension, qui provoque la formation d'un tartre, dont la matière est soustraite à la réaction et qu'il est difficile de détacher en fin d'opération.

- On évite difficilement toute carbonatation car au sommet du réfrigérant, l'eau refroidie est totalement décarbonatée et donc avide de CO<sub>2</sub>. Malgré la présence d'une garde à CO<sub>2</sub>, par suite de l'importance du reflux et l'effet étant cumulatif, au bout de 16 heures la quantité de CO<sub>2</sub> entraîné est loin d'être négligeable. Par ailleurs, l'essai à blanc est majoré en raison d'une légère attaque du verre.

Nous sommes parvenus à réduire de façon radicale la variabilité en agissant sur ces causes de dispersion la première précaution consistant en l'emploi de fioles en inox, qui élimine l'attaque du récipient.

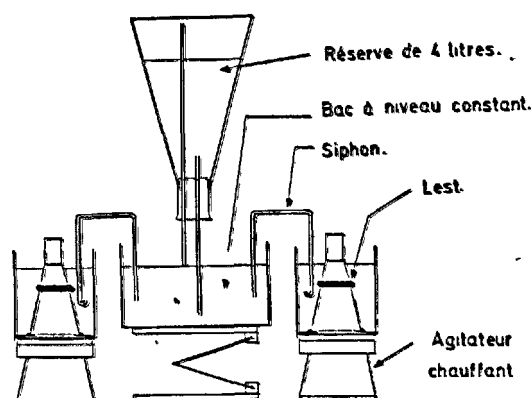

L'artifice principal réside dans le fait que la réaction a lieu dans un récipient hermétiquement fermé, placé dans un bain-marie à ébullition d'eau. Le milieu est donc porté à 100°C mais il ne bout pas. Pour éviter la mise en pression, on porte préalablement la suspension à l'ébullition sur un bec bunsen avec toile métallique, on retire prestement du feu et on ferme aussitôt par un bouchon d'élastomère siliconé. On place alors le récipient lesté dans un bain marie

d'eau à ébullition, conçu de telle façon qu'il permette l'agitation magnétique (l'inox est perméable aux champs magnétiques). Il n'y a de cette façon ni dépôts, ni projection, ni entartrage puisqu'il n'y a pas de gradient de température, ni carbonation puisque le récipient est hermétiquement fermé.

Lorsqu'on arrête la réaction, on refroidit le récipient sous un courant d'eau, sans l'ouvrir. L'intérieur se met donc en dépression et on fait pénétrer l'air en déformant le bouchon.

#### DISPOSITIF UTILISÉ POUR L'ESSAI CHAPELLE MODIFIÉ.

Figure 1

Le montage que nous avons utilisé (Fig. 1) répond aux impératifs requis. Il n'est toutefois pas superflu de signaler que sa réalisation en verre et la mise en œuvre de masses d'eau bouillante et de récipients chauds requièrent de sévères précautions d'utilisation pour éviter les accidents.

La détermination de l'activité pouzzolanique des constituants présents dans les ciments a été menée en parallèle à l'aide de l'essai Chapelle modifié tel qu'il a été décrit précédemment et par détermination aux rayons X de la phase vitreuse.

La figure 2 donne la relation existant entre la quantité de CaO consommée et le pourcentage de phase vitreuse.

Il apparaît ainsi qu'il existe une bonne corrélation entre les 2 mesures et les deux méthodes utilisées.

Ainsi donc dans le présent exposé, on s'est limité à relier l'activité du constituant secondaire déterminé à partir de la quantité de chaux consommée à diverses caractéristiques des mortiers.

#### Essais physiques

L'étude a été menée sur 6 ciments industriels CPJ constitués par des pouzzolanes (Z) ou des cendres (C) et sur 5 pouzzolanes (Bizac - Volvic - Dômes - Paugnat Cinérîte), une cendre volante et une cendre fondue. Avec ces sept matériaux à effet pouzzolanique, on a confectionné au laboratoire, 63 ciments à partir de trois clinkers différents dont les teneurs en  $C_3A$  étaient 1,5 - 9,5 et 14 %. Pour chacun des constituants secondaires, on a utilisé les pourcentages de

10, 20 et 35 % du poids de clinker. Après broyage à la finesse Blaine 9000  $cm^2/g$  le constituant secondaire a été mélangé dans les proportions indiquées précédemment à chacun des clinkers broyés à une finesse de 3200  $cm^2/g$ .

Figure 2

CaO consommée en fonction des % de phases vitreuses des pouzzolanes utilisées dans les ciments CPJ industriels et CPJ fabriqués en laboratoire

La figure 3a donne la courbe granulométrique des diverses pouzzolanes et cendres après broyage, ainsi que celles des 3 ciments utilisés dans les mélanges.

#### COURBES GRANULOMÉTRIQUES

Figure 3 B

DÉTERMINÉES AU GRANULOMÈTRE À LASER

CLINKERS N°1, 2, 3 et

CPJ (90% de Clinker N°1 et 10% de Z)

Les figures 3b, 3c et 3d représentent les courbes granulométriques des ciments CPJ constitués avec le clinker n° 1 à 1,5 % de  $C_3A$ .

On constate ainsi que pour 10 % d'ajouts il n'y a pratiquement pas de différence granulométrique entre le ciment d'origine et le CPJ reconstitué. A partir de 20 %, l'augmentation du pourcentage d'éléments inférieurs à 16  $\mu$  croît en fonction du pourcentage de constituants secondaires. Cette remarque s'applique également aux deux autres CPJ à  $C_3A$  plus élevé et aux ciments indus-

triels utilisés dans la recherche.

Figure 3 C

Figure 3 D

CPJ ( 80% de Clinker N°1  
et 20% de Z )

CPJ ( 65% de Clinker N°1  
et 35% de Z )

Le pouvoir hydraulique ou liant des constituants secondaires utilisés, se traduisant sur mortier par un accroissement plus ou moins marqué des résistances, il va de soi que plus une pouzzolane ou cendre est réactive, plus cet accroissement est élevé et plus son échéance est rapprochée de la date de fabrication.

L'étude comparative des mortiers ISO confectionnés avec des CPA et les mêmes CPA additionnés de 10 à 35% de Z ou de C (CPJ industriels et de laboratoire) montre que quelque soit la quantité de CaO consommée mesurée, aucun ciment CPJ ne conduit avant 28 jours à des résistances du mortier supérieures à celles des témoins CPA. A 28 jours, les cendres volantes et fondues associées à des ciments à teneur en  $C_3A > 8\%$  ont des résistances supérieures à celles du témoin (Fig. 4a, 4b, 4c, 4d - Tableau I).

Résistances à la compression en fonction de l'âge et de la CaO consommée mesurée à l'essai Chapele modifié

CPJ (à base de Z) industriels

CPJ N°1 avec clinker à 15%  $C_3A$   
et 20% de Z ou C

Si l'on étudie l'évolution des résistances des ciments à partir de la progression de celles du mortier ISO aux échéances X supérieures à 28 j, on a :

pour les ciments aux pouzzolanes :

$$R_z = R_{ZX} - R_{Z28}$$

et pour les ciments CPA :

$$R_T = R_{TX} - R_{T28}$$

R = Résistances à la compression du mortier  
X = Age du mortier aux échéances de 180 j - 1 an.

La valeur  $R_z - R_T = (R_{ZX} - R_{Z28}) - (R_{TX} - R_{T28})$  renseigne sur la progression du pouvoir hydraulique des pouzzolanes.

CPJ N°2 avec clinker à 9%  $C_3A$   
et 20% de Z ou C

CPJ N°3 avec clinker à 14%  $C_3A$   
et 20% de Z ou C

En reliant  $R_z - R_T$  aux valeurs de CaO consommée mesurée dans les divers ciments aux pouzzolanes, on peut connaître à partir du mortier confectionné avec les ciments CPJ la relation qui peut exister entre la progression du pouvoir liant du constituant secondaire et son activité pouzzolanique.

L'étude de la représentation graphique de  $R_z - R_T$  (Fig. 5a - 5b) pour différents âges en fonction de CaO consommée fait apparaître tout d'abord que, à 180 jours, la famille de pouzzolanes dont la CaO consommée est supérieure à 0,33 g a une progression des résistances supérieure à celle des témoins :

$$R_z - R_T > 0.$$

A 1 an, les pouzzolanes à faible réactivité commencent à avoir des qualités liantes, certaines dont la CaO consommée est de  $> 0,25$  présentent un  $R_z - R_T > 0$ . Par contre, toutes choses étant égales par ailleurs, la gamme des valeurs négatives de cette différence se trouve réduite :

$$R_z - R_T \text{ passe ainsi de } (-6,5, 0) \text{ à } (-4,0).$$

Ceci est vérifié autant sur les ciments industriels que sur ceux du laboratoire.

On peut donc estimer que les pouzzolanes à faible réactivité ne présenteront un pouvoir hydraulique qu'à partir d'un an.

tances dans le temps, à l'effet pouzzolanique, du constituant secondaire mesuré à partir du ciment lui-même.

En effet, le pouvoir hydraulique des pouzzolanes mesuré sur mortier est en parfaite corrélation avec la quantité de chaux consommée déterminée à l'aide de l'essai Chapelle modifié.

Dans le cas présent, les matériaux pouzzolaniques les plus actifs sont les cendres associées à des clinkers à forte teneur en  $C_3A$ .

**RESUME :** La présente étude porte sur l'hydratation de ciments composés, dont l'ajout est constitué par le résidu minéral du traitement des schistes bitumineux des gisements bulgares. On a utilisé pour cela deux sortes de clinker (à faible et à forte teneur en alite) et deux sortes de schistes ainsi cuits. L'activité de ces schistes cuits dépend de leur composition minéralogique et de la température atteinte pour leur production. Les éprouvettes ont été étudiées au spectrographe infrarouge et au microscope électronique. On observe une vitesse plus élevée de l'hydrolyse des composants du clinker et un début de réaction entre la chaux dégagée et le schiste cuit, qui conduit à un développement plus grand du C-S-H et de la portlandite au cours de l'hydratation. On observe aussi une absorption du  $\text{Ca(OH)}_2$  par le schiste cuit, qui forme à la surface des grains des cristaux aciculaires. On en a déduit le moyen d'accroître au maximum la compacité, à long terme, des pâtes de ces ciments. Une interprétation des propriétés des produits obtenus a pu être faite en se basant sur la composition et la morphologie des schistes cuits.

**SUMMARY:** Having a knowledge of the special features of the cement stone structure and the factors of its determination is of a great theoretical and practical importance. Up to now investigations were carried on with individual clinker minerals and real cements. It might be said there is little information about the structure and the properties of the cement stone received during the process of hydration of cements with the mineral residuum obtained during thermal treatment of bulgarian shales.

This work deals with the processes of hydration of the cements with such additive and the developing of the cement stone structure. Two kinds of clinker (with high and low amount of alite) and two kinds of mineral residuum (shale ash) with different hydraulic activity were used. This different hydraulic activity is determined by the difference in the mineral composition of the shales and the temperature treatment for extracting their organic ingredients. The samples were examined by means of infra-red spectroscopy and scanning electron microscopy. Were established the peculiarities of the processes of hydration - the greater rate of hydrolysis of the clinker minerals, the initial stage of interaction between shale ash and  $\text{Ca(OH)}_2$ , the relative amount of the C-S-H phase and portlandite during the course of hydration. The consumption of  $\text{Ca(OH)}_2$  for the pozzolanic reaction, formation of the products of interaction on the shale ash grains were established. The view of the new formed phase in the initial stage of the interaction was shown - very fine needle-like crystals. The interaction between the investigated additives and  $\text{Ca(OH)}_2$  was followed and were expressed some thoughts concerning the formation of especially dense cement stone structure in the later periods of hydration. On the base of the view and the morphology of the products of interaction the interpretation of some properties of the investigated cements was done.

Studying the structure of cement stone and the factors of its determination contribute to the clarification of the mechanism of formation of the dense structure of the portland cement stone and enable to control this process in using binders.

Up to now there have been carrying on investigations on the base of the individual clinker minerals (1,2) or real cements (2,3,4). It has been obtained information about the composition and morphology of the hydration products and expressed some thoughts with respect to the mechanism of contact formation between the different phases and their distribution in the hardened binder pastes. There is little information about the structure and properties of cement stone containing different kinds of additives. Mineral residuum received from shales during their thermal treatment aiming to extract their organic ingredients is such an additive interesting from theoretical and practical point of view.

We have used the mineral residuum received during thermal treatment of Bulgarian shales in semi-industrial equipment in temperature interval 823 - 1023°K. It is granular material with grain size less than 2,5 mm. Thermal treatment in above mentioned conditions determines hydraulic activity of the mineral residuum (shale ash) and the possibility of its using as additive in cement.

In our previous work (5) was shown the possibility of using the above mentioned shale ash as additive to the grinded clinker. Cements with good physico-mechanical properties were obtained. Having in mind the conditions of the shale thermal treatment and the phase composition of shale ash it was interesting to study its reaction with cement and establish the character of the products of this interaction. Two kinds of portland cement clinker with different content of alite and belite (samples from series "A" with  $C_3S = 68,86\%$  and  $C_2S = 9,18\%$  and samples from series "B" with  $C_3S = 40,80\%$  and  $C_2S = 28,52\%$ ) and two kinds of shale ash with different hydraulic activity were used. From the above mentioned materials by combined grinding using the corresponding quantity of gypsum were prepared mixtures with 15 and 40% shale ash and were moulded specimen-prisms (1 x 1 x 3 cm) using water from 24 to 32% depending on the percentage of shale ash. The samples obtained were kept in water and after certain periods the process of hydration was discontinued by chemical dehydrogenation.

Infra-red spectroscopic measurements were carried out on a UR - 20 Zeiss infra-red spectrophotometer over the wavelength 400 - 4000  $\text{cm}^{-1}$  using the Nujol mull or KBr disc as appropriate. On freshly broken surfaces were identified the type and morphology of the reaction products between

the grains of shale ash and portland cement clinker. The investigated surfaces were covered with a thin layer of aluminium and by means of scanning electron microscope (type JEOL ISM S - 1) were taken the photos of the typical parts. Some of the taken infra-red spectra and micrographs are shown on the figures below.

Fig. 1. Infra-red spectra of pure clinker cements. a - 0, b - 3, c - 28 and d - 90 days of hydration.

Fig. 2. Infra-red spectra of cements with clinker from series "A" (3) and series "B" (4) and shale ash (40%) with high hydraulic activity.

Infra-red spectra of the investigated pure clinker cements (fig.1) contain absorption bands of alite at 895 and 935  $\text{cm}^{-1}$  and at 465 and 520  $\text{cm}^{-1}$ . Comparing with pure  $C_3S$  the bands maxima in the region 850 - 950  $\text{cm}^{-1}$  were shifted to the high frequency spectra region. This is due to the incorporation of small quantities of

$\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Mg}^{2+}$ ,  $\text{Ti}^{4+}$ ,  $\text{Fe}^{3+}$ ,  $\text{Al}^{3+}$  and others in crystal lattice of  $\text{C}_2\text{S}$  to form alite. Belite is characterised with absorption bands at 895 and 995  $\text{cm}^{-1}$  and at 520 and 545  $\text{cm}^{-1}$ . Absorption bands at 415 and 525  $\text{cm}^{-1}$  are due to the  $\text{C}_2\text{A}$ . Comparing the form and intensity of alite's and belite's bands one can see what is the relative amount of these two minerals in the cements investigated. The sample 1 contains more alite whereas the sample 2 contains more belite.

In the spectra of cements with shale ash absorption bands due to the amorphous  $\text{SiO}_2$  with maximum at 804  $\text{cm}^{-1}$ , calcite with maximum at 435  $\text{cm}^{-1}$  and the dublet band for quartz at 804 and 784  $\text{cm}^{-1}$  can be seen.

The process of hydration is associated with gradually disappearing of the bands due to the clinker minerals and appearing of new absorption bands of the hydration products. The principal products established during portland cement hydration are calcium silicate hydrate with absorption bands at 965-975  $\text{cm}^{-1}$  and 980-990  $\text{cm}^{-1}$ ;  $\text{Ca}/\text{OH}/_2$  giving strong sharp peak at 3640  $\text{cm}^{-1}$  and calcium sulphoaluminate most probably monosulphate with absorption maxima at 1170 and 3675  $\text{cm}^{-1}$  (6).

Fig. 3. Infra-red spectra of cements with clinker from series "A" (5) and series "B" (6) and shale ash (40%) with low hydraulic activity.

In the course of hydration of pure clinker cements (fig.1) the intensity of the bands at 465 and 520  $\text{cm}^{-1}$  decreases sharply and in the region 800-1100  $\text{cm}^{-1}$  forms a complex band with absorption maxima at 890, 945 and 1080  $\text{cm}^{-1}$ . This is connected with decreasing the quantity of alite and relative increasing this of belite. The absorption maxima at 925  $\text{cm}^{-1}$  is shifted to the longer wavenumbers up to 940  $\text{cm}^{-1}$  due to the formation of C-S-H phase. The bands at 605 and 662  $\text{cm}^{-1}$  disappear and the dublet at 1120 and 1150  $\text{cm}^{-1}$

changes in shoulder of the band at 1150  $\text{cm}^{-1}$ . This is connected with decreasing the quantity of gypsum and formation of calcium sulphoaluminate. At longer hydration was found that the amount of C-S-H phase, monosulphate and  $\text{Ca}/\text{OH}/_2$  has progressively increased.

At hydration of cements with shale ash were observed the same events as at this of pure cements, but undoubtedly was established the interaction between shale ash and  $\text{Ca}/\text{OH}/_2$  obtained during hydration of the clinker minerals. The mentioned interaction causes gradual decrease of the intensity of the  $\text{Ca}/\text{OH}/_2$  bands in the course of hydration (fig. 2-3). Comparing the infra-red spectra for the samples of the two series we can see that the  $\text{Ca}/\text{OH}/_2$  remaining at the end of the process is more in samples containing clinker with higher amount of  $\text{C}_2\text{S}$  (fig.2). At the same time using the shale ash with lower hydraulic activity the rate of assimilation of  $\text{Ca}/\text{OH}/_2$  is lower and the samples contain a little bit more portlandit (fig.3). Comparing very carefully the intensity of the bands of C-S-H phase we can see that this phase is more in the samples with shale ash.

The regularities established with infra-red spectroscopy were confirmed with scanning microscope study and were observed the view and morphology of the new phases.

According to Copeland (4) the first elements of the cement stone structure were ettringite, main constituent of C-S-H gel and needles growing from the clinker grains surface. After a few hours in the space filled with water and out of cement grains were formed small crystals of  $\text{Ca}/\text{OH}/_2$ . In the case of cements with shale ash this  $\text{Ca}/\text{OH}/_2$  reacts with the hydraulic active phases. The result of this reaction is C-S-H gel, formed very near to the shale ash grains. Therefore the samples with shale ash at different age would show less amount of  $\text{Ca}/\text{OH}/_2$  and more C-S-H phase. It is considered that portlandit crystals act the main role in formation of the initial cement stone strength. Adopting this conception we might explain in a satisfactory way the low initial strength of the investigated samples (5).

At the same time we have to differentiate the C-S-H phase resulting from the process of hydration of the clinker minerals from this one resulting from interaction between shale ash and  $\text{Ca}/\text{OH}/_2$ . The first has the possibility to grow in the pores of cement stone, while the second is formed on the grains of shale ash and is characterised with small needle-like crystals. They are result from interaction with  $\text{Ca}/\text{OH}/_2$  in over-saturated solution and their morphology is according this conditions. Hence the interaction products so formed, are not able to grow continuously in length and the number of contacts between them in the initial moment of interaction is small. This one explains the smaller strength of cements with hydraulic active additives at the beginning of the process of hardening.

Fig. 4. Micrographs of the samples from clinker with high content of  $C_3S$  and shale ash with high hydraulic activity. a,b,c,d - 15 % shale ash, e,f,g,h - 40 % shale ash. a,e - 3, b,f - 7, c,g - 28, d,h - 90 days of hydration.

Fig. 5. Micrographs of the samples from clinker with high content of  $C_3S$  and shale ash with low hydraulic activity; a,b,c,d - 15 % shale ash, e,f,g,h - 40 % shale ash; a,e - 3, b,f - 7, c,g - 28, d,h - 90 days of hydration.

Fig. 6. Micrographs of the samples from clinker with low content of  $C_3S$  and shale ash with high hydraulic activity. a,b,c,d - 15 % shale ash, e,f,g,h 40 % shale ash; a,e - 3, b,f - 7, c,g - 28, d,h - 90 days of hydration.

Fig. 7. Micrographs of the samples from clinker with low content of  $C_3S$  and shale ash with low hydraulic activity. a,b,c,d - 15 % shale ash, e,f,g,h - 40 % shale ash. a,e - 3, b,f, - 7, c,g - 28, d,g - 90 days of hydration.

On the electron microscope's photographs shown at fig. 4 - 7 it is seen that the structure of the investigated cements has a very fine morphology. It is known that (7) cements with hydraulic active additives have a higher rate of hydrolises of silicates. This is second reason because of which the products of C-S-H gel are not able to form long filaments. The greater quantity of calcium silicate hydrates formed for a definite period of time causes formation of many and short filaments. The number of contacts between them is small, and the structure is with the lower physico-mechanical properties. In the course of hydration and hardening the so formed elements of the structure interweave, form a dense skeleton and cement stone increases its strength.

At the same time it might be said that the C-S-H phase formed very near to the shale ash grains hardly has high proportion C/S;  $\text{Ca}/\text{OH}/_2$  is comparatively in smaller amount that the active additive and in the initial moment of reaction would form low-basic calcium silicate hydrates. Therefore it might be said that at hydration of cements with shale ash besides the two phases ("inner" and "outer" C-S-H gel) formed near to the clinker grains, at the boundary surface of the shale ash grains is formed C-S-H phase with lowest basicity. The morphology of the so formed phase - plates, discs - confirms this (fig. 4,5,6). From another side "The outer" C-S-H phase, which is richer at CaO forms fibrous new formations. In other words during the later periods of hydration, when the puzzolanic reaction is in its advanced stage the basicity of the calcium silicate hydrates increases and in the samples with lower amount of shale ash is observed fibrous C-S-H gel (fig. 4,5 ). The time is a factor which in a very great degree influences the type of the cement stone structure. Calcium silicate hydrates owing their origin to the reaction between C<sub>2</sub>S and water change continuously their composition while those received from C<sub>3</sub>S do not so. According to this circumstance is the continuous change of the morphology of C-S-H phase observed at the photos above.

The received picture allows to follow the intensity of interaction between hydraulic additive and  $\text{Ca}/\text{OH}/_2$ . From the most general point of view this interaction might be explained with thermodynamic instability of the system  $\text{Ca}(\text{OH})_2$  - hydraulic additive - water. It might be said that seven days are enough for beginning of interaction in this system. As it was already said, the low-basic C-S-H gel was formed with very fine particles. The process of interaction is more clearly expressed in the samples prepared from clinker with high amount of alite and a shale ash with high hydraulic activity (fig. 4). In the case of samples of series "B" and shale ash with lower hydraulic activity (fig. 7) at the seventh day was observed only the initial stage of interaction. Very clearly expressed products of puzzolanic reaction were observed in the samples containing

clinker with low amount of alite and shale ash with high hydraulic activity (fig.6).

At the longer periods of hydration (28 days) at the every combination between used materials might be seen clearly the interaction between the two components (fig.4-7). But it has to be underlined that depending on the activity of the shale ash used, side by side with the products of interaction were observed and crystals of portlandit. Their relative amount is more in the samples with low hydraulic active shale ash.

The study carried out and the result obtained indicate that the shale ash received from bulgarian shales has hydraulic properties, reacts with  $\text{Ca}/\text{OH}/_2$  in cement stone and influences the type of its structure. It might be said that at the seventh day of hydration the puzzolanic reaction has already begun. But the influence of the new formed C-S-H phase on the physico-mechanical properties of the samples investigated is clearly observed in the later stages of hydration (5). In the structure of cement stone it has to be differentiated from one side "outer" high basic C-S-H phase and "inner" low-basic C-S-H phase formed at the clinker grains, and at the other side, another C-S-H phase with the relatively lowest basicity and formed at the shale ash grains. These three phases during the process of hydration form contacts between them. When the process of interaction between  $\text{Ca}/\text{OH}/_2$  and shale ash is in advanced stage, the conditions are created for decreasing the whole amount of portlandit in cement stone. As the result of the latter the long fibrous new formations of C-S-H phase are formed and grown. Everything mentioned above leads to the creation of especially dense structure of cement stone and the connected with this properties of shale ash cements.

## An examination of Ordinary Portland cement blended with pulverised-fuel ash

### *Examen du ciment Portland ordinaire mélangé à des cendres volantes*

W.A. GUTTERIDGE, Mr. Cement and Concrete Association, Materials Research Department, Slough, England.

RESUME : Des échantillons de cendres volantes ont été examinés par diffraction X pour mesurer ce que l'on appelle : leur indice de cristallisation. En effectuant des mesures quantitatives par diffraction X sur des ciments contenant des ajouts de cendres volantes, on a montré que les résultats permettaient l'analyse quantitative des constituants minéralogiques de ce ciment composé; ils permettent aussi, si l'on dispose d'un échantillon de ciment Portland pur ayant servi à la fabrication de ce ciment composé, de connaître l'analyse quantitative et les proportions du clinker et des cendres volantes.

SUMMARY : Samples of pulverised fuel ash (ash) have been examined using X-ray powder diffraction and an estimate of a so-called "crystallinity index" obtained. Using quantitative X-ray diffraction it has been shown that Ordinary Portland cement blended with ash can be analysed either in terms of the ash and synthetic cement minerals or equally well when a sample of the Ordinary Portland cement is available, in terms of the cement and the ash.

## INTRODUCTION

In general, the values obtained from a quantitative X-ray powder diffraction analysis (QXDA) of either a cement or a clinker are precise but not absolute. They are relative only to the intensity data of the compounds used to provide the basis for the analysis. Every laboratory strives to ensure that these compounds (or their intensity data) are representative. Nevertheless it is still assumed by many that intensity data from say an alite (or alites) used at one laboratory are identical to those obtained at another laboratory. That variability exists is reflected in the results obtained from the international QXDA surveys of 1964 (1) and 1973 (2). In certain circumstances however it is possible to analyse a cementitious mixture not just in terms of compounds thought to represent the mixture but in terms of the actual components. Cement blended with either pulverised-fuel ash or slag is such a mixture. The analysis would be given in terms of the proportions of cement and ash (or slag) used in the blend.

Results are presented here for clinker and cement blended with ash. No attempt has been made to analyse the ash in terms of its individual compounds. A so-called "crystallinity index" has been used to characterise each ash.

The analytical procedure is that used at the Cement and Concrete Association for the analysis of anhydrous Portland cement and clinker, the analysis being given in terms of a set of synthetic cement minerals. This procedure has been tested using mixtures containing between two and eight synthetic cement minerals in several combinations. It has been shown by the author that the method is reliable and will produce an analysis of an acceptable precision. Three such analyses are given in Table I together with appropriate 95 percent confidence limits (95% CL).

standard the intensity  $I_p$  can be normalised using the intensity  $I_s$  from a selected diffraction of the internal standard (3), (4), (5) to give

$$I_p/I_s = N_p$$

It can be shown (6) that  $I_c/I_s = \sum_{c=1}^M (N_c)_p \cdot w_c$

where  $(N_c)_p$  is the normalised intensity at the angle 2-theta of a binary mixture (or primary standard) containing only the particular compound c and the same weight fraction  $w_s$  as is contained in the multicomponent mixture;  $w_c$  is the weight fraction of compound c in the multicomponent mixture.

The weight fraction  $w_c$  of each compound in the multicomponent mixture is obtained by minimising the sum of the squares of the errors for the intensity data collected by step counting at each of the 2-theta values and solving the resultant normal equations.

A reliability factor R is computed where R is given by

$$R = \sum_{p=1}^{P=T} \left( N_p - \sum_{c=1}^{C=M} (N_c)_p \cdot w_c \right)^2 / \sum_{p=1}^{P=T} (N_p)^2$$

Finally the weight fraction of each component in the mixture is expressed as a weight percentage and a total  $w_T$  obtained.

Both R and  $w_T$  are used to assess the reliability of the analysis. It has been found by the author that when  $w_T$  is  $100 \pm 2$  and R is less than 0.02 the analysis is reliable.

Experimentala) Sample preparation and data collection

A set of X-ray intensity data were collected on

Analyses obtained from mixtures containing synthetic cement minerals and analysed in terms of the same synthetic minerals using X-ray diffraction (weight percentage)

Procedure

The analytical procedure uses intensity data collected by step-wise counting and the fact that in any powder diffraction pattern obtained from a mixture containing M components, the intensity  $I_p$  diffracted at any angular position 2-theta is related to the linear sum of the intensity  $I_c$  diffracted by each component at the angle 2-theta. When such a mixture contains a weight fraction  $w_s$  of an internal

punched paper tape, by step counting for 20 seconds at intervals of 0.05 degrees 2-theta from 12 degrees to 45 degrees 2-theta, for each sample of ash (in its as-received condition) using a Philips vertical circle powder diffractometer with pulse height discrimination and copper K-alpha radiation.

Primary standards were prepared using 1g of rutile (TiO<sub>2</sub>) as the internal standard and 5g of one of the following, a cement, a clinker and a pulverised-fuel ash. These mixtures were ground for 40 minutes

in an agate ball mill using 10ml of cyclohexane as a grinding aid.

Intensity data were collected, on punched paper tape, from these primary standards by step counting at each interval of 0.05 degrees 2-theta over the range 24.8 to 38.25 degrees 2-theta using a Philips vertical circle powder diffractometer with pulse height discrimination and copper K-alpha radiation. Twelve primary standards were prepared in this way using four Portland cements, a sulphate resisting Portland cement clinker and seven samples of pulverised-fuel ash.

An additional eight mixtures were prepared each containing rutile (having the same weight fraction  $w_s$  as used in the primary standards) together with one of the seven samples of ash and either the sulphate resisting Portland cement clinker or one of the Portland cements. These mixtures were to be the subject of the QXDA and were made in exactly the same way as the primary standards. Intensity data were also collected in exactly the same way as was used with the primary standards. Nominal compositions are given in Table II.

TABLE II				
Mixture No.	Clinker or Cement		Ash

7	3	40	5	60
8	4	30	6	70

Nominal composition of the blended mixtures containing pulverised-fuel ash and either a cement or a clinker (weight percent)

#### b) Data processing

Intensity data obtained from the pulverised-fuel ash in its as-received condition and collected over the angular range 12-45 degrees 2-theta were processed by removing a linear background and then fitting an eighth order polynomial in  $\sin^2 4\theta$  to data comprising the "amorphous halo". The total integrated intensity defined by the polynomial represented the diffracted intensity  $I_A$  from the "amorphous halo" in each sample of ash. The ratio

$$\frac{(\text{Total integrated diffracted intensity} - I_A)}{(\text{Total integrated diffracted intensity})} \times 100$$

was used to give a value for the "crystallinity index" of the ash.

The X-ray intensity data collected from the eight mixtures were processed by:-

- (i) location and subtraction of background data.
- (ii) location of the mid-chord at 80 percent of the peak height (80% PH) of the Rutile (110) diffraction.

(iii) interpolation of the intensity data until the 80% PH of the Rutile (110) diffraction was at 27.475 degrees 2-theta.

(iv) determination of the integrated intensity of the Rutile (110) diffraction.

(v) normalisation of the intensity data.

#### c) Analysis

Each mixture was analysed in two ways. First in terms of an ash and either a cement or a clinker and second in terms of an ash and a set of synthetic cement minerals. Two sets of seven analyses were obtained from each mixture of cement and ash. For example the QXDA intensity data recorded from mixture number one (which contained only ash No 7 and cement No 5) was first analysed in terms of the primary standard (PS) data for both ash No 7 and cement No 5. Six other results in this set were obtained by substituting (one at a time) the PS data for the remaining six ashes for that of ash No 7. The second set of seven analyses were obtained using PS data from a set of synthetic minerals instead of that for the cement and repeating the procedure outlined above with each ash in turn. Of these fourteen analyses only one is specific to the actual components of the mixture in that pulverised-fuel ash No 7 and cement No 5 were used. The other thirteen analyses indicate the range of results which are obtained when a mixture is analysed in terms of components which are similar to, but not identical with the components in the mixture.

Analyses are given in Table III for the four Portland cements and the SR Portland cement clinker used in this work. These results are based on synthetic cement minerals. The crystallinity indexes obtained from the seven samples of ash are given in Table IV. The analyses obtained from mixtures 2, 3 and 4 are given in Tables V and VI whilst those results obtained from mixture 8 are given in Tables VII and VIII.

\*denotes analysis using the correct reference components.

#### Discussion

Results given in Table IX show that satisfactory analyses are obtained when the blended mixtures are analysed in terms of their particular components. The agreement between the results in Table IX and the nominal composition given in Table II is good.

By chance the pulverised-fuel ashes used in this work appear to fall into two groups when classified according to their crystallinity index. Samples 1,4, 5,6 and 7 have an index in the range  $20 \pm 6$  whereas sample 2 and 3 are significantly different in that their index is in the range  $58 \pm 4$ . It would not be surprising therefore to find a similarity in the analyses given by ashes in the same group. This is shown by the results given in Table VII for a mixture containing an ash from group one i.e. having an index in the range  $20 \pm 6$ . Those analyses which have been obtained using other ashes in this group are similar in as far as a mean value of 68.8 ( $\sigma = 0.36$ ) is obtained for the ash content of this mixture. This contrasts with the value of 62.8 ( $\sigma = 3.96$ ) obtained from the two ashes of group two. The contrast is more marked in the results given in Table VIII where a mean value of 70.1 ( $\sigma = 1.1$ ) is

obtained using ashes in group one and 59 ( $\sigma = 5.65$ ) using the two ashes of group two. In general it appears from the results presented here that acceptable analyses are obtained only when the analysis is given in terms of an ash whose crystallinity index is similar to that of the ash used in the blend. This criterion applies when the analysis is in terms of either an ash and a cement or in terms of an ash and synthetic cement minerals.

#### CONCLUSION

A blended mixture of pulverised-fuel ash and cement can be analysed equally well either in terms of the ash and synthetic mineral or in terms of the ash and the cement used in the blended mixture. There is some evidence that for the analysis to be acceptable the ash used in the calibration should have a similar crystallinity index to that in the unknown blend.

# Mécanisme d'hydratation d'une cendre de lignite calcaire

## *Hydration mechanism of a fly ash produced from calcareous lignite*

A. CARLES-GIBERGUES, Département de Génie Civil de l'Institut National des Sciences Appliquées de Toulouse,

B. THENOZ, Institut de Géotechnique de l'Université Paul Sabatier de Toulouse et

A. VAQUIER, Institut de Géotechnique de l'Université Paul Sabatier de Toulouse, France.

RESUME : Les cendres volantes de GARDANNE (FRANCE) proviennent de la combustion de lignites calcaires. Elles sont utilisées pour leurs propriétés hydrauliques. Elles renferment essentiellement de la chaux vive, de l'anhydrite et de la larnite associées à une phase vitreuse.

Gâchées avec de l'eau à température ordinaire, ces cendres manifestent une forte réactivité : il apparaît rapidement de la Portlandite, responsable de la prise, puis de l'ettringite. Par la suite, C H diminue progressivement, jusqu'à disparaître, en se combinant au silicium, libéré par le verre et par  $\beta$ -C<sub>2</sub>S, sous forme d'un C S H ; parallèlement, se forme C<sub>2</sub>ASH<sub>8</sub>.

La vitesse de cristallisation de C H et, par voie de conséquence, la vitesse de prise des pâtes cendre-eau est accélérée par la diminution de la quantité d'eau de gâchage et par l'accroissement de la température. L'ettringite, par contre, se décompose au-dessus de 60°C.

C'est la pression de cristallisation de l'ettringite dans des espaces intergranulaires trop faibles qui fissure puis ruine précocement les pâtes pures. Par contre, si la cendre est incorporée, en petite quantité, dans un squelette de gros éléments (grave routière, par exemple) il existe des cavités suffisamment grandes pour assurer la libre expansion de l'ettringite. Dans ce cas, l'enchevêtrement des aiguilles de C<sub>6</sub>A<sub>3</sub>H<sub>30</sub> vient s'ajouter à l'action liante de C H qui est, plus tardivement, renforcée puis définitivement remplacée par celles de C S H et C<sub>2</sub>ASH<sub>8</sub>.

SUMMARY : Fly ash of GARDANNE plant are produced from calcareous lignite coal. They have cementitious properties. The major components are crystalline : lime, anhydrite and larnite. Glassy phase represents some 30 percent of fly ash.

The material reacts with water : C H is formed, which causes the set and ettringite appears more slowly. Afterwards, the amount of C H decreases : this mineral combines with silica, released by the glass and C<sub>2</sub>S, to form C S H : subsequently C<sub>2</sub>ASH<sub>8</sub> appears.

The rate of hydration of C and setting of pastes are much increased by rise in temperatures (from 2°C to 60°C), and decrease of water : fly ash ratio. Crystallisation of ettringite is also accelerated up to 40°C : the mineral decomposes above 60°C.

The crystallisation pressure of the needles of C<sub>6</sub>A<sub>3</sub>H<sub>30</sub> growing in too little intergranular spaces, introduces stresses in hardened young pastes and leads to breakdown.

On the other hand, when fly ash is introduced in coarse aggregates (i. e. in road bases) ettringite develop freely in the large voids of the mix : so, an important contribution to strength is made by the filling of these spaces. In final stage of hydration, C S H and C<sub>2</sub>ASH<sub>8</sub> are responsible for rise in compressive strength up to 15 MPa at the age of 180 days.

Ces cendres résultent de la combustion des lignites calcaires du bassin de GARDANNE (FRANCE). Les stériles des combustibles sont, pour la majorité, de la calcite, du gypse, de l'illite, du quartz et de la pyrite. Ils donnent naissance à des cendres relativement pauvres en verre et surtout caractérisées par leurs oxyde et sulfate de calcium cristallisés ; elles font prise au contact de l'eau. A ce titre, elles ne sont pas utilisées comme addition pouzzolanique mais bien comme liant de graves routières. Cette communication, suite des travaux exposés dans une précédente publication (1), se propose d'expliquer l'influence des divers paramètres qui commandent l'hydratation du matériau.

### 1 - CONSTITUTION MINÉRALOGIQUE DE LA CENDRE

Les variations de teneurs relatives des minéraux des stériles se répercutent sur la composition chimique des cendres. Aussi, indiquons-nous sur le tableau I les limites 1 et 2 à l'intérieur desquelles se sont situés les échantillons que nous avons étudiés.

TABLEAU I - Composition chimique de la cendre

	Cendre totale		Verre
	lim. 1	lim. 2	
SiO <sub>2</sub>	24,8	21,0	32,5
Al <sub>2</sub> O <sub>3</sub>	14,9	14,7	43,2
Fe <sub>2</sub> O <sub>3</sub>	6,8	6,6	7,6
CaO	42,9	47,2	11,2
MgO	1,8	0,8	2,4
K <sub>2</sub> O	1,0	0,4	1,2
Na <sub>2</sub> O	0,8	0,4	1,2
SO <sub>3</sub>	7,0	9,1	0

L'étendue de variation est moins grande que celles rapportées par des auteurs étrangers concernant d'autres types de cendres de lignites (2) (3).

De nombreux grains sont sous forme de sphérules vitreuses : elles sont essentiellement silico-alumineuses et renferment parfois du fer qui les teinte alors en rouge. Les autres particules sont cristallisées en chaux vive, anhydrite, hématite, magnétite, quartz et larnite. L'existence de ce dernier minéral, qui a fait l'objet de controverses, a été, d'une part, constatée par J. MILLET (4) et, d'autre part, est clairement montrée par les diffractogrammes X (figure 1) réalisés sur la cendre brute (1a), sur la cendre traitée à l'eau sucrée (1b), sur ce résidu attaqué par l'acide salicylique (1c).

Le bilan quantitatif des diverses phases s'établit aux valeurs suivantes :

chaux vive : 28 %	quartz : 5 %
anhydrite : 15 %	hématite+magnétite : 4 %
larnite : 14 %	verre : 34 %

FIGURE 1 - Mise en évidence de  $\beta$ -C<sub>2</sub>S dans la cendre

Nous avons reporté dans le tableau I la composition chimique -calculée- du verre. Celle-ci s'applique à l'ensemble de la phase vitreuse : elle varie très largement d'une sphérule à l'autre, comme l'ont montré de nombreux auteurs, travaillant sur des cendres de houille, dont B. ALPERN a été l'un des premiers (5).

La répartition de ces constituants varie considérablement avec la granulométrie : c'est ainsi que l'anhydrite se concentre dans la partie la plus fine et que la chaux s'y raréfie.

La masse volumique absolue du matériau avoisine 28 kg/dm<sup>3</sup> ; sa surface spécifique (Blaine) varie entre 2 500 et 3 200 cm<sup>2</sup>/g et sa granulométrie s'étale, en pratique, de 0,5 à 100  $\mu$ m.

### 2 - HYDRATATION DE LA CENDRE

Nous avons mené deux séries d'expériences.

Tout d'abord, et en vue de préciser les mécanismes exacts qui commandent la prise de la cendre, nous avons déterminé les éléments susceptibles de passer en solution. Pour ce faire, comme le conseille COTTIN (6), nous avons jugé préférable d'éviter aussi bien les suspensions très diluées que les rapports solide/liquide élevés et avons choisi la valeur eau/solide, E/S = 10.

Nous avons ensuite cherché à approcher les conditions réelles d'hydratation de la cendre utilisée comme liant en Travaux Publics ; nous avons donc étudié le comportement de pâtes gâchées avec peu d'eau, au rapport E/S = 0,20.

## 2.1 - Cendre placée dans un excès d'eau

La cendre de GARDANNE agitée dans dix fois son poids d'eau, à température ordinaire (19 à 21°C), subit une dissolution extrêmement rapide et fort importante puisque la perte de poids atteint 3 % après 1 heure, 6 % à 2 heures et se fixe à 9 % au bout de 4 jours. Dans les mêmes conditions, pour une cendre de houille silico-alumineuse, on note respectivement, 0,6 % - 0,9 % et 1,2 %.

Comme il fallait s'y attendre, la cendre relâche surtout de la chaux et des sulfates (figure 2). Le passage en solution de la chaux est extrêmement rapide et important ; il précède celui des sulfates.

FIGURE 2 - Dissolution de la cendre dans l'eau

La partie vitreuse de la cendre témoigne d'une réactivité non négligeable : silicium et aluminium se retrouvent eux aussi en solution, très vite, mais à des taux évidemment bien inférieurs.

L'étude, par diffractométrie X, montre qu'il s'ensuit des transformations de la constitution minéralogique du matériau. Sur la figure 3, nous avons reporté l'évolution des hauteurs des raies de diffraction, caractéristiques de :

- la chaux, C, plans (200) et (220)
- l'anhydrite,  $C\bar{S}$ , réflexion  $\begin{smallmatrix} 002 \\ 1020 \end{smallmatrix}$
- l'association chaux+larnite : plans (111) de C, (103), (121), et (200) de  $\beta$ - $C_2S$

rapportées à celle de la réflexion (101) du quartz. L'examen des courbes amène à distinguer deux périodes qui s'articulent approximativement au quinzième jour.

FIGURE 3 - Hydratation de la cendre dans un excès d'eau (E/S = 10)

## 2.1.1 - Hydratation durant les 15 premiers jours

La chaux vive diminue très rapidement au cours des premières heures, plus lentement ensuite ; elle disparaît pratiquement au bout de quinze jours. La dissolution de l'anhydrite est un peu plus lente à démarrer mais, au bout de quelques heures, elle acquiert une vitesse constante jusqu'à disparition du minéral qui intervient au treizième jour.

La larnite se dissout beaucoup plus lentement que la chaux, comme en témoigne la décroissance, avec le temps, de l'intensité du pic à 2,778 Å ( $C + C_2S$ ), nettement moins rapide que celle de la somme des diffractions de (200) et (220) de  $CaO$ .

Simultanément, apparaissent des minéraux hydratés ; au bout d'une heure, de la portlandite, puis, après une heure trente, de l'ettringite.

Ces deux composés sont discernables, tout d'abord, par microscopie électronique à balayage (figure 4), mais aussi, plus tardivement, au microscope optique.

FIGURE 4 - Cendre hydratée 1H30 (E/S = 10)\*  
(E : ettringite ; P : portlandite)

On se rend compte que les cristaux de portlandite se multiplient et forment un squelette qui rigidifie le matériau. Les cristaux d'ettringite, seulement visibles en petit nombre sur la figure 4 (car l'hydratation n'a duré que 1 heure 30), sous forme de prismes trapus, se développent par la suite surtout perpendiculairement à la surface des grains. Ils reproduisent un arrangement, décrit notamment par A. GRUDEM (7), caractéristique des structures type-ettringite qui apparaissent dans les jeunes pâtes de ciment. Ces prismes s'allongent avec le temps, écartant progressivement les grains de cendre et détruisant ainsi l'assemblage précédemment réalisé par la soudure des plaquettes de portlandite.

### 2.1.2 - Hydratation à longue échéance

La consommation de la chaux vive étant achevée au quinzième jour, il ne se forme pratiquement plus de portlandite. Bien au contraire, ce minéral diminue progressivement jusqu'à totale disparition au seizième mois. Ce phénomène est expliqué par la libération continue de silice, à partir de la phase vitreuse et de la larnite qui amène la formation d'un silicate de calcium hydraté, dont les amas de gel spongieux sont bien visibles sur la figure 5.

FIGURE 5 - Cendre hydratée 20 mois (E/S = 10)  
(E : ettringite, P : portlandite)

La totalité de l'anhydrite ayant disparu au quinzième jour, il n'apparaît pratiquement plus, au-delà de ce terme, d'ettringite supplémentaire : à la longue, elle se convertit partiellement en  $C_4ASH_{12}$ . Dans ce milieu où la chaux devient de plus en plus rare et où l'aluminium continue à être libéré par les sphérules vitreuses, on met en évidence, en proportions notables, aux longues échéances, de la gélénite hydratée  $C_2ASH_8$ . Ceci s'accorde bien avec les résultats de LOCHER qui a établi l'instabilité de  $C_2ASH_8$  en présence de chaux (8) et ceux de DRON (9) dans son étude des laitiers.

### 2.2 - Cendre gâchée en pâte pure

Compte tenu de l'absence d'agitation qui freine le passage des ions en solution, le comportement de la cendre au contact de faibles quantités d'eau

(E/S = 0,20), ne diffère pas fondamentalement de celui des suspensions diluées (figure 6).

FIGURE 6 - Hydratation de la cendre en pâte pure  
(E/S = 0,20)

C'est ainsi que la teneur en chaux vive décroît régulièrement pour s'annuler à 6 mois : la portlandite devient décelable au bout de 4 heures. Il faut attendre 7 heures environ pour noter une diminution significative de C S conjuguée à l'apparition d'ettringite. Cette dernière atteint pratiquement un palier au bout de 3 mois (épuisement de C S) et C H y parvient en 6 mois.

### 3 - FACTEURS PRINCIPAUX COMMANDANT L'HYDRATATION

Nous avons limité notre étude aux deux paramètres qui nous paraissent devoir jouer un rôle primordial et qui, de surcroît, varient fortement sur un chantier : proportion d'eau de gâchage et température.

#### 3.1 - Influence de la proportion d'eau de gâchage

Celle-ci intervient sur le délai d'apparition des hydrates, puis sur la vitesse de croissance de ceux-ci, mais aussi sur le comportement dimensionnel du matériau hydraté.

##### 3.1.1 - Vitesse de formation des hydrates

Une première indication, globale, susceptible d'intéresser le praticien, est fournie par la vitesse de prise des pâtes pures (mesurée suivant la norme P 15-431). Comme on pouvait s'y attendre, la prise est d'autant plus tardive que E/S est grand. On remarque que c'est spécialement dans le domaine des E/S élevés - qui se rapproche le plus des conditions de chantier - qu'une variation de teneur en eau a les plus fortes répercussions sur le délai de début de prise. C'est ainsi qu'en s'écartant seulement de  $\pm 4\%$  d'une teneur en eau de 36 %, on fait varier le délai de prise du simple au double. L'examen diffractométrique de pâtes gâchées aux rapports E/S de 0,2 - 0,3 - 0,4, montre que la cristallisation de C H dépend notablement de la teneur en eau (figure 7). Des quantités croissantes d'eau retardent la saturation en C H et, par voie de conséquence, l'apparition de portlandite. Si l'on admet que la rigidification de la pâte est précisément

due à la formation de C H, il y a un bon accord entre vitesse de prise et délai d'apparition de C H. Par la suite, du moins au long des 4 premiers jours où ont été faits nos essais, il n'y a pas de différence significative dans la vitesse de cristallisation de C H lorsque le rapport E/S varie de 0,2 à 0,4.

En ce qui concerne l'ettringite, la précision de la méthode de mesure n'a pas mis en évidence de différence de comportement liée à E/S.

### 3.1.2 - Comportement dimensionnel du matériau hydraté

Les déformations dues à l'hydratation de la cendre ont été déterminées concurremment par deux méthodes.

a - mesure du volume apparent de la pâte, enfermée dans une membrane très souple et imperméable (par pesée dans un liquide) ;

b - mesure de la longueur d'une plaque, maintenue à température et humidité constantes, au moyen d'un appareil mis au point par C. H. DETRICHE (10).

Sans vouloir entrer dans les controverses qui ont pu naître entre les tenants de ces deux techniques, il est rare que les résultats fournis par ces deux types de procédés coïncident, ainsi que l'on fait remarquer J. BARON et M. BUIL (11). Nos propres essais n'ont pas dérogé à cette règle. Nous avons retenu comme étant les plus significatifs les résultats des essais volumétriques. D'une part, il s'agit d'appréhender le comportement d'un matériau qui sera utilisé en masse et non en couche mince. D'autre part, à cause d'un premier gonflement parasite qui apparaît dans l'essai monodimensionnel, dès que  $E/S > 0,25$ , en raison de la trop grande fluidité de la pâte et que nous avons jugé beaucoup plus perturbateur que le très léger fretage exercé par la membrane élastique dans l'essai volumétrique.

Les courbes enregistrées, à 20°C, pour les 4 rapports E/S 0,166 - 0,2 - 0,25 et 0,30 (figure 7), présentent la même allure générale : une première phase de retrait, provoqué par la diminution de volume apparent qui accompagne l'extinction de la chaux vive, précède un gonflement très important, lié à la cristallisation de l'ettringite.

FIGURE 7 - Variations de volume au cours de l'hydratation de la cendre. (température : 20°C)

Le retrait s'effectue suivant une loi en  $A+B \log(\text{temps})$ , A et B étant des constantes dépendant de E/S ; c'est également, dans le même laps de temps, à une loi logarithmique qu'obéit la croissance des réflexions (001) et (101) de C H. Cela établit bien que l'ampleur du retrait initial est liée au degré d'avancement de l'hydratation de C H.

Par la suite, il y a compétition entre ce retrait et l'expansion due à la cristallisation plus tardive de l'ettringite. Bien que la progression de l'hydratation de l'ettringite soit pratiquement indépendante de la teneur en eau, on s'explique toutefois que le délai nécessaire à l'annulation du retrait s'allonge lorsque E/S croît (passant de 4 h. pour E/S = 0,166 à 20 h. pour E/S = 0,30) par la plus grande porosité des pâtes à fort E/S. Dans ce cas, les espaces intergranulaires sont les plus grands, donc les plus longs à combler par les aiguilles d'ettringite.

### 3.2 - Influence de la température

Elle intervient sur les délais de début de prise, mais aussi sur la vitesse des transformations structurales et sur le niveau des performances mécaniques à long terme.

#### 3.2.1 - Vitesse de prise

Indiquons tout d'abord que la vitesse de prise des pâtes pures est fortement influencée par les variations de température de l'ambiance.

FIGURE 8 - Influence de la température sur le délai de début de prise

La figure 8 l'indique clairement. On ne manquera pas de remarquer que c'est pour les E/S assez élevés (0,30 par exemple) et pour des températures inférieures à 20°C, conditions qui règnent fréquemment dans l'emploi de la cendre en Travaux Publics, que l'action de la température est la plus accentuée ; ainsi, un abaissement de la température ambiante de 18 à 12°C double le délai de début de prise.

#### 3.2.2 - Transformations structurales

Des pâtes gâchées au rapport E/S = 0,25, ont été conservées à des températures de 2°C, 8°C, 20°C, 40°C et 60°C. Nous avons suivi, par diffractométrie X,

l'avancement des modifications structurales en déterminant la vitesse d'extinction de CaO et mesurant la vitesse de formation de l'ettringite.

FIGURE 9 - Influence de la température sur l'hydratation de la cendre ( $E/S = 0,25$ )  
(C : CaO ; E : ettringite)

On constate (figure 9) que l'extinction de la chaux est accélérée par la chaleur et ceci dans tout l'intervalle  $2^{\circ}\text{C} - 60^{\circ}\text{C}$ . Par contre, en ce qui concerne  $\text{C}_6\text{AS}_3\text{H}_{30}$ , si sa formation s'accélère bien de  $2^{\circ}\text{C}$  à  $40^{\circ}\text{C}$ , un freinage intervient dès que la température avoisine  $60^{\circ}\text{C}$ . Le minéral devient instable : ceci est confirmé par sa totale disparition des pâtes conservées 7 mois à  $60^{\circ}\text{C}$ .

Par ailleurs, nous avons observé que les pâtes maintenues à basse température manifestent les meilleures résistances mécaniques. Les spécimens conservés à  $60^{\circ}\text{C}$  et  $40^{\circ}\text{C}$ , pendant 7 mois, sont redevenus pulvéreux ; à  $20^{\circ}\text{C}$ , leur cohésion est négligeable ; au-dessous de  $8^{\circ}\text{C}$ , leur structure est encore compacte et leur résistance à la traction (par fendage) atteint 0,7 à 1 MPa.

#### 4 - CONCLUSION

Il convient essentiellement de noter que la cendre de GARDANNE, selon qu'elle est hydratée en pâte pure ou fortement diluée dans un squelette très poreux, et bien que les réactions d'hydratation soient les mêmes, manifeste deux comportements différents.

A court terme et à température ordinaire, apparaît d'abord de la chaux éteinte responsable de la prise, puis de l'ettringite. Si la cendre a été gâchée en pâte pure, par suite de l'exiguïté des vides intergranulaires, la croissance des aiguilles de  $\text{C}_6\text{AS}_3\text{H}_{30}$  amène rapidement la fissuration, puis la désaggrégation du matériau hydraté. Par contre, lorsque cette même cendre est incorporée en faible proportion dans un arrangement de gros granulats (par exemple une grave routière traitée par 3 à 5 % de cendre), il existe une porosité suffisamment grande pour que le développement des cristaux d'ettringite n'écarte pas les éléments déjà soudés par la portlandite. On peut même penser que, par sa cristallisation enchevêtrée, cette ettringite renforce largement la cohésion du matériau hydraté, ce qui s'accorde avec les observations faites notamment par D. CZAMARSKA et al. (12) sur des bétons.

A long terme, la libération d'alumine et de silice par le verre et de silice par  $\text{C}_2\text{S}$  provoque la disparition de C H qui se transforme en un C S H auquel vient s'ajouter, plus tardivement, du  $\text{C}_2\text{ASH}_8$ . Ces deux constituants contribuent, par leurs propriétés hydrauliques marquées, à accroître les performances mécaniques du matériau durci ; c'est ainsi que les résistances à la rupture par compression monoaxiale de mélanges graves-cendres de GARDANNE dépassent largement 15 MPa.

## The reactions of fly ash and Portland cement with relation to the strength of concrete as a function of time and temperature

### *Les réactions des cendres volantes sur le ciment portland et leur effet sur la résistance du béton en fonction du temps et de la température*

P.L. OWENS, Technical Manager, Pozzolan Limited, Chester, U.K. and  
F.G. BUTTLER, Chemistry Department, Teeside Polytechnic, Middlesbrough, U.K.

**RESUME :** Quand le béton de ciment Portland subit des élévations de température, dues à la chaleur d'hydratation du ciment, sa résistance à long terme et sa durabilité s'en trouvent affectées. En outre, si ce béton subit de fortes élévations de température (par exemple plus de 60°C) dans son jeune âge, il en résulte un matériau amoindri et de résistance limitée à long terme, bien inférieure à celle du même béton conservé dans l'eau à 20°.

En utilisant un ciment Portland additionné de proportions variables de cendres volantes de qualité contrôlée, et en le soumettant à différentes sortes d'hydratation et de cure, on a établi que la résistance de ce ciment hydraté, aux divers âges, était en relation étroite avec la proportion de  $\text{Ca(OH)}_2$  présente dans ce ciment hydraté. Il aussi été établi qu'en augmentant la proportion de cendres volantes, non seulement on augmentait les résistances (qui d'ailleurs croissent plus vite quand la température de cure augmente), mais aussi que la proportion de chaux libre diminuait.

**SUMMARY :** Where Portland cement concrete is subjected to rises in temperature, due to the effect of the heat of hydration of the cement, the long term strength and durability of that concrete is usually adversely affected. Further when Portland cement concrete is subjected at early ages, to excessively large temperature rises i.e. exceeding 60°C, the result is a concrete of restricted and limited strength reached within days, in contrast to that which is expected from the long term storage of concrete in water at 20°C.

By simulating different typical curing regimes to which concrete can be subjected the strength of the hydrate at different ages, with various combinations of Portland cement and controlled quality fly ash, can be related to the quantity of lime, as  $\text{Ca(OH)}_2$ , found in the structure of the hydrate. It was also found that as the proportion of fly ash increased not only was there an improvement in strength, which increased with temperature of curing, but that in the hydrate there was an incidental reduction in the quantity of lime.

Within the range from nil to 75% fly ash as a proportion of the cement content, at about 30% fly ash, a maximum strength was attained at 28 days from curing at 80°C, this coincided with a reduction of about 50% in lime content of the hydrate. However, this amount of lime is more than sufficient to provide adequate protection to embedded steel reinforcement.

## 1.0 INTRODUCTION

1.1 When concrete made with Portland cement undergoes an early age temperature rise, such as that caused by the heat of hydration of the cement, the strength at 28 days is reduced in proportion to the size of the temperature change (1).

1.2 This reduction of strength can be partly explained by the combination of the impaired bond at the interface of paste and aggregate, known as micro-cracking (2) and by the macro-fracture of the gel structure by the expansion of air and water (3). However, if these phenomenon normally occur in concrete, how can the significant increase of strength be explained that occurs to concrete by the use of a composite cement, such as made of Portland cement and fly ash.

1.3 Research has shown that under comparable high temperature curing conditions, the 28 day strength of Portland cement concrete can be 60% or less of that made with a composite cement (4). This indicates, that whilst concretes made with different types of cement can undergo similar orders of temperature change, during hydration, there could be a significant difference in the chemical structure of the hardened paste.

## 2.0 EXPERIMENTAL

2.1 For this research to have practical application the test specimens required conditions of curing typical of that known to occur in concrete at early ages (5). The profiles of temperature and time known to be caused as a result of cement hydration are mainly dependant on the quality of cement and the dimensions of the element. Thus both the greater the cement content and/or size of the element, the greater will be the profile of temperature with time.

2.2 Figure 1 illustrates four profiles of temperature and time that are typical for a range of different conditions. Profile A represents for instance the standard curing of test specimens at 20°C, and profile D which could be typical of that within an element that has dimensions exceeding 2.5m x 2.5m x 2.5m, cast with concrete made with 450 kg/m<sup>3</sup> Portland cement.

Fig. 1 - Typical temperature/time profiles for concrete.

2.3 The technique for inducing the temperature rise in the test specimens, similar to that of the profiles in Figure 1 was to match by simulation the different curing regimes. This was done by having a series of 7 water baths each held at a constant temperature of 20, 30, 40, 50, 60, 70 & 80°C. Then by the transfer of sealed test specimens at various predetermined times the heating and cooling cycles of each profile of temperature could be simulated to those shown in Figure 2.

Fig. 2 - Curing cycles simulated to typical temperature/time profiles.

2.4 The authors have also observed from other research

i) Other than under adiabatic conditions the peak temperature experienced in most concrete elements usually occurs within 50 hours after casting.

ii) At 20°C the pozzolanic reaction between Portland cement and fly ash commences usually at about 11 days.

2.5 The means of correlating the effects of the different temperature profiles with both the maturity and the test results of the specimens, was to assume the equivalent period at 20°C was to the base temperature of -10°C (6). Thus the relative maturity of specimens cured by different regimes of temperature could be assessed to approximately 11 days or 8000°C hours (266.67 hours at 20°C.) Then by making the curing regimes conform with convenient factors of maturity i.e. 1.0, 1.125, 1.5 & 2.0, the test results could be correlated to 8000°C.

2.6 In conjunction with the primary test age at 11 days, the test times at 50 hours and 28 days were included so that crushing strength, the more conventional method of assessment, could be related to the different levels of maturity.

## 3.0 DETAILS of materials, mixes and tests

3.1 The criteria for the Portland cement selected was that it should be from a source with characteristics as close to the mean of that for all UK produced Ordinary Portland cements. Details of the cement used together with the mean and range of variability of 25 UK sources (excluding N. Ireland) are shown in Table 1.

See table I

Page IV - 65

3.2 The fly ash conformed with UK Agreement Board Certificate ABC 75/283 ( 7 ). The results are compared in Table 1 with

- i) the typical chemical composition of UK fly ash, calculated to 3.0% loss on ignition, after ( 8 ) and
- ii) the mean quality of fly ash to ABC 75/283 produced during the period July, 1978 to June, 1979.

3.3 The mix was mortar, based on 1:3; cement:sand, to BS 4550 Part 6 quality. The mortar was machine mixed by a standard procedure, with sufficient water to attain a measured ASTM flow consistency of 100 - 110%. In each mix the fly ash substituted a proportion of the Portland cement in increments from nil to 15, 30, 45, 60 & 75%. In consequence the proportion of gauging water required was reduced relative to the amount of fly ash used from 0.495 for the control mix with no fly ash to 0.465, 0.445, 0.415, 0.40 & 0.39 respectively

3.4 From each mix 18 No. 50 mm cube specimens were made, compacted by vibration in 2 layers, then sealed and stored immediately, still in the mould, in water at 20°C. All specimens were removed from the moulds at 22 hours, sealed in polythene air evacuated envelopes and returned to the respective curing regime. At the appropriate time 3 specimens from each mix were tested for the determination of crushing strength and  $\text{Ca(OH)}_2$  content.

3.5 The technique used for the determination of  $\text{Ca(OH)}_2$  content was by the carbonation method of thermal analysis ( 9 ). This was effected by drilling to the centre of each of 3 cubes and immediately testing each of the drillings.

#### 4.0 TEST results

4.1 The results of the crushing tests at 50 hours, 11 days and 28 days are shown diagrammatically in Figures 3, 4, & 5.

Fig. 3 - Effect of fly ash on the 50 hour strength as affected by maturity.

Fig. 4 - Effect of fly ash on the 11 day strength as affected by maturity.

Fig. 5 - Effect of fly ash on the 28 day strength as affected by maximum curing temperature

4.2 The results for the amount of  $\text{Ca(OH)}_2$  present at 11 days are shown diagrammatically in Figures 6, 7, & 8.

Fig. 6 - Calcium Hydroxide in mortar at 11 days

Fig. 7 - Percent Calcium Hydroxide removed in mortar at 11 days.

Fig. 8 - Percent Calcium Hydroxide remaining at 11 days.

#### 5.0 DISCUSSION of the results

5.1 The crushing strength of the mortar with no fly ash cured at 20°C at 50 hours, 11 and 28 days was 19.1, 36.3 & 41.8 N/mm<sup>2</sup> respectively. Although the mortar was different in every respect i.e. mix proportions, size of aggregate and water/cement ratio, very close agreement was obtained to the

respective concrete crushing strength shown in Table 1.

5.2 The reduction of 32 percent in 28 day crushing strength of the mortar, with no fly ash, cured at more than 60°C is similar in magnitude to that found by other research (1).

5.3 For comparable curing conditions, at and exceeding 60°C, the 28 day crushing strength of the mortar with no fly ash was less than 70% of that made with 30% fly ash, this follows the effects found in (4).

5.4 Figure 3 shows that

- i) The strength at 20°C decreases proportionally with the percentage fly ash.
- ii) The increase in strength with maturity of the mortar with no fly ash is not maintained above 2750°C hours, where increased maturity reduces the strength.
- iii) Corresponding with increases in both fly ash content and maturity, the strength of the mortar increases. The optimum strength occurs with about 35% fly ash at a maturity of 3470°C hours. This approximates with a 2.64 factorial increase in strength for 2.33 factorial increase in maturity.

5.5 As Figure 4 shows at 11 days the trend is similar to that at 50 hours, in that:

- i) The crushing strength at 20°C proportionally decreases with the amount of fly ash, indicating little or no pozzolanic reaction.
- ii) The reduction in strength with increasing maturity for the mortar containing no fly ash is in agreement with other research (1).
- iii) By doubling the maturity and increasing the fly ash to 50%, twice the strength is obtained. However, the maximum strength obtained corresponds with about 30% fly ash.

5.6 Figure 5 shows the effect of fly ash on the 28 day crushing strength as affected by the early curing regimes and that:

- i) The crushing strength at 20°C is no longer proportional to the increase in fly ash, and there is indications of a strong pozzolanic reaction at all percentages of fly ash.
- ii) The strength, as affected by the early age curing regime of mortar without fly ash, is decreased, but increased at all percentages of fly ash, particularly at 75% where the 20°C strength is doubled by curing at 80°C.

5.7 Figure 6 shows the percentage Ca(OH)<sub>2</sub> plotted with respect to both the percentage fly ash and the maturity in °C hours. The Ca(OH)<sub>2</sub> is expressed as a percentage of the anhydrous weight of the sample, as the total loss on ignition of each sample was known from the thermogravimetric analysis.

The surface denoted by the solid lines in Figure 6 shows the amount of Ca(OH)<sub>2</sub> found to be present, and the surface denoted by the dashed lines the amount of Ca(OH)<sub>2</sub> that would have been present, from the cement, if there had been no reaction with the fly ash.

With each of the curing regimes the amount of  $\text{Ca(OH)}_2$  present, is proportional to the amount of Portland cement used and, therefore the amount of  $\text{Ca(OH)}_2$  formed for each concentration of Portland cement was calculated from the results obtained with no fly ash.

5.8 It is apparent from Figure 6 that:

- i) For samples cured at  $20^\circ\text{C}$  for 11 days there is a straight line relationship between the percent  $\text{Ca(OH)}_2$  and the percentage fly ash, indicating no pozzolanic reaction, which confirms the strength observations in 5.5.i.
- ii) For all other samples, in which both the maximum temperature attained and the period the samples experienced temperatures in excess of  $20^\circ\text{C}$ , the linear relationship ceases to exist between the percent  $\text{Ca(OH)}_2$  and the percentage of fly ash. In every case the fly ash reduced the amount of  $\text{Ca(OH)}_2$  present when compared with similar samples cured at  $20^\circ\text{C}$ .
- iii) Where no fly ash was used there was an increase in the percentage of  $\text{Ca(OH)}_2$  when the curing temperature exceeded  $20^\circ\text{C}$ .

5.9 The difference between the two surfaces illustrated in Figure 6, corresponds with the amount of  $\text{Ca(OH)}_2$  which has been removed by reaction with the amount of fly ash present. This difference is shown in Figure 7 where the percentage  $\text{Ca(OH)}_2$  removed is plotted with respect to both the amount of fly ash and the maturity at 11 days. Figure 7 also shows that the greatest amount of  $\text{Ca(OH)}_2$  was removed from specimens containing about 30% fly ash. Since the amount of  $\text{Ca(OH)}_2$  removed must have reacted with the fly ash, and if it is assumed that such a reaction increases the strength of the mortar, then this result implies that the greatest increase in strength with the curing regimes used, should occur with this amount of fly ash. This conclusion is seen from Figure 4 to be in very good agreement with the strength of the mortars at 11 days.

5.10 Figure 8 shows the amount of  $\text{Ca(OH)}_2$  that has been removed expressed as a percentage of that available from the cement. It is evident that the quantity removed increases with the percentage of fly ash. With the greatest percentage of fly ash very little free  $\text{Ca(OH)}_2$  remained in the hydrate. Such evidence is important when considering the necessity of having sufficient  $\text{Ca(OH)}_2$  present from the cement for good corrosion protection to the steel reinforcement of structural concrete. However, it should be noted that although some 50% percent of the available  $\text{Ca(OH)}_2$  has been removed when using about 35% fly ash, the amount of  $\text{Ca(OH)}_2$  remaining is more than sufficient to maintain a pH of about 12.5 with good corrosion protection.

#### 6.0 CONCLUSIONS

6.1 By subjecting mortars to curing temperatures similar to those that can occur in practice the effects on concrete strength can be simulated.

6.2 The adverse effects of high curing temperatures on the strength of Portland cement mortars can be related to the amount of lime in the hydrate.

6.3 If high temperatures are likely to be experienced in practice, gains in strength are likely to occur with cements composed of Portland cement and fly ash.

6.4 The amount of residual lime in the hydrate, even when 75% fly ash was used, is sufficient to afford inhibition of corrosion to embedded steel reinforcement.

# Hydration of cements with pozzolanic additions

## *Hydratation des ciments avec additions pouzzolaniques*

J. GRZYMEK, Professor, Stanislaw Staszic Academy Of Mining and Metallurgy in Cracow Poland.,  
W. ROSZCZYNSKI, Assistant,  
K. GUSTAW, Assistant professor.

**RESUME :** Des recherches ont été faites sur la cinétique de l'hydratation des ciments contenant des ajouts de gaize ou de diatomites. Pour faciliter les comparaisons, on a essayé simultanément les mêmes ciments, additionnés de filler calcaire. Les observations ont duré une année, en utilisant la calorimétrie, l'analyse aux rayons X, l'A.T.D. et la porométrie. Les propriétés physiques fondamentales de ces ciments ont aussi été mesurées.

On a pu ainsi déterminer les variations qualitatives et quantitatives des pâtes hydratées, en fonction de l'ajout pouzzolanique. Une attention particulière a été portée à la composition minéralogique des pâtes pendant l'hydratation. Des relations ont été établies entre le processus d'hydratation de ces ciments et leurs propriétés physiques.

**SUMMARY :** Investigations concerning the kinetics of pozzolanic cements hydration were carried out for the cements with the additions of diatomite /high silica pozzolana//and lime-gaize /silica-lime pozzolana/. For comparative reasons similar investigations were carried out for the ordinary Portland cement and for cement with the addition of limestone. The processes of hydration was examined from its very beginning over one-year period. The following investigations methods were used: calorimetric analysis of the heat evolved during hydration, as well as X-ray diffraction, DTA and porosimetric analyses of cement pastes. The basic physical properties of cements were also determined.

The results of the investigations allowed to determine various qualitative and quantitative changes which occurred in the hydration process under the influence of pozzolanic additions. Special attention was paid to the phase contents of the hydrating pastes. The relations between the hydration processes of the examined cements and their physical properties were also analysed.

## INTRODUCTION

The process of hydration of pozzolanic cements is a very complicated and difficult to be fully explained because of the fact that it is differently influenced by different pozzolanic addition. The papers published till today dealt mostly with the influence of natural volcanic pozzolanic materials and with such artificial pozzolanic additions as flying ashes /1,2,3,4/. The number of investigations on natural pozzolanic materials of sedimentary origin is however much smaller /5/. Numerous investigations have already thrown some light on the process of hydration of pozzolanic cements, several problems remain however still unsolved.

The present investigations have been carried out in order to determine the influence of diatomites with high silica content and of

gaizes containing silica and lime on the hydration of pozzolanic cements. Diatomites are well known and widely used as pozzolanic additions /6/, the suitability of gaizes has been recently established in the result of our former investigations /7,8/.

The investigations comprised determinations of hydration heat, of phase composition, of porosity and of the specific surface area of pozzolanic cements in the process of binding and hardening. To facilitate the comparison pure Portland cements /without additions/ and cements with limestone additions were parallelly investigated.

## MATERIALS USED IN INVESTIGATIONS

Materials used in investigations are characterized in the table I. These materials were mixed together in appropriate proportions

TABLE I

	Diatomite	Gaize	Limestone	Portland clinker	Gypsum

and ground to cements with following compositions:

- cement 1 - 95% clinker + 5% gypsum  
 cement 2 - 52% clinker + 3% gypsum  
                   + 45% diatomite  
 cement 3 - 52% clinker + 3% gypsum  
                   + 45% gaize  
 cement 4 - 52% clinker + 3% gypsum  
                   + 45% limestone

Investigations were carried out on pastes and mortars obtained from these cements.

#### DETERMINATION OF THE DEGREE OF HYDRATION

Heat of hydration was determined dynamically in almost adiabatic conditions using a differential calorimeter system. Calorimetric investigations were carried out for mortars containing cement, sand and water in following weight proportions: 167 : 751 : 100. During first three days of hydration the determinations were carried out continuously.

X-ray, DTA and porosimetric determinations were carried out on pastes with W/C = 0,5 after 1, 3, 7, 28, 90 and 365 days of curing in normalized conditions.

#### CALORIMETRIC ANALYSIS

Curves illustrating the evolution of hydration heat as determined from calorimetric investigations are shown in figure 1.

Fig. 1 - Heat evolution during hydration of cements

Fig. 2 - Diffractograms of cement pastes after 90 days of hydration

All additions investigated in this paper i. e. diatomite, gaize and limestone accelerate the apparition of the maximal heat effect. This fact can be explained as follows: pozzolanic additions i. e. diatomite and gaize bind and remove calcium hydroxide from the reaction interface and accelerate the process of hydration owing to the fact that the hydration rate is influenced by the concentration of  $\text{Ca}(\text{OH})_2$  in the solution. Calcium carbonate contained in the limestone and gaize reacts with  $\text{C}_3\text{A}$  very fast and with a great heat effect to form a hydrated calcium compound of the formula  $\text{C}_3\text{A} \cdot \text{CaCO}_3 \cdot 12\text{H}_2\text{O}$ . All additions under investigation exhibit a remarkable grindability and appear therefore in cement mixtures in form of very fine grains which separate the cement grains and accelerate the reaction between cement and water facilitating the access of water molecules. Micrograins of additions act simultaneously as crystallization nuclei in the first stage of hydration.

#### X-RAY INVESTIGATIONS

From all results of X-ray investigations diffractograms shown in figure 2 have been chosen to illustrate the phase composition of cements pastes after 90 days of hydration.

X-ray investigations have demonstrated that the additions affect the qualitative phase composition of hydration products in a very small extent. The relative amounts of diffe-

rent products changing in the function of time are however very strongly influenced by the introduced additions. The influence exerted by additions is better observable after longer hydration times; diffractograms taken after 90 days have been therefore selected to be presented in this paper.

Cement pastes with diatomite and gaize additions contain great quantities of CSH especially after longer hydration times. This can be explained by the assumption that active silica contained in these additions reacts with calcium hydroxide formed in the result of hydrolysis from calcium silicates.

X-ray investigations prove - in the case of all examined pastes - that clinker minerals and active additions successively disappear with increasing hydration time. In the case of cements with additions the hydration of alite occurs faster than in the case of pure Portland cement. This phenomenon can be clearly observed in the case of diatomite and gaize additions. Already in the course of some first hours of hydration considerable amounts of ettringite are formed. After three days the ettringite content begins to decrease and the  $C_3A \cdot CaSO_4 \cdot 12H_2O$  - content correspondingly to increase. Gypsum additions can not be detected already after 24 hours of hydration. After longer hydration times /90 and 365 days/ formation of  $CaCO_3$  and  $C_3A \cdot CaCO_3 \cdot 12H_2O$  is observed. It must be however emphasized that in the case of cements with limestone and gaize additions great amounts of  $C_3A \cdot CaCO_3 \cdot 12H_2O$  have been observed already in the very first stages of hydration. This can be explained taking into account the activity of  $CaCO_3$  contained in limestone and gaize towards  $C_3A$  /9/.

#### DTA INVESTIGATIONS

The DTA method creates the opportunity to determine the amount of water bound in hydration products, type of these products and their content in the paste. The  $Ca(OH)_2$  content can be determined with a considerable exactness owing to the fact that the endothermic heat effect which appears at  $500^\circ C$  and corresponds to dehydration of this compound does not coincide - in the majority of cases - with other thermal effects. The calcium hydroxide content in the paste after different hydration times illustrates the influence of additions on the rate of hydration. The amounts of  $Ca(OH)_2$  in function of time for pastes containing pozzolanic active additions are shown in figure 3.

Fig. 3 -  $Ca(OH)_2$  content in cements pastes in function of time.

The curves presented in figure 3 prove that with increasing hydration time the  $Ca(OH)_2$  content in the case of pure Portland cement pastes increases and amounts to 19,8% after 90 days. The  $Ca(OH)_2$  content increases most rapidly in the first stage of hydration. In the case of cements containing limestone additions the shape of this curve is almost the same. Substitution of 45% clinker by limestone results in decreasing the  $Ca(OH)_2$  content. In the case of cements with diatomite and gaize additions the maximal  $Ca(OH)_2$  content appears between the 7th and 28th day of hydration. After this period the  $Ca(OH)_2$  content in pastes begins slowly to decrease and amounts after 90 days to 2,26 for diatomite and to 5,06 for gaize additions. Active silica contained in these additions reacts obviously with  $Ca(OH)_2$  formed in the process of hydration, binds it up to hydrated calcium silicates and decreases therefore its content in the paste. The amounts of active  $SiO_2$  in gaizes are smaller than in diatomite; the quantities of  $Ca(OH)_2$  bound by gaize are therefore smaller than in the case of diatomite.

#### DETERMINATIONS OF THE SPECIFIC SURFACE AREA AND OF POROSITY

Specific surface areas determined according to the BET method after different hydration times for cements pastes under investigation are presented in table II.

Specific surface areas increase from the be-

T A B L E II

Cement	Specific surface area in $m^2/G$ after different hydration times					
	1 day	3 days	7 days	28 days	90 days	365 days
1	26,3	32,0	38,1	49,7	48,2	35,9
2	42,0	47,3	62,1	64,9	51,9	49,8
3	36,1	42,8	53,4	62,0	54,2	42,3
4	37,2	43,1	53,4	57,4	47,4	38,1

ginning to the 28th - 90th days of hydration, pass a maximum and then slowly decrease. Such changes result from the fact that the porosity of pastes is also changing in the process of hydration. The porosity of pastes decreases - generally taken - with increasing degree of hydration, but simultaneously changes also the size distribution of pores /the number of micropores increases and the number of meso- and macropores decreases/. In the result the specific surface area of hardening pastes firstly increases and then begins to decrease when the decreasing porosity has reached a definite level /usually between the 28th and the 90th day of hydration/.

Specific surface area and porosity of cement pastes containing diatomite are greater than those found for gaize and limestone additions. Smallest values of specific surface area and of porosity were observed in the case of pure cement pastes /without additions/.

#### INFLUENCE OF ADDITIONS ON THE PROPERTIES OF HARDENED PASTES AND MORTARS

Compressive strengths of mortars obtained from investigated cements are shown in figure 4.

Fig. 4 - Compressive strength of examined cement mortars

In the first stage of hardening the compressive strength of specimens containing addition is smaller than that of mortars obtained from pure Portland cement. This can be easily understood in view of following facts:

- 1/ 45% of cement have been substituted by materials which do not increase the compressive strength in the first stage of hydration,
  - 2/ all introduced additions increase considerably the porosity of mortars.
- After longer hydration times, when the products of reaction between pozzolanic additions and calcium hydroxide begin to be already important, the compressive strength of cements with diatomite and gaize additions considerably increases.

Figure 5 illustrates the relation between porosity of pastes and their compressive strength. The influence of porosity on compressive strength is more pronounced at lower porosities i.e. after longer hardening

Fig. 5 - Compressive strength in function of porosity of cement pastes

times /28 - 365 days/. As easily seen from figure 5 compressive strengths of different pastes can be different inspite of the fact that the porosities are similar. This is due to the fact that the compressive strength of cement pastes do not depend on their porosity only but also on their qualitative and quantitative phase composition /10/.

T A B L E   I I I						
Cement	Compressive strength after 3 years storing   N/mm <sup>2</sup>

1	10,0	67,2	4,0	38,9	0,2	20,0
2	8,4	42,8	5,3	45,3	3,9	41,6
3	8,8	47,2	6,5	51,4	6,0	44,4
4	4,9	19,5	4,7	31,6	3,2	25,4

B - bending strength

C - compressive strength

All investigated additions increase the corrosion resistance of cement mortars to sulphates. The results of determinations are shown in table III.

The positive influence of diatomite is due to pozzolanic reaction which results in binding calcium hydroxide and in formation of low-basic hydrated calcium silicates resistant to corrosion. Decrease of calcium hydroxide content in the mortar prevents formation of greater quantities of gypsum /under the influence of sulphates contained in the solution/ and of ettringite. The resistance improving influence of limestone can be explained by reaction with  $C_3A$  and formation of  $C_3A \cdot CaCO_3 \cdot 12H_2O$  which is insoluble in aggressive sulphate solutions. Gaize improves the corrosion resistance owing to pozzolanic reactions and owing to the binding of  $C_3A$  by  $CaCO_3$  contained in this addition.

Cements containing diatomite and gaize additions are characterized by smaller /57 - 62%/ hydration heats than that observed in pure Portland cement mortars.

#### CONCLUSIONS

Pozzolanic additions i.e. diatomite and gaize have been proved to exert a considerable influence on the process of hydration of cements. Limestone additions participate also actively in this process. Additions change the properties of cements in which they have been introduced. Owing to their properties the diatomite, gaize and limestone added cements can find use as low-caloric binding materials highly resistant against aggressive sulphate solutions. Cements with gaize additions exhibit especially usefull properties.

### *Préparation des ciments aux cendres volantes.*

H.C. ALSTED NIELSEN, F.L. Smidth et Co. A/S Vigerslev Alle 77 DK-2500 Valby Copenhagen, Denmark.

RESUME : Il est toujours possible d'utiliser des cendres volantes pour la production de clinker. Elles peuvent être ajoutées au mélange cru destiné aux fours à voie sèche alors que, pour le procédé humide, elles nécessitent certaines modifications.

Les cendres volantes à haute teneur en carbone doivent être insufflées dans la zone de cuisson, ce qui permet de tirer profit de leur pouvoir calorifique.

Seules des cendres volantes de composition uniforme et appropriée et de basse teneur en carbone peuvent être utilisées comme composant dans le ciment fini. Les travaux d'essais et de perfectionnement dont il est fait ici mention, indiquent comment broyer les cendres volantes.

SUMMARY: Fly ash may always be used in the manufacture of clinker. It can be added to the raw mix for dry process kilns, but only with certain modifications for the wet process.

High-carbon fly ash should be insufflated into the burning zone, whereby advantage can be taken of the heat value.

Only fly ash with a consistent, suitable composition and a low carbon content should be used as a constituent of finished cement. The testing and development work reported here indicates how fly ash cement should be milled.

## 1. INTRODUCTION

Fly ash is, and will be, collected at our power stations in large quantities; one of the areas where this material can be put to use is in the manufacture of cement and concrete.

Technically, fly ash can be utilized in several ways at a cement works; the optimum utilization for any fly ash will be a function of its fineness, chemistry, and homogeneity.

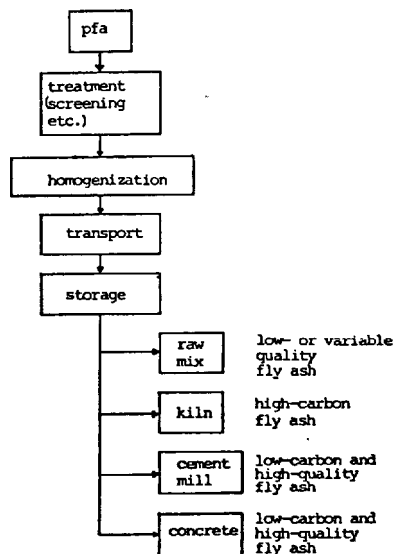

Fig. 1 - Utilization of FLY ASH (PFA)

When of a sufficiently high standard, fly ash may be added directly to concrete. Similarly, cement clinker can be milled together with gypsum and fly ash, yielding either a modified Portland cement or a fly ash cement, depending on the relative amounts of clinker and fly ash. Also in this instance, a consistently high quality of the fly ash is essential.

However, when fly ash either varies in quality or is of low quality as, for example, with respect to colour due to carbon content, special precautions have to be taken; one way is to treat fly ash as a conventional raw material, using it as part of the raw mix - meal or slurry - which is fed to the kiln. In this way fly ash of varying chemical composition can be utilized without impairing the quality of the cement.

When the coal content of fly ash is high, a better method would be to insufflate the fly ash into the burning zone of the rotary kiln. In this manner it is possible to utilize the heat value remaining in the residual carbon of the fly ash.

The method chosen to utilize each fly ash should be decided on its individual merits; a combination of two or more methods can also prove to be the optimum solution.

PFA - pulverized fuel ash or fly ash - can also be upgraded. Stockpiling of ash in a large homogenizing plant or in silos is possible and at times quite desirable, either when fly ash is drawn from different sources, or when coal of various origins is burned.

Residual carbon in PFA is an undesirable constituent, due to its colour as well as to its tendency to absorb concrete additives. Many plants have tried to overcome these difficulties by removing the carbon from the PFA; the coal can be separated off by screening, as the coal particles are concentrated in the coarser fraction of PFA (above 100 microns). Other solutions are to burn off the carbon, or for instance to submit the coal to a flotation process.

The best solution of all, of course, exists when the power plant regards the fly ash as a product; this means using boilers designed for coal combustion, operating them as base load utilities, and burning blended coal.

This procedure must yield a PFA with suitable, consistent chemical and mineralogical composition, and containing less than 2-3% residual coal.

## 2. CEMENT WITH PFA

Our testing and development work has shown us how to utilize fly ash from different sources and of varying composition.

Fig. 2 - Shear testing of PFA and cement and silo dimensions for mass flow.

Inferior grades of PFA should always be used as raw material. At a cement plant operating according to the dry process, fly ash can easily replace part or all of the shale or clay in the raw mix. Certain factors have to be considered when designing the handling facilities for PFA, owing to its easy flowability. Fig. 2 shows the easy flow of a dry fly ash compared to that of a Portland cement.

At a wet process plant, the hydraulic properties of fly ash prove to be a drawback to its use in the kiln slurry, thickening the slurry, raising its viscosity, and increasing the water content required for acceptable flowability. One solution to the problem is to add a retarding agent, but usually the costs involved are too high.

A more economical way is to prepare the slurry within 1-2 hours before usage. Research work at our laboratories has indicated that such a slurry may be handled in a pressure filter, thereby reducing the amount of water evaporated in the rotary kiln.

In both wet and dry process kilns, PFA can be insufflated directly into the burning zone, thus utilizing the heat value. This method is the best solution when dealing with high-carbon fly ash, which may be injected in an amount of up to 8% by weight of clinker.

### 3. FLY ASH CEMENT

High-quality fly ash can be utilized directly in cement. The desired cement product might be one with a low PFA-content or with up to 30% of PFA. The qualities required are the following:

High fineness  
Low carbon content  
High glass content  
Low alkali content

Fig. 3 - Variation in compressive strengths with the PFA content in per cent. Inter-ground cements at 42% residue on 25  $\mu$  by air elutriation.

In judging the strength development, however, it can be concluded that an addition of fly ash results in a reduction in early cement strength as shown in Fig. 3.

The figure shows compressive strength obtained with cements of constant fineness. Cement and fine, low-carbon fly ash were ground together in a ball mill. The cement and fly ash compositions are shown in the Table.

TABLE		
Analysis	Cement	Fly Ash
SiO <sub>2</sub> %	21.4	46.9
Al <sub>2</sub> O <sub>3</sub> -	5.2	23.1
Fe <sub>2</sub> O <sub>3</sub> -	3.1	8.7

+ 0.25 mm		3
+ 0.09 mm		18
+ 0.063 mm		23
+ 0.045 mm		29
+ 0.02 mm		50
Blaine, cm <sup>2</sup> /g		4250
Spec. gravity g/cm <sup>3</sup>		2.4

The decrease in compressive strengths can be partly compensated for by finer grinding. For instance, examination of Fig. 4 reveals that increased grinding improves the compressive strength; however, some difference in strength is likely to remain at the higher fly ash substitution levels. Part of this remaining difference could be eliminated by further prolonged grinding, using more energy per ton cement produced.

Fig. 4 - Variation in strength with grinding energy and PFA cement.

The milling of cement and fly ash can be carried out in several ways. Clinker, gypsum, and fly ash may be fed to the same mill, grinding either in open or in closed circuit, with an air separator.

Fly ash may also be mixed directly with Portland cement, since the fly ash from some installations is extremely fine.

Fig. 5 shows suggestions for some possible milling circuits.

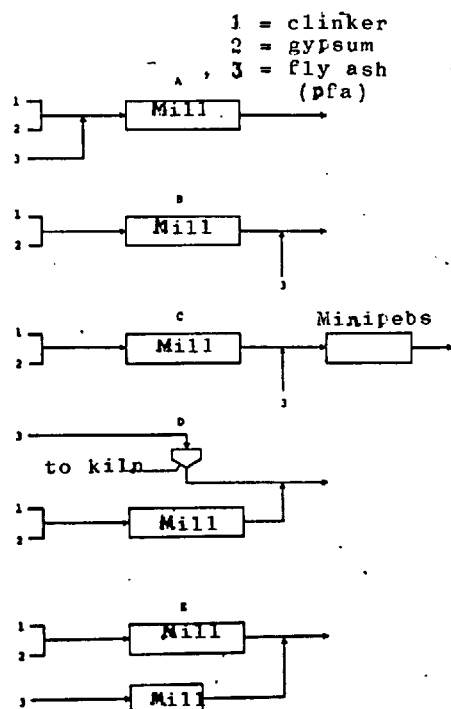

Fig. 5 - Milling circuits.

We have studied these circuits in a large number of test grinds, accurately recording the specific power consumption and measuring the compressive strengths of the resulting cements. One set of results appears on Fig. 6.

Here intergrinding (Circuit A) gives the best overall performance, followed by the circuit in which only the finest part of the fly ash is utilized for mixing into cement (Circuit D).

Using the PFA as received (Circuit B) appears to be a less suitable way of preparing fly ash cement.

Fly ash is fine, and a special mill might be used for its grinding before mixing with Portland cement (Circuit E). Judged on the basis of energy consumed, the final result is better than using PFA as received, but is not so good as when PFA is separated, and only the fine fraction is utilized. The PFA was ground in an ordinary Cylpebs mill to a 5.5% residue on 25 microns and a specific surface of 5000  $\text{cm}^2/\text{g}$ , according to the Blaine method.

Effect of different grinding layouts

Fig. 6 - 15% PFA cement

In fact, fly ash is so fine that a special mill with quite small grinding media should be employed as for instance the Minipebs mill. In this way a saving in the overall consumption of energy between 5 and 10% can be achieved.

A method combining the advantages of Minipebs grinding and of combined grinding is shown in the layout labeled Circuit C.

Although combined grinding appears to be the optimum solution, possibly owing to the mutual abrasion of fly ash and cement, further studies have been made of separate grinding of cement and of fly ash. The reason for this is that, generally, when grinding two materials of different hardness or toughness, a saving in energy is obtained if each material is ground in its own mill.

In our grinding experiments we have carried out three test series:

Series 1 30% PFA, Total 35 kWh/t  
Series 2 15% PFA, total 35 kWh/t  
Series 3 30% PFA, total 45 kWh/t

With the three series we varied the extent of grinding of fly ash (PFA) and of Portland cement (96% clinker + 4% gypsum). The degree of milling was varied in such a manner that the total energy consumption for grinding the mixture of Portland cement and fly ash added up to either 35 kWh/t or 45 kWh/t.

Fig. 7 - PFA cement with 30% PFA. Mixed from separately ground Portland cement and fly ash - power consumption of the mixture equal to 35 kWh/t.

Fig. 8 - Fly ash cement containing 15% fly ash. A total energy consumption of 35 kWh/t has been achieved by mixing separately ground Portland cement with separately ground fly ash.

The results appear in Fig. 7, Fig. 8, and Fig. 9. Each of these figures contains two sets of curves, one for the Blaine surfaces of Portland cement, fly ash, and PFA cement obtained at a given specific energy input, while the second set describes the strength found for the mixtures (PFA cements), also as a function of the distribution of energy between Portland cement and fly ash.

All the results indicate that the long-term strength level (90 days) improves as more of the energy input is used for grinding the fly ash.

Good short-term strengths (3 days) can be obtained, even with a PFA cement containing 30% of fly ash, provided that the Portland cement-part receives proportionally more of the grinding energy than the fly ash. It appears that the finer Portland cement results in an early strength development.

The very early (1 day) strengths are always on the low side. The strengths at intermediate testing ages (7 days, 28 days) tend to be low. The highest 7-day strengths are found when grinding is concentrated on the Portland cement-part, while the optimum 28-day values are achieved at equal milling of cement and fly ash.

In other words, it is possible to design the strength development of a PFA cement to suit the market conditions by concentrating the grinding on either the Portland cement or the fly ash.

#### CONCLUSION

Fly ash (PFA) may always be used in the manufacture of clinker. It can be added to the raw mix for dry process kilns, but only with certain modifications for the wet process, unless the fly ash is non-hydraulic.

High-carbon fly ash should be insufflated into the burning zone, whereby advantage is taken of the heat value. Fly ash up to 8% of clinker by weight can be injected with air into the burning zone.

Only fly ash with a consistent and suitable composition and a low carbon content should be used for cement grinding.

For production of a PFA cement with a fly ash content of up to 15%, milling can with advantage be carried out by combined grinding of the three materials (clinker, raw gypsum, and fly ash) in one mill.

For higher fly ash contents, separate grinding of fly ash and Portland cement presents some advantages, as it is possible to design the rate of strength development to suit the market requirements.

Up to a certain level increased comminution will be beneficial. When considering separate grinding, more grinding energy results in an equalizing of the optimum grinding values for clinker and fly ash, respectively (Fig. 9).

Fig. 9 - Fly ash cement containing 30% PFA. A total energy consumption of 45 kWh/t has been achieved by mixing separately ground Portland cement and fly ash.

Fig. 10 - Comparison between interground and separately ground fly ash cements. Total grinding energy 35 kWh/t. 30% fly ash.

Except after 90 days, a fly ash cement with 30% fly ash will have strength inferior to a Portland cement. The relative strengths for a PFA cement and an ordinary Portland cement, both ground with an energy consumption of 35 kWh/t, are shown in Fig. 10. Combined grinding presents an acceptable solution to the grinding problem. However, separate grinding has the advantage that planned levels of strength are achievable; indeed, either short-term or long-term strengths can be emphasized, (starting with the same clinker and fly ash).

# Cementitious Fly Ashes - Structural and Hydration Mechanism

## *Cendres volantes hydrauliques. Mécanisme de l'hydratation et de la formation de la structure*

R.C. JOSHI, Associate Professor and M.A. WARD, Professor, Department of Civil Engineering.  
The University of Calgary, Calgary, Alberta, Canada.

**RESUME :** Certaines cendres volantes, provenant du traitement des roches bitumineuses et des lignites du Canada et des Etats-Unis, présentent des propriétés hydrauliques, peu différentes de celles du ciment Portland. La littérature technique et le travail présenté dans cette communication ont montré que ces cendres étaient très dissimilaires physiquement et chimiquement, ce qui suggère que leurs propriétés hydrauliques ne résultent pas de leur composition. A l'aide d'un microscope électronique à balayage, complété par l'analyse aux rayons X, on a observé que le calcium réactif ou peu réactif se présentait sous des formes variées. Dans les cendres provenant des roches bitumineuses, les composés du calcium apparaissent comme formant une enveloppe amorphe ou cristalline autour de chaque grain de cendre. Après hydratation, ces composés présentent une morphologie très variée. Les liaisons entre les grains sont principalement dues à ces composés hydratés, qui sont donc à l'origine des propriétés hydrauliques de ces sortes de cendres volantes. Les recherches se poursuivent, afin de bien identifier les composés de ces enveloppes, soit avant, soit après hydratation.

**SUMMARY:** Some sub-bituminous and lignite fly ashes produced in Western Canada and the United States exhibit cementitious properties when mixed with water, not unlike portland cement. The literature and work reported here indicates that these ashes are dissimilar both physically and chemically which suggests that the self-hardening property of these ashes is not related to their fundamental composition. Using a scanning electron microscope and probe and complementary x-ray analysis it was determined that calcium is present in the reactive and relatively un-reactive ashes in a variety of forms. In the highly reactive sub-bituminous ashes studied, calcium compounds appear to be present as amorphous and crystalline coatings around the individual ash particles. Upon hydration these compounds produced hydration products with varied morphology. These products are the principal binding agents which give these ashes their unique cementitious properties. Work is continuing in an effort to identify the calcium compounds present in the fly ash and the resulting hydration products.

## INTRODUCTION

Sub-bituminous and lignite fly ashes unlike bituminous fly ashes possess self-hardening properties (4). Some sub-bituminous fly ashes when mixed with water hydrate in a similar manner to portland cement (13). It is known that the rate and degree of self-hardening resulting from hydration of these ashes varies significantly despite similarity of chemical and physical properties of different ashes (5).

Until a few years ago the majority of the fly ash produced in Canada and the United States was the result of burning relatively high sulphur bituminous coals. Environmental concerns and increased energy demands forced exploitation of low sulphur sub-bituminous and lignite coal deposits located in the mid-west and on the eastern slopes of the Rockies, far from the principal population and industrial centers (3). Physical, chemical and engineering properties of sub-bituminous fly ashes are significantly different from those of the bituminous ashes (3,4).

Sub-bituminous ashes are generally light cement grey to light cream in color. Bituminous fly ashes on the other hand are light to dark grey. The specific gravity of bituminous fly ashes varies between 1.80 and 2.84 (1). A survey of the data from various sources suggests that sub-bituminous ashes appear to possess higher specific gravities than the bituminous ashes.

The majority of the sub-bituminous fly ashes produced in Great Britain possess self-hardening properties (10,12). Presence of free lime in British fly ashes is suspected to be the source of this self-hardening. However, no test data is available to prove or disprove this hypothesis. The water soluble fraction of some fly ashes has been correlated with the degree of self-hardening (12). However, the solubility of fly ash in water is generally less than 3 percent and it can not be used as a guide for the degree or rate of self-hardening.

The earliest data on North American cementitious fly ashes was reported by Mateos (7). Although the source of self-hardening could not be positively identified, free lime in the fly ash, detected by x-ray analysis, was suspected to be the principal contributing factor in imparting the cementitious value to the fly ash. Due to the preponderance of non-cementitious bituminous fly ashes in the United States in the 1960's Mateo's observations went almost unnoticed.

Polish investigators, from a study of fly ash produced from brown coal, have reported that lime, detected by the heat of reaction between fly ash and dilute hydrochloric acid, is related to the degree of self-hardening (9). However, the same test does not seem to be applicable when used with similar fly ashes produced in Canada and the United States.

This paper presents the results of a study of the self-hardening properties of three Canadian sub-bituminous fly ashes. The hydration of the fly ashes were studied by x-ray analysis and a scanning electron microscope with microprobe. Based on laboratory test data and comparison of these results with data from three different fly ashes from the United States, the hydration mechanism and the self-hardening properties of the sub-bituminous fly ashes are discussed.

## SOURCE OF FLY ASHES INVESTIGATED

The majority of the sub-bituminous fly ash collected in Canada is produced in the province of Alberta. Fly ash samples from the Wabemun, Sundance and Forestburg power plants in Alberta were selected for this study. These ashes are derived from burning sub-bituminous coal from Whitewood, Highvale, and Battle River mines in the Wabemun, Sundance and Forestburg power plants, respectively.

Sub-bituminous fly ashes from three different power plants in two different States of the United States were selected for comparative studies. The names of the power plants indicate the states in which they are located. Wyoming I, and Kansas I power plants burn sub-bituminous coal from Campbell County in Wyoming. The second power plant in Kansas burns sub-bituminous coal from Medicine Bow County in Wyoming.

## LABORATORY STUDIES

Elemental analysis on different fly ashes was performed. Data on elemental analysis of various fly ashes was also obtained from suppliers or from other sources for comparison and to assess the variability with time for these ashes. Typical elemental analysis of the three Canadian fly ashes are presented in Table 1. Chemical composition of some of the U.S. fly ashes are given in Table 2.

TABLE I			
Chemical Constituent	Weight %		
	Forestburg	Sundance	Wabemun
SeO <sub>2</sub>	48-57	46-52	56-69

\*All figures rounded to nearest integer, \*\*Not determined.

Moisture-density tests were performed to determine the optimum moisture content and maximum density of the fly ashes according to American Society for Testing Materials specification ASTM D-698-70. The results are presented in Table III. Wyoming I and, Kansas I fly ashes produced from Campbell County coal were very reactive and hardened within less than an hour after mixing. These two fly ashes also generated appreciable heat of hydration immediately after mixing with water. The optimum moisture content and maximum dry density of Wyoming I, and Kansas I fly ashes have been estimated. Similar data has been obtained for other highly reactive fly ashes (4,12).

TABLE III				
Fly Ash Sources	Color	Average Specific Gravity	Optimum Moisture Content %	Maximum Dry Density $\text{kg/m}^3$
Forestburg	Light Buff Grey	1.95-2.0	18	1350
Sundance	"	2.0-2.43	20	1290
Wabemun	"	1.98-2.2	16	1530
Wyoming I	Light Cream	2.65	12	1840
Kansas I	"	2.61	13	1710
Kansas II	"	2.4-2.44	15	1630

The self-hardening characteristics of the three Canadian fly ashes were determined by conducting unconfined compressive strength tests on compacted fly ash samples moist cured from 1 to 28 days, Table IV. Tests were also conducted to determine if the hardened ash samples would retain strength after saturation or inundation with water. Although data are not presented in Table V, observations and strength tests indicated that generally the samples cured for less than 2 weeks disintegrated when soaked in water. However the samples of Canadian ashes cured for more than 2 weeks did not disintegrate when water saturated and retained 75 to 100 percent of their initial compressive strength. Some of the samples even gained strength on inundation in water.

TABLE IV			
Curing Period Days	Unconfined Compressive Strength $\text{kN/m}^2$		
	Forestburg	Sundance	Wabemun
0	111	56	75
1	497	221	335
7	522	190	367
19	847	590	393
28	2408	870	752

NOTE: Average strength obtained from 3 or more samples

TABLE V			
Curing Period	Unconfined Compressive Strength $\text{kN/m}^2$		
	Wyoming I	Kansas I	Kansas II
1 hour	2256	-	-
1 day	7700	5940	498
7 days	6303	-	546
14 days			392

NOTE: Average strength obtained from 3 or more samples

Data on self-hardening characteristics of the three U.S. fly ashes are also presented in Table V. All the samples of U.S. fly ashes tested for strength after curing 1 to 28 days, retained their shape on inundation in water.

X-ray and scanning electron microscope (SEM) studies were conducted to observe changes due to hydration in ash particle mineralogy and morphology. Specimens for SEM and x-ray studies were prepared from raw and hydrated fly ashes then stored in sealed containers or vacuum desiccators to avoid contact with moisture or atmospheric carbon dioxide. The fly ash specimens for SEM study were initially coated with gold but such samples exhibited excessive charging under the electron beam. When the specimen was mounted on a carbon stud and coated with carbon no such problem was encountered. Elemental analyses of fly ash particles and hydration products were obtained using an EDAX energy dispersive electron microprobe attachment to the SEM. Micrographs of some raw and hydrated fly ashes are presented in Figure 1 through 8.

Fig. 1 - Forestburg Fly Ash (2000 x)

Fig. 2 - Sundance Fly Ash (2000 x)

Fig. 3 - Wabemun Fly Ash (2000 x)

Fig. 4 - Kansas II Fly Ash (1000 x)

Fig. 5 - Fly Ash Hydration Product (28 days) (2000 x)

Fig. 6 - Fly Ash Hydration Product (28 days) (5000 x)

Fig. 8 - Fly Ash Hydration Product (28 days) (10,000 x)

X-ray diffraction traces using molybdenum radiation were obtained for the raw and hydrated fly ashes. Unfortunately space does not permit reproduction of the diffraction traces. However results of the x-ray studies are considered in the Discussion.

#### DISCUSSION OF RESULTS

Data in Table IV indicates that the three Canadian sub-bituminous fly ashes exhibit completely different rates and degrees of self-hardening. Forestburg fly ash achieved the highest strength at the end of 28 days. Sundance and Wabemun fly ashes could attain only about one third of the 28 day compressive strength of the Forestburg fly ash even at the end of 4 weeks curing. The chemical composition of the four ashes varies between 11 to 14 percent. The variations in other chemical constituents are also not significant; certainly not significant enough to suggest a reason for the observed variations in the degree of self-hardening.

It is interesting that Wyoming I and Kansas I fly ashes, produced from the same coal and having a similar chemical composition and containing almost the same amount of calcium oxide, also exhibit variations in the degree of self-hardening. One day cured samples of Wyoming I fly ash attained a compressive strength of  $7700 \text{ kN/m}^2$  whereas one day cured samples of Kansas I fly ash samples attained a compressive strength of only  $5440 \text{ kN/m}^2$ . Furthermore, examination of data in Table II and V indicates that Kansas II fly ash containing about 10 percent calcium oxide exhibited very low degree of self-hardening.

Even if free lime in fly ash is assumed to be the source of self-hardening as suggested by various investigators (7,12), then the rate and degree of self-hardening of the fly ash would be controlled by the pozzolanic reactions between free lime and aluminosilicious glassy fly ash particles (2). Such pozzolanic reactions are known to occur at relatively slow rate (2). As a result the rate of self-hardening of the fly ashes due to the presence of free lime will be rather slow. Therefore, rapid rate of the hydration reaction and strength development, in Wyoming I, Kansas I, and other similar fly ashes (4) cannot be attributed to this factor.

Joshi and Rosaure (6), from a study of synthetic fly ashes, observed that adding extra calcium oxide or lime to a fly ash does not increase the reactivity of the ash to the level exhibited by fly ash containing the same amount of calcium oxide formed during the sintering process in the suspension fired furnace. Data on lime-fly ash mixtures reported by various other investigators (2) also indicates that increasing the calcium oxide content by adding lime does not increase the rate of self-hardening to the degree characteristic of the Wyoming I and Kansas I fly ashes.

All these observations suggest that calcium in the fly ashes has to be present in some form other than calcium oxide to cause variations in the rate and degree of self-hardening. The total calcium determined by chemical methods and reported as calcium oxide in the fly ash obviously does not provide any clue to the self-hardening potential of the sub-bituminous fly ashes.

X-ray studies indicated that all the fly ashes contained substantial amounts of amorphous material.

The crystalline material in the fly ashes contained quartz, mullite, hematite, magnetite, calcium hydroxide and possibly  $\alpha\text{-C}_2\text{S}$ . One strong peak with a d-spacing of 2.29 Å was observed in raw Forestburg fly ash. The 2.29 Å peak was considerably reduced in hydrated paste of the Forestburg fly ash. In addition, medium size peaks in the vicinity of 2.75 Å and 2.78 Å were observed in raw samples of Forestburg fly ash. These peaks possibly belong to some form of calcium silicate or calcium aluminate. However, in the absence of second and third order peaks, none of the strong peaks could be positively identified. Similar but less intense peaks at 2.29 Å, 2.76 Å, and 2.78 Å could be identified in the other two Canadian fly ashes. Minor peaks attributable to calcium oxide and calcium hydroxides were also observed. The intensity of many of these peaks was reduced significantly in the diffraction patterns of the hydrated samples of the fly ash. It would appear that calcium is present in various forms in the raw ashes. If small amounts of calcium are present in the silicate or aluminate forms it may be that these are the components that impart the self-hardening property to the fly ash. It is also hypothesized that the calcium compounds which could not be identified are possibly present in partly amorphous and partly crystalline form. It is known that compounds present in an amorphous form have distorted crystal structures and will tend to be highly reactive (11).

Wyoming I and Kansas I fly ashes had the sharpest defined peaks in the vicinity of 2.74 to 2.78 Å d-spacing. There were various other peaks in these two fly ashes which could not be positively identified. Further work is needed to evaluate the significance of unidentified peaks in relation to self-hardening of the sub-bituminous fly ashes.

An examination of SEM micrographs shown in Figures 1, 2 and 3 indicates that raw Canadian fly ashes generally contained smooth spherical particles. Some of the spherical particles are hollow and are filled with other smaller particles. Very few irregularly shaped particles are observed in any of the three Canadian fly ashes. There was no observable difference in particle size or morphology of the three Canadian ashes.

Kansas II fly ash, which contained about 18 percent calcium oxide, consisted of clusters of irregularly shaped particles, Figure 4. Elemental analysis of one of these particle clusters indicated a presence of calcium and silicon almost in equal proportion.

Elemental analysis was also performed on raw Canadian fly ashes. A selected field of view was mapped for calcium, aluminium, and silicon. Observations indicated that all the three elements were distributed evenly over the field of view. Elemental analysis of individual fly ash particles on EDAX indicated that, except for irregularly shaped particles, all other particles contained more than one element. The irregularly shaped particles contained mainly silicon. The irregularly shaped particles are possibly quartz particles which become surrounded while passing through the hot zone of the suspension fired furnace. Individual spherical particles contained calcium, silicon, iron, aluminium and occasionally sulfur in various proportions. The spherical particles never showed the presence of less than two elements, and calcium was always one of the elements. It is believed the exterior of all the spherical particles is coated

with some calcium compound. It is possibly for this reason that the elemental mapping on the EDAX indicated the presence of calcium uniformly over the field of view.

Micrographs of hydrated Canadian fly ashes, Figures 6 to 8, indicate that the majority of the hydration products were fibrous. Some hexagonal shaped particles were also observed as seen in Figure 9. An examination of Figures 6 and 7 indicates that hydration products were always formed on the surface of spherical particles. Figure 7 indicates that cementitious products have been formed by peeling off the exterior surface of the particles.

Elemental analysis of fibrous particles as well as hexagonal and tubular particles indicated the presence of calcium, silicon and aluminium. The proportion of calcium, silicon and aluminium varied for different hydration products. It should be noted that elemental analysis using the EDAX may be influenced by the presence of other particles close to or under the particle to be analyzed. However, intense calcium and silicon peaks could always be seen whenever any of the new hydration products suspected to be a cementitious compound were analyzed. Fibrous morphology of hydration products containing calcium and silicon suggests the presence of calcium silicate hydrate I.

Based on the explanation given above it can be argued that the majority of the fly ash particles are coated with calcium compounds. The composition and structure of the calcium compounds cannot be positively identified at this time. It is clear however that coating of calcium compounds, around the spherical particles, provides cementation between different particles as seen in Figure 8. Minnick (8) also observed the presence of a reactive amorphous material coating, even on iron rich magnetite particles.

#### CONCLUSIONS

1. The sub-bituminous Canadian fly ashes investigated possessed varying degrees and rates of self-hardening.
2. The degree and rate of self-hardening is not directly related to the fundamental chemical or physical properties of the ashes.
3. Calcium is present in fly ashes in various forms. In the sub-bituminous fly ashes investigated calcium compounds appear to be present as coatings around the individual particles. These calcium compounds react to provide fibrous hydration products which provide particles with their cementitious properties.
4. Further research is necessary to identify the calcium compounds present and to confirm the suggested hypothesis.

#### ACKNOWLEDGEMENT

Funds for this research were provided by the National Science and Engineering Research Council of Canada. Fly ash samples and strength test data on some of the fly ashes from the United States were obtained from Woodward Clyde Consultants of Kansas City, Missouri. The Kansas I fly ash sample was furnished by Mr. P. Tansey of Kansas City Power & Light Company. Dr. L. N. M. Parti and Mr. D. Lam conducted many of the tests on the Canadian fly ashes.

# The influence of pulverized fuel ash on the early and long term strength of concrete

## *Influence d'une addition de cendres volantes sur la résistance à court terme et à long terme du béton*

J.G. CABRERA, Lecturer, Department of Civil Engineering, the University of Leeds, U.K. and  
C. PLOWMAN, Scientific Officer, Central Electricity Generating Board, North Eastern Region,  
Scientific Services Department, Grande-Bretagne.

RESUME : L'étude a porté sur les résistances à court terme et à long terme de bétons préparés en remplaçant une partie du ciment Portland par quatre cendres volantes produites en Grande Bretagne. Les modifications de la résistance à la compression simple sont dues à des réactions qui ont été étudiées grâce à la diffraction X; elles concernent le  $C_3A$  et le  $C_4AF$  extraits du ciment Portland ordinaire, et hydratés après mélange intime avec la cendre volante et du quartz finement broyé. On a constaté qu'un remplacement du ciment par des cendres volantes jusqu'à 30 % augmentait les résistances à long terme (91 jours) par rapport aux bétons sans cendres volantes. Les cendres volantes conservées à l'état humide ont une plus faible activité. A court terme, l'augmentation des résistances varie avec le pourcentage de cendres volantes. Il est proposé d'expliquer ces augmentations de résistance par deux mécanismes :

- a) un effet physique qui résulte de la forme des grains de cendres et de leur surface spécifique,
- b) un effet chimique qui résulte lui-même de deux réactions : b1) Un retard à l'hydratation du  $C_3A$  et du  $C_4AF$ , qui réduit la chaleur dégagée et stimule la formation des silicates hydratés; b2) une réaction véritablement pouzzolanique que l'on a détectée, dès l'âge de trois jours, grâce au microscope électronique à balayage.

ABSTRACT: A study of the early and long term strength of concrete mixes prepared with four British pulverised fuel ashes used as part replacement of ordinary portland cement is presented. The mechanism and reactions responsible for changes in the unconfined compressive strength were studied by XRD of  $C_3A$  and  $C_4AF$  extracted from the ordinary portland cement and hydrated with PFA and with inert ground quartz. It is shown that with the hopper ashes replacement of cement up to 30% resulted in higher long term (91 days) strengths as compared with the concretes without PFA. The conditioned PFA 2 performed poorly in relation to its cement-concrete counterpart. Hopper ashes gave higher early strengths at varying percent replacements. It is proposed that the mechanism by which strength changes is a two-fold mechanism: a) a physical effect which depends on the shape and specific surface of the PFA and b) a chemical effect consisting of two distinct reactions: 1st. a retardation of the hydration of  $C_3A$  and  $C_4A$  which effectively reduces the heat of hydration and encourages the formation of silicate hydrates, and 2nd. a proper pozzolanic reaction which was detected as early as three days of age by the use of a Scanning Electron Microscope.

## INTRODUCTION

The use of Pulverized Fuel Ash (PFA) as part replacement of portland cement for the manufacture of concrete dates back to 1914 (1), although research on the properties of PFA and PFA-concrete started seriously around 1940 (2). Today the use of PFA in concrete is still very limited, specially in the U.K. where not more than 1% of the total production of PFA is utilized as part replacement of portland cement. By the end of this century coal will play a major role in the production of energy since it comprises about 80% of the world energy reserves, these amount to 70,000 million Tonnes in Western Europe alone (3). It seems clear then that PFA will become an abundant source to be used as pozzolanic material, specially for the replacement of cement which as it is known requires high levels of energy for its production.

Reports in the literature regarding the influence of PFA on the properties of concrete are mostly related to the measurement of physical properties. The mechanism by which PFA alters the engineering properties of concrete are not really clear, hence the contradictions found in the literature.

This paper presents a limited study on the influence of PFA from four power stations on the properties of concrete. Ordinary portland cement was replaced by 15, 30 and 45% of each PFA and unconfined compressive strength measurements were made up to 91 days. The influence of PFA on the process of hydration was studied only with reference to the  $C_3A$  and  $C_4AF$  hydration process. The methodology used is explained and interpretations are made in the light of the physical and chemical results obtained.

## ENGINEERING PROPERTIES OF PFA-CONCRETE

The properties which are of importance for the evaluation of PFA-concretes are: workability, strength, creep and shrinkage and durability. Different authors have reported sometimes contradictory results for the same property. Referring to workability, for example, the majority of reports (e.g. 4,5) agree that PFA improves the workability of concrete when PFA has been properly selected, however there is no agreement as to the properties which should be measured to select a PFA material. Scholtz (5), for example, recommends selection of PFA in terms of specific surface, while some standards (6) recommend the use of particle size. Apparently it is implied that the finer the ash the better the workability of concrete. This concept is by no means proved since it will imply that the finer the ash the higher the strength of the concrete. Some authors have reported that there is no relation between fineness and strength (7,11). Cabrera and Gray (7) showed that high specific surface ashes may not necessarily be fine grained since it is the irregular carbonaceous particles which contribute greatly to the specific surface.

The strength of PFA-concrete has been studied and reported by many investigators. Most reports refer to the long term beneficial effects of PFA, based on the accepted idea that the reaction of PFA with cement is that of a pozzolana, i.e. reaction of soluble silica and alumina from the PFA with calcium hydroxide produced by hydration of the calcium silicates in the cement to form hydrated calcium

silicates and aluminates. However, there are still some reports which indicate that PFA-concretes did not reach the strength of their cement-concrete counterparts even at the age of 5 years (9). With reference to short term strength there is still great controversy. Some authors report improved strengths while others report inferior strengths (5,9,10,11,12). Here again the contradictions have their origin in the fact that there is no agreement as to the properties of PFA which should be measured to qualify it as a suitable material. Furthermore, there is no agreement in relation to the actual concrete mix design (10,13,14).

There is general agreement with relation to the influence of PFA on creep and shrinkage properties of concrete. Scholtz (5) indicated that using PFAs with specific surface areas between 1.2 to 1.3  $m^2/g$ , creep and shrinkage were reduced by 20%, while Ryan (15) reported reductions up to 30% of the shrinkage measured in plain concretes.

It is generally accepted that concretes with PFA exhibit lower permeabilities than their portland cement-concrete counterparts, this fact alone has been used to explain the improved resistance of PFA-concrete to sulphate attack. Davis (16) measured the permeability of plain and PFA-concrete where PFA replaced 30% of the cement; the permeability was reduced to 1/5 of the permeability of the plain concrete, thus reducing penetration of potential harmful solutions. Dikeou (17) reported improved resistance of PFA-concrete to sulphate attack and showed that the effectiveness of PFA in improving resistance to sulphate attack increased with the severity of exposure to sulphates.

## MECHANISMS OF PFA-CEMENT REACTION

Pozzolanic reactions are the acknowledged mechanism occurring between PFA and cement in the presence of water. Changes in the properties of concrete produced with PFA have invariably been interpreted using the pozzolanic properties of PFA. Minnick (18) and Plowman (19) have summarized some of the possible reactions of PFA-cement-water systems and Jambor (22), Raask and Bhaskar (21), Shikami (22), among others have proposed methods to evaluate the pozzolanic activity of PFA by either measuring release of silica or reduction of calcium hydroxide generated by the hydration of cement. While these methods have given satisfactory results for particular conditions, their general use is not warranted. There are still some questions which have to be answered, for example when does the pozzolanic reaction between PFA and cement take place? Various investigators have attempted to answer this question but the data which have been published are inconsistent. Guillaume, for example, came to the conclusion that the reaction between PFA and cement starts from an age of about 14 days (23), while Venaut (24) stated that pozzolanic reaction is not detected before 28 days.

It is apparent that with regard to the mechanism or mechanisms of reaction more studies are necessary, in particular the chemistry of early reactions which do not seem to exist in the literature, and also the extent of the physical effects of PFA in the composition of the water/solids ratio, as well as the influence of PFA in the morphology of the reactions products.

## MATERIALS AND METHODS USED IN THE INVESTIGATION

Pulverized Fuel Ashes from four power stations in the north of England were used. Their properties are given in Tables 1, 2 and 3. PFA 1, PFA 3 and PFA 4 were hopper ashes, while PFA 2 was collected from a disposal stockpile where the ash is conditioned with approximately 12% of water.

Ordinary portland cement and quartzitic coarse and fine aggregates were used for the preparation of the concrete mixes. Cement was replaced by PFA in proportions of 15, 30 and 45%. Cubes of 10 cm side were prepared and cured in water at 18°C for varying periods up to 91 days. The cubes were tested in unconfined compression at the end of each curing period. The reported results are the average of three specimens per point. Immediately after testing, small pieces of the fractured concrete cubes were freeze-dried and stored in sealed containers for later studies of the micromorphology of the reaction products.

The early chemistry of PFA-cement hydration was studied using only PFA 3 and  $C_2A$  and  $C_4AF$  obtained directly from the ordinary portland cement. Chemical separation of  $C_2A$  and  $C_4AF$  were carried out by extracting the calcium silicate and calcium oxide phases from the ordinary portland cement with a maleic acid/methanol solution. Calcium sulphate was removed with ammonium chloride solution. These methods have been described in the literature (31). X-ray diffraction of the residue detected only  $C_2A$  and  $C_4AF$ . Since the maleic acid passivated the residual compounds they were reactivated by ignition at 800°C.

Hydrations were carried out not only with the  $C_2A$  and  $C_4AF$  but with mixtures in which the dilution effect was studied by replacing the aluminates with 30% of ground quartz (to pass sieve of 45  $\mu$ ) so as to separate any effect due to dilution occasioned by incorporating 30% PFA 3 in the aluminate residue.

Each hydration process was followed with a Philips APD-10 computer controlled diffractometer, programmed to scan over an angular range of 5° 2 $\theta$  - 40° 2 $\theta$ . Cu radiation was used at 45 kV, 55 mA, and the diffractometer was fitted with a graphite monochromator. The scanning rate was 16° 2 $\theta$  per minute, the programme allowed recycling immediately after each scan. To avoid the possibility of rapid carbonation of calcium aluminate hydrates which may occur in air, each sample was mixed dry; 0.7 ml of distilled, deionised and freshly boiled water was then added and mixed. The wet mixture was immediately placed in the diffractometer which was modified so as to provide a nitrogen atmosphere which eliminated the possibility of carbonation.

In order to detect phase changes at very early ages (from as early as one minute) a fast scanning speed of 16° 2 $\theta$ /minute was necessary. This resulted in two problems: a) poor peak resolution, b) slightly reduced peak intensity due to the relatively long response time of the chart recorder. Therefore no attempt was made to obtain absolute measurements of the amount of each phase, but it was found to be perfectly feasible to measure the change in intensity of a peak, even in the case of quite severe overlaps.

Ash Source	Ash Code	Specific Gravity	Specific Surface, m <sup>2</sup> /g
Ferrybridge 'C'	PFA-1	2.22	1.26

## RESULTS AND DISCUSSIONS

Hydration of  $C_2A$  and  $C_4AF$ 

Most studies of the hydration of calcium aluminates and alumino-ferrites, and subsequent reactions with calcium and sulphate, have been carried out with laboratory synthesised calcium aluminates as starting materials. Times quoted by various investigators (27,28,29,30) regarding transformation of ettringite into monosulphate are quite different. Collepardi et al. (27) attributed this to differing experimental procedures and to the type and reactivity of  $C_4AF$ ; for this reason the experiments reported in this investigation were carried out with starting material separated from an ordinary cement clinker.

The process of hydration for the  $C_2A$  and  $C_4AF$  is shown in Figure 1. The initial crystalline hydration product is  $C_2AH_8$ . Substitution of  $Al_2O_3$  by  $Fe_2O_3$  can occur, forming a solid solution series whose end members are  $C_2AH_8$  and  $C_2FH_8$ . No attempt was made to distinguish between substituted products. Similar solid solution series exist for other hydrates. As shown in Figure 1  $C_2AH_8$  reaches a maximum concentration at about 15 minutes. Both  $C_2A$  and  $C_4AF$  have reacted to a considerable extent by this time, but no  $C_4AH_{19}$  is detectable. It does, however, appear after about one hour, with very low crystallinity. The XRD peaks of  $C_4AH_{19}$  gradually narrow down with time, indicating a gradual increase in crystallinity. It is possible, then, that it is present at an earlier age as an amorphous phase. The initial hydration reactions may therefore be:

Ash Code	Percentage by weight										
	Loss on ignition	SiO <sub>2</sub>	Al <sub>2</sub> O <sub>3</sub>	Na <sub>2</sub> O	MeO	K <sub>2</sub> O	Fe <sub>2</sub> O <sub>3</sub>	TiO <sub>2</sub>	CaO	SO <sub>3</sub>	Cl
PFA-1	4.95	48.41	25.43	0.58	1.19	3.64	8.28	0.93	1.52	0.28	0.03
PFA-2	3.11	50.98	26.42	0.77	1.19	3.71	9.45	0.93	1.19	0.16	0.04
PFA-3	3.29	49.01	27.73	0.75	1.30	4.05	8.77	0.96	1.20	0.58	0.01
PFA-4	2.52	52.62	26.45	1.11	1.33	3.90	8.98	0.98	1.49	0.63	0.02

Table 3 Chemical compositions and loss of ignition of the ashes

The findings of many workers (31) that  $C_3A$  hydrates initially faster than  $C_4AF$  are confirmed in the present work. The subsequent reaction of  $C_2AH_8$  appears to be mainly with  $C_4AF$ , the product being  $C_3(AF)H_6$ . This may be:

The effect of diluting the aluminates by incorporating 30% of inert material (ground quartz) is shown in Figure 2. The rate of reaction is slower in comparison with the undiluted material. Figure 3 shows that 30% substitution by PFA results in much more marked retardation of the initial reaction. Much less  $C_2AH_8$  is produced and the diffraction peaks disappeared significantly faster. Unlike the two previous hydrations, ettringite ( $C_3A \cdot 3CS \cdot 31H$ ) was detected after less than two minutes, reaching a maximum after eleven minutes. After 20 minutes ettringite was no longer detectable, but the monosulphate ( $C_3A \cdot CS \cdot 12H$ ) was identifiable. The basal spacing of the monosulphate (8.9Å) subsequently reduced to 8.2Å. Consideration of this, and other peaks on the XRD trace leads to an identification of  $C_4AH_{13}$ . In view of the precautions taken to exclude carbon dioxide, it is improbable that this compound contained "essential carbonate". However, it is possible that it may contain "essential sulphate", and is likely to be a solid solution as described by several workers (31).

It is well known that gypsum retards the hydration of  $C_3A$  and  $C_4AF$  by forming a layer of ettringite (27,32). Since studies of the release of ions from British PFAs in neutral and also alkaline solutions (33,34) have shown that calcium and sulphate are released at a very early stage (within 1 to 2 minutes) in sufficient quantity to form a saturated solution with respect to gypsum, it was thought that the mechanism of retardation of the aluminates hydration might be similar to the manner in which gypsum controls the hydration process. Experiments carried out substituting PFA by equivalent sulphate concentrations provided by gypsum reported elsewhere (35) have shown that the retardation with gypsum does not occur to the same extent as with the addition of solid PFA, even when sufficient solid gypsum to replenish the calcium and sulphate in solution is provided. Thus it is clear that PFA is a more effective retarding agent than gypsum. Why this is so will be discussed later on in conjunction with

findings related to the physical properties of PFA-concrete.

#### Early and Long Term Strength of PFA-Concretes

Early strength of concrete is a very important property, specially from the point of view of economy and facility of construction procedures. The three day strength chosen as the early strength of the mixes used in this study is presented in Figure 4. For convenience strengths are expressed as a percentage of the control portland cement concrete as a function of percentage of cement replacement. It can be observed that each PFA gives a different strength-replacement relation. The hopper ashes gave greater early strengths for various replacement percentages while the conditioned ash PFA 2 resulted in lower early strengths even at 15% replacement.

The long term strengths are shown in Figure 5 a, b, c, and d. It can be observed that for the hopper ashes replacement up to 30% resulted in considerably increased strengths at 91 days. Replacement at 45% level gave in all cases lower long term strengths. PFA 2 showed the poorest performance at early and long term strength.

Attempts to relate the strength behaviour to the intrinsic properties of the PFAs used were not successful. For example, specific surface values show that PFA 2 should have given the best results in terms of the requirements of specifications (6), but in reality the PFA with the lowest specific surface gave the best results. A number of countries advocate the use of an arbitrary percentage of retention on a 45  $\mu$  sieve above which a PFA should not be acceptable, here again observing the results of particle size distribution it can be ascertained that there is no relation between size and strength.

#### MECHANISM BY WHICH PFA INFLUENCES CONCRETE STRENGTH

From the results of this investigation and the data of other workers it is apparent to the authors of this work that the mechanism by which PFA influences the engineering properties of concrete is a two-fold mechanism:

Figure 4 Relation between three day strength and percentage of cement replacement for the ashes used in the study

- a) a predominantly physical effect which consists of reducing the water demand without decreasing the workability of the mix and allowing better packing of the hydration products and the unhydrated particles.

During the production of the mixes for this study it was observed that the same water/cement ratio gave increasing values of slump for increasing replacement of cement. Although recognizing that the slump test is too coarse a measure of workability, nevertheless it gives an indication of the effects of PFA on water demand. Other authors have consistently reported very low values of permeability for PFA-concrete mixes, this tends to confirm the idea of better packing properties of a mix containing PFA.

Figure 6 shows schematically the probable behaviour of PFAs. Considering that there is a maximum practical limit of replacement as indicated by the dashed vertical line, a particular PFA will probably show one of the trends indicated, depending on whether the specific surface is relatively low, intermediate or high and/or whether the shape of the particles is 100% round smooth shape or whether there is a significant amount of coarse irregular, and porous particles.

- b) a double chemical effect which consists of: 1) retarding the hydration of  $C_3A$  and  $C_4AF$ . The immediate beneficial consequence is a reduction in the heat of hydration, but most important the retardation of the aluminate's hydration produces

Figure 5 Unconfined compression strength-age relations (a) PFA 1, (b) PFA 2, (c) PFA 3 and (d) PFA 4

Figure 6 Schematic representation of water requirements for different PFA materials

been presented by Jelenic et al. (36). They studied the effect of gypsum on the hydration and strength of various portland cements and showed that at increased percentages of  $SO_3$  there is a reduction of aluminates hydrates and a corresponding increase in the silicate hydrates. They showed, furthermore, that there exists an optimum percentage of  $SO_3$  for maximum increase in strength; 2) a pozzolanic reaction proper between the soluble silica and alumina of the PFA and the calcium hydroxide produced by the hydration of the cement. As it has been indicated in the review of mechanisms of reaction, workers do not agree on the time at which the pozzolanic reaction can be detected.

During this investigation limited use of an SEM (JEOL-35) allowed a study of the early and long term morphology of reaction products. Figure 7 shows evidence of formation of reaction products at the PFA-cement interface and Figure 8 shows poorly crystalline compounds. The age of the specimen was only three days, thus it appears that pozzolanic reaction products may be formed earlier than other investigators have reported. There is some evidence for an early pozzolanic reaction from experiments which are now in progress. These demonstrate a reduction at 3 days in the quantity of  $Ca(OH)_2$  present in cement pastes with PFA replacement, compared with controls with no

as a counter-effect the possibility of increasing the volume of calcium silicates, which will undoubtedly result in increased ultimate strengths. Evidence for this proposition has

replacement. Figures 9 and 10 correspond to specimens with long term hydration. It can be clearly seen that the reaction products have a morphology similar to the type I calcium silicates (Figure 8) and type III calcium silicates (Figure 9) (39).

Figure 9 Long term cured specimen showing type I reaction products on the surface of a PFA particle.

Figure 10 Long term cured specimen showing type III reaction products resulting from the PFA-cement reaction.

Several attempts have been made to relate development of strength to the structure of the reaction products of portland cement. Feldman and Beaudoin (37), for example, studied porosity and particle type in relation to strength development. They indicated that for any given porosity there is an optimum blend of particle types, i.e. at the same porosity the average strength of a composite

particulate material depends on the intrinsic strengths of coarse, dense, crystalline particles and the better bonding properties of finely divided low-density, amorphous material. Their results included a PFA-cement paste which in comparison to a pure cement paste showed higher strength at the same porosity. They believed that the optimum blend of particle types was probably the one corresponding to the PFA-cement paste. Taylor (38), in a recent review of mechanisms and products of cement hydration, has pointed out the fact that strength development of blended cements might not be explained by the chemical reactivity of the PFA alone but also by the effect that unreacted particles of these materials have on the microstructure. This tends to support the idea proposed by the authors of this paper in relation to a mechanism which is a combination of physical and chemical effects.

# The effect of curing temperature on the development of strength of mortar containing fly ash

## *L'effet de la température de conservation sur le développement de la résistance du mortier contenant des cendres volantes*

J.A. DALZIEL, Mr. Materials Research Department, Cement and Concrete Association, Slough, England.

RESUME : Des prismes de mortier ISO-Rilem ont été faits avec du ciment Portland ordinaire ainsi qu'avec ce même ciment contenant 20 % de cendres volantes. Des comparaisons ont été faites sur le développement de la résistance à la flexion et à la compression de ces mortiers jusqu'à l'âge d'un an après une conservation continue dans l'eau à 20, 35, 50, 65 et 80°C. Pour des températures de conservation inférieures à 50°C, la présence de cendres volantes a augmenté à long terme la résistance à la flexion de 40 % approximativement, et la résistance à la compression de 15 % approximativement. Aux jeunes âges la résistance a augmenté avec l'augmentation de la température de conservation aussi bien pour le mortier pur que pour celui contenant des cendres volantes, mais il a été ensuite plus rapide pour ce dernier à cause de la pouzzolanité de la cendre qui a fortement contribué à la résistance dès les premiers jours. A 20°C, le mortier avec cendres volantes ne dépasse pas la résistance du mortier pur avant 150 jours, mais cela se produit après 28 jours à 35° et après 6 jours à 50°C. Pour les deux genres de mortier, la résistance à long terme était plus faible pour les éprouvettes conservées à température plus élevée.

SUMMARY : ISO-Rilem mortar prisms were made using ordinary Portland cement and with 20% of the cement replaced by fly-ash. Comparisons are made between the development of flexural and compressive strength of these mortars up to an age of one year after continuous water cure at 20, 35, 50, 65 and 80°C. For curing temperatures up to 50°C, the presence of fly ash increased the long term flexural strength by approximately 40% and the long term compressive strength by approximately 15%. For young specimens, the rate of gain of strength increased as the curing temperature increased for both the plain and fly ash mortars but was more rapid in the latter case due to the ash pozzolanicity contributing effectively to the strength at earlier ages. At 20°C the fly ash mortar did not exceed the strength of the plain mortar before 150 days whereas it exceeded it after 28 days at 35°C and after 6 days at 50°C. With both mortars the long term strength was lower for specimens cured at the higher temperatures.

## INTRODUCTION

Raising the curing temperature of mortars and concretes made with Portland cement improves the strengths at early ages but invariably causes a reduction in the strength which is attained in the long term. When a reactive fly ash is incorporated in the mix, an additional contribution is made to the strength due to its pozzolanicity. This contribution is also temperature dependent being negligible at early ages and at low or normal temperatures but becomes increasingly significant as the curing temperature is raised. This effect, which is of great importance in the manufacture of precast products, depends on the age of the mix when the temperature is raised and also on the rate, magnitude and duration of the increase. Kohno, Emura and Kinoshita (1) subjected fly ash concrete to short periods of heating to 65, 80 and 90°C soon after moulding. They found the rate of gain of strength at one day was greatly increased as the temperature increases and that the strength was also improved by delaying the time at which the heating was applied. In all cases, however, the 28 day strengths were less than that of normally cured concrete. Venuat (2) cured specimens normally at 20°C for one or two days before subjecting them to short periods at 80°C and found that, whilst this had little effect on the specimens which did not contain fly ash, it substantially increased not only the short term strength of the fly ash mixes but also improved the long term strength as well. Phat (3) employed longer periods of heating of 1, 3 and 7 days at 5, 20, 40 and 60°C followed by 7 days normal cure and in all cases found that the higher temperatures improved the strength development of specimens containing fly ash. Kokubu, Miura, Takano and Sugiki (4) who mixed and cured concrete at 10, 21 and 30°C found after three months the strength of specimens containing no fly ash were lower the higher the temperature but for fly ash specimens the reverse was true. Nasser and Marzouk (5) have reported the effect of temperatures up to 230°C on the properties of mass concrete containing fly ash.

In this investigation the mortar specimens were cured for 24 hours in a 20°C fog-room before being water cured at elevated temperatures until shortly before testing.

## TEST SPECIMENS

40 x 40 x 160 mm mortar prisms were made accordingly to ISO-Rilem recommendation R679 (similar to the French Afnor NP-P 15-451 and the German DIN 1164 standards). These had a water/binder ratio of 0.5 and an aggregate/cement ratio of 3. The specimens were compacted in their moulds by using a jolting table. After demoulding the specimens were weighed in air and water and then placed immediately in water baths at the appropriate temperature. Two hours before testing they were returned to water at 20°C. The physical and chemical analyses of the Portland cement and the fly ash used are given in Table I.

## PROGRAMME OF TESTS

Two mortar mixes were employed, one with the Portland cement and the other with 20% by weight of the cement replaced by the fly ash. No adjustment was made to the water content to compensate for the

TABLE I

	Portland cement	Fly ash
Density (kg/m <sup>3</sup> )	3150	2300
Specific surface (m <sup>2</sup> /kg)	330	340
Loss on ignition	1.75%	4.92%
45µm residue	-	14%
SiO <sub>2</sub>	22.02%	49.92%
CaO	64.60%	-
Al <sub>2</sub> O <sub>3</sub>	3.99%	24.32%
Fe <sub>2</sub> O <sub>3</sub>	1.74%	9.76%
MgO	1.20%	-
Alkalies (as Na <sub>2</sub> O)	0.53%	-
SO <sub>3</sub>	3.36%	-
Free CaO	1.54%	-
Moisture	-	0.27%
C <sub>3</sub> S	51%	-
C <sub>2</sub> S	25%	-
C <sub>3</sub> A	7.5%	-
C <sub>4</sub> AF	5.2%	-
CaSO <sub>4</sub>	5.7%	-

increased workability of the fly ash mix. Specimens of each mix were cured at 20, 35, 50, 65 or 80°C after an initial 24 hour at 20°C, and tested at 3, 7, 28 and 56 days. Specimens cured at 20, 35 and 50°C were also tested after 184 and 365 days. The mean bulk density, flexural strength and compressive strength were determined from three specimens for each condition (from 6 specimens for the 20°C conditions).

## DENSITY

The bulk density at demoulding was on average 0.6% greater for the fly ash cement mortar specimens than for the plain cement specimens despite the fact that the fly ash had a density 0.7 that of the cement it replaced. This difference, although small, was statistically significant and corresponded to a reduction of 2% in the volume of entrained air of the mix containing fly ash. A reduction in voidage of this magnitude would be expected to increase compressive strength by at least 4%. At later ages the 20 and 35°C cured specimens had increased in density to a greater extent than the specimens cured at higher temperature whilst maintaining the density differential between the two mixes.

## COMPRESSIVE STRENGTH

Figure 1 shows the compressive strength of the two mortars as a function of age and curing temperature. The results obtained with the plain cement mortar show that elevated curing temperatures increase early age strength but reduce later age strengths. With the exception of the 80°C cured mortar, which failed to gain strength significantly after 7 days, the temperature-strength inversion occurred at approximately 28 days after which strength was lower the higher the curing temperature.

Increasing the curing temperature had a greater effect on the fly ash cement mortar, accelerating to a considerable extent the development of strength at early ages. Whilst the strength-temperature inversions again occurred, they were generally at much later ages, and the specimens were cured for

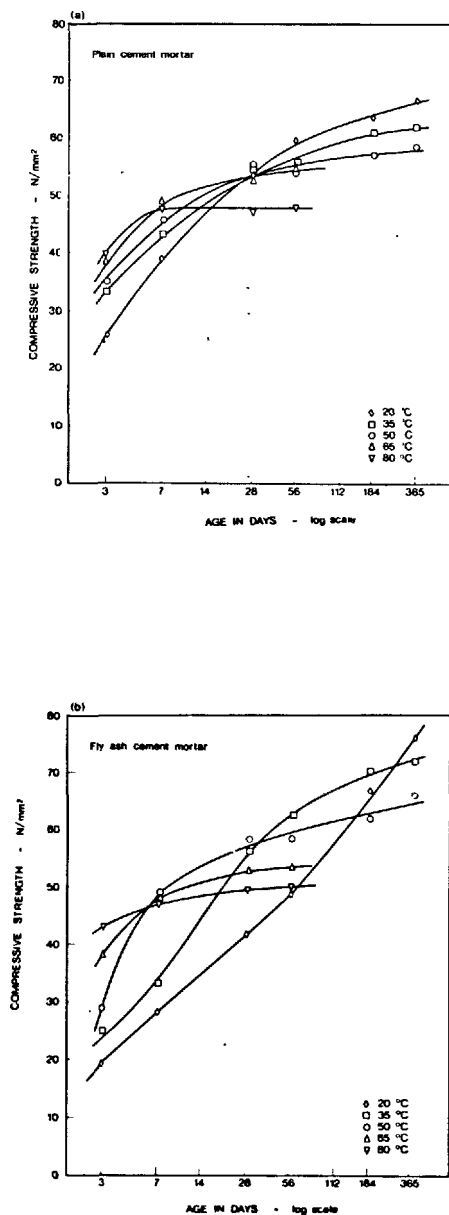

FIGURE 1. Compressive strength as a function of age and curing temperature.

See figures 2 and 3 PAGE 5

one year before the 35°C cured specimens were less strong than the 20°C cured ones. This is broadly in agreement with the results of Kokubu, Miura, Takano and Sugiki (4) discussed earlier. In order to compare the strength development of the two mortars, the ratio of the fly ash cement mortar strength to the plain cement mortar strength at the same age and curing condition is shown as a function of curing age and temperature in Figure 3(a). The fly ash cement mortar was stronger than the equivalent plain cement mortar when this ratio exceeded unity. This did not occur with the 20°C cured specimens until approximately 150 days. For the 35°C cured specimens the age was reduced to approximately 24 days and to only 6 days for the 50°C cured specimens. At 65°C the fly ash cement mortar behaved little differently from the plain cement mortar although at 80°C it was stronger at early ages but the strength ratio decreased with time of curing. Lühr and Efes (6) showed, with similar prisms cured at 20°C, that the age at which fly ash cement mortars exceed the strength of the equivalent plain mortar depended on the relative fineness of the Portland cement and the fly ash. The strength development up to 28 day was shown to be mainly a function of the cement fineness and after 28 day to be also a function of the fineness of the fly ash. Homma and Kikuchi (7), relating the strength development of mortars containing fly ash up to 90 days to Feret's coefficient to avoid the effect of water/cement ratio, found the coefficient exceeded that of plain cement mortar after four weeks at 20°C but after only 7 days at 40°C. From Feret's coefficient, in this investigation, if the fly ash acted as an inert filler the strength ratio would be expected to be 0.75 at all ages. Although the ratio appears to start from this figure, it rises, in the case of the 20, 35 and 50°C cured specimens, to show a strength advantage of approximately 15% after one year for the fly ash cement mortar.

The contribution to strength made by the fly ash alone may be estimated by subtracting 0.75 of the plain mortar strength from that of the equivalent fly ash mortar. If this contribution is plotted against age for the various curing temperatures, curves very similar in shape to those shown in Figure 3 result. After one year the highest pozzolanic contribution from the fly ash was in the specimens cured at 20°C. As the curing temperature increased this contribution decreased. The highest long term strengths for both mixes were for those cured at 20°C. It is interesting to note that Mateos (8) found that sand, lime fly ash mixtures cured at 10, 20, 40, 60 and 120°C showed no temperature-strength inversions up to 28 days.

#### FLEXURAL STRENGTH

Figure 2 shows the flexural strength of the mortars as a function of age and curing temperature. In contrast to the effect on compressive strength, for the plain cement mortars the effect of moderately increased curing temperature was small except at early ages. Curing at 65 and 80°C was again detrimental to long term strength and again the temperature strength inversion effect occurred.

The effect of increased curing temperature on the strength development of the fly ash cement mortar was striking. After 7 days the effect of raising the temperature from 20 to 50°C was to almost double

the flexural strength and at one year there was still a 26% strength advantage. At all the ages and temperatures tested, there was a significant increase in strength over the 20°C cured specimens although for the 65 and 80°C specimens this increase was reduced.

Again in order to compare the strength development of the two mortars, the ratio of the flexural strength of the fly ash cement mortar to that of the plain cement mortar is shown in Figure 3(b) as a function of age and temperature. For the 20°C cured specimens, the fly ash cement mortar had to be cured for one year before it attained the same flexural strength as the plain cement mortar. For the 35°C cured specimens this age was reduced to 14 days and at one year the fly ash cement mortar was over 30% stronger. Only 3 days curing at 50°C was required to equal the plain mortar strength. The trend of the curves indicate that the fly ash mortars would eventually achieve a flexural strength 30 to 40% higher than the plain cement mortar but for the 20°C cured specimens this would take several years of continuous curing to achieve.

#### CONCLUSIONS

Although this investigation was undertaken with a single fly ash cement combination and with temperature increases held constant for longer periods than would occur in practice, the conclusions drawn are probably valid for any reactive fly ash used at this level of cement substitution.

1) Raising the curing temperature moderately accelerates the pozzolanic contribution made by the fly ash to strength development more than it does the contribution made by the hydration of Portland cement. This also implies the corollary that low temperatures would adversely affect the strength development of a fly ash mortar to a greater extent than to a Portland cement mortar. In consequence laboratory tests at 20°C will have little relationship to the behaviour of structural concrete containing fly ash in which temperature changes occur due to heat of hydration and changes in ambient temperature.

2) Replacing 20% by weight of a Portland cement by fly ash has the effect of reducing the short term compressive strength when cured at 20°C. A moderate temperature rise during the early stages of strength development, as a result of heat of hydration or heat applied externally, can substantially reduce this early age strength loss. The effect of reduced long term strength potential resulting from such a rise in temperature is compensated for by the effect the fly ash has in actually increasing this potential compared with the equivalent plain Portland cement mix.

3) Including fly ash in a mix can substantially increase the flexural strength of mortar but this improvement may take several years to materialize if the curing takes place at 20°C.

**RESUME :** Les propriétés techniques des ciments à base de cendres se définissent par l'apparition au début de l'hydratation d'un vide sphérique d'une épaisseur de 1 à 3  $\mu\text{m}$  autour du grain de cendre, qui se remplit progressivement de cristaux de portlandite, d'ettringite et, aux stades plus avancés, d'hydrosilicates formés par corrosion superficielle de la particule-cendre. La vitesse de la corrosion est fonction de l'état de la particule.

En fin de durcissement la structure de la pierre du ciment à base de cendres rappelle par sa compacité et ses traits morphologiques celle des ciments sans additions.

On a détecté dans les mâchefers de basicité élevée, également utilisés en qualité d'addition pouzzolanique aux ciments, des cristaux de phases alitiques comportant la "river texture" propre à l'alite. La phase alitique se caractérise par une texture en petits blocs avec un grand nombre de dislocations. L'introduction de modificateurs ( $\text{CaO}$ ,  $\text{FeO}$ ) modifie l'activité des verres de laitier. On peut obtenir des ciments de haute qualité en utilisant non seulement des cendres volantes acides, mais également basiques, à teneur en  $\text{CaO}_{\text{libre}}$  jusqu'à 20 %.

**SUMMARY:** The technological properties of ash cements are determined by the existence at the initial period of hydration of a 1-3  $\mu\text{m}$  spherical pore, around the ash particle and gradual suturing of it by crystals of portlandite, ettringite and at later stages, by hydrosilicates formed by surface corrosion of the ash particle. The rate of corrosion depends on the state of the particle.

At the late ages of hardening the ash cement stone structure is similar to the structure of additive-free cements as regards the density and morphological properties.

Crystals of alite phases with a characteristic river pattern are detected in high-base fuel slags which are also used as a pouzzolan additive to cements. Alite phases are characterised by fine-block structure with a plurality of dislocations. Introduction of modifiers ( $\text{CaO}$ ,  $\text{FeO}$ ) changes activity of slag glass.

High-quality cements can be obtained when using not only acid but also base fly-ash containing up to 20%  $\text{CaO}_{\text{free}}$ .

Les problèmes d'utilisation des cendres et des mâchefers des centrales thermiques dans la production du ciment ont été depuis longtemps l'objet d'études (1,3), mais, pratiquement, leur mise en oeuvre demeure très limitée. Le tableau I fournit des données sur le volume de production et de consommation de cendres de centrales thermiques pour quelques pays économiquement développés. En 1975 l'industrie du ciment des USA a utilisé pour la production du ciment moins de 0,5 million de tonnes de cendres volantes et 0,4 million de tonnes de mâchefers, de plus, environ 0,6 million de tonnes ont servi à remplacer partiellement le ciment en béton et ceci pour une production totale de cendres de 54 millions de tonnes (4). En U.R.S.S., les cendres des centrales thermiques sont utilisées régulièrement en grand volume dans deux usines de ciment et, à un moindre degré, dans six cimenteries. En 1977 le volume total de cendres consommées a atteint environ 900 mille tonnes (5). En outre une certaine quantité de cendre a servi directement à la préparation du béton.

Tableau I		
Production et consommation des cendres et des mâchefers des centrales thermiques (pour les années 1974-1975) en millions de tonnes/an		
Pays	Volume de rejets de centrales thermiques	Utilisé pour la production du ciment
U.R.S.S.	69,0	0,80
USA	54,0	0,90
Grande-Bretagne	11,0	0,14
France		1,00
Japon		0,50
Pologne	12,0	1,00
Hongrie	5,0	0,13
Bulgarie	6,5	0,06
RDA	13,3	0,10

Dans d'autres pays la consommation de cendres ne dépasse également pas un million de tonnes par an.

Une étude plus profonde des processus d'hydratation et des caractéristiques techniques de construction doit contribuer à une plus large utilisation des ciments de cendre.

Les caractéristiques techniques de construction les mieux étudiées sont celles des ciments de cendre avec addition de cendres volantes acides. Ces ciments se caractérisent généralement par un durcissement ralenti aux premiers stades, une aptitude à un long accroissement de la résistance, un

abaissement de dégagement de chaleur, une résistance élevée aux actions corrosives (la tenue de l'armature en acier n'y est prise en général en considération), une déformation limitée, due au retrait et au gonflement, un besoin élevé en eau (1,6).

Sont moins connues les propriétés des ciments aux cendres basiques, contenant l'oxyde calcique libre, ainsi qu'aux mâchefers. L'expérience d'emploi de ces matériaux s'est révélée intéressante principalement en U.R.S.S. (7,8).

Comme il a été noté dans (2) les caractéristiques techniques et de construction des ciments aux cendres sont conditionnées par l'existence dans la période initiale d'hydratation et de durcissement d'un pore annulaire épais de 1 à 3  $\mu$ m autour du grain de cendre rempli de phase liquide. Ce pore se remplit progressivement, d'abord de cristaux aciculaires de portlandite et d'ettringite puis d'hydrosilicates semblables au tobermorite, engendrés par l'interaction dans la zone de contact du portlandite avec le verre aluminosilicateux, constituant la surface de la particule de cendre. On fournit plus loin de nouvelles données sur l'hydratation des ciments de cendre. Le processus de remplissage du vide se voit distinctement sur la figure 1 (Dosage des cendres - 15%, durée de durcissement - 28 jours).

Fig.1. Remplissage du pore annulaire autour du grain de cendre par des cristaux de portlandite et d'ettringite (10 000 X, âge - 28 jours).

Le remplissage complet du vide n'a lieu qu'après un délai de 3 à 6 mois (Fig.2), mais, même après ce délai, il subsiste une frontière nette entre la particule de cendre et la pierre de ciment. À la place du vide disparu, on observe une frange de nouvelles formations, tandis que la masse principale de la particule de cendre demeure inchangée. Donc la structure et les propriétés de la pierre de ciment de cendre durcie sont fonction de l'état de la zone de contact et non pas de la quantité de cendres étant entrée en réaction.

Sous cet angle sont d'un grand intérêt les études de la résistance des ciments de cendre à granulométrie différente des cendres,

Fig.2. La frange de gel hydrosilicateux ayant remplacé le vide annulaire autour de la particule de cendre (10 000 X, âge - 180 jours).

entreprises au "NIITzement" par G.G.Lepchenkova et Z.B.Entine.

La cendre prélevée à la centrale thermique était dispersée en fraction  $< 40 \mu\text{m}$ , de  $40$  à  $80 \mu\text{m}$  et  $> 80 \mu\text{m}$ . On a utilisé dans l'étude les deux premières fractions de chaque cendre. Le rendement par rapport à la masse totale de l'échantillon ainsi que la composition chimique de fractions de cendre sont données au tableau II pour deux centrales thermiques.

Tableau II						
Désignation de la cendre	Dimension de la fraction, $\mu\text{m}$	Rendement de la fraction, %	$\text{SiO}_2$	$\text{Al}_2\text{O}_3$	$\text{Fe}_2\text{O}_3$	$\text{CaO}$
1.1	40-80	49	56,08	28,45	7,15	3,33
1.2	$< 40$	47	49,22	34,91	6,98	3,47
2.1	40-80	40	61,24	27,92	4,65	1,53
2.2	$< 40$	57	63,12	27,55	4,44	1,25

L'analyse aux rayons X a montré que la composition en phases des fractions de cendre à éléments gros et fins était à peu près la même. Les deux cendres étaient composées pour l'essentiel de phase vitreuse, quant aux phases cristallines, elles contenaient de quartz  $\alpha$  et la sillimanite. À en juger par l'intensité des principales réflexions du quartz  $\alpha$ , la teneur en phases cristallines dans la fraction à éléments fins était supérieure à celle de la fraction à gros éléments, mais ces différences étaient peu sensibles.

La figure 3 a, b montre la résistance des ciments à cendres fine et grosse, tandis que la figure 4 a, b fournit la résistance des mêmes ciments après étuvage.

Comme il s'ensuit des résultats fournis, au début de durcissement jusqu'à 1 à 3 mois, les ciments à cendres fines retardent en résistance sur les ciments aux cendres à gros grains mais, par la suite, rattrapent et dépassent ces derniers.

Fig.3. Résistance des ciments à cendres de fractions fine (x) et grosse (o); a) cendre de la centrale thermique de Troitsk; b) cendre de la centrale thermique de Chitchechino.

Fig.4. Résistance des ciments à cendres de fractions fine et grosse après étuvage. Les désignations sont les mêmes que sur Fig.3.

Après étuvage, les ciments à cendres de fraction fine continuent à retarder en résistance, même à des délais plus longs, allant jusqu'à six mois.

Ces résultats s'expliquent si l'on tient compte que pour des dosages en masse égaux, la surface totale des particules de cendres de fraction fine est de beaucoup supérieure à celle des cendres de grosse fraction. En conséquence, le volume total des pores annulaires formés au début d'hydratation autour des grains de cendre est plus grand et, partant, leur résistance est plus faible. C'est seulement après le rem-

plissage suffisant des vides par des nouvelles formations que la résistance des ciments à cendre de fraction fine devient plus grande.

Après étuvage, quand les vides se remplissent relativement vite de formations à gros cristaux, la couche de contact demeure affaiblie durant des délais plus longs.

La formation, dans la pierre qui durcit, autour des grains de cendre de vides annulaires remplis de phase liquide, conditionne toutes les propriétés principales des ciments de cendre. L'influence de la formation et du remplissage des vides sur la cinétique de l'augmentation de la résistance ainsi que leur action compensatrice exercée sur les déformations dues au retrait et au gonflement deviennent ainsi immédiatement compréhensibles. La présence de vides saturés d'eau et repartis de façon uniforme entraîne également un abaissement de la résistance au gel des ciments de cendre. Mais en même temps il est évident que les ciments de cendre constituent une pierre de ciment d'une longue durée de vie, de plus la corrosion prolongée des particules de cendre contribue à un meilleur compactage et solidification.

L'accroissement de la masse de cendre étant entrée en réaction n'augmente pas sensiblement la résistance du ciment de cendre. On en obtient la preuve en analysant les données d'essais mécaniques des ciments dont l'un a été obtenu par mélange du ciment avec des cendres volantes et l'autre par mouture simultanée du clinker et des mêmes cendres volantes. Pour un degré de dispersion de la cendre brute de 2800-3000 cm<sup>2</sup>/g la résistance des deux ciments était à peu près la même à tous les temps de durcissement. Pourtant l'utilisation dans le béton a révélé d'importants avantages des ciments obtenus par mélange avec des cendres volantes non moulues. Dans ce cas le besoin en eau du béton diminue de 20 à 30 l/m<sup>3</sup>, ce qui se traduit, pour une même résistance, par un abaissement de consommation du ciment de 7 à 15%. Le tableau III nous fournit les données correspondantes.

Tableau III			
Mode d'obtention du ciment	Consommation du ciment, kg/m <sup>3</sup>	Résistance du béton, MPa	
		7 j.	28 j.
Par broyage simultané	240	15,3	25,2
idem	320	25,0	32,3
Par mélangeage	184	14,4	20,6
idem	246	23,5	33,4

Les données fournies montrent que la meilleure méthode d'obtention des ciments de cendre est de mélanger le ciment avec des

cendres volantes finement dispersées. Ce mode s'avère également judicieux sous l'angle de gain en énergie électrique. Pourtant certaines centrales thermiques de l'U.R.S.S., en particulier celles de Lady-jeno et de Kourakhovo, produisent des cendres volantes de dispersion très grossière, à surface spécifique de 1800-2000 cm<sup>2</sup>/g et contenant des grains moins de 80 μm que pour 50 à 55%. Dans ce cas la mouture simultanée de la cendre avec le clinker est obligatoire et il est recommandé de l'introduire dans la deuxième chambre du moulin à ciment ou dans le séparateur, au cas où la mouture s'effectue en cycle fermé.

Avec l'installation dans les nouvelles centrales de chaudières puissantes à mâchefer liquide il se pose un nouveau problème pour l'utilisation des cendres et des mâchefers de centrales thermiques. Ici on obtient le mâchefer granulé par granulation de la matière fondue au moyen de l'eau.

Le mâchefer est généralement constitué de granules compactes de couleur sombre, qui quelquefois, se présentent sous forme de lamelles ou de fils clairs. La composition chimique varie largement: SiO<sub>2</sub> - de 35 à 65%, Al<sub>2</sub>O<sub>3</sub> - de 10 à 25%, CaO - de 1 à 50%, FeO jusqu'à 20%. Le mâchefer peut comporter de sensibles quantités de phases cristallines, mais, en règle générale, ce sont les matières vitreuses qui y dominent. Dans la phase vitreuse on distingue un grand nombre de régions polymérocristallines de composition mullitique (au cas d'une teneur en CaO jusqu'à 10%), méllilitique et même wollastonitique (teneur en CaO - 10 à 40%), parfois gehlenitique (teneur en CaO - 40 à 50%). Dans la phase cristalline on rencontre quelquefois le mullite, le gehlenite, le pseudowollastonite, le β - C<sub>2</sub>S ainsi que d'autres minéraux (8).

Même avec l'élévation de la teneur totale en CaO le mâchefer est dénué de chaux libre et sa calcination n'implique pas de pertes.

Les études entreprises par "Guiprotzement" (S.D.Okorokov, L.J.Goldstein, V.V.Andreev) de l'activité des mâchefers ont montré qu'avec l'accroissement de la teneur en CaO on assiste à une dépolymérisation de l'ossature aluminosilicateuse du verre, ce qui est confirmé par les études des spectres infrarouges. L'affaiblissement de l'ossature implique une augmentation de la teneur en alumine soluble dans les matières vitreuses du mâchefer et, partant, une élévation de l'activité hydraulique de ce dernier. Les données correspondantes sont groupées au tableau IV. L'activité des mâchefers était appréciée d'après la résistance du ciment à centre-mâchefer contenant 29% de clinker, 66% de mâchefer et 5% de gypse.

Toutefois un important accroissement de la teneur en CaO dans le mâchefer et, surtout, l'augmentation du module basique des mâchefers ( $M_0 = \frac{CaO+MgO}{SiO_2+Al_2O_3}$ ) au-dessus de 1,0

entraîne une sensible chute d'activité, car alors le mâchefer est essentiellement composé de phases cristallines.

Tableau IV				
CaO, %	Al <sub>2</sub> O <sub>3</sub> , %		Limite de résistance, Mpa	
	Contenu total	En solution	7 j.	28 j.
2,09	25,45	néant	6,8	14,4
21,07	20,98	1,15	8,3	15,9
29,21	17,30	3,84	10,5	21,5
40,63	12,32	9,13	9,9	23,4

D'après les données fournies par Andreiev V.V., Goldstein L.J. et Okorokova S.D., l'accroissement de la teneur en FeO dans les mâchefers basiques jusqu'à 4% ne se répercute pas sur leur activité, mais, si cette proportion est dépassée, la résistance des ciments obtenus avec ces mâchefers diminue de façon sensible (Fig.5). Cela s'explique pour l'essentiel par la variation du contenu en matière vitreuse dans le mâchefer.

Fig.5. Influence de l'oxyde ferreux sur la résistance des ciments de mâchefer:

○ - premier groupe; □ - deuxième groupe.

Cependant dans les cas heureux où la composition du mâchefer se rapproche de celle du clinker, la cristallisation du mâchefer fondu se solde par une augmentation de la résistance limite. C'est ainsi, par exemple, qu'on observe dans les mâchefers cristallisés de certains gisements du bassin houiller de Kansk-Atchinsk une importante quantité d'alite (tableau V).

Il est possible d'obtenir des superciments, ne différant presque pas en résistance et en rythmes de durcissement des ciments sans constituants secondaires, avec une teneur en ces mâchefers allant jusqu'à 60% et plus.

Tableau V			
Désignation du produit	Alite, %	Bélite, %	Substance intermédiaire, %
Mâchefer	36	31	33
Clinker	66	11	23

On a étudié au microscope électronique la texture fine de l'alite isolée des mâchefers obtenus dans des conditions semi-industrielles par la méthode de séparation densimétrique des phases minérales. On distingue nettement sur les microfilms (Fig.6) les figures en "river" texture propres à l'alite témoignant de sa texture en fines cellules. Cette texture, comme on le sait, est en rapport avec la densité des dislocations dans l'alite. Ce facteur exerce une grande influence sur la broyabilité des mâchefers et contribue à une meilleure expression de leur activité pendant le broyage.

Fig.6. Figures en "river" texture des cristaux de l'alite isolée des mâchefers.

L'emploi des résidus de centrales thermiques se heurte encore au problème de l'utilisation des cendres volantes basiques contenant 7 à 20% de chaux libre. Habituellement ces cendres sont considérées comme inutilisables en qualité d'adjuvant minéral actif au ciment.

Cependant l'expérience acquise en U.R.S.S. dans l'utilisation des cendres basiques montre qu'il est possible d'obtenir à leur base des ciments de haute qualité et qui, de plus, possèdent des propriétés spécifiques fort intéressantes.

C'est ainsi que la cimenterie de Founane-Kounda produit jusqu'à 350 mille tonnes par an de ciment Portland aux cendres schisteuses. Ce ciment contient pour 20 à 25% de fines cendres schisteuses de la centrale thermique Pribaltifskaja, dont la teneur en CaO est de 7-10% (?) et la classe de résistance 500 (d'après la norme sovié-

tique Gost 10178-76). Sous l'angle de la résistance et des rythmes de durcissement, le ciment Portland aux cendres schisteuses est supérieur au ciment sans additifs produit par la même usine. De plus son besoin en eau est plus faible et la résistance après l'étuvage plus grande, ce qui augmente l'intérêt de son utilisation dans la réalisation d'articles préfabriqués en béton armé par traitement à la chaleur humide. On n'utilise pour la fabrication du ciment Portland aux cendres schisteuses que les plus fines fractions de cendres schisteuses dont la surface spécifique est d'environ 4000 cm<sup>2</sup>/g. Cependant un intérêt particulier présente l'utilisation de la masse principale des cendres volantes dont la surface spécifique est de l'ordre de 1700 à 2500 cm<sup>2</sup>/g et la teneur en CaOlib oscille entre 12 et 20%.

Comme l'ont montré les études au microscope électronique cette cendre est composée d'un mélange de particules sphériques vitrifiées finement dispersées dont la constitution et les propriétés sont analogues à celles des cendres acides, et d'agglomérats cristallins informes composés de chaux libre et d'anhydrite.

Les études ont montré que le CaOlib de la cendre possède une grande activité, grâce à quoi le ciment de cendre supporte les épreuves d'uniformité de variation du volume pour une addition de cendre jusqu'à 20% et une teneur en CaOlib dans le ciment jusqu'à 3,5-4%. Le tableau VI fournit les données sur la résistance des ciments avec constituants secondaires, sous forme de 15-18% de cendres volantes, les plus répandues en U.R.S.S. dans les charbons de Kansk-Atchinsk (1) et les schistes d'Estonie (2). La surface spécifique des ciments est d'environ 3000 cm<sup>2</sup>/g.

Les particules acides et basiques de la cendre se comportent différemment lors de la formation de la pierre de ciment.

Autour des bulles vitrifiées de la cendre se forme un vide annulaire qui, par la suite, en se corrodant suit le schéma d'hydratation et de durcissement décrit plus haut pour des ciments à cendres acides.

Tableau VI					
Designation du ciment	Durcissement normal			Etuvage	
	3 j.	7 j.	28 j.	1 j.	28 j.
1	20,7	37,0	46,7	29,0	43,0
2	31,2	39,4	51,3	41,1	54,2

Les particules contenant du CaO s'hydratent assez vite. L'hydratation des particules de CaO s'achève déjà au bout de 1-3 jours avec formation de cristaux assez gros de portlandite ce qui entraîne une certaine expansion et un compactage de la pierre de ciment.

Par la suite, la portlandite peut entrer en interaction avec la partie acide de la cen-

dre en accentuant sa corrosion et augmentant ainsi la résistance et la durée de vie de la pierre.

Par un choix optimal de la quantité et de la dispersion de la cendre ainsi que d'autres procédés technologiques, on arrive à contrôler non seulement la résistance mais également les déformations linéaires de la pierre de ciment, ce qui est très important, en particulier, pour l'obtention de bétons à faible perméabilité.

#### CONCLUSIONS.

L'étude des processus d'hydratation des ciments de cendre permet de dégager dans ces derniers de précieuses qualités pour l'industrie du bâtiment. Dans les conditions de manque aigu d'énergie et de combustible le développement de la production de ciment de cendre s'avère particulièrement efficace. En même temps on contribue à la résolution des problèmes de l'environnement.

# The influence of the production technology of fly ash cements upon their hydration and hardening

## *L'influence de la technologie sur l'hydratation et sur le durcissement des ciments de cendre volante*

R. KOVACS, Ph. D. Deputy Head of Dept. Cement, Central Research and Design Institute for Silicate Industry, Budapest, Hungary.

**RÉSUMÉ :** Les propriétés des ciments et leur vitesse d'hydratation dépendent, dans une grande mesure de leur technologie de production. La broyabilité différente du clinker et des cendres volantes rend possible de choisir, au point de vue des propriétés désirées des ciments aux cendres volantes, la technologie approchant l'optimum du broyage.

On a examiné les propriétés physiques et l'hydratation des ciments aux cendres volantes à des teneurs différentes en cendres volantes et broyés de manière différente. En partant des résultats obtenus, nous donnons des propositions concernant la technologie optimale du broyage des ciments de cendre volante, qui est appelé "broyage isochrone".

**SUMMARY:** The properties and the rate of hydration of cements depends considerably on their production technology. The difference between the grindabilities of clinker and fly ash enables to choose a grinding technology which is approximately optimal regarding the desired properties of the fly ash cements.

The physical properties and hydration of fly ash cements ground in different ways and containing various amounts of fly ash were investigated. On the base of the results recommendations were made for the application of the most effective / the so called isochronous / grinding technology in fly ash cement production.

## INTRODUCTION

The manufacture of energy-saving products as well as the application of such technologies is gaining more and more ground nowadays. Such type of product are fly ash cements, too, since proportionally to the amount of fly ash added less energy is consumed for the quarrying and drying of raw materials and for clinker burning.

That is why the production of fly ash cements is in Hungary, too, ever widening. The amount of the fly ash used as an admixture is expected to reach 250 thousand tons while that of fly ash cements 2 million tons in 1980. The possibilities, however, are not at all exhausted by this but although further extension of production and utilization is limited by the lower initial strength and higher sensitivity to early freezing of fly ash cements as compared to the Portland cements. /For this reason maximal fly ash content is limited by Hungarian Standard to 20 %/.

It is known that the initial strength of cements depends on a number of production technological factors /mineralogical composition of the clinker, the fineness and granulometric composition of the cement as well as its  $SO_2$ -content, etc./. The aim of our research was to determine those technological parameters of fly ash cement production by which the initial strength can be increased in the simplest way and with the least energy consumption.

The literature in this field is rather poor /1-3/ mentioning first of all the positive role of increased  $C_2S$  content.

## THE RELATIONSHIP BETWEEN THE HYDRATION AND STRENGTH OF FLY ASH CEMENTS

In the course of our former research /4,5/ the hydration processes of fly ash cements were studied in details. It was concluded that the hydration products of fly ash cements were practically the same as those of pure Portland cement, i.e. a gel phase consisting of calcium silicate and calcium aluminat-hydrates /later partially crystallizing/, calcium hydroxide and -carbonate. The correlation of the amounts of the individual phases, however, is different e.g. in fly ash cement there is more gel phase than in the Portland one but less calcium-hydroxide /portlandite/. The amount of carbonate phase is also somewhat higher.

The deviations in certain properties of fly ash cements as compared to those of the Portland cements can be explained by the differences between the rates of growth and compositions of the hydrate phases.

It was also found that the hydration processes of fly ash cements are exactly expressed by the change of their strength with time. The strength of such cements is lower at the beginning because the amount of the active component /the clinker/ in them is less and their structure is also looser.

Due to the increasing amount of secondary hydrate compounds formed in the reaction of the fly ash and the lime released during hydration of the clinker minerals as well as to the filling up of the pores the density of the cement stone increases and its strength will match or even exceed that of the fly ash-free cement.

From the above mentioned it can be concluded that higher initial strength of fly ash cements can be achieved by increasing the hydration rate. In order to do so experiments were carried out varying the different technological parameters.

## INVESTIGATION OF THE ROLE OF VARYING THE CLINKER COMPOSITION

Clinkers of free  $CaO$ -contents below 0,1 % were burnt from raw mixes of identical lime saturation factor /0,9/ having different silica /2,0 + 2,4/ and alumina /0,6 + 1,4/ moduli, in a laboratory silite rod furnace at 1400°C. The duration of burning altered between 3-5 hours depending on the moduli.

The 15 different clinkers thus obtained were pre-ground to a cca. 200  $m^2/g$  specific surface and after the adding 6 % gypsum on the one hand and 6 % gypsum plus 20 % fly ash on the other they were post-ground in a laboratory Bond-mill for about 35-40 minutes.

The specific surface and the chemical composition of the fly ash used were the following: 530  $m^2/kg$ ;  $SiO_2$  - 57,46;  $Al_2O_3$  - 17,95;  $Fe_2O_3$  - 8,43;  $CaO$  - 7,07;  $MnO$  - 2,40;  $SO_3$  - 1,71; loss on ignition - 3,02 %.

Plotting the initial strengths as a function of the moduli of the cements prepared in the described way in a space diagram an increasing tendency towards the corner characterized by  $Al_i = 1,4$  and  $SM = 2,4$  was observed. That is why the investigations were extended to the contacting clinker composition range / $SM = 2,4 + 2,6$  and  $Al_i = 1,4 + 1,7$ /

Fig. 1. - Effect of the modular composition of clinker upon the 3 days compression strength /MPa/ of pure /a/ cement and that containing 20 % fly ash /b/

Fig 1. shows the initial strengths of these experimental cements in a space diagram. On the base of this as well as the results of long-term investigations not given here in details it can be concluded that the optimal clinker composition to produce fly ash

cements using the given fly ash /typical for the Hungarian acidic fly ashes/ is characterized by the following moduli: SM about 2,5 and AM = 1,6 - 1,7 /provided the LSF is cca. 0,9/. In the future we wish to extend our investigations to clinkers of a lime saturation factor higher than 0,9 and aluminates moduli higher than 1,7.

#### INVESTIGATION OF THE ROLE OF THE GYPSUM CONTENT OF CEMENT

It is known that the amount of the gypsum required for the regulation of setting depends on the composition and grinding fineness of cements. Since these characteristics of the fly ash cements differ from those of the Portland cement, we thought it necessary to investigate the gypsum-demand of these cements.

In the course of the research on the one hand the gypsum content of industrial fly ash cements were increased by adding further 1 to 4 % gypsum, on the other hand cements of different fineness were ground from industrial clinkers with various gypsum addition. The optimal gypsum content was determined based on the strength-changes of the cements thus obtained.

Because of the lack of space we cannot give the results in details, only the conclusions are summarized here briefly.

For the cements containing no and 10 % fly ash, resp. the optimal gypsum addition is practically the same and, depending on the grinding fineness, amounts to 4-5 % for cements with a specific surface in the range of 300-350  $\text{m}^2/\text{kg}$  and 6-7 % in case of a surface of 400  $\text{m}^2/\text{kg}$  and higher, resp.

The optimal gypsum content of cements containing about 20 % fly ash amounts to 5 % for a specific surface of 300-350  $\text{m}^2/\text{kg}$  and 6 % for 400  $\text{m}^2/\text{kg}$  and higher, resp.

It can be stated in general that the gypsum demand of fly ash cements is less modified by the change of its fineness than in case of the pure cement.

These results refer to the mixtures made of usual Portland cement clinker containing about 50 %  $\text{C}_3\text{S}$ , 25 %  $\text{C}_2\text{S}$ , 10 %  $\text{C}_3\text{A}$  and 8 %  $\text{C}_4\text{AF}$  and of the acidic fly ash mentioned above.

#### INVESTIGATION OF THE ROLE OF THE GRINDING TECHNOLOGY

Two basic technological variants of making fly ash cements are known: blending and inter-grinding.

In the blending technology fly ash is added to the ready-ground cement and the mixture is properly homogenized. Among the sub-versions of this technology the preliminary fine grinding of the fly ash as well as the different points and ways of introducing the fly ash can be mentioned. The advantage of the blending technology lies in its simplicity but as a disadvantage it should be

mentioned that it cannot be applied for all types of fly ash and the initial strength of the cements produced this way is generally low.

In the intergrinding technology the fly ash is ground together with the clinker and gypsum in the mill to make cement. According to the terminology suggested by us, complete intergrinding means the simultaneous feed of the fly ash, gypsum and clinker into the mill, while partial intergrinding means that the intergrinding takes place only in the final phase of the grinding process of the clinker.

There are further sub-versions within this, i.e. when the whole amount of the fly ash is fed into the mill or when the fine-fractions of it are previously separated and only the coarse ones let to be interground with the clinker.

During the laboratory, pilot plant and industrial scale experiments carried out by us several versions of the intergrinding technology were studied in details.

In the course of laboratory experiments we used the clinker and fly ash of the above mentioned compositions. To investigate the effect of the duration of intergrinding the following method was applied.

10 and 20 %, resp. of fly ash and 5 % of gypsum were added to the clinker pre-ground to different fineness /specific surface/ and these mixtures were post-ground for different times then the properties of the cements thus obtained were investigated.

Fig.2 - Change of the specific surface of the pure /—/ cement and those containing 10 % /- - -/ and 20 % /- . - -/ fly ash as a function of grinding time

Fig.2 and Fig.3 show the grinding curves and the compressive strengths, resp., of the cements. It can be seen from these figures that, starting from a clinker with a specific surface of about 200  $\text{m}^2/\text{kg}$ , in order to reach identical specific surface of about 300  $\text{m}^2/\text{kg}$  post-grinding times of 130 minutes for pure cement, 20 and 10 minutes resp., for the cements containing 20 and 10 % fly ash, resp., were necessary /ce-

Fig. 3 - Effect of the duration of grinding upon the compressive strength of the pure cement /—/ and those containing 10 % /- - -/ and 20 % /- . . -/ fly ash

ments 1, 2 and 3/. The hydration of the cements post-ground for short times is poorer its hardening is slower thus their initial strength does not reach that of the pure cement.

The specific surface of the fly ash cements /cements 4 and 5/ post-ground for identical time /according to our terminology: isochronously post-ground/ with the pure cement /cement 1/ is considerably higher showing the effect of fly ash as a grinding aid. At the same time their strength at all ages is identical to or even surpasses that of the pure cement.

The same conclusion can be drawn when comparing the finenesses and strengths of the cements pre-ground to a specific surface of about 250  $\text{m}^2/\text{kg}$  and isochronously post-ground for a shorter time /30 minutes/ /cements 6, 7 and 8/. As an experiment a cement of high initial strength with a specific surface of ca. 350  $\text{m}^2/\text{kg}$  was also obtained by post-grinding the cement 6 for 170 minutes. It can be stated that the strength characteristics of the fly ash cements obtained by considerably shorter post-grinding i.e. by considerably lesser energy consumption match or exceed those of the pure cement already after 28 days.

Investigating the effect of the pre-grinding fineness similar experiments were carried out with cements made from clinkers pre-ground to a specific surface of about 150, 200 and 250  $\text{m}^2/\text{kg}$  and containing 0, 10 and 20 % fly ash, and 6 % gypsum, post-ground uniformly for 60 minutes. Fig. 4 and Fig. 5 show the grinding curves and the compressive strengths of these cements.

From these results it can be concluded that the grindability-improving effect of fly ash manifests itself more obviously in case of the clinkers pre-ground to higher specific surfaces i.e. fly ash admixture helps at that point where otherwise the grindability would show already decreasing tendency. It can be seen from the figures that the

Fig. 4 - Change of the specific surface of the cements containing 0, 10 and 20 % fly ash as a function of pre-grinding fineness and duration of grinding

Fig. 5. - Effect of the pre-grinding fineness upon the compressive strength of the pure cement /—/ and those containing 10 % /- - -/ and 20 % /- . . -/ fly ash  
Pre-grinding fineness: a - 150, b - 200 and c - 250  $\text{m}^2/\text{kg}$

dependence of the 1- and 3-days strength of cements upon the pre-grinding fineness of the clinker is more expressed than that of the 28-days strength.

Investigating the granulometric composition of the cements prepared in laboratory experiments as well as their separated clinker and fly ash fractions obtained using a liquid of a 2,6  $\text{kg}/\text{m}^3$  density /which was possible due to the different densities of clinker and fly ash being 3,1 and 2,2  $\text{kg}/\text{m}^3$  resp./ interesting conclusions could be drawn.

It was pointed out that when intergrinding clinker and fly ash in the coarse grinding range both components become finer but the clinker only to a smaller extent. In the fine grinding range, however, mainly the

fineness of the fly ash changes only while that of the clinker remains practically unchanged. Due to this the major part of the fine fraction of fly ash cements interground for longer time is represented by the finest fly ash particles and there are much less fine clinker particles in it. That is why the initial hydration of such cements is slower. We suppose this to be one of the main reasons why the initial strength of these cements is lower than that of the pure cement.

Similar results were obtained in the course of the pilot plant experiments not described here in details due to the lack of space.

The industrial scale experiments were carried out on a closed circuit cement mill sized  $\phi 4 \times 12$  m equipped with a static air swept classifier /seriesly connected with a grits-separator and two  $\phi 5,6$  m air classifiers with distribution plates/ /Fig.6/. In the course of the experiments the load of the mill, the amount of fly ash and the point of introducing it into the mill as well as the rpm of the air classifier were varied.

Separating in heavy liquid the cement samples taken at different points of the mill system the fly ash content of them and following this the specific surface and granulometric composition of the separated clinker component were determined. Tables I and II give the results in abstracted form.

Compressive strength							
MPa	1 day	13,0	8,20	13,4	7,6	11,2	8,2
	3 days	21,0	16,5	22,6	16,2	18,3	16,3
	7 days	27,5	22,1	32,2	24,3	26,7	23,3
	28 days	35,9	34,4	42,2	35,6	35,6	35,0
	90 days	44,5	44,8	48,7	46,0	45,2	46,6

As a summary it can be stated from these that when grinding pure cement the highest initial and final strength was observed at a 70 t/hour mill performance. The initial strength of fly ash cements - almost independently from the mill performance /72-96 t/hour/ - is lower in every case than that of the pure cement, after 28 days their

strengths are practically identical, while after 90 days the former usually exceeds the latter.

In case of complete intergrinding, when fly ash was fed into the mill together with the clinker, the specific surface of the cement amounted at the different loads to 290-295, while that of the clinker varied only bet-

TABLE II

Effect of the place of introducing the fly ash into the closed circuit system				
Place of sampling and its mark	Mill I.		Mill II.	
	Fly ash introduced into			
	the air classifier		the mill	
	Fly ash content, %	Specific surface, $\text{m}^2/\text{kg}$	Fly ash content, %	Specific surface, $\text{m}^2/\text{kg}$
Mill outlet $/M_K/$	2,55	203,8	20,48	239,2
Air classifier fine fraction $/M_{SZ}/$	18,75	268,3	22,17	261,7
Electric precipitator outlet $/M_P/$	6,64	416,0	29,66	448,2
Final product $/M_V/$	20,10	272,5		

ween 161-196  $\text{m}^2/\text{kg}$ . This proves the conclusion drawn for laboratory experiments i.e. in this case the major part of the fine fractions is represented by fly ash.

We also tried to introduce fly ash into the air classifier.

The air classifier separated the fine part /about 88 %/ of the fly ash i.e. really it was introduced into the product by simple "blending". Only the coarse fraction /about 12 %/ of the fly ash was interground in the mill thus the positive influence of the fly ash upon grinding couldn't become effective.

The results of the industrial scale experiments proved that by adding fly ash a plus performance of about 20 % can be achieved - at identical energy consumption - but the price of this is the decrease of the initial hydration and initial strength of the cement.

Fly ash cements of high initial strength cannot be produced in the investigated mill system since the optimal technology necessary for it - i.e. the partial intergrinding - cannot be realized in this system. On the base of the experiences of the experiments the possibilities and conditions of optimizing such mill systems for the production of fly ash cements are being investigated in our Institute.

## CONCLUSIONS

Summarizing the experiences of the laboratory, pilot plant and industrial scale experiments the following main conclusions can be drawn:

- on the base of the investigations carried out thus far the optimal clinker composition to produce fly ash cements is characterized by a silica module of about 2,5 and alumina module between 1,6-1,7;
- the optimal gypsum content of fly ash cements, depending on the quality of clinker and fly ash, is about 6 %;
- the grindabilities of the clinker and fly ash are different which should be

taken into account when the grinding technology is to be chosen and designed;

- an effective method of accelerating the hydration and increasing the initial strength of fly ash cements is the partial intergrinding /the separate pre-grinding of the clinker followed by the simultaneous post-grinding of the clinker and fly ash/;
- the optimal pre-grinding time /and the specific surface to be obtained, resp.,/ of the clinker depends on the quality of the clinker and fly ash and on the fineness of the latter, resp.. In the case of the materials investigated by us in order to achieve the best initial strength of fly ash cements containing 10-20% fly ash the clinker should be pre-ground to a specific surface of about 200 - 250  $\text{m}^2/\text{kg}$ .

## Comparaison de la réactivité de différentes pouzzolanes

### *Comparison of the reactivity of different pozzolane*

B. MORTUREUX, H. HORNAIN, E. GAUTIER et M. REGOURD. Département Microstructure C.E.R.I.L.H., Paris, France.

**RESUME :** La réactivité de six pouzzolanes d'origine et de composition diverses, la microstructure de leurs hydrates ont été étudiées grâce à la diffraction des rayons X et la microscopie électronique à balayage, d'une part dans des pâtes 80 % Pouzzolane + 20 %  $\text{Ca(OH)}_2$ , d'autre part dans des pâtes de ciment Portland à 20 % de Pouzzolane. Le taux de fixation de  $\text{Ca(OH)}_2$  dans les pâtes de ciment a été comparé aux résistances mécaniques des mortiers ISO.

D'après l'analyse minéralogique, quatre des pouzzolanes sont d'origine volcanique (feldspathique, zéolitique, vitreuse), une autre, siliceuse, d'origine sédimentaire, la dernière une cendre volante de centrale thermique.

L'activité de ces ajouts est fonction de leur composition chimique, leur nature minéralogique, leur surface spécifique. Certaines pouzzolanes telles les cendres volantes qui s'hydratent peu aux brèves échéances, peuvent être activées par étuvage.

**SUMMARY :** The reactivity of six pozzolana of different origin and composition and the microstructure of their hydrates were studied by X-ray diffraction and scanning electron microscope. Two paste samples series were studied, one containing 80 % pozzolana + 20 %  $\text{Ca(OH)}_2$  and the other Portland cement + 20 % pozzolana. The combination rate of  $\text{Ca(OH)}_2$  in the cement pastes was compared to the mechanical resistances of ISO mortars.

According to mineralogical analysis, four of the pozzolana are of volcanic origin (feldspar, zeolitic, vitreous), an other of sedimentary siliceous origin and the last, power station fly ash.

The activity of these additives is in function to their chemical composition, their mineralogical nature and their specific surface. Certain pozzolana, such as fly ash, which hydrate only slightly over short periods can be activated by thermal treatment.

## INTRODUCTION

Les pouzzolanes peuvent être définies comme des matériaux ayant une aptitude à réagir avec la chaux en présence d'eau et à former des composés possédant des propriétés liantes (1). Les pouzzolanes naturelles sont d'origine volcanique ou sédimentaire; elles sont soit vitreuses et se présentent comme une ponce contenant des inclusions de silico-aluminates alcalins cristallisés, soit cristallisées, et contiennent des zéolithes (silicoaluminates alcalins hydratés). Les pouzzolanes naturelles d'origine sédimentaire peuvent être des argiles que l'on utilise après torréfaction ou des terres à diatomées constituées de squelettes siliceux : la gaize utilisée en France est une roche sédimentaire. Les pouzzolanes artificielles comme les cendres volantes sont essentiellement vitreuses, elles contiennent en inclusion des silicoaluminates (mullite) et de la magnétite.

Toutes ces pouzzolanes ont en commun une teneur élevée en  $Al_2O_3$  et  $SiO_2$  qui leur confère un caractère acide et une grande affinité pour la chaux; la somme  $Al_2O_3 + SiO_2$  est de l'ordre de 70 % et peut atteindre 80 %.

Les études précédentes (2) ont montré que la quantité de chaux fixée par les pouzzolanes variait avec leurs caractéristiques physiques et chimiques : à court terme l'activité dépendrait surtout de la surface spécifique (BET) et à plus long terme de la teneur en silice et alumine réactives.

## ANALYSE des POUZZOLANES

Nous avons dans notre étude de ciments aux pouzzolanes utilisé 6 produits d'origine et de nature différentes : un tuff de Naples, une pouzzolane phlégréenne, un trass du Rhin, une pouzzolane naturelle de Volvic (France), une cendre volante de Violaines (France) et une pouzzolane siliceuse provenant du Maroc. Les trois premières nous ont été aimablement fournies par le Prof. R. SERSALE que nous tenons à remercier ici.

Ces produits ont été caractérisés par analyse chimique et leur composition minéralogique a été précisée par diffraction des rayons X et microscopie optique.

La composition chimique des 6 pouzzolanes est présentée dans le tableau suivant :

TABLEAU 1 : Analyse chimique des pouzzolanes

	Trass	Tuff	Phlégréenne	Volvic	Cendre de Violaines	Opale du Maroc
P. au f.	10.00	12.16	3.40	0.61	1.85	12.15
CaO	3.20	1.80	3.90	6.70	1.50	6.83
$SiO_2$	55.90	53.60	57.20	54.30	52.50	70.45
$Al_2O_3$	16.80	16.10	17.90	16.80	28.20	2.35
$K_2O$	4.70	7.90	8.00	2.60	4.40	0.32
$Na_2O$	3.19	3.67	3.56	4.47	0.82	0.49

- Le trass du Rhin et le tuff de Naples sont des pouzzolanes à zéolithes. Les minéraux identifiés sont pour le tuff : une zéolithe type herschélite, de l'analclime, des feldspaths potassiques et une phase vitreuse peu importante. Dans le trass, le

minéral dominant est la chabasie, on trouve également du quartz (10 à 12 %), de l'analclime et des feldspaths; la phase vitreuse est très peu importante (3).

- Les deux pouzzolanes à phase vitreuse (Volvic et Phlégréenne) donnent par DRX un anneau dont l'intensité permet de déterminer le pourcentage de verre : 50 % pour la phlégréenne et 20 à 25 % pour Volvic (4).

Les minéraux cristallisés identifiés dans la pouzzolane phlégréenne sont des feldspaths (sanidine), de l'analclime et une zéolithe potassique déjà rencontrée dans le tuff de Naples, du quartz, de l'augite et de la dolomite. On remarque la forte concentration en alcalis : 12 % au total.

Dans la pouzzolane de Volvic, le minéral cristallisé principal est l'andésine mais on trouve également du quartz, du diopside et de la magnétite. La perte au feu est particulièrement faible.

- Dans la pouzzolane microcristallisée à haute teneur en silice du Maroc, les minéraux identifiés par DRX sont, outre l'opale, des formes bien cristallisées de silice (quartz et cristobalite) assez rares, de la dolomite et quelques phosphates; les pourcentages d'alcalins sont faibles et il est clair que l'essentiel de la réactivité provient de la silice.

- Dans la cendre volante le verre est très abondant, les quelques minéraux cristallisés sont la mullite, la sillimanite, la magnétite et un peu de quartz.

Ces analyses ont été complétées par quelques observations au microscope optique et électronique à balayage ainsi que par des analyses ponctuelles à la microsonde électronique.

Les pouzzolanes à phase vitreuse (phlégréenne et Volvic) se distinguent par des grains à contours anguleux parfois dévitrifiés qui ne subissent pas de changement d'aspect après attaque acide tandis que les grains de zéolithe sont rapidement attaqués par  $HNO_3$ .

Vus au MEB, les grains de Volvic ou de phlégréenne présentent une surface lisse tandis que dans le trass et le tuff on trouve des grains zéolithiques à surface rugueuse, spongieuse. La surface spécifique de tels grains est certainement supérieure à granulométrie égale.

L'opale apparaît comme très finement divisée. L'aspect des grains de cendre volante, sphériques, est bien connu (5, 6, 9).

La finesse des produits utilisés était la suivante (surface Blaine en  $cm^2/g$ ) :

Cendre	Trass	Tuff	Phlégréenne	Volvic	Opale	Ciment
4300	7300	5300	2900	4300	7200	3920

Un essai complémentaire de pouzzolanité a, par ailleurs, été effectué à finesse Blaine égale.

## ESSAI de POUZZOLANICITE

Les méthodes chimiques habituellement utilisées pour évaluer l'activité pouzzolanique consistent soit à déterminer la quantité de chaux fixée par la pouzzolane après un certain temps de contact, soit à déterminer le taux de silice et d'alumine solubilisées par un traitement approprié (alumine et silice "réactives")

(8, 10, 11, 12). Nous avons utilisé la diffraction des rayons X pour déterminer la quantité de chaux fixée aussi bien dans les ciments aux pouzzolanes que dans des pâtes pouzzolane-chaux, cette technique permettant en même temps de caractériser l'évolution des minéraux de la pouzzolane : 4 g de pouzzolane étaient ajoutés à 1 g de  $\text{Ca(OH)}_2$ , la poudre homogénéisée était gâchée à l'eau distillée avec un rapport e/s = 0.6, les éprouvettes démoulées au bout de 48 heures et conservées dans une atmosphère à 100 % d'humidité à l'abri du  $\text{CO}_2$ .

La chaux  $\text{Ca(OH)}_2$  restante a été dosée par DRX (méthode de l'étalon interne Si) en utilisant les 3 raies de diffraction X à 4.92, 3.11 et 2.63 Å. Pour 1 g de pouzzolane, les quantités de chaux consommées sont les suivantes à 7 et 21 jours :

	Trass	Tuff	Opale Maroc	Phlégré- enne	Volvic	Cendre de Violaines
7 j	0.14 g	0.14	0.13	0.09	0.04	0
21 j	0.18 g	0.19	0.23	0.14	0.08	0.08

On peut voir que l'opale a le mieux réagi puisque la quantité de  $\text{Ca(OH)}_2$  fixée à 21 j correspond à 90 % de la quantité totale disponible au départ ceci étant probablement en rapport avec la grande division de la silice.

Les produits d'hydratation du type C-S-H sont bien visibles sur le diagramme de diffraction à 21 jours (raie large à 3.05 Å).

Le trass présente une bonne réactivité ainsi que le tuff : ce sont les zéolithes qui ont réagi comme le montre la diminution de leurs raies de diffraction X.

La phlégréenne, de finesse inférieure aux précédentes, montre cependant une bonne réactivité; la pouzzolane de Volvic réagit peu (30 % de la chaux fixée à 21 j).

La cendre de Violaines n'avait pas fixé de chaux d'une manière décelable par DRX à 7 jours; à 21 j le taux de fixation est égal à celui de la pouzzolane de Volvic mais il est certain qu'aux échéances plus longues la réactivité de la cendre serait au moins égale à celle des autres pouzzolanes comme l'a montré l'essai sur ciment.

Ce dosage de la chaux consommée par les pouzzolanes a été complété par l'observation du produit formé au moyen du MEB (échéance 21 jours).

- Sur la cendre volante, la première hydratation donne de l'ettringite et un peu de C-S-H (peu de  $\text{Ca(OH)}_2$  fixée). La surface des grains ronds paraît corrodée; l'ettringite est en fines aiguilles.

- Sur le trass qui a fixé 70 % de la chaux disponible, le C-S-H semble très dense et recouvre tous les grains, son aspect est parfois feuilleté; d'après le spectre d'émission X, le produit d'hydratation contient beaucoup plus de Ca que le minéral anhydre; la chaux n'est pas entièrement combinée et se retrouve en plaquettes.

- Sur le tuff jaune de Naples le silicate hydraté paraît dense et recouvre les grains; son aspect est assez voisin de celui du trass (2 pouzzolanes de même composition chimique à l'exception des alcalis).

- Sur la pouzzolane phlégréenne nous trouvons un as-

pect moins compact : beaucoup de grains ont une surface assez peu attaquée et il est visible que la réaction pouzzolanique concerne surtout la fraction fine du produit (fig. 1).

- Sur l'opale du Maroc (fig. 2) on retrouve le maximum de réactivité avec un maximum de compacité de l'éprouvette, on ne distingue plus les grains, le silicate hydraté C-S-H recouvre tout et assure un bon pontage entre les grains. Ce produit d'hydratation sur l'opale nous a paru assez épais pour faire un dosage des éléments Ca et Si à la microsonde électronique. Sur 200 mesures, la valeur moyenne du rapport C/S est 0.85.

Fig. 1.- Phlégréenne

Fig. 2.- Opale du Maroc

Microstructure des pâtes pouzzolane-chaux hydratées 21 jours.

- Sur la pouzzolane phlégréenne les valeurs de C/S trouvées sont plus dispersées sans doute en raison de microcristaux de  $\text{Ca(OH)}_2$  non encore fixés par la pouzzolane : les valeurs restent cependant centrées autour de 0.75 mais il faut également tenir compte des alcalis ( $\text{K}_2\text{O}$ ). Le dosage moyen donne alors  $(\text{C}+\text{K})/\text{S} = 0.8$ .

La microsonde électronique donne également des images de la répartition des éléments dans la pâte; celles-ci montrent que l'hydratation est très limitée sur des grains massifs, de feldspath par exemple, dans la phlégréenne. Tandis que des grains plus petits ou moins compacts (zéolithes) donnent une meilleure diffusion de Si et Al dans la pâte.

Un deuxième essai de pouzzolanité a été fait avec les six pouzzolanes broyées à la même finesse Blaine ( $7000 \text{ cm}^2/\text{g}$ ). Cet essai donne le même classement des six pouzzolanes pour la fixation de chaux (fig. 3 et 4).

Fig. 3

Fixation de la chaux par les pouzzolanes de surfaces spécifiques différentes

Fig. 4

Fixation de la chaux par les pouzzolanes de surface spécifique égale à  $7000 \text{ cm}^2 \cdot \text{g}^{-1}$

Nous retiendrons de cet essai les conclusions suivantes : les pouzzolanes à zéolithes sont très réactives vis-à-vis de la chaux, le tuff de Naples est de ce point de vue légèrement supérieur au trass à finesse égale. La pouzzolane phlégréenne (50 % de verre) fixe moins de chaux que les pouzzolanes à zéolithes (7). L'opale a une excellente réactivité qui dépasse celle des autres pouzzolanes puisque dans notre essai la quasi totalité de la chaux est fixée à 21 jours. La cendre de Violaines réagit lentement et ceci en rapport avec sa finesse : un essai à 3 mois nous a montré une forte fixation de chaux.

La pouzzolane de Volvic a une réactivité très appréciable par rapport aux pouzzolanes italiennes bien que la réaction soit plus lente. La surface spécifique BET des six pouzzolanes broyées à  $7000 \text{ cm}^2 \cdot \text{g}^{-1}$  (ss Blaine) est la suivante :

PZ	Trass	Tuff	Phlégréenne	Cendre de Violaines	Volvic	Opale du Maroc
$S(\text{m}^2/\text{g})$	6.6	12.7	3.0	1.6	0.8	36

Le classement des six pouzzolanes par la surface BET est le même que dans l'essai de pouzzolanité; on remarque la valeur très élevée obtenue avec l'opale du Maroc. Les deux pouzzolanes à zéolithes ont un BET nettement supérieur à celui de la phlégréenne ou de Volvic; pour la cendre volante, la surface BET varie avec le degré de broyage; pour une finesse Blaine de 4500 nous ne trouvons par la méthode BET que  $4000 \text{ cm}^2/\text{g}$  ce qui explique le faible taux de fixation de  $\text{Ca}(\text{OH})_2$ .

#### CIMENTS aux POZZOLANES et à la CENDRE VOLANTE

Le ciment utilisé était un CPA; sa composition chimique était la suivante :

CaO libre	$\text{SO}_3$	p.f.	$\text{SiO}_2$	$\text{Al}_2\text{O}_3$	$\text{Fe}_2\text{O}_3$	CaO	MgO	$\text{Na}_2\text{O}$	$\text{K}_2\text{O}$
2.00	3.43	4.63	19.12	4.11	2.23	61.77	3.60	0.20	0.73

La composition minéralogique a été déterminée par diffraction des rayons X :

$\text{C}_3\text{S}$  60 %;  $\text{C}_2\text{S}$  15 %;  $\text{C}_3\text{A}$  8.5 %;  $\text{C}_4\text{AF}$  5 %; MgO libre 2 % et sulfate 7 %.

Des microéprouvettes de pâte pure de ciment à 20 % de pouzzolanes ont été préparées avec un rapport  $e/c = 0.33$  et examinées après 28 jours, 3 et 6 mois; 1 et 2 ans de conservation dans l'eau.

Nous avons aussi mesuré la résistance à la compression et à la flexion d'éprouvettes de mortier ISO  $2 \times 2 \times 16 \text{ cm}$  conservées en eau douce et en eau de mer. Outre les 6 pouzzolanes, un laitier HF a servi à préparer des éprouvettes dans les mêmes conditions à titre de comparaison.

La microstructure des éprouvettes de pâte pure ou de mortier a été étudiée par DRX, MEB et microsonde électronique.

Il y a progression constante de la fixation de la chaux libérée par le Portland pour toutes les pouzzolanes. La cendre se classe à part ayant peu réagi jusqu'à 6 mois et davantage entre 6 mois et un an.

A 6 mois, pour 1 g de  $\text{Ca}(\text{OH})_2$  libéré par le ciment et présent dans l'échantillon témoin CPA pur, les quantités de  $\text{Ca}(\text{OH})_2$  présentes dans les différents CPAZ sont les suivantes :

	Témoin	Cendre	Phlégréenne	Trass	Tuff	Volvic
6 mois	1 g	0.55	0.65	0.60	0.60	0.75
1 an	-	0.35	0.60	0.50	0.55	0.70

Un laitier de référence donne 0.50 g à 1 an. On trouve donc un maximum de CaO fixé par la cendre volante (35 % seulement de la chaux présente dans le témoin pour 20 % d'ajout); viennent ensuite le trass, le tuff, la phlégréenne et la pouzzolane de Volvic. Il y a une bonne corrélation entre la fixation de chaux dans les éprouvettes de pâte pure et les résistances à la compression sur mortier ISO à 6 mois comme à 1 an. Nous n'avons pas fait à 2 ans de mesures de chaux fixée mais noté les résistances des mortiers :

	Témoin	Cendre	Phlégréenne	Trass	Tuff	Volvic	Laitier
6 mois	70 MPa	77.5	54	60	62.5	63	70
1 an	70.5	85	58	76	60	65	75
2 ans	73.7	86	63	69	67.5	67	75

On note une certaine égalisation des résultats entre le tuff et la phlégréenne; le trass reste meilleur, presque à égalité avec le témoin mais seule la cendre volante donne des résultats supérieurs au témoin; la cendre donnait aussi dès 3 mois d'excellentes résistances à la flexion avec des valeurs nettement supérieures à  $R_f$  témoin (11.2 MPa contre 9.1 à 6 mois et 12 MPa contre 10 à un an).

Ce critère de la quantité de  $\text{Ca}(\text{OH})_2$  restant dans les éprouvettes peut paraître insuffisant; on remarque par exemple que les constituants du clinker sont plus hydratés avec la pouzzolane phlégréenne à 1 an comme à 6 mois; il en est de même avec la pouzzolane de Volvic qui donne de bonnes résistances.

Trois ciments aux pouzzolanes (Volvic, Tuff et Phlégréenne) restent riches en  $\text{Ca}(\text{OH})_2$ ; leur résistance en eau douce est inférieure à celle du témoin et ils donnent par ailleurs de mauvaises résistances en eau de mer.

Nous avons étudié par diffraction X et MEB la microstructure des hydrates à un an.

Avec la cendre volante les hydrates identifiés par DRX sont l'ettringite,  $\text{C}_4\text{AH}_13$ , C-S-H et de la chaux  $\text{Ca}(\text{OH})_2$  peu abondante. La figure 5 représente un grain couvert d'hydrate; cette hydratation pouvant avoir lieu à la fois à l'intérieur et à l'extérieur du grain; le C-S-H formé est pauvre en chaux (rapport  $\text{CaO}/\text{SiO}_2$  proche de 1) (9).

Sur la pouzzolane phlégréenne de granulométrie assez grossière, la bordure d'hydrate autour des grains paraît mince, la chaux encore très abondante. Le silicate C-S-H de la pouzzolane est plus pauvre en K et plus riche en Ca que l'anhydre, mais il contient moins de Ca que le reste de la pâte et davantage d'Al (Fig. 6).

Le diagramme de diffraction X du tuff à 1 an est voisin de celui de la phlégréenne : on remarque l'abondance d'aluminate hydraté (ettringite et  $\text{C}_4\text{AH}_13$ ). Les phases zéolithiques ont pratiquement disparu comme sur le trass, on retrouve de la portlandite en amas dans l'éprouvette (Fig. 7 et 8).

Sur le trass on trouve de faibles zones d'hydratation autour des grains et l'analyse élémentaire montre qu'elles sont plus pauvres en K et Na que l'anhydre et plus riches en Ca (Fig. 9).

Sur l'échantillon Volvic, la proportion d'ettringite est assez élevée à 1 an; cela tient sans doute à la plus grande proportion de sulfates disponibles par rapport au clinker puisque la pouzzolane est peu active. La chaux  $\text{Ca}(\text{OH})_2$  est moins abondante que sur le CPA témoin mais plus qu'avec les autres ajouts; les raies de diffraction des feldspaths sont peu altérées; comme pour la phlégréenne, le ciment paraît plus hydraté qu'avec les autres ajouts.

Avec l'opale du Maroc l'étude en pâte pure a montré un très fort effet pouzzolanique avec diminution de la chaux dès l'échéance de 3 mois et une atténuation rapide de la bande de diffraction de la silice.

Nous avons par ailleurs utilisé une méthode de détermination accélérée des résistances par étuvage dans l'eau à 80°C d'éprouvettes de mortier. Les échéances choisies étaient à 20 h, 44 h, 146 h, un même degré d'avancement de la réaction étant obtenu dans un temps environ 25 fois plus court qu'à 20°C. La résistance des éprouvettes à 30 % de Volvic ou d'opale du Maroc a été comparée à celle d'éprouvettes témoins de CPA pur d'une part, de CPA additionné de 30 % de quartz d'autre part. La figure 10 montre clairement l'effet pouzzolanique obtenu (zone hachurée) dès l'échéance de 20 h. Le développement des résistances est moins rapide avec Volvic mais la réaction pouzzolanique est cependant nettement visible par rapport à l'inerte dès 20 h (équivalent 28 j).

Un même résultat avait été obtenu avec un ciment à 30 % de cendre volante étuvé 7 j à 80°C (fig. 11 & 12).

## CONCLUSION

Nous pensons avoir montré que la valeur pouzzolanique d'un ajout doit être appréciée en fonction de plusieurs éléments tels que la composition chimique, la minéralogie, la finesse du broyage, la surface spécifique BET.

Pour les pouzzolanes à phase vitreuse, plus celle-ci est abondante meilleure est la réactivité mais à finesse égale les pouzzolanes à zéolithes réagissent plus rapidement que les premières. Les cendres volantes peuvent donner d'excellents résultats mais la finesse de broyage joue un grand rôle.

Nous avons montré que la vitesse d'hydratation de la pouzzolane et les résistances obtenues sur mortier étaient en rapport avec la fixation de  $\text{Ca(OH)}_2$  mais d'autres éléments doivent parfois être pris en compte comme l'interaction ciment-pouzzolane.

L'essai accéléré par étuvage semble un moyen très intéressant d'évaluation rapide d'une pouzzolane.

# Caractérisation de la pouzzolanité de cendres volantes

## *Characterization of the pozzolanicity of fly ash*

A. VERHASSELT, Docteur en Sciences, Chercheur, Centre de Recherches Routières, Bruxelles, Belgique.

**RESUME :** En partant de la description d'un matériau pouzzolanique, quatre grandeurs, qui permettent d'évaluer le niveau de pouzzolanité à travers les manifestations chimiques et mécaniques de celle-ci, ont été définies : l'activité, la réactivité, l'efficacité pouzzolanique et l'efficacité pouzzolanique relative.

Avec comme objectif une appréciation valable et non équivoque de la pouzzolanité d'un matériau à partir de ces grandeurs, une méthode d'essai a été mise au point et testée, son originalité résidant dans la manière de combiner les différents paramètres mécaniques et chimiques mesurés. Cette méthode permet, dans un premier stade, de classer les matériaux pouzzolaniques par rapport à un produit de référence suivant leur qualité pouzzolanique et la vitesse d'évolution des réactions pouzzolaniques. Dans un second stade, sur base d'un indice de qualité pouzzolanique, chiffre synthétisant l'ensemble des résultats, elle permet de les répartir entre différentes classes pouzzolaniques qui ont pour but d'orienter le matériau examiné vers des utilisations en rapport avec son indice : matériau à traiter (amélioration ou stabilisation), liant pouzzolanique, ajout pour ciment....

Une pouzzolane broyée et quelques cendres volantes étudiées selon la méthode standardisée décrite se sont réparties entre trois classes, mais d'une manière plus fréquente entre les deux auxquelles correspondent les utilisations appropriées du type "liant pouzzolanique" et "ajout pour ciment".

Pour ces échantillons, aucune relation entre les différentes grandeurs pouzzolaniques déterminées et les caractéristiques physico-chimiques mesurées ne s'est dégagée.

**SUMMARY :** Based on the description of a pozzolanic material four quantities have been defined : pozzolanic activity, reactivity, efficiency and relative pozzolanic efficiency. These quantities enable us to assess the pozzolanic level of a material through the chemical and mechanical signs of its pozzolanicity.

With a view to making a valid and unequivocal assessment of the pozzolanicity of a material upon those quantities, a testing method has been developed and tried; its originality lies in the manner of combining the different measured mechanical and chemical parameters. This method enables us in a first stage to classify pozzolanic materials compared to a reference product according to their pozzolanic quality and to the evolution rate of pozzolanic reactions. In a second stage it allows to divide them into different pozzolanic classes on ground of a pozzolanic quality index that synthesizes the obtained results as a whole. The purpose of those classes is to associate the use of the material investigated to its index : material to be treated (amelioration or stabilization), pozzolanic binder, admixture for cement....

One milled pozzolana and a few flyashes have been studied according to the described standardised method. They spread over three classes, but mainly over those two that correspond to their use as "pozzolanic binder" or "admixture for cement".

For those samples no relation between the different determined pozzolanic quantities and measured physico-chemical properties has emerged.

## 1. INTRODUCTION

Les cendres volantes, rebut des centrales électriques consommant du charbon, trouvent de plus en plus de débouchés dans la construction routière, dans le génie civil et dans l'industrie cimentière (réf. 1, 2).

Une grande partie des utilisations possibles se basent sur le caractère pouzzolanique plus ou moins prononcé de ces cendres. Si le concept de la pouzzolanité semble assez bien établi, il n'en va pas de même pour l'appréciation quantitative de celle-ci ou de son niveau (réf. 3, 4): les voies suivies considèrent, en effet, soit l'aspect chimique soit l'aspect mécanique des manifestations de la pouzzolanité alors que les deux sont intimement liés.

Une méthode de caractérisation globale et non équivoque a été mise au point et appliquée à différents matériaux pouzzolaniques et, entre autres, à différentes cendres volantes. Cette caractérisation permet de proposer des utilisations adéquates en rapport avec le niveau de pouzzolanité des matériaux.

## 2. DEFINITIONS

D'une manière générale, une cendre volante est un matériau pouzzolanique, c'est-à-dire un matériau silico-alumineux, généralement pauvre en oxyde de calcium sous forme liée ou disponible (souvent moins de 5%), et dont la solubilisation partielle par l'attaque d'une solution aqueuse d'hydroxyde de calcium conduit à la formation de substances ayant des propriétés liantes analogues à celles d'un liant hydraulique.

D'un point de vue pratique, c'est donc un matériau qui a la faculté de former à la température ordinaire, en présence d'eau et par combinaison avec de la chaux, des composés hydratés et stables, résultat d'une réaction chimique dite pouzzolanique dont un autre résultat est l'obtention d'un mélange durci.

Il résulte de ce qui précède que, pour caractériser d'une manière valable et non équivoque la pouzzolanité (ou son niveau) d'une cendre volante ou d'un autre matériau pouzzolanique, il est nécessaire de considérer simultanément les aspects chimique et mécanique des manifestations de cette pouzzolanité. Dans ce but, quatre grandeurs, calculées à partir d'essais effectués dans des conditions standardisées, précisées au § 3, ont été définies :

- (1)  $\Delta R'_c$  ou  $\Delta S_t$  : activité pouzzolanique (aspect mécanique) définie conventionnellement comme l'augmentation de résistance à la compression uniaxiale ( $\Delta R'_c$ ) ou à la traction par compression diamétrale ( $\Delta S_t$ ), en  $\text{MN/m}^2$ ;
- (2)  $\Delta \text{CaO cons}$  : réactivité pouzzolanique (aspect chimique) définie conventionnellement comme la quantité d'oxyde de calcium consommée, en pourcent en masse de mélange sec décrit au § 3;
- (3) EPz : efficacité pouzzolanique (aspects mécanique et chimique combinés) définie par le rapport
 
$$\frac{\text{activité pouzzolanique}}{\text{réactivité pouzzolanique}} = \frac{\Delta R'_c \text{ ou } \Delta S_t}{\Delta \text{CaO cons}}$$

qui représente l'augmentation de résistance ( $R'_c$  ou  $S_t$ ) associée à une consommation de un pourcent d'oxyde de calcium, en  $\text{MN/m}^2 \cdot \% \text{ CaO cons}$ .

- (4) EPzR : efficacité pouzzolanique relative : rapport de l'efficacité pouzzolanique du matériau étudié à celle de l'hydroxyde d'aluminium, choisi comme matériau pouzzolanique de référence.

Par extension et pour permettre une comparaison avec d'autres essais (l'essai Chapelle, par exemple), on peut généraliser les deux premières grandeurs en les rapportant à la concentration de matériau pouzzolanique dans le mélange sec (18,75g/100g pour le mélange utilisé) et définir ainsi une activité et une réactivité pouzzolaniques spécifiques.

## 3. DESCRIPTION RESUMEE D'UNE METHODE D'APPRECIATION DU NIVEAU DE POZZOLANICITE D'UN MATERIAU

Les grandeurs définies ci-dessus sont évaluées à partir de mesures (1) de résistance à la compression uniaxiale ou à la traction par compression diamétrale (vitesse 1, 27 mm/min) et (2) de consommation d'oxyde de calcium pour des mélanges constitués de :

- . 12 parts de sable normalisé (réf. 5)
- . 4 parts de liant pouzzolanique, composé de 3 parts de matériau pouzzolanique à étudier et de 1 part de chaux grasse hydratée (réf. 6, 7)
- . et de 1,6 parts d'eau, soit une teneur en eau de 10%.

Fig. 1: Efficacité pouzzolanique relative de quelques matériaux (cendres volantes nos 9, 17, 18, 21, 32, 33 et 44, pouzzolane P2, limon n°362 et farine de quartz n°14) en fonction de la consommation de CaO - Essais de  $R'_c$

Les éprouvettes cylindriques de 5 cm de diamètre sur 10 cm de haut après moulage à une masse volumique apparente sèche de  $1,85 \text{ g/cm}^3$  par compression sur les deux faces, sont conservées à  $20^\circ\text{C}$  et  $40^\circ\text{C}$  en atmosphère humide saturée. Les essais sont effectués à 0, 7 et 28 jours d'âge, l'essai à 0 jour servant de blanc.

Pour la détermination de l'oxyde de calcium consommé, la méthode est décrite dans la référence 8 : elle repose sur des extractions successives par une solution de saccharose ( $\text{CaO}$  non fixé) et par une solution de tampon formique ( $\text{CaO}$  fixé et consommé).

Pour l'interprétation des résultats des quatre essais (7 et 28 jours à  $20^\circ\text{C}$  et  $40^\circ\text{C}$ , l'âge 0 servant de point de départ pour le calcul de  $\Delta R'_c$  ou  $\Delta S_t$  et de  $\Delta \text{CaOcons}$ ) trois stades successifs sont envisagés :

1° vue détaillée : mise en diagramme de l'efficacité pouzzolanique relative en fonction de la réactivité pouzzolanique ( $\text{EPzR}$ ,  $\Delta \text{CaO}$ ) : le graphique peut se présenter sous forme d'une droite ou d'une courbe dont la concavité peut être tournée vers le haut ou vers le bas (fig. 1). Diverses informations peuvent en être déduites, entre autres : comportement du liant pouzzolanique à court et à long terme, importance de l'effet de la température, résistance que pourrait atteindre le mélange à différents degrés d'avancement de la réaction, vitesse de réaction, estimation

de la dose de chaux nécessaire pour atteindre une résistance donnée.

2° caractérisation globale : sur la base du calcul des valeurs moyennes (résultats à 7 et 28 jours, à  $20^\circ\text{C}$  et  $40^\circ\text{C}$ ), d'une part, de l'oxyde de calcium consommé et, d'autre part, de l'efficacité pouzzolanique relative, valeurs moyennes  $\Delta \text{CaOcons}$  et  $\text{EPzR}$  qui sont les coordonnées du "point moyen", on peut situer le matériau dans une grille "qualité du matériau pouzzolanique-évolution des réactions pouzzolaniques", comme il est montré dans la fig. 2. Cette qualité est d'autant meilleure qu'est élevée la valeur de l'efficacité pouzzolanique relative et le durcissement du mélange se déroule à une vitesse d'autant plus grande que l'évolution des réactions pouzzolaniques est rapide.

3° caractérisation globale synthétique : la caractérisation globale de la pouzzolanité d'un matériau basée ainsi sur la détermination des deux paramètres  $\Delta \text{CaOcons}$  et  $\text{EPzR}$ , peut être exprimée plus synthétiquement par le résultat de leur produit, c'est-à-dire par un seul chiffre que l'on propose d'appeler "indice de qualité pouzzolanique ( $\text{IQPz}$ )" :

$$\text{IQPz} = \text{EPzR} \cdot \Delta \text{CaOcons} \quad (1)$$

Cet indice serait ainsi pour les matériaux pouzzolaniques ce qu'est le coefficient d'activité  $\alpha$  pour les laitiers granulés.

Cet indice permet de caractériser d'une manière simple et globale la pouzzolanité d'un matériau

**TABEAU I : Exemple de classification des matériaux pouzzolaniques sur base de leur indice de qualité pouzzolanique (en considérant, par exemple, la résistance à la compression uniaxiale)**

Classe	Position du point moyen représentatif du matériau (voir figure 2)	Indice de qualité pouzzolanique $\text{IQPz}$ (voir figure 3)	Exemples d'utilisations appropriées
0	entre 0 et la courbe $\Delta R'_c = 1 \text{ MN/m}^2$	$0 \leq \text{IQPz} < 3,6$	tel quel * ou après traitement à la chaux, au ciment, à la chaux et au ciment ou avec un mélange chaux/gypse
1	entre les courbes $\Delta R'_c = 1$ et $\Delta R'_c = 2 \text{ MN/m}^2$	$3,6 \leq \text{IQPz} < 7,15$	- après traitement à la chaux ou au mélange chaux/gypse - comme liant pouzzolanique de qualité médiocre (après mélange avec de la chaux ou avec de la chaux et du gypse)
2	entre les courbes $\Delta R'_c = 2$ et $\Delta R'_c = 3 \text{ MN/m}^2$	$7,15 \leq \text{IQPz} < 10,7$	- comme liant pouzzolanique de qualité croissante, le matériau étant utilisé en fonction de sa classe et des buts poursuivis (sous-fondations, fondations, fabrication de blocs...) ou - comme ajout pour ciment ou comme substitut du clinker du ciment (ciments aux cendres volantes ou aux pouzzolanes)
3	entre les courbes $\Delta R'_c = 3$ et $\Delta R'_c = 4 \text{ MN/m}^2$	$10,7 \leq \text{IQPz} < 14,3$	
4	entre les courbes $\Delta R'_c = 4$ et $\Delta R'_c = 5 \text{ MN/m}^2$	$14,3 \leq \text{IQPz} < 17,9$	
5	au-delà de la courbe $\Delta R'_c = 5 \text{ MN/m}^2$	$17,9 \leq \text{IQPz}$	

\* si le matériau n'est pas à déclasser sur le plan géotechnique ou sur le plan économique

donné et constitue dès lors un moyen de comparaison facile de différents matériaux pouzzolaniques. On perd toutefois une partie des informations : lors de la comparaison de deux matériaux d'indice de qualité pouzzolanique équivalent, il se peut que pour l'un deux, une efficacité pouzzolanique relative moyenne  $\overline{EPzR}$  beaucoup plus petite soit compensée par une évolution des réactions ( $\Delta CaO_{cons}$ ) beaucoup plus rapide ; lors de la formulation d'un mélange, il sera nécessaire de tenir compte de ces faits pour les proportions matériau pouzzolanique/chaux.

Les courbes d'égale augmentation de résistance (fig. 2) étant également des courbes d'indice de qualité pouzzolanique constant ( $\overline{EPzR} \cdot \Delta CaO = \text{constante}$ ), elles peuvent servir à délimiter des classes de matériaux pouzzolaniques, classes qui ont pour but d'orienter le matériau examiné vers des utilisations en rapport avec son IQPz. Un exemple de classification est proposé dans le tableau I et la fig. 3 donne l'aspect synthétique ainsi obtenu pour différentes cendres volantes et pour quelques autres matériaux pouzzolaniques.

Fig. 2: Caractérisation de la pouzzolanité de différentes cendres volantes (nos 9, 17, 18, 21, 32, 33 et 44) et de quelques autres matériaux à titre de comparaison (pouzzolane P2, limon n° 362 et farine de quartz  $SiO_2$  n° 14) sur base de la position du "point moyen" :

. efficacité pz moy. en traction $\overline{EPz}$	MN/m².%CaO	n. d.	0,0274 <sup>±</sup> 0,003 <sub>5</sub>

#### 4. DONNEES CONCERNANT LE MATERIAU POZZOLANIQUE DE REFERENCE, L'HYDROXYDE D'ALUMINIUM

L'hydroxyde d'aluminium  $Al(OH)_3$  utilisé est de l'hydrargillite pure en poudre très fine (produit Merck n°1093). Deux échantillons différents, dont les principales caractéristiques figurent au tableau II, ont été étudiés du point de vue de leur pouzzolanité dans les conditions standardisées décrites au § 3. Les résultats sont donnés dans le même tableau.

Par définition, leur efficacité pouzzolanique relative vaut 1. En conséquence : leur qualité pouzzolanique est médiocre (mais l'évolution des réactions est rapide), leur indice de qualité pouzzolanique vaut 2, 8 et

2, 6 respectivement pour l'échantillon A et B et ils font partie de la classe 0.

Ce type d'hydroxyde d'aluminium convient bien comme matériau pouzzolanique de référence, car son efficacité pouzzolanique ne dépend pas ou peu du degré d'avancement des réactions ni, dans les limites des essais effectués, des caractéristiques physico-chimiques de l'échantillon (mais elles influencent la réactivité pouzzolanique de celui-ci : voir tableau II). Les valeurs adoptées comme référence pour l'efficacité pouzzolanique de l'hydroxyde d'aluminium sont 0,28 et 0,027  $MN/m^2 \cdot \%CaO$  cons respectivement pour les essais en compression et pour ceux en traction par compression diamétrale.

## 5. APPRECIATION DE LA POZZOLANICITE DE CENDRES VOLANTES

Le niveau de pouzzolanité de différentes cendres volantes et, à titre de comparaison, de quelques autres matériaux a été évalué suivant la méthode décrite au § 3. Les résultats sont rassemblés dans le tableau III où figurent aussi les principales caractéristiques physico-chimiques de ces matériaux.

Ce tableau ainsi que les figures 1, 2 et 3 montrent, pour les matériaux étudiés, que :

- il y a des différences relativement importantes quant à la pouzzolanité ou à son niveau ;
- en général, l'efficacité pouzzolanique relative moyenne en traction par compression diamétrale est un peu plus grande que celle en compression uniaxiale. La différence dépassant assez rarement 10%, on pourrait donc en pratique se limiter à un seul type de mesure de résistance mécanique, soit par compression simple soit par compression diamétrale (le choix étant fonction de l'équipement du laboratoire et de l'expérience acquise).

En ce qui concerne plus particulièrement les cendres volantes, les constatations sont les suivantes :

- le niveau de pouzzolanité diffère assez fortement de l'une à l'autre et ceci ne peut pas être mis en relation avec le fait que la cendre provient d'une production récente ou d'un dépôt âgé de plusieurs années ;
- pour ces échantillons, il ne se dégage aucune relation entre le niveau de sa pouzzolanité (aussi bien à travers la réactivité que l'activité ou l'indice de qualité pouzzolanique) et une des caractéristiques physico-chimiques déterminées : l'IQPz augmente de 3 unités environ à plus de 5 pour des valeurs équivalentes de la masse volumique (cendres n° 9 et 32), de la masse volumique apparente après sédimentation dans le toluène (n°44 et 18), de la surface spécifique Blaine (n°9 et 33), du passant au tamis de 45 µm (n°9 et 33 et n°44 et 17 ou 32) ;
- la cendre volante qui consomme le moins de CaO est celle qui a la plus grande efficacité pouzzolanique relative moyenne (échantillon n°17) et inversement pour l'échantillon n°21. Or à l'analyse chimique, la cendre n°17 se révèle comme étant celle contenant la plus haute teneur en imbrûlés. La présence de ce carbone imbrûlé ne semble donc pas être un facteur affectant a priori négativement la pouzzolanité du matériau.

Les résultats obtenus pour ces échantillons de cendres volantes montrent clairement que, pour exploiter au mieux les propriétés pouzzolaniques d'un matériau, il est nécessaire d'apprécier sa pouzzolanité en même temps à travers les aspects chimique et mécanique des manifestations de celle-ci.

Le niveau de pouzzolanité étant fortement lié à la granularité du produit, son appréciation doit se faire sur le matériau dans son état naturel ou après broyage suivant le type d'utilisation prévu.

## 6. CONCLUSIONS

Les manifestations de la pouzzolanité d'un matériau ayant en même temps un aspect chimique et

mécanique, une appréciation valable et non équivoque du niveau de cette pouzzolanité doit faire appel simultanément à ces deux aspects.

La méthode d'essai décrite permet, dans des conditions standardisées, de déterminer les paramètres mécaniques et chimiques nécessaires à cette appréciation et de là, in fine, de répartir les matériaux entre différentes classes pouzzolaniques auxquelles correspondent des utilisations appropriées.

Les résultats obtenus pour diverses cendres volantes et une pouzzolane broyée ont montré l'utilité d'une telle méthode, car il ne se dégage aucune relation entre les différents aspects de la pouzzolanité et une des caractéristiques physico-chimiques mesurées.

Pour six des sept cendres volantes étudiées, les utilisations appropriées sont du type "liant pouzzolanique" ou "ajout pour ciment", la septième cendre ainsi que la pouzzolane broyée, étant plutôt à considérer comme un matériau à utiliser après traitement (amélioration ou stabilisation).

## REMERCIEMENTS

L'auteur remercie Monsieur J. Reichert, Directeur, Monsieur J. Verstraeten, Directeur -Adjoint - Chef de la Division Recherches et Monsieur J. Huet, Chef du Service des Méthodes de Mesure du Centre de Recherches Routières sous la direction de qui ce travail a été effectué.

Il remercie également le Pool des Calories pour son aide financière dans la réalisation d'une partie de ces travaux.

# Sur le mécanisme de l'expansion des ciments expansifs

## *Expansion Mechanisms of Expansive Cements*

V. MOLDOVAN, Professeur, ing. dr. Institut de Construction Bucarest, Roumanie,  
N. BUTUCESCU, Ingénieur, Institut de Recherche pour Matériaux de construction Bucarest.

**RESUME:** La composition des ciments expansifs et les conditions d'utilisation sont étroitement liées au mécanisme d'expansion déterminé par la formation d'ettringite.

Les recherches effectuées sur quelques ciments:

(a) ciment expansif constitué d'un mélange de ciment portland + ciment alumineux + gypse + pouzzolane;

(b) ciment portland (contenant 11%  $C_3A$ ) + 12% gypse

(c) ciment alumineux (contenant 70% CA) + 12% gypse

permettent de conclure que la formation d'ettringite (mis en évidence par analyse diffractométrique aux rayons X) a déterminé une expansion (sur éprouvettes 4x4x16 cm) de 10 mm/m pour le ciment (a), 4 mm/m pour le ciment (b) et sans expansion pour le ciment (c).

La composition chimique de la phase liquide en équilibre avec les ciments étudiés met en évidence la présence d' $Al_2O_3$  en solution seulement pour le ciment (c). Des recherches électro-microscopiques des pâtes et des suspensions soulignent le fait que la cristallisation d'ettringite dans l'espace intergranulaire ne produit pas une expansion et c'est vrai même pour le ciment expansif dans un excès d'eau. La vraie cause de l'expansion c'est la cristallisation d'ettringite, en l'absence d' $Al_2O_3$  en solution, à la surface des grains anhydres par voie topochemique; elle contribue à l'accroissement des résistances mécaniques.

**SUMMARY:** The composition of expansive cements and the conditions of use are closely linked with the expansion mechanism determined by the formation of ettringite.

Research carried on with such cements:

(a) expansive cement made up of a mixture of Portland cement + aluminous + gypsum + pozzolanas;

(b) portland cement (containing 11%  $C_3A$ ) + 12% gypsum;

(c) aluminous cement (containing 70% CA) + gypsum,

lead us to the conclusion that the formation of ettringite (evinced by X-ray diffraction) determined an expansion (on prism 4x4x16 cm) of 10 mm/m for cement (a), 4 mm/m for cement (b) and without expansion for cement (c).

The chemical composition of the liquid phase in equilibrium with the studied cements evinced existence of  $Al_2O_3$  in solution only for the cement (c). Electronmicroscopical research of pastes and suspensions underlies the fact that the crystallization of ettringite in intergrain space does not produce an expansion, as this is true even for expansive cement E when an excess of water is used. Expansion is in fact determined by crystallisation of ettringite, in the absence of  $Al_2O_3$  in solution, on the surface of anhydrous grains topochemically and contribute to the increase of mechanic strength.

## 1. GENERALITÉS

De nombreuses recherches pendant les dernières années donnent des explications différentes au mécanisme d'expansion des ciments expansifs dont l'expansion est basée sur la formation d'ettringite. Ainsi l'expansion est attribuée: à la formation d'ettringite sans dissolution des sels anhydres [1], à la transformation du monosulfate hydraté en trisulfate hydraté [2], à la pression osmotique de la solution [3], à la cristallisation d'ettringite via solution [4], soit à la structure colloïdale d'ettringite qui gonfle par adsorption d'eau [5]. Les expansions élevées et les grandes résistances mécaniques dans la période initial d'hydratations des plusieurs ciments actuelles sont conditionnées par le mécanisme de la formation d'ettringite, par sa structure et ses propriétés.

A l'occasion des travaux d'imperméabilisation du métro de Bucarest nous avons étudié le mécanisme d'expansion du ciment expansif "E" constitué en principal d'un mélange: clinker portland + ciment alumineux + gyps + pouzzolane. La composition chimique des constituants et du ciment "E" est présentée dans le tableau I.

Compos. chimique	$S_1O_2$ ins%	$Al_2O_3$ %	$Fe_2O_3$ %	CaO %	MgO %	$SO_3$ %	$Na_2O + K_2O$ %	P <sub>c</sub> %
clinker portland	21	5,75	5,35	64,5	0,89	0,61	0,84	0,76
ciments alumineux	6,49	41,6	15	32,3	0,40	0,10	0,36	0,9
ciment expansif "E"	28,2	9,53	4,53	45,2	1,49	5,71	1,16	3,49
gyps	92% $CaSO_4 \cdot 2H_2O$ *							

\* notations abrégées:  $C_a = CaSO_4$ ;  $S = S_1O_2$ ;  
 $C = CaO$ ;  $F = Fe_2O_3$ ;  $A = Al_2O_3$ ;  $H = H_2O$

Pour étudier le mécanisme d'expansion nous avons préparé deux autres composition en utilisant:

- le clinker portland (ayant 11%  $C_3A$ ) (tableau I) + 12% gyps, noté  $A_G$ ;

- le ciment alumineux, ayant 70%  $CA$ , (tableau I) + 12% gyps, noté  $A_G$ .

Nous avons utilisé comme méthodes de recherche: l'analyse diffractométrique aux rayons X, la mesure des variations dimensionnelles des éprouvettes, l'analyse chimique de la phase liquide et la microscopie électronique.

## 2. RESULTATS

2.1. L'analyse diffractométrique a été effectuée sur les mélanges:  $CA + gyps$  (1:3) et  $C_3A + gyps$  (1:3). Nous avons préparé des pâtes (rapport  $\frac{eau}{solide} = 1$ ) en solution saturée en chaux ou en utilisant de l'eau distillée. Les résultats obtenus à 1 et 7 jours sont présentés dans le tableau II:

Nr.	Mélange analyse	Temps jours	Intensité de la raie caractéristique*	
			$C_sH_2$	$C_3A \cdot 3C_sH_2$
1.	$CA + C_s + H_2O$	1	145	40
2.	$CA + C_s + Ca(OH)_2$	1	115	40
3.	$CA + C_s + H_2O$	7	70	125
4.	$CA + C_s + Ca(OH)_2$	7	70	108
5.	$C_3A + C_s + H_2O$	1	138	65
6.	$C_3A + C_s + Ca(OH)_2$	1	135	57
7.	$C_3A + C_s + H_2O$	7	45	145
8.	$C_3A + C_s + Ca(OH)_2$	7	28	180

\* Les déterminations pratiques ont été effectuées par nos collaborateurs ing.dr. F. Paul et ing. M. Crișan.

Pendant la période 1 à 7 jours la formation d'ettringite est intense pour tous les systèmes étudiés au fur et à mesure que la quantité du gypse diminue. Nous n'avons pas constaté la présence d'hydroaluminate de calcium monosulfaté.

2.2. Les variations dimensionnelles des pâtes ( $\frac{eau}{ciment} = 0,35$ ) sur éprouvettes  $4 \times 4 \times 16$  cm ont été déterminées pour les ciments:  $E$  (expansif),  $P_E$  (portland + 12% gyps) et  $A_G$  (alumineux + 12% gyps). Les éprouvettes ont été conservées dans l'eau pendant les 28 premiers jours, puis à l'humidité de 65% et à la température  $20^\circ C$  jusqu'à 240 jours. Les résultats sont

présentés sur la figure 1.

Fig.1. Les variations dimensionnelles des éprouvettes pour les ciments E, P<sub>E</sub>, A<sub>G</sub>

Il en résulte des variations dimensionnelles résiduelles à 240 jours: + 5 mm/m pour le ciment E, - 1 mm/m pour le ciment P<sub>E</sub> et - 5 mm/m pour le ciment A<sub>G</sub> qui n'est pas un ciment expansif et qui a eu une très grande contraction.

L'analyse diffractométrique aux rayons X effectuée le trentième jour sur les pâtes durcies, a bien mis en évidence les raies caractéristique de l'ettringite pour tous les ciments étudiés.

2.3. La composition chimique de la phase liquide en équilibre avec les ciments étudiés (E, P<sub>E</sub>, A<sub>G</sub>) au cours d'hydratation dans les premiers 7 jours effectuée sur le fil-trat (rapport  $\frac{\text{eau}}{\text{ciment}} = 1$ ) est présentée dans le tableau III.

Dans nos conditions de travail (rapport  $\frac{\text{eau}}{\text{ciment}} = 1$ ) la basicité élevée et l'insolubilisation d'Al<sub>2</sub>O<sub>3</sub> est assurée pour le ciment E dans les 3 premiers jours, pour le ciment P<sub>E</sub> pendant les premiers 10 heures et pour le ciment A<sub>G</sub> la quantité de CaO n'atteint pas le degré de saturation et diminue après 3 heures ce qui détermine la

présence d'Al<sub>2</sub>O<sub>3</sub> en solution.

Les faits expérimentaux (fig.1 et tableau III) mettent en évidence le fait que seulement l'absence d'Al<sub>2</sub>O<sub>3</sub> en solution peut déterminer des expansions en accord avec la théorie d'Henri Lafuma [1]. Mais la contribution indubitable de l'ettringite à l'accroissement des résistances mécaniques dans la période initiale de durcissement souligne la complexité du phénomène en ce qui concerne la cinétique de la formation d'ettringite. En fonction de la basicité de la solution (influencée par la présence des alcalis), des cristaux d'ettringite peuvent se former dans l'espace intergranulaire ou des cristaux d'ettringite peuvent se former à la surface des grains anhydres et ce le cas des ciments expansifs, comme nous avons constaté par des nombreuses observations électromicroscopiques présentées ci-dessous.

TABLEAU III								
Ciment	Composition de la phase liquide g/l	T E M P S						
		10 min	1 h	3 h	10 h	24 h	3 j	7 j
E	CaO	1,14	1,24	1,8	1,81	1,83	0,92	0,486
	SO <sub>3</sub>	1,25	1,33	1,6	1,76	1,82	0,64	0,345
	Al <sub>2</sub> O <sub>3</sub>	0,0016	0,0016	0,0018	0,0020	0,0022	0,0020	0,0021
	Na <sub>2</sub> O+K <sub>2</sub> O	0,80	1,10	1,30	1,56	1,65	2,00	2,32
	PH	11,5	11,5	11,5	11,5	11,5	11,5	11,5
P <sub>E</sub>	CaO	1,46	1,71	1,54	0,98	0,30	0,29	0,24
	SO <sub>3</sub>	1,75	1,63	1,66	1,00	0,25	0,022	0,027
	Al <sub>2</sub> O <sub>3</sub>	0,0042	0,052	0,043	0,054	0,054	0,083	0,088
	Na <sub>2</sub> O+K <sub>2</sub> O	1,75	1,85	1,70	2,50	4,10	4,93	5,75
	PH	11,7	11,8	11,8	11,5	11,7	11,8	11,8
A <sub>G</sub>	CaO	0,365	0,776	0,511	-	0,113	0,113	0,022
	SO <sub>3</sub>	0,585	0,932	0,64	0,45	-	0,048	0,049
	Al <sub>2</sub> O <sub>3</sub>	0,40	0,40	0,427	0,47	-	0,506	0,480
	Na <sub>2</sub> O+K <sub>2</sub> O	0,003	0,003	0,002	0,003	0,005	0,005	0,17

2.4. Les recherches electronomicroscopiques effectuées sur pâtes ( $\frac{\text{eau}}{\text{ciment}} = 0,35..1$ ) et sur des suspensions ( $\frac{\text{eau}}{\text{ciment}} = 25..50$ ) aqueuses dans le 5 premières heures d'hydratation ont mis en evidence quelques faits experimentaux présentés ci-dessous.

L'hydratation du ciment E en pâtes est caractérisée par l'apparition des produits d'hydratation de type ettringite à la surface des grains anhydres (fig.2). Dans la période initiale d'hydratation il n'y a pas des produits d'hydratation dans l'espace intergranulaire.

Fig.2. Produits d'hydratation (ettringite)  $\frac{a}{c} = 0,50$ ; 30 min, 30.000 x  
Pour un excès d'eau, la majorité des produits d'hydratation dans l'intervalle

5 min-1 heure sont apparus dans l'espace intergranulaire (fig.3). Le processus est semblable pur le ciment P<sub>E</sub>.

Fig.3. Produits d'hydratation (ettringite)  $\frac{a}{c} = 25$ ; 15 min, 5.000 x.

Dans le cas du ciment A ce qui caractérise l'hydratation c'est l'apparition des produits d'hydratation via solution dans l'espace intergranulaire.

### 3. CONSIDERATIONS SUR LE MÉCANISME D'EXPANSION

Les recherches de fractométriques et par l'analyse thermodynamique (les dernières n'étant pas présentées dans le présent article) n'ont pas mis en evidence l'existence du monosulfate hydraté.

La forme extérieure et les dimensions des cristaux d'ettringite sont influencées par les conditions de leur formation. L'apparition d'ettringite par cristallisation dans l'espace intergranulaire, en présence d' $\text{Al}_2\text{O}_3$  en solution, ne produit pas une expansion. La vraie cause de l'expansion c'est la formation d'ettringite à la surface des grains anhydres en présence d'une solution saturée en  $\text{Ca}(\text{OH})_2$  et en l'absence d' $\text{Al}_2\text{O}_3$  en solution. Des pressions de cristallisation locales déterminent l'augmentation du volume du système déformable. Une explication semblable a été donnée dans la recherche [6]. La saturation en  $\text{CaO}$  de la solution avec l'insolubilisation d' $\text{Al}_2\text{O}_3$  est décisive plutôt que la valeur du pH de la solution [7] influencée aussi par la présence des alcalis du ciment. Les faits expérimentaux présentés et des calculs thermodynamique [8] sont favorables à la réaction de gypse dissout sur les aluminates solides.

La voie par laquelle les cristaux d'ettringite sont apparus à la surface des grains anhydres c'est l'hydratation sans dissolution des aluminates anhydres en présence du gypse, mécanisme basé sur la grande mobilité du  $\text{CaO}$  des composants anhydres et hydratés. Des phénomènes de recristallisation d'ettringite pendant l'hydratation ont été aussi observés. Les cristaux d'ettringite peuvent s'enchevêtrer entre eux ou avec des autres produits. La valeur élevée de l'expansion et les grandes résistances mécaniques de plusieurs ciments expansifs actuels doivent être liées aux propriétés d'ettringite comme élément de résistance pendant son existence. Dans le cas des produits durcis la formation d'une petite quantité d'ettringite par voie topochimique à la surface des grains anhydres peut provoquer la pulvérisation des produits.

## Magnesium oxide additive for producing selfstress in mass concrete

### *Oxyde de magnésium, additif producteur d'autocontrainte dans la masse du béton*

P.K. MEHTA and D. PIRTZ, Professors, and  
G.J. KOMANDANT, Lecturer, Department of Civil Engineering, University of California, Berkeley,  
California 94720, U.S.A.

SUMMARY: The hydration reaction of MgO was investigated for obtaining expansion in typical mass concretes. The rate of hydration of MgO additive was found to be sensitive not only to the calcination temperature and particle size of MgO, but also to curing temperature of concrete. The additive made by calcination above 970°C was too slow to hydrate, whereas the material calcined below 900°C hydrated too rapidly to be useful for producing self-stress in concrete. Particles > 1180  $\mu\text{m}$  produced large differential expansions in concrete which led to internal distress. Expansive additive for portland cement in the form of 5% MgO calcined at 900-950°C, and sized to 300-1180  $\mu\text{m}$ , hydrated at a rate which was considered adequate with regard to expansion and self-stress necessary for producing crack resistance in typical mass concrete structures exposed to 32-54°C.

RÉSUMÉ: La réaction d'hydratation de MgO a été étudiée afin d'obtenir une expansion dans la masse de bétons typiques. Le taux d'hydratation de MgO a été trouvé sensible non seulement à la température de calcination et à la taille de la particule MgO mais aussi à la température de cure du béton. L'additif préparé, par calcination au-dessus de 970°C, s'hydratait trop lentement tandis que le matériau calciné en-dessous de 900°C s'hydratait trop rapidement pour être utile dans la production d'une autocontrainte du béton. Les particules supérieures à 1180  $\mu\text{m}$  ont produit de grandes expansions différentielles dans le béton entraînant des détériorations internes. L'additif expansif pour le ciment Portland, sous la forme de 5% MgO calciné à 900-950°C et de taille comprise entre 300 et 1180  $\mu\text{m}$  s'est hydraté à un taux qui a été considéré comme adéquat vis-à-vis de l'expansion et de l'autocontrainte nécessaires à la production d'une résistance à la fissuration dans la masse de bétons de structure typiques exposés à 32-54°C.

## INTRODUCTION

Mass concrete structures may crack due to thermal tensile stresses unless appropriate measures are taken to control the temperature gradient within the structure. Excessive tensile stresses capable of cracking concrete can occur when concrete under restraint cools from higher temperatures caused by the heat of cement hydration to ambient temperatures.

Currently, the primary measure taken to prevent cracking consists of controlling the temperature rise by cooling the concrete. The control of temperatures in hardened concrete is an expensive procedure, at times involving internal cooling by pipe-refrigeration techniques. An alternative or supplemental procedure which needs to be investigated is to reduce the potential tensile stress which may develop on cooling by producing chemical prestress. It is theorized that the compressive stress thus established would tend to offset tensile stresses induced by cooling.

To achieve the maximum benefits in mass concrete from chemical prestressing, the compressive stresses should be formed after the temperature rise has occurred, but prior to any significant cooling of the concrete. Since mass concrete has limited ability of developing and retaining chemical prestress at early ages, the commercially available expansive cements, based on ettringite formation or  $\text{Ca}(\text{OH})_2$  formation from  $\text{CaO}$ , are of little benefit because they would undergo expansion before the maximum temperature has been reached in concrete, with the compressive stress relaxed prior to the beginning of cooling. On the other hand, expansive cements deriving their expansion from hydration of  $\text{MgO}$  to  $\text{Mg}(\text{OH})_2$  may prove useful here because the hydration-expansion phenomena due to  $\text{MgO}$  can perhaps be appropriately delayed. Several investigators have reported that the amount of expansion by  $\text{MgO}$  hydration can be controlled by calcination temperature and grain size of the product. However, in concrete there is little published information correlating the effects of heat treatment and particle size of  $\text{MgO}$ , and curing conditions, on expansion.

## MATERIALS AND PROCEDURE

The  $\text{MgO}$  used in this investigation was a high-purity pelletized material produced commercially by calcination of magnesite to  $900^\circ\text{C}$ .  $\text{MgO}$  calcined to higher temperatures were produced in the laboratory by further heat treatment of the material in an electrical furnace. Unless otherwise specified, an ASTM Type II portland cement was used for making expansive cements containing  $\text{MgO}$  as additive.

Curing temperatures in the range  $32$ – $54^\circ\text{C}$ , which is typical temperature range for uncooled mass concrete, were investigated. Hydration rates at  $32^\circ\text{C}$  were studied for  $\text{MgO}$  alone, and expansion due to  $\text{MgO}$  hydration was studied both in cement pastes and concrete. Natural sand and gravel were used for making the fineness modulus of sand 150 by 300 mm concrete cylinders containing  $\text{MgO}$  expansive cements, 2.6, and the maximum aggregate being 38 mm. The mix proportions used were typical of mass concrete in dam construction:

cement =  $124 \text{ kg/m}^3$  concrete  
 water =  $85 \text{ kg/m}^3$  concrete  
 sand =  $571 \text{ kg/m}^3$  concrete  
 gravel =  $1594 \text{ kg/m}^3$  concrete

EFFECT OF HEAT TREATMENT TEMPERATURE AND PARTICLE SIZE OF  $\text{MgO}$  ON HYDRATION:

From a preliminary investigation it was established that  $\text{MgO}$  exposed to  $>1300^\circ$  hydrated too slowly, even in  $<45 \mu\text{m}$  size fraction. Therefore, studies on hydration rates of  $\text{MgO}$  at  $32^\circ\text{C}$  were limited to the material heat treated for one hour at 900, 1000, 1100, 1200, or  $1300^\circ\text{C}$ , and subsequently fractionated into 300–150, 150–75, 75–45, and  $<45 \mu\text{m}$  fractions. The theoretical water requirement for complete hydration of  $\text{MgO}$  to  $\text{Mg}(\text{OH})_2$  corresponds to 0.45 water-solids ratio by weight. However, pastes were made with 0.6 water-solids ratio, and stored at  $32^\circ\text{C}$  in air-tight plastic vials for 90 days. At various intervals, the hydrating material was pulverized, dried at  $110^\circ\text{C}$ , and subjected to X-ray diffraction and ignition loss analyses.

For comparison purposes the data from the ignition-loss test are shown in Table 1. It is obvious from the data that, even for the  $<45 \mu\text{m}$  size fraction,  $\text{MgO}$  heated to 1200 and  $1300^\circ\text{C}$  hydrated at undesirably slow rates. Also, the 900 and  $1000^\circ\text{C}$  material hydrated too rapidly when particles were smaller than  $45 \mu\text{m}$ . It was concluded, therefore, that potentially useful  $\text{MgO}$  additives should comprise coarse fractions of the material heat treated at  $<1200^\circ\text{C}$ .

Table 1 Effect of Calcination Temperature and Particle Size of  $\text{MgO}$  on Degree of Hydration at  $32^\circ\text{C}$

calcination temperature, $^\circ\text{C}$	particle size, $\mu\text{m}$	Percent $\text{MgO}$ hydrated at age, days:

## EXPANSION IN CEMENT PASTE PRISMS:

The next phase of study involved direct investigation of free expansion of portland cement prisms containing  $\text{MgO}$  additives made by heat treatment in the temperature range  $900$ – $1150^\circ\text{C}$ . Varying amounts of 45–150  $\mu\text{m}$  additive, made under different conditions of heat treatment were added to the portland cement. The pastes were made with 0.35 water-solids ratio by weight, and cast into 80 by 14 by 3 mm prisms. The prisms were demolded at age 1 day, and then stored in water at  $32^\circ\text{C}$  up to age 90 days. The expansion data are shown in Table 2.

The expansion data from the cement paste prisms No. 1-4 showed that, generally, the expansion was directly proportional to the amount of the expansive additive present. Correlation between the rates of hydration of pure MgO (Table 1) and the degree of expansion when MgO hydrated as additive present in the portland cement (Table 2), was found to be poor. For instance, at the 32°C curing temperature, both the 45-75  $\mu$ m and the 75-150  $\mu$ m fractions of the 900°C MgO were almost completely hydrated in 28 days, however, 5 to 30 percent of the 45-150  $\mu$ m materials (Specimens 1-4), when added to the portland cement, produced less than 50 percent of the 90-day expansion during the same time period. A probable explanation for this lack of correlation is that MgO hydration in the alkaline medium of hydrated portland cement would be considerably slower than MgO hydration in a neutral environment.

FIG. 1. EXPANSION OF CEMENT PASTE PRISMS CONTAINING 10% MgO (45-150  $\mu$ m)

sion of cement pastes the expansion data of Specimen Nos. 2, 6, 8, 13, 15 and 16, which contained 10% MgO additive by weight of cement, are plotted in Fig. 1. As expected, the data showed that in the 900-1200°C range, increasing temperatures of MgO heat treatment produced correspondingly lower expansions in the prisms.

#### EXPANSION IN CONCRETE CYLINDERS:

Due to the restraining effect of aggregates in concrete the expansions were expected to be much lower than obtained in the corresponding cement paste

Table 3 Expansion in Concrete Cylinders

I	950	1180-600	5	32-43-54	35	130	275	610	635	635	635	85	89	
J	950	2360-1180	5	32-43-54	70	440	960	1015	1030	1030	1030	60	65	

In Table 2, comparison of the expansion data between specimen No. 1 and 5, and specimen No. 6 and 7 showed the effect of duration of the heat treatment period on the rate of expansion of the cements containing the MgO additives. In general, the expansion rates were significantly reduced with increase in the calcination time of MgO from 1 to 4 hours. In order to illustrate the effect of calcination temperature of MgO on expan-

prisms. From the data in Table 2, it was obvious that the heat treatment of MgO additive above 950°C would produce very low expansions in concrete within the desired time period. In order to obtain reasonable levels of expansion, it was decided to experiment with coarse fractions of MgO produced in the temperature range 900-950°C. A preliminary investigation showed that expansions were negligible when

MgO particles were less than 150  $\mu\text{m}$ . Some concrete cylinders were cured continuously at 32°C, then at 43°C for the next 7 days, and thereafter for 28 or more at 54°C. The higher curing temperature are presumably attained in mass concrete when concrete making materials are not precooled, and heat of hydration of cement is not dissipated by cold water circulation through concrete.

From the results shown in Table 3, the effect of particle size of MgO, especially of coarse fractions, on concrete expansion was highly pronounced in specimens exposed to warm curing cycle typical of uncooled mass concrete. For instance, Specimen D showed much higher expansions than Specimen C, and Specimen F showed higher expansion than Specimen E. Similarly, for Specimens G-J, the 90-day expansions were correspondingly greater for the 32-43-54°C curing cycle. It may also be noted from the data that potential expansions were stabilized earlier for the 32-43-54°C curing cycle than for the normal or 32°C curing.

#### CONCLUSION

It is concluded that carefully calcined and sized MgO powders have the potential of being useful as expansive agents for preventing cracks in mass concrete due to thermal stresses. At curing temperatures typical of uncooled mass concrete, 5 percent MgO addition to a portland cement produced a satisfactory rate of expansion provided the heat treatment of the MgO was limited to 900-950°C temperature range and the material was sized to 300-1180  $\mu\text{m}$  particles.

# Microstructure and hydration of high alumina cement clinkers

## *Microstructure et hydratation des ciments à haute teneur en alumine*

P. KITTL, Researcher, Department of Materials (IDIEM), University of Chile, Santiago, Chile,  
J.H.C. CASTRO, Professor, Department of Materials Engineering, Federal University of Sao Carlos,  
S.P. Brasil,  
L.C. POMPEU, Ceramica Saffran s/A, Betim-M.G., Brazil.

RESUME : La réactivité des ciments à teneur en alumine élevée et variée a été étudiée par des examens microstructuraux. Plusieurs compositions ont été essayées, allant de  $C_{12}A_7$  à  $CA_{3.5}$ ; les échantillons étaient préparés par fusion, suivis d'un rapide refroidissement (état vitreux). On a observé que les premiers avaient une faible réactivité avec l'eau, et que les derniers avaient par contre une grande capacité d'hydratation.

On a constaté une amélioration de la capacité d'hydratation, par la dévitrification des échantillons vitreux. Le retard à l'hydratation serait provoqué par une couche épitaxiale de 5.000 Å d'épaisseur environ, qui se développe sur les surfaces vitrifiées et les protège de l'action de l'eau. Dans les zones dévitrifiées, le mécanisme de l'hydratation est basé sur l'action de H, et la formation en rosette de  $CAH_{10}$ .

SUMMARY: The reactivity of high alumina cements of several compositions with water was studied under controlled microstructure conditions. Several compositions ranging from  $C_{12}A_7$  to  $CA_{3.5}$  were prepared by melting followed by fast cooling (vitreous state) while others of them, by sintering. The first group, shows low reactivity with water, meanwhile the last one has high capacity of hydration. By devitrification, the hydration capacity of the glass samples was developed. It was also found that the hydration mechanism in the vitreous state consists in the growth of an epitaxial layer of about 5000 Å which interrupts a further hydration process. Instead, in the devitrified state the hydration mechanism is based on defoliation by the action of H and the formation of  $CAH_{10}$  rosette shaped.

## INTRODUCTION

Mention may here be made of Locher's<sup>(1)</sup> work in simply composed glasses of the C-A-S system, in which all the hydraulic strengths must be activated by CH products during hydration. A recent work on an industrial aluminous clinker<sup>(2)</sup> gives evidence that the glass state in a high alumina cement clinker do not present hydraulic strengths without an activation process, even if its composition would be CA, which is the aluminous clinker with the higher hydraulic strength<sup>(3)</sup>. In consequence some investigations must be done relating the microstructure of high aluminous clinkers and its hydration, because those reported strengths are concerned to a sintered CA. Obviously high alumina sintered cement clinkers are in the crystalline state. These can be obtained by devitrification<sup>(4)</sup>, with appropriate heat treatments in a glass of the same stoichiometric composition.

## MATERIALS AND METHODS

The compounds appearing in the binary C-A system are normally given<sup>(5)</sup> by  $C_3A$ ,  $C_{12}A_7$ , CA,  $CA_2$  and  $CA_6$ , the portion which is near adjacent to the  $C_{12}A_7$  composition have two eutectic points at 1360°C so this is the sinterization temperature. Samples of compacted powder with a composition  $C_{12}A_7$  ( $C_{1.71}A$ ), CA,  $CA_{1.5}$  were fused in a graphite crucible using an induction furnace and subsequently quenched to room temperature in a steel sheet. In this way a practically transparent material was obtained. Half of the samples were annealed at 1300°C during two hours and then slowly cooled in the furnace. After this treatment the specimens presented a complete opaque yellow colour. This glass of calcium aluminates were mounted in plastic molds and polished until the 0.1  $\mu$ m grade diamond paste with querosene in order to avoid hydration. Thereafter they were etched with H from half a minute up and afterwards, observed in a reflection optical (ROM) and a scanning electron (SEM) microscopes. Back X-ray reflection patterns were taken from some of these samples.

Other compacts of CA,  $CA_{1.5}$ ,  $CA_2$ ,  $CA_{2.5}$ ,  $CA_3$ ,  $CA_{3.5}$ , composition were sintered at 900°C, 1000°C, 1100°C, 1200°C, 1300°C, 1400°C and 1450°C during two hours and cooled in the furnace. The presence of free lime was detected by maintaining the samples during 30 days in a receptacle at 25°C saturated with water vapour. Those specimens which did not desinte-

grate by the expansion produced by the free C hydration, were considered totally combined. This fact occurred with the samples:  $CA_{3.5}$  at 900°C;  $CA_{3.5}$  and  $CA_3$  at 1000°C and at 1100°C;  $CA_{3.5}$ ,  $CA_3$ ,  $CA_{2.5}$ ,  $CA_2$  and  $CA_{1.5}$  at 1200°C and 1300°C;  $CA_{3.5}$ ,  $CA_3$ ,  $CA_{2.5}$ ,  $CA_2$ ,  $CA_{1.5}$  and CA at 1400°C and 1450°C. The presence or absence of free lime was tested by X-rays and differential thermal analysis, but the most simple method used for detecting the uncombined C was the exposition to humid air. The material without combined lime was pulverized and mixed with water in a water/clinker relation 0.3 (w/c) in weight. In order to inquire the material strength, compacted bars were manufactured. The paste thus formed was also observed in the SEM.

## RESULTS

The ROM observations of the vitreous material reveal the presence of dendrites. They can be noticed after water etching (Figs. 1, 2 and 3) as intense coloured ones over a less coloured background. All those colours, arise from the interference of the light with an epitaxial layer of a thickness corresponding at least to the wave length of the observed color (5000 Å). Normally the epitaxial layers which grow on the dendrites are thicker than those of the surroundings. Furthermore, these last becomes thinner as the distance from the dendrite increase finally disappearing. As it is evidenced from the SEM observations, it was not possible to detect any surface level difference.

As a consequence of the treatment the samples were devitrified, showing all of them a yellow colour. They became completely brittle and the back reflection X-ray diagrams revealed that the rings changed from continuous to finely fragmented, which corresponds to the formation of small crystalline grains. Also when they were water etched a very strong surface hydration effect takes place which can be observed better by ROM after metallization<sup>(6)</sup> (Fig.4). The hydration products were clearly seen by SEM, they preferentially concentrates (Fig.5) in the polishing lines, which means that the mechanical distortions increase the water reactivity of the samples. At higher magnifications it can be detected the devitrified material grains and the hydration process also (Fig.6). Hydration seems to consist (Fig.6) in a defoliation process producing rosette

shaped leafs (Fig.7). This early hydration product of the compounds  $C_{12}A_7$ -CA has the same morphology that the one obtained with identical treatments in the aluminous industrial clinkers<sup>(2)</sup> and can be identified as  $CAH_{10}$ . This phase arise as the hydration product of aluminates with low C content.

In the case of the sintered compounds, all of them show a strong hydraulic strength irrespective of the presence of additives. The paste reveals hexagonal<sup>(7)</sup> crystals which probably must be  $C_3AH_6$  (Fig.8).

#### DISCUSSION

In the case of compounds in the vitreous state,

which always can be activated with CH in aqueous solution, the hydration process was interrupted by the epitaxial layer already observed. The reactivation by CH consist in the dissolution of this layer. When the thermal treatment allows crystalline growing hydration occurs by a defoliation mechanism. It is supposed that H penetrates between the crystalline layers raising them as leafs. Therefore two processes occurs: a) in the glass state, thin hydrated epitaxial sheets subsequently dissolved (puzolanic reactor) by CH in solution are formed; b) in the crystalline state, the penetration of H between the crystalline layers produces leafs of  $CAH_{10}$  which afterwards dissolve precipitating crystals of probably

Fig. 7.- Devitrified  $C_{12}A_7$  glass annealed at  $1300^{\circ}\text{C}$  for two hours and subsequently hydrated during half a minute. SEM.

Fig. 6.- Devitrified  $C_{12}A_7$  glass annealed at  $1300^{\circ}\text{C}$  for two hours and subsequently hydrated during half a minute. SEM.

$C_3AH_6$ . The second mechanism is the one occurring in the hydration of the sinterized products. The hydraulic activation produced in the devitrified glasses must be strongly connected with the rearrangement of quenched-in vacancies, which is in turn related with the material brittleness and also with the fragmentation of the X-ray diffraction rings. All of these facts are in agreement with research works entailing lattice defects with hydration<sup>(8)</sup>.

# Investigations on two special cements

## *Etude de deux ciments spéciaux*

Y. EFES, Institut für Bauforschung der Rheinisch-Westfälischen Technischen Hochschule Aachen,  
Federal Republic of Germany.

RESUME : Deux ciments spéciaux - un ciment à durcissement exceptionnellement rapide et un ciment de lave - ont été étudiés pour leur agrément par l'autorité de surveillance de constructions.

Le ciment à durcissement exceptionnellement rapide (CDER) était composé de clinker portland, de ciment alumineux, de produits d'addition et de sulfate de calcium. Mortiers et bétons ont été essayés avec ce ciment. La vitesse de la carbonatation des mortiers de CDER était nettement moins élevée que celle des deux mortiers de ciment normalisés avec à peu près la même résistance à la compression après 7 jours. Les bétons faits avec le CDER atteignaient déjà, après 2 heures, une résistance à la compression comprise entre 3,0 et 6,5 N/mm<sup>2</sup>. La résistance à la compression était, après 28 jours, entre 30,2 et 46,6 N/mm<sup>2</sup>.

Le ciment de lave était obtenu par broyage d'une gachée de clinker portland, de sable de lave et de sulfate de calcium. Après une évolution des résistances initiales relativement rapide (résistance à la compression du mortier 19,8 N/mm<sup>2</sup> après 2 jours), cette évolution, après 7 jours, devenait semblable à celle du ciment de trass de la même classe de résistance. Comparé avec les ciments normalisés (ciment de trass et ciment de haut-fourneau), la carbonatation du mortier de ciment de lave se produisait à une vitesse peu élevée, mais il avait une résistance peu élevée à l'action du gel-dégel.

SUMMARY: Two special cements -one extra rapid hardening cement and one lava cement- have been tested for approval by the construction supervising authority.

The extra rapid hardening cement (ERHC) consisted of portland cement clinker, aluminous cement, additives and calcium sulphate. Mortars and concretes have been tested with this cement. The carbonation rate of the ERHC mortars has been significantly lower than that of the two standard cement mortars with nearly the same compressive strength after 7 days. Concretes with the ERHC obtained a compressive strength between 3.0 and 6.5 N/mm<sup>2</sup> already after 2 hours. The compressive strength was between 30.2 and 46.6 N/mm<sup>2</sup> after 28 days.

The lava cement is made by grinding a mixture of portland cement clinker, lava sand and calcium sulphate. After a relatively quick initial strength development (mortar compressive strength 19.8 N/mm<sup>2</sup> after 2 days), it showed a similar strength progress as a trass cement of the same strength class after 7 days. Compared with standard cements (trass cement and blast-furnace slag cement), mortar of lava cement carbonated at a lower rate, however it showed a somewhat lower resistance to freezing and thawing cycles.

## INTRODUCTION

In recent years the building and construction supervising authorities of the Federal Republic of Germany have approved the use of several nonstandard special cements. The Institut für Bauforschung (Institute for Building Research) has carried out some of the investigations on three of these cements in order that their use may be approved. The three cements in question are two extra rapid-hardening cements of different compositions and a lava cement. A report has already been published (1) on the properties of one of the extra rapid-hardening cements, a portland cement modified with the  $C_{11}A_7CaF_2$  phase. The following will describe the results of the investigations on the two remaining special cements.

## EXTRA RAPID-HARDENING CEMENT

The Extra Rapid-Hardening Cement (ERHC) tested consisted of a mixture of 82 % by mass portland cement clinker and 18 % by mass aluminous cement to which additives and calcium sulphate were admixed. The additives were to regulate setting and hardening.

As shown in Table I, this cement exhibits a somewhat lower  $SiO_2$ ,  $CaO$  and  $SO_3$  content and a higher  $Al_2O_3$ ,  $Fe_2O_3$  and  $Na_2O$  content, due to the aluminous cement constituent, when compared to portland cement.

Table I - Chemical composition of the ERHC and the Lava Cement examined (percent by mass)

Components	ERHC	Lava Cement
$SiO_2$	17,55	21,14
$Al_2O_3$	10,76	6,71
$TiO_2$	0,58	0,53
$Fe_2O_3$	4,83	3,19
$MnO$	0,02	0,09
$CaO$	59,46	53,30
$MgO$	0,69	2,07
$Na_2O$	0,87	0,23
$K_2O$	0,54	0,98
$SO_3$	2,71	2,34
Insoluble residue	0,33	5,52
Loss on ignition	1,70	3,95

The ERHC develops a mortar compressive strength (DIN 1164) of approx. 5 N/mm<sup>2</sup> after only 2 hours. During hydration substantially the same hydration products are formed as in a portland cement. An increase in the duration of hydration displays an increase in the production of hydrogarnet and CSH-phases. On the other hand, a reduction in  $Ca(OH)_2$ , monosulphate hydrate and ettringite may be observed as also is an increase in the formation of hydrogarnet with increasing storage temperatures up to 80 °C (2). Some of the properties of the cement tested according to DIN 1164 are given in Table II.

Table II - Properties of the ERHC and the Lava Cement according to DIN 1164

Properties	ERHC	Lava Cement
Density (kg/dm <sup>3</sup> )	3,16	3,04
Finess		
Specific surface (Blaine) (cm <sup>2</sup> /g)	5580	4910
Retained on the sieve 0,02 DIN 4188 (% by mass)	0,20	<0,10
Setting times		
Initial setting time (h-min)	0-51	3-00
Final setting time (h-min)	0-54	3-40

In the investigations, mortar and concrete tests were carried out. The strengths, carbonation behaviour of mortars, steel corrosion in mortars, and the compressive strength, carbonation behaviour, time-dependent consistency, static modulus of elasticity, time deformation under load and shrinkage of concretes were tested.

## Mortar Tests

The carbonation and corrosion tests were carried out with the following mortar mix proportions by mass:

- A) 1.00 cement : 2.16 sand <sup>1)</sup> : 0.45 water  
 B) 1.00 cement : 3.38 sand <sup>1)</sup> : 0.60 water  
 C) 1.00 cement : 4.92 sand <sup>1)</sup> : 0.70 water

For purposes of comparison, mortars were produced also according to DIN 1164 with the standard cements PZ 35 F and HOZ 45 L (45 % by mass slag) which exhibited approx. the same 7-day compressive strength (see Table III).

Table III - Compressive strength of the ERHC and the standard cements

Age (d)	Compressive strength (N/mm <sup>2</sup> )		
	ERHC	PZ 35 F	HOZ 45 L
2	26,4	24,5	19,5
7	37,9	35,6	37,9
28	44,5	44,9	55,9

The mortars with the ERHC possessed a weaker consistency than those with standard cements. The spread (flow table) measured, e.g. with mixture A, 245 mm whereas with PZ 35 F and HOZ 45 L the measurements were 183 mm and 180 mm respectively.

Four series of prisms (40 mm x 40 mm x 160 mm) were produced from the above mortars according to DIN 1164 and cured as shown in Table IV. The test specimens of the series cured according to regimes III and IV each contained a steel rod, inserted diagonally, 5 mm diameter and 119 mm in length. The rods touched the corners of the test specimens by means of steel pins which were attached to both ends of the rods. The corners of the specimens were sealed

<sup>1)</sup> Standard sand according to DIN 1164.

after demoulding with epoxy resin. These experiments were designed to determine a possible influence of the ERHC in the various mortar mixtures on the extent of steel corrosion (rusting) in comparison to the standard cements.

The curing series I (rapid test) and II were examined at different ages for carbonation depth with the aid of the phenolphthalein method. The test results are shown in Fig. 1 a to c. The carbonation depth  $d_k$  of the mortar with the ERHC was in both cases the lower compared to those with the standard cements.

Table IV - Curing regimes of the specimens for the carbonation tests

Curing regimes	Pre-curing <sup>1)</sup>				Main-curing			
	Time <sup>2)</sup> (d)	Med.	Temp. (°C)	R.H. (%)	Time (d)	Med.	Temp. (°C)	R.H. (%)
I	7 +7	water air	20 20	- 65	360	air + <sup>3)</sup> CO <sub>2</sub>	20	65
II	7 +7	water air	20 20	- 65	360	air	20	65
III	7	water	20	-	360	air	20	a) 65 b) 95
IV	7	water	40	-	360	air	20	a) 65 b) 95

- 1) After demoulding
- 2) Including the time with mould in moist air (ERHC: 1 h; standard cements: 1 d)
- 3) 3 % by volume
- 4) Consisting of cycles of 28 days a) plus 2 days b)

The regression analyses of the results yielded the lines shown in Fig. 1 a to c, which were calculated with the equation  $d_k = a + v_k \sqrt{t}$ , where  $t$  is curing time. The slope of the lines corresponds to the carbonation rate  $v_k$ . From the ratio of  $v_k$  values of both curing regimes I and II we can determine an acceleration factor of  $b_k = v_{kI} / v_{kII}$ . These results are given in Table V. The acceleration factors of all three cements are similar to each other so that the above comparison of  $v_k$  may be used for both curing regimes.

As is known, carbonation generally results in greater strength. After total carbonation of the mortar specimens with the ERHC, the compressive strengths were 99 % and 71 % (w/c = 0.60 and 0.70) respectively higher than after pre-curing. Thereby, a hardening portion due to hydration of approx. 10 % was estimated. The increases in flexural strength were 83 % and 47 % respectively. These increases in strength were greater than with the standard cements.

The carbonation depths of the mortar prisms cured according to regimes III and IV approximated to that of the prisms of regimes I

and II. The rust areas appearing on the steel rods inserted in the mortars with the ERHC were generally neither more nor greater than those inserted in the standard cements. Rust formation was limited to the carbonation zones (e.g. see Fig. 2).

Fig. 1a-c - Mean carbonation depths of the mortar and concrete test specimens  $d_k$  dependent on the time of the main curing  $t_k$

#### Concrete tests

Three concretes with approximately the same consistency (spread <sup>1)</sup> = 400 ± 20 mm) were produced for these tests. The mix proportion of the concretes was as follows (by mass):

<sup>1)</sup> According to DIN 1048.

Table V - Carbonation rate  $v_k$  and acceleration factor  $b_k$  for the mortars produced from the ERHC and the standard cements (time of curing: up to 360 days)

Mixes	ERHC		PZ 35 F		HOZ 45 L	
	I	II	I	II	I	II
	$v_k$ (mm d <sup>-0,5</sup> )

I, II: Curing regime according to Table VI

Fig. 2 - Rust formation on the steel rods and carbonation zones of the mortar with the ERHC and w/c = 0.70 (curing regime III)

- I) 1.00 cement : 5.37 aggregate 1) : 0.45 water  
 II) 1.00 cement : 7.01 aggregate 1) : 0.55 water  
 III) 1.00 cement : 8.02 aggregate 1) : 0.70 water

A workability time for the test concretes of approx. 10 min was determined using the spread and compacting factor 2) dependent on the time after the addition of water at 20 °C.

The compressive strength of the 200 mm cubes made of these concretes (produced and cured according to DIN 1048) consisted after only 2 hours of between 3.0 and 6.5 N/mm<sup>2</sup> (see Fig. 3). The 28-day compressive strength was 30.2 to 46.6 N/mm<sup>2</sup>. At the age of 360 days the compressive strength was roughly 20 % greater.

The carbonation depth of the concretes also given in Fig. 1a to 1c (measured on the cubes for strength tests) was comparable to the results of the mortar tests.

1) Grading corresponded to B<sub>32</sub> (concretes I and II) and B<sub>32</sub>/C<sub>32</sub> (concrete III) according to DIN 1045.

2) According to DIN 1048.

Fig. 3 - Compressive strength of concretes produced with the ERHC

In further concrete tests (curing : 7 d in moist air, then in normal climate 20 °C/65 % R.H.) described in detail in (3), the static modulus of elasticity was determined on cylindrical specimens. At the age of 35 days this was - in the sequence of concretes I to III - 30070, 31500 and 29910 N/mm<sup>2</sup> respectively, and at the age of 1 year 31660, 31460 and 23450 N/mm<sup>2</sup>. On the concretes I to III a shrinkage of 0.58, 0.47 and 0.77 mm/m respectively, was measured after 1 year. The creep strain of the concrete specimens subjected to a stress of 1/3 of the 7-day compressive strength was measured, at an age of loading of 360 days, 1.05, 0.94 and 1.11 mm/m respectively. Final creep coefficients of 3.55, 4.58 and 5.35 respectively were calculated.

#### LAVA CEMENT

The Lava Cement in question is a puzzolanic cement of the strength class Z 35 F according to DIN 1164. This cement is produced by grinding of 75 + 7.5 % by mass portland cement clinker and of 25 + 7.5 % by mass lava sand of grain size < 4 mm with the addition of calcium sulphate. The chemical composition of the cement tested (Table I) is similar to the mean composition of trass cements in the Federal Republic of Germany (4). The lava used comes from the Eifel area and contains, however, less SiO<sub>2</sub>, Al<sub>2</sub>O<sub>3</sub> and alkalis (with approx. 39, 12 and 4 % by mass respectively) and more CaO and Fe<sub>2</sub>O<sub>3</sub> (with approx. 15, 11.5 % by mass respectively) than the trasses (5). Table II contains some of the physical properties of the Lava Cement according to DIN 1164.

#### Mortar Tests

The compressive and flexural strengths of the Lava Cement were determined, with reference to DIN 1164, on mortar specimens in comparison to two standard cements, a trass cement Z 35 L and a HOZ 35 L (with 54 % by mass slag). From the results given in Figs. 4a and 4b, it is evident that the early strengths of the Lava Cement are greater than those of the comparison cements. The strength development after a period of 7-days, however, is similar to that of the trass cement. The strengths of the Lava Cement between 28 and

90 days are inferior to those of the portland blast-furnace slag cement which increases more rapidly.

Fig. 4a,b - Mortar compressive and flexural strength of the Lava Cement and the standard cements

#### Concrete Tests

The carbonation behaviour of Lava Cement in comparison to that of the standard cements was examined using concrete with fine aggregate (maximum size: 8 mm) with a mix proportion by mass of 1.00 cement : 3.00 aggregate <sup>1)</sup> : 0.50 water. The prisms produced according to DIN 1164 (40 mm x 40 mm x 160 mm) were cured after demoulding 28 days in water at +20 °C and after this, 7 days in the air at normal climate of 20 °C/65 R.H. Thereafter, one set of test specimens remained stored in the air whilst a second set was cured under the same climatic conditions in air enriched with 10 % by volume CO<sub>2</sub>. The carbonation depths were also determined on the concrete test specimens with a mix proportion by mass of 1.00 cement : 7.19 aggregate <sup>2)</sup> : 0.60 water with all three cements. The pre-curing period of the specimens in water, later cured in the air, was 35 days. The carbonation rates given in Table VI were lowest for the concretes containing Lava Cement. Most evident were the differences produced by curing in CO<sub>2</sub> enriched air (Fig. 5).

Fig. 5 - Mean carbonation depths of the concrete specimens  $d_k$  dependent on the time of the main curing in air with 10 % by volume CO<sub>2</sub>.

Freeze-thaw-cycling tests were carried out on prisms of concrete with fine aggregate <sup>3)</sup> of the same dimensions. The prisms were pre-cured for 28 days in water at +20 °C. After this they were subjected to an 8-hour freeze-thaw-cycle of between +20 °C and -20 °C. After 150 cycles the compressive strength measured 56 % and the flexural strength 16 % of the strength after pre-curing. The loss in strength after subjection to freeze-thaw-cycles was greater with Lava Cement concretes than with

<sup>3)</sup> Grading A<sub>8</sub>/B<sub>8</sub> according to DIN 1045

the concretes produced with the two standard cements (trass cement : 93 % and 45 % : portland blast-furnace slag cement : 77 % and 36 % respectively).

The compressive strength of a concrete produced from Lava Cement (mix proportion by mass of 1.00 cement : 6.50 aggregate <sup>1)</sup> : 0.55 water) was also determined. The spread (flow test) of the concrete was 370 mm. Production, curing and testing of the test specimens took place according to DIN 1048. At the ages of 7, 28 and 90 days mean compressive strengths of 27.7, 38.5 and 46.0 N/mm<sup>2</sup> respectively were found.

#### CONCLUSIONS

The ERHC is characterised by very high early strengths in the first few hours and a very short workability period. Because of the positive results from carbonation tests, there can be no doubts as far as this is concerned about its use. Although for the quantity of alumina present the formation of convertible low calcium content calcium aluminate hydrates cannot be expected, losses in strength are possible at high temperatures upwards of approx. 60 °C. The ERHC can not be used for prestressed concrete.

The Lava Cement represents a complement to the existing puzzolan cements and is to a large extent comparable to their properties. Due to the finess of grinding it possesses a greater early strength. Lava Cement is permissible for reinforced concrete but not for prestressed concrete.

# Post-Hydration Compressed Expansive Clinker Pastes

## *Pâtes de clinker dilaté compressé après hydratation*

R. SH. MIKHAIL and S. HANAFI, Department of Chemistry, Faculty of Science, Ain Shams University, Abbasia, Cairo, Egypt,  
S.A. ABO-EL-ENEIN, Chemistry Department Qatar University, Doha, State of Qatar.

**RESUME :** Le clinker de ciment expansif du type I est préparé à partir de kaolin, de gypse et de carbonate de calcium. Deux méthodes sont utilisées pour confectionner des éprouvettes de pâte de ce ciment : la première, en mélangeant le clinker broyé à l'eau dans un rapport eau sur ciment ( $\frac{E}{C}$ ) égal à 0,25; la seconde, en préparant tout d'abord la pâte comme dans la première méthode (toujours avec le rapport  $\frac{E}{C} = 0,25$ ), mais en comprimant la pâte fraîche à des pressions de 50, 200 et 500 kg/cm<sup>2</sup>.

Sont exposées, pour ces diverses valeurs de la compression, les conséquences sur la cinétique de l'hydratation, la microstructure et la structure des pores des pâtes durcies. On a observé que l'ettringite était la phase principale aux divers âges de l'hydratation. L'état physique de l'ettringite varie en fonction de l'espace disponible pour sa formation et sa cristallisation; l'ensemble limité des pores, utilisable pour l'hydratation des constituants du ciment, conditionne très strictement la structure des pâtes durcies.

**SUMMARY:** Type I expansive cement clinker was prepared from kaolin, gypsum and calcium carbonate. Two methods were used for the preparation of expansive clinker pastes; the first involves mixing the anhydrous expansive clinker with a low water/cement (W/C) weight ratio of 0.25, and the second involves using the same W/C ratio of 0.25 followed by compression of the fresh paste at pressures of 50, 200 and 500 Kg/cm<sup>2</sup>.

The results of compressive strength, hydration kinetics, microstructure and pore structure of the hardened pastes are presented. Ettringite was found to be the dominant phase prevailing at the various ages of hydration. The physical state of Ettringite was found to vary according to the space available for its formation and crystallization; the limited pore system available for the hydration products affected strongly the microstructure of the hardened pastes.

## INTRODUCTION

The development of the expansive cement, which has an expansion that equals or exceeds the shrinkage of portland cement, has in principle made it possible to prevent shrinkage crack of concrete. Several publications concerning the expansion-shrinkage characteristics of expansive cement have been reported in the literature (1-5). Expansive cement also makes it possible to produce prestressed concrete by chemical prestressing (5-7).

The mineral composition and crystal structure of calcium sulpho-aluminous clinker have been examined by various investigators (8-10). The main component of calcium sulphoaluminous clinker and the hydration characteristics have also been investigated (11,12).

For the formation of ettringite ( $C_3A \cdot 3\bar{C}\bar{S} \cdot 32H_2O$ ), it is necessary that the cement clinker should contain sufficient amounts of free  $CaSO_4$  and  $CaO$ . Expansive clinkers containing these two free components have usually been made using bauxite as a raw material, but other investigators have examined the possibility of replacing this by kaolin (13-16).

In the present paper, we present results on hydration kinetics, total porosity, compressive strength, surface properties and microstructures of low porosity expansive clinker pastes prepared by the post-hydration compression technique, as compared with the normal low porosity pastes, made without compression.

## EXPERIMENTAL

The expansive cement clinker used in this study was prepared from kaolin (Aswan, Egypt) and chemically pure calcium carbonate and gypsum. The relative amounts required to produce type I expansive clinker were calculated using Nakamura's equations (13) as follows:

$$\begin{aligned} \text{Kaolin} &= 100 \\ \text{Calcium carbonate} &= 1.78 [(0.55 + 0.183 n) P + 1.17F + 1.87S] \\ \text{Gypsum} &= 1.13 [0.445 (1 + m) P + 1.13S] \\ \text{where } P &= (\% Al_2O_3 - 0.426\% Fe_2O_3) \text{ in kaolin,} \\ F &= \% Fe_2O_3 \text{ in kaolin,} \\ S &= \% SiO_2 \text{ in kaolin,} \\ m &= \text{molar } CaSO_4/C_4A_3\bar{S} \text{ ratio in the expansive clinker,} \\ \text{and } n &= \text{molar } CaO/C_4A_3\bar{S} \text{ ratio in the expansive clinker.} \end{aligned}$$

The molar  $\bar{C}\bar{S}/C_4A_3\bar{S}$  and  $C/C_4A_3\bar{S}$  ratios required to produce type I expansive clinker are 8 and 6, respectively.

Type I expansive clinker was made by following the same procedure described in earlier studies (14,15). The three main constituents were ground separately in a porcelain ball mill to pass completely through a 200-mesh B.S. sieve, then mixed in the ball mill with few number of balls for 6 hours, and burned as pellets for two hours at  $1150^\circ C$ . The product was cooled slowly and ground to a

Blaine area of  $4300 \text{ cm}^2/\text{g}$ .

The oxide composition of the clinker produced was found to be:  $SiO_2$ , 10.74;  $Al_2O_3$ , 8.90;  $Fe_2O_3$ , 0.70;  $CaO$ , 48.23 and  $SO_3$ , 31.65, respectively. This corresponds to the phase composition of:  $C_4A_3\bar{S}$ , 17.06;  $2(C_2S) \cdot \bar{C}\bar{S}$ , 41.17;  $C_4AF$ , 2.13;  $\bar{C}\bar{S}$ , 30.44 and  $\bar{C}$ , 9.40, respectively.

Post-hydration compressed pastes were made at pressures of 50, 200 and  $500 \text{ kg/cm}^2$ ; the expansive clinker was mixed with water ( $W/C = 0.25$ ) for 3 minutes continuously and then compressing at the pressures mentioned above into cylindrical specimens having 2 cm diameter and approximately 2 cm height. The specimens were cured in a moist cabinet for 6 hours and then cured in water at room temperature until the desired time of testing was reached. The times of hydration selected were 1,3,7,28,90 and 180 days. The normal low porosity pastes were prepared by mixing the anhydrous expansive clinker with a water/cement ratio of 0.25 followed by moulding, without any compression, into cylindrical specimens having 2 cm diameter and approximately 2 cm height.

Compressive strength and total water content ( $W_t$ ) determinations were carried out on the fresh specimens. Hydration was stopped for one representative sample from each specimen by immersion in 50 ml. of acetone-methanol mixture (1:1 by volume) stirred mechanically for one hour. The solid part was separated by filtration through a Gooch crucible, G4, washed with acetone-methanol mixture followed by several washings with ether. The solid was then dried at  $50^\circ C$  for one hour to complete evaporation of the ether. The combined water content ( $W_c$ ) was determined as the ignition loss of the dried solid.

The total porosity was calculated from the densities using the following expression:  $100 (\rho_T - \rho_B)/\rho_T$  where  $\rho_T$  is the true density and  $\rho_B$  is the bulk density.

Nitrogen and water vapour adsorptions were carried out on the dried samples. SEM examination was done on freshly fractured specimens, coated with 300-400 Å layer of gold, using a JEOL JSM-25 high resolution scanning electron microscope.

## RESULTS AND DISCUSSIONS

## 1. COMPRESSIVE STRENGTH, TOTAL POROSITY AND HYDRATION KINETICS

The results of compressive strength tests, non-evaporable water contents ( $W_n$ ) and total porosity of the hardened pastes are shown in Fig. 1, for various ages of hydration. In the pastes investigated, the non-evaporable water content was found to decrease with increasing the pressure used in the compression, and to increase markedly during the early stages of hydration, indicating that the hydration reaction starts with a fast step which is comparable with the "pre-dormant period" in the hydration of normal

Fig. 1- Non-evaporable water, total porosity and compressive strength of the pastes investigated.

hydration behaviour of various types of cements (17,20).

The total porosity of the post-hydration compressed expansive clinker pastes showed an initial increase during the first 7 days of hydration, and then it decreased. The earlier increase in the total porosity may be attributed to the instability of the binding centres in the initial hydration products which permits the diffusion of the water of curing in the paste during the recrystallization (stabilization) of the initial hydrates, leading to expansion of the paste. However, when the paste had achieved stability by recrystallization of the initially formed hydrates, the total porosity decreased as a result of the accumulation of the hydrates within the pore system. There appeared to be only small variations due to the limited initial porosity as controlled by the post-hydration compression technique. The expansion characteristics of the hardened expansive cement pastes including this expansive clinker were presented in earlier publications (15,16). In the normal low porosity pastes made without compression, the total porosity decreases continuously with age of hydration. This is due to the easier access of water and the availability of the space to accommodate the hydration products. Their accumulation in the pore system leads to the normal behaviour of a continuous decrease of total porosity with age. In general, the total porosity decreases, as expected, with increase in the compression pressure.

The results of compressive strength tests show an initial increase in the early stage of hydration followed by a decrease during the recrystallization of the initial hydrates. The accumulation of hydrates in the pores causes a development in the strength of the paste during the final stages of hydration (cf. Fig. 1). Compression causes an increase in compressive strength.

The results of X-ray diffraction, DTA and SEM showed that the trisulphate hydrate (ettringite) represents the dominant hydration product in these expansive clinker pastes. A small amount of the monosulphate hydrate also was present.

It is postulated that the mechanism of hydration and hardening of these expansive clinker pastes is the following: (1) A fast reaction taking place as a result of topochemical interaction between water and the bare surface of the sulphotoaluminous clinker ( $C_4A_3S$ ), in presence of  $CaSO_4$  and  $CaO$  in solution, leading to the formation of an almost impervious coating of microcrystalline or gel-like ettringite around the clinker particles (20-22); this is the "pre-dormant" period. (2) The ettringite layer by virtue of its low permeability, causes a retardation of hydration; this leads to a slow "dormant" period. During the dormant period, the initially formed ettringite recrystallizes on the surface of the clinker grains. This recrystallization and grain growth causes gaps between grains, and hence an increased accessibility of water through the crystalline

cements (17,18). The duration of this period was found to vary with the initial porosity of these compressed pastes; it ends before one day in the relatively higher porosity pastes, (with no compression or compressed at 50 kg/cm²), and after 3 days in the lower porosity pastes (compressed at higher pressures). The non-evaporable water content then increased slowly, reflecting a slow step in the hydration; this step is similar to the "dormant period" in cement hydration (17,18). This period is shortened markedly with increase in the initial water/solid ratio (initial porosity as controlled by the pressure used in compression), and it is strongly diminished by suspension hydration in which a large amount of water is normally used (19). Finally the non-evaporable water content increases markedly indicating an "acceleration period" similar to the

coat into the unhydrated part of the grains. The result is an increase in the rate of hydration; this is the "acceleration" period. (3) Finally, the hydration reaction is again slowed down as a result of deposition of ettringite within the transport limiting pores of these pastes. As a consequence, the diffusion of water through the dense hydration products into the unhydrated part of clinker grains becomes the rate controlling step. A schematic representation of the mechanism is shown in Plate I.

Plate I. Schematic representation of the suggested mechanism

**Stage I: "Predormant period"**

Rapid step which leads to the formation of a thin layer of microcrystalline hydrate on the unhydrated clinker grains (U).

**Stage II: "Dormant period"**

Crystallization of the initial hydrate takes place which is relatively slow step.

**Stage III: "Acceleration period"**

Water becomes again accessible through the crystalline coat into the unhydrated part of grains leading to a fast reaction.

**Stage IV: "Diffusion period"**

Almost all the pore system becomes filled with hydration products and the diffusion of water through the dense structure of hydrates into the unhydrated part of grains becomes the rate controlling step.

## 2. SURFACE PROPERTIES

Typical adsorption-desorption isotherms of nitrogen at 77.2°K on the hardened expansive clinker pastes are shown in Fig. 2. The isotherms show no hysteresis loops, indicating that the adsorption of nitrogen on these hydrated pastes is completely reversible for all pastes cured for up to 90 days. For the pastes cured for 180 days, small hysteresis loop is obtained.

The  $V_t$ - $t$  plots shown in Fig. 3 also indicate that these pastes behave as non-microporous solids. This is evidenced by the linear character of the  $V_t$ - $t$  plots, up to relative vapour pressure close to the saturation

pressure of the adsorbate. Therefore, although these pastes possess extremely low porosities, their hydration product (ettringite) represents an open-pore system simulating non-porous solids.

Some surface characteristics derived from nitrogen adsorption are shown in Fig. 4; this figure includes the surface area derived from the BET equation,  $S_{BET}$  ( $m^2/g$ ), and the total pore volume calculated from the saturation point of the adsorption isotherm,  $V_p$  (ml/g).

Evidently, the surface area and the total pore volume show a first increase with curing age up to 3 days hydration followed by a decrease. The early increase in the surface area and the total pore volume is due to the recrystallization of the initially formed ettringite; recrystallization results in an increased accessibility of nitrogen, to measure additional parts of the pore system of the paste. However, the accumulation of ettringite within the limited pore system causes a decrease in the accessibility of nitrogen to measure the total porosity of the paste. The recrystallization of ettringite

Fig. 2- Adsorption-desorption isotherms of nitrogen on the post-hydration compressed expansive clinker pastes (compressed at 200 kg/cm<sup>2</sup>).

Fig. 3-  $V_L$ - $t$  plots of nitrogen on the post-hydration compressed expansive clinker pastes (compressed at 200 kg/cm²).

into large rod-like crystals (*vide infra*) is accompanied by a decrease in its specific surface area.

In the final stages of hydration, the normal low porosity pastes possess high surface area and pore volume as compared with the post-hydration compressed pastes; this is mainly attributed to the relatively higher porosity of these pastes which permits the growth of a large number of crystallites (hydration products). Such increase in the number of these crystallites in the paste leads to high surface area and total pore volume at the final stages of hydration. Post-hydration compressed pastes however, possess a more limited and smaller pore spaces; therefore, the hydration process is controlled by the limited space available in the hardened paste. It is noticed that lower values of surface areas and pore volumes were obtained during the final stages of hydration of the pastes compressed at 50 and 200 kg/cm²; in these pastes recrystallization and crystal growth of the hydration products within the limited pore system is

Fig. 4- Variation of the nitrogen surface area and total pore volume with age of hydration of the hardened pastes.

still possible. However, in the later stages of hydration of the pastes compressed at the highest pressure used (500 kg/cm²), relatively higher values of surface areas and total pore volumes were obtained. This result is interesting and is probably associated with the microcrystallinity of the hydration products formed within the limited pore system of the paste. The available pore space has reached such a small size which actually hinders the growth of microcrystallites into larger crystals; microcrystallites have larger surface area than large crystals.

### 3. MORPHOLOGY AND MICROSTRUCTURE

X-ray diffraction of the anhydrous type I clinker showed the presence of  $\text{CaSO}_4$ ,  $\text{CaO}$ ,  $\text{C}_4\text{A}_3\text{S}$  and  $2(\text{C}_2\text{S}) \cdot \text{CS}$  phases.

SEM micrographs were obtained at various ages of hydration, and those for the pastes pressed at 200 kg/cm² are typical representatives of the series of micrographs obtained, and which support the above mentioned conclusions.

Fig. 5- SEM micrographs of the hardened expansive clinker pastes compressed at 200 kg/cm<sup>2</sup>.

a- Cured for one day      b- Cured for 3 days  
c- Cured for 7 days      d- Cured for 28 days

After one day hydration, large crystals of the principal phase,  $C_4A_3S$ , prismatic crystals of  $2(C_2S) \cdot C\bar{S}$ , hexagonal crystals of  $Ca(OH)_2$  and small round crystals of gypsum were the main phases present together with microcrystalline ettringite as the only hydration product identified (Fig. 5a). The gel-like ettringite recrystallizes after 3 days hydration into rod-like particles in the dense structure of the remaining unhydrated grains (Fig. 5b). The microstructure after 7 and 28 days hydration displayed a dense structure of large rods of fully crystalline ettringite as the dominant hydration product (Fig. 5c and d). At all ages of hydration,  $Ca(OH)_2$  crystals were clearly detected. Gypsum is noticed to be consumed after 7 days.

#### CONCLUSIONS

From the results obtained in this study the following conclusions could be derived:

1. The rate of hydration of expansive clinker is high during the early stage of hydration (pre-dormant period), low in the intermediate stage of hydration (dormant period), and then it increases again indicating an acceleration as a result of recrystallization of the initial hydrates (acceleration period). The final stage in the mechanism of hydration is a very slow diffusion process.
2. An earlier increase in the total porosity was obtained in the post-hydration compressed pastes and this may be attributed to the instability of the binding centres in the initial hydration products. However, when the paste had achieved stability, the porosity decreased as a result of

accumulation of the hydrates within the pore system.

3. The results of surface area and pore volume measured by nitrogen confirm the proposed hydration mechanism in terms of the accessibility of nitrogen molecules towards the pore system of the hardened low porosity pastes.
4. X-ray and SEM studies showed that the ettringite phase predominates at all ages of hydration with varying degree of crystallinity.
5. Compressive strength values show an initial increase followed by a decrease during the recrystallization of the initial hydrates. Later, the accumulation of hydrates in the pores causes a noticeable increase in the strength of the paste.

# On alunite expansive cement and concrete

## *Ciment expansé d'alun et béton précontraint*

WU CHUNG-WEI, Chief engineer, vice director, Research Institute of Building Materials Professor, Qing-hua University,

WANG YAN-SHENG, Engineer, Research Institute of Building Materials, Chine Populaire.

RESUME : Depuis une vingtaine d'années, six types de ciment expansif sont produits en Chine, dont la plupart sont des ciments d'auto-contrainte; leur pouvoir d'auto-contrainte est de 3 à 8 N/mm<sup>2</sup>. Parmi eux, une grande quantité de ciment d'auto-contrainte de silicate et d'aluminate sont utilisés pour fabriquer des conduites d'eau en béton précontraint; leur production a dépassé 2.000 km/an. Le ciment expansif d'alun (l'alun naturel étant utilisé comme matière première principale), lui, est un ciment à retrait compensé, utilisé avec succès depuis ces dernières années pour les constructions souterraines, les travaux d'étanchéité et la construction de réservoirs.

Cet article montre la possibilité de remplacement d'alun cuit par l'alun naturel; il énumère les avantages du ciment expansif d'alun naturel, en les expliquant par l'action d'hydratation et la microstructure. L'indice d'expansion ( $\epsilon$ ) proposé par les auteurs, comme rapport entre l'expansion libre et l'expansion contrariée, et les courbes d'évolution de l'expansion avec le temps exposés dans cet article, contribueront à améliorer la propriété du ciment et du béton expansifs, et aboutiront ainsi à une application plus étendue.

SUMMARY: During the past 20 years, six types of expansive cements have been produced in China. Most of them are self-stressing cements with different self-stress levels of 3 to 8 N/mm<sup>2</sup>. Some have been widely used to manufacture self-stressing concrete pressure pipes amounting to 2,000 kilometers a year. Alunite (uncalcined) expansive cement as a shrinkage-compensating cement has been used successfully for years in underground and waterproofing structures and tanks and as joint-fillers.

In this paper, the feasibility of uncalcined alunite to replace the calcined and the merits of this alunite cement are explained through hydration and micro-structure studies. The authors propose a new expansion index  $\epsilon$  = free expansion ( $e_1\%$ ) / restrained expansion ( $e_2\%$ ) and a revised time-dependent curve of highly restrained expansion. Both of them may prove useful in further development and wider application of expansive cements and concretes.

## INTRODUCTION

During the past 20 years, six types of expansive cements have been investigated and produced in China. They are silicate expansive cement (type M), aluminate expansive cement, sulfo-aluminate expansive cement, alunite expansive cement, low-heat expansive cement and gypso-aluminate cement. They are mostly self-stressing cements with different self-stress levels of 2 to 8 N/mm<sup>2</sup>. Silicate expansive cement and aluminate expansive cement have been widely used to manufacture self-stressing concrete pressure pipes, amounting to 2,000 kilometers a year, 90% for city water-supply and the rest for gas pipelines, etc. Alunite (uncalcined) expansive cement as a shrinkage-compensating cement has been used successfully for years in underground and waterproofing structures and tanks and as joint-fillers.

## ALUNITE EXPANSIVE CEMENT

Our alunite expansive cement consists of natural alunite rock (containing 20-50 %  $K_2SO_4 \cdot Al_2(SO_4)_3 \cdot 4Al(OH)_3$ ), cement clinker, anhydrite and fly-ash or blast furnace slag. The main physical properties of the alunite expansive cement are as follows:

1. Time of setting: Initial 1:30-4:00 hrs  
Final 2:30-6:00 hrs
2. Free expansion ( $e_1$ ) of cement paste in water (Table 1).

Table 1

Age	1 day	28 days	1 year
$e_1(\%)$	$\geq 0.15$	0.5-1.2	$\leq 1.2$

3. Mortar strength (1:3 earth-dry mortar method) (Table 2).

Table 2

Age	1 day	7 days	28 days	1 year	3 years
Compressive (N/mm <sup>2</sup> )	30-40	40-60	60-80	90	100
Tensile (N/mm <sup>2</sup> )	1.3-2.5	1.6-3.0	3.0-4.5	5.0	6.0

In comparison with the alunite expansive cement of other countries as well as some other expansive cements, our cement has the following distinguishing features: first, regular setting, hence no retarder is needed; second, high strength at later age, which guarantees the integrity and structural safety of concrete; and third, the most important, low expansive index  $\xi$ , newly proposed for the evaluation of expansive cements and concretes. As  $\xi$  is defined by the

Table 3

% of reinforcement ( $\mu$ )		0.24	0.56	1.08	1.57
$\xi$ value	Alunite cement concrete	1.70	3.03	4.50	4.76
	Type "M" cement concrete in China				>15 ( $\mu=1.4$ )
	Type "M" cement concrete in USSR (1)			7-20 ( $\mu=1.0$ )	
	CSA cement concrete in Japan (2)			approx. 5-14 ( $\mu=1.0$ )	

ratio of free expansion to restrained expansion at certain degree of restraint, a low  $\xi$  value means small difference between free and restrained expansion, i.e., no excessive expansion will occur where there is

least or no reinforcement. With low  $\xi$ , the prevailing worry about scaling of coverage and nonuniformity of concrete quality will prove unnecessary. Table 3 shows the  $\xi$  values of our alunite cement in comparison

with the approximately  $\xi$  values of some other cements under various percentages of reinforcement.

#### HYDRATION AND MICRO-STRUCTURE

1. Chemical analysis shows that natural alunite rock dissolves in water at a much lower rate than calcined alunite and supplies  $\text{SO}_3$  and  $\text{Al}_2\text{O}_3$  for ettringite formation. The solution process is accelerated at the presence of  $\text{CaO}$  and  $\text{CaSO}_4$ .
2. Based on X-ray diffraction analysis data of the alunite cement paste cured in water at different ages, a semi-quantitative diagram was plotted (Fig. 1), by which the hydration kinetics of the cement can be visualized to a certain degree. The continuous but slow formation of ettringite after 7 days is due to the existence of alunite rock.

Fig. 1 The semi-quantitative diagram of the alunite cement paste.

1 -  $\text{C}_3\text{S}$ , 2 -  $\text{CaSO}_4$ , 3 - natural alunite rock, 4 - ettringite, 5 -  $\text{Ca}(\text{OH})_2$

3. The formation of ettringite in the liquid phase and the precipitation of ettringite in pores and fissures of mortar and concrete ( see SEM micrograph, Fig. 2) are closely related to the characteristics of hardened concrete, including comparatively small free expansion, effective restrained expansion, low expansion index, high strength at later age, impermeability, etc. The data of pore measurement (Table 4) by the mercury penetration method confirm that the

accumulation of ettringite in pores and fissures persistently improves the structure of concrete.

Fig. 2 The precipitation of ettringite in pores.  
1:1 mortar, W/C = 0.3, 7 day water curing

Table 4

Curing ages	Total porosity ( $\text{cm}^3/\text{g}$ ) (pores sizes 55,000-25Å)	Most probable pore radius (Å)
1 day	0.0881	182
7 days	0.0603	159
14 days	0.0595	114
28 days	0.0472	65
1 year	0.0295	41

Notes: 1:1 mortar, W/C = 0.28,  
water curing before test

4. The C-S-H gel formed at the same time with ettringite has the dual functions of cementing and cushioning. The crystallization of the C-S-H gel at later ages strengthens the hardened cement paste as shown in the TEM micrograph at the age of 10 months (Fig. 3).
5. The addition of fly-ash as stabilizer can also expedite the hydration process at early age.

#### EXPANSION UNDER RESTRAINT

The prerequisite of self-stressing and shrinkage-compensating is proper restraint. Without restraint there will be no prestress. In fact, nearly all parts of structures and elements made of expansive concrete are under certain restraint functioned by reinforce-

Fig. 3 Alunitic cement paste  
10 month water curing

ments, foundations or neighbouring blocks. Self stressing concrete as well as shrinkage-compensating concrete for joint-filling are usually under high restraint.

In the investigation of restrained expansion of alunitic and other expansive concretes, we found that:

1. By SEM observation, ettringite crystals in alunitic expansive cement paste under restraint are usually of smaller size and have closer spacing in comparison with those without restraint. (Fig. 4, 5)

Fig. 5 Ettringite crystals without restraint  
1:1 mortar, 7 day water curing

Fig. 4 Ettringite crystals under restraint  
1:1 mortar, 7 day water curing

2. The alunitic expansive cement mortar under restraint has lower porosity and better pore gradation (size distribution). (Fig. 6)

Fig. 6 Pore size distribution of alunitic cement mortar

1- Without restraint, 28 day water curing  
2- Under restraint, 28 day water curing

3. The boundary fissures around sand grains in alunitic cement mortar under restraint are much thinner and are clogged with ettringite crystals. (Fig. 7, 8)  
As for expansion under high restraint, there have been doubts upon the effectiveness of shrinkage compensa-

Fig. 7 Boundary fissure

Fig. 8 Crystals clogging in fissures

tion due to the sensitiveness of contraction at drying (3). The conventional time-dependent curve (curve 1 in Fig. 9) of highly restrained expansion supports these doubts. Taking advantage of elastic recovery at drying, we have revised the conventional curve 1 and changed it to curve 2, which shows the delay of cracking from  $t_1$  to  $t_2$ . If creep in tension is taken into consideration, the revised curve may be further modified to curve 3 in Fig. 9, and cracking is

eliminated. Our successful experiences in utilizing alunite expansion cement concrete to fill a number of very rigid joints justify the above modifications.

Fig. 9 Time-dependent curves of expansion

- 2- Revised curve
- 3- Revised curve further modified by creep in tension
- 4- Free expansion curve
- $\gamma$  = Elastic recovery after stress-release at drying
- $\delta$  = Contraction pending cracking

#### CONCLUSION AND PROSPECT

1. Alunite (uncalcined) expansive cement marked with low expansion index, high strength at later age, impermeability and other merits is one of the effective shrinkage-compensating cements.
2. Proper restraint is necessary not only for the required prestress but also for good quality concrete.
3. The modification of restrained expansion curve gives a good picture of the effectiveness of expansive cements in reduction or even elimination of cracking.
4. Good results may be expected from addition of a small amount of expansive agent to most portland cements in cement factories or to most concretes in mixing plants to improve the general quality of concretes.

ACKNOWLEDGEMENT

The authors wish to thank Messrs. You Bao-kun, Deng Shen-cai and Miss Zhang Gui-qing for their help and cooperation in the whole investigation.

# Expansion of sulfoaluminate under under-saturated CaO

## *Expansion du sulfoaluminate en solution sous saturée en CaO*

XUE JUN-GAN, Engineer, Vice-Director, Cement Research Institute,  
CHEN WEN-HAO, TONG XUE-LI, ZHAO YU-PING, Engineers, Cement Research Institute,  
XU JI-ZHI, Technician, Cement Research Institute, Chine Populaire.

RESUME : L'étude de l'hydratation, en présence de gypse, de mélanges d'aluminates de chaux de rapports C/A variés (par exemple  $C_3A$ ,  $C_{12}A_7$ , CA, et  $CA_2$ ) et celle de ciments alumineux expansifs du type M, a été faite, en examinant les caractéristiques de l'expansion.

- Elle a montré que :
- 1) l'importance de l'auto-contrainte produite par l'expansion du sulfoaluminate dépend de la morphologie et de la proportion de l'ettringite formée; elle dépend aussi de la résistance du ciment hydraté au moment où se forme l'ettringite et du processus de formation du gel d'ettringite.
  - 2) si la phase aqueuse intersticielle est sous-saturée en chaux, l'ettringite se forme en plus grande quantité, mais est moins expansive dans le gel hydro-alumineux produit; la croissance de la résistance et de l'expansion sont alors compatibles; la microstructure de la pâte hydratée est plus dense, et le taux d'expansion libre du béton plus limité.

Deux types de ciment expansif en ont été déduits, en faisant varier le taux de saturation en chaux; ils ont été utilisés pour construire des conduites de 500 mm de diamètre autocontraint, la précontrainte s'élevant à 8 N/mm<sup>2</sup>. Ces conduites ont été installées dans des centrales hydro-électriques, dont l'une a une chute de 160 m.

SUMMARY: The effect of hydration products of mixtures of calcium aluminate compounds of various C/A ratio (i.e.  $C_3A$ ,  $C_{12}A_7$ , CA and  $CA_2$ ) with gypsum and of hydration products of aluminate and Type-M expansive cements on the characteristics of expansion have been investigated.

It has been shown that: Firstly, the magnitude of self-stress resulted from sulfoaluminate expansion is affected by the morphology and amount of ettringite being formed; The strength of the hardened cement paste at ettringite formation; and the morphology, amount and mode of the gel phase that is formed simultaneously. And secondly, at the condition of under-saturated CaO concentration, since more ettringite of less expansibility is formed with hydro-alumina gel in the same reaction, and the development of strength and expansion of the hardened paste are mutually compatible, the micro-structure of the paste is therefore denser, and the ratio of free against restraint expansion is relatively small in the concrete. Two kinds of high self-stressing cements which expand at the condition of under-saturated CaO have been developed and concrete pipes of 500 mm diameter with self-stressing value up to 8 N/mm<sup>2</sup> have been produced. These pipes have been used in penstocks of three water power stations with head up to 160 meters.

## INTRODUCTION

Since the use of expansion of ettringite to compensate the shrinkage of hardened cement paste by Lossier(1), Mikhailov(2), Klein(3,4), Budnikov(5) and others have successively developed Type-M, Type-K and gypsum-aluminate expansive cements.

According to Mikhailov(2,6), Schwiete(7), Mehta(8,9) and others, only ettringite formed at the condition of saturated CaO expands, while Budnikov and Kravchenko (5) stated to the contrary, that the ettringite formed at under-saturated CaO also expands.

In order to make use of the expansion produced by ettringite to the benefit of the structure of hardened expansive cement paste and to obtain a higher self-stress value, the characteristics of expansion of sulfoaluminate at the condition of under-saturated CaO have been investigated.

## THE MORPHOLOGY OF THE ETTRINGITES UNDER VARIED CONCENTRATIONS OF CaO

Optical and electron microscopy have been employed in studying the morphology of ettringites formed in the following systems, i.e.,  $\text{CA-CaO-CaSO}_4\text{-H}_2\text{O}$ ,  $\text{CA}_2\text{-CA-C}_{12}\text{A}_7\text{-}$  and  $\text{C}_3\text{A-CaSO}_4\text{-H}_2\text{O}$ ,  $\text{C}_2\text{AS glass-CaO-CaSO}_4\text{-H}_2\text{O}$  and  $\text{CAS}_2\text{ glass-CaO-CaSO}_4\text{-H}_2\text{O}$ , as well as those formed in hardened pastes of aluminate self-stressing cement and Type-M expansive cement. The concentrations of the liquid phases of these systems have also been analysed. It has been shown that under the condition of saturated CaO, ettringite of smaller size is formed and it often forms near the surface of the original aluminate phase; but at the condition of under-saturated CaO, larger size ettringite is formed and often at a distance from the surface of the original aluminate phase. The hexa-prismatic ettringite in the hardened paste of the Type-M expansive cement, as an instance of ettringite formed under saturated CaO,

exhibits a dimension of  $0.1\text{-}0.2 \times 0.5\text{-}1.0 \mu\text{m}$  (Fig. 1.A), and the ettringite in the paste of the aluminate self-stressing cement, as an instance of ettringite formed under under-saturated CaO, exhibits a dimension of  $0.5\text{-}1 \times 4\text{-}6 \mu\text{m}$  (Fig. 1.B).

A. Type-M self stressing cement paste B. Aluminate self-stressing cement paste  
Fig. 1. The surface replicas of hardened pastes of Type-M and aluminate self-stressing cements

## THE QUANTITY OF ETTRINGITE AND GEL PHASE

The physical properties of 1:1 sand mortars made from the mixtures of  $\text{CA}_2$ , CA,  $\text{C}_{12}\text{A}_7$  and  $\text{C}_3\text{A}$  with gypsum are shown in Table 1. X-ray diffraction and differential thermal analysis have been employed in the study of hydration products of the pastes. Results indicate that ettringite is formed in all the pastes. There are found 9.8 and  $5.7 \text{ \AA}$  peaks in the X-ray diffraction patterns and an endothermic peak at  $150^\circ\text{C}$  in the DTA curves. Also formed is  $\text{AH}_3$  in pastes of mixtures of  $\text{CA}_2$ , CA and  $\text{C}_{12}\text{A}_7$  with gypsum with broad humps of 4.83 and  $4.35 \text{ \AA}$  in the diffraction patterns and an endothermic peak at  $290^\circ\text{C}$  in the DTA curves. As shown in Table 2, the amounts of  $\text{AH}_3$  gel formed in the various mixtures vary by the following order:  $\text{CA}_2 > \text{CA} > \text{C}_{12}\text{A}_7$ , but there has not been noticed formation of  $\text{AH}_3$  in paste made from the mixture of  $\text{C}_3\text{A}$  and gypsum. The shape of  $\text{AH}_3$  exhibits equant particles with a dimension up to  $0.1 \mu\text{m}$  in the electron microscope. The chemical analyses of liquid phases of the pastes indicate that in the paste of mixture of  $\text{C}_3\text{A}$  and gypsum, the concentration of CaO is in saturated state during the first seven days, while in other pastes, the concentrations of CaO are in

under-saturated state. The residual gypsums in the pastes were determined by the selective resolution method developed by the authors(10). The quantities of ettringite and gibbsite in the pastes and their ratios are shown in Table 2.

results indicate that: Firstly, for the same mixture the expansion generally increases as the quantity of ettringite increases, irrespective of the CaO concentration being saturated or not in the liquid

phases of the pastes. However, the ettringite formed during the early hardening stage contributes only to development of skeleton which imparts strength but not expansion in spite of its quantity. As it can be seen from Table 2, in the specimens of the four aluminates, ettringites formed in one day moist curing as actually determined amount to 10.0 to 81.9% of the theoretical maximum ettringite that can be formed (the latter implies that when the gypsum originally

- \* Percentage of ettringite actually determined as against the theoretical total amount of ettringite that can be formed if gypsum originally present were all converted to ettringite.

present in the system has all been converted to ettringite). Secondly, under the condition of saturated CaO concentration, the formation of the smaller ettringite exhibits larger expansion; while under the condition of under-saturated CaO concentration, the formation of the large ettringite exhibits smaller expansion. Finally, in order to provide consistency for the development of strength and expansion, there must be presence of a definite amount of gel phase at the time of ettringite formation. As the ratio of ettringite to gel phase in the hardened pastes affects to a great extent the characteristics of strength and expansion of the hardened pastes, so it also affects the value of self-stress.

#### THE STRENGTH AND SELF-STRESSING VALUE OF HARDENED PASTES

The magnitude of self-stressing value in hardened pastes is affected not only by the quantity and morphology of ettringite but also by the strength of the hardened pastes. Therefore, the relation between self-stressing value calculated as per unit weight ettringite ( $\text{N/mm}^2 / \text{g}$  ettringite) and compressive strength of the aluminate self-stressing cement paste has been investigated, the result of which being shown in Fig. 2. In order to obtain a higher self-stressing value, it is necessary that, on the one hand, the ettringite be formed at the time when the paste has attained a relatively high strength, and on the other hand, a sufficient quantity of gel phase be formed in the mean time.

#### THE CHARACTERISTICS OF THE EXPANSION OF SULFOALUMINATE AT THE CONDITION OF UNDER-SATURATED CaO

The aluminate self-stressing cement paste has been chosen as the typical example of expansion of sulfoaluminate at the condition of under-saturated CaO, and the Type-M expansive cement paste as that of

Fig. 2 Relation between self-stressing value calculated as per unit weight ettringite and compressive strength of the aluminate self-stressing cement paste

expansion of sulfoaluminate at the condition of saturated CaO. The following aspects have been investigated and compared in the study, i.e. the CaO concentrations of liquid phases, the formation of hydrates and their consistency, the quantity of ettringite formed at the respective stages of hydration, the structure of cement pastes and the properties of the expansive cements and their concretes. The test results are summarized in Table 3. As can be seen from Table 3, at the condition of under-saturated CaO concentration, since a large amount of ettringite species of less expansibility is formed with hydroalumina gel in the same equation of chemical reaction, the development of strength and expansion of the hardened paste is compatible. Therefore, the micro-structure of the paste is denser, and the ratio of free against restraint expansion is relatively small in the concrete. The expansive concrete is thus provided with a protecting layer of superior quality. All of the above factors result in a self-stressing cement concrete with a high self-stressing value and low gas-permeability. These are the characteristics of the expansion of sulfoaluminate under the condition of under-saturated CaO.

THE HIGH SELF-STRESSING CEMENTS HAVE BEEN DEVELOPED

Aluminate and sulfoaluminate self-stressing cements have been developed in China. The former is an inter-ground product of high alumina cement clinker with CA and CA<sub>2</sub> as its main constituents and a certain amount of gypsum. The latter is an interground product of calcium sulfoaluminate clinker with C<sub>4</sub>A<sub>3</sub>S and  $\beta$ -C<sub>2</sub>S as its main constituents and a certain amount of gypsum. The characteristics of both cements lie in the expansion of sulfoaluminate at the condition of under-saturated CaO. The annual production of each cement amounts to about 20,000 tons and both are being used to manufacture concrete pipes for water, oils and gases.

Recently, improvements have been made in the manufacture of aluminates self-stressing cement concrete. The concrete pipes of 500 mm diameter with self-stressing value up to 8.0-10.0 N/mm<sup>2</sup> and inner pressure of fracture up to 2.4 N/mm<sup>2</sup> have been produced, and put in trial use in penstocks of three water power stations with head up to 160 meters.

#### PROSPECTS

There had been much controversy about the use of expansive cement for self-stressing concrete during the 3rd Symposium held at London in 1952. Since then it has been used in concrete of low self-stressing value. In view of the fact that the durability of protecting layer of concrete will deteriorate under the extreme expansion of concrete, Polivka(11) emphasized that the practical self-stressing value should not exceed 3.5 N/mm<sup>2</sup>. We are of the opinion, however, that with fuller knowledge about the peculiarity of expansion of sulfoaluminate at the condition of under-saturated CaO we can do much to finally solve the problem of the quality of the protecting layer of self-stressing concrete. Now that the high self-

stressing cement and its concrete have been developed and concrete with self-stressing value up to 8.0 N/mm<sup>2</sup> have been produced, we can well anticipate that the value of chemical pre-stress will eventually approach that of mechanical pre-stress.

RESUME : Le mécanisme des déformations volumiques des ciments expansifs de compositions différentes est étudié.

Les études complexes des processus physico-chimiques, des auto-contraintes et des déformations ainsi que des variations volumiques, dans les structures soumises aux déformations, a montré que l'augmentation localisée de volume des phases solides dont la formation est le résultat de la réaction du composant-expandeur a pour base l'expansion des ciments. Dans le processus du durcissement des ciments se produit l'augmentation volumique des particules dans la phase expansive (ettringite ou  $\text{Ca}(\text{OH})_2$  qui amène à la naissance dans la structure du ciment durci des contraintes internes (auto-contraintes)  $\sigma$ . A un certain niveau de  $\sigma$  suffisant pour vaincre la résistance de la structure, a lieu la déformation (l'expansion) de la structure. Pour déterminer expérimentalement les auto-contraintes, on a utilisé les méthodes des compensations mécanique et magnétique des déformations d'expansion.

SUMMARY: Mechanism of volumetric strains in expanding cements of different composition has been studied.

It has been shown from complex investigations of physicochemical processes, own stresses and strains as well as from volumetric changes in deformed structures that localized increase in volume of solid phases which are formed as a result of expanding component reaction is the basis of cements expanding. In the process of cements hardening the volume increase of particles in expanding phase (ettringite or  $\text{Ca}(\text{OH})_2$ ) leads to development of inner (own) stresses  $\sigma$  in the structure of cement stone. Under a certain critical level  $\sigma$  sufficient for overcoming of structure resistance, the deformation of the structure, or its expanding, takes place. For experimental determination of own stresses there have been used some methods of mechanical and magnetic compensation of expansion strains.

L'un des cas le plus intéressant des propres déformations des structures en ciment est l'augmentation du volume observée lors le durcissement des ciments expansés.

Les études du mécanisme de l'expansion des ciments, présente un intérêt considérable pour la élaboration de la théorie générale des déformations des structures dispersées; aussi ces études sont d'une grande importance pratique pour les développement de la technologie dans le domaine des ciments et des bétons irrétrécissables, expansifs et autocontraints, étant donné que ciments et bétons mentionnés soient produits sur la base de ces structures.

L'analyse des données cités dans les oeuvres littéraires concernant le problème de l'aptitude de ciments à l'expansion montre que, malgré un nombre important des travaux effectués dans ce domaine et des hypothèses proposées (I-5), le mécanisme de l'expansion du ciment durci n'est pas encore tiré à claire jusqu'à la fin.

La plupart des chercheurs en envisageant les processus qui se passent dans les systèmes expansives ont principalement accordé leur attention à l'étude des réactions chimiques qui amènent à la formation de la phase d'expansion. Cependant, l'expansion en qualité de l'effet volumique ne peut pas être compris seulement à la base des représentations chimiques. En dehors de l'étude des processus physico-chimiques qui provoquent l'apparition des déformations est très importante la considérations du côté géométrique des structures poreuses soumises aux déformations, c'est à dire des variations volumiques qui se passent à l'intérieur de la structure simultanément avec la variation volumique des particules isolées dont cette structure est composée.

En étudiant le mécanisme de l'expansion il faut prendre en considération les problèmes de la mécanique des déformations, notamment l'interdépendance entre les propriétés de résistance et les propriétés de déformation du ciment durci ainsi que l'interdépendance entre les propres contraintes accompagnant le processus du durcissement des ciments expansifs.

L'objectif de l'ouvrage présent est l'examen de l'ensemble complexe de phénomènes ayant lieu dans les structures expansives.

Les différents types des ciments expansifs d'alumosulfates tels que le ciment d'aluminat gypse (à haute teneur en alumine) (GGC-abbreviations russes); le ciment autocontraint (NC), le ciment autocontraint alunitisé (ANC) ainsi que les composantes sur la base de ciment de portland, contenant l'adjuvant CaO (RPC) en qualité de constituant d'expansion (Table I) ont été les objets de ces études.

Lors la réalisation des études dans le domaine des processus physico-chimiques ayant lieu pendant le durcissement des ciments mentionnés ont été déterminés:

- la cinétique et le caractère de la cris-

TABLEAU I

tallisation des phases d'expansion;  
- la cinétique de la fixation de l'eau durant le processus de durcissement et d'expansion des ciments;  
- la composition de phase des nouvelles formations des hydrates;  
- la micro-structure du ciment durci;  
- les déformations linéaires des éprouvettes.

Nous allons nous arrêter tout d'abord sur l'examen des compositions expansives les plus répandues c'est à dire des compositions sur la base de sulfo-aluminates - GGC, NC et ANC. Malgré la diversité des hypothèses proposées expliquant le processus de l'expansion de tels ciments l'opinion est telle que à la base de ce processus est la réaction de la formation de hydro-sulfoaluminate de calcium - d'ettringite -  $3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot 3\text{CaSO}_4 \cdot 3\text{H}_2\text{O}$ , suivie par l'augmentation en 2,3 fois de volume des phases solides.

Les études que nous avons réalisées montrent que l'ettringite est un produit initial de l'interaction du gypse avec une composante d'aluminate qui se passe pendant le durcissement de tous les types des ciments éprouvés. D'après les données de l'analyse XR et de l'analyse derivatographique (DTA), la formation de l'ettringite est enregistrée dans le ciment durci quelque minutes après le gâchage.

La stabilité d'ettringite durant le durcissement ultérieur est conditionnée surtout par la proportion des minéraux d'aluminate et du gypse dans la composition des ciments éprouvés. Dans la pierre de ciment durci ayant la GGC, et contenant 30% du gypse (composition n° 1, table I), l'ettringite formé présente une composition stable et une composition qui ne subit aucune transformation de phase pendant toute la période du durcissement du ciment. Dans le même temps, un liage un épuisement total du gypse s'étant produit, on peut observer dans certaines compositions de NC-N (composition n° 3, table I) une transition partielle de l'ettringite en mono-sulfo-aluminate de calcium -  $3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{CaSO}_4 \cdot 12\text{H}_2\text{O}$  (6). Cette transformation de phase est conditionnée par la surabondance de la composante d'aluminate par rapport au gypse dans la composition du ciment et celle-ci se passe en parfaite conformité de conditions d'équilibre dans le

système de  $\text{CaO-Al}_2\text{O}_3\text{-CaSO}_4\text{-H}_2\text{O}$ , étudié minutieusement par D'Ans et par Eick (7).

Les études complexes physico-chimiques étant réalisées il s'est avéré, pourtant, que la valeur d'expansion des ciments aluminosulfatés n'est pas liée d'une manière univalente avec la quantité de l'ettringite formé. Pour affirmer ce fait il suffit de comparer les données sur la déformations des ciments du type GGC et GGC-C que nous avons obtenues. (Les compositions n° 1 et n° 2, table I) (Fig. I).

Fig. I - La cinétique de la cristallisation d'ettringite (I, I') et de développement des déformations d'expansion (2, 2') au cours du durcissement de GGC (I, 2) et de GGC-C (I', 2').

Comme le montre la figure I, durant le durcissement de deux types de ciments mentionnés, se forme à peu près la même quantité d'ettringite (~56%), tandis que les déformations d'expansion dans le cas d'utilisation de GGC ne présentent que 0,16%, donc dans le cas d'utilisation de GGC-C cette valeur s'approche déjà à 6% vers le 3ème jour de durcissement. Dans les compositions de NC les déformations d'expansion peuvent aussi toucher à des valeurs considérables (4% et plus), alors que la quantité maximale de l'ettringite formée ne dépasse pas 30%, c'est à dire que cette quantité est de 2 fois plus petite que dans les compositions de GGC et de GGC-C considérées plus haut (6, 8).

Il est évident qu'il est nécessaire de chercher la cause de cette différence des déformations dans les conditions différentes de la cristallisation de l'ettringite.

Les analyses microscopiques montrent (6) que, compte tenu de la phase liquide, la cristallisation de l'ettringite peut se passer soit dans les pores du ciment durci en pro-

voquant les déformations tout à fait médiocres (tout comme dans le cas de GGC), soit bien ce processus se localise sur les grains des aluminates de calcium qui font partie du composant d'expansion. Avec cela une influence déterminante sur le caractère de la cristallisation de l'ettringite est exercée par la teneur en  $\text{CaO}$  dans la phase liquide du ciment durci. Dans le cas où la réaction de la formation de l'ettringite se localise sur la surface des particules des aluminates de calcium, ces particules se régénèrent peu à peu en un agrégat polycristallin et s'augmentent volume comme un entier unifié. Telles particules deviennent, par conséquent, la source des déformations pour toute la structure dans son ensemble.

Dans les ouvrages (8-9) est montré que le mécanisme analogue d'expansion a lieu aussi dans le cas si nous utilisons  $\text{CaO}$  et  $\text{MgO}$  comme les adjuvants d'expansion.

La réaction de hydratation de  $\text{CaO}$  et de  $\text{MgO}$  ayant lieu dans la structure durcissante du ciment durci et accompagnée par un plus que double augmentation de volume des phases solides est la cause d'expansion de tels ciments (composition n° 6, Table I). Il est connu que la hydratation de  $\text{CaO}$  a déjà lieu même si les valeurs de tension de vapeur d'eau sont assez médiocres, c'est à dire en absence de la phase liquide; avec cela est lié, en particulier, son application en qualité de l'agent de dessèchement. En se basant sur ce fait certains chercheurs considèrent le processus de hydratation de  $\text{CaO}$  comme la réaction de phase solide. En tout cas, indépendamment de mécanisme détaillé de cette réaction, il est évident qu'elle est d'un caractère localisé et n'est pas accompagnée par le transport, aux espaces de pores du ciment durci durant son durcissement, de la masse de hydrate au cours de sa formation.

Ainsi, la capacité à la manifestation de déformations d'expansion des structures du ciment ayant des compositions différentes détermine non une simple augmentation de volume des phases solides qui résulte de la réaction du composant d'expansion, mais le caractère local du dégagement des produits de sa hydratation.

Envisageons maintenant le côté géométrique des déformations des structures expansives. Il est possible de supposer, que la déformation observée pendant le durcissement des ciments expansifs est un certain total de l'ensemble des microdéformations élémentaires dont la naissance est le résultat de l'augmentation du volume des particules du composant expansif faisant partie de leur structure (8). Puisque l'augmentation de volume des particules unitaires du composant d'expansion est à ce qu'il paraît la cause provoquant l'augmentation de volume total de la structure dans l'ouvrage présent nous sommes intéressés avant tout au rapport entre l'accroissement de volume total de la structure ( $V_s$ ) et l'ac-

croissement de volume des phases solides ( $\Delta V_t$ ). La méthodologie de l'étude est décrite en (8). Les modèles des courbes structurales, obtenus pour les différentes compositions expansives sont présentées aux Figures 2 et 3. En faisant l'analyse des courbes on porte avant tout l'attention sur le fait qu'entre les valeurs  $\Delta V_s$  et  $\Delta V_t$  il n'y a pas de relation linéaire à laquelle on pouvait s'attendre dans le cas où l'expansion de la structure n'était déterminée que par une simple augmentation de volume des phases solides.

Donc, durant la hydratation de GGC, malgré l'augmentation de volume des phases solides résultant de la cristallisation de l'ettringite, le volume de la structure presque ne change pas (Figure 2, courbe 1). En tenant compte de ce que  $\Delta V_s = \Delta V_t + \Delta V_p$ , avec  $\Delta V_s \approx 0$  et  $\Delta V_t \gg 0$ ,  $\Delta V_t = -\Delta V_p$ , où  $V_p$  - et le volume des pores.

Ainsi, dans le cas de l'absence de la déformation extérieure de la structure, l'augmentation de volume des phases solides résultant de la cristallisation du composant d'expansion est compensée par la diminution de la porosité, c'est à dire, les nouvelles formations en se cristallisant de la solution sursaturée se déposent à l'intérieur des pores remplies par la solution. Cette conclusion, comme il a été déjà montré, est confirmée par un contrôle immédiat au microscope du caractère de la cristallisation de l'ettringite durant la hydratation de GGC.

Fig. 2 - La variation de volume des éprouvettes ( $\Delta V_s$ ) en fonction de l'augmentation de volume des phases solides ( $\Delta V_t$ ) au cours de durcissement de GGC (1) et de GGC-C (2).

A l'introduction dans le GGC de l'adjuvant de CaO (composition 2, Table I), à partir d'une certaine valeur critique  $\Delta V_t$  le volume de la structure commence à augmenter brusquement (Figure 2, courbe 2). Le chan-

gement, du caractère de la courbe structurale est dans le cas présent au changement du caractère de la cristallisation de la phase d'expansion de ces ciments - de l'ettringite.

Pour toutes les autres compositions des ciments expansifs (NC, ANC, RPC) qui ont été étudié les courbes structurales représentant le rapport  $\Delta V_s = f \Delta V_t$  ont le même caractère de "S" pareil à la courbe pour la composition de GGC-C. En qualité d'exemple à la Figure 3 est présentée la courbe du rapport  $\Delta V_s$  de  $\Delta V_t$  pour RPC contenant 10% de CaO (composition 6, Table I). Avec la courbe principale structurale à la Figure sont aussi présentées les données concernant la cinétique de la hydratation de CaO et le données concernant la fixation de l'eau durant le durcissement de la composition donnée de RPC.

Fig. 3 - La variation de volume de l'éprouvette ( $\Delta V_s$ ) en fonction de l'augmentation de volume des phases solides ( $\Delta V_t$ ) au cours de durcissement de RPC additionné par 10% CaO.

Par la similitude mentionnée dans le caractère des courbes structurales est témoigné le fait que le mécanisme de l'expansion est toujours pareil indépendamment de la différence dans la nature des composants d'expansion utilisés.

L'analyse des régularités obtenues montre que le processus d'expansion comprend les trois étapes successives et interdépendantes. La section I des courbes structurales (Figure 3), correspondant au stade initial de formation de la structure est caractérisée par l'augmentation de volume des phases solides pour le compte de hydratation des minéraux de clinker de ciment et du des composant d'expansion, le volume de la struc-

ture étant pratiquement invariable. Par la suite, l'augmentation localisée de volume des particules du composant d'expansion amène à un accroissement progressif des contraintes internes dans la structure du ciment durci au cours de sa formation. A un moment déterminé les contraintes mentionnées touchent à une valeur suffisante pour surmonter la résistance de la structure et puis ces contraintes relaxent et provoquent sa déformation. A la période de l'expansion intensive correspond la section II des courbes structurales. A cette section une accroissement relativement médiocre de  $\Delta V_t$  provoque une grande augmentation de volume total de la structure et une grande augmentation de volume des pores puisque  $\Delta V_s \gg \Delta V_t$  et par conséquent,  $\Delta V_s \approx \Delta V_p$ . L'expansion des éprouvettes prend sa fin, en général simultanément avec l'achèvement de la réaction du composant d'expansion.

La section III des courbes structurales est caractérisée par l'augmentation continuée de volume des phases solides qui se réalise à présent surtout pour le compte de hydratation des minéraux siliceux du ciment. Ces processus amènent au rétablissement des liaisons déréglées, au compactage de la structure et à l'accroissement de sa résistance mécanique.

Pour confirmer les thèses exposées plus haut ont été effectuées les essais directs ayant pour but la détermination expérimentale des propres contraintes qui accompagnent le processus du durcissement des ciments expansifs.

Pour mesurer ces propres contraintes dans les systèmes expansifs sont utilisées les deux méthodes que nous avons mis au point.

La première méthode est basée sur le phénomène de la compensation mécanique des déformations d'expansion du matériau. Cette méthode étant au cours d'élaboration on a adopté en qualité de la caractéristique des contraintes internes la pression la plus petite qui résulte de l'action de la charge extérieure et qui ne provoque pas d'augmentation de volume de la structure. Pour mesurer la valeur mentionnée nous avons créé le spécial dispositif de mesure qui représente un levier d'équilibrage, muni d'un système automatique de chargement qui effectue son action sur l'éprouvette par l'intermédiaire de poinçon ayant le contact avec sa surface. Au cours de processus d'expansion le ciment durci étudié exerce une pression sur le poinçon ce qui met en marche le système automatique de chargement. D'après la charge indispensable pour la réduction de volume du ciment durci à la valeur initiale on détermine l'effort qui se développe au cours de durcissement des ciments (la pression d'expansion).

La deuxième méthode de mesure des propres contraintes est basée sur l'utilisation des capteurs annulaires magnéto-élastiques créés par TsNIISK Koutcherenko (IO) dont l'anneau rigide en matériau ferromagnétique est l'élément principal.

Pour réaliser les mesures, le capteur est placé au centre de moule cylindrique, après quoi le moule est rempli par la pâte de ciment étudiée et les contacts de sortie du capteur sont mis en connexion avec les appareils de mesure. Par suite de l'expansion du ciment durci étant donné qu'il existe un facteur restrictif - la forme, qui empêche sa déformation, les contraintes radiales mécaniques exercent l'action sur la capteur. Avec cela dans le matériau de l'anneau a lieu la modification des propriétés magnétiques par la transformation desquelles en signal électrique on trouve à l'aide des courbes d'étalonnage les valeurs des propres contraintes qui surgissent dans le matériau.

A la Figure 4 sont présentés les résultats de mesure de  $\sigma$  au cours de durcissement de ANC les méthodes citées étant utilisées. Pour faire une comparaison à la Figure sont aussi présentées les courbes de cinétique de la cristallisation de la phase d'expansion du ciment donné - d'ettringite (Courbe 1) et de développement des déformations d'expansion (Courbe 2). Comme on peut voir à la Figure, les courbes de cinétique de développement des propres contraintes (courbes 3,4) et la courbe de déformations d'expansion, se ressemblent et sont analogues à un S.

Au cours de 15-30 minutes (des le début) on peut observer sur toutes les courbes une courte période d'induction coïncidant avec la période de formation de la structure de la pâte de ciment. A ce stade, l'action du composant d'expansion n'amène pas à l'apparition des contraintes puisque la structure du ciment durci n'a pas encore gagné résistance indispensable.

Par la suite, dans la mesure de durcissement du ciment durci, la cristallisation d'ettringite localisée à la surface des grains de base du ciment amène à un accroissement successif des contraintes à l'intérieur de ce ciment durci. A ce stade, l'essentiel pour le comportement des éprouvettes est l'existence (la présence) ou l'absence de limitation (restriction) de leur déformation. En absence de limitation les propres contraintes ayant touché à un niveau déterminé provoquent une expansion considérable du ciment durci (plus de 5%), (Courbe 2), suivie par l'ameublissement de la structure et par l'abaissement de sa résistance. La limitation rigide de la déformation dans la même période étant donnée nous fixons le surgissement et le développement intensif des propres contraintes (Courbes 3,4). Comme il est montré à la Figure, le développement des propres contraintes ainsi que l'expansion qui a lieu dans le ciment durci en ANC de la composition donnée sont les plus intensifs pendant les 2 heures des le début de hydratation. En comparant les données obtenues avec les résultats des essais physico-chimiques du même ciment on peut voir que la période de développement intensif des contraintes et des déformations correspond par le temps à une cristallisation la

Fig. 4 - La cinétique de cristallisation d'ettringite (1), de développement des déformations d'expansion (2) et des propres contraintes (3,4) au cours de durcissement de ANC

3 - Les données de la méthode des capteurs magnéto-élastiques

4 - Les données de la méthode de la compensation mécanique des déformations d'expansion.

plus active de la phase d'expansion du ciment donné - d'ettringite (Courbe 1).

Les études ont montré qu'au cours de durcissement d'autres types des ciment expansifs - de NC et de RPC sont observées les régularités analogues dans la cinétique de développement des propres contraintes, toutefois, les valeurs maximales de ces contraintes sont parfois plus grandes (8,0-10,0 N/mm<sup>2</sup>)

#### CONCLUSION

Est étudiée la nature physico-chimique des déformations volumiques des compositions expansives des composés différents. Par les méthodes de la composition mécanique des déformations d'expansion d'utilisation des capteurs magnéto-élastiques à été réalisé le mesure direct des propres contraintes accompagnant le processus de durcissement des ciments éprouvés.

La comparaison des données obtenues avec les résultats des études physico-chimiques montre que c'est les réactions du composant d'expansion amenant à une augmentation locale

de volume des phases solides dans la structure du ciment durci au cours de durcissement qui sont à la base de développement des propres contraintes et des déformations.

**RESUME :** Le système  $\text{CaO} - \text{Al}_2\text{O}_3$  a été étudié par plusieurs chercheurs et à l'heure actuelle la composition de ce système est bien connue. Toutefois, l'analyse de la composition des phases des clinkers industriels montre qu'il est difficile d'obtenir l'équilibre chimique et des phases dans les conditions du four rotatif, et le clinker contient des aluminates de calcium qui diffèrent par leur composition de ceux prévus par le calcul.

C'est pourquoi les auteurs étudièrent le processus de formation des minéraux lors de l'agglomération du clinker dans les conditions de laboratoire, semi-industrielles et industrielles. On a établi la succession de formation des minéraux, la température optimale de cuisson du clinker.

On a montré l'influence qu'exerce le milieu réducteur et l'introduction d'additions dans le mélange cru sur la pureté du produit obtenu et la composition du ciment.

**SUMMARY :** The  $\text{CaO}-\text{Al}_2\text{O}_3$  system has been studied by many investigators and the composition of the compounds in this system is well known at present. However, analysis of industrial clinker phase compositions reveals that chemical and phase balance is difficult to achieve in rotary furnaces, and the composition of calcium aluminates in clinker differs from the estimated one.

To clarify this point the authors have studied the process of mineral formation during sintering of clinker under laboratory, semi-industrial and industrial conditions. The sequence of formation of minerals and the optimum temperature of clinker sintering have been established.

The influence of the reducing medium and additives to the raw mix on the purity of the target product and cement composition has been shown.

L'ordre de formation des minéraux lors du chauffage du mélange de CaO avec  $Al_2O_3$  fut étudié par beaucoup de chercheurs (7-9) mais jusqu'à présent ils ne sont pas unanimes en ce qui concerne ce problème.

D'après les données du travail (3), lors de la cuisson du mélange cru de  $12CaO$  et  $7Al_2O_3$  jusqu'à  $1400^\circ C$  il se forme le monoaluminate de calcium  $CaO \cdot Al_2O_3$  (CA) et seulement à  $1450^\circ C$  s'achève la fixation complète de la chaux avec la formation de  $12CaO \cdot 7Al_2O_3$  ( $C_{12}A_7$ ).

Les calculs thermodynamiques de V. Babouchkine, G. Matvéev, O. Mitshedlov-Pétrossian (2) montrèrent que la composition du minéral primaire varie pour différent rapport entre CaO et  $Al_2O_3$  dans le mélange. Pour la valeur du rapport égale à 1:1, c'est la formation de CA qui est la plus probable, et pour le rapport 1:2, celle de  $CA_2$ .

Les auteurs (4, 5) estiment que CA est le produit primaire de la cuisson. T. Robson (6) indique que lors de la cuisson du mélange  $CaO - Al_2O_3$  il y a toujours  $C_{12}A_7$ , car ce composé se caractérise par une vitesse élevée de croissance des cristaux.

En confirmant cette opinion Scholze et Kumm (7) établirent que 1 % de CaO,  $Al_2O_3$ ,  $K_2O$ ,  $Fe_2O_3$  diminue cette vitesse au différent degré, mais dans les conditions relativement identiques la vitesse de croissance des cristaux de  $C_{12}A_7$  est supérieure à celle de tout autre aluminat de calcium.

Y. Boutt et V. Timachev (1) estiment que la succession de formation des aluminates de calcium dans la série  $CA - C_{12}A_7 - CA_2$  se conserve lors de la cuisson des mélanges de composition  $CaO:Al_2O_3 = 12:7$ ; 1:1 et 3:1. Pour l'excès de  $Al_2O_3$  l'analyse a lieu dans le sens de  $CA - CA_2 - CA_6$ .

En analysant toutes ces données on peut aboutir à la conclusion qu'il est très difficile d'obtenir l'équilibre chimique dans les conditions du four rotatif et qu'après la cuisson le clinker contiendra des aluminates de calcium qui diffèrent par leur composition des aluminates prévus. La différence entre les compositions en phases théorique et réelle sera plus importante en présence dans la matière crue d'additions :  $SiO_2$ ,  $Fe_2O_3$ ,  $Mn_2O_3$ ,  $MgO$ , etc. Leur influence sur les propriétés du ciment est bien connue :  $SiO_2$  fixe  $Al_2O_3$  et CaO en gehlenite, matériau hydrauliquement inerte.  $Fe_2O_3$  forme l'alumoferrite de calcium - le constituant à durcissement lent.  $MgO$  dans la composition de la spinelle  $MgO \cdot Al_2O_3$  diminue également la résistance du ciment.

Quelques travaux montrent que la silice et les oxydes de fer entrent en petites quantités dans la solution solide d'aluminates de calcium et seulement en présence d'une grande quantité de  $SiO_2$  et  $Fe_2O_3$ , ils forment de nouvelles phases dans la composition du clinker de ciment alumineux à teneur d'alumine élevée.

T. Robson se réfère dans son travail (8) à Dayal et Glaser qui affirment que la con-

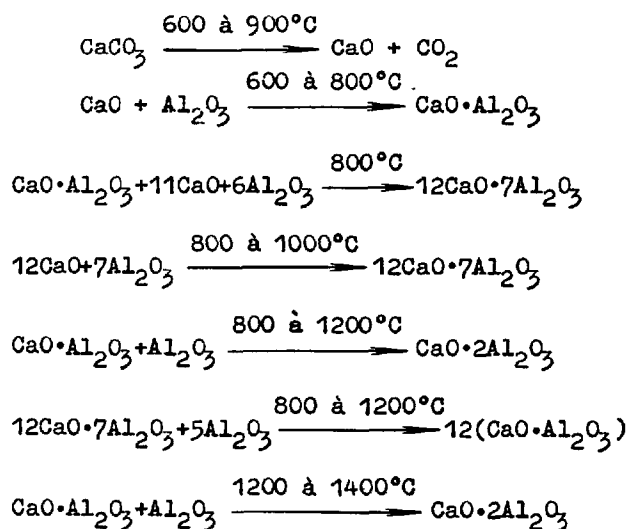

centration limite de  $Fe^{3+}$  capable de remplacer  $Al^{3+}$  dans le réseau de CA est de 4,5 %. Dans ce cas l'hydratation de CA contenant  $Fe^{3+}$  est plus rapide que celle du monoaluminate de calcium pur. Les auteurs montrent que  $CA_2$  peut aussi contenir dans la solution solide jusqu'à 5,7 % de Fe et son hydratation s'accélère. Les ions fer peuvent également pénétrer dans le réseau de  $C_{12}A_7$ .

K. Soudzouki (9) estime que Si et Fe ou Si + Fe pénètrent dans le réseau de CA et modifient ses paramètres, ce qui fait varier l'activité hydraulique de CA.

Le milieu gazeux exerce également une grande influence sur la composition en phases du clinker de ciment alumineux à teneur d'alumine élevée lors de sa cuisson. Dans la référence (10) on suppose que l'oxygène est nécessaire pour la formation du composé  $C_{12}O_7$ . Dans les conditions réductrices de la cuisson le composé  $C_5A_3$  est stable.

Nos recherches ont pour but d'étudier le processus de formation des minéraux lors de la cuisson des mélanges crus de  $CaCO_3$  et  $Al(OH)_3$  chimiquement purs, calculés pour la formation de CA et  $CA_2$ .

Sur la base des examens aux rayons X, la succession de formation des minéraux, lors du chauffage du mélange de composition  $CaO:Al_2O_3 = 1:2$ , peut être représentée comme suit :

La décomposition du constituant calcique avec séparation de CaO conditionne son interaction avec  $Al_2O_3$  du mélange cru avec formation de CA et  $C_{12}A_7$ . L'apparition de l'aluminat  $C_{12}A_7$  à côté de CA est une conséquence de la dissociation rapide de  $CaCO_3$  dans l'intervalle de  $600$  à  $800^\circ C$  avec formation dans le système  $CaO - Al_2O_3$  d'une grande quantité de  $CaO$  libre.

Comme la mobilité des ions  $Ca^{2+}$  est beaucoup plus grande que celle des ions  $Al^{3+}$ , la couche de diffusion des nouvelles formations à la surface limite des phases so-

lides est enrichie en  $\text{Ca}^{2+}$ . Lorsque la température croît jusqu'à  $1200^\circ\text{C}$  l'activité de  $\text{Al}^{3+}$  augmente, ce qui contribue à l'accélération de l'interaction de l'alumine avec  $\text{CaO}$ . Par suite la quantité d'aluminates de calcium dans les agglomérés augmente brusquement, la quantité de  $\text{C}_{12}\text{A}_7$  diminue et  $\text{CA}_2$  fait son apparition. À la température de  $1200^\circ\text{C}$ , lorsque la partie considérable de  $\text{CaO}$  est fixée en  $\text{CA}$ , la formation ultérieure du minéral  $\text{CA}_2$  a lieu grâce à la réaction d'interaction de  $\text{CA}$  avec  $\text{Al}_2\text{O}_3$ .  $\text{C}_{12}\text{A}_7$  avec  $\text{Al}_2\text{O}_3$  forme  $\text{CA}$  qui forme aussi  $\text{CA}_2$  au cours de la réaction avec  $\text{Al}_2\text{O}_3$ .

L'étude microscopique des échantillons cuits montre que sur les grains d'alumine apparaît d'abord une petite couche des produits d'interaction de  $\text{Al}_2\text{O}_3$  avec  $\text{CaO}$  et l'épaisseur de cette couche augmente progressivement (fig. 1). Au centre du grain se trouve l'alumine non réagie et aux bords, une frange de nouvelles formations. Avec l'élévation de la température de cuisson, le coefficient moyen de réfraction de la lumière des grains fins des nouvelles formations varie de  $1,609 \pm 0,002$  (à  $800^\circ\text{C}$ ) jusqu'à  $1,650 \pm 0,002$  (à  $1200^\circ\text{C}$ ). Même les échantillons cuits à  $1400^\circ\text{C}$  contiennent, à côté de gros cristaux de  $\text{CA}_2$  et  $\text{CA}$ , des grains d'alumine ayant sur sa surface une frange de nouvelles formations.

Fig. 1 - Produits d'interaction de l'alumine avec la chaux. Lumière passante, avec l'analyseur, X 600.

Les données obtenues témoignent du processus non équilibré de cristallisation des phases. Après la cuisson à  $1400^\circ\text{C}$  les mélanges calculés pour l'élaboration de  $\text{CA}_2$  contiennent réellement, à côté de  $\text{CA}_2$  et  $\text{CA}$ , de l'alumine libre.

Les recherches ultérieures furent menées

sur les mélanges avec  $\text{CaO}:\text{Al}_2\text{O}_3 = 1:1$ . On procédait à la cuisson des échantillons sous forme de granules jusqu'à leur agglomération à  $1400^\circ\text{C}$ . Par examen aux rayons X on a établi qu'il se forme dans le clinker  $\text{C}_{12}\text{A}_7$ ,  $\text{CA}$  et il y a  $\text{Al}_2\text{O}_3$  libre.

On a également établi que le processus de formation des minéraux dépend de la durée et de la température de cuisson. Lorsque le temps de séjour du mélange dans la zone de la température élevée augmente de 10 à 60 minutes, le degré de transformation de  $\text{CaO}$  croît de 6,5 fois. A en juger d'après l'intensité des raies de diffraction de  $\text{CA}$  ( $d = 2,97 \text{ \AA}$ ) et de  $\text{CA}_2$  ( $d = 3,51 \text{ \AA}$ ), à  $1300^\circ\text{C}$  le clinker contient une quantité relativement plus grande de monoaluminate de calcium, à  $1350^\circ\text{C}$  le clinker est représenté par une quantité presque égale de  $\text{CA}$  et de  $\text{CA}_2$ , et à  $1400^\circ\text{C}$  la teneur de  $\text{CA}_2$  dépasse la quantité de  $\text{CA}$  dans le clinker.

Notons que les clinkers obtenus par cuisson à la température de  $1400^\circ\text{C}$  ne sont pas monophases, tandis que les échantillons de  $\text{CA}$ ,  $\text{CA}_2$  produits par fusion à  $1600^\circ\text{C}$  ne contenaient pas d'impuretés d'autres phases.

Pour étudier l'influence de  $\text{Fe}_2\text{O}_3$  sur la composition en phases du clinker et les propriétés du ciment, on a préparé six mélanges à raison d'obtenir  $\text{CA}$  : le mélange I - sans additions ; les autres mélanges avec addition de  $\text{Fe}_2\text{O}_3$  en quantité de 0,05 ; 0,11 ; 1,0 ; 2 et 3% de la masse du mélange.

Les expériences montrèrent que la température de cuisson des clinkers, avec addition de  $\text{Fe}_2\text{O}_3$  dans le mélange cru, diminue de  $30-70^\circ\text{C}$  et d'autant plus que la teneur du mélange en  $\text{Fe}_2\text{O}_3$  est plus élevée.

Les examens aux rayons X permirent d'établir que pour la teneur du mélange en  $\text{Fe}_2\text{O}_3$  jusqu'à 2 %, la composition en phases du clinker est représentée par le monoaluminate de calcium et une petite quantité de  $\text{CA}_2$  et  $\text{C}_{12}\text{A}_7$ . Dans ce cas, avec l'augmentation de la quantité de  $\text{Fe}_2\text{O}_3$  dans le mélange la quantité de  $\text{CA}_2$  et de  $\text{C}_{12}\text{A}_7$  diminue, tandis que la quantité de  $\text{CA}$  augmente (fig. 2). L'augmentation de  $\text{Fe}_2\text{O}_3$  au-dessus de 2,40 % s'accompagne d'une apparition dans l'échantillon de l'alumoferrite de calcium.

L'étude microscopique des échantillons montre que la préparation de l'échantillon 1 se compose des cristaux sous forme de tables de différentes dimensions. Les indices de réfraction sont  $N_g = 1,665$ ,  $N_p = 1,643$ . L'addition de  $\text{Fe}_2\text{O}_3$  dans le mélange cru contribue à la formation de cristaux plus grands. Leurs indices de réfraction augmentent jusqu'à  $N_g = 1,667$  à  $1,669$  et  $N_p = 1,650$  à  $1,667$ .

Les propriétés physico-mécaniques des ciments obtenus (tableau I) témoignent de l'influence favorable exercée par une petite quantité de  $\text{Fe}_2\text{O}_3$  dans la composition de  $\text{CA}$  sur ses propriétés. La résistance mécanique de la pierre de ciment de  $\text{CA}$

Fig. 2 - Radiogrammes de CA avec différentes additions de  $\text{Fe}_2\text{O}_3$ . 1 - sans addition ; 2, 3 - avec addition de  $\text{Fe}_2\text{O}_3$  en quantité de 1,2 et 3,7 %.

se trouve en pleine conformité avec la composition en phases du clinker. L'augmentation de la quantité de CA dans le clinker entraîne celle de la résistance de la pierre de ciment. Lorsque la teneur du clinker en  $\text{Fe}_2\text{O}_3$  se trouve dans les limites de 1,2 à 2,4 %, il se forme pratiquement le produit monphasé contenant seulement CA. La résistance de la pierre de ciment au cours de 24 heures de durcissement augmente respectivement. L'apparition dans la composition du clinker de l'alumoferrite de calcium conduit à une certaine diminution de la résistance du ciment durci.

Tableau I						
Quantité de $\text{Fe}_2\text{O}_3$ dans le clinker	$S_v$ cm <sup>2</sup> /g	Prise, heures minutes		Résistance à la compression, kgf/cm <sup>2</sup>		
		début	fin	1 jour	3 jours	28 jours
0,006	2770	0-10	1-05	385	407	555
0,14	2880	0-50	1-45	465	582	735
0,60	2780	3-10	5-50	435	627	755
1,20	2780	3-50	6-20	510	640	680
2,40	2800	4-10	7-10	505	680	680
3,70	2800	4-40	7-30	475	623	675

On étudiait l'influence exercée par l'addition de  $\text{SiO}_2$  et  $\text{MgO}$  au mélange cru sur les propriétés du ciment alumineux à teneur d'alumine élevée sur les mélanges calculés pour l'obtention de  $\text{CA}_2$ . L'échantillon obtenu par cuisson du mélange de matériaux

chimiquement purs sans addition de  $\text{SiO}_2$  et  $\text{MgO}$ , se caractérise par une grande quantité de CA à côté de  $\text{CA}_2$  et  $\alpha\text{-Al}_2\text{O}_3$  (fig. 3).

Fig. 3 - Radiogrammes de CA avec additions de  $\text{SiO}_2$  et de  $\text{MgO}$ . 1 - sans additions ; 2, 3 - avec addition de 2 et 4 % de  $\text{SiO}_2$  ; 4, 5 - avec addition de 3 et 5 % de  $\text{MgO}$ .

D'après les calculs, l'échantillon dans lequel étaient introduits 2 % de  $\text{SiO}_2$  doit contenir 8 % de gehlenite et l'échantillon contenant 1,5 % de  $\text{MgO}$  doit avoir dans sa composition 6,5 % de spinelle  $\text{MgO} \cdot \text{Al}_2\text{O}_3$ . Toutefois, sur les radiogrammes de ces échantillons les raies de diffraction avec les distances réticulaires caractéristiques de ces composés, n'étaient pas décelées. On a établi que les échantillons sont représentés principalement par  $\text{CA}_2$  à côté duquel il y a  $\alpha\text{-Al}_2\text{O}_3$ , CA mais en quantité plus petite que dans l'échantillon du clinker obtenu par cuisson du mélange cru sans additions. Il est également établi que l'introduction de  $\text{SiO}_2$  et de  $\text{MgO}$  dans le mélange cru modifie la composition en phases du clinker et conditionne l'augmentation de l'activité hydraulique du ciment jusqu'à la limite déterminée. L'accroissement de la résistance du ciment durci s'observe lorsque la teneur du clinker en  $\text{SiO}_2$  est jusqu'à 3 % et en  $\text{MgO}$  jusqu'à 4 %. L'augmentation ultérieure de ces oxydes s'accompagne d'une apparition dans le clinker de la gehlenite et de la spinelle et respectivement d'une diminution de la résistance de la pierre de ciment (fig. 3).

Les recherches ultérieures furent menées avec utilisation du mélange cru préparé à partir du calcaire et de l'alumine technique et contenant (%) :  $\text{SiO}_2$  - 0,8 ;  $\text{Al}_2\text{O}_3$  - 66,4 ;  $\text{CaO}$  - 18,5 ;  $\text{Fe}_2\text{O}_3$  - 0,1 ;  $\text{Mn}_2\text{O}_3$  - 0,05. On étudiait l'influence des additions

pour le mélange cru de minéralisateurs et de modificateurs ainsi que du caractère du milieu gazeux lors de la cuisson du clinker sur sa composition.

Les études de l'influence des additions de  $\text{CaSO}_4$ ,  $\text{CaF}_2$  et  $\text{H}_3\text{BO}_3$  en quantité de 1 % de la masse du mélange montrèrent que le processus de clinkérisation s'accélérait en présence de ces additions. Le degré de transformation maximal de  $\text{Al}_2\text{O}_3$  est observé lors de l'introduction dans le mélange cru de  $\text{CaF}_2$ .

L'action intensifiante des additions indiquées conduit à une fixation plus complète de  $\text{Al}_2\text{O}_3$  avec formation de  $\text{CA}$ , et  $\text{CA}_2$  lorsque la quantité de  $\text{Al}_2\text{O}_3$  dans le clinker diminue ; il se forme alors une plus grande quantité de  $\text{CA}_2$  par rapport à sa quantité dans le clinker sans additions de minéralisateur.

La variation du rapport  $\text{CA}:\text{CA}_2$  dans le clinker influe respectivement sur la résistance du ciment durci. Dans les premiers délais de durcissement sa résistance (lorsqu'on utilise le clinker obtenu à partir du mélange sans additions) est supérieure à la résistance des autres clinkers et dans les délais avancés cède aux autres clinkers (fig. 4).

Fig. 4 - Résistance de la pierre de ciment en clinker obtenu par cuisson : 1 - sans additions ; 2 - avec addition de  $\text{CaF}_2$  ; 3 - avec addition de  $\text{H}_3\text{BO}_3$ .

La cuisson du mélange cru avec et sans additions indiquées fut effectuée dans le milieu oxydant et réducteur.

Les expériences ont montré que lors de la cuisson dans le milieu réducteur l'introduction des additions dans le mélange cru contribue à la volatilité des oxydes  $\text{Fe}_2\text{O}_3$  et  $\text{SiO}_2$ , alors que dans le milieu oxydant leur quantité reste pratiquement invariable.

Les spectres de la résonance paramagnétique électronique (RPE) obtenus à l'aide du radiospectromètre RE-1301 donnèrent les résultats suivants : lors de la cuisson dans l'atmosphère oxydante on observe une

grande intensité de 6 raies de la structure hyperfine (SHF), ce qui est dû à la présence d'ions Mn. L'intensité des raies SHF reste pratiquement la même lors du changement du type de l'addition. En même temps, dans le spectre RPE on voit apparaître, avec additions de  $\text{CaSO}_4$  et  $\text{CaF}_2$ , une ou deux raies-satellites. L'intensité des raies SHF dans le spectre des échantillons obtenues dans le milieu réducteur tombe brusquement. En comparant l'intensité des raies SHF de l'échantillon sans additions avec l'intensité des raies SHF des échantillons avec additions on peut faire la conclusion suivante : la plus grande influence sur les processus ayant lieu lors de la cuisson est exercée par  $\text{CaF}_2$  dont la présence dans le milieu réducteur n'entraîne pas seulement la réduction des ions  $\text{Fe}^{3+}$  et  $\text{Mn}^{2+}$  jusqu'à oxyde ou métal mais aussi la sublimation des fluorures de ces éléments (et de  $\text{SiO}_2$  dans une certaine mesure), ce qui s'accompagne d'une disparition presque complète des raies SHF. Ceci est confirmé également par l'analyse chimique (tableau II).

Tableau II					
Teneur du clinker en oxydes étrangers					
n <sup>os</sup> des échantillons	Type de l'addition	Milieu oxydant		Milieu réducteur	
		$\text{Fe}_2\text{O}_3$ , %	$\text{SiO}_2$ , %	$\text{Fe}_2\text{O}_3$ , %	$\text{SiO}_2$ , %
I	-				
1	-	0,1	0,8	0,08	0,80
2	$\text{CaSO}_4$	0,1	0,78	0,03	0,72
3	$\text{CaF}_2$	0,11	0,76	0,02	0,70

Ainsi il fut établi que la composition en phases du clinker de ciment alumineux à teneur d'alumine élevée dépend de la température et du caractère du milieu gazeux de cuisson ainsi que de la présence d'impuretés et d'additions de modificateurs dans le mélange cru.

# Chemistry of arresting strength retrogression in structural high alumina cements

## *Les causes chimiques des baisses ou des limitations de résistance dans les structures en ciment alumineux*

P. BHASKARA RAO and V.N. VISWANATHAN, Cement Research Institute of India, M-10, NDSE-II, New Delhi-110049, Inde.

**SUMMARY:** The conversion of metastable hydrates of high alumina cement has been accepted as a fact to reckon with. One possible method of preventing the formation of cubic  $C_3AH_6$  and arresting strength retrogression would be by providing an alternative but safer path of reaction for hexagonal aluminate hydrates. Such a possibility can be realised through the reaction of these hexagonal hydrates with C-S-H gel leading to the formation of Strätlingite, which contributes to high compressive strength. The success of this method depends on the timing of availability of C-S-H gel for reaction with the metastable aluminate hydrates, before they are converted to  $C_3AH_6$ .

A comparative study of the hydration of CA in presence of (i) C-S-H gel and (ii)  $\beta$ - $C_2S$  with varying degrees of fineness of CA has been made. The mineralogical composition and strength development of hydrating specimens were studied as a function of time. While gehlenite hydrate was the major hydration product in all the specimens, no  $C_3AH_6$  could be found at any stage. There was no metastable hexagonal hydrate detectable beyond two weeks of hydration, showing thereby that gehlenite hydrate was readily formed and this precluded any possibility of conversion to  $C_3AH_6$  even in future. Attack of  $CO_2$  on paste specimens produced some  $C_4ACH_{12}$ , while in the mortar specimens, practically free from  $CO_2$  attack, the formation of  $C_4ACH_{12}$  was negligible. The rate of hydration of  $\beta$ - $C_2S$  is probably enhanced in presence of CA. The mortar specimens showed satisfactory strength development with only gehlenite hydrate as the major hydrated phase.

**RESUME:** La conversion des hydrates métastables du ciment alumineux a été acceptée comme un fait dont il faut tenir compte. Une méthode éventuelle d'empêcher la formation de  $C_3AH_6$  cubique et d'arrêter la rétrogradation de la résistance serait de prévoir une autre voie, mais plus sûre, de réaction pour les hydrates hexagonaux des aluminates. Une telle possibilité peut être réalisée par la réaction de ces hydrates hexagonaux avec le gel C-S-H menant à la formation de la Strätlingite, ce qui contribue à une haute résistance à la compression. Le succès de cette méthode dépend du moment où le gel C-S-H est disponible pour la réaction avec les hydrates métastables des aluminates avant qu'ils ne soient convertis en  $C_3AH_6$ .

Une étude comparée de l'hydratation du CA à divers degrés de finesse et en présence du (i) gel C-S-H et (ii)  $\beta$ - $C_2S$  a été effectuée. La composition minéralogique ainsi que le développement de résistance des échantillons hydratants ont fait l'objet d'une étude en fonction du temps. Alors que l'hydrate de la gehlénite était le produit d'hydratation principal dans tous les échantillons, on n'a pas pu trouver du  $C_3AH_6$  à n'importe quelle étape. Il n'y avait pas d'hydrate hexagonal métastable, qui était décelable au delà de deux semaines d'hydratation, démontrant ainsi que l'hydrate de la gehlénite se formait facilement, et ceci excluait toute possibilité de conversion en  $C_3AH_6$  même à l'avenir. L'attaque du  $CO_2$  sur les échantillons de pâte a produit du  $C_4ACH_{12}$ , alors que dans le cas des échantillons de mortier, qui sont pratiquement exempts de l'attaque du  $CO_2$ , la formation du  $C_4ACH_{12}$  était négligeable. Le taux d'hydratation du  $\beta$ - $C_2S$  est probablement augmenté en présence du CA. Les échantillons de mortier ont révélé un développement satisfaisant de la résistance avec seulement l'hydrate de la gehlénite comme phase importante d'hydrate.

## INTRODUCTION

The conversion of high-alumina cement consisting of the transformation of hexagonal aluminate hydrates to the cubic  $C_3AH_6$ , has been accepted as a fact to reckon with (1). In spite of several precautions recommended, including the use of low water/cement ratio, service temperature and humidity, it is being increasingly realised that the hexagonal hydrates  $CAH_{10}$  and  $C_2AH_8$  can not be permanently stabilised by any of the known physical means (2,3) or through chemical additives (4,5). In this context alumina-belite cements (6) are claimed to be free from the phenomenon of conversion and strength retrogression, but very little is known as to how the formation of  $C_3AH_6$  is prevented on hydration. On the other hand, a recent study on a closely similar system called Porsal cement containing the mineral assemblage,  $\beta$ - $C_2S$ ,  $CA$ ,  $C_{12}A_7$  and  $C_2A_3S$  has revealed the presence of some  $C_3AH_6$  along with gehlenite hydrate and tetracalcium aluminate hydrates in the hydration products (7).

A chemical solution to the problem of formation of  $C_3AH_6$  and moderating, if not arresting, the strength retrogression could be in providing an alternative but safer path for the reaction of the metastable hexagonal hydrates with C-S-H gel leading to the formation of  $C_2ASH_8$  (gehlenite hydrate or Strätlingite), which also contributes to high compressive strength (8). Such a combination of stable hydration products rich in gehlenite hydrate is expected to be resistant to sulphate attack owing to a favourable (C+M)/(A+S) ratio even at the micro level (9). For example, in the case of conventional HAC this ratio is not favourable after conversion where gibbsite and  $C_3AH_6$  phases exist separately at the micro level, although this ratio is unaffected by conversion at the macro level. The success of forming  $C_2ASH_8$  as a major phase depends on the timing of the availability of C-S-H gel for reaction with the metastable aluminate hydrates, before the latter decay by conversion. Towards this end, a comparative study of the hydration of CA in presence of (i) C-S-H gel and (ii)  $\beta$ - $C_2S$  with varying degrees of fineness of the CA component has been made.

## EXPERIMENTAL

(1) Materials: Monocalcium aluminate (CA) was prepared by firing at  $1400^\circ C$  a stoichiometric mixture of calcium carbonate and alumina gel. Even after repeated firings the presence of  $CA_2$  and  $C_{12}A_7$  in small quantities could not be avoided and the material was used as such. The material was ground to pass through 150 micron sieve and separated into two fractions: (a) -150, +75 micron and (b) -75 micron sizes.

Dicalcium silicate was prepared by

standard methods using 0.5%  $B_2O_3$  to stabilise the  $\beta$ -form. The entire material was ground to pass through 75 micron sieve and used as such.

Calcium silicate hydrate (C-S-H) gel was prepared by the hydration of  $\beta$ - $C_2S$  in a slurry form with a water/cement ratio of ten for five months, followed by filtration and vacuum drying at room temperature.

Dehydrated alumina: Chemically pure chromatographic grade alumina (E. Merck, Darmstadt) was used without further treatment.

(ii) Paste hydration studies: Using the coarse and fine fractions of CA respectively two pastes were prepared with a CA/C-S-H gel ratio of 1:2 and a water/solid ratio of four and maintained at  $27 \pm 2^\circ C$ . They were denoted as coarse and fine (C and F) pastes.

(iii) Compressive strength: Two series of mortars comprising of the coarse and fine fractions of CA were made with the composition, CA:  $\beta$ - $C_2S$  : Dehydrated alumina = 2:3:10. The water/(CA +  $\beta$ - $C_2S$ ) ratio was kept at 1.9. The mortars were cast into cylinders 1.25 cm X 1.25 cm, demoulded after 24 hours of storage in >90% RH atmosphere at room temperature. The cylinders were cured later in water at  $27^\circ C$ . Compressive strengths of cylinders were tested at various ages with the help of a one tonne testing machine provided with necessary arrangement for testing small specimens.

(iv) XRD studies: The pastes as well as mortars were examined for their mineral assemblage at various ages with the help of a Philips 1120 model x-ray diffractometer using Cu-K $\alpha$  radiation and Ni filter.

(v) Thermal Analysis: TGA and DTA of hydrated pastes aged 11 weeks and cylinders aged 10 weeks were recorded on a Derivatograph (Hungarian Optical Works, Budapest) at  $8^\circ C/min$ .

## RESULTS

The mineralogical composition of pastes and cylinder specimens at various ages excluding those minerals present in the starting materials are given in Tables I and II respectively. The typical powder x-ray diffractograms of the pastes at the age of 11 weeks and cylinders at 10 weeks respectively are presented in Fig.1. The mineralogical studies showed that the principal phase formed was always  $C_2ASH_8$  only. No  $C_3AH_6$  was observed in any of the samples.

The paste hydrated specimens showed, besides gehlenite hydrate, a carbonated form of calcium aluminate hydrate,  $C_4ACH_{12}$  due to the progressive carbonation, to some degree, of the samples inadequately protected against exposure to air. The

minor new phases observed in the pastes were  $C_2AH_8$  and  $CAH_{10}$ , which did not persist beyond two weeks. Of the two,  $C_2AH_8$  was more prominent, while  $CAH_{10}$  was observed in only one sample in trace quantities.

In the case of cylinders,  $C_2AH_8$  was observed in small amounts only up to seven days and no  $CAH_{10}$  was detected at any stage. Carbonation from atmosphere was extremely low, as can be expected in set mortars, and the only carbonated form of aluminate hydrate,  $C_4\bar{A}CH_{12}$ , was observed only in traces.

The differential thermograms of pastes and cylinder samples, after 11 and 10 weeks of ageing respectively, are presented in Fig.2. The thermograms of both the pastes showed only two major endothermic peaks at

Fig.1 x-ray diffractograms of pastes (11 weeks) and cylinders (10 weeks)

G =  $C_2ASH_8$ , B =  $\beta-C_2S$ , C =  $C_4\bar{A}CH_{12}$

160°C and 300°C respectively, due to  $C_4\bar{A}CH_{12}$ . No endothermic peak attributable to  $C_2ASH_8$  (low intensity peak reported at 230°C (10)) was separately visible, perhaps masked by the broad 160°C endothermic peak of the carboaluminate. The thermograms of cylinders showed endothermic peaks at 100°, 150°, 250° and 310°C. The alumina used as aggregate for cylinders also had a small endothermic peak around 140°C due to adsorbed water. In view of this, the first two peaks may be considered as manifestations

Fig.2 Differential thermograms of Pastes (11 weeks) and cylinders (10 weeks)

of adsorbed water held by alumina and any excess C-S-H gel and part of the combined water of C-S-H gel. The 250°C peak is believed to be due to gehlenite hydrate. However, the sharpness of the peak vis-a-vis broad peaks reported earlier for  $C_2ASH_8$ , and the inability to find a similar peak in the pastes where gehlenite hydrate is expected to be in higher concentration not diluted with aggregate, leave some uncertainty in this assignment. The low intensity endothermic peak at 310°C can not be explained at present.

The compressive strengths of cylinders are reported in Table III. The order of strengths of the specimens was markedly lower than those of HAC reported in literature, partly due to high initial water/solid ratio intentionally employed in order to observe whether  $C_2ASH_8$  would be stable, unlike  $CAH_{10}$  known to be unstable even under moderately high water/solid ratios. The results of compressive strengths showed that the strength increased progressively with age indicating the continued availability of aluminate hydrate through CA hydration to

react with C-S-H gel. The strengths of the fine specimens were always higher than those of the coarse specimens at equal ages.

#### DISCUSSION

Considering the mineralogical composition of all the specimens and that  $\beta$ - $C_2S$  hydrates through topochemical mechanism in contrast to  $\gamma$ - $C_2S$  which hydrates mostly by a "through solution" mechanism (11), the hydration reactions can be fitted into a generalised scheme, as follows:

Reactions (I), (II), (III), (VI) and (VII) are well known in literature. Reaction (IV) was also recently reported (8) and the present results support the feasibility of reaction (V) proceeding with a reasonable rate. The effect of atmospheric  $CO_2$  on  $CAH_{10}$  and  $C_2AH_8$  is believed to be in the form of (VIII) and (IX), resulting essentially in low carbonate aluminate hydrates, unless  $CO_2$  is deliberately made available in high concentration (3).

Age	Compressive strength, MN/m <sup>2</sup>	
	Coarse cylinder	Fine cylinder
1d	0.4	1.0
7d	1.5	2.3
28d	2.6	4.1
56d	n.d.	4.8
85d	4.74	6.0

The absence of  $CAH_{10}$  in all the specimens, except in one in trace quantities, shows that the rate of consumption of  $CAH_{10}$  is by far greater than its rate of production. The marked absence of  $C_3AH_6$  in all the specimens in spite of the high water/solid ratios, rules out reaction (VI) as the major consumer of  $CAH_{10}$ . The lower concentration of carboaluminate as compared to  $C_2ASH_8$  even in the case of pastes leads to the conclusion that reaction (IV) is faster than (VIII). By similar arguments it can be seen that reaction (V) is faster than (IX) and reaction (VII) is very insignificant. The presence of  $C_2AH_8$  in low concentration at least in the initial stages, as against the total absence of  $CAH_{10}$  shows that reaction (V) is relatively slower than reaction (IV).

Reaction (III) is of no consequence for pastes and will only determine the progress of reactions (IV) and (V) in cylinders. Even in the case of cylinders the absence of  $\text{CAH}_{10}$  together with the absence of  $\text{C}_3\text{AH}_6$  and carboaluminate shows that C-S-H gel is always available in adequate quantity for reaction (IV). The low concentration of  $\text{C}_2\text{AH}_8$  found is to be attributed to the relative slowness of reaction (V) as compared to (IV) rather than to the non-availability of C-S-H gel. Such a rapid generation of C-S-H gel from  $\beta\text{-C}_2\text{S}$  is probably because of its consumption by aluminate hydrates, thereby making available a fresh surface of  $\text{C}_2\text{S}$  grains for subsequent hydration. It may, hence, be said that the thickness of C-S-H layer around the  $\text{C}_2\text{S}$  grains is greatly reduced overcoming thereby the hindrance for diffusion of water. Further, the reactions (VI) and (VII) are comparatively slower than (VIII) and (IX) at the concentration of  $\text{CO}_2$  available to the system through ordinary air.

The formation of  $\text{C}_3\text{AH}_6$ , being dependent on the availability of  $\text{CAH}_{10}$  or  $\text{C}_2\text{AH}_8$ , can not take place even in later ages because of the non-accumulation of these phases. Therefore, any strength drop owing to the conversion of hexagonal aluminate hydrates to  $\text{C}_3\text{AH}_6$  neednot be apprehended because the hexagonal forms are readily fixed up as gehlenite hydrate.

The proportions of  $\beta\text{-C}_2\text{S}$  and CA in cylinders are adopted from those known in alumina-belite cements and are not necessarily stoichiometric to form gehlenite hydrate. The silicate portion is rather high and, therefore, some C-S-H gel is left unreacted even at long ages. The unreacted C-S-H is indicated by the  $150^\circ\text{C}$  peak in thermograms of cylinder samples.

The presence of some  $\text{C}_2\text{AH}_8$  in the coarse paste and its total absence in fine pastes at 14 days shows the effect of fineness probably because the coarse grains provide the centres for local accumulation of the metastable hydrates. The mineralogy of cylinder specimens is unaffected by the fineness of CA, within the range used in the investigation. However, too coarse a fraction of CA is likely to result in local accumulation of hexagonal hydrates, which may eventually be converted to  $\text{C}_3\text{AH}_6$  and be unavailable for gehlenite hydrate formation. The compressive strength of fine cylinders is markedly higher than the coarse cylinders at least up to 12 weeks which is self-explanatory.

#### CONCLUSIONS

The hydration of CA and  $\beta\text{-C}_2\text{S}$  together gave mainly  $\text{C}_2\text{ASH}_8$ . Higher calcium

aluminate hydrates were found as carboaluminates in paste specimens only when there was some access to  $\text{CO}_2$ . The formation of  $\text{C}_3\text{AH}_6$  was found to be altogether prevented by the reaction of the metastable hexagonal aluminate hydrates with C-S-H gel and formation of gehlenite hydrate. The progressive formation of  $\text{C}_2\text{ASH}_8$  resulted in a continuous rise in strength. The ultimate phases formed in set mortars, namely, gehlenite hydrate and some C-S-H gel are stable unless exposed to excess  $\text{Ca}(\text{OH})_2$  (12), which is an abnormal condition in practice and should be least expected in this system.

Hence, the success of the technology of arresting drop in strength will depend on optimising the properties and fineness of aluminates and  $\beta\text{-C}_2\text{S}$  such that there is no accumulation of hexagonal aluminate hydrates. The fineness of both components can be increased to improve upon the early strength with the same limitations again that the hydration of CA should not be too fast as to lead to the accumulation of metastable aluminate hydrates. On the other hand a minimum fineness of CA is also required to avoid any local accumulation of hexagonal aluminate hydrates. Further, the presence of small quantities of  $\beta\text{-C}_2\text{S}$  even after the consumption of hexagonal aluminate hydrates may be beneficial for long-term strength.

**RESUME :** Le clinker de ciment, d'une composition chimique usuelle, très fortement broyé, en l'absence de gypse, donne un liant, différent du ciment Portland. Ce liant possède la particularité de faire prise et de durcir, à des températures inférieures à 0°. On a vérifié, sur des éprouvettes de pâte de mortier et de béton, que ce ciment faisait prise et durcissait normalement, à des températures de -35°, en laboratoire, et de -20° sur chantier, lorsque ce clinker était additionné de lignosulfonates, de carbonates ou de bicarbonates alcalins et d'eau. Cette propriété, nouvelle dans la chimie et la technologie du ciment, a donné l'idée d'utiliser ce ciment, sans protection spéciale, pour les constructions à réaliser en hiver.

Le ciment sans gypse est un ensemble comprenant ce clinker, un plastifiant, un retardateur de prise et un accélérateur de durcissement. Les lignosulfonates peuvent être employés comme plastifiants. Les dérivés de la lignine peuvent être partiellement ou entièrement remplacés par le produit de la condensation des phénols sulfonates et du formaldéhyde, ou un sel de l'acide naphthaléno-sulfonique. Le carbonate ou le bicarbonate alcalin peuvent être remplacés par un hydroxyde alcalin. On comprend bien l'influence de chacun de ces composants du ciment sans gypse. L'addition de gypse à ce ciment, dans les mêmes proportions que pour le ciment portland, a un effet défavorable sur ses propriétés rhéologiques.

**SUMMARY:** Cement clinker of ordinary chemical composition, ground with a grinding aid, but without the presence of gypsum and processed with a low water-to-cement ratio, presents a hydraulic binder which differs from existing portland cements. This binder has the capability of setting and hardening at temperatures below 0°C. The setting and hardening of gypsum-free cement, where a clinker-lignin derivate-alkali carbonate or bicarbonate-H<sub>2</sub>O system was predominantly used, was verified in the form of pastes, mortars and concretes under laboratory conditions up to temperatures of -35°C and in conditions of an open-air building site up to temperatures of -20°C. This qualitatively new factor in the chemistry and technology of cement has led to the idea of using this binding agent for construction work without any protection against the weather.

Gypsum-free cement can be described as a clinker-plasticizing agent-set retarder - hardening acceleration agent - H<sub>2</sub>O system. Lignosulfonate or sulfonated lignin can be used as plasticizing agents. The lignin derivate can be partially or entirely replaced by the condensation product of sulfonated phenols with formaldehyde or the salt of naphthalene-sulfonic acid. Alkali carbonate or bicarbonate can be replaced by alkali hydroxide. The influence of individual components in the gypsum-free cement is comprehensive. Gypsum additives to this cement in concentrations normal for portland cement lead to a marked deterioration of rheological characteristics.

The use of ordinary portland cement /which is essentially a clinker-gypsum system/ at temperatures below  $0^{\circ}\text{C}$  is connected with a number of difficulties; at such temperatures it is impossible to achieve a high initial and final strength. The problem of concreting under low temperatures is at present solved on the basis of various methods, one of which is the use of quick-binding cements. These cements must have sufficiently high increments in strength, so that no damage is done by the frost.

A new impetus in the area of quick-binding high-strength cements has been provided by the work connected with the names of P.A. Rebinder and S. Brunauer in which gypsum-free have been studied. Lukyanova, Segalova and Rebinder /1,2/ have studied a clinker-calcium lignosulfonate -  $\text{H}_2\text{O}$  system and designed a calcium lignosulfonate -  $\text{K}_2\text{CO}_3$  system to control the beginning of the setting of cement pastes. With this combination they were successful in substantially postponing the beginning of the setting process and a marked acceleration of hardening. Brunauer et al. /3/ designed a clinker /with a specific surface of  $600-900 \text{ m}^2/\text{kg}$ / - residue of grinding aid - calcium lignosulfonate- $\text{K}_2\text{CO}_3$  -  $\text{H}_2\text{O}$  system. Excellent results were obtained in pastes, mortars and concretes when this system was used; the achieved strength was higher by several times than those achieved with normal portland cements.

Research /4-6/ carried out in Czechoslovakia since the end of the sixties has led to the development of gypsum-free cements which are called modified quick-binding high-strength cements /MQHC/. By MQHC we have in mind the following system: clinker /with a specific surface of  $200 - 3000 \text{ m}^2/\text{kg}$ / - a lignin derivative - alkali carbonate or bicarbonate- $\text{H}_2\text{O}$ . MQHC differs from normal portland cement by a number of characteristics:

- a/low porosity of hardened cement stone
- b/excellent workability with low water content
- c/high short- and long-term strength
- d/possibility of substantial acceleration of hardening by small increments of surrounding temperature
- e/increased resistance to corrosion.

A highly significant characteristic of MQHC is their capability of setting and hardening at temperatures below  $0^{\circ}\text{C}$ . This new factor in the chemistry and technology of cements is the subject of the present communication.

In the experiments described in this communication, MQHC was made from clinker normally produced at the Czechoslovak Cement Works at Hranice. The grinding of MQHC was done in the absence of gypsum and with grinding aid additives. The MQHC used had a specific surface /Blaine/ of 420,  $600 \text{ m}^2/\text{kg}$  /with a lignin derivative as a grinding aid/ and  $900 \text{ m}^2/\text{kg}$  /with ethylene glykol as a grinding aid/. The chemical composition of the clinker used is given in table I.

Table I.- Chemical Composition of Clinker /in %/

CaO	62,3
$\text{SiO}_2$	19,8

annealing loss	1,6

The produced MQHC were processed into pastes  $w=0.25$ , mortars  $w=0.30$  and concretes  $w=0.33$  to  $0.35$ , by using normal technological facilities. For regulating the beginning of the setting process, a sodium lignosulfonate -  $\text{NaHCO}_3$  system was used, while in the case of the mortars and concretes a further setting regulator was added - sodium potassium tartrate. After the cement pastes were mixed /at temperatures between  $+10$  to  $+15^{\circ}\text{C}$ / they were placed in a nonset state into an environment where temperatures were maintained at constant levels within the range of  $+20$  to  $-35^{\circ}\text{C}$ . The strength of the pastes /bodies sized  $2.2.2 \text{ cm}$ / was determined after the bodies had been cured for 30 minutes at temperatures of  $+20^{\circ}\text{C}$  after taking them out of the air-conditioned area. The results achieved in compression strength are summed up in tables II and III.

The results achieved indicate, that MQHC processed in the form of pastes, mortars and concretes are capable of setting and hardening at temperatures well below  $0^{\circ}\text{C}$ . This capability is the result of the higher values of hydration heat at the beginning of the hydration process and the higher reactivity of the MQHC components as a consequence of their higher specific surface. The capability of setting and hardening at low temperatures is also caused by the presence of additives which by their cryoscopic effect lower the temperature at which water freezes. The high strength achieved in MQHC in comparison to portland cements are also caused by the possibility of processing the MQHC with a low water content.

Our findings confirm previous data /12/ on the hydration capability of clinker materials at temperatures below  $0^{\circ}\text{C}$ . In the hydration of clinker minerals at low temperatures, anomalous behaviour of water in the porous structure occurs /7/. In such structures water can

exist in the form of "modified water", in a liquid state well below  $0^{\circ}\text{C}$ . Such water is then probably capable of a hydration process with clinker minerals even at low temperatures.

Fig.1 - Fracture surface, paste  $w=0.25$ , 360 days, curing at  $+20^{\circ}\text{C}$

Fig.2 - Fracture surface, paste  $w=0.25$ , 360 days, curing at  $-35^{\circ}\text{C}$

Fig.3 - Detail from fig.2.

Also the structure of hardened cement pastes which have been cured at temperatures in the range of +20 and -35°C were studied. Figure 1. shows the structure of the fracture surface of MQHC pastes /with 600 m<sup>2</sup>/kg/, cured at the temperature of +20°C for a period of 1 year, while figures 2. and 3. show the same paste cured without interruption for a 1 year at the temperatures of -35°C /the compression strength achieved was 28 MPa/. On the basis of these microphotographs it is possible to conclude that hydrosilicates and Ca(OH)<sub>2</sub> are practically indistinguishable, and also a high degree of compactness. The high number of interfaces indicates the high mechanical strength of hardened MQHC. The influence of lower temperatures during MQHC hardening is apparent by the higher level of development of the crystalline structure /figures 1,2,3/.

The capability of MQHC to set and harden at low temperatures represents a new factor, which makes MQHC qualitatively different from existing portland cements. It should be stressed that the clinkers from which the MQHC were made have the same chemical composition as the clinkers from which normal Czechoslovak portland cements are made. For this reason MQHC represent a higher quality of utilization of clinker, which has a high energy input, than is the case in normal portland cements.

In our experiments we also studied the possibility of a modified use of the clinker - sodium lignosulfonate - alkali carbonate - H<sub>2</sub>O system. Our study of pastes /w=0.25/, which set at temperatures between +20 and -30°C, indicates that lignosulfonate can be replaced, for instance by sulfonated lignin. Lignin derivatives can partially or completely be replaced by other plasticizing agents, for instance by the condensation product of sulfonated phenols and formaldehyde, the salt of naphthalene sulfonic acid. Alkali carbonates and/or bicarbonate can be replaced by hydroxide. The presence of hydroxide is then manifest by shortening of the beginning of setting.

On the basis of our existing knowledge concerning gypsum-free cements we are able to define them in general terms as a clinker - plasticizing agent - set retarder - hardening acceleration agent - H<sub>2</sub>O system. This system includes water because some components must be dissolved in water. The action of individual components within the system is comprehensive. The presence of alkali carbonate in connection with lignin derivative /and probably also in the case of a different plasticizing agent/ causes an improvement of the plasticizing qualities of the lignin derivative, because it prevents the forming of its insoluble calcium salt.

The component which postpones the beginning of the setting process /and makes it possible to process these systems in real time as pastes, mortars and concretes/ are substances based on lignin or carbohydrates which accompany them, or hydroxy-acids, sulfonated phenols and others. Probably also

alkali carbonate participates in the process of slowing down setting, as a consequence of carboaluminates. The component which accelerates the hardening process is alkali carbonate and/or bicarbonate or hydroxide. The presence of lignosulfonate in the majority of cases leads to higher increments in strength than when other plasticizing agents are used. The addition of lignosulfonate to a different plasticizing agent is connected with a shortening of the beginning of setting /cf - Table VI./

Table VI.- The Beginning of Setting of Pastes w=0.25 /specific surface of clinker 900 m<sup>2</sup>/kg/, +20°C

system	time
clinker+1,8% NaLig+1,2% Na <sub>2</sub> CO <sub>3</sub> +0,7% T+H <sub>2</sub> O	2.5 hours
clinker+1,0% NS+1,2% Na <sub>2</sub> CO <sub>3</sub> +0,7% T+H <sub>2</sub> O	2.5 hours
clinker+1,0% NS+0,3% NaLig+1,2% Na <sub>2</sub> CO <sub>3</sub> +0,7% T+H <sub>2</sub> O	2 hours
clinker+0,8% SF+1,2% Na <sub>2</sub> CO <sub>3</sub> +H <sub>2</sub> O	10 hours
clinker+0,8% SF+0,3% NaLig +1,2% Na <sub>2</sub> CO <sub>3</sub> +H <sub>2</sub> O	2 hours

Note: NaLig - sodium lignosulfonate  
T - sodium potassium tartrate  
NS - sodium salt of naphthalene-sulfonic acid  
SF - condensation product of sulfonated phenols and formaldehyde

The presence of lignosulfonate seems to influence reactivity of C<sub>3</sub>A, when the hydration process is accelerated. The absorption of lignosulfonate on the surface of C<sub>3</sub>A, on the other hand, causes a slowing down of the hydration process and the resulting effect is determined by the sum of both precesses /2,8/. Increasing the lignosulfonate to a specific limit means a loss of initial and final strengths. A loss of strength is determined by the irreversible absorption of lignosulfonate in C<sub>3</sub>S which blocks further hydration /9,10/.

The presence of sulphates in the studied systems is undesirable after a certain limit. Their presence from the burning process /after a certain limit of SO<sub>3</sub> has been surpassed/, as well as a gypsum additive, causes undesirable changes in volume which can in the long-term even lead to destructions. The negative influence of gypsum in the clinker-lignosulfonate - carbonate - H<sub>2</sub>O system during setting with a low water content is apparent made by sulfoaluminates being formed and transformed only after the solid and compact structure of the hydrosilicates has de-

veloped. And this also causes undesirable changes in volume. A gypsum additive to the clinker - lignosulfonate - carbonate -  $H_2O$  system in concentrations usual for portland cement also causes an increase in cement paste viscosity, and as a consequence of the forming of an insoluble form of calcium lignosulfonate, a strong decrease in the workability of mortars with a low water coefficient occurs.

Another characteristic of the hydration of gypsum-free cements, so far determined in the clinker-derivate of lignin-alkali carbonate /hydroxide/ -  $H_2O$  system, is the limited formation of  $Ca(OH)_2$  in initial stage of hydration. This fact follows from the structure of hardened pastes where it is impossible to distinguish between hydrosilicates and  $Ca(OH)_2$ , and also from the data determined by X-ray diffraction /as also found by Odler, Schönfeld and Dörr/11//.

#### CONCLUSIONS

Finely ground clinkers of a normal chemical composition processed with a low water-to-cement ratio and in the presence of additives other than gypsum, produce a hydraulic binder which is capable of setting and hardening at temperatures well below  $0^\circ C$ . This qualitatively new factor in the chemistry and technology of mortars has led to the idea of using this binder for construction work in winter conditions.

Our future work will concentrate upon the technology of concreting with these cements under normal and low temperatures and upon a study of the reactions taking place in the hydration of gypsum-free cements.

#### ACKNOWLEDGEMENTS

The authors of this communication should like to thank the group of employees of building organisation "Pozemní stavby" at Karlovy Vary, who worked under the supervision of Mr. Vojtěch Janda, for their selfless fulfilling of all demanding tests, when during the winter of 1978-79 they were the first in Czechoslovakia to successfully carry out experimental construction work using MQHC without any protection against the weather, during a period when average day-time temperatures reached  $-8^\circ C$ .

## Hydratation du ciment alumineux en présence d'agrégat siliceux et calcaire

### *Hydration of aluminous cement in the presence of silicic and calcareous aggregate*

L. CUSSINO, Recherche et développement, UNICEM S.p.A., Casale Monferrato,  
A. NEGRO, Institut de chimie générale et appliquée, Politecnico de Turin, Italie.

RESUME : On sait que les bétons préparés avec du ciment alumineux subissent avec le temps une perte de résistance mécanique à la suite d'une réaction de conversion, pendant laquelle les aluminates de calcium hydrates métastables se transforment en composés plus stables.

Après que les Auteurs aient montré la possibilité d'une réaction entre les aluminates hydratés et le carbonate de calcium, ils ont voulu étendre leur expérimentation aux ciments alumineux.

Dans ce but, ils ont effectué des essais jusqu'à 5 ans sur des mortiers et bétons en utilisant des agrégats siliceux et calcaires. Les essais mécaniques ont montré que l'agrégat calcaire atténue ou élimine la perte de résistance mécanique des bétons.

L'analyse aux rayons X et à l'ATD, a montré qu'il se produit une réaction entre l'agrégat calcaire et les produits d'hydratation du ciment : la formation de carboaluminate semble limiter la conversion des aluminates de calcium hexagonaux en aluminat cubique.

Les Auteurs attribuent à cette réaction le bon comportement mécanique, dans le temps, des bétons expérimentés.

SUMMARY : It is well known that concretes made with aluminous cement lose their mechanical strength over time following a conversion reaction during which metastable calcium hydrate aluminate are transformed into more stable compounds.

The Authors have shown previously that it is possible that hydrate aluminates react with calcium carbonate and experiments were therefore extended to aluminous cements.

For this purpose, tests were carried out on mortars and concretes using silicic and calcareous aggregates with up to 5-year lives.

Mechanical tests showed that calcareous aggregate attenuates or eliminates the loss of mechanical strength in mixes.

X-ray and ATD studies showed a reaction between calcareous aggregate and the products of cement hydration : the formation of carboaluminate seems to limit the conversion of hexagonal calcium aluminates into cubic aluminate.

The good mechanical behaviour over time of the mixes experimented is held to be attributable to this reaction.

## INTRODUCTION

Le béton préparé avec du ciment alumineux présente des résistances mécaniques remarquables après de courtes périodes de conservation, un caractère réfractaire, une résistance chimique aux sulfates et aux cycles de gel et de dégel. Mais, malheureusement, ce béton présente, dans le temps une diminution de résistances mécaniques et une augmentation de porosité laquelle le rend sensible même à l'aggression chimique. La réaction d'hydratation indiquée ci-après, exprimée sous forme non stoechiométrique, puisque les quantités des produits sont influencées par différents facteurs extérieurs, est la plus importante et se produit pendant les premiers stades de la prise du ciment :

Les produits de cette réaction sont métastables : le gel d'alumine se transforme en gypse  $\text{AH}_3$ , tandis que le  $\text{CAH}_{10}$  et le  $\text{C}_2\text{AH}_8$  se transforment en  $\text{C}_3\text{AH}_6$  et  $\text{AH}_3$  selon les réactions :

Ces réactions sont très importantes car elles influencent les résistances mécaniques des bétons, donc, leur durabilité (1). Cependant, jusqu'à aujourd'hui, il n'y a pas encore eu d'accord sur le mécanisme suivant lequel la conversion des aluminates métastables ( $\text{CAH}_{10}$  et  $\text{C}_2\text{AH}_8$ ) en aluminate stable ( $\text{C}_3\text{AH}_6$ ) agirait à l'égard des résistances mécaniques (2).

Certains auteurs, pour limiter les inconvénients dus à la conversion, ont suggéré d'ajouter au béton frais des additifs tels que les tensioactifs, les polysaccharides, les alcools polyoxyhydriques, les sels inorganiques (3).

Selon Mehta (4) le  $\text{C}_4\text{A}_3\text{SO}_3$  empêche pratiquement la conversion des hydrates hexagonaux en hydrate cubique; Ueda et Kondo (5), au contraire, ont trouvé qu'à 50°C, en présence de ce sulfoaluminate, la conversion se produit quand même et les résistances mécaniques diminuent avec la conservation.

Par contre d'après Collepardi et coll. (6), la conversion trouve un obstacle dans la présence du sulfo-aluminate, avec un effet d'autant plus marqué que la température est plus basse et que l'addition de  $\text{C}_4\text{A}_3\text{SO}_3$  est plus élevée.

Enfin, Ramachandran et Feldmann (2) ont étudié l'hydratation du CA à de faibles rapport eau/liant à 20°C et à 80°C.

Ils ont remarqué que les échantillons hydratés à 80°C présentaient un retrait considérable, contrairement aux échantillons hydratés à 20°C, et que leur résistance mécanique était la plus élevée.

Les méthodes exposées ci-dessus présentent des inconvénients : ou bien elles perdent en efficacité lorsque la température de conservation dépasse la température ambiante, ou bien elles sont difficiles ou chères à réaliser.

Dans un article récent (7) nous avons signalé qu'en hydratant le CA en présence de carbonate de calcium, la conversion des aluminates hydratés  $\text{CAH}_{10}$  et  $\text{C}_2\text{AH}_8$  ne se produisait pas, ou bien elle était très limitée par la formation de  $\text{C}_3\text{A} \cdot \text{CaCO}_3 \cdot 11\text{H}_2\text{O}$ .

Les résultats présentés concernent les essais effectués sur des mortiers et des bétons fabriqués avec du ciment alumineux fondu et avec un agrégat calcaire et siliceux.

Une première observation menée sur des échantillons vieillis jusqu'à 5 ans a offert une vue d'ensemble intéressante : les résistances mécaniques du mortier et du béton fabriqués avec un agrégat siliceux avaient subi une détérioration progressive et constante déjà après 28 jours, tandis que le béton avec un agrégat calcaire avait manifesté une amélioration constante de la résistance mécanique que l'on remarque encore à l'échéance de 5 ans.

Sur la base de ces résultats il nous a semblé utile de réaliser une seconde expérimentation dans laquelle, à tous les essais de résistance mécanique étaient associés des analyses chimico-physiques de façon à suivre l'évolution de l'hydratation.

Les résultats de ces observations, menées jusqu'à présent à la fin de deux années, sont indiqués ci-après dans leur expression la plus significative.

## PARTIE EXPERIMENTALE

Pour la préparation des échantillons utilisés pour les essais de résistance à compression nous avons employé un ciment alumineux toujours de la même marque dans les deux expérimentations, mais représentés bien sûr par deux échantillons différents. L'analyse chimique des deux échantillons de ciment et celle des agrégats pour mortiers et bétons sont indiquées dans le Tableau I.

TABLEAU I					
Oxides	Ciment		Agréгат		
			Siliceux		Calcaire
	N. 1	N. 2	Mortier	Béton	
SiO <sub>2</sub>	3,32	2,65	86,60	73,60	0,70
Al <sub>2</sub> O <sub>3</sub>	39,58	40,50	5,08	6,94	0,18
Fe <sub>2</sub> O <sub>3</sub>	13,73	12,77	2,13	1,78	0,14
FeO	2,80	3,88	—	—	—
TiO <sub>2</sub>	1,90	1,95	—	—	—
CaO	36,80	36,60	1,64	5,23	54,80
MgO	0,59	0,54	0,29	5,27	0,43
K <sub>2</sub> O	0,05	0,05	1,27	1,19	0,02
Na <sub>2</sub> O	0,04	0,05	1,26	1,55	0,05
SO <sub>3</sub>	0,03	0,05	0,00	0,00	0,00
p.a.f.	0,31	0,60	0,85	3,59	42,85

Les alcalins contenus dans les agrégats ne présentent aucune caractéristique de solubilité ni dans l'eau ni dans une solution aqueuse de chaux. Avec le ciment N. 1 nous avons réalisé les échantillons suivants.

- A - Echantillons en mortier plastique type ISO, fabriqués avec du sable siliceux conformément aux Normes Italiennes.
- B - Echantillons de béton avec agrégat calcaire : Ø max 25 mm.; courbe granulométrique continue; ciment : 350 Kg./m<sup>3</sup>; E/C = 0,50; Slump 9 cm.; tassement par table vibrante; masse volumique au démoulage 2,44.
- C - Echantillons de béton avec agrégat siliceux : caractéristiques du béton comme en B, excepté E/C = 0,54; masse volumique 2,44.

Avec le ciment N. 2 nous avons réalisé les échantillons suivants.

- D - Echantillons en mortier plastique comme en A.
- E - Echantillons en mortier plastique comme en A en utilisant du sable calcaire granulé fractionné dans les mêmes granulométries prévues pour le sable normal.
- D' - Echantillons en mortier plastique comme en D et, donc, avec du sable siliceux, mais en utilisant comme liant un mélange à 75/25 respectivement de ciment alumineux et poudre de calcaire broyé à environ 5.000 cm<sup>2</sup>/g de surface Blaine.
- D'' - Echantillons en mortier plastique comme en D', en substituant dans le mélange du liant la poudre siliceuse broyée à environ 4.000 cm<sup>2</sup>/g de surface Blaine.
- F - Echantillons de béton avec agrégat calcaire concassé : Ø max 20 mm.; courbe granulomé-

trique continue; ciment : 350 Kg/m<sup>3</sup>; E/C = 0,60; Slump 8 cm.; tassement par table vibrante; masse volumique 2,41.

- G - Echantillons de béton avec agrégat siliceux roulé : caractéristiques du béton comme pour F, excepté E/C = 0,54; Slump 10 cm.; masse volumique = 2,43.
- H - Echantillons de béton avec agrégat siliceux comme pour G. Le liant, au lieu d'être seulement du ciment alumineux, se compose d'un mélange à 75/25 respectivement de ciment alumineux et poudre de calcaire à surface Blaine de 5.000 cm<sup>2</sup>/g; liant 350 Kg/m<sup>3</sup>; E/C = 0,51; Slump 12 cm.; masse volumique = 2,40.

Pour les échantillons A, B et C nous avons retenu les résultats jusqu'à la fin des cinq ans, pour les autres jusqu'à deux ans.

Les échantillons de mortier, après le démoulage, ont été conservés dans l'eau conformément aux Normes Italiennes; les échantillons de béton ont été conservés dans une chambre conditionnée à 20°C ± 1°C et une humidité relative non inférieure à 90%.

Avec les échantillons D' et H nous avons voulu vérifier si une addition au ciment de 25% de pierre calcaire finement broyée provoquait, avec les années, un effet positif sur les résistances mécaniques tant des mortiers que des bétons. A chaque échéance à laquelle nous avons exécuté les essais mécaniques nous avons effectué l'analyse aux rayons X et l'ADT pour déterminer phases qui se formaient au cours de l'hydratation.

## RESULTATS ET DISCUSSION

Le Tableau II présente les résultats des essais mécaniques à compression des mortiers et des bétons fabriqués avec le ciment alumineux. Les résultats fournis par les échantillons A, B et C sont suffisamment éloquentes pour démontrer que tant le mortier que le béton avec agrégat siliceux après 28 jours de conservation révèlent une rétrogradation de résistance mécanique, montrant, à 5 ans, une perte de résistance respectivement de 60% et 50% environ.

Par contre, le béton avec l'agrégat calcaire a toujours révélé jusqu'à 5 ans des augmentations de résistance.

Les échantillons D fabriqués avec le ciment N. 2 ont révélé un processus de rétrogradation moins marqué que les échantillons A, en ayant toujours une valeur assez considérable (18,8%).

Le comportement des échantillons E a montré qu'en substituant au sable siliceux le sable calcaire d'une même granulométrie, ou réussit presque à éviter, au moins jusqu'à deux ans, la perte de résistance.

T A B L E A U I I

Age	Echantillons										
	A	B	C	D	E	D'	D''	F	G	H	
1 j	748	621	519	675	489	581	567	538	526	446	Kg/cm <sup>2</sup>

2 ans	609	1065	291	729	803	846	534	873	532	725	Kg/cm <sup>2</sup>
5 ans	384	1102	285								

Les valeurs les plus basses de résistance à compression, en termes absolus, par rapport à celles de l'essai précédent découlent de la différence de la nature des sables.

Les résultats des essais sur les échantillons D' et D'' mettent en évidence l'effet avantageux de la poudre de calcaire qui, jusqu'à 1 an, réussit à sauvegarder les résistances et à limiter la perte de résistance à 5%, à 2 ans de conservation.

Les échantillons D'' révèlent au contraire une aggravaation en pour-cent du processus de rétrogradation et donc le renforcement de l'effet négatif de la silice en poudre.

En effet, en comparant ces résultats avec ceux que nous avons obtenus pour les échantillons D, on remarque que la diminution du pourcentage de résistance passe de 18,8 à 24,1.

Fig. 1 - Résistances à compression en fonction du temps des bétons B, C, F, G, H

Les résultats offerts par les échantillons F, G, H repropo<sup>s</sup>ent des considérations analogues à celles qui découlent des résultats des essais sur mortier. En effet, cet échantillon de ciment assure lui aussi des résistances à compression qui augmentent dans le temps s'il est utilisé dans des bétons avec agrégat calcaire, tandis qu'il montre des pertes considérables dans le béton avec agrégat siliceux.

Une confirmation de l'effet positif de la poudre de calcaire est fournie par les échantillons H qui montrent une stabilisation des résistances mécaniques même dans un béton fabriqué avec agrégat siliceux.

Pour mieux montrer leur comportement nous présentons dans la Figure 1 les courbes de résistance mécanique en fonction du temps des bétons B, C et F, G, H.

L'examen aux rayons X a mis en évidence, pour tous les échantillons contenant l'agrégat siliceux, la formation initiale de  $C_2AH_8$  et  $CAH_{10}$  et leur transformation ensuite en  $C_3AH_6$  et  $AH_3$ .

Pour tous les échantillons contenant l'agrégat calcaire il y a, au contraire formation de  $CAH_{10}$  et  $C_3A \cdot CaCO_3 \cdot 11H_2O$  déjà aux premières échéances, tandis que le  $C_3AH_6$  n'apparaît qu'en très petite quantité, dans les bétons après deux ans de conservation (Figure 2).

Fig. 2 - Spectres de diffraction X des échantillons B et C après 5 ans, et H après 2 ans

L'ATD confirme les constatations faites par l'examen aux rayons X.

Dans les échantillons fabriqués avec agrégat siliceux, apparaît sur la courbe thermique, après 28 jours, le pic à  $\sim 330^\circ C$  attribuable au  $C_3AH_6$  : ce pic augmente en intensité au fur et

à mesure que la période de conservation avance. Sur les courbes thermiques des échantillons fabriqués avec agrégat calcaire, après 28 jours de conservation, apparaît le pic à  $\sim 180^\circ C$  dû au carboaluminate. Le pic du  $C_3AH_6$  ne peut être relevé sur aucune courbe thermique (Figure 3).

Fig. 3 - Thermogramme des échantillons B et C à 5 ans et de l'échantillon H à 2 ans de conservation

Il est donc confirmé que la présence d'un agrégat calcaire, quelle que soit sa granulométrie, limite la conversion des aluminates hydrates hexagonaux en aluminate cubique : le fait que cette conversion ne se produit pas, ou qu'elle se produit d'une façon très limitée et qu'il se forme du carboaluminate, a comme résultat la progression de résistances mécaniques.

Essayons maintenant d'expliquer le rôle joué par le  $C_3A \cdot CaCO_3 \cdot 11H_2O$ , en considérant, avant tout, les variations de volume molaire à la suite des réactions [2] et [3].

Sur la base de l'équation [2],  $C_3AH_6$  et  $2AH_3$  occupent ensemble 47,3% de l'espace occupé par  $3CAH_{10}$  avant sa transformation : il n'y a aucun doute que l'eau constituant 52,7% du volume total est responsable de la porosité.

Sur la base de l'équation [3], le solide occupe 66,5% et l'eau 33,9%.

Il est donc évident qu'à la suite de la dessiccation la porosité révèle élevée (8) : d'après certains auteurs (9-11) elle se révèle déterminante pour la chute des résistances mécaniques.

Si, par contre, il se forme de carboaluminate, étant donné son volume molaire élevé, il est à présumer qu'une partie des espaces libres soit occupée par ce composé, avec une réduction de la porosité.

Nous avons vérifié cela en estimant le volume total des pores des échantillons D et E après 28 et 360 jours de conservation au moyen d'un porosimètre à mercure.

Echantillons	Conservation	
	28 jours	360 jours
D	52,69	66,61
E	65,96	38,36

Il est donc confirmé que la conversion provoque une augmentation de porosité, tandis que la formation de  $C_3A \cdot CaCO_3 \cdot 11H_2O$  la réduit de 42% environ. En plus, à l'examen les courbes de répartition du volume des pores indique qu'à l'échéance de 28 jours celles des échantillons D et E sont assez semblables, mais qu'à l'échéance de 360 jours pour l'échantillon D nous avons une accentuation des macro-pores, tandis que l'échantillon E présente une porosité plus fine et uniforme.

En outre la formation de carboaluminate en soustrayant de l'eau et en empêchant la formation de  $C_3AH_6$ , réduit probablement la formation des macropores associés à ce composé, ce qui a été mis en évidence par Mehta et Lesnikoff (12) avec des observations au MEB.

Enfin l'habitus lamellaire du  $C_3A \cdot CaCO_3 \cdot 11H_2O$  pourrait jouer un rôle important sur l'empilement des cristaux pour la réalisation d'une structure plus compacte.

## CONCLUSIONS

L'emploi d'agréats calcaires pour préparer des mortiers ou des bétons alumineux, permet d'arriver, même à de longues échéances, à des résistances mécaniques très élevées, grâce au fait que l'agréat calcaire, réagissant avec les constituants du ciment, donne lieu à du carboaluminate, empêchant ou limitant la conversion et diminuant la porosité du béton.

# The relationship between cement clinker composition and strength recovery of hydrating high alumina cement during conversion

## *La relation entre la composition du clinker de ciment et la capacité de récupération du ciment alumineux*

H.G. MIDGLEY, Concrete Research Laboratory, Civil Engineering Division, The Hatfield Polytechnic, Hatfield, Herts, U.K.

RESUME : Après la baisse de résistance subie par le béton de ciment alumineux (h.a.c.) du fait de la conversion cristalline de ce ciment, une petite récupération de la résistance peut se produire. Cette récupération est attribuée à la présence, dans le ciment, de silicates susceptibles de s'hydrater tardivement (pleochroïte et  $\beta$ -C<sub>2</sub>S). Il y a probablement une proportion critique de silice dans ces clinkers, car s'il y avait trop de silice, un silicate inerte (gélénite) se formerait.

SUMMARY: After the loss in strength suffered by HAC concretes during conversion a small recovery in strength may ensue, this recovery is related to the presence of hydratable silicate minerals in the H.A.C. (pleochroite and  $\beta$ -C<sub>2</sub>S). There is probably a critical amount of silica in the clinker for if too much is present the inert silicate mineral gehlenite will be formed.

INTRODUCTION:

It has been suggested (1,2,3,4,5) that the strength development curves for U.K. manufactured H.A.C. concretes take the form with time the strength rises to a maximum followed by a fall to a minimum and then followed by a small rise in strength. It has been suggested (1) that this recovery in strength may be due to the formation of Stratlingite ( $C_2ASH_8$ ). On the other hand, some non U.K. H.A.C. concretes may show no such recovery in strength even after 21 years (6,7.)

To see if the composition of the cement clinker has any effect on the strength development curves, three H.A.C. samples have been examined. A, a commercial H.A.C. of U.K. manufacture; B, a commercial H.A.C. of U.S.A. manufacture, and C, a white H.A.C.

EXPERIMENTAL:

The chemical analysis of the cements are given - Table 1 and the mineral composition by QXRF(5) in table 2.

Table 1.  
Chemical analysis (wt.%)

	A	B	C
SiO <sub>2</sub>	4.0	9.5	0.2
Al <sub>2</sub>	37.9	41.6	71.8
CaO	37.5	38.7	27.1
Fe <sub>2</sub> O <sub>3</sub>	9.8	3.6	0.0
FeO	5.7	-	0.0
SO <sub>3</sub>	0.1	0.8	0.3
Na <sub>2</sub> O	0.1	0.1	0.1
K <sub>2</sub> O	0.1	0.5	trace
Loss on Ign.	0.7	0.1	0.1

Table 2.  
Mineral composition of H.A.C. by Q.X.R.D. (wt.%)

	A	B	C
CA	45	30	54
fss*	7	7	1
Wustite	10	6	0
Pleochroite	16	2	0
C <sub>2</sub> AS	3	31	0
C <sub>12</sub> A <sub>7</sub>	1	20	2
C <sub>2</sub> S	4	2	0
CA <sub>6</sub>	0	0	42
CT	3	3	1

\* ferrite solid solution ( $C_2F - C_6AF_2$ )

The SiO<sub>2</sub> content ranges from 0.2% in A, to 9.5% in C; the pleochroite content ranges from 16% in A to zero in C, BC<sub>2</sub>S from 4 in A to zero in C. The high SiO<sub>2</sub> content (9.5%) of B gives rise to 31% of the inert mineral gehlenite, while the intermediate SiO<sub>2</sub> content (4%) of A produces only 3% gehlenite. Pleochroite is considered to be reactive and produce strength (9), BC<sub>2</sub>S is highly reactive and strength producing while gehlenite, at normal temperatures is unreactive (10).

The compressive strength of neat cement paste cures (12.5mm side) made with w/c ratios of about 0.27 stored 1 day in moist conditions at 18°C and then in water at 50°C are given in table 3.

Cement A shows the typical strength development curve with a rise to the maximum of 154N/mm<sup>2</sup> at 7 days, the fall to the minimum of 79N/mm<sup>2</sup> at 28 days and the subsequent rise to 105N/mm<sup>2</sup>. Cement C shows the rise to the maximum of 138 at 7 days and then the steady fall with no recovery. Cement B shows only a very small strength recovery.

Table 3.

Compressive strength (N/mm<sup>2</sup>) of neat cement cubes, W/C 0.27, stored at 18°C 1 day and then in water at 50°C.

Age	1	7	14	28days	3	6	12months
A	150	154	139	79	89	108	105
B	86	72	59	59	31	38	40
C	92	138	124	93	74	66	57

The degree of conversion, Dc, (1), was determined for all specimens table 4. All show a high rate of conversion and eventually a high degree of conversion.

Table 4.

Degree of conversion, Dc, % of pastes cured 18°C 1day and then 50°C.

	1	7	14	28days	3	6	12months
A	15	40	15	65	75	85	90
B	0	40	30	45	65	70	75
C	27	50	55	60	80	80	90

Discussion

Discussion

The amount of strength recovery in  $N/mm^2$  from the minimum to the strength at 1 year are given in table 5; the  $SiO_2$  and silicate mineral contents are also given.

Table 5

Strength recovery of neat cement pastes cured at  $50^\circ C$ ; minimum to 1 year strength.  $SiO_2$  content wt%, (table 1), mineral content wt% (table 2)

	Strength recovery	$SiO_2$	Pleochroite	$BC_2S$	$C_2AS$
A	26	4.0	16	4	3
B	9	9.5	2	2	31
C	0	0.2	0	0	0

From the data in table 5 it can be seen that as the amount of pleochroite increases so the amount of strength recovery increases. However, there is no simple relationship between silica content and strength recovery. Cement B with 9.5%  $SiO_2$  but 31% gehlenite and only 2% of pleochroite and  $BC_2S$  has a small strength recovery when compared with cement A with 4%  $SiO_2$  but 16% pleochroite and 4%  $BC_2S$  and only 3% gehlenite. Cement C shows no strength recovery at 1 year since it contains only 0.2%  $SiO_2$  and no measurable silicate minerals.

Conclusions

It is concluded from an examination of the mineralogy of three high alumina cement that the small recovery in strength observed during the conversion reaction of hydrating HAC following the initial loss in strength may be correlated with the presence of hydratable silica bearing minerals, pleochroite and  $BC_2S$ . The strength recovery in absolute terms is not related to the total silica content of the clinker for, if the quantity of  $SiO_2$  is increased too much, the gehlenite, a non-reactive mineral is produced at the expense of the hydratable silicate minerals. It seems likely that there will be a critical amount of silica needed in the cement to produce a maximum strength recovery of H.A.C. concrete during conversion.

# Property and Application of Thermosetting Cement

## *Propriétés et applications du ciment thermo-durcissant*

GUNJI SHIKAMI, HIROFUMI SHIMATANI, RYOICHI SHIKATA, MICHIO MITSUHASHI, Japon.

**RESUME :** Les ciments thermo-durcissant (ci-après : CTD) sont des ciments composés principalement d'aluminate de calcium, de sulfate de calcium et de silicate de calcium, et dont la prise est ralentie par un agent retardateur.

Ce ciment peut avoir un durcissement rapide, en le chauffant à une température appropriée et en le faisant reposer. Ainsi on peut le malaxer et le mettre en forme, puis après la mise en forme, en faisant une opération de chauffage à 80°C-30 minutes, on peut avoir un ciment ayant un temps de prise long et un durcissement rapide.

On a observé que le durcissement rapide de ces ciments était dû à la formation rapide d'ettringite; cette dernière formation peut être ralentie par un mélange de semi-hydrate de gypse et d'acide citrique.

En faisant chauffer ce ciment à une température de 70 à 80°C on a la formation de l'ettringite en 30 minutes environ, la formation de celle-ci est alors terminée, et après cela il n'y a presque pas d'augmentation ou de diminution de celle-ci.

Le chauffage initial contribue à l'amélioration de la qualité de durcissement rapide ainsi qu'à la stabilisation volumique à long terme. D'autre part, comme on ne chauffe pas pendant longtemps à température élevée, on évite une réduction de la réactivité du  $C_3S$ . Le CTD montre une bonne qualité comme liant du béton.

**SUMMARY :** Thermosetting cement (hereinafter referred to as TSC) mainly consists of calcium aluminate, calcium sulfate and calcium silicate, and its flash setting is prevented by addition of a retarder. With this cement, upon appropriate hot curing before setting time rapid hardening can be obtained. That is, through the heating process at 80°C for 30 minutes after mixing and placing at ordinary temperatures a cement with the longer setting time and rapid hardening is made available.

Flash setting of this kind of cement was known to be on account of rapid formation of ettringite, which thus could be retarded by coexistence of calcium sulfate hemihydrate and citric acid. When this cement is heated prior to setting up to 70 - 80°C, formation of ettringite is accelerated and completed in about 30 minutes, which remains nearly unchanged after that. Therefore, the early heating does much toward improving rapid hardening and stability of volume for a prolonged period. Furthermore restricted hot curing time at high temperatures is also effective to prevent lowering reactivity of  $C_3S$ , which contributes to increasing strength of TSC at prolonged period. TSC indicates superior properties as a binder for GRC.

## 1. Introduction

Trials to receive rapid hardening of cement arrived at a level of hardening in several hours due to development of a regulated cement (it is known as Jet Cement in Japan). It is also possible to make it rapid further, however, the higher in rapid hardening the shorter in setting time, which makes handling of mortar and concrete difficult, thus being limited in rapid hardening.

The authors studied on a cement with rapid hardening in addition to the comparatively longer setting time, and finally succeeded in development of a thermosetting cement with rapid hardening by heating (hereinafter referred to as TSC).

In this report mechanism of retarded setting of TSC, mechanism of early strength appearance as well as optimum heating temperature and time were studied, the results of which are stated below.

## 2. Hydration of thermosetting cement

As indicated in Table I, TSC contains as hydraulic compound calcium silicate mainly comprising  $C_3S$ , and calcium aluminate mainly comprising CA, to a mixture of which an appropriate amount of insoluble anhydrite and calcium sulfate hemihydrate as well as a little amount of citric acid for adjusting retarded setting are added. The better fineness is favorable, but it is about  $7000 \text{ cm}^2/\text{g}$  in Blaine.

## 2-1. Setting of thermosetting cement

In Fig. 1 which indicates changes with the passage of time of TSC's heat evolution at ordinary temperatures, the first peak is considered to correspond with formation of ettringite from measurement of XRD. The time of appearance and heat evolution rate of the first peak are known to be markedly retarded by addition of hemihydrate as well as citric acid. The time of appearance of the first peak nearly corresponds with the setting time of those cements made in trial, which indicates that abundant formation of ettringite has resulted in

Cement 1: TSC as shown in Table I.  
Cement 2: Cement 1 not containing citric acid  
Cement 3: Cement 2 not containing hemihydrate  
Fig. 1. Effect of hemihydrate and citric acid on the early hydration of TSC at  $20^\circ\text{C}$  ( $W/C=0.65$ )

Table I. Finess, chemical composition and mineralogical composition of TSC

Blaine (cm <sup>2</sup> /g)	chemical composition (%)								mineralogical composition (%)								
	Ig.loss	Insol	SiO <sub>2</sub>	Al <sub>2</sub> O <sub>3</sub>	Fe <sub>2</sub> O <sub>3</sub>	CaO	SO <sub>3</sub>	Total	C <sub>3</sub> S	C <sub>2</sub> S	CA	C <sub>3</sub> A	C <sub>4</sub> AF	CaSO <sub>4</sub>	CaSO <sub>4</sub> .1/2H <sub>2</sub> O	Ca(OH) <sub>2</sub>	Total
6800	2.8	0.1	13.9	9.6	4.4	58.1	9.8	98.7	40	9	7	5	10	11.5	4.5	6	93

setting of TSC. The comparatively longer setting time is apparently based on the results of chemically controlled formation of ettringite.

## 2-2. Hydration in heating

Fig. 2 shows the rate of hydration accelerated by heating the TSC paste. When compared with identification with XRD the first peak mainly corresponds with formation of ettringite at every temperature, and in case of  $70^\circ\text{C}$  already in the first peak formation of monosulfate is also included. According to Fig. 3, which shows the analytical results of ettringite and monosulfate obtained from stoichiometry<sup>1)</sup>, the higher the hot curing temperature is, the more formation of monosulfate accelerates, thus it is known that ettringite is formed less and monosulfate is formed more. That is, from the results of Figs. 2 and 3 it is known that prolonged hot curing is not necessary but only 20 - 30 minutes is sufficient to complete formation of ettringite. Fig. 4 also supports an accelerated hydration of TSC by heating.

Fig. 2. Effect of temperature on heat liberation of TSC. (by conduction calorimeter : ( $W/C=0.65$ ))

Fig. 3. Effect of temperature on the amount of hydrates formed in hardened TSC.

Furthermore, hydration at a high temperature in restricted time followed by  $20^\circ\text{C}$  water curing was examined to confirm this point. Fig 5. shows the decreasing rate of hydraulic minerals (hydration rate)

Fig.4. SEM micrograph of hardened TSC. (1.5 μm)

obtained for the purpose of knowing a trend of chemical reaction rate with TSC. CA with the lowest reaction rate among calcium aluminates indicated different reaction rate by length of retention time at 80°C. On the other hand Fig. 6 shows formation of ettringite and monosulfate, in which even in 30 minutes of retention time formation of ettringite is completed in an early stage hardly showing an increase in the later period, with only monosulfate being increased. Furthermore when cured at a high temperature for a prolonged period, formation of

Fig.5. Effect of retention time at 80°C on hydration of  $C_3S$  and CA. (by XRD)

Fig.6. Effect of retention time at 80°C on the amount of hydrates formed in hardened TSC.

ettringite is a little less, which results in a little more of monosulfate.

Thirty minutes after mixing paste was heated for 30 minutes up to 80°C and composition of liquid phase was pursued, the results of which are shown in Fig.7. By heating up to 80°C saturated  $SO_4^{2-}$  ion and  $Ca^{2+}$  ion decrease and the  $Al_2O_3$  concentration of liquid increases. From this it is known that with hot curing most of ettringite and monosulfate are formed in this period.

Fig.7. Effect of raising temperature on the composition of liquid phase of TSC. (W/C=10)

On the other hand referring to the reaction rate of  $C_3S$  in TSC, as known from Fig.5, the longer the retention time at 80°C is, the more the reaction rate after completion of hot curing increases giving an effect on the strength of about one-day period. However, the reaction rate of the later period decreases on the contrary as the early high temperature curing time is longer, thus making development of strength in the later period lower. (See Fig. 8)

From the above results it was known that the optimum curing of TSC at high temperature is to be 70 - 80°C for from 30 minutes to 2 hours, having formation of ettringite nearly completed, thus high reaction rate of  $C_3S$  being maintained.

### 3. Properties of TSC mortar

The working time of TSC mortar is shorter than that of Portland cement mortar being easily influenced by temperature. With a mortar of S/C = 0.6 - 2, W/C = 0.35 - 0.6 the working time is 1 - 2 hours at ordinary temperatures and 0.5 - 1 hour at 30°C.

Mortar strength differs by heating conditions as shown in Fig. 8. The test results revealed that the early heating at 70 - 80°C for 30 minutes gives the highest strength. When temperature is too low or heating is too short (deficient maturity) damage of texture by expansion is caused in the later period, and too long heating markedly reduces later development of strength, which well corresponds with the results of hydration in heating discussed in 2-2.

Practically, in addition to high strength volume stability must be satisfied. To obtain volume stability for long time it is necessary to complete formation of ettringite in the early stage of heating, and with TSC it can be achieved by means of controlling the amount of ettringite and restricted hot curing at early period.

Fig. 8 Effect of steam curing temperature and time on the compressive strength of TSC mortar.

#### 4. Application of thermosetting cement

When used as a binder for GRC, TSC indicates the superior properties as follows:

- (1) It enables early release of mold: When GRC was molded by spraying with a glass fiber content of 3 - 5 (wt% / mortar), bending strength of 120 - 180 kgf/cm<sup>2</sup> in one hour was obtained allowing an easy release of mold after steam curing at 80°C for 30 minutes.
- (2) It has high strength: GRC using TSC showed an improvement of 20 - 25% in bending strength and 10 - 40% in impact strength compared with that of Portland cement.
- (3) It makes deterioration of GRC strength lower: The accelerated deterioration test in hot water at 80°C revealed that TSC showed less deterioration of alkali resistant glass fiber than that of Portland cement, thus decrease of strength with GRC is kept minimum.

In addition to the above, for cement products which require rapid hardening and early release of mold TSC can be used in the same way as Portland cement.

# Synthèse vers 750°C et propriétés d'un " $\beta$ C<sub>2</sub>S sulfaté"

## *Synthesis at about 750°C and properties of a sulphated $\beta$ C<sub>2</sub>S*

R. STRUILLLOU, M. ARNOULD, Centre de Géologie de l'Ingénieur, Ecole des Mines, 60, boulevard Saint-Michel, 75006 Paris, France.

RESUME : On montre qu'on peut obtenir un liant fortement hydraulique par cuisson vers 700-750°C, d'un mélange de nitrate de calcium, de silice et de gypse (CSH<sub>2</sub>). Le Ca(NO<sub>3</sub>)<sub>2</sub> fond à 561°C, puis se décompose en donnant des vapeurs nitreuses recyclables, et de la chaux qui se combine à la silice. La réaction, en présence d'une phase fondue, est rapide (20 minutes à 750°C). Le produit formé a pour formule chimique approximative

Cette formule pourrait correspondre à un mélange intime et en toutes proportions de  $\beta$ C<sub>2</sub>S et d'un autre minéral de formule hypothétique (6C<sub>2</sub>S, CS). Si on a dans le cru la relation molaire  $S < 0,1(S+S)$ , l'intégration de CS à C<sub>2</sub>S est complète. Sinon du CS libre en excès subsiste en fin de cuisson. Le produit hydraulique formé présente, en diffractométrie RX, les pics du  $\beta$ C<sub>2</sub>S, mais moins hauts, élargis, et légèrement déplacés. Il possède des propriétés hydrauliques bien meilleures que celles du  $\beta$ C<sub>2</sub>S pur et donne des résistances à court et moyen terme comparables à celles des ciments portland classiques. Mais si ce produit présente l'avantage de pouvoir être fabriqué à une température relativement basse, sa synthèse, par la voie nitrique, a l'inconvénient majeur de présenter un bilan énergétique nettement plus défavorable que celui des procédés industriels classiques.

SUMMARY : We show that we can get, from a mixture of calcium nitrate, silica and gypsum(CSH<sub>2</sub>) a highly hydraulic cement, by burning at about 700-750°C. The Ca(NO<sub>3</sub>)<sub>2</sub> smelts at 561°C, then decomposes while giving recoverable nitrous vapours and lime which combines with silica. The reaction in the presence of a liquid phase is quick (20 minutes at 750°C). The product so formed has a chemical formula which is approximately

This formula could correspond with a mixture homogeneous in all proportions of  $\beta$ C<sub>2</sub>S and of another mineral with a hypothetic formula (6C<sub>2</sub>S, CS). If the molar relation  $S < 0,1(S+S)$  is realized in the material, CS disappears and seems to enter completely into C<sub>2</sub>S. In the other case, free CS is found after burning. The hydraulic product so formed presents, in X.Rays diffractometry, the rays of  $\beta$ C<sub>2</sub>S but less high, wider and a little misplaced. This product has much higher hydraulic properties than pure  $\beta$ C<sub>2</sub>S, and gives short and middle-term mechanical resistances comparable with those of classical portland cements. But if this product can be made at a rather low temperature, its synthesis, by the nitric way, has the great disadvantage of presenting a very much unfavourable energetic balance than this of classical industrial processes.

Actuellement, toute méthode diminuant la consommation de l'industrie cimentière en produits pétroliers présenterait un intérêt certain, en particulier si elle permettait de remplacer le fuel par une autre source d'énergie. Une voie consisterait à obtenir, à relativement basse température, des liants à propriétés hydrauliques équivalentes à celles des ciments portland à C<sub>3</sub>S. Les essais réalisés au Centre de Géologie de l'Ingénieur de l'Ecole des Mines de Paris, avec l'aide financière du Ministère de l'Industrie et du Ministère de l'Équipement, montrent qu'il est possible de fabriquer un tel liant entre 700°C et 750°C.

#### METHODE D'OBTENTION DU LIANT EN LABORATOIRE

La décarbonatation du calcaire étant très lente au-dessous de 850°C, nous avons remplacé CaCO<sub>3</sub> par Ca(NO<sub>3</sub>)<sub>2</sub> en réalisant, à partir du mélange cru initial (23% SiO<sub>2</sub> + 77% CaCO<sub>3</sub>), la succession de réactions de base suivantes, avec trempe à l'air des produits en sortie du four :

- dans le four réglé entre 700°C et 900°C (en général 750°C) :

Ca(NO<sub>3</sub>)<sub>2</sub> fond à 561°C, dès l'entrée dans le four, et la réaction (3) se réalise donc en présence d'une phase liquide jusqu'à décomposition totale du nitrate par la réaction (2). Dans nos conditions opératoires, les réactions étaient terminées au bout d'environ 20 minutes à 750°C. Les vapeurs nitreuses étaient simplement récupérées à mesure de leur formation, mais elles pourraient être traitées pour reconstitution du stock d'acide nitrique et recyclage. En laboratoire, on peut remplacer l'acide nitrique par le nitrate d'ammonium plus facile d'emploi. Les résultats sont identiques après passage dans le four.

Avec ces réactions de base, on aboutit à un silicate bicalcique de forme β (dit BC<sub>2</sub>S) présentant, en diffractométrie RX, des pics élargis et à intensités relatives différentes par rapport aux pics du BC<sub>2</sub>S obtenu classiquement par réaction sans nitrate au-dessus de 900°C (fig. 1 A et B). Ceci est l'indice d'une plus mauvaise cristallinité du produit. Ses propriétés hydrauliques restent cependant très médiocres et proches de celles du BC<sub>2</sub>S classique en particulier à court terme.

Il n'en est par contre pas de même si on incorpore au mélange cru initial de silice et de calcaire, une faible proportion de gypse (CSH<sub>2</sub>) ou de sulfate de calcium anhydre (CS) (environ 0,25g de gypse pour un 1g de SiO<sub>2</sub> et 3,3g de CaCO<sub>3</sub>). Dans ce cas, on obtient, à la sortie du four, un produit très mal cristallisé et doué de propriétés hydrauliques intéressantes. Il présente en diffractométrie RX, les pics du BC<sub>2</sub>S mais très faibles, très élargis, mal individualisés et légèrement déplacés par rapport à ceux du BC<sub>2</sub>S obtenu en l'absence de CS. Celui-ci n'apparaît pratiquement pas en diffractométrie RX et semble avoir été incorporé au BC<sub>2</sub>S en perdant son individualité. C'est ce BC<sub>2</sub>S particulier, très déformé, qui fera l'objet de notre analyse. Nous l'appellerons "BC<sub>2</sub>S sulfaté" (fig. 1 C et D).

Il faut remarquer qu'en présence comme en l'absence de sulfate, la transformation de la silice n'est pas totale. On évite la formation d'un excès de chaux

libre en diminuant la proportion de calcaire c'est-à-dire en utilisant environ 3g de CaCO<sub>3</sub> pour 1g de SiO<sub>2</sub>.

#### PROPRIETES DU "BC<sub>2</sub>S sulfaté"

La masse volumique du "BC<sub>2</sub>S sulfaté" est d'environ 2,9g/cm<sup>3</sup>. En l'absence d'impuretés, il est d'un blanc très franc. A la sortie du four, le produit est très friable et donne facilement, par broyage rapide, de très grandes surfaces spécifiques (5000 à 15000cm<sup>2</sup>/g Blaine).

La figure 1 permet de comparer les diffractogrammes RX (K<sub>α</sub>Cu), réalisés dans les mêmes conditions opératoires, d'une part sur des BC<sub>2</sub>S sans sulfate (A et B) cuits, à partir de spongolithe, l'un (A) avec 3% de CaCl<sub>2</sub> pendant 2 heures à 1000°C sans nitrate, l'autre (B) pendant 20 minutes à 750°C en milieu nitraté, et d'autre part sur des "C<sub>2</sub>S sulfatés" typiques cuits à 750°C pendant 20 minutes en milieu nitraté et obtenus à partir de crus à 6% de gypse (CSH<sub>2</sub>) l'un (C) à poussière de quartz broyé, l'autre (D) à silice organique (spongolithe).

Dans l'ensemble, les pics sont les mêmes, mais leur allure est très différente. La plus mauvaise cristallinité correspond à la silice organique (D), ce qui a été vérifié aussi bien pour la spongolithe que pour des diatomites et pour la gaize, qui donnent des produits équivalents. De plus, le quartz semble favoriser l'appartenance d'une proportion non négligeable de γC<sub>2</sub>S non hydraulique (C). Ceci pourrait expliquer que les propriétés hydrauliques des produits à base de silice organique sont sensiblement meilleures que celles des produits provenant de quartz broyé. Cette différence apparaît clairement sur la figure 2 qui montre que sur éprouvettes de pâtes pures (d = 1,2cm ; h = 1,3cm, Méthode DALZIEL-1971) compactées à sec à porosité n = 0,45 et durcies à 40°C, on obtient, au bout de 24 heures, pour les "C<sub>2</sub>S sulfatés" cuits à 750°C, des résultats comparables à ceux du CPA400 en partant de silice organique, et à ceux du CPA325 en partant de quartz broyé. Cette figure 2 montre, par ailleurs, que si on remplace 10% du quartz par de la silice organique (spongolithe) on obtient un produit qui se place à peu près à mi-chemin entre le CPA400 et le CPA325. On constate que, parallèlement, la hauteur relative du pic du γC<sub>2</sub>S diminue quand la proportion de silice organique augmente.

La figure 3 donne l'évolution dans le temps, à 40°C, des résistances des micro-épreuves de type DALZIEL compactées à sec aux porosités n = 0,45 et n = 0,30, d'une part pour un CPA400 et, d'autre part pour "BC<sub>2</sub>S sulfaté" obtenu à partir d'un cru à 6% de gypse et à spongolithe.

A partir de 5 heures (0,2 jour), le CPA400 et le "BC<sub>2</sub>S sulfaté" sont à peu près équivalents.

La figure 4 permet de comparer les résistances des éprouvettes de pâtes pures gâchées avec un rapport "eau sur ciment" de 0,50 puis vibrées et durcies à 20°C et ceci pour le CPA400, le C<sub>3</sub>S pur, le BC<sub>2</sub>S classique pur et le "BC<sub>2</sub>S sulfaté" obtenu à partir d'un cru à 6% de gypse et à spongolithe.

L'évolution dans le temps du "BC<sub>2</sub>S sulfaté" est comparable à celle du C<sub>3</sub>S ou du CPA400. Elle est environ 10 à 15 fois plus rapide que celle du BC<sub>2</sub>S pur classique non sulfaté.

Quelques essais réalisés sur mortiers normalisés ont donné, pour le "BC<sub>2</sub>S sulfaté", des performances comparables à celles du CPA325. Mais on peut se demander si les liants n'ont pas été trop finement broyés (8000cm<sup>2</sup>/g Blaine), ce qui les a rendus très avides d'eau et donc inadaptés aux conditions opératoires.

Fig. 1 : Comparaison des diffractogrammes RX ( $K_{\alpha}Cu$ ) de  $BC_2S$  fabriqués dans diverses conditions.

- (A) 2h à 1000°C sans nitrate et sans sulfate mais avec 3% de  $CaCl_2$  (cru spongolithe)  
 (B) 20' à 750°C avec nitrate et sans sulfate (cru spongolithe)  
 (C) 20' à 750°C avec nitrate, 6% de  $C\bar{S}H_2$  (cru quartz broyé) - apparition de  $\gamma C_2S$   
 (D) 20' à 750°C avec nitrate, 6% de  $C\bar{S}H_2$  (cru spongolithe).

Fig. 2 : Comparaison des résistances en compression  $R_c$ , à 1 jour, sur pâtes pures des CPA325 et CPA400 et des " $BC_2S$  sulfatés" obtenus pour diverses proportions "quartz sur silice organique" des crus traités avec 6% de  $C\bar{S}H_2$  à 750°C pendant 20 minutes (essais sur micro-éprouvettes compactées à sec à porosité  $n = 0,45$  et durcies à 40°C).

Fig. 3 : Comparaison de l'évolution dans le temps des  $R_c$  sur pâtes pures d'un CPA400 et d'un " $BC_2S$  sulfaté" (cru spongolithe à 6% de gypse) - essais sur micro-éprouvettes ( $d = 1,2cm$  ;  $h = 1,3cm$ ) durcies à 40°C après compactage à sec à porosité  $n = 0,45$  ou  $n = 0,30$ .

Fig. 4 : Comparaison de l'évolution dans le temps des  $R_c$  sur pâtes pures d'un "BC<sub>2</sub>S sulfaté" (cru spongolithe à 6% de gypse), d'un CPA400, du C<sub>3</sub>S pur et du BC<sub>2</sub>S pur classique non sulfaté - essais sur micro-éprouvettes ( $d = 1,2\text{ cm}$ ;  $h = 1,3\text{ cm}$ ) gâchées avec  $E = 0,5C$  puis vibrées et durcies à  $20^\circ\text{C}$ .

toires normalisées. Le retrait des mortiers a été légèrement supérieur à celui des mortiers courants, ce qui s'explique par leur richesse en eau due à la finesse du liant.

Tous les résultats cités précédemment correspondent à des liants utilisés sans ajouts d'accélérateurs de durcissement ( $\text{CaCl}_2$  par exemple). Ceux-ci agissent sur le "BC<sub>2</sub>S sulfaté" à peu près de la même façon que sur les ciments portland ordinaires.

#### MECANISMES DE FORMATION DU "BC<sub>2</sub>S sulfaté"

Pour essayer d'interpréter ce qui se passe dans le four lorsqu'on cuit, vers  $750^\circ\text{C}$ , un mélange de silice, de nitrate de calcium et de sulfate de calcium, on peut s'appuyer sur deux types d'observations.

D'une part, la figure 5 donne la relation linéaire existant, dans les produits cuits, entre les pourcentages de CS libre (dosés par diffractométrie RX - étalon interne ZnO) et les pourcentages totaux de CS présents en réalité (CS libre + CS incorporé). La droite, parallèle à la bissectrice des axes, recoupe l'abscisse pour un pourcentage total de CS égal à 12,5% du produit cuit ( $\text{SiO}_2 + \text{CaO} + \text{CaSO}_4$ ), ce qui correspond à 9,5% du produit cru ( $\text{SiO}_2 + \text{CaCO}_3 + \text{CaSO}_4$ ). Schématiquement, on peut donc admettre que si le cru contient moins de 9,5% de CS, celui-ci disparaît à peu près complètement lors de la cuisson et semble donc être incorporé au "BC<sub>2</sub>S sulfaté". Au-delà de ce seuil, l'excès de CS se retrouve à l'état libre dans le produit cuit. Cependant la première branche curviligne de la figure 4 montre que la réalité est un peu plus compliquée que ce schéma, et que la saturation du BC<sub>2</sub>S en CS est progressive. En tous cas, si le cru contient moins de 6% de CS, son incorporation au BC<sub>2</sub>S est pratiquement totale.

D'autre part, la figure 6 donne l'évolution, à différents stades de la cuisson à  $750^\circ\text{C}$  en milieu nitraté, des composants du système, avec cru de quartz ( $1g \text{ SiO}_2 + 3,3g \text{ CaCO}_3$ ). Les phases cristallisées ont été dosées par diffractométrie RX avec la boehmite comme étalon interne. On voit qu'au bout de 4 minutes,

Fig. 5 : Relation entre les quantités totales de CS présentes dans les mélanges à "BC<sub>2</sub>S sulfaté" cuits et les quantités de CS y restant à l'état libre (dosage par diffractométrie RX - étalon interne ZnO).

il ne reste plus que 25% de quartz cristallisé, alors que le C<sub>2</sub>S n'apparaît pas encore. Au bout de 10 minutes, 95% du C<sub>2</sub>S est déjà formé alors qu'il reste encore 10% de quartz cristallisé. A la fin de la cuisson, il reste environ 7% du quartz non utilisé.

Fig. 6 : Evolution (en %), en fonction du temps de cuisson à  $750^\circ\text{C}$  en milieu nitraté de la quantité de quartz cristallisé subsistant dans le mélange, et de la quantité de C<sub>2</sub>S formé (dosages par diffractométrie RX - étalon interne boehmite).

Il apparaît donc que le quartz est très rapidement amorphisé, sinon dissous, par le nitrate de calcium fondu. Le C<sub>2</sub>S ne se forme qu'à mesure de la décomposition du nitrate de calcium (réaction 2). Il est possible, sinon probable, que CS subisse, lui-aussi, une attaque comparable à celle du quartz de la part du nitrate fondu. Dans ces conditions, il est impossible de savoir si le "C<sub>2</sub>S sulfaté" se forme par diffusion des ions calcium et soufre à l'intérieur du quartz amorphe mais solide ou à l'état de gel, ou, au contraire, par cristallisation à partir d'un bain fondu nitraté homogène ayant dissous le quartz et le sulfate de calcium.

Quoiqu'il en soit, il semble bien que le  $C_2S$  soit susceptible d'incorporer à son réseau cristallin environ 12%, en poids, de  $CS$ , en le déformant légèrement, mais en lui gardant cependant ses caractères cristallographiques de base, en particulier les mêmes pics de diffractométrie RX.

On peut représenter l'ensemble de ces observations en proposant pour le " $\beta C_2S$  sulfaté", une formule chimique globale :

Cette formule ne prétend pas avoir une valeur structurale quelconque. Elle n'est qu'une synthèse commode des observations réalisées.

On pourrait d'ailleurs aussi considérer le " $\beta C_2S$  sulfaté" comme un mélange intime, et en toutes proportions, de  $C_2S$  pur et d'un produit de formule conventionnelle approximative :

Une telle formule est très éloignée de celle du silico sulfate ( $2 C_2S, CS$ ) ou sulfo-spurrite non hydraulique (PLIEGO - CUERVO - V.B., GLASSER F.P. 1978-1979). La présence de ce minéral dans notre " $\beta C_2S$  sulfaté" semble donc devoir être exclue. D'ailleurs il n'y a jamais été identifié sur les diagrammes RX.

#### CONCLUSION

Il apparaît possible de synthétiser à des températures de l'ordre de 700 à 800°C, des liants à propriétés comparables à celles des ciments portland courants, en partant pratiquement des mêmes matières premières. Le cas du " $\beta C_2S$  sulfaté" décrit en est un exemple. Il en existe probablement d'autres susceptibles de fabrication industrielle. La méthode utilisée, à 750°C en milieu nitraté, pour la synthèse du " $\beta C_2S$  sulfaté" n'est pas favorable d'un point de vue énergétique, la consommation globale d'énergie étant de l'ordre du triple de celle des procédés actuels de fabrication de ciment. En effet la réaction (2) de dénitruration est très endothermique. Cette méthode par la voie nitrique ne présenterait donc de l'intérêt que si l'énergie pouvait être fournie à bas prix, par des déchets par exemple, dans un procédé utilisant l'avantage du faible niveau de la température de cuisson (750°C). Mais dans la mesure où on sait que le " $\beta C_2S$  sulfaté" présente des propriétés hydrauliques intéressantes, on peut espérer trouver une méthode pour le fabriquer d'une façon plus avantageuse du point de vue énergétique.

V. SERBINE, Docteur ès Sciences Techniques,  
L. KALITA, Ingénieur.

RESUME: On a étudié le ciment contenant le sulfosilicate et le sulfoaluminate de calcium, ainsi que les processus de clinkerisation et du durcissement du ciment sulfaté. On a trouvé que le pH de ce ciment en cours de durcissement est inférieur de 2,0 - 2,5 à celui du ciment portland.

A l'aide de la méthode élaborée on a mis en évidence la stabilité élevée des fibres en verre contenant les oxydes de bore et d'aluminium dans le ciment sulfaté.

On a étudié les propriétés du système verre-ciment sulfaté.

SUMMARY: Cement including calcium sulfo-silicate and calcium sulfo-aluminate has been investigated. Clinker formation and hardening processes of sulfating cement has been studied. It is established that pH of hardening cement is 2,0 - 2,5 units lower than pH of portland-cement.

According to elaborated methods high resistance of alumo-boron-silicate fiber in sulfating cement is determined.

Properties of glass fiber cement in which sulfating cement is used as matrix has been explored.

Il y a assez longtemps que les ciments renforcés de fibres de verre constituent un objet de recherches scientifiques détaillées. On sait que l'armature constituée de fibres inorganiques est très efficace en raison de sa résistance élevée à la rupture par traction et de sa masse volumique faible. On dispose de données sur les méthodes de confection de différents éléments de construction, mais leur mise en oeuvre est freinée par une faible stabilité dans le temps des propriétés mécaniques.

Selon plusieurs auteurs, l'abaissement de résistance mécanique résulte de l'interaction du milieu alcalin du ciment durcissant avec les fibres de verre. Ce point de vue est confirmé par le fait que les fibres de verre perdent leur résistance mécanique après avoir été placées dans des solutions de NaOH, KOH,  $\text{Ca}(\text{OH})_2$  ayant un pH égal à 12,4 ce qui correspond au pH du ciment durcissant.

La stabilité dans le temps du système verre-ciment peut être améliorée par les méthodes suivantes: utilisation de fibres de verre résistant mieux à l'action des alcalis, enrobage des fibres, introduction des ajouts dans le liant, utilisation de ciments spéciaux ne détruisant pas les fibres de verre.

L'on sait que les fibres de verre se portent bien dans les ciments alumineux, mais ceux-ci ne sont pas largement utilisés en Génie Civil. Ces derniers temps on a élaboré le ciment sulfoalumosilicaté qui peut fournir une solution à ce problème.

Ce ciment est exempt de silicate tricalcique et d'aluminate tricalcique. Ses principaux constituants sont: le sulfoaluminate de calcium  $3(\text{CA})\cdot\text{CaSO}_4$  et le sulfosilicate de calcium  $2(\text{C}_2\text{S})\cdot\text{CaSO}_4$ . On peut confectionner ce ciment à partir des matières premières suivantes: argile kaolinique, calcaire, gypse. En guise du gypse il est possible d'utiliser le phosphogypse qui est un résidu de la fabrication de l'acide phosphorique et des engrais phosphatés à partir des phosphates.

Etant donné que la composition des phases du clinker sulfaté diffère beaucoup de celle du

clinker de ciment portland, on propose la formule suivante pour l'évaluation du coefficient de saturation:

$$\text{CS} = \frac{\text{C}_0 - 0,55\text{A}_0 - 1,05\text{F}_0 - 0,7(\text{SO}_3)_0}{1,867\text{S}_0} \quad (1)$$

où  $\text{C}_0$ ,  $\text{A}_0$ ,  $\text{F}_0$ ,  $(\text{SO}_3)_0$ ,  $\text{S}_0$  sont les teneurs en  $\text{CaO}$ ,  $\text{Al}_2\text{O}_3$ ,  $\text{Fe}_2\text{O}_3$ ,  $\text{SO}_3$ ,  $\text{SiO}_2$  dans le mélange cru. On suppose que tout le  $\text{SiO}_2$  fait partie de  $2(\text{C}_2\text{S})\cdot\text{CaSO}_4$  et de  $\text{C}_2\text{S}$ , ainsi que tout le  $\text{Al}_2\text{O}_3$  entre dans  $3(\text{CA})\cdot\text{CaSO}_4$  et  $\text{C}_4\text{AF}$ . L'oxyde de fer entre dans  $\text{C}_4\text{AF}$ .

En outre on introduit le degré de saturation des silicates et aluminates par le gypse ( $\text{DS}_{\text{SO}_3}$ ).

$$\text{DS}_{\text{SO}_3} = \frac{(\text{SO}_3)_0 - 0,261\text{A}_0 + 0,166\text{F}_0}{0,667\text{S}_0} \quad (2)$$

Lorsque  $\text{DS}_{\text{SO}_3} = 1$ , on constate la formation des composés:  $2(\text{C}_2\text{S})\cdot\text{CaSO}_4$  et  $3(\text{CA})\cdot\text{CaSO}_4$  saturés au maximum par le sulfate. Lorsque  $\text{DS}_{\text{SO}_3} > 1$  il y a de l'anhydrite en excès.

Les processus de clinkérisation dans les mélanges des matières premières contenant des sulfates se distinguent de ceux, qui ont lieu lors de la cuisson du clinker portland.

Nous avons étudié les processus de formation des minéraux du clinker dans les mélanges contenant des sulfates. Pour cela on a préparé les mélanges à deux et à trois composants (craie-kaolin et craie-kaolin-phosphogypse). Les mélanges étaient soumis à l'analyse thermique différentielle ainsi qu'à la cuisson entre  $600^\circ$  et  $1300^\circ\text{C}$  à des températures par intervalles de  $100^\circ$  avec des paliers de 20 minutes. On a soumis à l'analyse aux rayons X les mélanges obtenus, et on a déterminé la teneur en chaux libre et les pertes au feu.

L'analyse thermique différentielle du mélange craie-kaolin met en évidence deux effets endothermiques aux températures  $575^\circ$  et  $930^\circ\text{C}$  et un crochet exothermique à  $995^\circ\text{C}$ . Les traces de chaux libre font leur apparition à  $700^\circ\text{C}$ , sa teneur maximum est atteinte à  $1000^\circ\text{C}$ . A  $1300^\circ\text{C}$  il ne reste que

2,8 % de chaux libre. A la température de 1250°C la chaux est combinée à 93,1 %.

La courbe de l'analyse thermique différentielle du mélange contenant du gypse est caractérisée par l'effet endothermique double aux basses températures, dû à la déshydratation du gypse. L'effet endothermique dû à la décarbonatation de la calcite est déplacé de 930° jusqu' à 900°C. On peut juger de l'intensification des processus de formation du clinker d'après les variations de teneur en chaux libre. Elle fait son apparition à 600°C, sa teneur maximum est atteinte à 900°C, à 1300°C il ne reste que 0,8 % de CaO, à la température de 1250°C la chaux libre est combinée à 98,5 %.

L'analyse aux rayons X a démontré que dans les mélanges ternaires les raies du sulfo-silicate de calcium ont fait leur apparition à 1000°C et celles du sulfoaluminate à 1100°C.

Les processus d'hydratation des clinkers contenant des sulfates diffèrent de ceux du clinker de ciment portland. Ce sont l'ettringite et l'hydrosilicates du groupe de la tobermorite qui se forment en premier lieu. La chaux libre est absente.

Le durcissement des ciments contenant des sulfates est assez rapide. Leur résistance à trois jours atteint 50-70 % de celle à 28 jours. Il sont plus stables vis-à-vis des sulfates. De tout ceci nous pensons pouvoir conclure, que ces ciments doivent être moins agressifs par rapport aux fibres de verre. Le pH de ces ciments varie aux alentours de 9,8-10,0 ce qui est inférieur

de 2,0-2,5 à celui du ciment portland et du même ordre que celui des ciments aluminieux.

L'étude de la stabilité des fibres de verre dans les ciments sulfatés, le ciment portland et le ciment alumineux au gypse a été faite par une méthode accélérée.

Nous avons élaboré cette méthode en nous basant sur le fait, que la vitesse de réaction entre le ciment durcissant et les fibres de verre croît avec la température. C'est pourquoi, après avoir déterminé le coefficient thermique d'accroissement de la vitesse de réaction et ayant choisi la température, il est possible de calculer la durée du traitement par étuvage des compositions verre-ciment, ce qui correspondra à la durée et la température d'exploitation de ces compositions dans les conditions naturelles. Comme paramètre caractérisant la résistance des compositions verre-ciment, nous avons choisi la limite de rupture par traction des éprouvettes renforcées de fibres en verre alcalin, non-alcalin et contenant Zr. Les compositions chimiques sont présentées dans le tableau I.

L'armature a permis de réduire la dispersion des résultats d'essais et d'abaisser le coefficient de variation lors des essais parallèles jusqu'à 2-7 %. Ayant fait les essais préalables nous avons évalué le coefficient thermique de croissance de la vitesse de réaction lors d'une montée en température de 10°C, celui-ci étant égal à 2,69 en moyenne. Cela nous a permis d'aboutir à la formule suivante:

TABLEAU I  
Compositions chimiques des fibres de verre

Verre	Teneur en oxydes, %						
	SiO <sub>2</sub>	Al <sub>2</sub> O <sub>3</sub>	CaO	MgO	B <sub>2</sub> O <sub>3</sub>	ZrO <sub>2</sub>	K <sub>2</sub> O+Na <sub>2</sub> O
alcalin	70,12	2,19	6,96	5,49	-	-	15,36
non-alcalin	52,29	16,17	16,48	5,16	9,45	-	0,51
contenant Zr	61,89	2,13	5,39	1,46	-	15,63	13,48

$$t_2 = \frac{t_1}{\frac{T_2 - T_1}{2,69 \cdot 10}}, \quad (3)$$

dans laquelle:

$t_1$  = durée d'exploitation des compositions dans les conditions normales, en heures

$t_2$  = durée du traitement par étuvage, en heures

$T_1$  = température d'exploitation des compositions, en °C

$T_2$  = température de l'étuvage, en °C.

Pour les essais nous nous sommes procurés du ciment obtenu par voie sèche dans un four rotatif 3,5/3,0 x 60 m. La cuisson a été faite à 1280 - 1310°C. La composition minéralogique:  $2(C_2S) \cdot CaSO_4 = 40,14 \%$ ,  $3(CA) \cdot CaSO_4 = 15,09 \%$ ,  $C_2S = 27,34 \%$ ,  $C_4AF = 1,52 \%$ . Parallèlement on a fait des essais de ciment portland et de ciment alumineux au gypse. Le tableau II montre les caractéristiques des ciments.

Les résultats de ces essais sont présentés dans le tableau III. La résistance des compositions à base du ciment alumineux au gypse s'abaisse dans le temps, comme dans le cas du ciment sulfaté. Mais leur résistance résiduelle après 10 ans est de 2 ou

3 fois supérieure à celle des compositions à base du ciment portland. Il faut noter, que cet abaissement est appréciable jusqu'à l'âge de 5 ans.

TABLEAU II  
Caractéristiques des ciments

Ciment	Rapport E/C	Résistance à la rupture par compression, en N/mm <sup>2</sup> , après		
		3j.	7j.	28j.
sulfaté	0,45	19,0	30,0	46,0
portland	0,40	24,3	35,9	47,2
alumineux au gypse	0,30	32,8	38,1	41,0

On a fait l'examen au microscope électronique des surfaces des fibres avant et après les essais accélérés. La surface des fibres dans le ciment portland est recouverte d'une couche continue de produits de réaction du ciment avec le verre et ceci sous forme d'hydrosilicates de différente basicité. La surface des fibres dans le ciment sulfaté ou alumineux au gypse est moins corrodée.

#### CONCLUSIONS

Les recherches accomplies montrent que le ciment sulfaté est un liant convenant à la

TABLEAU III  
Influence du ciment sur la résistance des compositions verre-ciment

confection des éléments de construction en béton renforcé de fibres de verre. La production du ciment sulfaté ne comporte aucune difficulté. La température de cuisson plus basse (1250-1280°C) permet de réduire la consommation de combustible. En outre, la possibilité d'utiliser certains déchets de l'industrie chimique présente un intérêt pour la protection de l'environnement.

# The chemical resistance of high alumina cement concrete

## *La résistance chimique du béton de ciment alumineux*

H.G. MIDGLEY, Concrete Research Laboratory, Civil Engineering Division, The Hatfield Polytechnic, Hatfield, Herts, U.K.

RESUME : Le béton de ciment alumineux (h.a.c.) résiste à l'attaque des sulfates, des chlorures et de l'eau de mer, à condition qu'il ait été préparé correctement et correctement mis en oeuvre. Mais si ce ciment a accompli, en grande partie, sa conversion cristalline et si le béton est fissuré (notamment par la précontrainte), il peut subir une attaque fissurante par les sulfates. L'eau de mer et les chlorures semblent n'entraîner qu'une faible attaque fissurante.

L'hydrolise alcaline et la carbonatation en présence d'hydroxydes alcalins peuvent provoquer la destruction complète du ciment de ces bétons (h.a.c.).

### SUMMARY:-

High alumina cement concrete (hacc) is resistant to sulphates, chlorides and sea water if correctly made and used in the correct manner. If, however, the hacc is highly converted and cracked (for example prestressing cracks) then it may be disruptively attacked by sulphates. Sea water and chloride appear to have little disruptive effect.

Alkaline hydrolysis, the carbonation in the presence of alkaline hydroxides can completely disrupt the cement part of hacc.

## 1. INTRODUCTION:

High alumina cement concrete has the reputation of being a chemically resistant construction material. However, there have been reports that hacc may be vulnerable to sulphate attack (1); chloride attack (2) and may be vulnerable to sea water. Hacc may also be disrupted by atmospheric CO<sub>2</sub> in the presence of sodium potassium hydroxide pollution. This paper reports on the conditions where hacc may be vulnerable.

## 2. Sulphate attack

Hydrated hacc is based on hydrated calcium aluminates which might react with CaSO<sub>4</sub> to form ettringite, but it has been shown (2) that only 3CaO Al<sub>2</sub>O<sub>3</sub> 6H<sub>2</sub>O, the cubic hydrate formed in conversion of hacc will react.

Hacc with conversion increases in porosity by about 10 %, but if massive hacc is exposed to ground sulphates (e.g. MgSO<sub>4</sub>), then if fully converted (2) (Dc greater than 90%) ettringite of composition about 6CaO, 2Al<sub>2</sub>O<sub>3</sub>, 2.15SO<sub>3</sub>, 0.02 SiO<sub>4</sub>, 0.65 OH, 32H<sub>2</sub>O will be formed, but even after 18 years the depth of penetration is only about 5mm. These findings are in agreement with laboratory experiments with varying degrees of conversion made with various mixes and w/c ratios (Table 1) and exposed to saturated CaSO<sub>4</sub> solution had penetrations of only a few mm.

Table 1.

Mix composition cement/aggregate	w/c	curing conditions	Dc	Depth of penetrat: ion
1:3	0.35	1y 20°C + 1y sulphate	50	4
1:4½	0.48	do.	30	4
1:6	0.6	do.	30	6
1:3	0.35	9m@ 25 + 1y sulphate	50	3
1:4½	0.48	do.	45	5
1:6	0.60	do.	50	6
1:3	0.35	3m@ 38°C + 1y sulphate	80	3
1:4½	0.48	do.	80	5
1:6	0.60	do.	80	6
1:3	0.35	1month 50°C + 1y sulphate	85	9
1:4½	0.48	do.	90	10
1:6	0.60	do.	90	9

In the case of prestressed hacc beams used for roof support where there has been leakage of rain water through gypsum plasters (CaSO<sub>4</sub>2H<sub>2</sub>O), ettringite of composition 6CaO, 1.95Al<sub>2</sub>O<sub>3</sub>, 0.21Fe<sub>2</sub>O<sub>3</sub>, 2.51SO<sub>4</sub>, 0.48OH, 32H<sub>2</sub>O was found, in a few cases to a depth of 20mm. This reaction contributed to the failure of the roof beams (1). The hacc of the beam was highly converted (Dc greater than 90%), but by comparison with massive hacc it was concluded that some other path beside the increase in porosity on conversion is needed for the sulphate ions; and in the case of prestressed beams, microcracks are the most likely.

In another case ettringite was found at least 100mm from the surface of an hacc prestressed beam and the source of the sulphate ions was the Ordinary Portland cement screed of the floor deck; here the beam has cracked by the prestressing. Also the alkaline hydroxide solutions from the O.P.C. concrete had attacked the cement by "alkaline hydrolysis" (see later) which is likely to have made the concrete more vulnerable to sulphate attack.

If hacc concrete is of poor quality, e.g. made with too low a cement content and too high a w/c ratio it will be extremely vulnerable to acid sulphate attack if highly converted. Sewer linings which had been used in a site with acid sulphate ground water from old metallurgical tips showed considerable attack, ettringite of composition 6CaO, 1.78, Al<sub>2</sub>O<sub>3</sub>, 0.4 Fe<sub>2</sub>O<sub>3</sub>, 2.65SO<sub>4</sub>, 0.07SiO<sub>4</sub>, 0.29(OH), 32H<sub>2</sub>O was found.

To detect the ettringite in attacked hacc, the following techniques are useful:-

X-Ray diffraction with a characteristic reflection at 9.73Å. Differential Thermal analytical techniques with a strong sharply defined endotherm at about 100°C.

### Alkaline hydrolysis

Alkaline hydrolysis of hacc was first described (3) in 1936. This form of attack may completely disrupt the concrete reducing the cement part to a powder. It only takes place in the presence of sodium or potassium hydroxide solutions and CO<sub>2</sub>. The alkalis appear to act as carriers for the CO<sub>2</sub> which attacks the cementitious calcium aluminate hydrates to form AH<sub>3</sub> and CaCO<sub>3</sub>. It must be pointed out that carbonation of hacc in the absence of alkali hydroxides may be beneficial giving an increase in strength (4).

Experimental work has shown that pH alone (triethanolamine) in the presence of CO<sub>2</sub>; alkali hydroxides in the absence of CO<sub>2</sub>, Sodium and ammonium chloride of high pH in the presence of CO<sub>2</sub> will not cause the decomposition of hacc, but alkali hydroxides in the presence of CO<sub>2</sub> will rapidly decompose the calcium aluminate hydrates.

A number of examples of hacc prestressed beams which have suffered alkaline hydrolysis have shown that the concrete has always produced a fine loose powder which may be brushed away. Mineralogical analysis have shown the products to be AH<sub>3</sub> (either alpha or gamma) and CaCO<sub>3</sub>.

Chemical analysis of the acid soluble extract of the cement part of the hacc, for  $Al_2O_3$ ,  $K_2O$  and  $Na_2O$  have always shown that the ratio of  $Al_2O_3/Na_2O + 0.658K_2O$  (A/TA) to be low. (a high alkali concentration in relation to the  $Al_2O_3$  content of hac - 40%) From a statistical examination of the chemical analysis of U.K. hac the limit of A/TA has been found to be 75.3. From the analysis of 70 samples of hacc which showed powdering the A/TA ratio were 12.3, 25.8, 58.8, 48.4, 52.5, 12.9, while for an equal number of unattacked samples the ratio were 144, 218, 125, 259, 139, 343. By mineralogical techniques of the attacked samples only  $AH_3$  and  $CaCO_3$  were found, while in the unattacked samples,  $CAH_4O$ ,  $AH_3$ ,  $C_3AH_6$  etc. were detected. In some samples calcium aluminate hydrates ( $CAH_4O$  and  $C_3AH_6$ ) were detected but the A/TA ratio was low, 22.9, 26.7, 20.6, 50.3. These samples were considered to be vulnerable. The source of alkali hydroxides is usually external; e.g. from water leaching of porous ordinary Portland cement; but the source may be internal, the extractable  $K_2O$  from the micas in the aggregate have been found to provide the alkali hydroxides for alkaline hydrolysis. Alkaline hydrolysis depends on 4 factors; highly permeable concrete, moisture,  $CO_2$  and free alkali hydroxides. Any degree of conversion is vulnerable.

#### Sea water attack

High alumina cement concrete exposed to sea water will convert very slowly; between 0 - 15% in 34 years; there may be some superficial attack to form ettringite; but the concrete appears to be always sound.

If the hacc is used in a tidal zone then that part which is exposed to the air will convert more rapidly than the submerged part with the concurrent loss in strength due to conversion. However examination of laboratory structure specimens as well as existing structures shows that even in this region the attack was superficial.

#### Chloride Attack

No laboratory studies of chloride attack have been carried out and one example of suspected chloride attack of a structure has been seen. A prestressed hacc beam had been exposed to road de-icing salt. One beam had a failure of the end shearing, with exposure of the tendon; the chloroaluminate  $C_3A$ .  $CaCl_2 \cdot 12H_2O$  was detected in the cement part of the hacc but it cannot be established if the formation of this mineral by chloride attack contributed to the failure or if the failure was due to the reduction in passivity to rusting of the tendon by the presence of the chloride ion.

## Ciment expansé composé d'un ciment normal et d'un ajout complexe

### *Expansive cement conceived on the basis of normal cement and a complex admixture*

N.B. DJABAROV, Docteur-Ingénieur et

Y.T. SIMEONOV, Professeur, Docteur-Ingénieur, Laboratoire Central de Mécanique Physique-Chimique,  
Académie Bulgare des Sciences, Sofia, Bulgarie.

RESUME : Un nouveau type de ciment expansif, composé d'un ciment normal et d'un ajout complexe a été récemment élaboré. Grâce à l'ajout, la structure et les propriétés mécaniques des ciments ordinaires sont modifiées de manière qu'ils se transforment en ciments spéciaux, expansifs.

Suivant les besoins de la construction et de l'industrie des éléments préfabriqués, les ciments normaux peuvent ainsi obtenir les qualités désirées : soit un ciment à retrait compensé, soit un ciment expansif ou bien un ciment autocontraint.

L'expansion des ciments ainsi modifiés peut être contrôlée avec précision et atteindre les valeurs exigées (de 0,1 à 4 % pour un mortier standard de ciment : sable = 1:3 ou béton).

L'expansion se produit et se termine définitivement dans les 1 à 3 premiers jours, aussi bien dans la conservation dans l'eau que dans celle à l'air.

Compte tenu de leur grande expansion, ces nouveaux ciments expansifs possèdent des résistances mécaniques relativement élevées. Ils manifestent aussi une résistance contre la pénétration et le passage de l'eau bien augmentée et un fluage et une déformabilité diminués.

SUMMARY : A new type of expansive cement conceived on the basis of normal cement and a complex admixture was recently elaborated. By means of the admixture the structure and the mechanical properties of ordinary cements are modified in such manner that they are transformed in special expansive cements.

According to the needs of construction and prefabricated elements industry the normal cements can obtain the very exactly regulated qualities of a shrinkage compensated cement, or of expansive cement, or of selfstressing cement.

The expansion of the modified cements can be precisely controlled and to receive the needed value - 0,1 to 4 % for standard mortar cement:sand = 1:3 or concrete. The expansion is displaying and is definitively terminated in the initial 1 - 3 days of hardening under water or only on the air.

Comparatively to the great expansion the new expansive cements have high mechanical strengths. They are manifesting also increased resistance against water leakage and diminished creep and general deformation.

Les difficultés d'obtenir un ciment expansif des qualités sûrement réglées et contrôlées et la complexité de sa technologie de production sont bien connues. Pour surmonter ces défauts au Laboratoire Central de Mécanique Physico-Chimique de l'Académie Bulgare des Sciences ont été entrepris des études visant la modification des ciments normaux au moyen d'un adjuvant complexe en ciments spéciaux - expansifs. Ainsi le ciment portland devient un liant beaucoup plus universel. Cela découvre la possibilité de le transformer très facilement et conformément aux besoins de la construction et de l'industrie des éléments de construction en ciment de retrait compensé, ou en ciment expansif ou en ciment autocontraint.

Grace à l'adjuvant expansif (AE) au ciment durcis se forme la quantité nécessaire d'ettringite pour rendre sa structure beaucoup plus dense et pour provoquer expansion d'une grandeur désirée. Pour ce but les composants de l'adjuvant contiennent les éléments nécessaires pour la formation d'ettringite pendant une période déterminée du durcissement.

La structure du ciment avec et sans l'adjuvant expansif a été étudiée par différentes techniques, mais dans cette brève communication l'effet de l'adjuvant expansif est illustré par l'analyse thermique d'un ciment portland. Sur les figures 1 et 2 sont données schématiquement les courbes de thermogravimétrie différentielle (TGD), d'analyse thermique différentielle (ATD) et de thermogravimétrie (TG) après 1 jour de durcissement. Les données expérimentales confirment en générale au point de vue qualitative la présence des produits d'hydratation similaires, mais présentent des grandes différences quantitatives. Le ciment durcis avec l'adjuvant expansif contient beaucoup plus d'ettringite. L'analyse prouve aussi que l'hydratation entière est plus avancée. Au contraire - la quantité du portlandit est un peu diminuée.

L'adjuvant "AE" forme l'ettringite supplé-

mentaire indépendamment de la composition du ciment employé comme base. Pour cela non seulement le ciment portland normal peut être modifié en ciment expansif, mais aussi d'autres types, comme portland du durcissement rapide, ciment à laitier de haut-fourneau, ciment pouzzolanique etc.

Fig. 1 - Analyse thermique d'un ciment portland normal.

Fig. 2 - Analyse thermique d'un ciment portland normal + l'adjuvant expansif.

Les qualités mécaniques des ciments (déformation, résistance) sont examinées avec un mortier normalisé avec le rapport ciment : sable = 1:3 et rapport E/C = 0,5. La méthode employée est identique à celle qu'on utilise dans plusieurs pays comme méthode-standard pour éprouver les qualités des ciments. Cette méthode était préférée, car elle possède tous les avantages d'une méthode standardisée, usage de même équipement etc. En utilisant

des mortiers plus riches en ciment ou du ciment pur, comme est pratiqué largement pour établir les qualités des ciments expansifs connus, les résultats sont relevés et l'expansion et la résistance obtenues sont beaucoup plus hautes comparées aux résultats obtenus en utilisant le mortier normalisé ou le béton.

Pour prouver l'application d'adjuvant expansif pour différents types des ciments sont donnés des exemples d'un ciment du durcissement rapide CPR, de deux ciments portland normal CPN et CPN<sup>x</sup> et d'un ciment à laitier de haut-fourneau avec différentes quantités de l'adjuvant expansif AE, AE<sup>x</sup> et AE<sup>xx</sup>.

Les ciments à laitier de haut-fourneau CLHF sont à peine connus comme base des ciments expansif ou plus tôt d'essai d'obtenir seulement un ciment d'un retrait compensé. Pour cela la production d'un ciment expansif à la base de ces ciments à prix bas présente un intérêt technique et économique particulier.

Les ciments expansifs connus montrent habituellement une expansion seulement en durcissant sous l'eau ou par mouillage abondant - conditions qui sont difficiles à réaliser en pratique. Pour cela les qualités des ciments expansifs conçus à la base d'un adjuvant complexe étaient établies aussi dans des conditions à durcissement seulement à l'air, sans aucun mouillage.

Tableau I montre l'expansion libre du mortier normalisé en conditions du durcissement sous l'eau ou seulement à l'air.

Au tableau II sont donnés quelques exemples de l'expansion restreinte du mortier d'un CPN + AE au moyen d'une barre d'acier située longitudinalement dans la prisme. En changeant le diamètre de la barre, sont obtenus différents rapports en % entre la section de l'armature et la section de la prisme du mortier.

Les résultats expérimentaux montrent que tous les types des ciments étudiés peuvent

TABLEAU I			
Type du ciment	Expansion libre, %, après jours		
	1	3	28
Durcissement sous l'eau			
CPR	-	-	-
CPR+AE <sup>x</sup>	0,29	0,38	0,38
CPR+AE <sup>xx</sup>	0,41	1,11 <sup>±</sup>	1,11
CPN	-	-	-
CPN+AE <sup>x</sup>	0,29	0,31	0,31
CPN+AE <sup>xx</sup>	0,89	0,91	0,92
CPN <sup>x</sup>	-	-	-
CPN <sup>x</sup> +AE <sup>x</sup>	1,59	1,98	1,98
CPN <sup>x</sup> +AE <sup>xx</sup>	4,11	4,14	4,14
CLHF	-	-	-
CLHF+AE	0,47	0,49	0,49
CLHF+AE <sup>x</sup>	1,69	1,72	1,72
Durcissement à l'air			
CPR		retrait	
CPR+AE <sup>x</sup>	0,07	0,09	0,08
CPR+AE <sup>xx</sup>	0,09	0,18 <sup>±</sup>	0,18
CPN		retrait	
CPN+AE <sup>x</sup>	0,05	0,03	0,01
CPN+AE <sup>xx</sup>	0,13	0,12	0,09
CPN <sup>x</sup>		retrait	
CPN <sup>x</sup> +AE <sup>x</sup>	0,32	0,30	0,27
CPN <sup>x</sup> +AE <sup>xx</sup>	0,50	0,46	0,44
CLHF		retrait	
CLHF+AE	0,13	0,13	0,13
CLHF+AE <sup>x</sup>	0,27	0,27	0,25

Remarque<sup>±</sup>: Pour ces prismes les mesures de l'expansion sont faites à l'âge de 7<sup>ème</sup> jour, au lieu de 3<sup>ème</sup>.

être modifiés en ciments expansifs avec une expansion très justement réglable par la quantité de l'adjuvant expansif. Selon les besoins de la construction on peut obtenir dans les conditions du durcissement normalisé une expansion libre de 0,1 à 4 % et de plus. C'est-à-dire on peut obtenir selon la valeur de l'expansion tous les types des ciments expansifs: ciment avec un retrait compensé, un ciment d'expansion moyenne et un ciment autocontraint avec une grande expan -

sion. L'expansion se manifeste pendant la période initiale du durcissement et se termine définitivement jusqu'au troisième jour. A l'âge de 28 jours et plus tard le volume est tout-à-fait stable.

En durcissement à l'air les ciments sans l'adjuvant expansif montrent seulement un retrait. En employant l'adjuvant complexe tous les types des ciments changent à fond leur comportement et manifestent une expansion bien exprimée. Cela facilite et enlève beaucoup l'usage des ciments expansifs conçus à la base des ciments normaux et d'adjuvant.

TABLEAU II			
Armature d'acier % de la section de la prisme	Expansion restreinte d'acier de l'armature et du mortier, % après jours		
	1	3	28
0,20	0,22	0,23	0,23
0,44	0,10	0,12	0,12
1,23	0,04	0,04	0,04

L'expansion restreinte est aussi bien exprimée même avec un pourcentage de l'armature assez haut. Cela témoigne les possibilités d'assurer l'obtention d'un ciment autocontraint de haute qualité, qui est objet d'une autre étude spéciale.

Les résistances mécaniques des ciments CPR, CPN, CPN<sup>x</sup>, CIHF avec ou sans l'adjuvant expansif sont présentées au tableau III. Celles d'un ciment portland normal CPN<sup>xx</sup>+AE examinées pour une expansion restreinte sont données au tableau IV.

Les résultats expérimentaux montrent qu'il existe une correspondance bien définie entre l'expansion et la résistance mécanique. En réglant le degré de l'expansion on peut prévoir et obtenir une résistance mécanique désirée. Pour le durcissement sous l'eau la résistance initiale pour une expansion de 0,3-0,5 % est à peu près celle du ciment

TABLEAU III		
Type du ciment	Résistance en compression, N/mm <sup>2</sup> , après jours	
	1	28
Durcissement sous l'eau		
CPR	19,7	57,2
CPR+AE <sup>x</sup>	18,0	57,2
CPR+AE <sup>xx</sup>	14,8	41,9
CPN	11,6	49,0
CPN+AE <sup>x</sup>	19,4	46,9
CPN+AE <sup>xx</sup>	9,2	28,4
CPN <sup>x</sup>	5,4	40,3
CPN <sup>x</sup> +AE <sup>x</sup>	3,0	20,9
CPN <sup>x</sup> +AE <sup>xx</sup>	1,0	8,6

CIHF+AE	8,5	33,5
CIHF+AE <sup>x</sup>	6,6	24,7
Durcissement à l'air		
CPR	18,0	45,7
CPR+AE <sup>x</sup>	20,0	52,1
CPR+AE <sup>xx</sup>	19,0	50,8
CPN	-	41,7
CPN+AE <sup>x</sup>	-	46,4
CPN+AE <sup>xx</sup>	-	49,1
CPN <sup>x</sup>	-	29,8
CPN <sup>x</sup> +AE <sup>x</sup>	9,2	33,2
CPN <sup>x</sup> +AE <sup>xx</sup>	12,2	31,3
CIHF	3,5	21,4
CIHF+AE	9,8	42,0
CIHF+AE <sup>x</sup>	5,2	44,2

sans adjuvant expansif (CPR), ou avec 1,2 fois plus haute (CIHF), ou bien 1,7 fois plus haute (CPN). Pour une expansion libre beaucoup plus grande de l'ordre 0,9-1,1 % la résistance est déjà un peu plus basse (CPR et CPN) en comparaison avec les mêmes ciments non modifiés. En augmentant encore l'expansion libre vers 1,7-2 % la résistance est presque égale (CIHF) à celle du même ciment sans adjuvant ou de 40 % plus basse (CPN<sup>x</sup>). En accroissant l'expansion à une très haute valeur de plus de 4 % (CPN<sup>x</sup>), quoique les prismes reçoivent des fissures,

elles gardent leur intégrité et manifestent certaine résistance mécanique - 20 % par rapport au ciment sans adjuvant. Pour la plupart des ciments avec AE la résistance à l'âge de 28 jours garde en général son rapport envers cette des ciments respectifs, mais sans l'adjuvant. Cela témoigne une bonne accroissement de la résistance mécanique avec l'avancement du temps, similaire à ce des ciments normaux employés comme base.

Pour le durcissement à l'air, c'est à dire dans les conditions réelles, tous les ciments modifiés en ciments expansifs pour les différentes valeurs de l'expansion (tableau III) possèdent une résistance supérieure à celle des mêmes ciments, mais sans AE. L'accroissement des résistances est particulièrement bien exprimé pour les ciments CIHF.

Les hautes valeurs de la résistance mécanique comparées aux grandes expansions obtenues s'expliquent par le fait que l'expansion se manifeste à la période initiale du durcissement. A ce temps là le ciment durcissant support beaucoup plus mieux les déformations sans empêcher la formation de la structure et le développement de la résistance mécanique.

TABLEAU IV		
Armature d'acier, % de la section de la prisme	Résistance en compression du mortier, N/mm <sup>2</sup> , après jours	
	1	28
0,20	11,5	37,5
0,44	12,9	40,6
1,23	13,6	38,4

L'étude à conditions restreintes montre qu'en augmentant le pourcentage de l'armature envers la section du mortier la résistance mécanique s'accroît (tableau IV). Cet accroissement de la résistance peut être encore plus grand si la restriction de l'expansion est spaciale et non pas seulement

dans une direction.

Les qualités des ciments expansifs conçus à la base des ciments normaux et d'un adjuvant expansif étaient étudiées aussi sur éprouvettes du béton<sup>¶</sup>.

TABLEAU V			
Type du ciment	Expansion libre du béton, %, après jours		
	1	3	28
Durcissement à l'air			
CPN <sup>xxx</sup>	-0,02	-0,06	-0,09 <sup>¶</sup>
CPN <sup>xxx</sup> +AE	0,06	0,10	0,10
CPN <sup>xxx</sup> +AE <sup>x</sup>	0,08	0,12	0,13
CIHF <sup>x</sup>	-0,03	-0,07	-0,11 <sup>¶</sup>
CIHF <sup>x</sup> +AE	0,02	0,05	0,04

Remarque<sup>¶</sup>: Le retrait est marqué par "-".

TABLEAU VI		
Type du ciment	Résistance en compression du béton, N/mm <sup>2</sup> , après jours	
	1	28
Durcissement à l'air		
CPN <sup>xxx</sup>	1,3	24,1
CPN <sup>xxx</sup> +AE	6,1	33,1
CPN <sup>xxx</sup> +AE <sup>x</sup>	6,1	28,6
CIHF <sup>x</sup>	0,7	18,0
CIHF <sup>x</sup> +AE	5,3	20,4

Quelques exemples du béton d'un ciment portland normal CPN<sup>xxx</sup> et un ciment à laitier de haut - fourneau CIHF<sup>x</sup> avec différentes quantités ou sans adjuvant expansif (AE, AE<sup>x</sup>) sont donnés pour l'expansion libre au tableau V et pour la résistance mécanique au tableau VI. Le béton est avec 420 kg ciment pour un m<sup>3</sup> et d'un diamètre des agrégats jusqu'à 20 mm. Le durcissement du béton est à l'air sans d'être mouillé.

Remarque<sup>¶</sup>: Dans les études du ciment expansif à la base du CIHF et des bétons expansifs a pris part aussi Dr. Ing. V. Petkova.

Les résultats expérimentaux montrent que sous l'influence de l'adjuvant expansif le béton, de même que le mortier, change profondément ses propriétés. Au lieu du retrait de 0,09 - 0,11 % jusqu'à 28-ème jour il manifeste une expansion bien exprimée de 0,04 - 0,13 % pour le même âge.

A cause de sa structure beaucoup plus dense et l'augmentation de la phase cristalline (ettringite) le béton à la base d'un ciment avec l'adjuvant expansif possède une résistance contre la pénétration de l'eau beaucoup plus haute et un fluage réduit, par rapport du même béton mais d'un ciment sans l'adjuvant expansif.

Des études durables sur les qualités mécaniques montrent que le fluage du béton à l'âge de presque une et demie année est 0,238 %, tandis que pour la même période celui avec le ciment portland normal modifié par différents quantités de l'adjuvant expansif est seulement 0,183 - 0,216 %. Respectivement les déformations entières des bétons sont pour le normal 0,358 % et pour l'expansif 0,061 - 0,150 %. Ces chiffres prouvent une réduction du fluage sous l'influence de l'adjuvant expansif de 1,1 à 1,3 fois et de la déformation entière de presque 2,4 à 5,9 fois.

Les résultats expérimentaux pour béton d'un ciment à laitier de haut - fourneau montrent la même tendance de réduction du fluage et de la déformation entière par suite de la modification du ciment CIHF à un ciment expansif.

La résistance du béton expansif contre la pénétration de l'eau est 3,5 à 5 fois améliorée en comparaison avec celle du béton des mêmes ciments, mais sans l'adjuvant expansif.

Les résistances mécaniques des bétons (tableau VI) sont augmentées d'une manière expressive par la modification des ciments au moyen de l'adjuvant complexe. L'élévation atteint une très haute valeur de 4,7 à 7,6 fois pour le premier jour et de 1,14 à 1,38

fois pour le 28-ème jour.

La méthode d'obtention des ciments expansifs à la base des différents ciments normaux et d'un adjuvant expansif complexe est brevetée en plusieurs pays et aux Etats Unis, l'Espagne, R. D. Allemagne etc. les brevets sont déjà publiés.

#### CONCLUSIONS

Une méthode très efficace et facilement réalisable d'obtention des ciments expansifs était créée. Au moyen d'un adjuvant complexe différents types des ciments ordinaires comme ciment portland normal, ciment du durcissement rapide, ciment à laitier de haut - fourneau etc. sont modifiés à des ciments spéciaux d'une expansion très justement réglable, qui se manifeste et se termine dans les premiers 1 à 3 jours du durcissement. Conformément la valeur de l'expansion on peut obtenir tous les types des ciments expansifs: ciment d'un retrait compensé, ciment d'expansion moyenne et ciment autocontraint.

Les nouveaux ciments expansifs montrent une expansion bien exprimée en durcissant sous l'eau ou seulement à l'air sans aucun mouillage.

En réglant le degré de l'expansion on peut prévoir et obtenir une résistance mécanique désirée. Parce que l'expansion se manifeste seulement à la période initiale du durcissement, quand le ciment durci supporte mieux les déformations, les ciments expansifs à la base de l'adjuvant complexe possèdent des hautes résistances mécaniques.

Les ciments expansifs conçus à la base des ciments normaux et d'adjuvant manifestent une résistance contre la pénétration de l'eau bien augmentée et un fluage et déformation entière diminués.

Les qualités des nouveaux ciments expansifs sont prouvées comme par mortier standard, ainsi que par béton.

# The structure and characteristics of bleached clinker

## *Structure et propriétés des clinkers de ciment blanc*

**RESUME :** Dans cette communication, nous exposons les résultats de recherches sur l'influence des amino-alcools (TEA, MEA) et de liquides silico-organiques sur le processus de blanchiment des clinkers de ciment portland blanc et sur leurs propriétés. On a établi qu'un refroidissement brusque dans une solution aqueuse à 1 à 2 % de mono et de triéthanolamine augmente le coefficient de réflexion diffuse (C.R.D.) du clinker blanc de 5 à 9 %. Le refroidissement brusque dans une solution à 0,5 % des liquides silico-organiques GKG-10 et GKG-11 augmente ce C.R.D. de 8 à 10 % par rapport au blanchiment aqueux. Pour mettre en évidence les conditions optimales de blanchiment du clinker, nous avons déterminé le C.R.D. de quelques constituants du clinker avec leurs éléments colorants, ces clinkers ayant été cuits en milieu légèrement acide et refroidis dans de l'eau additionnée des produits étudiés. L'analyse des données a montré que le refroidissement brusque du clinker, dans des solutions aqueuses, augmente sa blancheur de 2 à 6 %, si l'ajout est de l'oxyde ferrique, et de 5 à 9 %, s'il est de l'oxyde manganéux. A l'aide d'une méthode de résonance paramagnétique électronique, on a constaté un passage partiel des atomes de fer à la position IV-e et de ceux d'oxygène en VI-e. Cela favorise l'affaiblissement de la coloration du clinker et l'apparition d'une ligne d'absorption paramagnétique avec  $q = 2,040$ . Les résultats obtenus permettent de constater l'influence importante des additifs étudiés, en solution aqueuse, sur le blanchiment des clinkers contenant du  $Fe_2O_3$ , surtout lorsqu'ils sont cuits en atmosphère oxydante. L'influence des conditions de refroidissement des clinkers dans des solutions aqueuses, avec addition de manganèse, se manifeste par une corrélation des atomes de manganèse avec des valences différentes. On a montré que l'adsorption des agents blanchissants à la surface des grains du clinker, lors du blanchiment dans des solutions aqueuses d' amino-alcools ou de liquides silico-organiques, entraîne une amélioration de la broyabilité et de la granulométrie du clinker, et permet de se passer d'agents de mouture.

**SUMMARY :** Data are reported on the aminoalcohols (TEA, MEA) and silicone liquids influence upon the bleaching process, structure and characteristics of the white Portland cement clinker. The sharp cooling in the 1-2% aqueous solutions of monoethanolamine and triethanolamine is established to increase the diffusion reflection coefficient (DRC) of the white clinker by 5-9%. Sharp cooling in the aqueous solutions of the silicone liquids (0,5%) GKG-10 and GKG-11 increases DRC of the white clinker by 8-10%, in comparison with aqueous bleaching. In order to show the optimal conditions of clinker's bleaching we determined DRC of some clinker minerals with dyeing elements, which had been burned in slightly acid conditions and cooled in water and aqueous solutions of chemical additions under study. Data analysis showed that sharp cooling of clinker minerals in aqueous solutions of chemical additives increased the mineral whiteness. If we added ferrous oxide the mineral whiteness increased by 2-6%, if we added the manganese heptoxide the mineral whiteness increased by 5-9%. By the electron paramagnetic resonance method the particle transition of ferrous atoms from tetra coordination to sextant coordination was established it results in relaxation of mineral dyeing and in appearance of paramagnetic absorption lines from  $q=2,040$ . Our data allow to establish the considerable influence of the aqueous solutions of the additives under study on the mineral bleaching stages with  $Fe_2O_3$  additives,  $Fe_2O_3$  is especially effective for burning in oxidizing conditions. The influence of cooling conditions of minerals with manganese additives can be seen in different correlation of manganese atoms in different valence state. The bleaching agents adsorption at the surface of clinker granules in the process of bleaching in the aqueous solutions of amino alcohols and silicone liquids is shown to intensify the process of clinker grinding to improve the size distribution, it also allows to refuse from using clinker grinding aids.

It is known, that white cement and cement paint manufacture demands the raw materials of a special quality. However, the discovered supplies of limestones and kaolines cannot meet the requirements of still rising demands in cement paint. But the well-known methods of raw materials concentration to remove the dyeing oxides are very expensive and labour-consuming operations. That is why the choice of the technological parameters of clinker burning and cooling processes is more effective, these processes provide the increasing of clinker whiteness.

There are some published data (1), where authors speak about the usage of chemical industry wastes - phosphorus slag, cishtoff white slime as raw components in white Portland cement manufacture. The influence of silicate minerals, calcium aluminate, the degree of saturation and silica modulus on the white clinker DRC value is determined. The abnormal aluminous and silicious modulus, the degree of saturation of silicon by calcium oxide make the directional change difficult in phase composition and white clinker structure while burning. This makes the introduction of mineralizers into the raw meal necessary.

While choosing mineralizers, the electro-negativity of anions and cations, being the components of mineralizers, is of great importance. The most effective mineralizer is silicofluoric sodium, its cation has the lowest electronegativity, and anion - the highest, providing He-ion transition from tetrahedral coordination in to the octahedral coordination and formation of fine crystalline structure of the phase composition.(2)

We consider the increasing of clinker's whiteness by sharp cooling in water and in aqueous solutions of different salts and acids to be of great practical and theoretical interest. A.Grachyan and his colleagues made detailed investigation of physico-chemical principles of clinker's bleaching in water. (1) According to him, aqueous vapour dissolves in the clinker fusion, and hydrosilicate ions Fe-bonds and O<sub>2</sub> bonds being cleaved by them, provide the formation of Fe-ions octahedral coordination, which has lower dyeing power.

As a result of optimal conditions research of clinker's bleaching, we decided to use different water soluble chemical additives, which are more active, than water, concerning their physico-chemical aspects.

We used such bleaching agents as aqueous solutions of amino alcohols - monoethanolamine (MEA) and triethanolamine (TEA), and also such silicone liquids as sodium ethylsiliconate GKG-IO and sodium methylsiliconate GKG-II. Burning hot clinker was sharply cooled in aqueous solutions

of additives with different concentration: DRC was determined with the help of universal photometer (FM-56). The results of the MEA, TEA, GKG-IO, GKG-II solutions influence on clinker bleaching process are shown in table I.

TABLE I				
Solution concentration	Cooled clinker DRC, % (as to MC-I4)			
	in TEA	in MEA	in GKG-IO	GKG-II
0	-	-	-	-
0,5	87	91	93	95
1,0	88	90	91	93
1,5	90	88	90	93
2,0	94	87	88	91
3,0	94	86	87	90
4,0	90	86	87	88

Data analysis shows that if optimal concentration of the aqueous solutions for the amino alcohols are TEA - 2,5% and MEA-0,5% respectively, and for silicone liquids - 0,5%, then clinker DRC increases by 7-10% in comparison with DRC of the water cooled clinker. (3,4). DRC of the water cooled clinker equals to 85%. The increase in reflection capacity of clinker can be explained by the partial reduction of clinker with Fe<sup>+3</sup> ion solutions along with the formation of ion-grouping Fe<sup>+3</sup>-O-Fe<sup>+2</sup>, which is more weaker chromophore, than ion Fe<sup>+2</sup>.

The investigations of clinker with the help of scanning electron microscope showed, that mineral phases crystals in the clinkers, cooled in the surfactant solutions, were more resorbed, their surface was more effective, in comparison with the surface of water cooling clinker. Fixation of great number of fine crystals in clinker increases the dispersion of light, it provides increasing of clinker's whiteness. Small content of C<sub>4</sub>AF in the white clinker made it impossible to fix its structural changes while bleaching with the help of X-ray and infrared spectroscopic analyses, that's why we used the radiospectroscopic method of analysis.

Electron paramagnetic resonance spectra of the white clinker, cooled in water, contain paramagnetic absorption lines in the weak fields region and in the region of free electron factor. The character of absorption is conditioned by Fe<sup>+2</sup> ions in the four-fold coordination (O<sub>2</sub>) and by Mn<sup>+2</sup> ions in the six-fold coordination.

White clinker, cooled in the TEA solution has the same absorption character, however the intensity of absorption lines in the

region of weak fields considerably decreases at the expense of  $\text{Fe}^{3+}$  in the four-fold coordination, but Mn lines intensity increases.

It is known (5), that ferruginous compounds fusion dominate in the superficial zones of clinker particles.  $\text{Fe}^{3+}$  accumulation in the spaces between microcrystals is a favourable factor while clinker bleaching in the aqueous solutions of MEA, TEA, GKG-I, GKG-II, which are activated in the process of decomposition by the catalytic action of superheated steam. In the gas-vapour-air atmosphere of the clinker granules molecules and radicals of  $\text{H}_2$ ,  $\text{CO}$ ,  $\text{CO}_2$  and other appear, they have the reduction capacity. They diffuse into the clinker granules in the microcracks and micropores, interacting with the surface of cement particles, and partially reducing  $\text{Fe}^{3+}$  ions to the  $\text{Fe}^{2+}$  ions.

Considerable increase of the white clinker DRC with the help of aqueous solutions of MEA, TEA, GKG-I, GKG-II will agree with the data of the chemical analysis of  $\text{Fe}_2\text{O}_3$  content in the clinkers. (See table II)

Bleaching medium	Solution concentration, %	$\text{Fe}_2\text{O}_3$ content, %	Clinker DRC, % (to MS-I4)
Water	-	0,67	85
Triethanolamine	2,0	0,42	94
Monorthanolamine	0,5	0,50	91
GKG-I	0,5	0,45	93
GKG-II	0,5	0,40	95

Chemical analysis data about  $\text{Fe}_2\text{O}_3$  content in the clinkers prove our suggestion, that while clinker bleaching in the aqueous solutions of MEA, TEA, GKG-I, GKG-II there is some lowering in concentration of dyeing oxide:  $\text{Fe}_2\text{O}_3$  along with the improvement in its whiteness.

We determined the DRC of some clinker minerals with dyeing elements additives, burned in slightly acid conditions and cooled in water and aqueous solutions of TEA, GKG-II. The results show (table III), that the presence of surfactants in the aqueous solutions considerably influence the DRC of minerals dyeing oxides additives, it is connected with the changing of Fe and Mg atoms state in the minerals structure. In comparison with aqueous bleaching  $\text{C}_3\text{S}$  whiteness with  $\text{Fe}_2\text{O}_3$  additive increases by 2-9%, and

with  $\text{MnO}_2$  additive it increases by 5-10% depending on additive. Dicalcium silicate and tricalcium aluminate whiteness also changes depending on bleaching conditions, it exceeds DRC of aqueous bleaching minerals by 2-5% in proportion to amount of introduced dyeing oxides.

Aqueous solutions of TEA, GKG-II most prominently influence the aluminiferous and ferrous phases of cement clinker (table 3). Spectrophotometric analysis showed peaks displacement in the  $\text{C}_4\text{AF}$  reflection curves which was cooled in the additive solutions into the shortlength part of the visual spectrum, it testifies to the changing of aluminoferrite solid solutions structures.

Minerals.	DRC, % (MS-I4), cooled:		
	in water	in TEA solution	in GKG-II solution
$\text{C}_3\text{S}$	94	94	96
$\text{C}_3\text{S} + 0,3\% \text{Fe}_2\text{O}_3$	83	89	92
$\text{C}_3\text{S} + 0,2\% \text{MnO}$	80	87	90
$\beta - \text{C}_2\text{S}$	96	96	98
$\beta - \text{C}_2 + 0,3\% \text{Fe}_2\text{O}_3$	86	89	90
$\beta - \text{C}_2 + 0,2\% \text{MnO}$	82	88	88
$\text{C}_3\text{A}$	96	96	98
$\text{C}_3\text{A} + 0,3\% \text{Fe}_2\text{O}_3$	84	88	92
$\text{C}_3\text{A} + 0,2\% \text{MnO}$	79	82	85
$\text{C}_4\text{AF}$	16	28	32
$\text{C}_2\text{F}$	9	18	22

Considerable effect of  $\text{C}_4\text{AF}$  and  $\text{C}_2\text{F}$  bleaching in the presence of amino alcohols and silicone liquids in the cooling water is explained by the different total surface of contact of the dyeing elements with the reducible gas-vapour phase radicals.

X-ray analysis did not discover any qualitative differences in the mineral bleaching products. Quantitative analysis, determined according to the diffraction reflection changing ( $d=1,76\text{\AA}$ ), helped us to state that degree of hydration of tricalcium silicate, tricalcium aluminate of water cooling is 10-12%, and if we take the degree of hydration of tricalcium silicate,

tricalcium aluminate, cooled in aminoalcohol solutions, it will be lower aminoalcohol presence (MEA, TEA) in the bleaching water causes some redistribution of  $C_2S$  diffraction reflection. In this case line intensity increases from  $d=2,78\text{\AA}$  to  $d=2,79\text{\AA}$ . This fact agrees with the formation of some quantity of  $C_2S$  form in the mineral, it occurs at the expense of partial reduction of  $Fe^{+3}$  to  $Fe^{+2}$ , which promotes polymorphic transition to form. If we compare the infra-red spectra of minerals cooled in water and in amino alcohol and silicone liquid solution, we shall see that there is no structural changes in their crystal lattices.

**CLINKER GRINDABILITY.** Nowadays clinker grinding is the most energy-consuming operation in Portland cement manufacture. For clinker grinding process intensification different surfactants are used, they absorb at the cement particle surface with its polar side, forming protective monomolecular layer, they also decrease intermolecular cohesive forces action, and prevent finely ground material from cohesion.

Partial absorption of amino alcohol and silicone liquid aqueous solutions takes place at the surface of clinker granules during clinker bleaching process of white Portland cement in these solutions, and this intensifies the clinker grinding process. To determine MEA, TEA, GKG-10, GKG-11 aqueous solutions effect as grinding intensifiers, clinker being cooled in water and in additive aqueous solutions was fined in the mill, and in certain periods of time clinker residue was controlled on the sieve NO08. The results showed that required specific surface for white Portland cement  $3000-3400\text{cm}^2/\text{g}$  was established in 50 minutes in the case of water cooling cements, and in 35-40 minutes in the case of cements after cooling in the additive solutions. Therefore, if we use aqueous solutions of MEA, TEA, GKG-10, GKG-11 additives as bleaching agents, there is no sense in using different surfactants at clinker grinding because these additives intensify the grinding process by 20-25% in comparison with water cooling.

Some scientists established (6), that rational controlling of cement dispersion degree by improving its granule composition allows to increase its activity and to improve its properties.

Thus, it became obvious that cement obtained from clinkers, bleached in the additive solutions (50 - 57%) has the optimal granulometric composition (0-20 mcm), and fraction quantity 70 - 80 mcm, which hydrates slowly, has 5 - 10%.

## CONCLUSIONS

The scientific researches showed that amino alcohols (MEA, TEA) and silicone liquids (GKG-10, GKG-11) usage as bleaching agents helps to increase the diffusion reflection coefficient of the white clinker by 5-10% in comparison with aqueous bleaching. The effect is reached at the expense of reducing medium formation in the clinker granule pores at the additive decomposition into molecules and radicals of  $H_2$ ,  $CO$ ,  $CO_2$  type.

The rise of clinker mineral whiteness is connected with changing of dyeing element valente state. The less prominent factor is the change of coordination, particularly He-atoms coordination in the bleaching process. Besides, sharp cooling in aqueous solutions of MEA, TEA, GKG-10, GKG-11 allows to obtain mineral crystals of less size. It promotes the whiteness increasing at the expense of increasing the total surface of interaction of reducible molecules and radicals of gas-vapour phase with clinker microcrystals.

Amino alcohol and silicone liquids aqueous solutions intensify the clinker grinding process at the expense of its adsorption on granule surfaces while bleaching process. That is why we can refuse from using different grinding aids and still grinder's efficiency will be increased.

# Recherches sur les phases de ferrites de baryum dans la zone fortement basique du système $\text{BaO-Fe}_2\text{O}_3$

## *Research studies of the barium ferrites in the upper base part of the system $\text{BaO-Fe}_2\text{O}_3$*

V. VALKOV, Agrégé, Chargé de cours, Candidat ès Sciences Techniques, Institut Supérieur Chimique et Technologique, Sofia, Bulgarie,

A. DENEVA, Maître de Recherches, Candidate ès Sciences Techniques, Institut de Recherches Scientifiques des Matériaux de Construction, Sofia, Bulgarie et,

D. STAVRAKEVA, Agrégée, Chargée de Cours, Candidate ès Sciences Géologiques et Minéralogiques, Institut Supérieur Chimique et Technologique, Sofia, Bulgarie.

**RESUME :** Des recherches ont été entreprises, au moyen du microscope optique et des rayons X, sur le traitement à haute température et addition de baryte au clinker, de façon à provoquer la formation de diverses ferrites de baryum :  $\text{BF}$ ,  $\text{B}_3\text{F}_2$ ,  $\text{B}_2\text{F}$ ,  $\text{B}_5\text{F}_2$ ,  $\text{B}_7\text{F}_2$  et  $\text{B}_7\text{F}$ . On a observé la formation de  $\text{BF}$ ,  $\text{B}_2\text{F}$  et  $\text{B}_7\text{F}_2$ , mais il a été prouvé que  $\text{B}_3\text{F}$  ne se formait pas, car dans la cuisson en phase solide le  $\text{B}_3\text{F}$  se décompose en un mélange de  $\text{B}_2\text{F}$  et de  $\text{B}_7\text{F}_2$ , et dans la cuisson par fusion il se forme une solution solide de  $\text{B}_7\text{F}_2$  dans  $\text{B}_2\text{F}$ . Le composé  $\text{B}_7\text{F}_2$  a pu être analysé aux rayons X.

Les spectres Mössbauer des ferrites  $\text{BF}$ ,  $\text{B}_2\text{F}$  et des constituants  $\text{B}_3\text{F}$  et  $\text{B}_7\text{F}_2$  ont été obtenus; et il a été constaté la présence, dans ces ferrites, de fer trivalent. On a pu déterminer le nombre et la position des atomes  $\text{Fe}^{+3}$ , et la probabilité de formation de solutions solides de  $\text{B}_2\text{F}$  dans  $\text{B}_7\text{F}_2$ , au lieu du constituant  $\text{B}_3\text{F}$ . Ces résultats ont été utilisés pour l'identification des phases ferritiques dans les clinkers barytéux; ils présentent aussi un grand intérêt pour l'étude de la zone fortement basique du système  $\text{BaO-Fe}_2\text{O}_3$ .

**SUMMARY :** Optical-microscopic and X-ray phases researches of constituents, treated at high temperatures, have been carried out for the obtaining of barium ferrites :  $\text{BF}$ ,  $\text{B}_3\text{F}_2$ ,  $\text{B}_2\text{F}$ ,  $\text{B}_5\text{F}_2$ ,  $\text{B}_7\text{F}_2$  and  $\text{B}_7\text{F}$ . The formation of  $\text{BF}$ ,  $\text{B}_2\text{F}$  and  $\text{B}_7\text{F}_2$  has been confirmed. It has been proved that  $\text{B}_3\text{F}$  does not form itself as an individual compound. At solid phase caking of the constituent for  $\text{B}_3\text{F}$  a mixture is formed from  $\text{B}_2\text{F}$  and  $\text{B}_7\text{F}_2$ , while at its melt crystallization - a solid solution of  $\text{B}_7\text{F}_2$  in  $\text{B}_2\text{F}$ . X-rays data, for  $\text{B}_7\text{F}_2$  were obtained.

The Mössbauer ferrites spectra  $\text{BF}$ ,  $\text{B}_2\text{F}$  have been received and the presence of trivalent iron in them, the position numbers of  $\text{Fe}^{+3}$  and the probability of solid solutions formation of  $\text{B}_2\text{F}$  in  $\text{B}_7\text{F}_2$ , at the constituent for  $\text{B}_3\text{F}$ , have been established.

The results here used for the identification of the ferrites phase of the barium clinkers are of interest in the case of the research studies of the upper basic part of the system  $\text{BaO-Fe}_2\text{O}_3$ .

Le système  $\text{BaO}-\text{Fe}_2\text{O}_3$  a été étudié par Goto et Takada, Batti, Kurdowski, Valkov et Boyadjieva (1), (2), (3), (4).

La plus grande part des études est limitée à des constituants d'alcalinité  $\leq 2$ . Les données connues de Kurdowski (3) et Batti (2) pour les constituants plus haute-basiques sont contradictoires. D'après Kurdowski, sauf les ferrites de baryum connus  $\text{BF}$ ,  $\text{B}_2\text{F}$  et  $\text{BF}_6$ , ils existent encore  $\text{B}_3\text{F}$ ,  $\text{B}_4\text{F}_2$  et  $\text{B}_5\text{F}_3$ , et d'après Batti - une phase de constituant  $\text{B}_7\text{F}_2$  (On emploie des abréviations acceptées : B - BaO, F -  $\text{Fe}_2\text{O}_3$ ).

L'objet de notre étude est d'élucider les phases dans le domaine avec plus haut contenu de BaO, après le composé  $\text{B}_2\text{F}$ , et aussi de caractériser plus pleinement les ferrites de baryum, lesquels, il est possible qu'ils soient dans la composition des clinkers de silicate de baryum.

Des études optico-microscopiques et radiologiques de phases, ont été exécutées, les compositions  $\text{BF}$ ,  $\text{B}_3\text{F}_2$ ,  $\text{B}_2\text{F}$ ,  $\text{B}_4\text{F}_2$ ,  $\text{B}_3\text{F}$  et  $\text{B}_7\text{F}_2$  et les compositions  $\text{BF}$ ,  $\text{B}_3\text{F}$ ,  $\text{B}_2\text{F}$  et  $\text{B}_7\text{F}_2$  ont été étudiées aussi à l'aide de la spectroscopie de Mössbauer.

Les réactifs de départ  $\text{BaCO}_3$  et  $\text{Fe}_2\text{O}_3$  (p.a.) après être précisément dosés et homogénéisés avec de l'eau, puis séchés, sont tamisés, jusqu'à ce que la dernière fronde ait passée au tamis 0,08. Les mixtures obtenues sont briquetées et cuites à une température de  $1320^\circ\text{C}$  dans un four à appareils de chauffe en silite, après être restées pendant 10 heures dans le four à la température maximale et deux moutures intermédiaires pour faciliter les interactions des phases solides. Les spécimens ont été soumis à un refroidissement lent (24 heures). En outre, les constituants  $\text{B}_3\text{F}$  et  $\text{B}_7\text{F}_2$  ont été fondus à la température de  $1400^\circ\text{C}$  et brusquement refroidis. Les ferrites obtenus ont été étudiés parallèlement avec ceux provenant de la synthèse de la phase solide.

Les études microscopiques et radiologiques des phases montrent les résultats suivants:

Constituant  $\text{BaO}, \text{Fe}_2\text{O}_3$ . Une phase ferrique est établie microscopiquement, laquelle, d'après des données radiographiques - 3,15/10; 2,73/5/ et 2,68/3/, correspond à BF (4). Le ferrite de monobaryum, en lumière reflétée, se révèle sous l'aspect de formes irrégulières, isométriques, presque carrées et rhombiques ou rectangulaires allongées ou angulaires. La couleur est pris-pâle, faiblement rose, avec une grande capacité de réflexion; anisotropique et présentant un pléochroïsme marqué de réflexion. En lumière traversante il est caractérisé par des couleurs interférentielles gris-blanches ( $n_p = 2,14$  et  $n_g = 2,23$ ).

Constituant  $3\text{BaO}.2\text{Fe}_2\text{O}_3$ . Le produit n'est monophasé. Microscopiquement, en cas de grands agrandissements (900x avec objectifs d'immersion) les deux phases se déli-

mitent clairement. L'une est d'une plus grande capacité de réflexion, anisotropique et plus claire que l'autre, laquelle est de couleur rose-grise et isotropique. A l'aide des données radiographiques est établie aussi la formation de deux phases ferriques -  $\text{BaO}. \text{Fe}_2\text{O}_3$  et  $2\text{BaO}. \text{Fe}_2\text{O}_3$ .

Constituant  $2\text{BaO}. \text{Fe}_2\text{O}_3$ . A la synthèse exécutée il se forme un ferrite correspondant à la phase  $2\text{BaO}. \text{Fe}_2\text{O}_3$ . Dans lumière reflétée, la phase susmentionnée est claire-grise, isotropique, représentée par des sections isométriques, presque carrées. En immersion elle est avec des sections carrées très régulières. Le diffractogramme de  $\text{B}_2\text{F}$  montre correspondance avec (4). Quelques différences ont été enregistrées, principalement auprès les grands angles.

Constituant  $5\text{BaO}.2\text{Fe}_2\text{O}_3$ . Le modèle est biphasé. L'une des phases est rose-grise et s'inclut dans une autre de couleur jaune. La phase de couleur rose-grise a des sections presque carrées et correspond à  $\text{B}_2\text{F}$ . L'autre - de couleur crème-jaune subit un pléochroïsme de réflexion, elle est anisotropique et par cela elle diffère des décrites BF et  $\text{B}_2\text{F}$ . Selon ses constituants elle doit correspondre à  $\text{B}_3\text{F}$  d'après (3) ou à  $\text{B}_7\text{F}_2$  d'après (2). Dans le cadre radiologique de ce constituant, outre les distances intersuperficielles de  $\text{B}_2\text{F}$ , se présentent aussi encore deux autres réflexions correspondantes à 3,64-3,69 et 2,10 Å.

Constituant  $3\text{BaO}. \text{Fe}_2\text{O}_3$ . Dans les épreuves, traitées de manière thermique à une température de  $1300^\circ\text{C}$  on observe, microscopiquement, deux phases, analogiquement au constituant  $\text{B}_2\text{F}$ . De même, dans le radiogramme de cette épreuve, de pair avec le jeu entier des distances intersuperficielles de  $\text{B}_2\text{F}$ , apparaissent aussi des lignes supplémentaires: 3,66-3,69; 2,09-2,10 Å. Le même constituant, traité thermiquement à températures plus hautes -  $1400^\circ\text{C}$  jusqu'à obtention de fonte, se caractérise par sa monophasité. Le tableau microscopique du ferrite formé ainsi que son tableau radiographique diffractif correspondent à la phase  $\text{B}_2\text{F}$ . Cela montre que le diagramme de la phase dans le domaine du constituant  $\text{B}_2\text{F}$  répond au diagramme présenté par (2) et que le composé supposé  $\text{B}_7\text{F}_2$  (3) n'existe pas. Selon (2) la phase  $\text{B}_2\text{F}$  au-dessus de la température eutectique -  $1307^\circ\text{C}$ , représente la solution solide de  $\text{B}_7\text{F}_2$ . Donc, le schéma supposé de formation des ferrites pour ce constituant peut être exprimé de la manière suivante:  $\text{B}_3\text{F} \rightarrow \text{B}_2\text{F}$  (solution solide avec  $\text{B}_7\text{F}_2$ ), de la fonte et  $3\text{B}_3\text{F} \rightarrow \text{B}_2\text{F} + \text{B}_7\text{F}_2$ , au cas de synthèse de la phase solide.

Constituant  $7\text{BaO}.2\text{Fe}_2\text{O}_3$ . Les phases de cristal des modèles fondus à la température de  $1400^\circ\text{C}$  et brusquement refroidis représentent un produit monophasé. Microscopiquement, dans la lumière reflétée, la phase cristalline nouvellement formée est jaune de couleur, avec des sections

idiomorphologiques, rectangulaires ou arrondies, incluses dans des phases vitreuses. En immersion le ferrite synthétisé est vert de couleur, et parfois sa couleur approche le brun. D'après toutes les caractéristiques morphologiques et optiques, la phase  $B_7F_2$  est de système cristallographique rhomboïdal.

La figure 1 montre le diffractogramme ionique de  $B_7F_2$  obtenu de la fonte, lequel peut être accepté comme étalon, faute d'autres données dans la littérature pour ce composé.

Fig. 1 - Diffractogramme ionique de  $B_7F_2$

Les modèles traités à une température d'environ  $1320^\circ\text{C}$ , au cas de cuisson en phase solide, se caractérisent microscopiquement et radiologiquement comme biphasés. Dans des phases pareilles, celle qui prédomine, c'est  $B_7F_2$  et, en moindres quantités -  $B_2F$ . Les études des phases, par conséquent, du constituant  $B_7F_2$ , confirment pleinement l'aspect de la phase du système, donné par Batti (2), selon lequel, après le constituant eutectique, au-dessus de la courbe solide, la phase  $B_7F_2$  représente une solution solide de  $B_2F$  dans  $B_7F_2$ , de la même manière que représente  $B_7F_2$  dans  $B_2F$ , au-dessus de la même courbe de température.

A la Figure 2 est donnée la microstructure de  $B_7F_2$  obtenu de la fonte.

Les ferrites de baryum synthétisés suivant le procédé décrit  $BF$ ,  $B_2F$ , constituants de  $B_2F$  et  $B_7F_2$  (les derniers deux de fonte) sont étudiés aussi à l'aide de la spectroscopie de Mössbauer.

Le  $Co^{57}$  est utilisé en tant que source, en matrice de palladium.

Les spectres Mössbauer des ferrites de baryum sont donnés à la figure 3, et leurs paramètres - à la Table 1.

Le déplacement isométrique dans les limites au-dessous de  $0,4-0,5$  mm/s indique la présence de fer sous la forme de  $Fe^{2+}$ .

Le spectre de  $BaO.Fe_2O_3$  montre un champ ma-

Agrandissement 126x

Fig. 3 - Schéma des spectres de Mössbauer des ferrites de baryum: (1) -  $BF$ ; (2) -  $B_2F$ ; (3) - constituant  $B_7F$  ( $B_2F + B_7F_2$ -solution solide); (4) -  $B_7F_2$

Table 1

Phase	$\delta$	$\Delta$	H <sub>1</sub>
BaO.Fe <sub>2</sub> O <sub>3</sub>	0,19	0,32±0,03	470
2BaO.Fe <sub>2</sub> O <sub>3</sub>	0,16 0,00	0,32 0,64	- -
Constituant 3BaO.Fe <sub>2</sub> O <sub>3</sub> (Solution so- lide de B <sub>7</sub> F <sub>2</sub> dans B <sub>2</sub> F)	0,10±0,06 0,30±0,06	0,50±0,06 0,89±0,06	- -
7BaO.2Fe <sub>2</sub> O <sub>3</sub>	0,25±0,10 0,12±0,03	1,26±0,10 1,55±0,03	- -

Remarque:

 $\delta$  - déplacement isométrique concernant  $\Delta$ -Fe, mm/s $\Delta$  - séparation quadripolaire, mm/sH<sub>1</sub> - champ magnétique local, kOe

gnétique de structure arrangée, laquelle d'après H<sub>1</sub> = 470 kOe est proche à la structure du spinelle et du Fe<sup>3+</sup>, et est probablement dans une coordination sextuple.

L'ion ferrique dans BF se trouve en position une.

L'ion ferrique dans le spectre de B<sub>2</sub>F se trouve en deux positions.

Le spectre du constituant B<sub>3</sub>F est proche à B<sub>2</sub>F, mais il diffère par des changements dans les valeurs numériques des paramètres  $\Delta$  et  $\delta$  des deux positions de l'ion ferrique. C'est le résultat probablement de la formation de solutions solides de B<sub>2</sub>F avec B<sub>7</sub>F<sub>2</sub>.

Le spectre de B<sub>7</sub>F<sub>2</sub> diffère catégoriquement de celui de B<sub>2</sub>F. La seconde position de l'ion ferrique dans le ferrite, avec  $\Delta = 1,55 \pm 0,03$  montre sa présence dans la phase amorphe, à cause de quoi, dans la structure du cristal de B<sub>7</sub>F<sub>2</sub> l'ion ferrique est dans un état avec  $\Delta = 1,26 \pm 0,06$  et avec  $\delta = 0,25 \pm 0,06$  mm/s.

La grande quantité de phase amorphe ne donne pas la possibilité d'une détermination exacte du spectre de la phase cristal.

Prenant en considération la composition chimique des clinkers de baryum et la formation de ferrites de baryum avec alcalinité  $\geq 2$ , on peut en déduire que B<sub>2</sub>F et B<sub>7</sub>F<sub>2</sub>, ou bien des solutions solides à leur base, représenteront la phase ferrique dans les clinkers de baryum industriels.

## CONCLUSIONS

En généralisant les résultats des recherches faites, nous pouvons formuler les conclusions suivantes:

1. Les constituants des ferrites de baryum ont été étudiés microscopiquement et radiologiquement: BF, B<sub>2</sub>F, B<sub>3</sub>F<sub>2</sub>, B<sub>5</sub>F<sub>2</sub>, B<sub>7</sub>F et B<sub>7</sub>F<sub>2</sub>, et a été confirmée l'existence des phases BF et B<sub>2</sub>F. Dans les diffractogrammes d'ionisation obtenus, les distances intersuperficielles correspondent à (4), avec certaines différences dans les grands angles.

2. Le B<sub>3</sub>F, décrit par (3), n'a pas été établi ni à la synthèse en phase solide, ni de fonte. Le produit de la synthèse en phase solide sont les deux phases - B<sub>2</sub>F et B<sub>7</sub>F<sub>2</sub>, et de la fonte - solution solide de B<sub>7</sub>F<sub>2</sub> dans B<sub>2</sub>F.

3. La formation de B<sub>7</sub>F<sub>2</sub> est confirmée et, pour la première fois, sont données les distances intersuperficielles caractéristiques.

4. On a établi, à l'aide de la spectroscopie de Mössbauer, la présence de fer trivalent dans les ferrites: BF, B<sub>2</sub>F, constituants B<sub>3</sub>F et B<sub>7</sub>F<sub>2</sub>, le nombre des positions de l'ion ferrique dans eux, ainsi que la probabilité pour la formation de solutions solides de B<sub>2</sub>F, B<sub>7</sub>F<sub>2</sub> dans le constituant B<sub>3</sub>F.

5. Les résultats obtenus des études des ferrites de baryum ont été utilisées à la détermination des constituants de clinkers et ciments de baryum à leur base à une échelle semi-industrielle. (5)

## Calculation of hypothetically possible potential compositions of high-alumina cements

### *Calcul des compositions potentielles théoriquement possibles des ciments alumineux*

J. CALLEJA, Professor, Consejo Superior de Investigaciones Cientificas, Instituto "Eduardo Torroja" de la Construcción y del Cemento (I.E.T.C.C.) Madrid, Espagne.

RESUME : Malgré la grande complexité des systèmes de phases concernant le ciment alumineux, et le manque de connaissances suffisantes sur sa composition minéralogique, on a tenté dans ce travail d'établir des bases pour calculer quelques-unes de ses compositions potentielles possibles.

Il est évident que ces calculs sont appuyés sur des hypothèses discutables, mais le but principal du travail est celui de chercher une possibilité de corrélation entre les caractéristiques, propriétés et comportement du ciment alumineux "structural" et sa nature minéralogique sur des bases plus solides que celles simplement appuyées sur sa composition chimique.

Il peut être ainsi possible de trouver une aide pour chercher une solution plus complète et satisfaisante aux problèmes de la conversion, de la carbonatation et de l'hydrolyse alcali-carbonique, considérées comme les plus importantes concernant les ciments alumineux, tant du point de vue scientifique que technique.

SUMMARY: Despite the great complexity of the phase systems involved in high-alumina cement and the lack of sufficient knowledge on its mineralogical composition, attempts are made in this paper to establish bases for calculating some of its possible potential compositions.

Of course, such calculations are supported by some controvertible hypothesis, due precisely to the lack of knowledge, but the main aim of this paper is to look for a possibility of correlating some characteristics, properties and behaviours of "structural" high-alumina cement with its mineralogical nature on a more solid base than that barely consisting in its chemical composition.

So, conversion, carbonation and alkali-carbonic hydrolisis considered as principal scientific and technical problems inherent to high-alumina cements could perhaps find an aid to approach to a more complete and satisfactory solution.

## 1. - INTRODUCTION

A very concise and complete exposition of problems concerning high-alumina cements (HAC in the following), either on the aspects of their fabrication or on particulars related to their utilization has been made by J. TALABER at the VI ICCI, Moscow 1974 (1). Moreover, a survey summarizing the principal items treated at the Symposium on High-Alumina Cements held in the U.K. (December 1974) has been more recently published (2).

Summarizing in turn the outstanding features of the mentioned exposition by TALABER concerning anhydrous calcium aluminates and HAC, it must be pointed out that the binary and ternary systems C-A and C-A-S are complex, and correspondingly much more so when transformed into the quaternary and quinary systems C-A-S-F and C-A-S-F-F ( $F=FeO$ ).

Even for a long time the binary system C-A has been controverted, for some authors as NURSE and others have sustained the incongruity of the melting of  $C_{12}A_7$  and  $CA_2$  phases in dry atmospheres (3), whilst others either at the same time (as KIESSLING and others -mentioned by UDALOV and others-) or much more recently (as UDALOV and others) have supported the opposite opinion (4), not only regarding the mentioned compounds but also others such as  $C_5A_3$  and CA. Moreover, the nature of the atmosphere (oxidizing for  $C_{12}A_7$  and reducing for  $C_5A_3$ ) seems to be decisive as far as the congruity of the melting of such compounds is concerned. Furthermore, a change of atmosphere during heating may change the phases to one another (4).

According to TALABER (1) the three paragenesis fields of the ternary system C-A-S: CA- $C_{12}A_7$ - $C_2S$ , CA- $C_2S$ - $C_2AS$  and CA- $C_2AS$ - $CA_2$  may justify in principle the presence of some of the phases  $CA_2$ , CA,  $C_{12}A_7$ ,  $C_2AS$ ,  $C_2S$ .  $C_2S$  and  $C_2AS$  are always formed in the presence of S: the former if the S content is low, and the latter if it is high. The behaviour of HAC may depend much on the proportions of these phases, in the following way according to SOLACOLU mentioned by TALABER (1): Type I HAC containing mainly CA +  $C_{12}A_7$  develops a higher initial strength, whereas those cements of Type II mainly composed by CA and  $CA_2$  develop a lower initial strength, but a more intensive secondary or delayed hardening. In general  $C_{12}A_7$  is present in HAC in lower proportions, depending on the C/A ratio and probably on the higher amount of silica present in the cement composition (5).

On the other hand,  $C_2S$  behaves as in portland cement. As far as gehlenite  $C_2AS$  is concerned, it is considered as a non-desirable component, for it is a non-hydraulic alumina-consuming phase (6).

Much higher complication arises from the presence of a considerable amount of total iron-constituents in HAC (ferric and ferrous oxides, the former of which at least presumably may form calcium ferrites CF and  $C_2F$ , as well as solid solutions from  $C_2F$  to  $C_6A_2F$  (in between  $C_6AF_2$  and  $C_4AF$ ). A noticeable

amount up to 15 % of CF may enter in CA to form another solid solution (1).

Though HAC clinker is formed in most cases through fusion, no crystallization equilibrium is generally reached, so that it is very difficult and risky to apply any calculation of mineral (potential) composition to it, even restricted to the main components of the system C-A-S.

So, it has been not yet quite possible to calculate quantitatively the mineralogical composition of HAC clinker, either from its chemical composition or from that of their raw materials and mixtures. Mineralogical composition of HAC depends on the chemical composition of raw mixture, on heating and cooling (melting temperature and cooling speed), on the oxidizing or reducing atmosphere during the total manufacturing process (4) and on the type of manufacturing technology (melting, sintering or clinkerization). Different phases may result in each case as SUZUKI has pointed out as referred to pure phases and some solid solutions of them (5), so that raw mixtures with the same or very similar chemical composition may result in HAC of different mineralogical composition and/or properties. Nevertheless, the clinker cooling speed and the oxidizing/reducing conditions being almost constant for a given process, and the melting temperature conditioning mainly the ratio  $Fe^{3+}/Fe^{2+}$ , in turn taken into account in the chemical composition, this one may be considered as being the only main factor determining the mineralogical composition of HAC.

Anyway, considering that a given stoichiometry is practically maintained in a given manufacturing process, the base for possible calculations of quantitative potential compositions is the knowledge of the true qualitative mineralogical composition of a given HAC clinker. Nevertheless, characterization of HAC clinker is difficult by several of the most common techniques. As a result, morphology and composition of phases encountered are very different depending on several circumstances. Microscopically CA and  $C_2AS$  have been observed in some cases applying suitable techniques (7). But it is well known that quantitative determinations of  $C_2S$  by XRD techniques not always is easy, possible or reliable.

So, the lack of sufficient knowledge on mineralogical composition of anhydrous HAC implies a similar lack of knowledge on its hydration processes and hydration products formed, though studies have been made on their mineralogy (8), and mineralogical composition in the system C-A has been determined by means of potential analysis on the basis of phase diagrams, particularly as far as the principal phases CA and  $CA_2$  are concerned (9) (10).

Attempts have also been made to develop potential calculations of anhydrous HAC (11).

These difficulties may be some of the reasons why the main problems affecting "traditionally" to HAC, such as conversion -crystalline transformation of hexagonal hydrates to cubic hydrates-, (12) (13),

carbonation (14) and alcali-carbonic hydrolisis (15) are not yet either fully or satisfactorily explained, as the mechanisms in some cases, and mainly their kinetics, as well as the factors and conditions. -for instance, temperature (8) - affecting both, mechanisms and kinetics in most cases, seem not to be sufficiently known. Consequently, neither primary effects derived from such problems (as for instance the loss in strength -and even the strength development (16)-, the liberation of water and the increase of porosity), nor secondary (technical, practical) effects -as for instance refractory behaviour (17) (18) and reinforcement corrosion in reinforced concrete- can be completely or easily avoided or controlled.

## 2. - FURTHER APPROACHES TO POSSIBLE CALCULATIONS OF HAC POTENTIAL COMPOSITIONS

Independently of the degree of probability, these calculations must be based on conventional and arbitrary hypothesis, more or less justified. Anyway, the corresponding calculations and results may be very diverse. Much more so as each of the hypothesis adopted may present several different alternatives.

The present paper does not consider HAC other than those devised for hydraulic (structural) purposes. So, HAC of the higher contents of A for refractory uses are particularly discarded.

It is admitted that the chemical composition of ordinary structural HAC may usually vary between the following wide limits: A 39 to 42 % (40-42 %); C 37 to 42 % (37-40 %); F +  $\bar{F}$  9 to 18 % (15-17 %); S 1,5 to 6 % (1,5-3 %); T 1 to 2 %. The preceding wider limits may correspond to broader variations either from country to country (19) (20) or along the time in the same country. This could be the case in Spain. Narrower limits in brackets may correspond to variations observed in more recent time in Spain (21).

It is by no means intended to justify here the important scientific knowledge recently (22) (23) (24) and quite recently (21) gained from theoretical and experimental studies carried out by application of modern XRD, EMP, ROM, etc. techniques to phase equilibria systems of common refractory or structural HAC or to particular HAC. Special mention merits the work in course carried out by R. MARTINEZ and S. DE AZA (21). But it is obvious that the simple ternary system C-A-S is out of consideration for the two latter mentioned cements, owing to their usually high content of total iron compounds and to their relatively low content of S. Otherwise, ternary system C-A-F would be a closer approximation for them, as their three main chemical components amount to more than 90 % of their chemical composition.

From considerations on possible triangles of compatibilities of phases in solid state in both mentioned ternary systems (as in other ternary sub-systems in them), as well as on compositions and primary crystallization fields, it is possible to determine the dif-

ferent possible sequences of crystallization of phases. In fact, it has been recently confirmed that the sequence is CA, ferritic phases and  $C_{12}A_7$  in normal fused HAC (21).

Nevertheless, the quaternary system C-A-F-S (22) (23) is a further and closer approach, as the sum of principal chemical components may amount up to about 94 % of the total composition. In a similar manner the authors repeatedly mentioned (21) have established the compatibilities in solid state within the zone of the quaternary system corresponding to fused HAC with a mean chemical composition. According to it, mineralogical compositions might correspond to the quaternary sub-systems

or  $CAss-C_2Fss-C_2ASss-C_2S$

the former being in general more probable, according to the experimental and practical knowledge of hydraulic HAC (21). Practical considerations on hydration show that  $C_2AS$  is a non-desirable, non-hydraulically active phase, and that hydration of  $C_{12}A_7$  may be very rapid thus impairing setting of HAC. In the same way, according to compositions and primary volumes of crystallization, as well as to the possible eutectic surfaces, the authors (21) have determined the sequence of crystallization. They have concluded that the phases more probably formed for usual compositions of Spanish HAC are:

their relative probability depending mainly on the chemical composition of the system. It is obvious that systems I and II would be possible for compositions containing noticeable amounts of S; the higher the S content, the more probable the system II as compared with system I.

## 3. - CALCULATIONS

On the preceding bases exposed in 2, calculations of potential compositions have been developed for Spanish fused HAC. Assumptions made for it, according to experimental results of the mentioned recent studies (21) are: i) that ferrous compounds appear as wustite  $\bar{F}$ , a phase which is compatible with the other aluminous phases in the quaternary system C-A-F- $\bar{F}$ , and even with  $C_2S$  in the ternary sub-system  $C_2S-C_2AS-\bar{F}$ ; ii) that contrarily to what is generally admitted, the stable phase CT (perovskite), compatible with the other phases, does not appear as such, but in solid solution with the much more abundant ferritic phase; iii) that M (MgO),  $\bar{M}$  (MnO), etc., may form solid solutions with other phases.

Consequently, neither  $\bar{F}$  nor T,  $M$ ,  $\bar{M}$ , etc., are taken into account for calculations. They are merely included in what is called "rest" in table I. In this respect it is pointed out that two ways are possible

to simplify calculations: i) to reduce the total chemical analysis of HAC to the four major components (A, C, F, S), whereby values obtained for calculated phases would be higher than actual ones; ii) to include every other minor component in a "rest" (the same for chemical than for potential composition), whereby values obtained for calculated phases would be a little lower than actual ones. The latter way has been preferably chosen in this paper, as it is considered that only the main (hydraulic) phases are important for properties and behaviour of "structural" HAC.

One further assumption is that  $C_2F_{ss}$  which may widely vary in composition (at most between the extreme terms  $C_2F$  and  $C_6A_2F$ ) according to the F content, corresponds either to the term  $C_4AF_{ss}$  - probably more usual (21)-, or to the term  $C_6A_2F_{ss}$  in each of the systems I, II and III (sub-cases 1 and 2 of them in the following).

All the calculations are based on percentage contents of oxides expressed in the chemical analysis of HAC (indicated by the small letters corresponding to the symbolic capital letters representing oxidic components), and on the corresponding molar ratios. Final coefficients are given but with only two decimal figures.

### 3.1. - Calculations in the system I. 1:

a) s % of S fix s.  $2C/S = 1.866675$ . s % =  $c_1$  % of C  
to form s.  $C_2S/S = 2.866675$ . s % of  $C_2S$   
remaining  $(c-c_1) = c_2$  % of C

b) f % of F fix f.  $A/F = 0.638486$ . f % =  $a_1$  % of A  
and f.  $4C/F = 1.404687$ . f % =  $c_3$  % of C  
to form f.  $C_4AF/F = 3.043174$ . f % of  $C_4AF$   
remaining  $(a-a_1) = a_2$  % of A  
and  $(c_2-c_3) = c_4$  % of C

c)  $a_2$  % of A fix  $a_2$ .  $C/A = 0.550007$ .  $a_2$  % =  $c_5$  % of C  
to form  $a_2$ .  $CA/A = 1.550007$ .  $a_2$  % =  $(ca)_1$  % of CA  
remaining  $(c_4-c_5) = c_6$  % of C

d)  $c_6$  % of C fix  $c_6$ .  $7CA/5C = 3.945423$ .  $c_6$  % =  $(ca)_2$  % of CA  
to form  $c_6$ .  $C_{12}A_7/5C = 4.945423$ .  $c_6$  % of  $C_{12}A_7$   
remaining  $((ca)_1-(ca)_2)$  % of CA

Finally:  $C_2S$  % = 2.87 S %

$$C_4AF \% = 3.04 F \%$$

$$C_{12}A_7 \% = 4.95 C \% - 9.23 S \% - 5.21 F \% - 2.72 A \%$$

$$CA \% = 1.55 A \% - 0.99 F \% - 0.80 C_{12}A_7 \%$$

$$\text{or } CA \% = 3.72 A \% + 7.36 S \% + 3.17 F \% - 3.95 C \%$$

The same equations without terms in F may be applied to the ternary system  $C_{Ass}-C_{12}A_7ss-C_2S$ . On the contrary, if  $C_{12}A_7$  cannot be formed, then:

$$C_2S \% = 2.87 S \%$$

$$C_4AF \% = 3.04 \%$$

$$CA \% = 2.82 C \% = 5.26 S \% - 3.96 F \%$$

This is a possible but not probable case.

### 3.2. - Calculations in the system I. 2:

a) As in 3.1

b) f % of F fix f.  $2A/F = 1.276973$ . f % =  $a_1$  % of A  
and f.  $6C/F = 2.107031$ . f % =  $c_3$  % of C  
to form f.  $C_6A_2F/F = 4.384004$ . f % of  $C_6A_2F$   
remaining  $(a-a_1) = a_2$  % of A  
and  $(c_2-c_3) = c_4$  % of C

c) As in 3.1

d) As in 3.1

Finally:  $C_2S$  % = 2.87 S %

$$C_6A_2F \% = 4.38 F \%$$

$$C_{12}A_7 \% = 4.95 C \% - 9.23 S \% - 6.95 F \% - 2.72 A \%$$

$$CA \% = 1.55 A \% - 1.98 F \% - 0.80 C_{12}A_7 \%$$

$$\text{or } CA \% = 3.72 A \% + 7.36 S \% + 3.56 F \% - 3.95 C \%$$

### 3.3. - Calculations in the system II. 1:

a) As b) in 3.1

b) s % of S fix s.  $2C/S = 1.866675$ . s % =  $c_3$  % of C  
to form s.  $C_2S/S = 2.866675$ . s % =  $(c_2s)_1$  % of  $C_2S$   
remaining  $(c_2-c_3) = c_4$  % of C

c)  $c_4$  % of C fix  $c_4$ .  $A/C = 1.818160$ .  $c_4$  % =  $a_3$  % of A  
to form  $c_4$ .  $CA/A = 2.818160$ .  $c_4$  % of CA  
remaining  $(a_2-a_3) = a_4$  % of A

d)  $a_4$  % of A fix  $a_4$ .  $C_2S/S = 1.689304$ .  $a_4$  % =  $(c_2s)_2$  % of  $C_2S$

$CA\% = 1.55 A\% - 1.98 F\% - 0.80 C_{12}A_7\%$

or  $CA\% = 3.72 A\% + 3.56 F\% - 3.95 C\%$

## 4. - NUMERICAL EXAMPLES

Application of the preceeding potential calculations to more common ancient and present compositions of some Spanish HAC have been made. Table I shows chemical analysis in terms of the four major components and the "rest" defined in 3. Calculated potential compositions in terms of the phases corresponding to the systems described in 3.1 to 3.6 have been also included in the table. Seven examples have been chosen, the case 3.5a corresponding to the application of calculations in the system III.1 of 3.5, to the chemical composition of case 3.6, also corresponding to the system III.2 of 3.6.

TABLE I

	S	y	s	t	e	m	s
Chem. comp.	3.1	3.2	3.3	3.4	3.5	3.5 a	3.6
A	40.5	40.5	40.5	37.0	39.5	39.0	39.0
C	38.5	39.5	38.5	40.5	36.5	37.0	37.0
S	2.5	2.0	2.5	4.5	-	-	-

$C_4AF$	33.4	-	38.0	-	36.5	33.4	-
$C_6A_2F$	-	41.6	-	48.2	-	-	48.2
$C_2AS$	-	-	7.8	18.1	-	-	-
R	7.5	8.5	6.0	7.0	12.0	13.0	13.0
$\Sigma$	100.0	100.0	100.0	100.0	100.0	100.0	100.0

Examples show substantial variations in calculated potential compositions, even for very similar chemical analysis. Particular features of this subject may be: i) the different amounts of calculated  $C_4AFss$  and  $C_6A_2Fss$  in the respective systems, even for the same F content (cases 3.5a and 3.6); ii) the higher values of  $C_{12}A_7$  corresponding to the  $C_4AFss$  formation, as compared with those corresponding to the  $C_6A_2Fss$  formation (cases 3.5 or 3.5a and 3.6); iii) that all these influences and some others related to the A + C sum and/or to the A/C ratio seem to affect the contents of  $C_2S$  and/or  $C_2AS$  and that of CA, and consequently the properties and behaviour of HAC; iv) that changes introduced in composition of Spanish HAC (ancient case 3.4 as compared with modern cases 3.1 to 3.3) have resulted in an important increase of HAC quality; etc.

## 5. - CONCLUSION

Stoichiometric considerations and assumptions on formation of possibly existing phases in the extremely complex systems of real and practical -technical, commercial- HAC permit to develop hypothetical potential calculations for such systems; some of the presumably more common of them have been taken into account. Calculations show that even for very similar quantitative chemical compositions or HAC, referred either to percentages of oxides and/or to the ratios between them, may result in different qualitative and/or quantitative potential compositions. It is thought that these differences, when real, may affect to more or less hydraulic anhydrous phases, and to phases with a higher or lower speed of hydration and hardening. It is also thought that this may result in

hydration products of a higher or lower stability -susceptibility to changes provoked by temperature and/or humidity variations or by hydrolytic alkaline processes, carbonation, etc. -. These considerations on the exposed potential calculations might perhaps aid to interpretate the great difference in behaviour of apparently equal or very similar HAC, mainly as far as their bare chemical composition is concerned. As to the calculations applied to the present Spanish HAC with the following rounded mean chemical composition: A = 41.0 %; C = 38.0 %; F = 13 %; R = 5.5 %, its potential composition fits in the system  $\text{CaO}-\text{Al}_2\text{O}_3-\text{SiO}_2$ , with the following results:  $\text{CA} = 43.6\%$ ;  $\text{C}_{12}\text{A}_7 = 8.9\%$ ;  $\text{C}_4\text{AF} = 39.5\%$ ;  $\text{R} = 8.0\%$  (R includes S = 2.5 % which is assumed to be in solid solution with some of the other phases). This calculated potential composition agrees well with actual experimental results (21), which confirm the applicability of the mentioned system to the Spanish HAC.

#### ACKNOWLEDGEMENTS

The author wish to thank Dr. A. de BENITO for his ancient collaboration. And very specially his colleagues Prof. Dr. S. DE AZA and Dr. R. MARTINEZ for their most valuable comments, observations and criticism.

 N. CIOCEA, Scientific - researcher, Bucharest Polytechnical Institute, Roumanie.

**RESUME :** Une méthode pour obtenir des ciments alumineux de haute réfractarité est de remplacer une partie du  $CaO$  contenu dans les ciments alumineux de calcium par  $MgO$ ,  $BaO$  ou  $SrO$ . L'oxyde de calcium peut être remplacé en totalité par le  $SrO$  ou le  $BaO$ .

Le but de ce travail est d'étudier les caractéristiques des masses de ciment réfractaire obtenus par un remplacement total ou partiel du  $CaO$  par  $BaO+MgO$ . Les auteurs ont déterminé les propriétés physico-mécaniques des masses situées dans le pseudosystème  $BA-CA-MA-BA_6-CA_6$  ( $B = BaO$ ,  $C = CaO$ ,  $M = MgO$ ,  $A = Al_2O_3$ ) pour des pourcentages de  $MA$  de 20 et 50 %, respectivement. Ils ont aussi analysé l'influence exercée par des petites additions de  $SiO_2$  et de  $Fe_2O_3$  (introduites dans le système comme impuretés dans les matières premières) sur les propriétés des ciments alumineux étudiés.

**SUMMARY :** Aluminous cements possessing high refractoriness may be obtained starting from calcium - containing aluminous cements by means of a partial replacement of  $CaO$  by  $MgO$ ,  $BaO$  or  $SrO$ . This replacement may be total when barium or strontium oxides are used.

The present work deals with the study of the properties of some masses characterized as aluminous cements, obtained by a partial or total replacement of  $CaO$  by  $BaO+MgO$ . There were determined the physical - mechanical properties of the masses situated within the  $BA-CA-MA-BA_6-CA_6$  pseudosystem (where  $B = BaO$ ,  $C = CaO$ ,  $M = MgO$ ,  $A = Al_2O_3$ ), when the  $MA$  amount is of 20 and 50 %, respectively.

There was examined, too, the influence of small amounts of  $SiO_2$  and  $Fe_2O_3$  (brought into the system as impurities in the raw materials) on the properties of the aluminous cements studied in this work.

Dans la composition des ciments alumineux hydrauliques utilisés comme produits réfractaires les constituants majeurs sont les aluminates de calcium. Parmi ces ciments, les plus réfractaires sont ceux à haut contenu d' $\text{Al}_2\text{O}_3$  allant, par exemple, jusqu'à 79-81 %  $\text{Al}_2\text{O}_3$  (1, 2); des travaux et des brevets récents (3, 4) proposent comme méthode de préparation des ciments l'addition de l'oxyde d'aluminium pendant le broyage.

Des données plus récentes (5-13) ont montré qu'on peut aussi obtenir des ciments alumineux de haute réfractarité par le remplacement total ou partiel du  $\text{CaO}$  contenu dans les ciments alumineux à calcium par  $\text{MgO}$ ,  $\text{BaO}$ ,  $\text{SrO}$ . Ce remplacement peut être réalisé en totalité dans les cas du  $\text{BaO}$  et du  $\text{SrO}$ .

Dans ce travail nous avons étudié les propriétés des quelques masses caractérisées comme liants, obtenus par un remplacement total ou partiel du  $\text{CaO}$  par  $\text{BaO}+\text{MgO}$ . Nous avons déterminé les propriétés physico-mécaniques d'environ 85 masses situées dans la région moins basique du système  $\text{BaO}-\text{CaO}-\text{MgO}-\text{Al}_2\text{O}_3$ , plus exactement dans le pseudosystème  $\text{BA}-\text{CA}-\text{MA}-\text{BA}_6-\text{CA}_6$ , pour des proportions en MA de 20 % et 50 %, respectivement.

Les matières premières utilisées pour la synthèse ont été: carbonate de baryum, carbonate de calcium et carbonate basique de magnésium de pureté chimique et alumine tabulaire (plus de 99,5 %  $\text{Al}_2\text{O}_3$ ). Tous les clinkers ont été synthétisés à 1540°C; le temps de

cuisson a été 8 heures à cette température.

Pour déterminer le cours des procès de sinterisation et vitrification, nous avons déterminé la porosité des échantillons cuits et nous avons effectué des analyses roentgenographiques (voyez aussi (14)). Les résultats ont montré que pour la quasi-totalité des masses synthétisées l'équilibre thermique est achevé; les clinkers situés dans la région du  $\text{BC}_2\text{A}_4$  font exception. Les phases décelées dans les échantillons correspondant au composé  $\text{BC}_2\text{A}_4$  à 20 % MA et 50 % MA, cuits dans les conditions déjà mentionnées, ont été les suivantes:  $\text{BC}_2\text{A}_4$  et MA (prédominantes), BA, CA,  $\text{CA}_2$ . Ces phases ont été observées dans tous les masses à haut contenu potentiel en  $\text{BC}_2\text{A}_4$ .

Pour connaître les propriétés liantes des masses étudiées dans le pseudosystème  $\text{BA}-\text{CA}-\text{MA}-\text{BA}_6-\text{CA}_6$ , les clinkers ont été broyés jusqu'à un résidu nul sur le tamis de 0,06 mm, et ont été mesurées les valeurs de l'eau de consistance normale, du temps de prise - figure 1 - et de la résistance à compression (sur des échantillons hydratés, gardés en air pour 1, 3 et 7 jours) - figure 2. Les valeurs de l'eau de consistance normale ont été entre 24 et 30 %.

La plupart des ciments obtenus possèdent des résistances mécaniques à compression de plus de 100  $\text{daN/cm}^2$  après un jour et de 300  $\text{daN/cm}^2$  après 7 jours (dans des conditions comparables de synthèse et de mesure, les valeurs pour les échantillons de CA ont été de 300  $\text{daN/cm}^2$  après un jour et, respectivement, de 500  $\text{daN/cm}^2$  après 7 jours; les meil-

Fig. 1 - Les courbes de temps égal de fin de prise dans le pseudosystème  $\text{BA}-\text{CA}-\text{MA}-\text{BA}_6-\text{CA}_6$ .

- b - le plan à 50 % MA
- courbes déterminées avec certitude ;
- - - courbes probables

leurs résultats dans les mêmes conditions ont été 500 daN/cm<sup>2</sup> après un jour et 650 daN/cm<sup>2</sup> après 7 jours). Les courbes dans les figures 1 et 2 sont basées sur ces données.

Nous avons aussi déterminé la réfractairité dont les valeurs sont données dans la figure 3 (pour la plupart des ciments les réfractairités ont été de plus de 1750°C).

L'analyse des courbes de temps égal de fin de prise (figure 1) et de résistance égale à compression après 7 jours (figure 2) montre que les propriétés des ciments synthétisés respectent les règles de paragenèse lorsque l'équilibre thermique est achevé.

Nous avons mentionné que dans le cas des masses riches en  $BC_2A_4$  l'équilibre est partiellement achevé; de ce motif, le parallélisme entre les propriétés physiques et mécaniques du ciment et sa composition minéralogique potentielle (en conformité avec les règles de paragenèse) n'est pas observé dans tous les cas.

Dans les sous-systèmes  $BA_{ss}-BA_6-BC_2A_4-MA$  et  $BA_{ss}-CA_{ss}-BC_2A_4-MA$  les valeurs minimales du temps de fin de prise sont dirigées vers la pointe  $BA_{ss}$  ou vers

la pointe  $BC_2A_4$ . Le temps de prise augmente avec le contenu en spinel magnésien. Les valeurs maximum des résistances mécaniques sont aussi obtenus pour les échantillons riches en  $BA_{ss}$ ; l'augmentation du contenu en spinel magnésien jusqu'à 50% ne diminue pas les résistances mécaniques.

Les valeurs de la réfractairité des masses dans les sous-systèmes cités plus haut augmentent avec l'augmentation du contenu en  $BA$ ,  $BA_6$  et  $MA$  (figure 3).

Les masses situées dans le sous-système  $CA_{ss}-BC_2A_4-CA_2-MA$  (surtout celles riches en aluminates de calcium), quand sont cuites à 1540°C, possèdent des temps de prise plus longs et les résistances initiales (surtout les valeurs après un jour) sont diminuées. Pour obtenir des valeurs optimales du temps de prise et de la résistance initiale, les masses doivent être cuites à des températures plus basses (environ 1500°C (15)).

Les compositions situées dans les sous-systèmes  $CA_2-BC_2A_4-BA_6-MA$  et  $CA_2-CA_6-BA_6-MA$  sont d'une importance pratique réduite en ce que concerne leurs utilisations comme liants.

L'étude des propriétés des masses synthétisées nous a montré que les meilleurs valeurs ont été obtenues dans le cas de la masse notée par le symbole BA, qui est composée de 50 % BA et de 50 % MA. L'influence des additions de  $\text{SiO}_2$  et de  $\text{Fe}_2\text{O}_3$ , présentes comme impuretés dans les matières premières, a été étudiée sur cette composition, remplaçant une

fraction variable d' $\text{Al}_2\text{O}_3$  par les additions spécifiées plus haut. La composition oxydique du ciment alumineux de baryum et magnésium utilisé comme substance étalon et celle des ciments avec des additions de  $\text{SiO}_2$  et  $\text{Fe}_2\text{O}_3$  sont présentées dans le tableau I.

Les mélanges synthétisés ont été cuits 5 heures à  $1500^\circ\text{C}$ . Quelques propriétés des ciments obtenus sont présentées dans le tableau I.

9	30,1	14,17	46,23	7,5	2	4h30 min.	6h15 min.	400	490	1700
10	30,1	14,17	47,23	2,5	6	3h30 min.	7h10 min.	210	330	1790

Nous avons établi que l'utilisation des matières premières contenant des quantités relativement petites de  $\text{SiO}_2$  et de  $\text{Fe}_2\text{O}_3$  mène à une diminution de la résistance mécanique du ciment et de sa réfractarité. Il nous semble probable que l'action nocive du  $\text{SiO}_2$  est plus importante que celle du  $\text{Fe}_2\text{O}_3$ .

### CONCLUSIONS

Les données que nous avons présentées, concernant les propriétés des ciments dans le système  $\text{BaO-CaO-MgO-Al}_2\text{O}_3$  montrent que, pour obtenir des ciments de haute réfractarité et d'une haute résistance mécanique, les compositions choisies doivent être situées dans le sous-système  $\text{BA}_{\text{ss}}\text{-BC}_2\text{A}_4\text{-BA}_{\text{g}}\text{-MA}$  (dans la région plus riche en BA, le spinel magnésien peut être trouvé en proportions allant jusqu'à 50 %). La cuisson à des températures supérieures à  $1540^\circ\text{C}$  n'exerce pas une influence négative sur les propriétés des ciments.

Les masses situées dans le sous-système  $\text{BA}_{\text{ss}}\text{-CA}_{\text{ss}}\text{-BC}_2\text{A}_4\text{-MA}$  sont aussi des liants de bonne qualité, dont les propriétés sont en dépendance de la région où se trouvent.

Les masses dans le sous-système  $\text{CA}_{\text{ss}}\text{-BC}_2\text{A}_4\text{-MA}$  possèdent des résistances mécaniques élevées, mais leurs réfractarités sont plus basses. Le danger de la surcuisson paraît plus visible dans le cas des masses riches en CA et  $\text{CA}_2$ , quand le contenu en  $\text{BC}_2\text{A}_4$  augmente, les résistances décroissent et le danger de la surcuisson diminue.

Les masses réfractaires situées dans les autres sous-systèmes sont d'une importance technique réduite, compte tenu de leurs propriétés liantes.

L'utilisation des matières premières contenant  $\text{SiO}_2$  et  $\text{Fe}_2\text{O}_3$  (comme impuretés) pour obtenir des ciments étudiés, mène à une diminution de leurs résistances mécaniques et de leur réfractarité. L'influence des ces oxydes (surtout du  $\text{SiO}_2$ ), considérés séparément, semble d'être plus nocive que dans le cas de leur présence simultanée.

# Hydratation des mélanges silicates-aluminates de calcium

## *Hydration of calcium silicates and aluminates mixes*

B.F. COTTIN, Chef de Service, Laboratoire de Recherche Générale, Lafarge S.A., France.

RESUME : Il est bien connu que les mélanges de ciments Portland et de ciments alumineux peuvent donner, pour certaines proportions, des ciments à prise pratiquement instantanée.

L'étude cinétique des concentrations des solutions de gâchage, et leur comparaison avec le diagramme chaux - alumine - eau, permet de comprendre et d'expliquer, au moins en partie, ces phénomènes.

SUMMARY : It is well known that, for precisely defined proportions, mixes of Portland and high alumina cements give a practically instantaneous setting.

These phenomena are partly understood and explained by comparing kinetic studies of the concentrations of the mixing solutions with the lime - alumina - water diagram.

## INTRODUCTION

L'étude de l'hydratation des liants hydrauliques par analyse des filtrats de suspensions de ciments relativement dilués est depuis longtemps utilisée par un certain nombre d'auteurs. Les résultats les plus anciens, et les plus nombreux, se rapportent aux ciments alumineux dont le constituant principal est l'aluminate monocalcique CA. On peut citer en particulier les travaux de ASSARSON (1) - WELLS et CARLSON (2).

Plus récemment, le Professeur Barret et son équipe ont approfondi la connaissance des processus d'hydratation de l'aluminate monocalcique pur et du Ciment Fondu, ciment à haute teneur en alumine fabriqué dans des fours à fusion par Lafarge Fondu International : BESSIERES (3) - BARRET et MENETRIER (4) - BERTRANDIE (5). Leurs essais montrent que l'hydratation de ces ciments suit le schéma : passage en solution - temps de germination - précipitation et correspond très bien au diagramme chaux - alumine - eau étudié en particulier par JONES et ROBERTS (6) - PERCIVAL et TAYLOR (7) - FAURIE-MOUNIER (8).

Le ciment Portland et le  $C_3S$  ont aussi été étudiés par l'analyse des filtrats, et nous citerons parmi les derniers auteurs : YOUNG, TONG et BERGER (9) - SLEIGERS et ROUXHET (10) - MENETRIER (11). Cette dernière a même pu rattacher les premiers instants de réactions du  $C_3S$  avec l'eau au diagramme chaux-silice-eau tel qu'il a été défini par FLINT et WELLS (12) ou GREENBERG et CHANG (13).

L'expérience nous a montré que, aussi bien pour les ciments alumineux que pour les ciments Portland, l'évolution de l'analyse des filtrats de suspensions à rapport pondéral eau/ciment de 10 est bien représentative de la prise des pâtes de rapport E/C 0,5. En particulier, le début de prise coïncide avec le moment où le filtrat des suspensions commence à s'appauvrir en ions en solution, et où des hydrates apparaissent significativement dans le résidu solide. C'est la raison pour laquelle nous avons appliqué la méthode des analyses de filtrats aux mélanges ciment alumineux - ciment Portland, pour lesquels il est bien connu que certaines proportions conduisent à des prises si promptes que le gâchage est impossible.

## CONDITIONS EXPERIMENTALES

Nous avons étudié les mélanges 20/80 - 50/50 - 80/20 d'un Ciment Fondu commercial et d'un clinker de ciment Portland broyé sans gypse, dont les caractéristiques sont données ci-après :

Ciment Fondu :

$SiO_2$	$Al_2O_3$	$Fe_2O_3$	FeO	CaO	MgO	$TiO_2$	p. feu	SS Blaine
4,10	38,90	12,90	3,20	38,45	0,35	2,20	0,25	2890

Clinker de Portland :

$SiO_2$	$Al_2O_3$	$Fe_2O_3$	CaO	MgO	$SO_3$	p. feu	$K_2O$	$Na_2O$	CaO libre
22,95	5,00	2,80	67,60	0,65	0,35	0,45	0,15	0,09	0,70
$C_3S$	$C_2S$	$C_3A$	$C_4AF$	SS Blaine					
59	22	8,5	8,5	3050					

Nous avons utilisé la méthode décrite par COTTIN (14) pour les longues échéances dans laquelle l'analyse des oxydes CaO et  $Al_2O_3$  dissous dans le filtrat est complétée par l'examen en diffraction des rayons X du résidu solide, lavé à l'acétone et séché à l'éther sulfurique. Les essais ont été réalisés à la température de 21°C.

## RESULTATS DES ESSAIS

Les tableaux I à IV donnent les résultats obtenus aux échéances les plus significatives : concentration du filtrat en CaO et  $Al_2O_3$  (s'il y a lieu) - Rapport C/A molaire des ions

en solution - hauteurs des pics de diffraction des rayons X des anhydres résiduels et des hydrates formés dans le résidu sec - pourcentage d'eau liée du résidu sec par perte au feu à 1000°C après lavage à l'acétone et séchage à l'éther.

Echéance	Concentration mg/l		Rapport C/A molaire	Hauteurs de pics en diff. X				Eau liée %
	$Al_2O_3$	CaO		CA	$C_4AF$	$CAH_{10}$	$C_2AH_8$	
40 mn	1810	1040	1,05	138	69	-	-	0,40
1 h.	1815	1075	1,08	138	69	-	-	0,45
2 h.	1745	1015	1,06	144	66	-	-	1,00

17 h.	435	370	1,57	ε	48	180	165	43,10

TABLEAU I : Ciment Fondu

## 100 % Fondu

Les résultats obtenus sont classiques et se caractérisent par :

- Une augmentation très rapide des ions en solution dont la concentration atteint en moins d'une heure environ 19,2 millimoles par litre de CaO et 17,8 millimoles par litre de  $Al_2O_3$ .

- Une diminution très rapide entre 2 et 3 heures de ces concentrations, avec apparition des hydrates par diffraction X et augmentation significative de l'eau liée.

- La poursuite de l'hydratation avec diminution du  $C_4AF$  et surtout du CA résiduels, augmentation des pics de diffraction de  $CAH_{10}$  et  $C_2AH_8$ , très forte augmentation de l'eau liée et glissement progressif du C/A en solution de 1,05 environ à des valeurs plus importantes.

La cinétique de tous ces phénomènes est caractéristique d'un ciment dont la période dormante se termine un peu avant l'échéance de 3 heures.

Echéance	Concentration mg/l CaO	Hauteurs de pics en D.X.				Eau liée %
		$C_3S$	$C_2S$	CH	$C_4AH_{13}$

103 h.	1470	92	20	> 400		20,40

TABLEAU II : Clinker de Portland

## 100 % Portland

Dès une heure, la concentration de la chaux en solution est suffisamment élevée pour que l'alumine et la silice ne soient plus significativement décelables. Cette concentration atteint 31 millimoles par litre vers 14 heures, échéance à partir de laquelle apparaissent en diffraction X le premier hydrate bien cristallisé : la chaux hydratée, et une augmentation non négligeable de l'eau liée.

L'hydratation se poursuit relativement lentement pour atteindre vers 100 heures un état où la solution est encore saturée par rapport à la chaux hydratée (26 millimoles par litre) et où environ 50 % du  $C_3S$  sont hydratés avec 20 %

d'eau liée. La Portlandite diffracte énormément, par contre le  $C_4AH_{13}$  paraît plutôt mal cristallisé.

Nous nous trouvons dans le cas de l'hydratation d'un ciment

Portland non gypsé, c'est-à-dire où les silicates de calcium anhydres :  $C_3S$  sont "empoisonnés" par l'alumine et voient leur hydratation retardée : COTTIN et VIBERT (15).

#### 80 % Fondu - 20 % Portland

TABLEAU III : 80 % Ciment Fondu - 20 % Clinker de Portland

La mise en solution de la chaux et de l'alumine est au moins aussi rapide qu'avec le Ciment Fondu seul. A l'échéance de 1 heure, les concentrations sont encore plus élevées (21,0 et 19,0 millimoles par litre respectivement pour la chaux et l'alumine). Dès trois heures, les concentrations ont fortement chuté, l'eau liée est relativement importante, et 25% de l'aluminate monocalcique sont hydratés. On peut donc estimer que l'hydratation est commencée, bien que les hydrates n'apparaissent nettement en diffraction X qu'à partir de 4 heures.

Ces hydrates sont d'ailleurs les mêmes qu'avec le Ciment Fondu seul :  $CAH_{10}$  et  $C_2AH_8$ , mais leur intensité augmente peu avec le temps. Le C/A croît lentement de 1,10 à 1,20, et ne fait un bond au delà de 2 que lorsque  $C_3S$  commence à s'hydrater de façon significative après 9 heures. A partir de 24 heures apparaissent les pics de diffraction X d'un nouvel hydrate : la gehlenite hydratée  $C_2ASH_8$ . A 96 heures, le  $CAH_{10}$  semble diminuer alors que le  $C_2AH_8$  devient très important. Tout CA est hydraté mais seulement les 2/3 de  $C_3S$  ont réagi.

Echéance	Concentration mg/l		C/A molaire	Hauteurs des pics en diffraction X								Eau liée %
	Al <sub>2</sub> O <sub>3</sub>	CaO		CA	C <sub>3</sub> S	CAH <sub>10</sub>	C <sub>2</sub> AH <sub>8</sub>	C <sub>3</sub> AH <sub>6</sub>	C <sub>2</sub> ASH <sub>8</sub>	C <sub>4</sub> AH <sub>13</sub>	CH	
30 mn.	1925	1165	1,10	72	90	-	-	-	-	-	-	0,95
1 h.	1990	1200	1,10	71	85	-	-	-	-	-	-	0,95
2 h.	1985	1195	1,10	66	87	-	-	-	-	-	-	1,40
3 h.	1480	915	1,13	64	88	-	-	-	-	-	-	4,35
4 h.	1125	720	1,17	50	86	10	-	-	-	-	-	9,55
5 h.	1050	685	1,19	45	93	21	-	-	-	-	-	13,75
8 h.	1030	665	1,20	29	98	31	-	-	-	-	-	14,30
10 h.	970	660	1,23	18	94	23	-	-	-	-	-	17,25
14 h.	705	560	1,44	18	86	20	-	-	-	-	-	17,30

TABLEAU IV : 50 % Ciment Fondu - 50 % Clinker de Portland

### 50 % Fondu - 50 % Portland

La mise en solution est encore plus rapide, et les concentrations atteignent à une heure des niveaux encore plus élevés : respectivement 21,5 et 19,5 millimoles par litre pour la Chaux et l'Alumine. Comme précédemment, la chute des concentrations est déjà importante dès trois heures. Cependant ce n'est qu'à 4 heures, et pour une eau liée importante de près de 10 %, qu'apparaît le premier hydrate en diffraction des rayons X : le  $CAH_{10}$ . Son intensité croît peu, puis disparaît après 14 heures, tandis que le CA continue de s'hydrater fortement et l'eau liée de croître. A ce stade, les silicates de calcium ne paraissent pas avoir agi, et le C/A de la solution est d'ailleurs modéré : 1,44.

Echéance	Concentration mg/l		Hauteurs de pics en diffraction X						Eau liée %
	$Al_2O_3$	CaO	CA	$C_3S$	$C_2ASH_8$	$C_4AH_{13}$	CH		
30 mn	0	925	45	144	7	-	-		5,40
1 h.	-	1040	38	137	7	-	-		6,80

18 h.	25	1650	26	132	12	11	-		11,75
24 h.	20	1655	28	120	15	13	5		12,70
40 h.	5	1645	28	122	22	31	0		12,55
45 h.	0	1665	28	120	21	28	70		17,10
64 h.	0	1650	28	62	15	29	> 300		18,90
88 h.	0	1650	22	52	14	28	> 400		22,00
185 h.	0	1485	21	49	14	55	> 400		24,70

TABLEAU V : 20 % Ciment Fondu - 80 % Clinker de Portland

A partir de 24 heures, alors que presque tout le CA est hydraté, le  $C_3S$  commence à réagir. Il en résulte immédiatement la disparition de  $CAH_{10}$ , la formation de  $C_2ASH_8$  (très peu), de  $C_3AH_6$ , de  $C_2ASH_8$  et même de  $C_4AH_{13}$ , la disparition presque totale de l'alumine en solution avec une augmentation très importante du rapport C/A.

Entre 24 et 80 heures, la situation évolue relativement peu. Il faut signaler cependant l'apparition de Portlandite et la nouvelle augmentation de la chaux en solution qui atteint les valeurs sursaturées de 26 à 27 millimoles par litre.

### 20 % Fondu - 80 % Portland

Les résultats se différencient des précédents, et se rapprochent plutôt de ceux trouvés pour le Clinker de Portland seul. En effet l'alumine est pratiquement absente du filtrat, tandis que la chaux en solution croît relativement lentement jusqu'à sursaturation de 29 à 30 millimoles par litre, stable entre 15 et 90 heures.

Le mélange ne se comporte cependant pas comme le clinker de Portland seul car :

- Dès 30 minutes, il y a une quantité d'eau liée non négligeable, avec présence d'un peu de gehlénite hydratée  $C_2ASH_8$ .

- Une grande partie du CA s'hydrate pendant les 6 premières heures, avec augmentation de l'eau liée, sans que  $C_3S$  ne paraisse beaucoup réagir.

- Le  $C_4AH_{13}$  apparaît dès 9 heures, alors que la chaux hydratée ne se manifeste nettement qu'à partir de 45 heures, échéance à laquelle  $C_3S$  commence à s'hydrater plus rapidement.

Vers 180 heures, la situation se caractérise par la présence persistante de CA anhydre, qui paraît en pourcentage moins hydraté que le  $C_3S$ . La gehlénite hydratée et le  $C_4AH_{13}$  ne fournissent pas des pics de diffraction des rayons X très importants : seule la Portlandite diffracte remarquablement bien.

### DISCUSSION DES RESULTATS

Nous avons reporté sur la figure 1 l'évolution, en fonction du temps, des concentrations en CaO des filtrats pour les cinq

FIG. 1 - Variation de la concentration en CaO des filtrats en fonction du temps.

mélanges étudiés. (Les concentrations en alumine ne sont pas représentées pour ne pas alourdir le graphique). Les caractéristiques d'hydratation du Ciment Fondu seul et du mélange 80-20 le plus riche en Fondu obéissent au même principe : passage en solution de la chaux et de l'alumine et précipitation des hydrates au bout d'un temps suffisamment court pour que le palier à sursaturation maximum, et à rapport molaire C/A proche de 1, ait à peine le temps d'être atteint. Lors de l'hydratation, les concentrations en chaux et en alumine chutent rapidement, le rapport molaire C/A ayant tendance à augmenter vers des valeurs de quelques unités.

Le mélange 50-50 se comporte de la même façon en début de réaction avec l'eau, mais à partir d'une vingtaine d'heures, la concentration en alumine se met à tendre vers zéro, la teneur du filtrat en ions calcium atteignant une sursaturation de facteur environ 1,5 par rapport à  $\text{Ca(OH)}_2$ .

Avec le mélange riche en clinker de Portland : 20-80, et avec le clinker pur, le processus d'hydratation est totalement différent dès le début de la réaction : l'alumine n'est jamais significativement présente dans la solution, alors que la concentration en chaux du filtrat atteint rapidement la sursaturation de facteur environ 1,5. L'apparition de la Portlandite en diffraction X ne s'accompagne que d'une très lente diminution de la concentration de la solution, prouvant que les cristaux de  $\text{Ca(OH)}_2$  formés aux courtes échéances sont beaucoup plus solubles que la chaux hydratée compacte.

Ces caractéristiques d'hydratation, a priori contradictoires, s'expliquent très bien si l'on considère le diagramme  $\text{CaO} - \text{Al}_2\text{O}_3 - \text{H}_2\text{O}$  : figure 2. Nous y avons reporté les points représentatifs des concentrations des filtrats des trois mélanges qui s'hydratent en laissant passer de l'alumine en solution. La netteté avec laquelle ces points se

FIG. 2 - Représentation de l'analyse des filtrats dans le diagramme  $\text{CaO} - \text{Al}_2\text{O}_3 - \text{H}_2\text{O}$ . La courbe représente l'équilibre des hydrates hexagonaux à 21°C (d'après PERCIVAL et TAYLOR).

groupent sur la ligne de précipitation des hydrates hexagonaux, ou son prolongement vers les fortes concentrations, est remarquable. Pour le Ciment Fondu seul et le mélange à 80 % de Fondu, ces points ne franchissent pas le point à tangente verticale M de la courbe de précipitation des hexagonaux ( $\text{C}_2\text{AH}_8$ ). Par contre, la plus grande richesse en chaux du mélange 50-50 permet à la solution de décrire la branche  $\text{C}_4\text{AH}_{13}$  de la courbe de précipitation des hexagonaux, où l'alumine en solution est très faible.

Le cas du mélange à 80 % de clinker de Portland, et a fortiori celui du clinker seul, conduit dès les premiers instants d'hydratation à une représentation de la solution de gâchage bloquée sous la courbe  $\text{C}_4\text{AH}_{13}$ , donc sans alumine ou à peu près.

La forme caractéristique du diagramme  $\text{CaO} - \text{Al}_2\text{O}_3 - \text{H}_2\text{O}$  conduit à l'existence de solutions métastables dans deux domaines distincts pour une même concentration en chaux supérieure à 500 milligrammes par litre : cela explique très simplement les comportements en début d'hydratation des ciments alumineux, des ciments Portland et de leurs mélanges.

- Les solutions qui résultent du mélange de l'eau avec le ciment alumineux s'enrichissent en  $\text{CaO}$  et  $\text{Al}_2\text{O}_3$  en suivant un chemin proche, mais légèrement sous saturé par rapport à la courbe de précipitation des hydrates. Le temps de prise n'est donc pas instantané et résulte des réactions décrites par l'équipe de BARRET (5).

- Celles qui résultent de l'action de l'eau sur le Portland sont sous saturées par rapport à la courbe des hydrates hexagonaux  $\text{C}_4\text{AH}_{13}$  : le temps de prise est encore de quelques heures et correspond à la longueur de la période d'induction nécessaire pour précipiter les C-S-H et la portlandite.

- Les mélanges de ciments alumineux et Portland suivent l'un ou l'autre chemin, selon qu'il sont riches en l'un ou l'autre des constituants, sauf pour les proportions intermédiaires telles que les passages en solution de l'alumine du ciment alumineux et de la chaux du Portland ont des vitesses équivalentes. Dans ces conditions, le chemin suivi par la solution atteint très rapidement la courbe de précipitation des hydrates hexagonaux, vers le point M. La prise peut être alors rapide, et même instantanée. C'est d'ailleurs pour la même raison que  $\text{C}_{12}\text{A}_7$  et  $\text{C}_3\text{A}$  sont si actifs.

La nature des hydrates formés en fonction du temps est aussi intéressante à observer. Nous avons essayé de la schématiser dans la figure 3 où nous avons tracé les domaines d'existence des divers hydrates formés dans le diagramme : proportions des mélanges en abscisses - temps d'hydratation en ordonnées.

En première approximation, et si l'on considère la séquence des hydrates :  $\text{CAH}_{10} - \text{C}_2\text{AH}_8$ , nous pouvons dire que les hydrates deviennent d'autant plus riches en chaux, que pour une échéance donnée le mélange est plus riche en Portland, ou que pour un mélange donné l'échéance est plus grande. La première constatation est évidente ; la seconde provient du fait que les aluminates de calcium s'hydratent plus rapidement que les silicates, la proportion de ciment alumineux hydraté, pour un mélange donné, est d'autant plus élevée que le temps de réaction est plus court.

En réalité les phénomènes sont plus complexes, car il y a formation de grandes quantités du silico aluminat de calcium hydraté  $\text{C}_2\text{ASH}_8$  qui précipite dans un très large domaine, délimité par la courbe en tirets de la figure 3, lorsque les silicates s'hydratent en même temps que les aluminates.

## CONCLUSION

Le diagramme chaux-alumine-eau permet de bien rendre compte des débuts d'hydratation des mélanges ciments alumineux - clinker de Portland : en particulier il montre comment

les mélanges intermédiaires peuvent conduire à des prises promptes, et même des super raidissements, par précipitation immédiate d'aluminates de calcium hexagonaux.

Les phénomènes se compliquent évidemment si la partie silicate du mélange n'est plus un clinker broyé, mais un ciment gypsé : le sulfate de calcium apporte un certain nombre de paramètres supplémentaires liés à sa réactivité (semi hydra-

te - gypse - anhydrite - proportion et finesse), à celle du  $C_3A$  du ciment Portland (cubique - orthorhombique - finesse) et à la vitesse de passage en solution de la chaux (hydrolyse du  $C_3S$  - chaux libre).

Cependant le mode de raisonnement proposé reste aisément utilisable dans le cas des mélanges en diverses proportions d'un même ciment alumineux et d'un même ciment Portland.

FIG. 3 - Domaines d'existence des hydrates en fonction des proportions relatives Ciment Fondu - Clinker de Portland.  $C_2ASH_8$  est présent au dessus de la courbe en tirets

# Properties of Super Low Heat Cement concrete

## *Propriétés des bétons de ciment à très faible dégagement de chaleur*

T. GOTO, A. MATSUBARA, K. NAKANO, Japan.

**RESUME :** Avec l'accroissement des grandes structures en béton armé, la fissuration par contraintes thermiques du béton en masse soulève un problème.

Dans ces conditions, un ciment à très faible chaleur de réaction a été mis au point. Sa chaleur d'hydratation est d'environ 55 cal/g à l'âge de 28 jours, donc beaucoup plus faible que celle du ciment portland normal et même que celle du portland à dégagement de chaleur modéré, soit respectivement de 35 et 20 cal/g de moins.

La résistance et le retrait de ce béton de ciment sont semblables à ceux du béton de ciment portland normal ou à ceux du portland à dégagement de chaleur modéré; son essai de gel et dégel a donné un résultat favorable.

Ses propriétés thermiques aussi sont analogues à celles du béton usuel : coefficient de dilatation thermique de  $7 \text{ à } 9 \times 10^{-6}/^{\circ}\text{C}$ , conductivité thermique de 1.3 à 1.5 kcal/m.h. $^{\circ}\text{C}$ , chaleur spécifique de 0.22 à 0.28 kcal/kg $^{\circ}\text{C}$ , diffusibilité thermique de 0.0022 à 0.0026 m<sup>2</sup>/h. En outre, son élévation de température au calorimètre adiabatique est beaucoup plus faible que celle des bétons de ciment portland normal et de ciment portland à chaleur modérée pour un même rapport eau-ciment; soit respectivement de 8.8 $^{\circ}\text{C}$  et 8.4 $^{\circ}\text{C}$  en moins.

En utilisant ces données thermiques expérimentales, on calcule que la température maximale au coeur d'une masse de béton atteint celle mesurée au calorimètre adiabatique dès que l'épaisseur du béton dépasse 4 mètres. Pour une même épaisseur de béton, si l'on emploie ce nouveau ciment à très faible dégagement de chaleur, la température atteinte au coeur de la masse de béton est inférieure respectivement de 8 à 10 $^{\circ}\text{C}$  et de 4 à 8 $^{\circ}\text{C}$  à celle atteinte avec le ciment portland normal et le ciment portland à dégagement de chaleur modéré. Ce nouveau ciment est donc très efficace pour réduire l'élévation de la température dans une masse de béton.

**SUMMARY :** Increasing of large reinforced concrete structures, cracking caused by thermal stress has become a serious problem.

For reducing a heat of hydration, Super Low Heat Cement was developed. This cement has extremely low heat of hydration, that is, approximately 55 cal/g at age of 28 days, and it is about 35 and 20 cal/g lower than that of normal portland cement and moderate heat portland cement, respectively.

The strength, shrinkage and resistance to freezing and thawing of the concrete used this cement was about the same as the concrete used normal portland cement.

Thermal properties were also about the same range as the conventional concrete ; coefficient of thermal expansion:  $7 - 9 \times 10^{-6}/^{\circ}\text{C}$ , thermal conductivity: 1.3 - 1.5 kcal/m.h. $^{\circ}\text{C}$ , specific heat: 0.22 - 0.28 kcal/kg. $^{\circ}\text{C}$ , and thermal diffusivity: 0.0022 - 0.0026 m<sup>2</sup>/h. At the same water-cement ratio, adiabatic temperature rise of the Super Low Heat Cement concrete was 8.8  $^{\circ}\text{C}$  and 8.4  $^{\circ}\text{C}$  lower than that of normal portland cement and moderate heat portland cement concrete, respectively.

Using the measured thermal characteristic values, the prediction of temperature in mass concrete by numerical computation was carried out. According to the prediction, the maximum temperature rise in the Super Low Heat Cement concrete was 8 - 10  $^{\circ}\text{C}$  and 4 - 8  $^{\circ}\text{C}$  lower than those of normal and moderate heat portland cement concrete. It has become evident that use of this cement is very effective for reducing the temperature rise of mass concrete.

## INTRODUCTION

In recent year, large reinforced concrete structures have been increasing in Japan.

Such concretes for the structures have comparatively high cement contents, and therefore, thermally induced cracking become a serious problem because of high temperature rise in concrete by heat of hydration of cement.

To prevent such crackings, consideration must be given for mix proportion, practical and curing procedure. But it is a most important thing to use the cement which has satisfactorily low heat of hydration of cement.

For these requirements, Super Low Heat Cement was developed, and mainly consist of high early strength type portland cement clinker and high blaine blast furnace slag. This cement has approximately 55 cal/g of heat of hydration at age of 28 days. Compressive strength of this cement is about the same as that of normal portland cement.

In this report, test results of strength, shrinkage, resistance to freezing and thawing and thermal properties of the concrete using this cement, and the prediction of the temperature in the concrete by numerical computation were described.

## RESULTS AND DISCUSSION

## 1. Properties of Super Low Heat Cement

Chemical and physical properties of Super Low Heat Cement (S.L.H.C.), Normal Portland Cement (N.P.C.) and Moderate Heat Portland Cement (M.H.P.C.) are shown in Table-I, II.

Table - I Chemical Properties of Cements used

Type of Cement	lg. loss	insol	SiO <sub>2</sub>	Al <sub>2</sub> O <sub>3</sub>	Fe <sub>2</sub> O <sub>3</sub>	CaO	MgO	SO <sub>3</sub>	Total	Heat of hydration (cal/g)
										7D, 28D, 91D
S.L.H.C.	0.6	0.3	51.3	14.4	0.8	64.9	4.3	2.7	99.3	52.9 54.9 58.7
N.P.C.	0.5	0.3	22.1	5.2	3.2	64.4	3.6	2.0	99.1	81.8 89.3 92.7
M.H.P.C.	0.4	0.1	23.7	4.8	4.0	63.7	1.0	1.8	99.5	63.2 76.6 84.7

Table - II Physical Properties of Cement used

Type of Cement	Specific gravity	Specific surface (cm <sup>2</sup> /g)	Setting Time		Strength (kgf/cm <sup>2</sup> )					
			Initial	Final	Compressive			Flexural		
			h - m	h - m	3D	7D	28D	3D	7D	28D
S.L.H.C.	2.95	5,830	4 - 50	6 - 45	118	261	381	36	61	67
N.P.C.	3.17	3,170	2 - 35	3 - 45	134	232	408	32	52	78
M.H.P.C.	3.20	3,030	3 - 15	4 - 45	93	150	362	26	37	72

Fig.- 1 Characteristics of the Heat Liberation

As shown in Table-I, heat of hydration of S.L.H.C. is 60 and 70 percent or more of that of N.P.C. and M.H.P.C. at the age of 28 days, respectively. Heat of hydration at age of 7 days is 90 percent of that of age of 91 days. Result from heat of hydration test by conduction calorimeter shows that heat of hydration of aluminates at early stage of hydration is especially low (shown in Fig.-1), and the strengths of this cement is as same as that of N.P.C..

## 2. Properties of hardened S.L.H.C. concrete

Experiments of hardened concretes were carried out for several mixes shown in Table-III.

Table - III Mix Proportions of Concretes Tested

Mix	Slump (cm)	W/C (%)	Air (%)	S/A (%)	Unit Weight (kg/ m <sup>3</sup> )						A.E.A
					W	C	S	G	M.R.A		
S - 45	8.0±1.5	45	4.0±0.5	41	160	356	708	1079	0.89	0.042	
S - 55	8.0±1.5	55	4.0±0.5	43	159	289	789	1079	0.72	0.017

N - 65	8.0±1.5	65	4.0±0.5	42	165	254	757	1111	0.64	-	
M - 45	8.0±1.5	45	4.0±0.5	38	155	344	668	1159	0.86	-	
M - 55	8.0±1.5	55	4.0±0.5	40	156	284	722	1151	0.71	-	
M - 65	8.0±1.5	65	4.0±0.5	42	158	243	769	1129	0.61	-	

G<sub>max</sub>: 20 mm

S: S.L.H.C, N : N.P.C, M : M.H.P.C.

Aggregates used were sea sand (specific gravity: 2.54, finess modulus : 2.79) and crushed stone (specific gravity : 2.69, finess modulus : 6.72).

For concrete of these mixes, compressive, tensile, flexural strength, shrinkage, resistance to freezing and thawing and thermal properties were tested.

Strength test results and relations between compressive strength and cement water ratio are shown in Table-IV and Fig.-2, respectively. These results show that strength of S.L.H.C. concrete is the same or more of those of N.P.C. concrete.

Table - IV Results of Strength Tests

W/C (%)	Type of Cement	Compressive			Flexural			Tensile		
		7D	28D	91D	7D	28D	91D	7D	28D	91D
45	S.L.H.C.	-	426	486	-	72.9	74.2	-	35.2	44.9
	N.P.C.	318	420	468	52.7	58.4	62.8	28.9	34.1	36.1
	M.H.P.C.	259	444	512	39.9	54.7	66.8	20.5	30.3	36.2
55	S.L.H.C.	249	348	437	40.4	58.6	58.8	24.4	31.4	42.3
	N.P.C.	239	338	380	47.1	56.0	59.0	24.1	30.9	32.9
	M.H.P.C.	148	282	380	30.6	51.2	58.6	15.3	25.6	31.3
65	S.L.H.C.	-	287	331	-	66.3	74.3	-	27.9	34.4
	N.P.C.	152	215	289	32.1	45.4	49.6	15.1	21.4	25.4
	M.H.P.C.	85	190	285	23.1	44.8	55.2	8.4	20.2	26.6

Fig.- 2 Relation between Strength and C/W

Fig.- 3 Shrinkage of Several Concretes

As shown Fig.-3, shrinkage of S.L.H.C. concrete with 55 percent of water cement ratio is also about the same as that of N.P.C. concrete.

Freezing and thawing test was carried out for S-65 concrete according to ASTM C-666 B method, and there was little reduction of relative dynamic modulus of elasticity.

### 3. Thermal properties of S.L.H.C. concrete

Thermal properties-adiabatic temperature rise, coefficient of thermal expansion, thermal conductivity, specific heat and thermal diffusivity-were tested for S-45, 55, 65 (S.L.H.C. series), N-55 (N.P.C.) and M-55 (M.H.P.C.) concretes.

Test procedures used are;

#### (1) Coefficient of thermal expansion

Prism specimen (15x15x53 cm) in which mold strain gage (being able to measure temperature) was embedded, was immersed in the water cabinet in which temperature was able to control from 20°C to 70°C. At each temperature, strain and temperature in the concrete were measured.

#### (2) Thermal conductivity

Plate specimen (30x30x10 cm) heated one side of its surface up to a constant temperature at age of 14 days. When it reached to thermally steady state, thermal current density and surface temperature of opposite side was measured by the thermal current meter (Shotherm HFM, manufactured by SHOWA DENKO CO., LTD).

#### (3) Specific heat

Concrete pieces heated up to constant temperature put into the vacuum bottle including constant mass of water, and then temperature rise of water was measured.

#### (4) Adiabatic temperature rise

Mixed concrete was molded immediately, and temperature was measured continuously and automatically with adiabatic temperature rise testing apparatus from just after molding to age of 7 days.

#### (5) Thermal diffusivity

Thermal diffusivity was calculated by thermal conductivity, specific heat and density of concrete measured in this test.

The thermal properties are shown in Table-V, and show that coefficient of thermal expansion, thermal conductivity, thermal diffusivity and specific heat of S.L.H.C. concretes are equivalent to those of N.P.C. or M.H.P.C. concretes.

Table - V Thermal Properties of Concretes

Kind of Concrete	Coefficient of thermal expansion ( $\times 10^{-6}/^{\circ}\text{C}$ )	Thermal conductivity ( $\text{kcal}/\text{m.h.}^{\circ}\text{C}$ )	Specific heat ( $\text{kcal}/\text{kg.}^{\circ}\text{C}$ )	Adiabatic temperature rise $T_{\text{max}}$	Thermal diffusivity $\alpha^*$	( $\text{m}^2/\text{h}$ )
S - 45	8.51	1.49	0.28	28.8	1.49	0.0022
S - 55	7.97	1.48	0.24	27.3	1.50	0.0026
S - 65	7.73	1.39	0.22	26.2	1.52	0.0026
N - 55	9.89	1.48	0.28	36.1	1.08	0.0023
M - 55	9.44	1.39	0.28	35.7	0.60	0.0021

\*S-45, S-55, S-65;  $T = T_{\text{max}}(1 - (1 + \alpha t)e^{-\alpha t})$ , N-55, M-55;  $T = T_{\text{max}}(1 - e^{-\alpha t})$

Fig.-4 Adiabatic Temperature Rise of Concrete

Adiabatic temperature rise (shown in Fig.-4) of S.L.H.C. concretes are very low till 8 hours and after 3 days reaches to nearly maximum temperature, but maximum temperature is very low. Temperature rise curves of S.L.H.C. series are clearly different from those of N.P.C. and M.H.P.C..

On fitting these curves to the formula, curves of N.P.C. and M.H.P.C. concrete fit well to the following formula;

$$T = T_{\text{max}}(1 - e^{-\alpha t})$$

where  $T$  : temp. rise ( $^{\circ}\text{C}$ ),  $t$  : age (days)

$T_{\text{max}}$  : experimental constant

But curves of S.L.H.C. concretes fit well to the formula,  $T = T_{\text{max}}(1 - (1 + \alpha t)e^{-\alpha t})$ . From these experimental formulas,  $T_{\text{max}}$  of S.L.H.C. concretes are about 8  $^{\circ}\text{C}$  lower than those of N.P.C. and M.H.P.C.

Relation between  $T_{\text{max}}$  and cement content of concrete can be expressed as  $T_{\text{max}} = 11.1 \log C$ , in this test, and when the mix proportion of S.L.H.C. concrete is determined, the maximum temperature rise can be predicted.

#### 4. Prediction of temperature in the concrete mats

The maximum temperature rise in concrete were calculated, using the thermal characteristic values obtained in this test, by Schmidt's method on the unsteady state heat transfer. Relationship between the maximum temperature in concrete and depth of mat concrete is discussed.

Boundary conditions were assumed as follow, (1) at the boundary between concrete and air, thermal thickness of the concrete increased by 0.15 m, (2) at the boundary between concrete and foundation, temperature rise in the concrete was as half as adiabatic temperature rise. Adiabatic temperature rise was obtained from experimental formula and the constants

are shown in Table-V.

Fig.- 5 Relation between Maximum Temperature and Depth of the Concrete Mat

Results are shown in Fig.-5. When the depth of concretes become over 4 m, maximum temperatures are equivalent to  $T_{max}$  of adiabatic temperature rises. And the time required to reach the maximum temperature increases proportional to the depth, but is different some degree to the cement used. In M-55 concrete, the time tend to be longer than others. In either case, when the depth become over 4 m, the time becomes constant. As depth of concrete is over 1 m, maximum temperature in S-55 concrete will be 8 - 10 and 4 - 8 °C lower than in N-55 and M-55 concrete, respectively.

#### CONCLUSION

Properties of the concrete used Super Low Heat Cement developed newly were investigated, and the temperatures in concrete were calculated, using the thermal characteristic values obtained in this test, by Schmidt's method on unsteady state heat transfer. Relationships between the maximum temperatures in the concretes and depth of the concrete mats were discussed.

From these results the following conclusions can be drawn on Super Low Heat Cement concrete.

1. Strength and shrinkage of the concrete are equivalent to those used Normal Portland Cement.
2. The concrete is durable to freezing and thawing.
3. Thermal properties of concretes are about the same as conventional concretes; coefficient of thermal expansion:  $7 - 9 \times 10^{-6}/^{\circ}\text{C}$ , thermal conductivity: 1.3 - 1.5 kcal/m·h·°C, specific heat: 0.22 - 0.28 kcal/kg·°C, and thermal diffusivity: 0.0022 - 0.0026  $\text{m}^2/\text{h}$ .
4. Adiabatic temperature rise of the concrete is 8.8 °C and 8.4 °C lower than that using normal and moderate heat portland cement, respectively.
5. Calculated temperature rises in the concrete mats are 4 - 10 °C lower than conventional concretes.

# Solubilité dans l'eau de Ca et $\text{CAH}_{10}$ partiellement déshydraté

## *Solubility of CA and partially dehydrated $\text{CAH}_{10}$ in water*

P. BARRET, Professeur à l'Université de Dijon, Directeur du L.A. 23 (Réactivité des Solides)  
Ph. DUFOUR, Docteur en Chimie Physique, Ingénieur de Recherche (L.A. 23). France

RESUME : La solution obtenue à 21°C à partir de CA monoclinique reste métastable assez longtemps ( $t > 20\text{h}$ ) pour qu'il soit possible d'analyser sa composition :  $[\text{CaO}] \approx 20 \cdot 10^{-3} \text{ mol.kg}^{-1}$ ,  $\text{C/A} \approx 1,06$ . On montre que cette solubilité est atteinte et même dépassée par  $\text{CAH}_{10}$  déshydraté sous vide entre 70°C et 900°C, domaine dans lequel  $\text{CAH}_{10}$  subit une détérioration progressive de sa cristallinité et devient amorphe, se comportant alors comme une variété allotropique de CA. Le fait que  $\text{CAH}_{10}$  déshydraté amorphe fasse preuve d'une telle solubilité prouve que son éventuelle réhydratation directe au contact de l'eau est bien moins rapide que son passage en solution.

Cependant, cette solubilité, aussi bien que celle de CA est très inférieure à celle que l'on peut prévoir thermodynamiquement en utilisant les enthalpies libres de référence des partenaires de la réaction de dissolution. L'explication qui est ici proposée est celle de l'intervention d'une étape cinétique d'hydroxylation superficielle de la phase CA anhydre ou déshydratée, par interaction directe avec l'eau liquide. Cette étape précède le transfert en solution des ions de la surface du solide et l'on établit qu'elle participe, par son renouvellement, à une part importante de l'hydratation en même temps qu'elle contribue à plus de la moitié de l'abaissement de l'enthalpie libre dans le passage de CA à  $\text{CAH}_{10}$ . Il convient donc de ne pas confondre hydratation et précipitation des hydrates.

Les solutions données par  $\text{CAH}_{10}$  déshydraté amorphe laissent précipiter  $\text{CAH}_{10}$  comme celles données par CA, mais avec une cinétique différente d'où la possibilité de propriétés hydrauliques. Toutefois, celles-ci ne se manifestent pas par un durcissement de  $\text{CAH}_{10}$  déshydraté gâché en pâte sans doute en raison de sa grande surface BET. En revanche le durcissement a lieu si la température de déshydratation a dépassé 930°C, température à laquelle la recristallisation de CA est décelée. La mise en évidence par diffraction et microscopie électroniques à haute résolution de domaines distincts recristallisés comme des parties d'un même monocristal de CA suggère que la matrice amorphe, bien que désorganisée, conserve de la structure de  $\text{CAH}_{10}$  un souvenir suffisant pour induire une telle orientation commune.

SUMMARY : The solution obtained, at 21°C, from monoclinic CA remained metastable for a rather long time ( $t > 20\text{hr}$ ) so that it was possible to study its composition :  $[\text{CaO}] \approx 20 \cdot 10^{-3} \text{ mol.kg}^{-1}$ ,  $\text{C/A} \approx 1.06$ . It was shown that this solubility was reached and even exceeded by  $\text{CAH}_{10}$  dehydrated under vacuum between 70°C and 900°C, range in which  $\text{CAH}_{10}$  undergoes a gradual deterioration in crystallinity and becomes amorphous, then behaving like an allotropic variety of CA. The fact that amorphous dehydrated  $\text{CAH}_{10}$  shows such a solubility proves that its possible rehydration on contact with water is less rapid than its passage in solution.

However, this solubility and that of CA as well is much less than may be thermodynamically predicted by using the reference free enthalpies of the components of dissolution. The explanation below is that of the occurrence of a kinetic step of surface hydroxylation of the anhydrous or dehydrated CA anhydrous phase, through direct interaction with liquid water. This step occurs before the transfer into solution of solid surface ions and it is established that it participates, being renewed, largely to hydration while it contributes to half of the decline of the free enthalpy in the conversion from CA to  $\text{CAH}_{10}$ . Thus, hydration and precipitation of hydrates should not be mistaken.

The solutions resulting from amorphous dehydrated  $\text{CAH}_{10}$  cause  $\text{CAH}_{10}$  to precipitate like those resulting from CA but with a different kinetics hence possible hydraulic properties. However, the latter are not shown by hardening of dehydrated  $\text{CAH}_{10}$  as a paste possibly due its large BET surface. Alternatively hardening occurs if the dehydration temperature is above 930°C, temperature at which recrystallisation of CA is detected. Detection by high-resolution, electron microscope and diffraction of distinct recrystallised domains as parts of the same CA crystal suggests that the amorphous matrix, although it is disorganized, keeps a sufficient picture from the structure of  $\text{CAH}_{10}$  to induce such a common orientation.

## INTRODUCTION

Le durcissement des ciments alumineux est attribué au fait que leur principal constituant, l'aluminate monocalcique CA, donne une solution sursaturée par rapport aux différents hydrates : hydroxyde d'aluminium et aluminates de calcium hydratés ; ces phases apparaissent alors par précipitation conformément au mécanisme proposé dès 1887 par H. Le Chatelier (1).

Il est bien connu que les solutions aqueuses de CA pur atteignent à 21°C des concentrations telles que  $\text{CaO} : 19,8 \cdot 10^{-3} \text{ mol.kg}^{-1}$ ,  $\text{Al}_2\text{O}_3 : 18,6 \cdot 10^{-3} \text{ mol.kg}^{-1}$  (rapport C/A = 1,06). Après une période d'induction d'une vingtaine d'heures, ces solutions laissent précipiter notamment  $\text{CAH}_{10}$ , qui retiendra particulièrement notre attention, du fait que dans cet hydrate, le rapport C/A est le même que dans l'aluminate anhydre monoclinique CA, bien que la structure soit différente (une récente publication de Taylor et col. (2) considère cette phase comme appartenant au système hexagonal).

Or, nous avons observé expérimentalement que la déshydratation sous vide à relativement basse température (moins de 100°C) de  $\text{CAH}_{10}$  lui confère une solubilité en chaux et en alumine du même ordre de grandeur que celle de CA et que la solution obtenue laisse à son tour précipiter  $\text{CAH}_{10}$ . Le produit déshydraté doué de cette propriété apparaît d'ailleurs "amorphe" par diffraction X et électronique.

Ce problème de solubilité nous a donc paru intéressant à étudier ; la première hypothèse venant à l'esprit est que de petits germes de CA monoclinique doivent se former lors de la déshydratation de  $\text{CAH}_{10}$  à basse température. Les expériences que nous allons décrire n'ont pas confirmé cette hypothèse et c'est ce qui nous a amenés à reconsidérer le problème de la solubilité des phases partiellement déshydratées et anhydres d'un point de vue plus général.

Dès 1961, l'un de nous (3) avait entrepris avec F. Lavanant (4) l'étude de la déshydratation thermique des aluminates de calcium hydratés en mettant pour cela au point la thermogravimétrie (TG) sous pression de vapeur d'eau contrôlée, soit en isotherme, soit en température programmée avec une vitesse de montée linéaire aussi faible que 0,5 deg.heure<sup>-1</sup>. Mais le problème de la solubilité des phases déshydratées n'avait pas alors été abordé. Des ondulations reproductibles avaient été mises en évidence sur la courbe de TG de  $\text{CAH}_{10}$ , mais aucun palier caractéristique d'un hydrate intermédiaire stoechiométriquement défini n'avait été décelé. Les autres observations liées à la déshydratation, de l'ambiante à 180°C,

sous  $P_{\text{H}_2\text{O}} = 1,6 \cdot 10^{-3} \text{ N.mm}^{-2}$  étaient : a) la diminution progressive de l'intensité des raies de diffraction X jusqu'à leur disparition quasi totale pour H/A = 4, le produit déshydraté devenant "amorphe", b) la possibilité jusqu'à cette limite d'une réhydratation au contact de la vapeur d'eau, le spectre de diffraction X réapparaissant, mais avec un assez grand retard par rapport à la fixation pondérale de l'eau, c) l'accroissement considérable de la surface spécifique passant de 39 m<sup>2</sup>.g<sup>-1</sup> pour H/A = 6 à 128 m<sup>2</sup>.g<sup>-1</sup> pour H/A = 0,5, d) le caractère moléculaire de l'eau liée jusqu'à au moins H/A = 3,5 d'après le rapport d'hydrolyse du diborane.

Ces résultats confirmaient et complétaient les conclusions de travaux antérieurs, notamment ceux de Longuet (5), Schneider (6), Carlson (7) et Buttler (8).

## Etude expérimentale :

$\text{CAH}_{10}$  a été préparé suivant la méthode préconisée par Carlson (9) en agitant soit un ciment alumineux (Fondu Lafarge) soit du CA de synthèse dans de l'eau distillée décarbonatée à 1°C. Dans la gamme d'essais ici décrite et qui a eu un caractère essentiellement exploratoire, les échantillons de 3 g, étalés sur une nacelle de 9 cm<sup>2</sup> d'aire, ont été simplement déshydratés sous vide pendant 4 h, à une série de températures entre l'ambiante et 900°C. Les différentes observations ont été faites à partir de ces échantillons.

Pour affiner les recherches, de nouveaux essais sont actuellement en cours sur des échantillons déshydratés en thermobalance sous pression de vapeur d'eau contrôlée, afin de pouvoir faire la distinction entre le domaine où la déshydratation est réversible et celui où elle ne l'est plus.

Les échantillons de produit déshydraté à différentes températures ont été soumis à un ensemble de tests (10) : dissolution dans l'eau et étude cinétique d'évolution des mélanges solide-liquide et des filtrats prélevés à la concentration maximale ; diffraction X et électronique ; recuits au four à différentes températures ; échauffement sous l'impact du faisceau électronique et observations par diffraction et microscopie électronique à haute résolution ; spectrométrie IR ; analyse thermique différentielle (ATD) et mesure de la surface spécifique (BET).

## Résultats :

## - Essais de dissolution dans l'eau à 21°C :

Les échantillons préparés comme ci-dessus indiqués peuvent être caractérisés par deux données : la température de déshydratation sous vide  $\theta$ °C pendant une durée constante et le taux global de déshydratation  $\alpha$ , déterminé par perte au feu de l'eau liée résiduelle.

Chacun des échantillons a été soumis à l'essai de dissolution dans l'eau distillée décarbonatée avec un rapport pondéral liquide/solide :  $\ell/s = 20$ . Pour que les essais soient comparables, la vitesse de rotation de l'agitateur magnétique était soigneusement contrôlée.

La figure (1) rassemble à titre d'exemples quelques-unes des courbes obtenues.

Ces courbes comprennent une branche ascendante de forte pente, correspondant à une grande vitesse de dissolution. Les trois premières passent par un maximum supérieur à  $20 \cdot 10^{-3} \text{ mol.kg}^{-1}$  en CaO et  $\text{Al}_2\text{O}_3$ . Après ce maximum, elles présentent une brusque décroissance suivie d'une période de ralentissement puis d'une chute de concentration accélérée. La courbe obtenue après déshydratation à 930°C apparaît comme une limite des précédentes, le pseudo-palier ayant atteint sa longueur maximale (de l'ordre de 6 heures) ; mais la brusque décroissance initiale ne se manifeste plus après le maximum qui est légèrement inférieur à  $20 \cdot 10^{-3} \text{ mol.kg}^{-1}$  en CaO et  $\text{Al}_2\text{O}_3$ . La forme de cette dernière courbe rappelle celle de la courbe d'évolution classique de CA monoclinique pur de synthèse dans un rapport  $\ell/s = 20$  ; mais le temps nécessaire pour que les concentrations maximales soient atteintes est beaucoup plus court (moins de 1 heure au lieu de 4).

Le précipité obtenu dans les essais d'évolution des mélanges eau-produit de déshydratation de  $\text{CAH}_{10}$  à  $\theta < 900^\circ\text{C}$ , analysé par diffraction X, s'est avéré essentiellement formé de  $\text{CAH}_{10}$  accompagné, en fin de précipitation, d'une faible proportion de  $\text{C}_4\text{AH}_{13}$  et de

Fig. 1 - Evolution dans l'eau, dans un rapport pondéral  $L/s = 20$  du produit déshydraté à différents taux de déshydratation  $\alpha$  de  $CAH_{10}$  aux températures suivantes :  $\Delta$  90°C ( $\alpha = 0,74$ ) ;  $\blacksquare$  160°C ( $\alpha = 0,86$ ) ;  $\circ$  870°C ( $\alpha = 0,96$ ) ;  $*$  930°C ( $\alpha = 1$ ) ; —  $CaO$  ; ----  $Al_2O_3$ .

carboaluminate en dépit des précautions prises pour protéger de  $CO_2$  le milieu expérimental. Dans le cas des expériences d'évolution de mélanges eau-produit déshydraté à  $\theta > 930^\circ C$ , le précipité était constitué de  $CAH_{10}$ ,  $C_2AH_8$  et de gel d'alumine. Il en était de même pour le précipité recueilli en fin d'évolution de filtrats prélevés à la concentration maximale des mélanges eau-produit déshydraté à  $\theta < 900^\circ C$ .

#### - Etude par diffraction X et électronique du produit déshydraté :

Lorsque la déshydratation sous vide de  $CAH_{10}$  est effectuée pendant d'égales durées (4 h) à des températures successives croissantes, on observe, comme dans les essais effectués en thermobalance sous pression de vapeur d'eau contrôlée, une détérioration progressive de la cristallinité jusqu'à environ  $110^\circ C$ . A  $80^\circ C$  par exemple, les raies de diffraction X à 14 et 7 Å disparaissent. Pour  $110 < \theta < 300^\circ C$  le produit de déshydratation apparaît comme "amorphe", présentant par diffraction X et électronique un anneau de diffusion correspondant à une périodicité de  $d \approx 2,9$  Å pour laquelle la plupart des aluminates de calcium anhydres ou hydratés donnent une raie intense (figure 2). Bien que la solubilité en  $CaO$  et  $Al_2O_3$  du produit déshydraté atteigne et même dépasse celle de  $CA$  monoclinique de synthèse, aucune raie de diffraction X ou électronique du spectre de cette phase n'apparaît ; cela permet de conclure à l'absence de germes de  $CA$ , à moins que leur taille soit inférieure à la longueur de cohérence des rayons X et des électrons.

En revanche, les raies caractéristiques du spectre de diffraction X et électronique de  $CA$  commencent à apparaître dans le produit déshydraté lorsque la déshydratation de  $CAH_{10}$  a été effectuée dans l'intervalle de température  $900^\circ C < \theta < 930^\circ C$ . (figure 2).

Les taches du spectre de diffraction électronique de  $CA$  monocristallin apparaissent également à partir du produit amorphe déshydraté à  $\theta < 900^\circ C$  si l'on augmente suffisamment l'énergie du faisceau incident pour

Fig. 2 - (1) Anneau de diffusion à  $d = 2,9$  Å du spectre de diffraction X du produit de déshydratation sous vide de  $CAH_{10}$  à  $\theta = 890^\circ C$ . (2) Raies de diffraction de  $CA$  apparaissant dès la température de déshydratation de  $\theta = 905^\circ C$ .

que, sous l'influence du flux d'électrons, la température de l'échantillon s'élève localement à plus de  $900^\circ C$ .

Par interférence du faisceau incident et du faisceau diffracté dans les directions qui correspondent à une ou deux taches du spectre, on met en évidence les familles de plans réticulaires responsables de ces diffractions.

Il est remarquable de constater (figure 3) : 1) que ces plans réticulaires appartiennent à plusieurs domaines monocristallins distincts et éloignés les uns des autres au sein de la matrice de produit déshydraté amorphe ; 2) que néanmoins, les familles de plans réticulaires homologues dans ces domaines sont toujours orientées parallèlement ; 3) que les distances entre leurs plans sont exactement égales à celles qui existent entre les plans de même direction dans la structure de  $CA$  monoclinique ; 4) que les franges d'interférences d'orientations différentes, données par des domaines cristallisés distincts et éloignés les uns des autres, peuvent être associées à différents plans  $h, k, l$  d'une même zone  $u, v, w$  du réseau de  $CA$  ; 5) qu'un amas amorphe se transforme toujours, sous le faisceau d'électrons suffisamment accélérés, en un monocristal de  $CA$ .

Dans certaines conditions où il est possible de faire apparaître des domaines cristallisés en  $C_5A_3$ , les mêmes règles s'appliquent.

#### - Etude par spectrométrie infrarouge du produit de déshydratation à diverses températures :

Dans l'intervalle :  $21 \leq \theta \leq 900^\circ C$ , la large bande d'absorption comprise entre 500 et  $800\text{ cm}^{-1}$  située dans le domaine de vibrations des  $Al-O$  diminue progressivement en fonction du taux de déshydratation à mesure que la température augmente, ce qui permet de l'attribuer à l'interaction de l'eau, agissant sur ces vibrations ; il en est de même pour les bandes de déformation de l'eau à  $1640\text{ cm}^{-1}$  et de valence  $OH^-$  à  $3500\text{ cm}^{-1}$  sans que le spectre n'accuse d'importantes

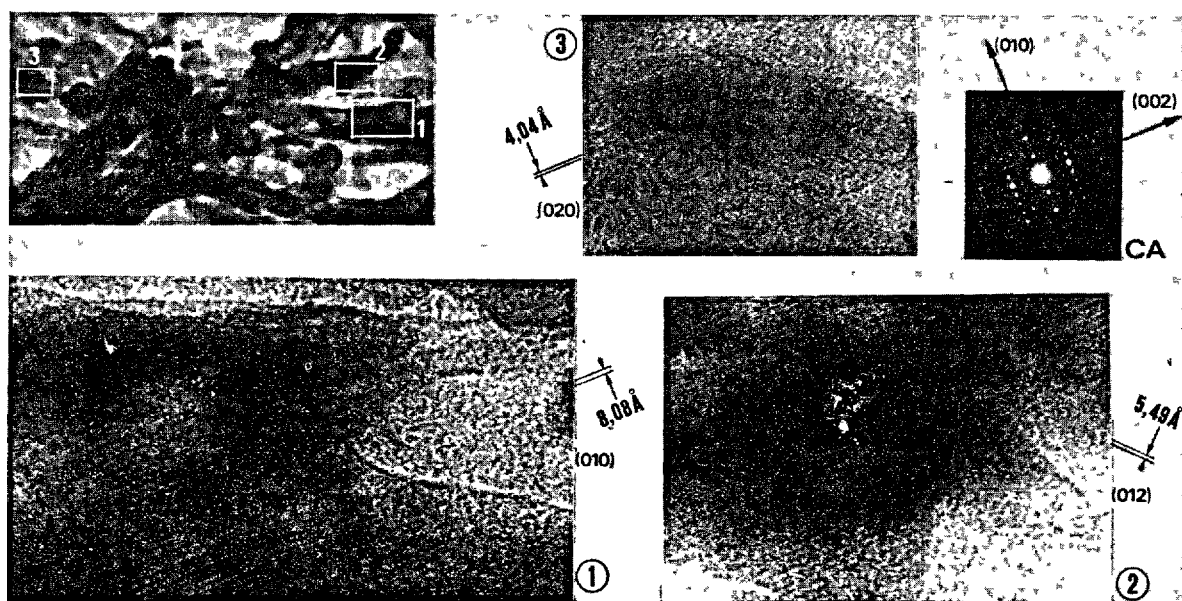

Fig. 3 - Familles de plans réticulaires homologues orientés parallèlement dans trois domaines monocristallins éloignés les uns des autres I, II et III au sein de la matrice amorphe du produit déshydraté. Les interférences correspondent aux directions (010) et (012) de CA.

modifications. Ce n'est qu'au-dessus de 900°C que celui-ci change brusquement d'aspect avec l'apparition des bandes de vibration entre 650 et 850  $\text{cm}^{-1}$ , caractéristiques des  $\text{AlO}_4$  dans  $\text{CaAl}_2\text{O}_4$  monoclinique (11). L'apparition de ce spectre coïncide donc avec celle des raies de diffraction X et du spectre de diffraction électronique de CA monoclinique, ainsi qu'avec l'apparition de la forme caractéristique de la courbe d'évolution de CA agité dans l'eau. Ces résultats sont en accord avec ceux obtenus en spectrométrie IR par Kondraszenkow et Zigun (12).

#### - Analyse thermique différentielle :

Les résultats sont également en bon accord avec ceux obtenus par ces auteurs, avec un pic endothermique à 139°C, encadré par deux épaulements, l'un à 107°C, l'autre à 263°C et un pic exothermique à 930°C. De légères variations de ces températures sont observées suivant le mode de préparation de l'échantillon.

#### - Variation de la surface spécifique en fonction de la température de déshydratation de $\text{CAH}_{10}$ :

L'étude de la variation de la surface BET au krypton du produit de déshydratation donne des résultats en bon accord avec ceux obtenus avec F. Lavanant avec l'azote (4) et également avec ceux des techniques précédentes. Au cours de l'amorphisation, la surface spécifique passe de 40  $\text{m}^2.\text{g}^{-1}$  environ à 140  $\text{m}^2.\text{g}^{-1}$  lorsque la température de déshydratation sous vide atteint 100°C. Mais une particularité qui demande à être confirmée par l'emploi d'autres gaz est l'apparition de minima dans la courbe de variation de la surface spécifique en fonction de la température de déshydratation, correspondant aux températures des pics et épaulements endo et exothermiques relevés en ATD. Si une telle particularité est aisément explicable pour le point à 930°C, en raison de la cristalli-

sation de CA, une interprétation physique ne peut être aisément donnée pour les points à plus basse température.

#### - Essais de durcissement des pâtes :

La formation d'une solution à plus de  $20.10^{-3} \text{ mol.kg}^{-1}$  en CaO et  $\text{Al}_2\text{O}_3$  à partir des échantillons de  $\text{CAH}_{10}$  déshydraté entre l'ambiante et 900°C et la précipitation de  $\text{CAH}_{10}$  de cette solution laissent supposer que ces échantillons déshydratés gâchés en pâte seraient susceptibles de durcir. Cependant, les essais se sont révélés négatifs : des échantillons déshydratés sous vide à diverses températures entre l'ambiante et 900°C demeurent friables, même plus de 48 heures après gâchage et n'offrent aucune résistance. En revanche, les échantillons déshydratés au-dessus de 930°C, dans lesquels la recristallisation en CA monoclinique s'est produite, donnent lieu à une prise et un durcissement normaux. Le critère de dissolution à  $20.10^{-3} \text{ mol.kg}^{-1}$  suivi de la précipitation de  $\text{CAH}_{10}$  apparaît donc comme une condition nécessaire, mais non suffisante de l'existence de propriétés hydrauliques dans le produit de déshydratation.

#### DISCUSSION

Comment interpréter les observations expérimentales qui paraissent converger vers la description suivante des phénomènes :

Le produit amorphe de déshydratation sous vide de  $\text{CAH}_{10}$  à  $\theta < 900^\circ\text{C}$  retrouve une solubilité comparable et même supérieure en CaO et  $\text{Al}_2\text{O}_3$  à celle de CA monoclinique obtenu à  $\theta \approx 1630^\circ\text{C}$ , bien que, dans ce domaine de températures, aucun germe de CA monoclinique n'ait pu être mis en évidence. D'autre part, quatre faits militent en faveur de l'idée de la conservation par la phase déshydratée amorphe, du souvenir de la

structure de  $\text{CAH}_{10}$  en dépit de sa désorganisation :

- L'amorçage d'autant plus rapide de la précipitation de  $\text{CAH}_{10}$  à partir de la solution aqueuse du produit déshydraté que le taux et donc la température de déshydratation ont été plus faibles.
- La cristallisation de domaines amorphes éloignés les uns des autres en des parties d'un même monocristal de CA, ce qui laisse supposer que leur cristallisation a été induite par une matrice ayant elle-même conservé les caractères d'un monocristal de  $\text{CAH}_{10}$ .
- La diminution progressive en fonction de la température de déshydratation de l'intensité des bandes d'absorption infrarouge sans importantes modifications du spectre jusqu'à  $900^\circ\text{C}$  et le brusque changement de celui-ci survenant à cette température avec l'apparition des bandes d'absorption de CA monoclinique.
- L'affaiblissement des raies de diffraction X de  $\text{CAH}_{10}$  sans aucun déplacement notable, quand le rapport H/A passe de 10 à 4 en même temps que l'augmentation de surface spécifique et la réversibilité de cette transformation par recombinaison de la vapeur d'eau.

Il paraît donc logique d'admettre que le départ de l'eau laisse un solide lacunaire qui, bien que désorganisé et fragmenté, ne subit pas de réarrangement en un nouvel édifice de structure différente tant que la température ne dépasse pas  $900^\circ\text{C}$ .

Ce point de vue paraît correspondre à celui exprimé par Buttler et Taylor dans une récente publication (2) : la détérioration croissante de la cristallinité lorsque le rapport H/A tombe au-dessous de 4 peut être attribué au fait que le départ de molécules d'eau supplémentaires peut seulement intervenir par déshydroxylation qui détruit nécessairement les anions hydroxoaluminates, soit :

Le réarrangement structural au-dessus de  $900^\circ\text{C}$  peut être représenté en éléments de structure par :

Mais comment peut-on expliquer, en l'absence de germes de CA, l'accroissement de solubilité de la phase amorphe en fonction de son taux de déshydratation, dans le domaine de  $\theta < 900^\circ\text{C}$  ?

Il est facile de prévoir par un calcul thermodynamique le sens de la variation de solubilité dans le passage de la phase cristallisée CA à la phase totalement déshydratée amorphe, si l'on admet de considérer celle-ci comme une variété métastable de CA. Lors de ce passage, l'accroissement d'enthalpie libre est :

$\Delta G_t^0 = \Delta G_a^0 - \Delta G_c^0$  où  $\Delta G_a^0$  et  $\Delta G_c^0$  sont les enthalpies libres de formation de la variété amorphe et de la variété cristallisée.

Le passage en solution de l'une ou l'autre de ces variétés est représenté par l'équation :

Soit  $\Delta G_1^0$  ou  $\Delta G_2^0$  l'enthalpie libre normale de cette transformation selon que  $\text{CaAl}_2\text{O}_4$  est la variété amorphe ou la variété cristallisée.  $\Delta G_2^0$  peut être obtenu à partir des données du tableau I.

$\Delta G_t^0$  est généralement petit, par exemple  $\Delta G_t^0 = 4,1 \text{ KJ.mol}^{-1}$  dans la transformation  $\text{SiO}_2$  vitreuse - tri-

dymite IV ;  $1,1 \text{ KJ.mol}^{-1}$  dans celle de l'aragonite en calcite.

A l'équilibre avec la solution, si l'on suppose une dissolution congruente de  $\text{CaAl}_2\text{O}_4$ , le produit  $xy^\pm$  de la concentration molaire massique des ions calcium par le coefficient d'activité est donné par :

$$xy^\pm = \left(\frac{K}{4}\right)^{1/3} \quad (4)$$

TABLEAU I				
	$\text{CaAl}_2\text{O}_4$	$[\text{Al}(\text{OH})_4]_{\text{aq}}^-$	$\text{Ca}_{\text{aq}}^{2+}$	$\text{H}_2\text{O}_l$
$\Delta G_{298}^0$ $\text{KJ.mol}^{-1}$	- 2206,62	- 1293,25	- 552,51	- 236,96

expression qui provient de la loi d'action de masse avec  $y = 2x$  ;  $y$  étant la concentration molaire massique des ions aluminates.

Il y aura deux valeurs  $K_1$  et  $K_2$  de la constante  $K$  correspondant à  $\Delta G_1^0$  et  $\Delta G_2^0$ .

Le sens de la variation de solubilité  $\delta(xy^\pm)$  pour une petite variation de  $\Delta G_2^0$  :  $\delta(\Delta G_2^0) = \Delta G_t^0$  s'obtient facilement au moyen de l'équation :

$$\delta(xy^\pm) = -0,210 \frac{\delta(\Delta G_2^0)}{RT} \exp \left[ -\frac{\Delta G_t^0}{3RT} \right] \quad (5)$$

Par exemple pour  $\Delta G_t^0 = -1 \text{ KJ}$ ,  $\delta(xy^\pm) = 0,0106 \text{ mol.kg}^{-1}$

Il y a donc accroissement de la solubilité en passant de la variété anhydre cristallisée à la variété déshydratée amorphe. Ainsi, on comprend que la déshydratation de  $\text{CAH}_{10}$  ait pu faire passer sa solubilité dans l'eau de quelques millimoles. $\text{kg}^{-1}$  à une valeur supérieure à la solubilité de CA monoclinique, soit plus de  $20.10^{-3} \text{ mol.kg}^{-1}$ .

Le calcul de  $xy^\pm$  à partir de l'équation (4) et des données du tableau I dans la même hypothèse  $\Delta G_t^0 = -1 \text{ KJ}$  donne :

$$(xy^\pm)_1 = 0,090 \text{ mol.kg}^{-1}$$

$$(xy^\pm)_2 = 0,078 \text{ mol.kg}^{-1} \quad (\delta = 0,012 \text{ mol.kg}^{-1})$$

mais pour pousser plus loin le calcul de la solubilité  $S = x$ , il faudrait exprimer  $y^\pm$  au moyen de la formule complète de Debye et Hückel. Si  $y^\pm \ll 1$ , les valeurs de  $S_1$  et  $S_2$  seront très grandes et en tout cas très supérieures à la valeur d'environ  $20.10^{-3} \text{ mol.kg}^{-1}$  habituellement observée.

Cette constatation ne semble ni fortuite, ni contingente aux incertitudes sur les données thermochimiques. En effet, nous avons vérifié que le calcul à partir des  $\Delta G^0$  de formation des constituants conduit à des valeurs de la solubilité généralement beaucoup plus élevées que celles qui sont observées ou admises, c'est le cas notamment pour  $\text{C}_3\text{S}$  et  $\text{C}_3\text{A}$ , d'après Stein (13).

Nous proposons une explication à de tels écarts (14) en partant de l'hypothèse d'une hydroxylation superficielle des phases anhydres ou déshydratées par interaction interfaciale directe avec les molécules d'eau. C'est alors la couche superficielle hydroxylée qui se dissout et non la phase solide anhydre. Il faut bien comprendre que l'hydroxylation superficielle est une étape cinétique et qu'elle est constamment renouvelée à mesure que les anions hydroxylés et les cations passent en solution.

A partir de ce postulat, les variations d'enthalpie libre  $\Delta G'$  et  $\Delta G''$  accompagnant respectivement le passage de l'anhydride CA à l'état superficiellement hydroxylé  $CA_{sh}$  et de celui-ci à  $CAH_{10}$  peuvent être calculées de deux façons différentes, en prenant comme référence la composition de la solution : a) en équilibre avec  $CA_{sh}$ , b) en équilibre avec  $CAH_{10}$ . Au point de vue dynamique, le cas a) correspond à la période d'induction de la solution métastable en quasi-équilibre avec  $CA_{sh}$  et dont la composition n'est pas changée par la formation des germes de  $CAH_{10}$  ; le cas b) correspond à la fin de la précipitation où la vitesse de croissance des germes est très grande de sorte que la solution est en quasi-équilibre avec  $CAH_{10}$  ; la dissolution de  $CA_{sh}$  ne change pas sa composition.

Les valeurs calculées sont approximativement les mêmes dans les deux cas, c'est pourquoi nous ne développerons ici que le premier mode de calcul a) :

Les réactions qui entrent en jeu sont :

I) Formation de l'état superficiellement hydroxylé :

II) Passage en solution de  $CA_{sh}$  :

III) Précipitation de  $CAH_{10}$  :

IV) Formation de gel d'alumine :

Dans le cas a)  $\Delta G_{II} = 0$  et  $\Delta G' = \Delta G_I$ . C'est équivalent d'écrire  $\Delta G' = \Delta G_I + \Delta G_{II} = \Delta G_{(I+II)}$ . Or la somme des équations I et II est l'équation (3). Par suite :  $\Delta G' = \Delta G^0 + RT \log_e xy^2 (\gamma^{\pm})^3$  avec  $\Delta G^0 = \Delta G_I^0$

ou  $\Delta G_2^0$  suivant que le solide de départ est le produit de déshydratation de  $CAH_{10}$  ou CA.

Les valeurs de x et y à introduire dans le calcul sont celles données au début pour la solution métastable à C/A = 1,06, mais y = 2[A]. Donc x =  $19,8 \cdot 10^{-3}$  mol.kg<sup>-1</sup>, y =  $37,2 \cdot 10^{-3}$  mol.kg<sup>-1</sup>. L'équation IV n'intervient que pour justifier le fait que C/A > 1, car lorsque C/A = 1,  $\Delta G_{IV} = -\infty$ .

Avec  $\Delta G_2^0 = 15,45$  KJ et en utilisant la formule simplifiée de Debye et Hückel :  $\gamma^{\pm} = 10^{-1,746\sqrt{x}}$  on obtient  $\Delta G' = -14,767$  KJ.

Ici  $\Delta G'' = \Delta G_{III}$  ; cette valeur changée de signe est l'affinité chimique de précipitation de  $CAH_{10}$  ; notons que dans le cas b), on aurait  $\Delta G'' = \Delta G_{II}$  dont la valeur changée de signe serait l'affinité chimique de dissolution de  $CA_{sh}$ .

En revenant au cas a)  $\Delta G'' = \Delta G_{III}^0 - RT \log_e xy^2 \cdot 10^{-3(1,746\sqrt{x})}$

A partir de la courbe expérimentale de solubilité de  $CAH_{10}$  sur le diagramme chaux-alumine-eau, on calcule :  $\Delta G_{III}^0 = -42,572$  KJ. Avec les mêmes valeurs de x et y que pour le calcul de  $\Delta G'$ , on obtient  $\Delta G'' = -12,355$  KJ. La diminution totale d'enthalpie libre  $\Delta G = \Delta G' + \Delta G'' = -27,122$  KJ correspond au passage de CA à  $CAH_{10}$  au contact d'une solution en équilibre avec  $CA_{sh}$ . Ainsi, l'hydroxylation superficielle représente une part importante du processus d'hydratation puisqu'elle entraîne la fixation de  $4H_2O$  sur 10 et qu'elle abaisse l'enthalpie libre de plus de la moitié de  $\Delta G$ .

## CONCLUSIONS

Hydratation et prise ne doivent donc pas être confondues, une partie de l'hydratation, énergétiquement la plus importante, ne servant qu'à préparer par interaction solide-liquide les espèces aptes à se dissoudre, alors que la prise est due à la précipitation des hydrates à partir de la solution ainsi produite. La déshydratation de  $CAH_{10}$  offre un bon exemple de réaction donnant un solide lacunaire non réorganisé qui, bien qu'amorphe, conserve de la structure initiale un souvenir suffisant pour orienter la cristallisation de domaines séparés en un monocristal de CA. Ce solide amorphe se comporte comme une variété plus soluble même que CA, mais qui en pâte ne durcit pas, peut être en raison de sa grande surface spécifique, alors que sa solution laisse précipiter les aluminates hydratés caractéristiques des propriétés hydrauliques.

# Méthode de modification des caractéristiques des ciments au moyen des adjuvants

## *Method for characteristics modification of cements by means of admixtures*

Y.T. SIMEONOV, Professeur, Docteur-Ingénieur et

N.B. DJABAROV, Docteur-Ingénieur, Laboratoire Central de Mécanique Physico-Chimique, Académie Bulgare des Sciences, Sofia, Bulgarie.

**RESUME :** Une nouvelle méthode de modification des caractéristiques des ciments au moyen des adjuvants complexes a été récemment développée. Cette méthode consiste en une action visant un effet physico-chimique bien défini sur la formation de la structure, les propriétés mécaniques des hydrates et leur quantité dans le ciment durcis.

En résultat le durcissement des ciments réels, produits en cimenterie, s'accélère considérablement et leurs résistances mécaniques s'accroissent pendant la période initiale 2 à 7 fois selon le type du ciment. A l'âge de 28 jours et plus tard la résistance des ciments modifiés à l'aide des adjuvants s'accroît constamment et surpasse celle des ciments non modifiés.

Par la méthode en question, qui a une application bien simple, grace aux adjuvants complexes, le ciment portland rapide se transforme en un ciment super-rapide, le ciment portland normal - en ciment portland rapide, les ciments du durcissement lent, comme par exemple le ciment à laitier de haut-fourneau - en ciment à durcissement et résistance normaux comme le ciment portland de haute qualité.

Les bétons à base de ces ciments modifiés accélèrent considérablement leur durcissement et augmentent leurs résistances mécaniques aussi. Le résultat est un effet technique et économique bien établi.

**SUMMARY :** A new method for characteristics modification of cements by means of complex admixtures was recently developed. This method consist of an action aiming a well defined physico-chemical effect on the structure formation, mechanical properties of hydrates and their quantity in the hardened cement.

In result the hardening of genuine cements i. e. produced in the cement industry is considerably accelerated and their mechanical strengths are augmented in the initial period 2 to 7 times according to the cement typ. On the age of 28 days and later the strength of the modified by means of the admixtures cements is constantly increasing and surpasses this of the not modified cements.

By the method in question, with a quite simple application, due to the complex admixtures the rapid hardening portland cement is transformed in super rapid hardening cement, the ordinary portland cement in rapid hardening portland cement, the slowly hardening cements, as for example the slag cement - in normally hardening cement with strengths like the high quality portland cement.

The concretes with these modified cements are also considerably accelerating their hardening and are increasing their mechanical strengths. The result is a well expressed technical and economical effect.

Au Laboratoire Central de Mécanique Physico-Chimique de l'Académie Bulgare des Sciences a été récemment développée une nouvelle méthode d'accélération du durcissement des ciments au moyen des adjuvants complexes. Les adjuvants peuvent être introduits préalablement vers les ciments dans les cimenteries ou directement vers le béton a son malaxage.

Cette méthode consiste en une action visant un effet physico-chimique bien défini sur la formation de la structure, les propriétés mécaniques des hydrates et leur quantité dans le ciment durcis.

Dans la matrice du ciment en hydratation se forme l'hydrate de sulfoaluminate, qui rend la structure plus dense et joue la rôle de "microarmature". C'est pour cela que la composition des adjuvants complexes est choisie d'assurer tous les éléments nécessaires pour la formation d'ettringite supplémentaire indépendamment de la composition du ciment. Les adjuvants complexes contiennent des sels d'aluminium, des sulfates et de la chaux. A cause de la très haute activité des composants alumineux des adjuvants la formation d'ettringite a lieu dans le début du durcissement du ciment à la période où son effet pour améliorer la résistance mécanique est maximal.

Les études des hydrates en utilisant différentes techniques, comme l'analyse chimique, diffraction des rayons X, microscopie électronique à balayage, l'analyse thermique etc. prouvent que le ciment avec les nouveaux adjuvants contient beaucoup plus d'ettringite et manifeste aussi une hydratation des tous les minéraux du clinker plus avancée, comparé au même ciment, mais sans ces adjuvants. Sur les figures 1 à 4 sont données schématiquement des exemples d'analyse thermique. Les courbes d'analyse thermique différentielle (ATD), de thermogravimétrie différentielle (TGD) et de thermogravimétrie (TG) pour un ciment portland normal et pour un ciment à laitier de haut-fourneau avec ou sans l'adjuvant accélérateur

respectif, à l'âge d'un jour donnent une idée assez précise sur les changements considérables qui interviennent dans la quantité et la formation de la structure des hydrates sous l'influence des adjuvants.

Fig. 1 - Analyse thermique d'un ciment portland normal.

Fig. 2 - Analyse thermique d'un ciment portland normal + adjuvant accélérateur.

Les données expérimentales, d'ailleurs corroborées aussi par les autres analyses, confirment en général d'une manière quantitative la présence de produits d'hydratation similaires (certaines différences dans le degré de cristallisation), mais présentent de grandes différences quantitatives. L'effet prédominant, dû à l'ettringite, les effets des hydrosilicates et etc., montrent une

Fig. 3 - Analyse thermique d'un ciment à laitier de haut-fourneau.

Fig. 4 - Analyse thermique d'un ciment à laitier de haut-fourneau + adjuvant accélérant.

augmentation bien exprimée. Tandis que l'effet pour le portlandite est un peu diminué. Le déplacement des effets pour l'ettringite dans les ciments modifiés vers une température plus haute est une indication pour l'amélioration de la structure cristalline de cet hydrate sous l'influence des adjuvants. Au contraire les effets pour le portlandite dans les ciments avec adjuvants sont déplacés ordinairement vers une température plus basse. Sous l'influence des adjuvants les courbes TG montrent une augmentation bien exprimée de la quantité surtout de l'et -

tringite, mais aussi des hydrosilicates et d'autre produits hydratés, comme l'hydratation entière des ciments modifiés. Tandis que la quantité du portlandite est un peu diminuée.

En résultat le ciment acquiert l'accélération du durcissement cherchée, sans pratiquement de raccourcir le temps de prise. Sauf la grande amélioration des résistances mécaniques initiales les adjuvants complexes assurent aussi une liaison complète du plâtre ainsi qu'il ne rest libre, ce qui garantit une stabilité de volume du ciment durcis et excitent un accroissement des résistances mécaniques avec l'avancement du temps.

Pour montrer les possibilités d'accélérer le durcissement au moyen de la nouvelle méthode dans cette communication est fait un bref exposé sur l'augmentation des résistances mécaniques à différentes âges.

Plusieurs types du ciment portland sont choisis pour établir la plus grande universalité de la méthode. Son applicabilité pratique est témoignée par l'usage des clinkers réels, produisent en différentes cimenteries à Bulgarie et à l'étranger.

Les ciments portland de durcissement rapide sont notés en abrégé par CPR, CPR<sup>x</sup>, CPR<sup>xx</sup>, les ciments portland normaux par CPN, CPN<sup>x</sup>, CPN<sup>xx</sup> et les ciments à laitier de haut-fourneau - CIHF, CIHF<sup>x</sup>, CIHF<sup>xx</sup>.

Les propriétés mécaniques de ces trois ciments de chaque type sont examinées à la méthode standard recommandée par RILEM, ISO et Cembureau avec un mortier normalisé de ciment:sable = 1:3, avec un rapport E/C = 0,5 assurant une plasticité assez haute à l'ordre de 150 - 200 mm, établie par la méthode standard. Les résultats sont représentés au tableau I. Ils témoignent que les adjuvants complexes (AA) assurent pour tous les types des ciments une considérable accélération du durcissement.

Pour les ciments de type CPR la résistance mécanique initiale est 1,9 à 2 fois plus

TABLEAU I		
Type du ciment	Résistance à la compression, N/mm <sup>2</sup> , après jours	
	1	28
CPR	19,5	49,1
CPR+AA	36,7	60,4
CPR <sup>x</sup>	18,2	51,0
CPR <sup>x</sup> +AA	34,1	60,8
CPR <sup>xx</sup>	16,2	52,9
CPR <sup>xx</sup> +AA	32,2	68,4
CPN	12,7	49,2
CPN+AA	24,0	65,8
CPN <sup>x</sup>	12,6	48,7
CPN <sup>x</sup> +AA	23,4	56,4
CPN <sup>xx</sup>	8,9	41,1
CPN <sup>xx</sup> +AA	18,8	49,7
CIHF	1,7	37,5
CIHF+AA	12,5	49,4
CIHF <sup>x</sup>	2,4	33,4
CIHF <sup>x</sup> +AA	9,1	43,7
CIHF <sup>xx</sup>	3,0	39,1
CIHF <sup>xx</sup> +AA	5,9	47,4

haute, ce qui permet d'atteindre la production à la base d'un ciment portland rapide commercial d'un ciment portland super-rapide, ayant une résistance du premier jour très haute de 32 à 37 N/mm<sup>2</sup> (établie par la méthode standard plastique).

Les ciments CPN acquièrent les qualités des ciments CPR d'une haute qualité. La résistance initiale augmente de 1,9 à 2,1 fois atteignant 19 à 24 N/mm<sup>2</sup>, qui surpasse même celle du CPR, produit en cimenterie.

Les ciments à laitier de haut - fourneau, bien connues avec leurs durcissement lent, sous l'influence de l'adjuvant l'accélèrent de 2 à 7 fois et atteignent le durcissement et la résistance d'un CPN avec 6 à 13 N/mm<sup>2</sup> pour le premier jour.

A l'âge de 28 jours et plus tard la résistance mécanique des tous les types des ciments modifiés au moyen des adjuvants surpasse avec 7,7 à 16,6 N/mm<sup>2</sup> les résistances

des ciments non modifiés à la base desquels ils sont concus.

Les résultats expérimentaux témoignent la possibilité de transformer à l'aide des adjuvants complexes différents types des ciments portland à des ciments d'une classe supérieure, ce qui amène à un effet technique et économique bien exprimé.

Les études des ciments modifiés au moyen des adjuvants complexes en béton montrent qu'ils accélèrent considérablement son durcissement et augmentent sa résistance en bon corrélation avec les résultats obtenus en mortier normalisé. Cela assure la possibilité de réaliser plusieurs effets importants. On gagne de productivité en réduisant le temps nécessaire pour le démoulage du béton. Une économie de beaucoup d'énergie peut être réalisée en supprimant le traitement thermique du béton préfabriqué, ou bien en utilisant un traitement fortement raccourci et à une température plus basse. En employant le béton préchauffé sa température est préférable d'être aussi seulement de 30 à 50°C. Une température plus élevée n'est pas recommandable à cause de pouvoir mieux conserver l'ettringite, ce qui donne aussi un effet économique. La quantité du ciment pour la production d'un m<sup>3</sup> béton peut être fortement réduite. Au lieu du ciment de haute qualité et plus cher on peut utiliser un ciment de qualité et prix beaucoup plus bas.

Les adjuvants accélérants pour les différents types du ciment et leurs méthode d'emploi sont brevetés en plusieurs pays et déjà aux Etats Unis, Suède, R. D. Allemagne, Espagne etc. les brevets sont publiés.

En conclusion on peut dire qu'une méthode très efficace de modification des caractéristiques des ciments au moyen des adjuvants complexes était inventée et qu'elle donne

larges possibilités de transformer différents types des ciments à une classe supérieure avec des grandes avantages techniques et économiques.

# Courbe d'instabilité minimale dans une solution métastable de CA

## *Minimum instability curve in a metastable solution of CA*

P. BARRET, Professeur à l'Université de Dijon, Directeur du L.A. 23 (Réactivité des Solides)  
D. BERTRANDIE, Docteur de l'Université de Dijon, CNRS (L.A. 23), France.

RESUME : Les conditions d'existence de la longue période de métastabilité (une vingtaine d'heures) que présentent les solutions saturées issues de l'aluminate monocalcique  $\text{CaAl}_2\text{O}_4$  sont étudiées. Or, dans ces solutions,  $C/A > 1$  (1,1) : ceci est justifié par le calcul qui montre que l'affinité chimique de la réaction d'hydrolyse des ions aluminates  $\rightarrow \infty$  lorsque  $[C/A]_l \rightarrow 1$ . Mais pourquoi la formation du gel d'alumine s'arrête-t-elle ? Un phénomène de même nature est observé si la solution est enrichie en chaux : l'enrichissement en chaux critique pour lequel la période d'induction est juste supprimée, est déterminé en fonction du taux de dilution. Le système réagit comme il le fait pour l'alumine, en éliminant spontanément la chaux excédentaire par précipitation d'un aluminate de calcium de rapport  $[C/A]_s$  (à l'état solide)  $> 1$ , comme  $\text{C}_2\text{AH}_8$ .

Le rapport  $[C/A]_l$  est ainsi ramené vers 1,1 et une nouvelle période d'induction d'une à plusieurs heures, selon que le précipité primaire est laissé dans la solution ou en est éliminé, coïncide avec le retour de  $[C/A]_l$  à cette valeur.

Un comportement analogue est observé aux différents taux de dilution de la solution initiale de sorte que trois types de courbes peuvent être mis en place sur le diagramme chaux-alumine-eau : une courbe (m) correspondant aux compositions où la nouvelle période d'induction est observée, encadrée de deux courbes (I) et (II) où la période d'induction primaire est juste supprimée, respectivement par enrichissement en chaux et par enrichissement en alumine.

L'interprétation thermodynamique rend exactement compte de la courbe (m) comme courbe d'instabilité minimale des solutions métastables. Ses points correspondent aux intersections des courbes d'affinité chimique de précipitation du gel d'alumine et de  $\text{C}_2\text{AH}_8$ , qui définissent des valeurs minimales communes des degrés de sursaturation de la solution par rapport à ces hydrates. La courbe (m) apparaît comme une courbe de transition entre ceux-ci. D'autres courbes analogues à (m) ont pu être prévues par le calcul.

SUMMARY : The conditions of occurrence of the long metastability period (about 20 hr.) shown by saturated solutions resulting from monocalcic aluminate  $\text{CaAl}_2\text{O}_4$  were investigated. Now, in these solutions,  $C/A > 1$  (1.1) : this is justified by calculation showing that the chemical affinity of the hydrolysis of aluminate ions  $\rightarrow \infty$  when  $[C/A]_l \rightarrow 1$ . But why does the formation of alumina gel stop ? A similar phenomenon was observed if the solution was enriched in lime : the critical enrichment in lime, for which the induction period is just inhibited, was determined as a function of the dilution ratio. The system reacted, as for alumina, spontaneously eliminating excess lime by precipitation of a calcium aluminate of ratio  $[C/A]_s$  (in the solid state)  $> 1$  such as  $\text{C}_2\text{AH}_8$ .

The  $[C/A]_l$  ratio came back to 1.1 and a new induction period ranging from 1 to several hours coincided with this value, depending on whether the initial precipitate was left within the solution or eliminated.

A similar behaviour was observed for the various dilution ratios of the initial solution so that three types of curve could be reported on the lime-alumina-water diagram : curve (m) corresponding to compositions for which the new induction period was observed, surrounded by two curves (I) and (II) for which the initial induction period was just inhibited by lime enrichment and alumina enrichment, respectively.

The thermodynamic interpretation accounts exactly for curve (m) as a minimum instability curve for metastable solutions. Its points correspond to the intersections of the chemical affinity curves of alumina gel precipitation and of  $\text{C}_2\text{AH}_8$ , which define the common, minimum values of saturation extents of the solution versus these hydrates. Curve (m) appears as a transition curve. Other curves similar to (m) could be calculated.

## INTRODUCTION

Lorsque l'aluminate monocalcique anhydre CA passe en solution, celle-ci demeure à l'état métastable pendant une vingtaine d'heures, durée de la période d'induction de nucléation des aluminates hydratés mais il est connu que, aux concentrations maximales atteintes en CaO et  $Al_2O_3$   $[C] = 19,8 \cdot 10^{-3} \text{ mol.kg}^{-1}$ ,  $[A] = 18,6 \cdot 10^{-3} \text{ mol.kg}^{-1}$  à 21°C, le rapport  $[C/A]_l$  de la solution est supérieur à 1 (1,06), alors que ce rapport dans le solide est  $[C/A]_s = 1$ . Ce fait peut s'expliquer par la réaction d'hydrolyse :

Mais pourquoi la précipitation de gel d'alumine qui a commencé dans la solution métastable s'arrête-t-elle avant que l'état d'équilibre de la réaction (I) ne soit atteint ? En effet, on calcule facilement, en prenant  $K_0 = 0,63$  comme valeur de la constante d'équilibre de l'équation (I), que la valeur d'équilibre du rapport  $[C/A]_l$  est 1,630. D'autre part, Le Chatelier (1) avait déjà remarqué que l'adjonction de chaux à la solution métastable de CA provoquait une précipitation prématurée. Ceci est à rapprocher de l'absence de période d'induction dans les solutions aqueuses obtenues au contact d'aluminates anhydres de  $[C/A]_s > 1$  comme  $C_{12}A_7$  et  $C_3A$  et également de l'absence de période d'induction dans la courbe d'évolution d'un ciment alumineux (Fondu Lafarge), dont nous avons établi expérimentalement que l'origine est précisément l'existence comme impureté de  $C_{12}A_7$  à quelques pour cent (2). Pour réunir ces faits dans une explication générale, nous avons entrepris un programme expérimental et proposé une interprétation thermodynamique répondant à la question posée (3,4,5).

## ETUDE EXPERIMENTALE

Les deux parties du programme expérimental prévu : 1) recherche de la variation initiale de composition à imposer à une solution saturée de CA pour raccourcir ou supprimer la période d'induction, 2) étude cinétique de l'évolution provoquée, ont été effectuées à trois températures différentes : 21°C, 8°C et 35°C.

Les trois paramètres dont dépend l'état de la solution métastable étant les fractions anioniques X d'ions  $OH^-_{aq}$  et Y d'ions  $[Al(OH)_4]^-_{aq}$  et la concentration molaire massique x en ions  $Ca^{2+}$ , la façon la plus simple d'imposer à ces paramètres une brusque variation initiale consistait à ajouter à un volume  $V^0$  de filtrat saturé de CA, de concentration en CaO :  $c^0 = n^0/V^0$ , un volume V d'eau de chaux de concentration  $c = n_c/V$ . Ces quantités peuvent être calculées approximativement (sans tenir compte des variations des volumes molaires partiels) pour obtenir un mélange de rapport  $[C/A]_l = r$  et de concentration absolue en chaux  $c^0/q$  (facteur de dilution  $q > 1$ ). Les expressions obtenues sont :

$$V = V^0(rq/r^0 - 1) \quad (1)$$

$$c = c^0(r - r^0)/(rq - r^0) \quad (2)$$

( $r^0 = [C/A]_l^0$  du filtrat saturé)

L'adjonction de chaux fait varier la fraction anionique X en  $OH^-_{aq}$  au détriment de la fraction  $Y = 1 - X$  en  $[Al(OH)_4]^-_{aq}$ , tandis que la plus ou moins grande dilution de l'eau de chaux ajoutée agit sur la concentration molaire massique x des ions  $Ca^{2+}$  dans le mélange et sur celles y et  $\psi$  des anions  $[Al(OH)_4]^-_{aq}$  et  $OH^-_{aq}$ .

Il convient en effet de noter, qu'en raison de la relation d'électroneutralité :

$$2x = y + \psi \quad (3)$$

$$\text{On a : } X = \psi/2x \text{ et } Y = y/2x \quad (4)$$

$$\text{Et qu'en outre : } [C/A]_l = 1/Y \quad (5)$$

A l'inverse, la fraction anionique Y en  $[Al(OH)_4]^-_{aq}$  aurait pu être augmentée au détriment de celle X en  $OH^-_{aq}$ , par l'addition d'un aluminat de calcium anhydre de rapport  $[C/A]_s < 1$ , comme  $CA_2$ , mais cette méthode aurait été illusoire, en raison d'une précipitation immédiate de gel d'alumine.

Faute de pouvoir augmenter Y, nous avons eu recours à la simple dilution du filtrat de CA saturé. La dilution ne fait varier ni la fraction Y, car la loi d'action de masse appliquée à (I) donne :  $Y = K_0/(1 + K_0)$  ( $K_0$  = constante d'équilibre de (I) lue de la droite vers la gauche), ni le degré de sursaturation  $\beta = Y/K_0(1 - Y)$  de la solution par rapport au gel d'alumine. Mais, comme l'établiront précisément nos expériences, le degré de sursaturation critique, entraînant une précipitation immédiate, décroît lorsque la dilution augmente d'où la possibilité d'une précipitation de gel d'alumine par simple dilution.

La cinétique d'évolution des solutions en cours de précipitation a été suivie par prélèvements échelonnés dans le temps d'échantillons, à leur filtration en vue d'analyse du filtrat par spectrométrie d'absorption atomique et d'analyse par diffraction X du résidu solide également observé par microscopie électronique à balayage. La solution originelle était un filtrat prélevé au maximum de concentration par agitation soit d'un ciment alumineux, soit de CA pur dans 1000 g d'eau distillée décarbonatée dans un rapport pondéral liquide sur solide :  $l/s = 10$ .

## RESULTATS

## Essais de dilution à x constant :

Des expériences préliminaires à 21°C ont permis de faire varier la longueur de la période d'induction en ajoutant à 1 l de filtrat saturé d'un ciment alumineux (Fondu Lafarge) de composition :  $[C] = 19,7 \cdot 10^{-3} \text{ mol.kg}^{-1}$ ,  $[A] = 17,60 \cdot 10^{-3} \text{ mol.kg}^{-1}$  ( $[C/A]_l = 1,12$ ), les volumes de solution saturée de chaux donnés dans le tableau I. Cette addition ne fait pratiquement pas varier  $[C]$  dans le mélange, mais abaisse  $[A]$  et donc augmente  $[C/A]_l$ . En d'autres termes, Y va en diminuant à x constant.

TABLEAU I

Essais	V (ml) ajouté à 1 l	$[C/A]_l$	Période d'induction (heures)
B	0	1,12	11
a	36	1,16	6,5
b	54	1,18	3
c	72	1,20	0
d	125,5	1,26	Précipité au cours de l'addition de chaux
e	197	1,34	
f	653	1,85	

Les courbes correspondantes, sont rassemblées sur la figure 1 :

Fig. 1 - Courbes de variation de  $[C]$  dans un filtrat saturé B et dans un tel filtrat additionné de chaux en solution saturée : a, b, ... pour c, la période d'induction est juste supprimée ; pour d et e le précipité commence au cours de l'addition de chaux.

L'examen de cette figure attire les remarques suivantes :

- 1) Dans l'essai c, la quantité de chaux ajoutée est juste nécessaire pour supprimer la période d'induction et provoquer une précipitation immédiate.
- 2) En ce qui concerne la forme des courbes d'évolution : en même temps que le palier ou pseudo-palier est raccourci, une brusque chute de concentration initiale s'installe (courbe b) et s'accroît.
- 3) Quant à la forme des courbes de vitesse (figure 2), elle est très caractéristique et le minimum correspondant au palier qui subsiste entre les chutes de concentration initiale et finale que nous appellerons respectivement "provoquée" et "spontanée" coïncide avec un minimum du rapport  $[C/A]_L$ . (Y maximum).
- 4) En ce qui concerne la nature des hydrates apparaissant au début de la précipitation : dans les essais tels que B et a, c'est essentiellement  $CAH_{10}$ , tandis que lors de la brusque chute initiale de concentration qui se manifeste dans les essais tels que b c d e, le précipité est formé de  $C_2AH_8$  accompagné seulement dans l'essai b d'un peu de  $CAH_{10}$ .

Des résultats semblables peuvent être obtenus en partant de CA pur de synthèse, le rapport  $[C/A]_L$  à la saturation est généralement un peu plus faible  $1,06 < [C/A]_L < 1,10$  et le palier plus long (16-21h), mais l'adjonction de volumes croissants de solution de chaux saturée produit des effets analogues à ceux décrits ci-dessus avec un ciment alumineux.

#### Essais de dilution à Y constant :

Ces essais ont également été menés parallèlement sur le filtrat saturé d'un ciment alumineux et sur celui de CA pur. Le tableau II rassemble les valeurs moyennes d'essais effectués par dilution simple par l'eau distillée décarbonatée de filtrats saturés de CA à 21°C. Les résultats montrent qu'à dilution croissante, une période d'induction de plus en plus courte, jusqu'à l'annulation pour la dilution 2,4, précède la formation de gel d'alumine dont le précipité est

presque exclusivement constitué, jusqu'à la valeur  $[C/A]_L \approx 1,5$ . Notons que le gel d'alumine ne peut plus précipiter si  $[C/A]_L < 1,63$ , valeur qui correspond à la courbe d'équilibre de solubilité de ce constituant sur le diagramme chaux-alumine-eau. Vers  $[C/A]_L \approx 1,4$ , le gel d'alumine est mêlé à une proportion notable de  $C_2AH_8$ , puis pour  $[C/A]_L < 1,6$ ,  $C_2AH_8$  précipite seul avec des traces de monocarboaluminate  $3CaO, Al_2O_3, CaCO_3, 11H_2O$ .

Dilution	$[C]$ $10^{-3} \text{ mol.kg}^{-1}$	$[A]$ $10^{-3} \text{ mol.kg}^{-1}$	$[C/A]_L$	Période d'induc- tion heures
1	20,2	18,7	1,08	20
2	10,1	9,3	1,09	3,3
2,2	9,2	8,5	1,08	2,1
2,3	8,75	8,1	1,08	1,2
2,4	8,4	7,7	1,09	0

#### Essais de dilution à x et y variables :

C'est dans ce type d'essais, effectués à 21°C, 8°C, 35°C, qu'a été utilisée la méthode ci-dessus décrite, consistant à ajouter dans un filtrat de CA saturé un volume V de solution de chaux de titre c calculé (relations 1 et 2) pour obtenir un mélange de rapport  $[C/A]_L = r$  et de concentration en chaux q fois plus petite. Les résultats donnés ici sont ceux des études cinétiques de l'évolution des mélanges dont le rapport  $[C/A]_L$  a été amené initialement par cette technique à une valeur critique  $[C/A]_L^* = r^*$ , pour laquelle la période d'induction est juste annulée, à une suite de valeurs de  $x^*$  décroissantes.

L'allure des courbes d'évolution et de vitesse est analogue à celle des courbes c (figures 1 et 2).

Il n'est pas possible, faute de place, de donner les courbes d'évolution et de vitesse. Celles-ci ont la même allure, respectivement, que les courbes c des figures 1 et 2. La durée du palier intermédiaire est de 0h30 à 1h30 en présence des germes formés au cours de la précipitation initiale. Mais, si ces germes sont éliminés par filtration, cette durée s'étend à plusieurs heures. Dans les essais à 8°C, la précipitation immédiate est encore plus brusque qu'à 21°C et le palier intermédiaire, mieux dessiné, atteint habituellement 1 heure. Au contraire, dans les essais à 35°C, le palier intermédiaire est très atténué et pratiquement remplacé par une discontinuité de la pente des courbes d'évolution, à laquelle correspond un minimum de faible amplitude sur les courbes de vitesse. Mais, dans tous les cas, ce minimum est en bonne coïncidence avec le minimum de la courbe de variation du rapport  $[C/A]_L$ .

Le tableau III rassemble les données les plus caractéristiques relatives à ces évolutions provoquées par addition d'eau de chaux à trois températures différentes, notamment, pour 4 valeurs du facteur de dilution q, les couples de valeurs critiques ( $x^*$ ,  $r^*$ ), les valeurs de la fraction d'ions  $OH^-$  :  $X^*$  et du pH<sup>m</sup> qui leurs correspondent, ainsi que les valeurs des mêmes facteurs au minimum de vitesse : ( $x^m$ ,  $r^m$ ) et ( $X^m$ , pH<sup>m</sup>).

Fig. 2 - --- : vitesse de variation de  $[C]$  au cours des essais a, b, c, e du tableau I. — : variation concomitante de  $[C/A]_2$  : coïncidence des minima.

Fig. 3 - (I) et (II) Courbes de supersolubilité de  $C_2AH_8$  et du gel d'alumine. (m) courbe d'instabilité minimale. Les points 1, 2, 3, 4 correspondent aux essais à 21°C du tableau III et les points 5 et 6 aux dilutions 2,2 et 2,4 du tableau II.

TABLEAU III

$\theta$ °C	q dilu.	$x^*$ $10^{-3}$ mol. kg $^{-1}$	$r^*$	$x^*$	$pH^*$	$x^m$ $10^{-3}$ mol. kg $^{-1}$	$r^m$	$x^m$	$pH^m$
21	1,25	16,55	1,23	0,19	11,80	14,00	1,10	0,09	11,40
	1,50	13,95	1,28	0,22	11,79	11,50	1,15	0,13	11,48
	1,75	11,90	1,33	0,25	11,77	10,20	1,20	0,17	11,54
	2,00	10,54	1,41	0,29	11,78	9,50	1,22	0,18	11,53
	=====	=====	=====	=====	=====	=====	=====	=====	=====
8	1,25	15,50	1,21	0,17	11,72	13,10	1,09	0,08	11,32
	1,50	13,30	1,25	0,20	11,73	11,20	1,13	0,12	11,43
	1,75	11,20	1,33	0,25	11,75	9,90	1,22	0,18	11,55
	2,00	10,00	1,39	0,28	11,75	8,65	1,28	0,22	11,58
	=====	=====	=====	=====	=====	=====	=====	=====	=====
35	1,25	16,00	1,17	0,15	11,68	13,10	1,10	0,09	11,37
	1,50	12,85	1,27	0,21	11,73	11,40	1,18	0,14	11,50
	1,75	11,55	1,32	0,24	11,74	10,60	1,24	0,19	11,61
	2,00	10,55	1,39	0,28	11,77	9,85	1,28	0,22	11,64

Il convient de noter la corrélation qui existe entre les valeurs du rapport  $[C/A]_2$  ou  $X^*$  (puisque  $Y = 1 - X$  est la pente des droites  $[C/A]_2$  sur le diagramme chaux-alumine-eau) et celles de  $x^*$ , aussi bien d'ailleurs qu'entre  $[C/A]_2$  et  $x^m$  : plus la dilution est grande ( $x$  petit), plus la fraction d'ions  $OH^-$  :  $X^*$ , nécessaire au déclenchement immédiat de la précipitation initiale est importante ; il en est de même pour la fraction d'ions  $OH^-$  correspondant au palier inter-

médiaire  $X^m$ . Toutefois, le pH, donné par l'expression  $pH = 14 + \log_{10}(2xX)$  (6)

varie très peu en fonction de  $q$ , qu'il s'agisse de  $pH^*$  ou de  $pH^m$  et c'est là une propriété remarquable. En outre les valeurs absolues du pH entre  $pH^*$  et  $pH^m$  ne présentent un écart que de quelques dixièmes d'unités. La température n'a que peu d'influence sur ces valeurs.

La nature des précipités, selon qu'il s'agit de la précipitation provoquée initiale ou de la précipitation spontanée faisant suite au palier (ou période d'induction intermédiaire) et suivant la température, est instructive (tableau IV) :

TABLEAU IV

Précipitation	q	21°C	8°C	35°C
prov.	petit	$C_2AH_8 + CAH_{10}$ (traces)	$C_2AH_8 + CAH_{10}$ (un peu)	$C_2AH_8 + AH_3$ (traces)
	grand	$C_2AH_8 +$ monocarbo (traces)	$C_2AH_8 +$ monocarbo (un peu)	$C_2AH_8 +$ monocarbo
	=====	=====	=====	=====
spont.	petit	$C_2AH_8 + CAH_{10}$	$CAH_{10}$	$C_2AH_8 + AH_3$
	moyen		$CAH_{10} + C_2AH_8$ + $AH_3$	
	grand	$C_2AH_8 +$ monocarbo	$CAH_{10} +$ monocarbo	$C_2AH_8 +$ monocarbo

La différence de nature entre le précipité provoqué immédiat et le précipité spontané différé apparaît clairement : quelle que soit la température, le premier est formé essentiellement de  $C_2AH_8$  avec, à grande dilution, du monocarboaluminate inévitable en raison de l'impureté  $CO_2$ . La composition du second est tributaire de la température et peut être comparée à celle du précipité se formant spontanément après une période d'induction plus ou moins longue sans addition de chaux. Ainsi, à  $8^\circ C$ , la précipitation différée donne essentiellement  $CAH_{10}$  qui est stable à cette température, tandis qu'à  $21^\circ C$ , c'est  $C_2AH_8$  qui prédomine et à  $35^\circ C$ ,  $CAH_{10}$  n'est plus stable du tout en raison de la transformation :

La précipitation forcée initiale se caractérise au contraire par la formation d'un aluminate de calcium hydraté de rapport  $[C/A]_s > 1$ , ce qui traduit la réaction du système pour éliminer l'excédent de chaux qui lui a été imposé.

#### Report sur le diagramme chaux-alumine-eau :

Il est d'un grand intérêt de reporter sur le diagramme C-A-H les variations de  $[C]$  et  $[A]$  accompagnant l'évolution des solutions en fonction du temps. Ainsi, sur le diagramme à  $21^\circ C$  (fig. 3'), les points correspondant aux concentrations critiques, tirées des valeurs de  $x^*$  et  $r^*$  du tableau III, appartiennent à la courbe (I). Les segments de droite tels que 1, 2, 3, 4 représentent la variation de composition consécutive à la précipitation provoquée initiale. Les segments 1 et 2 sont nettement parallèles à la droite  $[C/A]_s = 2$  parce que le précipité est  $C_2AH_8$ . Les segments 3 et 4 ont une pente plus faible car le précipité est un mélange de  $C_2AH_8$  et de monocarboaluminate dont le  $[C/A]_s$  moyen est  $> 2$ . Les extrémités de ces segments, correspondant aux concentrations tirées des valeurs de  $x^m$  et  $r^m$  du tableau III, pour le minimum de vitesse, appartiennent à une courbe (m) que suivent approximativement les trajectoires du point représentatif de la composition au cours de la précipitation spontanée ultérieure. Par le point correspondant à la dilution 2,4 du tableau II, nous avons fait passer une droite hypothétique (II) qui est censée représenter l'ensemble des compositions critiques conduisant à une précipitation immédiate de gel d'alumine. Faute de pouvoir provoquer expérimentalement un enrichissement relatif en ions  $[Al(OH)_4]^-$  comme on l'a fait pour les ions  $OH^-$  à diverses concentrations en  $Ca^{2+}$ , cette courbe II reste imprécise et ne doit être considérée que comme logiquement probable.

#### Quel sens attribuer à ces courbes (I), (m) et (II) ?

Au point de vue cinétique, les courbes (I) et (II) peuvent être considérées comme les courbes de supersolubilité respectivement de  $C_2AH_8$  et du gel d'alumine ; c'est-à-dire qu'à l'extérieur de l'étroit couloir qu'elles délimitent, la solution métastable ne peut subsister sans être le siège d'une précipitation immédiate de  $C_2AH_8$  dans le domaine situé à droite de (I) et de gel d'alumine dans celui situé à gauche de (II). La courbe (m) qui représente les compositions auxquelles la solution est remanée spontanément pour corriger, par un précipité approprié, un enrichissement imposé en chaux ou en alumine, a été appelée par nous "courbe d'instabilité minimale". On retrouve les mêmes caractéristiques sur les diagrammes à  $8^\circ C$  et à  $35^\circ C$ .

#### DISCUSSION

##### Courbe d'instabilité minimale (m) :

Nous nous proposons de donner une interprétation thermodynamique des courbes d'instabilité minimale, telles que (m) dans une solution métastable. Pour cela, considérons, en plus de la réaction (I), la réaction de précipitation de  $C_2AH_8$  :

Comme la constante d'équilibre de l'équation (I) relative au gel d'alumine, lue de la droite vers la gauche (solubilité) a été désignée à l'aide de l'indice (o), nous conviendrons de réserver les indices 1, 2, 4 aux constantes d'équilibre de solubilité de  $CAH_{10}$ ,  $C_2AH_8$ ,  $C_4AH_{13}$ . Les valeurs approximatives de ces constantes, calculées à partir des diagrammes chaux-alumine-eau à  $21^\circ C$  (6),  $5^\circ C$  (7) et  $50^\circ C$  (8), sont rassemblées dans le tableau V :

TABLEAU V				
$^\circ C$	$K_o$	$K_1$	$K_2$	$K_4$
21	1,60	$2,65 \cdot 10^{-8}$	$1,65 \cdot 10^{-14}$	$6,50 \cdot 10^{-26}$
8		$5,23 \cdot 10^{-9}$	$6,80 \cdot 10^{-15}$	$4,88 \cdot 10^{-27}$
35		$1,30 \cdot 10^{-7}$	$3,0 \cdot 10^{-13}$	$8,27 \cdot 10^{-25}$

Avec les notations adoptées [relations (3) et (4)] et en exprimant le coefficient d'activité  $\gamma^\pm$  au moyen de la formule simplifiée de Debye et Hückel, soit par exemple à  $21^\circ C$  :

$$\gamma^\pm = 10^{-1,746\sqrt{x}} \quad (7)$$

Les expressions des affinités chimiques relatives aux équations (I) et (II) sont :

$$A_o = RT \log_e \frac{1}{K_o \left( \frac{1}{x} - 1 \right)} \quad (8)$$

$$A_2 = RT \log_e \frac{16(x\gamma^\pm)^6 (1-x)^2 x^2}{K_2} \quad (9)$$

Il est donc possible de construire les courbes représentant, pour différentes valeurs de  $x$ , les affinités chimiques en fonction de  $X$ . En fait, nous avons porté sur un graphique (figure 4) les valeurs des termes sous  $\log_e$ , que nous appelons "degrés de sursaturation" et que nous notons  $\beta_o$ ,  $\beta_2$  en fonction, non de  $X$ , mais compte tenu de (6), de  $\psi$  ou de pH pour différentes valeurs de  $x$ . On constate que les points d'intersection des courbes  $\beta_o$  et  $\beta_2$ , à valeurs de  $x$  égales, se placent sur une courbe (m') dont la transformée sur le diagramme C-A-H (figure 5) se confond avec la courbe expérimentale (m).

Toutefois, les coefficients stoechiométriques des équations (I) et (II) sont arbitraires ; les valeurs de  $\beta_o$  et  $\beta_2$  qui en dépendent le sont donc aussi. Une condition supplémentaire doit être recherchée pour fixer à 1 le rapport moléculaire de  $Al(OH)_3$  et  $C_2AH_8$ . Cette condition ne peut être qu'une équation chimique reliant ces deux corps dans ce rapport. Comme, en chaque point d'intersection,  $\beta = \beta_o = \beta_2$ , l'équation suivante, tirée des expressions (8) et (9) doit être satisfaite :

$$\frac{16(x\gamma^\pm)^6 (1-x)^2 x^3}{1-x} = \frac{K_2}{K_o} \quad (10)$$

Fig. 4 - Définition des courbes d'instabilité minimale par les interactions  $m'_4$ ,  $m'_\infty$  des courbes des degrés de sursaturation  $\beta$  en fonction du pH.

Fig. 5 - Report sur le diagramme C-A-H des courbes d'instabilité minimale théoriques  $m_{t_4}$ ,  $m_{t_2}$ ,  $m_{t_\infty}$ .

Cette équation correspond à l'état d'équilibre de la réaction :

$$2C_2AH_8 \rightleftharpoons Al(OH)_3 + [Al(OH)_4]^-_{aq} + 3OH^-_{aq} + 2Ca^{2+}_{aq} + \dots$$

$$\dots + 3H_2O_l \quad (III)$$

On l'obtient en ajoutant à l'équation (I), l'équation (II) inversée. Elle est la condition supplémentaire recherchée. Elle définit la courbe ( $m_{t_4}$ ) comme courbe d'équilibre de la transformation de  $C_2AH_8$  en gel d'alumine avec libération en solution des ions dans les mêmes proportions stoechiométriques que ceux donnés par la dissolution congruente de  $C_4AH_{13}$  :

La construction de la courbe ( $m_{t_4}$ ) est donc facile à réaliser : il suffit pour cela de multiplier  $K_4$  par une constante telle que :

$$\sqrt{\alpha} K_4 = K_2/K_0 \quad (11)$$

On obtient  $\alpha = 0,0016$  et l'on peut aisément vérifier que cette constante est celle de l'équilibre entre phases solides :

Nous pouvons prévoir par le calcul d'autres courbes d'instabilité minimale telle que ( $m_{t_2}$  ou ( $m_{t_\infty}$ ) marquant respectivement les transformations de  $CAH_{10}$  en gel d'alumine et de  $C_4AH_{13}$  en  $C_2AH_8$  (figures 4 et 5).

Le prolongement de la courbe d'instabilité minimale dans le domaine des solutions stables constitue la courbe de stabilité maximale de ce domaine.

## CONCLUSION

Nous avons défini expérimentalement un étroit couloir sur le diagramme C-A-H délimité par les courbes de supersolubilité du gel d'alumine et de  $C_2AH_8$  et dont la largeur correspond à une petite variation du pH. A l'extérieur de ce couloir, les solutions ne peuvent exister sans précipitation immédiate. A l'intérieur, leur durée de vie est nulle sur les courbes de supersolubilité et maximale sur la courbe (m) dite "d'instabilité minimale" que nous avons définie thermodynamiquement comme correspondant aux intersections deux à deux des courbes de degrés de sursaturation de  $AH_3$  et  $C_2AH_8$  en fonction du pH. Les variations de composition accompagnant l'évolution spontanée des mélanges CA-eau suivent ce chemin. La généralisation de la théorie permet de prévoir d'autres courbes du même type. (\*)

# Influence des conditions de synthèse de l'alumine sur sa réactivité vis-à-vis de la chaux

## *Influence of the alumina preparation conditions on the reactivity with the calcium oxyde*

B. GUILHOT\*, J.F. HUGO\*, A. MATHIEU\*\*, A. PETIT\*\*, France.

**RESUME :** De nombreux paramètres peuvent influencer sur les propriétés réactionnelles de l'alumine. L'influence du pH de fin de neutralisation du chlorure d'aluminium par l'ammoniaque ainsi que la température de calcination des gels d'alumine ainsi obtenus ont été étudiées.

Le pH de fin de précipitation a un rôle important sur l'état de cristallisation, l'aire spécifique et la teneur en composés chlorés présents dans les gels d'alumine.

Une élévation de la température de calcination atténue progressivement ces différences.

Après broyage et tamisage chaque alumine est mélangée avec du carbonate de calcium. L'évolution du mélange pendant la clinkérisation est suivie au microscope de chauffe.

C'est l'alumine obtenue au pH et à la température de calcination les plus bas qui entraîne le retrait le plus important.

L'analyse par diffraction X des différents clinkers montre qu'une augmentation de la température de clinkérisation provoque une diminution de la teneur en  $C_{12}A_7$ . Celle-ci est en relation avec le retrait.

On constate que la cinétique d'hydratation est maximale lorsque la température de clinkérisation est voisine de 1350°C.

**ABSTRACT :** Many parameters can influence the mechanism of the alumina properties. The influences of the pH of the neutralisation reaction of aluminium chloride and ammonium hydroxide and the calcination temperature of alumina gels have been studied.

The pH is an important factor on the crystallisation degree, the specific surface and chloride compound content of the alumina gels. The calcination temperature reduce these differences.

After grinding and screening, each alumina is blend with calcium carbonate. During the clinkerisation the evolution is observed by the heating microscopy technic.

The alumina synthetised with a low pH condition and calcined at low temperature give the largest shrinkage..

X Ray diffraction of the clinkers shows a relation between the clinkerisation temperature, the  $C_{12}A_7$  content and the shrinkage. We observe the maximum hydration kinetic when the temperature is about 1350°C.

## INTRODUCTION

Le procédé d'élaboration d'un solide peut avoir une grande influence sur ses propriétés réactionnelles. Dans ce travail nous examinons l'influence :

- du pH de fin de précipitation du gel d'alumine,
- de la température de calcination de l'alumine,

sur sa réactivité vis-à-vis du carbonate de calcium, ainsi que sur l'hydraulicité des aluminates de calcium obtenus.

## I) - SYNTHÈSE des ALUMINES

Les gels d'alumine sont préparés en milieu aqueux selon la réaction :

Les alumines sont ensuite obtenues par calcination des gels.

### I-1) - Conditions expérimentales

Une solution de chlorure d'aluminium hexahydraté (300 g/l) est mise dans un réacteur maintenu à 60°C. La solution d'ammoniaque 4 N est ajoutée à vitesse constante (1 ml/mn pour un volume initial de 200 cm<sup>3</sup>). Cette vitesse d'introduction a été choisie en fonction de la concentration initiale en ions Al<sup>3+</sup> et de la température de la solution pour que le système soit le plus proche de l'équilibre (1). L'agitation est maintenue constante quelle que soit la viscosité.

La pHmétrie permet de suivre l'évolution de la réaction.

Afin d'éliminer le sel formé (NH<sub>4</sub>Cl), tout en préservant au gel sa structure initiale (2), celui-ci, après filtration, est lavé au soxhlet pendant 24 heures dans le méthanol.

Après séchage à l'étuve à 100°C, le gel est fractionné. Chaque fraction est cuite à une température déterminée (800, 1000 ou 1300°C).

### I-2) - Caractérisation

Comme l'ont déjà souligné de nombreux auteurs (3) (4), les gels obtenus à des pH peu élevés sont très désorganisés et contiennent une forte proportion d'anions issus du sel d'aluminium. Par contre, ils contiennent peu de cations provenant de la base utilisée (< 0,35 %). Vers pH 10, les gels obtenus sont pratiquement purs, mais ils ne sont plus amorphes.

L'état de cristallisation joue un rôle important sur l'aire spécifique. C'est ainsi que le gel amorphe a une aire spécifique de 30 m<sup>2</sup>/g ; par contre lorsqu'il se présente sous forme de pseudoboehmite, elle est de 300 m<sup>2</sup>/g. Cristallisé sous forme de bayerite, elle est alors de 130 m<sup>2</sup>/g.

Des alumines de nature différente sont obtenues selon la température de cuisson de ces gels. A 800°C, les spectres de diffraction X révèlent la présence d'une phase mal cristallisée γ ou η (5). A 1000°C, on note l'apparition de la phase θ en proportion différente suivant la nature du gel initial.

Les surfaces spécifiques des produits, très différentes aux basses températures de cuisson, sont semblables pour des alumines cuites à 1300°C.

L'allure des signaux de thermoluminescence (TL) est différente suivant la température de calcination.

A basse température, les pics sont étalés. A haute température, les pics sont plus étroits (alumine α).

Bien que certains gels (gel A) aient une teneur en composés chlorés relativement importante, les alumines même cuites à basse température ont une teneur en chlore beaucoup plus faible (toujours inférieure à 0,4 %).

L'examen de ces résultats met en évidence les points suivants :

- le pourcentage de CA croît avec la température de clinkérisation quel que soit le cru initial,
- pour une température donnée de clinkérisation (1330°C par exemple), il apparaît que les aluminés issus du gel obtenu au pH le plus élevé (10,4) ont une plus grande réactivité vis-à-vis du carbonate de calcium.
- pour un gel déterminé, une augmentation de la température de calcination de ce gel favorise la cinétique de clinkérisation.

Il ressort de cet examen que l'amélioration de l'état d'organisation du gel constitue un paramètre favorable de la réactivité de l'alumine.

### III-2) - Calorimétrie

La cinétique d'hydratation des clinkers a été suivie par calorimétrie, le rapport E/C a été fixé à 1, la masse de l'échantillon étant de 500 mg.

Les courbes obtenues présentent les caractéristiques classiques des liants hydrauliques.

Figure N° 2

Thermogramme de l'hydratation des aluminates de calcium

L'analyse des courbes calorimétriques montre qu'il est délicat de faire des corrélations significatives entre les conditions d'obtention de l'alumine et la cinétique d'hydratation. On remarque en particulier que l'intensité du pic de mouillage, la période de latence ( $t_0$ ), la hauteur du signal calorimétrique ( $H$ ) sont aléatoires.

Par contre pour comparer les cinétiques d'hydratation nous avons défini un paramètre  $\alpha = \frac{H}{t_m - t_0}$  susceptible de rendre compte de la cinétique d'hydratation (accélération moyenne d'hydratation).

Nous avons remarqué que le coefficient  $\alpha$  était maximum pour une température de clinkérisation voisine de 1350°C, comme le montre la figure N° 3 relative à la série C et cela quelle que soit l'origine de l'alumine. Par contre le pH de fin de précipitation du gel ne paraît pas constituer un paramètre prépondérant.

Figure N° 3

Evolution du coefficient  $\alpha$  en fonction de la température de clinkérisation

### CONCLUSION

Les aluminés hydratés sont préparés en milieu aqueux par neutralisation du chlorure d'aluminium par l'ammoniaque.

Le pH de fin de précipitation (8,4 à 10,4) a un rôle important sur :

- la teneur en composés chlorés (7 à 0,7 %) présents dans les gels d'alumine,
- l'état de cristallisation et l'aire spécifique des gels (30 à 300 m<sup>2</sup>/g).

Par contre après cuisson, une élévation de la température de calcination (800 à 1300°C) atténue progressivement ces différences.

Chaque alumine est broyée et tamisée, puis mélangée avec du carbonate de calcium. L'évolution du mélange pendant la clinkérisation est suivie au microscope de chauffe.

L'examen des courbes de retrait en fonction de la température montre qu'une augmentation de la température de calcination de l'alumine provoque une diminution du retrait.

Les analyses par diffraction X des différents clinkers montrent que la teneur en CA est fonction de la température de clinkérisation. On peut aussi noter la relation entre le retrait et la teneur en C<sub>12</sub>A<sub>7</sub>.

Il est délicat, compte tenu des résultats obtenus, de faire des corrélations précises entre les conditions d'obtention de l'alumine et la cinétique d'hydratation de l'aluminate de calcium issu de la réaction de cette alumine avec le carbonate de calcium. On constate cependant que l'accélération de la cinétique d'hydratation est maximale lorsque la température de clinkérisation est voisine de 1350°C.

# High temperature cements with geothermal applications

## *Ciments pour applications géothermiques*

**ABSTRACT:** Performance requirements for cements utilized in geothermal and deep oil wells often exceed those of currently available cementing materials, whose upper temperature limits are about 200°C. Experiments undertaken were concerned with finding new cementing compositions and began with a study of the quaternary systems  $\text{CaO-Al}_2\text{O}_3\text{-SiO}_2\text{-H}_2\text{O}$  and  $\text{CaO-MgO-SiO}_2\text{-H}_2\text{O}$ . Three compositional regions have been delineated as potential high-temperature cements. Region I in the system  $\text{CaO-Al}_2\text{O}_3\text{-SiO}_2\text{-H}_2\text{O}$  intersects the  $\text{CaO-SiO}_2$  join between 45 and 65 wt %  $\text{SiO}_2$ . Xonotlite, foshagite, and truscottite crystallized within the temperature range studied and were responsible for favorable cementitious properties of these mixtures. Region II in the system  $\text{CaO-Al}_2\text{O}_3\text{-SiO}_2\text{-H}_2\text{O}$  centers around the anorthite composition,  $\text{CaO-Al}_2\text{O}_3\cdot 2\text{SiO}_2$ , and hexagonal anorthite was found to be cementitious. A third region of interest covers a broad band of compositions in the system  $\text{CaO-MgO-SiO}_2\text{-H}_2\text{O}$  between about 45 to 65 wt %  $\text{SiO}_2$  along the  $\text{CaO-SiO}_2$  join to about 45 to 55 wt %  $\text{SiO}_2$  along the  $\text{MgO-SiO}_2$  join. Diopside, chrysotile, antigorite, xonotlite, truscottite and foshagite contributed to favorable cementitious properties of these mixtures. Addition of magnesia to the  $\text{CaO-SiO}_2\text{-H}_2\text{O}$  join was best accomplished, in view of obtaining desirable physical properties, by the use of calcined chrysotile (asbestos).

Morphology and small size of the crystalline reaction products were, in large part, responsible for the cementitious quality of hydrothermally cured formulations. The following crystal habits resulted in the best cementing materials: needles, fibers, laths, and platelets.

Addition of alkalis to these systems produced several consequences. Addition of up to 10.0 wt %  $\text{Na}_2\text{O}$  and  $\text{K}_2\text{O}$  added as hydroxides on the mixing water, had little effect on bulk compositions between 35 and 55 wt %  $\text{SiO}_2$  in the system alkali- $\text{CaO-SiO}_2\text{-H}_2\text{O}$ . For mixtures containing over 55 wt %  $\text{SiO}_2$ , sodium was tied up in pectolite, a silicate phase, above 200°C, 68.9 MPa. At 200°C, 11A tobermorite plus truscottite crystallized from these compositions.  $\text{K}_2\text{O}$  was tied up in reyerite between 200-350°C for silica-rich mixtures. Bulk compositions approximating  $\text{CaO-MgO}\cdot 2\text{SiO}_2$  were relatively unaffected by the addition of alkalis. However, as little as 0.5 wt %  $\text{Na}_2\text{O}$  added to compositions approximated by  $\text{CaO-Al}_2\text{O}_3\cdot 2\text{SiO}_2$  was found to be deleterious to the hydrothermally cured cements. Analcite, a zeolite with a cubic habit, crystallized between 200-400°C.  $\text{K}_2\text{O}$  (0.5-10 wt %) also resulted in the formation of at least two unknown phases whose presence did not offset the unfavorable effect of analcite.

### RESUME :

On demande aux ciments utilisés dans les puits géothermiques ainsi que dans les puits profonds de forage de pétrole une performance qui dépasse souvent celle qu'offrent les matériaux liants que l'on trouve maintenant, et dont les limites d'utilisation se situent aux environs de 200°C. Les expériences que nous avons conduites furent orientées vers la recherche de nouvelles compositions de ciments, en commençant par l'étude des systèmes quaternaires  $\text{CaO-SiO}_2\text{-H}_2\text{O}$  et  $\text{CaO-MgO-SiO}_2\text{-H}_2\text{O}$ . Trois zones de compositions ont été cernées comme ciments potentiels pour usage à température élevée. La Zone I du système  $\text{CaO-Al}_2\text{O}_3\text{-SiO}_2\text{-H}_2\text{O}$  coupe la ligne de conjugaison  $\text{CaO-SiO}_2$  entre 45 et 65% de  $\text{SiO}_2$ . La xonotlite, foshagite et truscottite cristallisent dans l'intervalle de température étudié et sont responsables pour les propriétés liantes de ces mélanges. La Zone II du système  $\text{CaO-Al}_2\text{O}_3\text{-SiO}_2\text{-H}_2\text{O}$  est centrée autour de la composition de l'anorthite,  $\text{CaO-Al}_2\text{O}_3\cdot 2\text{SiO}_2$ , et on a trouvé que l'anorthite hexagonale a des propriétés liantes. Une troisième zone d'intérêt couvre une large gamme de compositions dans le système  $\text{CaO-MgO-SiO}_2\text{-H}_2\text{O}$  entre environ 45 et 65% de  $\text{SiO}_2$ , le long de la ligne de conjugaison  $\text{CaO-SiO}_2$ , à environ 45 à 55% de  $\text{SiO}_2$  le long de la ligne de conjugaison  $\text{MgO-SiO}_2$ . Le diopside, chrysotile, antigorite, xonotlite, truscottite et foshagite contribuent favorablement aux propriétés liantes de ces mélanges. Le meilleure façon d'incorporer la magnésie dans le système  $\text{CaO-SiO}_2\text{-H}_2\text{O}$  pour obtenir les propriétés physiques désirées est d'utiliser du chrysotile calciné (amiante).

La morphologie et la petite taille des produits cristallins de réaction sont, dans une large mesure, responsables pour la qualité liante des formulations à prise hydrothermale. Les formes cristallines suivantes produisent les meilleurs liants: aiguilles, fibres, lattes et plaquettes.

L'addition d'alcalis à ces systèmes a des conséquences diverses.  $\text{Na}_2\text{O}$  et  $\text{K}_2\text{O}$ , ajoutés jusqu'à 10% en poids comme hydroxides à l'eau du mélange, n'a que peu d'effet sur les compositions ayant entre 35 et 55% de  $\text{SiO}_2$  dans le système  $\text{CaO-SiO}_2\text{-H}_2\text{O}$ . Dans les mélanges contenant plus de 55% de  $\text{SiO}_2$ , le sodium est fixé dans le pectolite, phase silicatée, au dessus de 200°C et 68,9 MPa. A 200°C, de la tobermorite (11A) et de la truscottite cristallisent à partir de ces compositions. Pour des mélanges riches en silice,  $\text{K}_2\text{O}$  est fixé dans la reyerite entre 200 et 350°C. Les compositions autour de  $\text{CaO-MgO}\cdot 2\text{SiO}_2$  sont relativement insensibles aux additions d'alcalis. Toutefois, il fut trouvé que juste 0,5% de  $\text{Na}_2\text{O}$  ajouté aux compositions autour de  $\text{CaO-Al}_2\text{O}_3\cdot 2\text{SiO}_2$  est détrimental aux ciments à prise hydrothermale. L'analcite, une zéolite avec une structure d'halite cubique, cristallise entre 200 et 400°C.  $\text{K}_2\text{O}$  (0,5 to 10% en poids) provoque aussi la formation d'au moins deux phases inconnues dont la présence ne compense pas l'effet défavorable de l'analcite.

## INTRODUCTION

Performance requirements for cements utilized in geothermal and deep oil wells often exceed those of currently available cementing materials, whose upper temperature limits are about 200°C (1,2). Experiments undertaken were concerned with finding new cementing compositions, which began with the quaternary systems  $\text{CaO-Al}_2\text{O}_3\text{-SiO}_2\text{-H}_2\text{O}$  and  $\text{CaO-MgO-SiO}_2\text{-H}_2\text{O}$ . Next the studies were extended to include additions of  $\text{Na}_2\text{O}$  and  $\text{K}_2\text{O}$  to cover broader wall rock and brine composition ranges. Parallel with determination of phase relations, preliminary evaluations of cementing properties were made. The combination of detailed phase- and properties-studies led to delineation of compositional areas having potential geothermal and petroleum well applications. The present paper reports details of the hydrothermal reactions and phase relation determinations, while properties are described elsewhere (1,2).

## EXPERIMENTAL PROCEDURES

**Starting Materials.** Starting materials for phase relation studies included reagent grade oxides, gels,  $\text{B}_2\text{O}_3$  stabilized  $\beta\text{C}_2\text{S}$ , commercial portland cements and aluminous cements, silica modifiers (silicic acid, 5 micrometer quartz, Tripoli, perlite, dehydrated silica gel), an alumina modifier (metakaolinite) and a magnesia modifier (calcined chrysotile). X-ray analysis of the Class J oil well cement indicated the presence of  $\beta\text{C}_2\text{S}$ , quartz, and calcite. Examination of the aluminous cements indicated the presence of CA,  $\text{C}_{12}\text{AF}$ , and  $\text{C}_4\text{AF}$ .

Metakaolinite was prepared by heating high purity kaolinite at 750°C for four hours. The final product was an amorphous reactive aggregate with a bulk composition equivalent to dehydrated kaolinite. Chrysotile serpentine was calcined at 800°C for ten hours to produce a reactive mixture of very fine grained amorphous material, forsterite, and quartz.

**Hydrothermal Equipment and Sample Preparation.** Two types of autoclaves were used in synthesis studies: (1) Conventional 30 ml cold-seal Tuttle pressure vessels externally heated in Kanthal wound furnace assemblies; (2) 500 ml Inconel cold-seal vessels modified from the Barnes-Rocker Assembly and externally heated in Kanthal pot furnaces.

Preliminary studies were limited to small samples cured in conventional Tuttle pressure vessels. Starting materials, pastes or powders plus water, were placed in noble metal tubes and cured in an open system (tubes were not welded) or in a closed system (tubes were welded and weighed before and after curing to ensure containment). Phase relations were comparable for these preparation techniques which implies negligible ion transport.

Follow-up studies were made on selected formulations showing most potential. Pastes or slurries were cast in 25x50 mm plastic molds and were allowed to set for 30 minutes to 24 hours at room temperature and greater than 95% relative humidity. Then they were removed from the molds and cured in the 500 cc autoclaves. Deionized water was the pressurizing medium in both types of autoclaves.

**Curing Conditions.** Samples were cured at 200, 250, 300, 350, and 400°C over the pressure range 6.9-68.9 MPa. Pressure had little effect on the run products

crystallized. Most experiments were run at 68.9 MPa. Curing times varied from 24 hours to 98 days. Deionized water was used as the pressurizing medium.

**Mineralogical Examination.** Mineralogical analyses were carried out by x-ray powder diffraction using  $\text{CuK}_\alpha$  radiation. SEM images were used to describe morphologies of reaction products, and morphologies were then correlated with diffraction patterns. SEM imagery proved to be the most useful technique for identifying minor amounts of phases present.

**Physical Property Measurements.** Microhardness testing was performed using a Leitz microhardness tester and the Vickers indentation method with a 40X objective. Samples were embedded in epoxy and polished to a one micrometer diamond paste finish. Microhardness measurements were used as an approximation of relative compressive strengths. Compressive strength measurements were made on a Tinius Olsen Testing Machine. Samples were sawed so the tops and bottoms were parallel before testing. Permeability measurements on the larger samples were made with pressurized (up to 5.5 MPa) nitrogen gas flowing through the samples by measuring the displacement of water by the flowing gas. Water permeability was measured using pressurized water (13.8 MPa) flowing through the sample. Viscometers were used to analyze the properties of fresh cement slurries. Both a Brookfield Rheolog model 5XHBT and a Haake Rotovisco RV-3 Viscometer were utilized.

## EXPERIMENTAL RESULTS

Compositions were widely scattered throughout the portions of the quaternary systems and selected mixtures are shown in Figures 1 and 2. Since the system  $\text{CaO-SiO}_2\text{-H}_2\text{O}$  is a join of both quaternary systems of interest a detailed investigation of compositions between C:S = 2:1 and 1:2 was also undertaken.

**$\text{CaO-SiO}_2\text{-H}_2\text{O}$ .** Initial mixtures were prepared from a variety of starting materials including oxides, gels, and commercially available cements in order to establish approximate phase stabilities and to promote rapid commercial application of new formulations in well cementing. The use of gels was discontinued after initial experimentation resulted in irreproducible phase assemblages. Variations in solubility of the silica modifiers also produced discrepancies in the crystallized phases. Highly soluble forms of silica, such as Tripoli, silicic acid, and perlite, tended to facilitate metastable crystallization of silica-rich hydrates, such as truscottite and wairakite. Coarser grained quartz was slow to dissolve into solution at the temperatures studied and, therefore, produced metastable crystallization of silica-poor phases. These problems were eliminated by the use of 5 micrometer quartz. Differences in silica solubility were attributed to the differences in degree of crystallinity and grain size.

The equilibrium dehydration curve for the reaction  $\text{xonotlite} = \text{wollastonite} + \text{water}$  was found to be somewhat lower than previously reported (3-5). In this study, wollastonite was observed to form from xonotlite at  $385 \pm 5^\circ\text{C}$  and 68.9 MPa within ten days. Reactions were reversed but exact equilibrium conditions are still uncertain because of formation of intermediate or disordered phases, or a very fine scale mechanical mixture. Xonotlite, crystallized over the temperature range of 200-385°C at 68.9 MPa was found to enhance the cementitious properties of hydrothermally cured cements.

Figure 1. Projection of mixtures and compounds in the system  $\text{CaO}-\text{Al}_2\text{O}_3-\text{SiO}_2-\text{H}_2\text{O}$  onto the anhydrous join. Potential hydrothermal cement compositions, Regions I and II, are shown.

Figure 2. Projection of mixtures and compounds in the system  $\text{CaO}-\text{MgO}-\text{SiO}_2-\text{H}_2\text{O}$  onto the anhydrous join. Potential hydrothermal cement compositions are delineated.

Truscottite crystallized over a wide range of curing conditions. Formation of truscottite in this study was favored by use of the most soluble forms of silica, such as Tripoli, in bulk compositions containing greater than 55 wt %  $\text{SiO}_2$ . Once crystallized, truscottite persisted throughout the longest runs (90 days) at 250–350°C, 68.9 MPa. The presence of truscottite in run products was not detrimental to the cementing properties of mixtures.

Foshagite crystallized readily between 325 and 400°C from mixtures containing between 40 and 50 wt %  $\text{SiO}_2$ . The occurrence of the assemblage xonotlite plus foshagite appeared to enhance microhardness and compressive strength measurements.

Carbonation of lime in starting materials resulted in the inadvertent addition of a fifth component,  $\text{CO}_2$ , to several of the runs. Above 350°C, calcite and a calcium silicate, usually xonotlite, crystallized. Below 350°C, scawtite, a hydrated calcium silicate containing carbonate, formed. The presence of neither phase was found to be detrimental to the physical properties of mixtures investigated.

**$\text{CaO}-\text{Al}_2\text{O}_3-\text{SiO}_2-\text{H}_2\text{O}$ .** Modified commercial cements (Class J oil well cement and alumina cements, R and S), oxide mixtures and  $\beta\text{C}_2\text{S}$  plus silica and alumina modifiers were cured between 200 and 400°C at 68.9 MPa. Two compositional areas warranting further study are outlined in Figure 1.

Region I extends from approximately 45 to 65 wt %  $\text{SiO}_2$  along the  $\text{CaO}-\text{SiO}_2$  join and includes up to 10 wt %  $\text{Al}_2\text{O}_3$ . Phases responsible for the cementing properties within this region are xonotlite, truscottite and foshagite. The addition of up to 10 wt %  $\text{Al}_2\text{O}_3$  as reactive boehmite [ $\text{AlO}(\text{OH})$ ], or metakaolinite, had no appreciable effect on their formation.

Region II centers around the anorthite composition and extends from about 45 to 65 wt %  $\text{SiO}_2$  along the  $\text{CaO}-\text{Al}_2\text{O}_3-\text{SiO}_2$  join. Hexagonal anorthite and wairakite, a calcium zeolite, contributed to favorable cementitious properties between 200–400°C. Hexagonal anorthite and wairakite (above 350°C) were only crystallized in run products prepared from types S and R commercial cements plus silica and have been reported to be metastable although they were still present after 98 days (6,7). Crystallization of bichulite and the hilschite-grossular hydrogarnet series resulted in mixtures with very low compressive strengths. Bichulite readily formed above 300°C, whereas, variable compositions of the hydrogarnet series crystallized over the entire temperature range studied.

**$\text{CaO}-\text{MgO}-\text{SiO}_2-\text{H}_2\text{O}$ .** Mixtures in the system  $\text{CaO}-\text{MgO}-\text{SiO}_2-\text{H}_2\text{O}$  were prepared from Class J oil well cement,  $\beta\text{C}_2\text{S}$  plus silica modifiers (Tripoli or 5 micrometer quartz) and magnesia modifiers ( $\text{MgO}$  or calcined chrysotile serpentine). A large compositional area of interest is outlined in Figure 2. Crystalline phases responsible for the cementing properties include xonotlite (200–385°C), foshagite (300–400°C), truscottite (200–350°C), diopside (300–400°C), and serpentine polymorphs. Chrysotile, the fibrous form of serpentine, crystallized between 250 and 400°C, whereas antigorite, a platy polymorph readily formed below 250°C. Monticellite, an anhydrous magnesium silicate, crystallized between 300 and 400°C. Mixtures containing predominantly monticellite were not cementitious.

Compositions along the joins xonotlite-diopside (325–385°C), diopside-chrysotile (325–400°C) and xonotlite chrysotile (200–385°C) showed the most favorable physical properties and highest microhardness and compressive strength measurements (1,2).

The form in which magnesium was added to the  $\text{CaO}-\text{SiO}_2-\text{H}_2\text{O}$  join did not effect the phases crystallized. However, the use of calcined chrysotile resulted in much improved physical properties of the slurries as compared to the use of  $\text{MgO}$ . Addition of up to 10 wt % magnesia to the  $\text{CaO}-\text{SiO}_2-\text{H}_2\text{O}$  did not significantly effect the stability of hydrated calcium silicate phases.

<sup>1</sup>Abbreviations used for starting materials have the following meaning: A-O = ANORTHITE COMPOSITION from OXIDES; A-S5Q = ANORTHITE from Brand S CEMENT + 5  $\mu$ m QUARTZ; D-O = DIOPSIDE COMPOSITION from OXIDES; D-C5QCC = DIOPSIDE from  $\beta$ C<sub>2</sub>S + 5  $\mu$ m QUARTZ + CALCINED CHRYSOTILE; H-O = HILLEBRANDITE COMPOSITION from OXIDES; H-C = HILLEBRANDITE from  $\beta$ C<sub>2</sub>S; T-O = TRUSCOTTITE COMPOSITION from OXIDES; T-C5Q = TRUSCOTTITE from  $\beta$ C<sub>2</sub>S + 5  $\mu$ m QUARTZ; X-O = XONOTLITE COMPOSITION from OXIDES; X-C5Q = XONOTLITE from  $\beta$ C<sub>2</sub>S + 5  $\mu$ m QUARTZ.

<sup>2</sup>Na<sub>2</sub>O was added as NaOH dissolved in the mixing water.

<sup>3</sup>Abbreviations used have the following meaning: A = ANORTHITE; ANA = ANALCITE; D = DIOPSIDE; E = EPISTILBITE; HA = HEXAGONAL ANORTHITE; H = HILLEBRANDITE; P = PECTOLITE; T = TRUSCOTTITE; TA = TRICLINIC ANORTHITE; TOB = 11Å TOBERMORITE; X = XONOTLITE; d = disordered; m = minor.

## EXPERIMENTAL RESULTS II

In view of the range in petroleum and geothermal well wall rock compositions, and also the variations in minor oxide contents of commercial clinker, investigation of a wider range of potential compositions was undertaken. Mixtures with compositions of C:S = 2:1, 1:1, and 1:2, C:A:S = 1:1:2, and C:M:S = 1:1:2, were adjusted with 0.5, 2.0, and 10.0 wt % K<sub>2</sub>O and also with Na<sub>2</sub>O. Alkalies were added as dissolved hydroxides in the mixing water. Pastes were sealed in noble metal tubes and reacted for 3 to 28 days. Runs were made at 200–400°C at 50° intervals and 68.9 MPa. Both oxide mixtures and modified clinker formulations resulted in crystallization of similar phases after 28 days curing.

Compositions Containing Na<sub>2</sub>O. Data for mixtures modified with NaOH are listed in Table 1. Addition of 0.5–10 wt % Na<sub>2</sub>O had a negligible effect on run products for compositions approximated by the following compounds: CaO·SiO<sub>2</sub>, 2CaO·SiO<sub>2</sub>, and CaO·MgO·2SiO<sub>2</sub>. Xonotlite crystallized from mixtures with a C:S = 1:1 plus 0.5–10 wt % Na<sub>2</sub>O between 200–400°C at 68.9 MPa. Similar hydrothermal curing of C:S = 2:1 and C:M:S = 1:1:2 plus up to 10 wt % Na<sub>2</sub>O resulted in crystallization of hillebrandite and diopside, respectively. A minor amount of pectolite was detected in these two bulk compositions for samples cured 28 days at 200°C, 68.9 MPa.

On the contrary, a sodium zeolite, analcite, crystallized from a C:A:S = 1:1:2. The amount of analcite present increased at the expense of hexagonal anorthite with increasing sodium content. These two phases coexisted between 400 and 250°C. Below 250°C, epistilbite, another sodium zeolite and hexagonal anorthite crystallized (6). Nucleation and growth of triclinic anorthite from silica-modified aluminous cements was facilitated at 400°C by the addition of 10 wt % Na<sub>2</sub>O.

Pectolite, a fibrous Ca,Na silicate, crystallized from silica-rich compositions with a C:S = 1:2 between 250 and 400°C. The amount of pectolite in the run products increased with increasing Na<sub>2</sub>O in this bulk composition. It also resulted in formation and persistence of 11Å tobermorite and disordered truscottite at 200°C, 68.9 MPa. This assemblage persisted up to 28 days.

Compositions Containing K<sub>2</sub>O. Data for mixtures modified with K<sub>2</sub>O added as KOH to the mixing water are listed in Table 2. Addition of 0.5–10.0 wt % K<sub>2</sub>O had a negligible effect on run products for mixtures with the following compositions: C:S = 1:1 and C:S = 2:1. Xonotlite readily crystallized from the C:S = 1:1 bulk compositions. Addition of 2–10 wt % K<sub>2</sub>O apparently reduced the kinetic barrier for the dehydration reaction xonotlite = wollastonite + H<sub>2</sub>O. Delleite crystallized at 400°C, 68.9 MPa in place of hillebrandite from mixtures with C:S ratio = 2:1 (4).

Diopside crystallized between 300 and 400°C from mixtures adjusted to C:M:S = 1:1:2. Starting materials, including calcined chrysotile formulations, did not affect crystalline products. Below 250°C, an unidentified fibrous phase, U<sub>3</sub>, crystallized and persisted through the longest runs of 28 days. X-ray diffraction data for U<sub>3</sub> are presented in Table 3, and its presence in run products was not found to be unfavorable. U<sub>3</sub> may be a potassium-rich 11Å tobermorite.

<sup>4</sup>Abbreviations used are given in Table 1, foot-note 1.<sup>5</sup>K<sub>2</sub>O was added as KOH dissolved in the mixing water.<sup>6</sup>Abbreviations used are given in Table 1, foot-note 3. In addition, the following abbreviations were used: DEL = DELLAITE; R-T = REYERITE-TRUSCOTTITE; T-R = TRUSCOTTITE-REYERITE; U<sub>1</sub>-U<sub>3</sub> = UNKNOWNNS 1-3 RESPECTIVELY; W = WOLLASTONITE.

Silica-modified aluminous cements adjusted to approximately a composition of C:A:S = 1:1:2 plus 0.5 wt % K<sub>2</sub>O produced crystallization of the stable triclinic polymorph of anorthite along with hexagonal anorthite above 350°C, and hexagonal anorthite below 300°C. An unidentified phase, U<sub>1</sub>, crystallized below 250°C. U<sub>1</sub> was found in run products cured at 300°C when 2 wt % K<sub>2</sub>O was present and at 350°C when 10 wt % K<sub>2</sub>O was added. Its stability is questionable. Another unidentified phase, U<sub>2</sub>, crystallized between 350 and 400°C from mixtures containing 10 wt % K<sub>2</sub>O. X-ray data are presented in Table 3.

The addition of 0.5-10.0 wt % K<sub>2</sub>O to bulk composition of C:S = 1:2 produced the assemblage, xonotlite + wollastonite + truscottite at 400°C and truscottite + xonotlite between 300 and 350°C. Reyerite, a hydrated calcium-potassium silicate similar to truscottite, crystallized below about 350°C. U<sub>3</sub>, possibly a potassium-rich 11Å tobermorite phase, was also detected in these mixtures containing 10 wt % K<sub>2</sub>O and cured between 350 and 200°C.

## DISCUSSION

Hydrothermal curing of selected compositions in the systems CaO-SiO<sub>2</sub>-H<sub>2</sub>O, CaO-Al<sub>2</sub>O<sub>3</sub>-SiO<sub>2</sub>-H<sub>2</sub>O, and CaO-MgO-SiO<sub>2</sub>-H<sub>2</sub>O have been investigated at temperatures from 200-400°C and 6.9-68.9 MPa. Three compositional regions have been delineated as potential well cements. Region I in the CaO-Al<sub>2</sub>O<sub>3</sub>-SiO<sub>2</sub> system intersects the CaO-SiO<sub>2</sub>

join between 45 and 65 wt %  $\text{SiO}_2$  and may contain up to 10 wt %  $\text{Al}_2\text{O}_3$ . Xonotlite is the phase responsible for favorable cementing properties of these mixtures, and most silica-modified commercially manufactured well cements lie within Region I. Region II centers around the anorthite composition along the join  $\text{CaO-Al}_2\text{O}_3\text{-SiO}_2$ . Formulations prepared from commercial aluminous cements plus silica result in crystallization of the cementitious phase, hexagonal anorthite, between 250-400°C. It did not transform to triclinic anorthite nor did mixtures containing predominantly hexagonal anorthite show a decrease in compressive strength after 98 days. Problems associated with high temperature retardation in setting of these formulations require further research. The third region of interest covers a broad band of compositions in the system  $\text{CaO-MgO-SiO}_2\text{-H}_2\text{O}$  between about 45 to 65 wt %  $\text{SiO}_2$  along the  $\text{CaO-SiO}_2$  join and 45 to 55 wt %  $\text{SiO}_2$  along the  $\text{MgO-SiO}_2$  join. Xonotlite, truscottite, foshagite, diopside, and the serpentine polymorphs, chrysotile and antigorite, contributed to the favorable cementitious properties. As previously discussed, these phases form various stable assemblages over specific temperature intervals in the range 200 to 400°C between 6.9 to 68.9 MPa. Addition of magnesia to the  $\text{CaO-SiO}_2\text{-H}_2\text{O}$  join was best accomplished, in view of obtaining desirable physical properties, by the use of calcined chrysotile-serpentine (asbestos). Formulations prepared from portland cement adjusted to approximately the diopside composition with silica flour and calcined chrysotile resulted in superior physical properties of both the cements and slurries. As pointed out, it was necessary to add relatively soluble silica to these mixtures in order to prevent the crystallization of monticellite, which once formed, persisted over the range of curing conditions studied, and had an unfavorable effect on the cementitious quality of the cements.

Thermodynamic stability of several cementitious phases within a certain pressure/temperature regime is still questionable since reactions were difficult to reverse. Stability of hexagonal anorthite with respect to the triclinic polymorph has not been definitely demonstrated, although hexagonal anorthite, once crystallized, was not observed to transform to triclinic anorthite (6,7). In addition, the breakdown of truscottite to xonotlite plus silica has been questioned (8). Once crystallized, truscottite persisted in run products for 98 days. Work is presently being conducted to determine the temperature range of crystallization and relative stabilities of the unidentified phases reported here.

Morphology and size of the crystalline or semicrystalline reaction products were both responsible, in large part, for the cementitious quality of hydrothermally cured mixtures. The presence of fine needles, such as xonotlite; fibers, such as truscottite and foshagite; interlocking platelets, hexagonal anorthite; and intergrown needles such as diopside and pectolite, resulted in superior microhardness and compressive strength measurements (2). Cubic crystals such as analcite, grossular-hibschite (hydrogarnet series) and bicchulite, in addition to subhedral to euhedral grains of triclinic anorthite and monticellite, proved deleterious to the cementitious quality of hydrothermally cured mixtures.

Carbonation of free lime in some starting materials resulted in formation of scawtite below about 350°C and calcite above 350°C at 68.9 MPa. Values obtained to date for compressive strength and microhardness measurements indicate acceptable and even superior strengths for carbonate-containing cements.

Addition of up to 10 wt % of either  $\text{Na}_2\text{O}$  or  $\text{K}_2\text{O}$ , as hydroxides dissolved in the mixing water, had minor effect on crystalline run products for bulk compositions between 35 to 55 wt %  $\text{SiO}_2$  in the system  $\text{Alkali-CaO-SiO}_2\text{-H}_2\text{O}$ . This implies that alkalis present in hydrothermally cured normal cements are not "tied up" as stable crystalline phases, and therefore, remain in solution where they are available to react with aggregates or wall rock. The consequences of alkali-aggregate reaction at elevated temperatures and pressures is unknown at the present time. On the contrary, available sodium (up to 10 wt %) was tied up in the silicate phase, pectolite, in mixtures containing greater than about 55 wt %  $\text{SiO}_2$  (250-400°C, 68.9 MPa). The presence of 10 wt %  $\text{Na}_2\text{O}$  resulted in the crystallization and persistence of the assemblage 11A tobermorite plus truscottite at 200°C for up to 28 days. Potassium added to mixtures containing greater than 55 wt %  $\text{SiO}_2$  resulted in crystallization of reyerite, and an unidentified reaction product,  $\text{U}_3$ .

Bulk compositions approximating  $\text{CaO-MgO-2SiO}_2$  were also relatively unaffected by the presence of alkalis. Diopside formed as the crystalline product between 200 to 400°C, 68.9 MPa in the presence of 0.5-10 wt %  $\text{Na}_2\text{O}$  and  $\text{K}_2\text{O}$ . The only exception is that addition of 0.5-10 wt %  $\text{K}_2\text{O}$  resulted in formation of an unidentified fibrous phase,  $\text{U}_3$ , below 250°C. Above 250°C, alkalis are available to react with aggregate, whereas below about 250°C at least some potassium may be tied up in a crystalline reaction product that doesn't appear to be deleterious to the cement.

The presence of as little as 0.5 wt % alkalis to bulk compositions approximated by  $\text{CaO-Al}_2\text{O}_3\text{-2SiO}_2$  was found to produce unfavorable results. Available sodium was "tied up" in analcite, a cubic habit zeolite, over the entire temperature range studied. The availability of potassium facilitated nucleation and growth of triclinic anorthite, an apparently non-cementitious phase, between 350 and 400°C. The availability of potassium also resulted in crystallization of two unidentified phases  $\text{U}_1$  and  $\text{U}_2$ , the presence of which did not offset the adverse effects of analcite and/or triclinic anorthite.

It was concluded that alkali/aggregate (or wall rock) reactions in hydrothermally cured cements could be controlled and possibly eliminated by incorporating alkalis in crystal structures of stable hydrated silicate phases. To accomplish this, bulk composition of cements should be adjusted to greater than 60 wt %  $\text{SiO}_2$  with at least 20 wt % relatively soluble silica, such as silica flour or Tripoli. In addition, it was found that sodium added in the form of a  $\text{NaCl}$ -brine solution used as mixing water had little effect on the run products formed (1,2,9). The affinity of  $\text{Na}^+$  for  $\text{Cl}^-$  was much greater than for silicate complexes under all conditions investigated. Cubic halite crystals were found growing in pores and throughout the bulk paste (1,2).

# High strength cement in the $\text{CaO-Al}_2\text{O}_3\text{-SiO}_2\text{-SO}_3$ system and its application

## *Ciments à haute résistance, du système $\text{CaO-Al}_2\text{O}_3\text{-SiO}_2\text{-SO}_3$ ; leurs applications*

G. SUDOH, Dr. Eng., Manager of Research Department,  
T. OHTA, Senior Research Chemist and  
H. HARADA, Research Chemist, Chichibu Cement Co., Ltd., Japan.

SUMMARY : In a  $\text{CaO-Al}_2\text{O}_3\text{-SiO}_2\text{-SO}_3$  system, clinker containing  $\text{C}_3\text{A}_3\cdot\text{CaSO}_4$ ,  $\text{C}_2\text{S}$  and free  $\text{CaO}$  as the principal minerals was obtained when a raw mixture with a suitable chemical composition was burned at a temperature between 1250 to 1300°C using a rotary kiln. It was found that a rapid-hardening and high-strength cement could be produced when this clinker was ground with anhydrite to prepare cement ranging in  $\text{SO}_3/\text{Al}_2\text{O}_3$  molar ratio ( $\bar{S}/\text{A}$ ) from 1.3 to 1.9. According to the JIS R 5201 method, the compressive strengths of cement mortars of  $\bar{S}/\text{A}$  ratio of 1.3 were as follows :

Age	3h	7h	1d	3d	7d	28d
Strength ( $\text{N/mm}^2$ )	27	38	48	52	54	59

The rapid-hardening and high-strength properties of this cement could be attributed to the formation of needle-like ettringite of 1 to 2  $\mu\text{m}$  with a large specific surface, which filled the inner vacant spaces of the hardened body. Furthermore, the hardened body became stronger due to the hydration of  $\text{C}_2\text{S}$  at later ages.

The cements made from clinkers of this system showed various hydration characteristics which are not normally observed in portland cement. It was also made clear that these cements are applicable to special uses, such as admixtures for soil stabilization and hardening of sludge, as a hydraulic binder in fixation of harmful heavy metals and as a cement for excelsior board.

RESUME : Un clinker, appartenant au système  $\text{CaO-Al}_2\text{O}_3\text{-SiO}_2\text{-SO}_3$  et contenant principalement :  $\text{C}_3\text{A}_3\cdot\text{CaSO}_4$ ,  $\text{C}_2\text{S}$  et de la chaux libre, a été obtenu en cuisant au four rotatif, entre 1250 et 1300° C un cru de composition chimique appropriée. On a constaté qu'un ciment à durcissement rapide et à haute résistance pouvait être obtenu en broyant ce clinker avec de l'anhydrite, en proportions telles que le rapport molaire ( $\bar{S}/\text{A}$ ) soit compris entre 1,3 et 1,9. La résistance à la compression des mortiers de ces ciments, mesurée selon la norme japonaise JIS-R-5201 a été pour un rapport  $\bar{S}/\text{A} = 1,3$  :

Age	3 h	7 h	1 j.	3 j.	7 j.	28 j.
Résistance( $\text{N/mm}^2$ )	27	38	48	52	54	59

Le durcissement rapide et les fortes résistances de ces ciments peuvent être attribués à la formation d'aiguilles d'ettringite de 1 à 2 microns, qui remplissent les vides de la structure du ciment durci et augmentent la surface spécifique. De plus, la structure durcie devient de plus en plus résistante, grâce à l'hydratation, à long terme, du  $\text{C}_2\text{S}$ .

Les ciments fabriqués avec ces clinkers présentent des caractéristiques d'hydratation variées, qui n'ont pas été observées avec les ciments portland usuels. Il apparaît que ces ciments peuvent être utilisés pour des applications spéciales : stabilisation des sols - durcissement des boues - fixation des métaux lourds nocifs - ciment à hautes performances.

## INTRODUCTION

Some studies (1)(2)(3) have been made or reported about  $\text{CaO-Al}_2\text{O}_3\text{-SiO}_2\text{-SO}_3$  systems in relation to expansive cement. Most of them, dealing with  $\text{C}_3\text{A}_3\cdot\text{CaSO}_4$ , have been undertaken for the main purpose of clarifying the expansive properties of the cement and arriving at a manufacturing method. ( Hereafter,  $\text{C}_3\text{A}_3\cdot\text{CaSO}_4$  will be shortened to  $\text{C}_4\text{A}_3\bar{\text{S}}$ . ) The authors found the possibility of applying this system not only to expansive cement but also to a rapid-hardening, high-strength cement and other special admixtures.

Assuming that the ratios or the amounts of  $\text{C}_4\text{A}_3\bar{\text{S}}$ , free  $\text{CaO}$  and  $\text{C}\bar{\text{S}}$  in a cement should have much effect on the rate of the formation reaction of ettringite and on its character, the authors investigated the hydration characteristics of cements with various mineral compositions in  $\text{CaO-Al}_2\text{O}_3\text{-SiO}_2\text{-SO}_3$  systems. Moreover, extending research to the manufacturing of special cements, the authors determined the conditions of mineral composition of cement clinker, burning temperature, grinding and so on.

The present paper is mainly concerned with a high-strength cement using clinker of this system, and deals with the burning reactions and hydration characteristics.

## DETERMINATION OF MINERAL COMPOSITION FOR HIGH-STRENGTH CEMENT

The optimum mineral composition for high-strength cement was considered as a result of the following experiments. Three types of clinker were synthesized by use of limestone, two kinds of clay, by-product gypsum and re-

agent  $\text{Al}_2\text{O}_3$ . The raw materials were mixed at set proportions and ground to  $6000 \text{ cm}^2/\text{g}$  in Blaine specific surface. The raw mixtures were formed into pellets, which were burned in an electric furnace. The clinkers produced were examined by X-ray diffraction analysis to see whether the desired minerals had been formed. The chemical analyses and burning conditions of the clinkers are shown in Table I. The No. 1 clinker contained  $\text{C}_4\text{A}_3\bar{\text{S}}$  as its principal mineral, the No. 2 clinker  $\text{C}_2\text{S}$  and the No. 3 clinker free  $\text{CaO}$ .

Eighteen types of cement were prepared by blending and grinding mixtures of clinkers, anhydrite and quicklime as shown in Table II. Anhydrite was obtained by burning gypsum at  $1000^\circ\text{C}$  for 120 min., and quicklime by burning crushed limestone at  $1450^\circ\text{C}$  for 80 min. Each cement was ground to  $4500 \text{ cm}^2/\text{g}$ . The compressive strengths of mortars of the cements are also shown in Table II. The testing method was according to JIS R 5201 (  $\text{W/C} = 0.65$ ,  $20^\circ\text{C}$ , sand/cement = 2 ) except that test pieces of  $2 \times 2 \times 8 \text{ cm}$  were used.

In the A series shown in Table II, the cements were prepared with  $\text{C}_4\text{A}_3\bar{\text{S}}$  and free  $\text{CaO}$  constant while varying anhydrite and  $\text{C}_2\text{S}$  in amount. The amounts of  $\text{C}_4\text{A}_3\bar{\text{S}}$  and free  $\text{CaO}$  were 41 % and 0 %, respectively. Strengths of mortars increased for all ages with an increase in the amount of anhydrite. The optimum amount of anhydrite for high strength development is estimated to be about 30 %, and in that condition, the  $\text{SO}_3/\text{Al}_2\text{O}_3$  molar ratio (  $\bar{\text{S}}/\text{A}$  ) is calculated to be about 1.3.

In the B series, the cements were prepared with reference to the mineral composition of A-7 cement which showed good strength proper-

ties. The amounts of  $C_4A_3\bar{S}$  and anhydrite were fixed at 40~42 % and 27~31 %, respectively, and free CaO and  $C_2S$  were varied. When the amount of free CaO came to 9 % as a result of incremental raises, the compressive strength of mortar increased rapidly within 24 hours. However, the strength properties worsened because of undesirable expansion when CaO was added above 19 %.

From the above results, it became clear that a cement of a  $CaO-Al_2O_3-SiO_2-SO_3$  system has the properties of producing rapid hardening and high strength development when the proper mineral composition can be determined.

#### FUNDAMENTAL STUDIES OF RAPID-HARDENING AND HIGH-STRENGTH CEMENT

Many experiments were conducted on the basis of the above-mentioned results, and as a consequence, a special cement having properties of both rapid hardening and high strength was developed. This cement can also be said to be an energy-saving type as its clinker is burned in a relatively low temperature range of 1250 to 1300°C. The burn-

ing reactions and hydration characteristics of the cement are dealt with in the following.

#### (1) BURNING REACTIONS

The cement clinker has a special mineral composition; it contains  $C_4A_3\bar{S}$  and  $C_2S$  as the principal minerals, with free CaO amounting to about 9 %, and no free  $CaSO_4$  as shown in Table III. This prepared mixture, containing no free  $CaSO_4$  in the clinker, prevents volatilization of the  $SO_3$  component, which is very important in preventing environmental pollution.

The raw mixture was prepared by use of limestone, by-product gypsum, aluminous materials and clay to obtain the optimum chemical composition of the clinker as shown in Table

Table III Optimum chemical and mineral compositions of clinker (%)

Chemical composition					Mineral composition			
$SiO_2$	$Al_2O_3$	$Fe_2O_3$	CaO	$SO_3$	$C_4A_3\bar{S}$	$C_2S$	$C_4AF$	$f-CaO$
11.2	28.1	1.6	52.0	7.1	54	32	5	9

III. The raw mixture, ground to  $5500 \text{ cm}^2/\text{g}$ , was burned in an electric furnace at temperatures varied from  $1000$  to  $1350^\circ\text{C}$  at  $50^\circ\text{C}$  increments. The relationships between burning temperatures and clinker minerals were investigated by X-ray. The X-ray diffraction patterns of the clinkers are shown in Fig. 1.

While  $\text{C}_2\text{AS}$  and  $\text{C}_{12}\text{A}_7$  formed as aluminates in the temperature range of  $1000$  to  $1100^\circ\text{C}$ ,  $\text{C}_4\text{A}_3\bar{\text{S}}$  became stable above  $1150^\circ\text{C}$  with maximum formation in the  $1250$  to  $1300^\circ\text{C}$  range. Silicates coexisting with  $\text{C}_4\text{A}_3\bar{\text{S}}$  were  $2\text{C}_2\text{S}\cdot\text{C}\bar{\text{S}}$  and/or  $\text{C}_2\text{S}$ , the former formed mainly in the lower temperature range and the latter in the higher range.  $\text{C}_4\text{A}_3\bar{\text{S}}$  began to decompose with the formation of  $\text{C}_3\text{A}$  at  $1350^\circ\text{C}$ , and this was accompanied by an extreme decrease in free  $\text{CaO}$ .

From the above-mentioned results, it was made clear that a temperature range of  $1250$  to  $1300^\circ\text{C}$  is optimum for obtaining clinker containing  $\text{C}_4\text{A}_3\bar{\text{S}}$  and  $\text{C}_2\text{S}$  as the principal minerals and a sufficient amount of free  $\text{CaO}$ .

Fig. 1 X-ray diffraction patterns of clinkers

## (2) HYDRATION CHARACTERISTICS

Five types of cement of specific surface of  $4000 \text{ cm}^2/\text{g}$  were prepared by blending and grinding mixtures of the clinker and by-product anhydrite. The clinker, prepared to obtain the optimum chemical composition as shown in Table III, was burned at about  $1300^\circ\text{C}$  using a test rotary kiln. Table IV shows the preparation conditions of the cements and the compressive strengths of their mortars according to the JIS R 5201 method.

Table IV Preparation of cements and their mortar strengths

Cement	$\text{SO}_3$ (%)	$\bar{\text{S}}/\text{A}$ ratio	Compressive strength ( $\text{N}/\text{mm}^2$ )					
			3h	7h	1d	3d	7d	28d
C-1	10	0.5	7.4	10.0	13.7	13.6	13.9	12.7

H			—	—	13.8	27.9	28.3	48.6

H: High-early strength portland cement

The strengths of the mortars were increased at all ages when the amount of anhydrite was increased, and the cements showed both rapid-hardening and high-strength properties at  $\text{SO}_3$  content of 20 to 25 %, and with  $\bar{\text{S}}/\text{A}$  ratio of 1.3 to 1.9. C-1 cement, having a lesser amount of anhydrite, showed little increase in strength with elapse of time as well as lower strengths at very early ages. C-5 cement, having a larger amount of anhydrite, showed lowering of strength at 7 days due to undesirable expansion cracks. Table V shows compressive strengths in case of standard curing of concretes using various amounts of C-3 cement.

Three types of cement were examined to make clear differences in strength properties through conduction calorimetry, X-ray analysis and scanning electron microscopy. The cements were hydrated in paste form at  $20^\circ\text{C}$  and water-cement ratio (W/C) of 0.6. The pastes were sealed in polyethylene sheets, and were allowed to settle down in a room of temperature of  $20^\circ\text{C}$  until they could be ex-

amed.

All of the heat liberation curves had two peaks as shown in Fig. 2. It is estimated from the results obtained by X-ray analysis (Table VI) that the second peaks correspond to formation of ettringite, which is retarded with additional amounts of anhydrite.

In the case of C-1 cement, heat of hydration decreases at an early stage and monosulfate hydrate forms more stably than ettringite on the first day. As monosulfate hydrate grows in the form of thin plates having vacant spaces which are probably too large to be filled by the hydrate of  $C_2S$ , good strength properties cannot be expected in all ages. (Fig. 3(a))

In comparison with the above, the hydrate of C-3 cement having a suitable amount of  $SO_3$  is mainly ettringite. As is shown in Fig. 3 (b), ettringite is formed in needle-like shapes of 1 to 2  $\mu m$  which fill the inner vacant spaces of the hardened body with a large specific surface, and this provides for high-strength characteristics.

In the case of C-5 cement, as shown in Fig. 3(c), the hydrate is also ettringite, but its form is different from that of C-3 cement; needle-like ettringite aggregates densely surround the cement grains but are formed very little in the vacant spaces. It is estimated that these characteristic forms of hydrate result later in undesirable expansion.

It has been mentioned above that C-3 cement

Fig. 3 Scanning electron micrographs of hardened pastes at 1 day

has rapid-hardening and high-strength properties owing to the formation of minute ettringite. Moreover, the hardened structure

Fig. 4 Pore size distributions of cement mortars

becomes stronger by the hydration of  $C_2S$  over long periods of time. Fig. 4 shows pore size distributions of C-3 cement mortars compared with those of ordinary portland cement (O.P.C.) mortars. On comparisons of total pore volumes (T.P.V.) and pore size distributions of C-3 cement mortars with those of O.P.C. mortars, it is easy to understand the reason why C-3 cement exceeds O.P.C. in mortar strength. The T.P.V. of C-3 cement mortar decreases more and more owing to the hydration of  $C_2S$  over a long period of time and the hardened body is able to attain a high-strength characteristic.

#### APPLICATIONS OF CLINKERS OF $CaO-Al_2O_3-SiO_2-SO_3$ SYSTEM

Several kinds of special cement have been developed utilizing clinkers of this system. These types of cement are produced by grinding O.P.C. clinker, blast furnace slag and anhydrite with clinkers of this system which are prepared and burned to give the hydration properties necessary to meet their specific uses.

These cements possess various hydration characteristics due to formation of ettringite which are not seen normally with portland cement, and are applicable to special uses such as admixtures for soil stabilization and hardening of sludge (4), a hydraulic binder in fixation of harmful heavy metals (5) and as a cement for excelsior board.

#### CONCLUSIONS

Many studies have been carried out regarding clinkers of the  $CaO-Al_2O_3-SiO_2-SO_3$  system to clarify expansive properties and to consider utilization as an expansive admixture. As stated in this paper, however, cements of this system have multiple purposes, including that of high-strength cement. This is due to the hydration characteristics of  $C_4A_3S$  which hydrates in various ways according to the amounts of  $Ca(OH)_2$  and  $CaSO_4$ . It is thought that studies on special types of cement will be advanced further with more specialization in the future, and it may be anticipated that more research works on hydration mechanisms will be carried out employing  $C_4A_3S$ -calcium silicate and/or free  $CaO$ -calcium sulfate systems.

# Systeme aluminat de calcium - gypse - chaux - eau

## *On the calcium aluminate - gypsum - lime system*

A. BONIN, Ingénieur de Recherche, Laboratoire de Recherche Générale, Lafarge S.A.,  
B. CARIOU, Ingénieur, Laboratoire de Recherche Appliquée, Lafarge S.A., France.

RESUME : La mise au point des ciments expansifs de type M a montré le rôle important de la chaux vis-à-vis de la cinétique de gonflement de ces liants. L'expansion étant obtenue grâce à l'hydratation, en ettringite, du  $C_3A$  du clinker de Portland, en présence de gypse, une étude de cinétique de formation d'ettringite a été menée à partir des constituants purs.

Avec l'aluminat tricalcique  $C_3A$ , stoechiométrique pour la formation de l'ettringite, la présence de chaux en quantité inférieure à 1 % suffit pour bloquer pratiquement les réactions.

Dans le cas d'autres aluminates de calcium, où la chaux intervient en tant que réactant, elle provoque d'abord une accélération de la cinétique, puis un ralentissement pour les plus fortes proportions, plus ou moins marqué selon l'aluminat étudié.

SUMMARY : The studies about the shrinkage compensating cements of type M had shown that the kinetics of their expansion are very affected by the lime. The increase in volume is due to the  $C_3A$  hydration into ettringite, in the presence of gypsum. Therefore, we investigated the kinetics of ettringite formation from the pure components.

With the tricalcium aluminate  $C_3A$ , which is stoichiometric for ettringite formation, a content of lime as low as one percent is able to stop the reactions nearly completely.

In the case of other calcium aluminates, the lime is involved in the reactions as a reagent : at first it induces an increase in the kinetics ; then, for larger contents, a retardation more or less significant according to the calcium aluminate in question.

## INTRODUCTION

Au cours de nos études de liants hydrauliques divers (ciment portland, spéciaux, prompts, expansifs ...), nous avons été constamment confrontés au problème de l'hydratation des aluminates de calcium ( $C_3A - C_{12}A_7 - CA - C_4A_3S$ ) en présence de quantités plus ou moins grandes de sulfate de calcium et de chaux ou corps libérant de la chaux. C'est ainsi que nous avons été amenés à étudier des systèmes séparés - aluminat de calcium - gypse - chaux - eau. Nous nous proposons de faire la synthèse des résultats que nous avons obtenus.

Les aluminates de calcium des essais ont été préparés par cuisson au four électrique, de mélanges stoechiométriques des oxydes de base. Nous avons considéré qu'ils étaient purs, quand par diffraction des rayons X, on ne décelait plus la présence des produits de départ ( $CaO$  libre en particulier), ni celle d'aluminates autres pouvant se former de manière transitoire.

Les techniques d'investigation utilisées ont été essentielles :

- La microcalorimétrie isotherme qui nous permet d'enregistrer les dégagements de chaleur de réaction dès le contact de l'anhydre et de l'eau.
- La diffraction des rayons X pour identifier les hydrates formés et suivre la consommation des anhydres.
- Dans certains cas, la mesure de l'eau liée par perte au feu à  $1000^\circ$  sur échantillons dont l'hydratation est stoppée par lavage à l'acétone et séchage à l'éther.

SYSTEME  $C_3A$  - GYPSE - CHAUX - EAU

De nombreux auteurs (1 - 5) ont étudié ce système en raison de son importance dans les ciments Portland. Ils ont dans leur ensemble adopté un rapport molaire gypse/ $C_3A$  toujours inférieur à 0,4. Pour notre part, ayant été amenés à cette étude pour des questions de raidissement inhabituel, nous avons préféré opter pour un rapport plus élevé car aux premiers instants de l'hydratation, le  $C_3A$  en périphérie des grains (donc au contact de la solution) est tel que le rapport gypse/ $C_3A$  est certainement très grand. D'autre part, le seul hydrate se formant durant les premières minutes de l'hydratation étant l'ettringite, nous avons choisi la proportion de trois moles de gypse pour une de  $C_3A$ .

Ce mélange de base a été hydraté seul ou en présence d'une solution saturée de chaux, ou d'ajouts de chaux hydratée solide allant de très faibles teneurs jusqu'à 10 % (E/C = 1,0).

Le graphique N° 1 et le tableau N° I illustrent les réactions.

De l'ensemble de ces résultats, nous remarquons que :

- Dans tous les cas, le seul hydrate formé est l'ettringite.
  - L'hydratation du témoin ( $C_3A + 3$  gypses) est rapide et sans période dormante. On peut estimer que la réaction est effectuée à 60 % à 1 heure et à 85 % à 24 heures. Il n'apparaît aucun blocage.
  - Un ajout de 0,1 % de chaux hydratée semblerait accélérer la réaction d'hydratation. Par contre, 0,3 % la ralentit fortement, 0,5 % la bloque presque et 1 % la rend inexistante.
  - Le gâchage avec une solution saturée de chaux (correspondant à 0,15 % de chaux hydratée) la ralentit fortement.
- En résumé, il faut admettre que l'hydratation du mélange  $C_3A + 3$  gypses ne se bloque pas mais qu'il suffit de très peu de chaux hydratée pour la ralentir et même la stopper.

Pour les ciments, STEINOUR (6), STEIN (7), COTTIN (8), COLLEPARDI (9) admettent qu'en présence de gypse l'hydratation du  $C_3A$  est ralentie par la formation d'une coquille d'ettringite imperméable et protectrice. Nos observations ne sont pas en contradiction avec cette hypothèse et nous

24 h.	>230	20	61,8 %				

TABLEAU N° I - Cinétique de formation de l'ettringite du mélange  $C_3A + 3$  Gypses seul ou en présence de chaux

ajoutons que c'est grâce à la chaux (libre ou d'hydrolyse du  $C_3S$ ) saturant rapidement la solution en ions  $Ca^{++}$  que la coquille peut être bloquante, car moins bien cristallisée. S'il venait à manquer de la chaux en solution, l'ettringite formée assurerait moins bien son rôle protecteur, ou hydraterait plus de  $C_3A$  et on risquerait le raidissement.

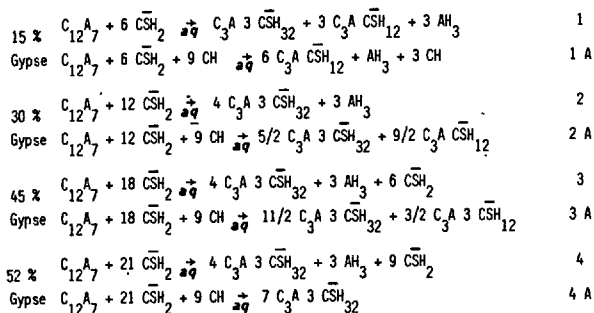

SYSTEME  $C_{12}A_7$  - GYPSE - CHAUX - EAU

Lors de l'étude de produits spéciaux, nous avons considéré l'hydratation du système à base de  $C_{12}A_7$ , dilué dans un inerte (mélanges du tableau N° II).

en poids				en mole		
inerte	$C_{12}A_7$	$CSH_2$	CH	$C_{12}A_7$	$CSH_2$	CH
			0			0

80	20	52	6	1	21	5,62
			8			7,50

TABLEAU N° II - Proportion pondérale et molaire des constituants des divers mélanges

Si on écrit les réactions théoriques d'hydratation de ces mélanges, avec les proportions extrêmes de chaux et en combinant le maximum de sulfate sous forme de sulfoaluminate (tri ou mono), on est conduit aux équations suivantes.

Selon ces équations, en l'absence d'ajout de chaux hydratée, il se forme toujours une quantité constante d'alumine libre. Le gypse est excédentaire pour les teneurs de 45 et 52 %. On obtient un mélange de mono et trisulfo pour le produit à 15 % de gypse et de l'ettringite pour les autres.

Un ajout de chaux hydratée au mélange à 15 % de gypse ne permet de combiner qu'une partie de l'alumine et tout le sulfate est sous forme de monosulfoaluminate.

Par contre, un ajout de 9 moles de chaux aux autres produits permet de combiner toute l'alumine et tout le gypse en un mélange de mono et trisulfo pour 30 et 40 % de gypse et en ettringite pure pour 52 %.

Nous avons déterminé les temps de prise Vicat et identifié semi quantitativement par diffraction des RX les phases présentes après 24 heures d'hydratation. Le tableau N° III donne les résultats obtenus.

Nous ne donnons que les courbes calorimétriques du mélange à 30 % de gypse, les autres étant semblables : graphique N° 2. On constate que :

- En diffraction X, on n'observe jamais l'alumine qui, quand elle existe, doit être sous forme amorphe.

- Les produits sans ajout de chaux hydratée se comportent comme le prévoient les équations 1 - 2 - 3 - 4.

- L'ajout de chaux hydratée au produit à 15 % de gypse ne provoque pas de phénomènes en contradiction avec l'équation 1A. Par contre, pour les produits à 30 - 45 et 52 % de gypse, on ne trouve aucun des comportements décrits par les équations 2A - 3A et 4A : il existe une teneur critique en chaux croissante avec la teneur en gypse, pour laquelle on observe une discontinuité de comportement :

- En dessous de cette valeur, les réactions sont fortement accélérées (temps de prise très raccourcis, augmentation importante du premier pic de calorimétrie). La presque totalité du gypse ainsi que toute la chaux sont consommés et le seul hydrate observé est l'ettringite.

- Au dessus de cette valeur, la situation est complètement inversée. Les réactions sont bloquées (absence de fin de prise, diminution importante du premier pic de calorimétrie, disparition totale du second). La quantité d'ettringite faite est réduite de moitié et il reste toujours de fortes quantités de gypse et de chaux hydratée.

L'explication de ces phénomènes n'est pas évidente. A priori, on pouvait penser que l'alumine amorphe libérée par l'hydratation des produits sans chaux, générerait le contact du  $C_{12}A_7$  avec la solution et ralentirait les réactions ; mais que par contre des ajouts de chaux consommant cette alumine permettraient d'accélérer l'hydratation. Cette hypothèse va dans le sens de nos observations d'une part en ce qui concerne les mélanges à 15 % de gypse et d'autre part pour ceux à 30 - 45 et 52 % à condition de ne pas dépasser la valeur critique d'ajout de chaux.

En ce qui concerne les blocages des produits plus riches en

GRAPHIQUE N° 2 - Courbes de dégagement de chaleur lors de l'hydratation du mélange à 30 % de gypse pour divers ajouts de CH

chaux, il faut faire intervenir comme dans le cas du  $C_3A$  une protection du  $C_{12}A_7$  par une pellicule d'ettringite dont la cristallisation (donc la plus ou moins grande imperméabilité) est influencée par la concentration en chaux de la solution. En supposant qu'il y ait compétition entre la cinétique de consommation de la chaux par l'alumine et sa vitesse de mise en solution, pour de faibles teneurs en chaux où la consommation l'emporterait, la solution ne serait jamais saturée en  $Ca^{++}$  alors que pour les plus fortes elle le serait rapidement. Dans ces conditions, la coquille d'ettringite mieux cristallisée aux faibles ajouts de chaux serait moins bloquante tandis qu'aux forts ajouts, moins bien cristallisée, elle isolerait plus efficacement le  $C_{12}A_7$  de la solution.

Une telle explication est en accord avec les résultats trouvés pour le  $C_3A$  où des quantités infimes d'ajout de chaux suffi-

sent pour bloquer l'hydratation, car dans ce système il n'y a pas d'excès d'alumine et la chaux d'ajout, aussi faible soit-elle, n'est jamais consommée et donne rapidement des solutions saturées en  $\text{Ca}^{++}$ .

#### SYSTEME CA - GYPSE - CHAUX - EAU

Un tel système est susceptible de se rencontrer dans les ciments prompts, constitués d'un mélange d'alumineux et de portland gypsé. Pour l'étudier, nous avons réalisé l'hydratation des mélanges du tableau N° IV.

en mole			en mole		
CA	CSH <sub>2</sub>	CH	CA	CSH <sub>2</sub>	CH
1	1	0	1	3	0
1	1	0,5	1	3	1
1	1	2/3	1	3	2
1	1	4/3	1	3	3

TABLEAU N° IV - Composition des mélanges de CA-Gypse et chaux étudiés

Les équations d'hydratation des mélanges à une mole de gypse peuvent s'écrire :

On remarque que le mélange équimolaire de CA et de gypse s'hydrate en libérant 2/3 de moles d'alumine. Un ajout de n moles de chaux permet de consommer n moles d'alumine mais entraîne aussi une augmentation de n moles de CA non hydratée. En ce qui concerne les équations 5 A - 5 B - 5 C, il y a risque de formation de monosulfoaluminate mais qui ne devrait pas se manifester à l'échéance de 24 heures.

Les équations théoriques d'hydratation des mélanges à 3 moles de gypse peuvent s'écrire :

Dans le cas des mélanges sans chaux, on a un gros excès de gypse et on libère 2/3 de moles d'alumine. L'ajout de n moles de chaux permet de consommer n moles de gypse et n/3 moles d'alumine : pour n = 2, l'hydratation du mélange conduit à 100 % d'ettringite.

Nous avons réalisé l'hydratation de ces mélanges au calorimètre à conduction. Les résidus de calorimétrie à 24 heures après stoppage d'hydratation ont été examinés en diffraction des RX pour juger de l'avancement des réactions. Le tableau N° V donne les estimations de la consommation des phases de départ. Les graphiques N° 3 et 4 donnent les courbes de dégagement de chaleur d'hydratation.

mélanges à 1 mole de gypse				mélanges à 3 moles de gypse			
mole de CH ajoutée	% CA consommé	% CSH <sub>2</sub> consommé	% CH consommé	mole de CH ajoutée	% CA consommé	% CSH <sub>2</sub> consommé	% CH consommé
0	70	69	-	0	100	27	-
0,5	73	quasi totale	100	1	60	62	100
2/3	64		100	2	55	66	100
4/3	55		95*	3	72	80	26

TABLEAU N° V - Estimation de la consommation des phases de départ des mélanges à 1 et 3 moles de gypse (\* présence de  $\text{C}_4\text{AH}_{13}$ )

GRAPHIQUE N° 3 - Courbes de dégagement de chaleur des mélanges CA + CSH<sub>2</sub> pour divers ajouts de CH

GRAPHIQUE N° 4 - Courbes de dégagement de chaleur des mélanges CA + 3CSH<sub>2</sub> pour divers ajouts de CH

On constate que :

- Le seul hydrate formé est l'ettringite. On ne voit pas l'alumine par diffraction des rayons X (elle est donc sous forme amorphe comme dans le cas du  $\text{C}_{12}\text{A}_7$ ). Dans tous les cas où les équations d'hydratation prévoient que la chaux hydratée se combine à l'alumine, on observe effectivement une consommation totale de l'ajout pratiqué.

- Pour les mélanges à une mole de gypse, la réaction est effectuée conformément à l'équation 5 et le degré d'avancement à 24 heures est de 70 %. La majeure partie de la réaction se produisant après 1 heure. En ajoutant de la chaux, on accroît considérablement le premier pic (sensiblement de 15 fois) et on retarde en les diminuant légèrement les pics situés après 1 heure. L'augmentation du 1er pic est indépendante de la teneur en chaux, par contre, le retard des autres est croissant avec l'ajout pratiqué. De toute manière, les réactions sont à peu près totales à 24 heures.

- Pour les mélanges à trois moles de gypse en absence de chaux, on consomme tout le CA et le tiers du gypse comme le prévoit l'équation 6. La réaction est totale à 24 heures (la plus grande partie s'effectuant après 1 heure). En ajoutant 1 mole de chaux, on augmente fortement le premier pic (sensiblement de 7 fois) mais on retarde fortement les autres pics en les écrasant. A 24 heures, les réactions ont un degré d'avancement réduit à 60 %. En continuant à augmenter l'ajout de chaux, on obtient une nette décroissance du 1er pic sans changer notablement les autres. Le degré d'avancement à 24 h de la réaction s'en trouve un peu diminué.

En résumé, on peut retenir qu'en présence d'une faible quantité de gypse, l'ajout de chaux hydratée accélère l'hydratation surtout dans les premières minutes et qu'on observe aucun blocage. En présence de quantités plus grandes de gypse les ajouts successifs de chaux, après avoir fortement accéléré l'hydratation, la ralentissent notablement sans tou-

tefois provoquer de blocage absolu.

# SYSTEME $C_4A_3\bar{S}$ + GYPSE + CHAUX + EAU

Un tel système se rencontre dans les ciments expansifs de type M. Pour l'étudier en laboratoire, nous avons réalisé l'hydratation des mélanges du tableau N° VI.

$C_4A_3\bar{S}$	$CSH_2$	CH	$C_4A_3\bar{S}$	2 $CSH_2$	CH	$C_4A_3\bar{S}$	8 $CSH_2$	CH
1	0	0	1	2	0	1	8	0
1	0	0,43	1	2	0,26	1	8	0,27
1	0	0,92	1	2	0,68	1	8	0,55
1	0	2,00	1	2	1,43	1	8	1,41
1	0	4,00	1	2	2,28	1	8	3,00
1	0	6,00	1	2	4,00	1	8	6,00
1	0	10,00	1	2	6,00	1	8	10,00

TABLEAU N° VI - Composition molaire des mélanges de gypse et de chaux étudiés

Les équations d'hydratation de ces mélanges sont :

On voit que  $C_4A_3\bar{S}$  s'hydrate en monosulfo avec libération d'alumine. Un ajout de 8 moles de chaux permet de fixer cette

GRAPHIQUE N° 5 - Courbes de dégagement de chaleur des mélanges  $C_4A_3\bar{S} + n CH$

alumine en  $C_4AH_{13}$ . En présence de 2 moles de gypse et 6 moles de chaux, on obtient du monosulfo pur et pour 2 moles de gypse et 6 moles de chaux, de l'ettringite pure.

Le tableau N° VII donne les phases obtenues par hydratation durant 24 heures. Les graphiques N° 5 - 6 - 7 montrent les courbes de dégagement de chaleur pendant les réactions.

GRAPHIQUE N° 6 - Courbes de dégagement de chaleur des mélanges  $C_4A_3\bar{S} + 2 CSH_2 + n CH$

On remarque que :

- Le  $C_4A_3\bar{S}$  seul s'hydrate de manière prépondérante en monosulfoaluminat selon l'équation 7 et l'alumine visible en diffraction des rayons X est mieux cristallisée. En accord avec l'équation 7 A l'ajout de CH permet de fixer l'alumine sous forme de  $C_4AH_{13}$ . Dans tous les cas, les réactions ont un degré d'avancement de 95 % en moyenne à 24 heures. Les microcalorimétries montrent en présence de CH une très forte accélération des phénomènes se traduisant par un premier pic considérablement augmenté et un déplacement des seconds pics vers les temps les plus courts. Nous n'observons jamais de blocage.

- Le mélange à deux moles de gypse s'hydrate en ettringite en accord avec l'équation 8. L'alumine formée est amorphe. Un ajout progressif de chaux permet d'obtenir, en accord avec l'équation 8 A un mélange de plus en plus riche en monosulfoaluminat. Nous ferons, en ce qui concerne les cinétiques de réaction, les mêmes remarques que pour le  $C_4A_3\bar{S}$  seul (en particulier l'absence de blocage).

- Le mélange à 8 moles de gypse, en absence de chaux, est complètement hydraté, à 24 heures, en ettringite. Il reste beaucoup de gypse et l'alumine libérée (équation 9) est amorphe. Des ajouts progressifs de chaux augmentent le premier pic de calorimétrie et font disparaître les seconds. Il semblerait que les réactions soient accélérées, cependant,

$C_4A_3\bar{S}$							$C_4A_3\bar{S} + CSH_2$							$C_4A_3\bar{S} + 8 CSH_2$

8	96	"	145	0			6,00	93	"	"	39	86	66	10,0	56	42	16	102		

TABLEAU N° VII - Consommation des anhydres et apparition des phases hydratées à 24 h des mélanges  $C_4A_3\bar{S}$  + gypse en fonction des ajouts de chaux hydratée

GRAPHIQUE N° 7 - Courbes de dégagement de chaleur des mélanges  
 $C_4A_3S + 8 CSH_2 + n CH$

on voit par diffraction des rayons X que globalement la quantité de  $C_4A_3S$  réagissant décroît notablement à partir d'un ajout de 6 moles de chaux (stoechiométrie de l'ettringite) qui n'est pas entièrement consommée. En forçant l'ajout de chaux hydratée, on ralentit encore l'hydratation. Il y a là un début de blocage des réactions moins caractérisé que pour le  $C_3A$  et le  $C_{12}A_7$  mais qui ne fait aucun doute.

En résumé, tous les mélanges  $C_4A_3S$  - gypse en absence de chaux hydratée s'hydratent rapidement. L'ajout de chaux hydratée accélère les réactions chaque fois que l'on favorise la formation de monosulfo et les ralentit quand on cherche à former l'ettringite pure.

#### CONCLUSION

Les mélanges d'aluminate de calcium, de gypse et de chaux peuvent avoir des comportements, lors des réactions d'hydratation, très différents selon la nature de l'aluminate de base et des hydrates susceptibles de se former.

On peut schématiquement considérer trois cas.

- Les mélanges ont la stoechiométrie pour la formation de monosulfoaluminate : Les réactions sont alors rapides et complètes sans phénomène de blocage (cas de  $C_{12}A_7 - CA - C_4A_3S$ ). La formation passagère d'un peu d'ettringite aux faibles échéances n'altère pas les cinétiques.

- Les mélanges ont la stoechiométrie pour la formation d'ettringite : On assiste alors en présence de CH à des blocages plus ou moins caractérisés. Ces blocages sont d'autant plus marqués que le C/A de l'aluminate de départ est plus grand (dans l'ordre  $C_3A - C_{12}A_7 - C_4A_3S - CA$ ).

- Les mélanges intermédiaires où les hydrates formés sont des mélanges de monosulfo, d'ettringite, de  $C_4AH_{13}$  et d'alumine (le plus souvent amorphe). Chaque fois que ces teneurs en gypse et en chaux augmentent et favorisent une proportion relative d'ettringite un peu prépondérante, on assiste à des blocages ou ralentissements.

En ce qui concerne l'alumine amorphe, elle aurait tendance à ralentir les réactions (sans doute en gênant la mobilité des ions en solution) et de faibles ajouts de chaux permettant de la consommer, surtout aux faibles échéances, accélèrent considérablement l'hydratation dans les premières minutes.

Le point qui nous paraît le plus important à souligner est le rôle bloquant de l'ettringite quand celle-ci se forme en présence de chaux excédentaire (Au tout début des réactions quand très peu d'ettringite s'est formée, on peut considérer qu'il y a de la chaux excédentaire même pour de faibles teneurs).

En fait, il faut raisonner en possibilité de sursaturation en ions  $Ca^{++}$  dans la solution où précipite l'ettringite. Plus

cette sursaturation a de risques d'être élevée (même momentanément), plus l'ettringite sera mal cristallisée et en conséquence plus bloquante.

A chaque fois que, dans des ciments, interviendra un système aluminate de calcium - gypse - chaux, il conviendra de s'intéresser aux conditions de précipitation des hydrates et les quelques conclusions de ce papier sont de nature à aider les raisonnements.

En particulier, ne faudrait-il pas voir là l'explication de la fausse prise carbonate ? En effet, il est plus séduisant de penser que c'est le manque momentané de  $Ca^{++}$  en solution (due à la précipitation de calcite) qui modifierait la cristallisation de l'ettringite permettant une hydratation accrue du  $C_3A$ , génératrice de raidissement, plutôt que d'admettre que c'est la très faible quantité de calcite (bien cristallisée et n'entraînant pas d'eau) qui provoque l'épaississement de la pâte.

# High strength slag-alkaline cements

## *Ciments de laitier alcalin, à haute résistance*

V.D. GLUKHOVSKY, Professor, Dr. Technical Sciences,  
G.S. ROSTOVSKAJA, Cand. Technical Sciences,  
G.V. RUMYNA, Cand. Technical Sciences, Institute of Civil Engineering, Kiev, U.R.S.S.

**RESUME :** Vers les années 50 de notre siècle, furent découvertes les propriétés liantes hydrauliques de composés chimiques contenant Li, Na, K, Rb, Cs ...; en 1960, leur mélange avec des produits hydrauliques entra dans la pratique courante de l'industrie de la construction; il s'agissait alors à la fois de métaux alcalins et alcalinoterreux. C'est le cas des ciments de laitier alcalin, qui ont été étudiés et fabriqués, non seulement en U.R.S.S., mais aussi en Pologne et brevetés en R.D.A., en R.F.A., en Grande Bretagne, en France et au Japon.

Les ciments de laitier alcalin sont obtenus par broyage des laitiers granulés produits par la métallurgie et l'électrothermie des minerais phosphoreux, avec addition d'une solution d'un composé de métaux alcalins, de façon à produire la réaction alcaline.

Les produits de l'hydratation de ces ciments sont : la silice acide et des hydrosilicates de calcium à faible basicité du type hydronephelite, natrolite, paragonite et muscovite; ils ne contiennent pas de chaux libre, ni hydroaluminates, ni hydrosulfoaluminates, ni hydrosilicates de calcium à forte basicité.

La résistance de ces ciments varie de 400 à 1200 kg/cm<sup>2</sup>. En ce qui concerne leur résistance à la corrosion, ils surpassent les ciments résistant aux sulfates; en ce qui concerne la vitesse de durcissement, ils sont comparables aux ciments alumineux.

**SUMMARY :** In the fifties of our century hydraulic binding properties of the compounds of Li, Na, K, Rb, Cs, were discovered and in 1960 mixed hydraulic binding systems were put into practice in the construction industry; these consist of both alkali and alkaline-earth metals. Belonging to them are the slag-alkaline cements which are investigated and manufactured not only in the USSR but in Poland and are patented in the GDR, FRG, Great Britain, France and Japan.

The slag-alkaline cements are ground products of granulated metallurgical and electrothermophosphorous slags with solutions of alkaline metals compounds added to them and producing alkaline reaction.

The hydration products of the slag-alkaline cements comprise silicic acid, low-basicity calcium hydrosilicates, as well as alkaline hydroalumosilicates of the hydronephelite, natrolite, paragonite and muscovite group; they contain no free lime, hydroaluminates, hydrosulphoaluminates and high-basicity calcium hydrosilicates.

The strength of the slag-alkaline cements ranges from 400 to 1200 kgf/cm<sup>2</sup>. In corrosion stability they excel the sulfate-resisting cement and in speed of the strength reaching - high alumina cement.

According to the forecasts, special-purpose concretes Grades up to 4000 will be developed by 2000, while the concretes of Grades 1400 will become a common everyday occurrence (1). Along this line of development it is proposed to increase concrete crack resistance and tensile strength; speed up strength growth; enhance abrasion- and frost resistance; reduce heat release during hydration; reduce permeability, etc.

The target set in this country is to considerably increase the production volume of high-strength cements by the 1980-ies and to get concretes Grades 600-1000 in volumes sufficient to meet the construction industry demands (2).

To solve these problems, the activity of the known cements has to be enhanced and new high-strength binding substances developed.

However, the research of many years in the field of enhancing the grades of the Portland cements, generalized in the publications of L.D.Yershov (3) and I.V.Kravchenko (4), shows that the possibilities of raising the activity of the system Portland cement - water are so far limited: neither the variations of mineralogical composition of the clinker, nor the increase of the specific cement surface right up to 900 m<sup>2</sup>/kg do not allow to enhance its grade to a considerable degree. In all cases, when determined by GOST 310.4-76, it remains within the range 500-700. On account of that the highest grade of industrially produced cement to GOST 10178-76 is limited by 600.

Notwithstanding the fact that the Portland cement will, probably, remain the determining binding substance in the nearest discernable future, we set a task to develop new highly-active mineral binding substances which would substantially enhance the strength of concretes, their frost- and corrosion resistance, and other qualities, as well as to considerably extend the raw materials basis of the fillers.

The essence of the idea of creating such binders consists in the exclusion from the cement composition of highly-basic minerals (C<sub>3</sub>A, C<sub>3</sub>S and C<sub>4</sub>AF) whose hydration products either have no essential effect on the synthesis of cement stone strength (C<sub>3</sub>AH<sub>6</sub>, C<sub>4</sub>OH<sub>2</sub>) or enhance its reaction capacity (C<sub>3</sub>AH<sub>6</sub>, C<sub>4</sub>AH<sub>13</sub>, C<sub>2</sub>SH<sub>2</sub>, Ca(OH)<sub>2</sub>) and in the introduction instead of them of caustic alkalis ensuring hydration of aluminosilicate substance of the cement.

To solve this problem helped the discovery in 1957 of hydraulic binding properties in the compounds of alkaline metals - the elements of the basic subgroup of the first group of D.I.Mendeleev's periodic system - Na, K and Li. As a result of this alkaline cements of the system R<sub>2</sub>O-R<sub>2</sub>O<sub>3</sub>-SiO<sub>2</sub> (6,7) were obtained which served as a prerequisite for the development of alkaline - alkaline-earth aluminosilicate cements represented

by the system of oxides R<sub>2</sub>O-R<sub>2</sub>O<sub>3</sub>-SiO<sub>2</sub>, where: R<sub>2</sub>O - oxides of alkaline metals Li<sub>2</sub>O, Na<sub>2</sub>O, K<sub>2</sub>O; R<sub>2</sub>O<sub>3</sub> - oxides of alkaline-earth metals MgO, CaO, SrO; R<sub>2</sub>O<sub>3</sub> - amphoteric oxides Al<sub>2</sub>O<sub>3</sub>, Fe<sub>2</sub>O<sub>3</sub>, Cr<sub>2</sub>O<sub>3</sub>, etc.

A variety of these cements are the slag-alkaline nonhydraulic binding substances which are the products of ground granulated metallurgical or electrothermophosphorous slags mixed with solutions of the compounds of sodium and potassium alkali metals producing alkaline reaction (8, 9).

Caustic alkali ROH, nonsilicate salts of weak acids R<sub>2</sub>CO<sub>3</sub>, R<sub>2</sub>SO<sub>3</sub>, R<sub>2</sub>S, RF, etc; silicate salts type R<sub>2</sub>O (0.5-2.5) SiO<sub>2</sub>, aluminosilicate salts type R<sub>2</sub>OAl<sub>2</sub>O<sub>3</sub>(7) can be used as alkali components of the slag-alkaline cements.

A distinguishing feature of these compounds as compared to similar calcic ones in their matchlessly great solubility. Therefore, the composition of substances participating in the process of condensing the slag-alkaline binding dispersions into a water-resisting stone differs from the composition of substances ensuring the synthesis of the water-resisting stone of calcium binders despite the fact that calcium oxide is present in the system.

By the composition of hydration products these cements can be described as a mixture of two hydraulic binding substances - alkaline aluminosilicates and alkali-earth silicates.

Their hydration products are represented, mainly, by silicic acid, low-basic calcium hydrosilicates of the CSH(B) group with d=3.07; 2.71; 2.11; 1.82Å, as well as by alkaline hydroaluminosilicates of hydronephelite type (R<sub>2</sub>OAl<sub>2</sub>O<sub>3</sub>·2SiO<sub>2</sub>·nH<sub>2</sub>O) with d=6.28; 3.66; 3.28; 2.80; 2.08Å; natrolite (R<sub>2</sub>OAl<sub>2</sub>O<sub>3</sub>·3SiO<sub>2</sub>·nH<sub>2</sub>O) with d=6.7; 4.10; 3.17; 2.82Å; analcite (R<sub>2</sub>OAl<sub>2</sub>O<sub>3</sub>·4SiO<sub>2</sub>·nH<sub>2</sub>O) with d=5.60; 3.45; 2.94; 2.09Å; muscovite and paragonite (R<sub>2</sub>O·3Al<sub>2</sub>O<sub>3</sub>·6SiO<sub>2</sub>·nH<sub>2</sub>O) with d=4.39; 3.18; 2.52Å). Apart from these, encountered are gismondite (CaOAl<sub>2</sub>O<sub>3</sub>·2SiO<sub>2</sub>·nH<sub>2</sub>O), hydrogarnets, and mixed sodium-calcic and potassium-calcic hydroaluminosilicates. They contain none of the new formations, such as free lime, hydroaluminosilicates, hydrosulphoaluminates and highly-basic calcium hydrosilicates characteristic of the Portland cement.

The solubility of low-basic calcium hydrosilicates is within the range of 0.035 to 0.05 g/l, whereas the solubility of alkaline hydroaluminosilicates is still lower. All of them are less soluble and more chemically stable than the determining highly-basic, and, consequently, more reactive new formations characteristic of the Portland cement stone (highly-basic calcium hydroaluminates and hydrosilicates and free lime the solubility of which is 0.5 to 1.3 g/l).

The specific features of chemical and mineralogical composition, the structure and nature of the new formations render singu-

lar properties to the slag-alkaline binders owing to which the latter can be used as special cements.

So, the slag-alkaline cements are distinguished by high strength which, depending on the chemical nature of the alkaline component is within the range of from 400 to 1200 kgf/cm<sup>2</sup> when testing bar samples made of cement mortar of 1:3 ratio, the samples being fabricated and tested to GOST 310.4-76. As to their corrosion resistance in waters with low hydrocarbonate hardness, in sulphate, magnesian and in sea water these cements surpass not only the common one but the sulphate-resisting cement as well. They are distinguished by low heat release, this being explained by low hydration energy of alkali metal ions (K - 82, Na - 99 kcal (g-ion) as compared to alkaline-earth metals (Ca - 361 kcal(g-ion)). This permits their use in the construction of heavy monolithic structures, such as dams. Their construction is 4 to 5 times lower than that in the Portland cement.

Slag-alkaline cements on the basis of low-modulus silicate salts ( $M_c = 0.5 - 1.5$ ) are high-speed cements: by the rate of strength gathering, after three days of hardening, they surpass not only the high-speed Portland and slag-Portland cements but the alumina cement as well. Thus, at the age of 24 hours the strength of these cements is 350, at the age of two days - 550, at the age of 3 days it is 750 kgf/cm<sup>2</sup>. Further on, unlike the alumina cement, the slag-alkaline cement continues to gather speed rapidly, so that by the 28th day it comprises 1000-1200 kgf/cm<sup>2</sup>.

Since the freezing temperature of concentrated water solutions of alkali metal compounds is considerably far below zero, the slag-alkaline cements can be used in winter concreting.

According to data of S.P. Mukhamedhalejeva, the slag-alkaline concretes are used to their best advantage in structures used under cold-temperature conditions. This is due to the fact that, unlike the water-saturated Portland cement stone, in freezing of water-saturated slag-alkaline stone to minus 15 - minus 20°C there is no spasmodic expansion of the substance filling the pores as a result of sudden freezing of the undercooled water. The cooling of a slag-alkaline stone right down to minus 30°C causes none whatsoever freezing destruction, this being explained by its porous structure (with the gellous pores prevailing), by the porous space containing alkali in the form of true solution whose freezing temperature is considerably below the freezing temperature of water and by gradual freezing-out of ice from the solution. Frost destruction of the slag-alkaline stone occurs, mainly, at the cooling down to minus 40°C and below. That, in particular, explains also the high frost-resistance of concretes on the slag-alkaline cement basis, the resistance exceeding 1000 cycles. The slag-alkaline cements

are also resistant to high temperatures, this permitting their use in the production of heat-resistant concretes.

Even the inferior-grade slag-alkaline cements, such as grade 400, enable to obtain concretes of grade 500-700, whereas for the traditional concretes of the same grades Portland cement of grades 500-600 is required. The cements of grades 1000-1200 can be employed for production of concrete grades 1000-1200, i.e. of concretes whose production, by the American predictions, is planned only by the year 2000.

The slag-alkaline cements extend the raw material basis of high-strength concretes, because they do not require the concentration of aggregates, permit the exclusion of coarse aggregates and the use of fine sands and sandy loams as fine aggregates. This is explained by the interaction of caustic alkalis springing up in the process of cement hydration with the aggregate agrillaceous minerals enveloping the particles of sandy and dust-like fractions, this resulting in the formation of unsoluble alkaline hydroalumosilicates. The latter, along with the products of slag-alkaline cement hydration, are partially cementing the sandy particles of the aggregate and completely the dust-like particles.

The pilot-plant production of the slag-alkaline cements and concretes on their basis was started in 1960, and their industrial production, in 1964.

By joint collaboration with the Scientific Research Institute of Cement, The Scientific Research Institute of Reinforced Concrete and other leading research and educational institutions of the country the standardization of the activity and other properties of the industrially-produced slag-alkaline cements was carried out (9) in 1977-1979.

Thus, high-strength cements grade 1000-1250 were obtained at plants producing and utilizing slag-alkaline cements in the cities of Perm, Tula, Krivoj Rog, Alma-Ata and Tashkent. The results of determining the activity of industrially-produced slag-alkaline cements based on various types of slags and alkali components are generalized and presented in a Table below.

Activity of slag-alkaline cements, depending on  
slag basicity and chemical nature of alkaline  
component

Table

Slag type	Ultimate strength, kgf/cm <sup>2</sup> , when used as alkaline components			
	soda ash	soda-alkaline melt	sodium disilicate	sodium metasilicate
Basic	$\frac{450}{65}$	$\frac{500}{70}$	$\frac{1000}{90}$	$\frac{950}{60}$
Neutral	$\frac{400}{60}$	$\frac{600}{90}$	$\frac{900}{90}$	$\frac{1250}{128}$
Acid	$\frac{380}{60}$	$\frac{600}{90}$	$\frac{800}{90}$	$\frac{1050}{120}$
Thermophosphorous (basic)	$\frac{500}{65}$	$\frac{550}{85}$	$\frac{1000}{85}$	$\frac{1150}{130}$

Note: over-the-line figure - compression strength  
under-the-line figure - bending strength.

These cements are used for the production of concrete grades 1000-1600 distinguished by high watertightness, high density, corrosion-, heat-, and frost resistance.

There can be no doubt that the new possibilities opened by the slag-alkaline cement in the field of the synthesis of artificial building conglomerates will, in due time, exclude the use of blast-furnace, electrothermophosphorous and the like slags for the production of low-grade slag Portland cements, Portland cement clinker, various aggregates, etc. But even now these cements command sufficiently broad raw material resources. It can be supplied by that amount of blast-furnace, electrothermophosphorous and other types of slag produced by the industry at the present time.

Thus, the analysis of the condition of the slag raw material resources in the USSR indicates that, even with the slag Portland cement production volume left unchanged, the amount of slag which could be used for the production of slag-alkaline cements would comprise over 45 mill. t (10). Organized production of slag-alkaline cements from the mentioned amount of slags will essentially increase the resources of constructional binding substances.

A considerable production volume of various slags is also noted in other countries. So, according to the figures of 1970-1973, the annual output only of blast-furnace slags comprised: in the USA - 22.8; Japan - 28.0; France - 14.1; FRG - 13.8; Great Britain - 11 mill. t (10).

Undoubtedly, the most efficient field of slag utilization is their use in cement production.

The raw material resources of the alkaline components can be presented by the following substances:

a) commercial products: soda, potash, sodium fluoride produced by the chemical

industry, and soluble alkaline silicates (sodium silicate solutions with silicate modulus 0.5 to 2.5);

b) side products: alkali melts, soda-alkaline melt, sodium metasilicate, etc.;

c) natural soda.

Sodium sulphate and sodium chloride serve as raw materials for the production of alkaline components, the resources of the former being practically unlimited.

Considering that the slag-alkaline cements are distinguished by a number of specific properties, they find their most expedient application in jobs on the level with the high-strength, high-speed and sulphate-resisting Portland cements, as in many cases instead of the alumina cement.

In the USSR a fifteen to twenty year experience has been accumulated in the production and service of concrete structures based on such cements which confirmed their high technological properties and service reliability.

Beginning with 1972 the slag-alkaline cements are studied and at present are produced in Poland. The results obtained in the studies and adoption of these materials in the building industry by the scientists of the Krakow Mining and Metallurgical Academy under the guidance of the Member of the Academy E. Grzymek are indicative of their efficiency (11).

In addition to that, building materials on the basis of slags and alkaline components are being developed from 1972 in other countries as well, this being confirmed by patents published in the GDR, FRG, Great Britain, France and Japan.

The above facts signify that the application of new cements containing the compounds of alkali and alkali-earth metals in the building industry is successfully expanding.

Their use in the Soviet Union made it possible to double the grade of construction cements and concretes, as well as to extend the range of aggregates, in particular the use of barkhan sands.

The economic efficiency of slag-alkaline cements is obtained through the utilization of industrial by-products, as well as due to high strength and long service life of structures made on their basis.

In addition, their efficiency rises when the grey iron and slag are produced in a combined process: as usual, molten iron and slag are poured out of the blast furnace. The slag is first granulated, then ground with simultaneous drying in air-pressure mills. Steam released from the blast furnaces can serve as heat source for slag drying and for operation of the air-pressure mills. In this case the grey iron and ground slag are produced simultaneously. The capital investment per 1 t of ground slag should not exceed 5-10 roubles. For the binder an alkaline component, such as sodium silicate, is also necessary. Its consumption comprises 5 to 8%, i.e. about 65 kg per one ton of slag. Thus, the capital investment for the alkaline component will comprise  $50 \times 0.005 = 3.25$  roubles per one ton of binder, the total being  $10 \cdot 0.935 + 3.25 = 12$  to 13 roubles. The capital investment per one ton of Portland cement is 40 roubles.

#### CONCLUSIONS

1. Hydraulic binding substances, - slag-alkaline cements grade 400-1200, have been developed and adopted in the industry. They are distinguished by high corrosion resistance, surpass the alumina cement by the rate of strength gathering, exhibit high density and low heat release. These properties predetermine their expedient use in special types of construction.

2. Slag-alkaline cements were introduced into construction practice in the USSR (1960) and in Poland (1974). An experience of many years (15 to 20 years) has been accumulated in the USSR in the production and operation of concrete structures based on such cements, confirming their high technological properties and operational reliability.

3. The raw material resources for these cements are provided by blast-furnace, electrothermophosphorous and other types of metallurgical slags combined with alkali-containing products both basic (soda, potash, sodium silicate solutions, etc.) and industrial by-products (soda-alkaline melt, soda melt, sodium metasilicate, etc.)

4. The net cost of slag-alkaline cements is lower than that of the Portland cements. Their economic efficiency is obtained by the utilization of inexpensive industrial by-products as well as due to the high strength and long service life of the structures.

**RESUME :** L'alynite, silicate tricalcique nouveau, est la phase minérale principale des ciments obtenus à partir des matières premières traditionnelles, avec addition de chlorure de calcium, d'après la technologie du sel élaborée en U.R.S.S.

L'analyse de la structure cristalline du minéral a démontré que la particularité distinctive principale de la constitution de l'alynite est la position des atomes de chlore dans une structure ferme, composée de huit cations de calcium, ce qui conditionne les propriétés spécifiques du silicate tricalcique avec des anions de O - Cl mélangés.

L'étude des particularités de la structure et des propriétés de l'alynite a permis d'établir qu'il existe au moins quatre modifications allotropiques du minéral -  $\gamma$ ,  $\beta$ ,  $\alpha'$  et  $\alpha$  ; avec cela, les formes de haute température sont caractérisées par le système cubique.

Le minéral est caractérisé par un nombre considérable de défauts de cristallisation sous forme de vacances d'oxygène et de ses associations. La haute symétrie du réseau cristallin du minéral se trouve en corrélation avec la capacité du minéral à contenir un grand nombre d'éléments; par rapport à l'alite, l'alynite dissout de 1,5-2,0 fois d'éléments modifiants de Al, de Fe, de Mg, etc.

La présence des atomes de Cl dans la structure de l'alynite assure des avantages importants à ces ciments par rapport au ciment portland connu : températures de formation plus basses (1000-1100°C), facilité de cristallisation dirigée, haut degré de solubilité des éléments additifs et modifiants, faible résistance au broyage, haute capacité d'hydratation.

Des ciments d'alynite sont caractérisés par la solidité et l'activité assez hautes, la pierre de ciment à sa base est caractérisée par une morphologie spécifique des formations hydratées.

Les particularités de la constitution et des propriétés de l'alynite déterminent les perspectives de la création des ciments nouveaux qui permettront de réduire les frais d'énergie pour la cuisson du clinker; leurs qualités techniques seront améliorées.

**SUMMARY :** Alinite - the new highly-based calcium silicate - is the main mineral phase of cement clinker which are produced from the traditional raw materials with addition of calcium chloride by the new salt technology, being developed in the USSR. The analysis of crystallographic structure of the mineral has shown, that the main feature of alinite is the peculiar position of chlorine atoms surrounded by eight calcium atoms which is stipulated by the specific properties of the new silicate with mixed "O-Cl" anions.

The existence of at least four modifications of alinite -  $\gamma$ ,  $\beta$ ,  $\alpha'$ ,  $\alpha$  has been established, and high-temperature forms have cubic syngonia. As for alinite, the mineral is characterized by a considerable number of defective centers, namely, oxygen vacancies and their associations with other atom vacancies. High crystallographic symmetry of alinite correlates with its ability to dissolved considerable number modifying elements - Al, Fe, Mg etc. in 1,5-2 times more than the known alite.

The presence of chlorine atoms in the structure of alinite calls forth a number of advantages of alinite cements in comparison with the portland cement - lower formation temperatures (1000-1100°C) and easier realization of directed crystallisation, the higher grade of grindability and dissolution of mixed and modifying elements, and high ability of interaction with water.

Alinite cements are notable for great activity and strength. Alinite cements stones are characterized by specific morphology of hydrated new formations.

The peculiarities of structure and properties of alinite determine the possibilities of creating new cements on the basis of alinite with less power consumption (energy) and with better construction properties.

L'un des constituants les plus importants du clinker de ciment, obtenu d'après la technologie de basse température (technologie de sel) est l'alynite, silicate de calcium nouveau(2). Ce composé cristallise en système quadratique, le groupe de Peudoroff est  $= I 4_2 m$ . Une cellule élémentaire avec des paramètres  $a = 10.471$ ;  $c = 8.614$  Å contient neuf atomes indépendants - trois Ca, un Si, quatre O et un Cl. Le comptage des multiplicités des positions cristallographiques aboutit à la formule chimique de l'alynite:  $Ca_{11}(Si, Al)_4O_{18}Cl$  avec  $z = 2$ .

D'ici la densité calculée  $= 3.10 \text{ g/cm}^3$ , tandis que sa valeur expérimentale  $= 3.075 \text{ g/cm}^3$ . Selon les données de l'analyse structurale aux rayons X, de grands cations de Ca sont disposés dans trois positions cristallographiques différentes et leur entourage est différent.  $Ca_2$  (dans un point particulier sur l'axe 4) se trouve au centre d'un cube suffisamment correct avec des distances  $Ca-O = 2.511-2.521$  Å et des arêtes  $O-O = 2.646-3.025$  (l'excentricité du cube  $= 1.14$ ).

$Ca_2$  se trouve aussi dans une position particulière sur l'axe 4 dans une face latérale, octaèdre aplati avec des distances équatorielles  $Ca-O = 2.432$  Å et méridionale (le long de l'axe 4)  $= 2.154$  Å. Enfin,  $Ca_1$  se trouve en position générale et a six anions voisins: cinq atomes de O ( $Ca-O = 2.270-2.529$ ) et un atome de Cl éloigné à  $3.271$  Å. Le polyèdre de coordination pour Ca<sub>1</sub> est un octaèdre, mais le Ca fortement modifié est déplacé du plan équatorial vers la moitié "d'oxygène" de l'octaèdre. Le cation de Si(Al) plus petit est localisé dans un tétraèdre standard avec  $Si-O = 1.629 - 1.666$  Å.

Fig.1. Couches caractéristiques de la structure cristalline de l'alynite. Les polyèdres de calcium avec les atomes de calcium dans les positions cristallographiques différentes sont représentés schématiquement.

Il est commode de représenter la structure cristalline de l'alynite composée des couches plates parallèles au plan  $xOy$  et alternant le long de  $[001]$ . Ces couches sont au nombre de six par cellule dont quatre sont représentées sur la fig. 1-a-d dans l'ordre de leur alternance. Le caractère de la jonction des couches en carcasse tridimensionnelle est illustré par la fig.2 représentant l'axonométrie de la moitié de la cellule élémentaire en polyèdres; les couches sont écartées l'une de l'autre le long de l'axe  $c$ , pour que la figure soit plus claire.

Fig.2. L'axonométrie 1/2 d'une cellule élémentaire de l'alynite. La suite des couches (de haut en bas) correspond à a-d sur la fig.1.

Si à l'intérieur de la couche les polyèdres sont liés par les sommets et les arêtes, les couches elles-mêmes se trouvent liées par les arêtes et les faces des Ca-octaèdres. On peut le voir d'une façon claire sur la fig.3 qui représente la section de la structure de l'alynite à la hauteur de  $y = 0$ .

Fig.3. Section d'une cellule d'alynite,  $y=0$ . La couche des polyèdres de Ca est représentée.

Chaque atome de chlore attire vers lui huit Ca-octaèdres qui se lient en couples par les faces et forment un cluster tétragonal symétrique autour de l'axe de quatrième ordre. Les groupes de cluster sont liés le long de l'axe  $c$  par les  $Ca_2$ -cubes en formant une colonne dont la section longitudinale est représentée sur la fig.4.

lignes avec  $g_1 = 2.0161$  et  $g_2 = 2.0024$  ( $A = 7,4G$ ). La cuisson à  $1950^\circ C$  permet de découvrir dans l'alynite des centres perforés dans la sphère même de coordination des atomes du chlore; le spectre ESR de ces centres découvre des lignes à quatre composantes avec  $g = 2.0081$  et  $A = 4,0G$  (fig.5).

Fig.5. Spectre ESR de l'alynite irradié. Le recuit à  $1950^\circ C$ , 10 min.

La structure extrafine des lignes d'absorption s'explique par l'interaction des trous avec le noyau de  $Cl^{35}$  ( $I=3/2$ , contenu naturel est 75,4%). Il est probable que la nature des centres perforés s'explique par la présence d'une quantité considérable d'aluminium (4% de la masse du minéral calculée à partir de  $Al_2O_3$ ), ainsi que par une certaine friabilité du réseau cristallin du minéral due à la présence d'une grande quantité des places vacantes dans le réseau.

L'alynite constitue 60-80% de la masse du clinker; la composition chimique de l'alynite dans le clinker varie dans les limites proches, en fonction de la quantité des éléments alliants de Al, de Fe, de Mg, de Cl et d'autres contenus dans les matières premières. L'alynite dans le clinker cristallise sous forme des prismes, des plaques hexagonales, des aiguilles qui sont le plus souvent les débris et les cristaux défigurés avec le faciès d'octaèdre quadratique.

Les dimensions des cristaux de l'alynite dans les clinkers différents peuvent varier dans les limites assez larges - à partir des portions d'un micron jusqu'aux centaines de microns. La microscopie optique permet d'observer la structure fine, moyenne et à gros grains des clinkers d'alynite. Et avec cela, dans tous les cas la cristallisation de l'alynite est assez distincte, à la surface des cristaux il y a des hachures, quelquefois on observe des macles polysynthétiques. Les études au microscope électronique permettent de déterminer d'une façon nette le caractère de la cristallisation de l'alynite dans le clinker (fig.6).

Fig.6. Cristaux de l'alynite dans le clinker. Répliques de charbon atténuées de platine,  $\times 4000$ .

Le coefficient de réfraction des cristaux de l'alynite  $N = 1.709 \pm 0.001$ . En fonction de la nature et de la quantité des éléments alliants le coefficient de réfraction des cristaux de l'alynite peut s'élever à 1.714-1.715. Nous avons effectué une étude de la solubilité des éléments alliants sur l'alynite polycristallin dans lequel nous avons introduit de différentes concentrations des oxydes de Al, Fe, Mg, Ba, K, Na, P, et B. La cuisson de l'alynite avec les admixtions indiquées et l'analyse des phases des produits de la cuisson effectuée à l'aide de la diffractométrie aux rayons X nous ont permis de déterminer les valeurs suivantes des limites de la solubilité des éléments alliants dans l'alynite (% de la masse du minéral):  $Al_2O_3$  - 4.5;  $Fe_2O_3$  - 3.0,  $MgO$  - 3.0,  $BaO$  - 2.5,  $K_2O$ ,  $Na_2O$  - moins de 0.5,  $P_2O_5$ ,  $B_2O_3$  - 1.0.

Les valeurs indiquées peuvent varier dans les limites  $\pm 10\%$ ; en cas de la présence complexe des éléments dans les produits de la cuisson on y observe jusqu'à  $\pm 20\%$  de la valeur absolue.

La contenance considérable des éléments dans le réseau cristallin de l'alynite liée à la haute symétrie de la structure et de sa "friabilité", explique les oscillations de la température de la fusion. En fonction de la composition chimique et de la quantité des admixtions alliantes la température de la fusion de l'alynite varie dans les limites de  $1420 - 1490^\circ C$ . La limite supérieure correspond à l'alynite avec un minimum d'impuretés. Le poids spécifique de l'alynite =  $3.075 g/cm^3$ ; il peut aussi varier d'une façon insignifiante en fonction de la nature et de la quantité des éléments alliants.

Nous avons également effectué des études de l'alynite à basses températures qui représentent un grand intérêt pour l'étude de la chimie physique de l'alynite. Ces études ont été effectuées la méthode de l'analyse structurale aux rayons X à l'aide du diffractomètre DRON-I muni d'un dispositif d'étu-

de à haute température aux rayons X GPVT - I500. L'échantillon étudié contenait des monocristaux de l'alynite de dimension de 3 mm émetteurs jusqu'aux dimensions de 50 microns. L'analyse des changements du tableau de diffraction à l'élévation de la température a permis de faire ressortir 4 séries principales de diffractions à intensité variable synchronisées.

Nous avons découvert la convertibilité des processus en cas du réchauffement ou refroidissement de l'alynite ce qui permet de considérer toutes les quatre séries en tant que les modifications polymorphes: 3 séries de réfractations des formes de haute température, à savoir:  $\beta$ ,  $\alpha'$  et  $\alpha$  ont été déterminées dans le cadre de la symétrie cubique (voir le tableau 2).

réseau cristallin), par la composition de la phase liquide de la solution de ciment (faible contenu d'alcalis, présence de Cl, concentration élevée de Ca), par la composition et la structure des nouvelles formations hydratées (formation sur la surface de l'alynite d'une enveloppe hydratée métastable, perméable et relativement bien cristallisée). Les particularités indiquées assurent une hydratation intense et le durcissement des ciments d'alynite aux températures normale et au-dessous de zéro (jusqu'à -5°C), ainsi qu'au traitement thermique et humide.

Puisque le clinker d'alynite a une haute porosité et une haute capacité de broyage, il est possible d'utiliser ces qualités pour intensifier l'hydratation et le durcissement des ciments en augmentant la finesse de bro-

Le clinker d'alynite utilisé pour la production du ciment contient, d'habitude, de 60 à 75% d'alynite. Pour la production du ciment a durcissement rapide et du superciment on utilise le clinker contenant jusqu'à 80 % d'alynite. Le reste de la masse du clinker contient l'orthosilicate, l'aluminate et le ferrite de la chlorure de calcium. La proportion de ces phases n'est pas strictement limitée; elle est déterminée par le choix des matières et la destination du clinker produit.

La haute activité d'hydratation des ciments d'alynite s'explique par les particularités de la structure de l'alynite (Présence des atomes "actifs" de Cl dans un motif structural original du réseau cristallin du silicate nouveau, un grand nombre des défauts du

yage. Ainsi, par exemple, quand la surface spécifique du ciment portland est  $3000 \text{ cm}^2/\text{g}$  et celle du ciment d'alynite  $4500 \text{ cm}^2/\text{g}$ , les consommations spécifiques d'énergie électrique sont identiques et font environ  $30 \text{ kWh/t}$ .

Il faut souligner qu'à la différence du ciment portland, une telle augmentation de la surface spécifique du ciment d'alynite n'exige pas une quantité d'eau plus grande, mais, par contre, moins grande. Les valeurs minimales de la quantité d'eau nécessaire eau/cim = 0.225-0.235 caractérisent les ciments d'alynite a surface spécifique  $4500 \pm 200 \text{ cm}^2/\text{g}$ .

Le sulfate de calcium introduit sous forme de calcium de gypse, de phosphogypse ou de borogypse est une composante obligatoire du

ciment d'alynite. Mais il ne joue pas le rôle de ralentisseur de la prise comme dans le cas du ciment portland, par contre c'est un intensificateur du durcissement.

Le contenu optimal de gypse dans le clinker d'alynite variant dans les limites 2-3,5% (calculées pour  $SO_3$ ) assure une augmentation de l'activité du ciment sans additions de 1,5-2,5 fois ce qui dépasse la vitesse moyenne de l'hydratation de l'alite de 1,5-2,5 fois. L'hydratation rapide de l'alynite et l'apport constructif de la phase d'aluminate assurent un durcissement rapide du ciment d'alynite dans le bas âge. En fonction du degré de dispersion du ciment la résistance des échantillons à l'âge de 24 heures est égale à 5-8% de l'activité de marque du ciment.

Le processus de la formation de la structure de la pierre de ciment ne cesse pas après la fin de l'hydratation de l'alynite (voir la fig. 7 a).

Fig. 7. Cynétique du durcissement des ciments d'alynite (a) et des bétons (b):

- a) - 1 - ciment à  $S_{sp} = 3600 \text{ cm}^2/\text{g}$  et le contenu de l'alynite à 60%; 2 - ciment à  $S_{sp} = 4080 \text{ cm}^2/\text{g}$  et le contenu de l'alynite à 75%.
- b) - 1 - de ciment d'alynite à durcissement normal;
- 2 - de même après le traitement à la vapeur;
- 3 - de ciment portland à durcissement normal;
- 4 - de même après le traitement à la vapeur.

Nous croyons que ce phénomène s'explique par la recristallisation des hydrosilicates primaires du type  $C_2SH_2$  en hydrosilicates secondaires du type CSH. Ce processus est suivi de la cristallisation de  $Ca(OH)_2$ , de l'augmentation du degré de polymérisation des hydrosilicates des déformations de retrait, de la réduction du contenu d'eau de cristallisation et de l'augmentation du contenu de l'hydrosilicate.

Nous supposons la possibilité de la formation des hydrosilicates de la chlorure de calcium au cours de l'hydratation et du durcissement de l'alynite, dont témoigne la morphologie originale des formations nouvelles cristallisant sous forme de pétales et de

plaques très fines. Le contenu des ions libres de Cl dans la pierre de ciment de l'âge différent ne dépasse pas 0,6% de la masse. A l'âge plus mûr ce contenu varie généralement dans les limites de 0,3-0,4%.

La perméabilité de la pierre de ciment d'alynite est de 5-10 fois inférieure à celle du ciment portland ce qui est lié aux différences dans leurs monostructures. Cette propriété assure une haute stabilité d'exploitation du béton d'alynite armé. Les bétons à la base du ciment d'alynite découvrent une résistance de 20-30% supérieure à celle des bétons à la base du ciment portland pour les dépenses identiques du ciment.

Un grand avantage des bétons à la base du ciment d'alynite traités à la vapeur est l'accroissement intense de leur résistance dans le processus du durcissement ultérieur dans les conditions normales (voir la fig. 7, b). A l'âge de 28 jours, cela assure un accroissement de la résistance des échantillons traités à la vapeur de 15-25% par rapport aux échantillons à durcissement normal.

Ces recherches ont contribué à obtenir des ciments de haute résistance et des bétons des marques 600-700.

**CONCLUSIONS:** La distinction principale de la constitution de l'alynite, nouveau silicate tricalcique de calcium contenant le chlore, est la présence des atomes de chlore dans les noeuds du réseau cristallin du minéral dans un complexe structural original sous forme d'un atome de Cl entouré de huit atomes de calcium.

Le caractère décrit de la présence du chlore dans la structure conditionne les propriétés spécifiques de l'alynite - formation aux températures 1000-1100°C, haute symétrie des réseaux cristallins de ses modifications, haut degré de solubilités des éléments modificateurs, faible résistance au broyage, haute capacité d'hydratation, morphologie originale des formations hydratées nouvelles.

Les qualités découvertes de l'alynite et des ciments à sa base permettent de considérer ce liant nouveau en tant qu'un concurrent sérieux du ciment portland traditionnel.

RESUME : Le problème de l'adjonction de phosphates alcalins dans certains ciments alumineux (SECAR 71) se pose pour diverses applications. Dans ce travail, les interactions possibles sont étudiées d'un point de vue fondamental, d'une part dans le domaine basse température (à l'ambiante et entre 0 et 100°C), d'autre part entre 100 et 1000°C. Dans le domaine basse température, l'influence de 5 % en poids d'hexacyclophosphate de sodium commercial sur l'évolution du SECAR agité dans l'eau est déterminée, ainsi que sur l'évolution d'un tel mélange gâché en pâte. Par la mise en oeuvre de divers moyens analytiques et calorimétriques, il a été établi que la prise phosphatique a lieu dans la période initiale et qu'elle fait avancer la prise hydraulique de plusieurs heures bien que les ions sodium libérés maintiennent un taux élevé d'alumine en solution.

Dans le domaine (100 - 1000°C), les transformations subies par différents types de phosphates de sodium : dihydrogénomonophosphate, hexacyclophosphate, sont systématiquement suivies à partir d'échantillons soit secs, soit gâchés avec de l'eau. Dans ces deux cas (à sec ou en présence d'eau), des essais analogues sont effectués comparativement sur des mélanges des mêmes phosphates avec différents oxydes : CaO, Al<sub>2</sub>O<sub>3</sub> et avec du SECAR 71. Les produits de réaction sont analysés en fonction de la température.

SUMMARY : The problem of adding alkaline phosphates in some aluminous cements (SECAR 71) is raised for various applications. The present work, the possible interactions are studied from a fundamental newpoint, on the one hand, in the low temperature range (room temperature and between 0 - 100°C), on the other, between 100 and 1000°C. In the former range the influence of 5 % weight of marketed sodium hexacyclophosphate on the evolution of SECAR stirred in water is determined, as well as the influence upon the evolution of such a mixture as paste. Using various analytical and calorimetric means it was established that phosphate setting occurs during the initial period and accelerates hydraulic setting by several hours although the sodium ions released keep a large extent of alumina in solution.

In the 100 - 1000°C range, the transformations undergone by various types of sodium phosphates : dihydrogenemono-phosphate, hexacyclophosphate were systematically followed either with dry samples or mixed with water. In both cases (dry or with water) similar tests were made comparatively with mixtures of the same phosphates with different oxides : CaO, Al<sub>2</sub>O<sub>3</sub> and SECAR 71. The reactions products were studied versus temperature.

## INTRODUCTION

L'étude des réactions des phosphates avec différents oxydes présente de nombreuses applications. Certains phosphates sont utilisés dans les ciments dentaires (1), (2) ; d'autre part lorsque des phosphates sont ajoutés au Portland (3), (4), (5), (6), les phénomènes observés lors de la prise sont complexes.

Le maintien de la cohésion d'un béton réfractaire jusqu'à la prise céramique, entre dans le cadre de cette étude. Les études antérieures à caractère fondamental sont peu nombreuses : Kingery (7) signale les possibilités de liaison par réaction de l'acide orthophosphorique avec des oxydes métalliques. La thèse présentée par Bouvier d'Yvoire (8) concerne l'étude de phosphates d'aluminium et de fer trivalent. Dans son mémoire, Forest (9) apporte une contribution à la recherche de nouveaux liants gâchés avec une liqueur phosphorique.

Nous nous proposons de préciser les conditions dans lesquelles s'effectue la "prise phosphatique", et d'analyser les réactions et les mécanismes qui entrent en jeu. Pour cela nous avons effectué deux types d'expériences portant :

1) sur l'évolution d'un mélange de SECAR 71 et de 5 % d'hexacyclophosphate de sodium par agitation dans l'eau, dans un rapport pondéral liquide/solide :  $\ell/s = 10$ , afin de situer dans le temps les réactions conduisant à la prise phosphatique et à la prise hydraulique, et d'étudier leurs interactions ; des essais sont effectués parallèlement sur des pâtes en utilisant l'effet thermique comme moyen de détection.

2) sur l'évolution thermique entre l'ambiante et 1000°C d'échantillons de dihydrogénomonophosphate de sodium ( $\text{NaH}_2\text{PO}_4$ ) et d'"hexacyclophosphate de sodium" d'origine industrielle (principal constituant :  $(\text{NaPO}_3)_6$ ).

L'évolution d'échantillons soit secs, soit humidifiés est étudiée dans deux séries d'essais menés parallèlement sur des échantillons purs et sur des mélanges de ces phosphates avec différents oxydes. Les essais ici rapportés n'ont qu'un caractère exploratoire, une étude en thermobalance étant actuellement effectuée dans des conditions de température et de pression de vapeur d'eau plus précises.

## ETUDE EXPERIMENTALE

## I - Etude à température ambiante :

a) Etude cinétique : L'influence d'une adjonction de 5 % d'hexacyclophosphate de sodium industriel sur l'évolution du SECAR 71 est analysée en suivant la cinétique des réactions en solution aqueuse. Pour cela, le SECAR 71 pur (puis le mélange SECAR 71 + 5 % d'hexacyclophosphate de sodium) est agité dans de l'eau (rapport pondéral  $\ell/s = 10$ ), à 21°C. L'évolution du système en fonction du temps est suivie point par point par prélèvements et dosages, par spectrométrie d'absorption atomique, des concentrations en solution, exprimées en  $\text{CaO}$  et  $\text{Al}_2\text{O}_3$ . (Notées [C] et [A]).

b) Essais en pâte : La prise du ciment mettant en jeu des phénomènes exothermiques, nous avons étudié la prise du SECAR 71 pur, puis du mélange SECAR 71 avec 5 % d'hexacyclophosphate de sodium en tenant compte de cet effet thermique. Le gâchage est effectué dans un rapport  $\ell/s = 0,33$ .

Pour cette étude, deux montages ont été réalisés.

(1 et 2) :

1) Le dispositif est constitué d'une nacelle cylindri-

que de 40 mm de diamètre et 20 mm de hauteur contenant le ciment, enfermé dans une enceinte en polystyrène expansé, et dans laquelle plonge un thermocouple ATE-BTE. Il s'agit donc d'une analyse thermique effectuée dans un système adiabatique.

2) Le second montage peut être considéré comme un système "adiabatique amorti", l'échantillon est étalé en couche mince sur une grande face d'une plaque de cuivre parallélépipédique (78x37x7 mm) de façon à évacuer rapidement la chaleur dégagée et maintenir l'échantillon dans des conditions quasi-isothermes. Cette plaque de cuivre constitue, avec une autre plaque identique à laquelle elle est reliée par un fil de constantan, un ensemble de deux couples cuivre-constantan montés en différentielle. Les deux plaques sont isolées thermiquement l'une de l'autre et placées dans un boîtier isolant en polystyrène expansé. Ce montage permet de situer dans le temps les divers dégagements de chaleur pouvant intervenir au cours de l'évolution de l'échantillon gâché avec de l'eau sans que les réactions ne soient perturbées par une élévation notable de température.

## II - Etude dans le domaine de température 100-1000°C :

a) Essais exploratoires : Afin d'élucider le problème, des essais de décomposition thermique ont été effectués de 100°C à 1000°C, dans un four tubulaire thermorégulé. L'échantillon (4g) placé dans une capsule en platine, est porté à la température désirée et y est maintenu pendant une heure à l'atmosphère libre. Lorsque les essais ont eu lieu sur les échantillons gâchés préalablement, le rapport pondéral  $\ell/s$  était de 0,3. Les essais effectués sur les phosphates seuls seront notés essais (A).

Par la suite, des mélanges de ces phosphates avec, soit de l'alumine, soit de la chaux ont été calcinés dans les mêmes conditions. Ces essais seront appelés B. Enfin des expériences comparatives (essais (C)), ont été effectuées encore dans les mêmes conditions, sur des mélanges phosphate + SECAR 71, et phosphate + SECAR 71 + alumine.

Tous ces échantillons sont analysés par diffraction des rayons X et chromatographie sur couche mince.

Remarque : Alors que dans les mélanges industriels la proportion en masse des phosphates ne dépasse pas 5 %, un rapport de 50 % a été utilisé ici, afin de pouvoir obtenir des informations analytiques précises par diffraction X et chromatographie. Mais, en dépit de cette forte teneur en phosphates, l'oxyde reste en excès dans la réaction de combinaison, comme le prouvent les spectres de diffraction X pris après le traitement thermique.

b) Etude en thermogravimétrie (TG) dans un domaine de température plus restreint : Ce travail, juste commencé, a permis de reprendre les essais de décomposition thermique, sous pression de vapeur d'eau contrôlée, mais seulement dans le domaine de température 80 - 400°C au moyen d'une thermobalance à hélice de silice, type Mac Bain. La pression de vapeur d'eau y est maintenue non saturante grâce à la thermorégulation à 80°C de ses parois et du tube réacteur ainsi que des canalisations et des vannes. Elle peut être régulée à une valeur constante grâce à un point froid constitué par un réservoir d'eau thermorégulée. Les variations de masse de l'échantillon sont enregistrées par un procédé optique (10, 11). Une thermobalance du même type mais qui permettra de couvrir le domaine de température 80 - 1000°C est en cours de réalisation.

A titre exploratoire, il est procédé à une analyse en montée linéaire de température ; mais pour plus de précision, l'échantillon est soumis, sous pression de vapeur d'eau constante à des paliers successifs, de température progressivement croissante, les écarts étant de faible amplitude :  $5^{\circ}\text{C}$ , dans les domaines où des transformations ont lieu. En outre, les échantillons sont analysés par diffraction des rayons X et par chromatographie sur couche mince (C.C.M.).

## RESULTATS ET DISCUSSION

### I - Etude à température ambiante.

a) Etude cinétique : Les courbes d'évolution du SECAR 71 pur et du mélange avec l'hexacyclophosphate de sodium ont été tracées, en suivant la variation de la concentration en alumine et en chaux dans la solution, en fonction du temps d'agitation. Les résultats obtenus sont reportés sur les courbes de la figure 1 :

Fig. 1 - Courbes de l'étude cinétique donnant l'évolution des concentrations  $[C]$  et  $[A]$ , ainsi que du pH en fonction du temps.  
Echelle du bas : mélange SECAR 71 + 5 % hexacyclophosphate de sodium en présence d'eau ( $\ell/s = 10$ ).  
Echelle du haut : SECAR 71 pur + eau ( $\ell/s = 10$ ).  
— :  $[A]$  ; - - - :  $[C]$  ; - · - · : pH du mélange avec phosphate ; - + - + : pH du SECAR 71 seul.

En ce qui concerne le SECAR 71 pur, la courbe présente un maximum à  $[C] = 19.10^{-3} \text{ mol.kg}^{-1}$  et  $[A] = 20.10^{-3} \text{ mol.kg}^{-1}$ . Les valeurs de  $[C]$  et  $[A]$  restent constamment très proches l'une de l'autre pendant toute l'évolution. La précipitation massive des aluminates de calcium hydratés débute 2h30 après le début de l'expérience. Puis  $[C]$  et  $[A]$  restent pratiquement constantes : ( $[C] = 6,8.10^{-3} \text{ mol.kg}^{-1}$ ,  $[A] = 7,2.10^{-3} \text{ mol.kg}^{-1}$ ) avec  $[C/A]_p = 0,94$ .

La figure 1 montre aussi les courbes obtenues lorsque 5 % d'hexacyclophosphate de sodium industriel sont ajoutés au SECAR 71. Pendant une période initiale de 1h30, la chaux et l'alumine en solution ne sont pas dosables par spectrométrie d'absorption atomique, car une précipitation spontanée se produit dans le filtrat en présence d'HCl. Néanmoins ces dosages ont été effectués par volumétrie (complexométrie avec l'E.D.T.A.).

Le précipité blanc et colloïdal, apparaissant dans le filtrat en présence d'HCl, analysé en C.C.M. donne des taches de triphosphate et de phosphates plus lourds. L'analyse X de ce précipité après calcination à  $1000^{\circ}\text{C}$ , montre qu'il est constitué d'un mélange  $\text{Al}(\text{PO}_4)$  et  $\text{Al}(\text{PO}_3)_3$ .

Les courbes d'évolution du SECAR 71 en présence d'hexacyclophosphate de sodium sont très différentes de celles obtenues avec le SECAR 71 seul. La concentration de la chaux en solution passe par un maximum ( $[C] = 15.10^{-3} \text{ mol.kg}^{-1}$ ) après 1 heure d'agitation à  $21^{\circ}\text{C}$ . Entre 1 h et 1h30, cette concentration diminue brusquement, jusqu'à  $[C] = 1,8.10^{-3} \text{ mol.kg}^{-1}$ . Aux environs de 3h, la chaux atteint  $5.10^{-3} \text{ mol.kg}^{-1}$ , pour se stabiliser ensuite à  $1,5.10^{-3} \text{ mol.kg}^{-1}$ . La concentration en alumine augmente rapidement mais régulièrement, et atteint le maximum pour  $27.10^{-3} \text{ mol.kg}^{-1}$  après 2h d'agitation. Au bout de 4h,  $[A]$  diminue mais reste voisine de  $20.10^{-3} \text{ mol.kg}^{-1}$ . Ainsi, après la précipitation, le rapport  $[C/A]_p$  tend vers 0,075. Parallèlement, une courbe représentant le pH de la solution en fonction du temps a été tracée. Elle révèle les deux "sauts" de pH, l'un à 1h30 (moment où  $[C]$  chute), l'autre vers 3h (lorsque les concentrations  $[C]$  et  $[A]$  arrivent à leur maximum). Puis le pH reste constant à 11,8.

Lors de ces essais, des échantillons de filtrat, prélevés respectivement après 10 mn, 1h, 2h, 3h, 4h, 8h et 11h, ont été analysés par C.C.M. Les taches observées sont nettement séparées sur le chromatogramme, ce qui permet d'identifier :

- à 10 mn, un monophosphate et des polyphosphates à longues chaînes (chaîne phosphorée  $> 4\text{P}$ ),
- à 1h, un diphosphate, ainsi que du tricyclophosphate et des phosphates à longues chaînes,
- à partir de 2h (jusqu'à 11h), le chromatogramme ne présente plus aucune tache, ce qui permet de conclure à la précipitation à peu près complète de tous les anions phosphates.

Ces résultats laissent penser que l'hexacyclophosphate de sodium subit très rapidement une hydrolyse interne, avec ouverture des cycles et formation d'ions phosphates (ou polyphosphates), réagissant avec les ions  $\text{Ca}^{++}$  pour donner un précipité de phosphate de calcium insoluble ; d'où la nette diminution observée de  $[C]$  dans la solution. En revanche, la précipitation des phosphates de calcium laisse les ions  $\text{Na}^+$  en solution, de sorte que la teneur élevée de celle-ci en alumine s'explique par le fait qu'elle s'y trouve sous forme d'aluminate de sodium.

b) Essais en pâte : Deux types d'essais ont été effectués comparativement sur du SECAR 71 frais, puis sur le mélange de ce ciment alumineux avec 5 % d'hexacyclophosphate de sodium. Les courbes obtenues à partir des dispositifs 1 et 2 sont reportées ci-dessous (figure 2).

L'essai 1 montre qu'un processus exothermique intervient dès le gâchage et arrive à son terme au bout de 45 mn. D'après nos expériences d'évolution à  $\ell/s = 10$ , cet effet thermique doit correspondre à la précipitation de phosphate de calcium. En fait, avec le dispositif (1), adiabatique, les résultats diffèrent suivant le taux de remplissage de la cellule de mesure. Ainsi pour un taux de remplissage de 100 % (cavité entièrement emplie), l'écart de température au sommet du premier pic peut être évalué à  $34,6^{\circ}\text{C}$  pour le SECAR pur, (figure 2, trait plein), à  $28^{\circ}\text{C}$  pour le mélange avec le phosphate (figure 2, pointillés). L'influence de cette élévation de température sur la prise hydraulique est importante

Fig. 2 - Courbes d'analyse thermique.

Dispositif (1) ;  $l/s = 0,33$  :

a : SECAR 71 seul.

b : SECAR 71 + 5 % hexacyclophosphate de sodium.

Dispositif (2) ;  $l/s = 0,30$  :

c : SECAR 71 seul.

d : SECAR 71 + 5 % hexacyclophosphate de sodium.

puisque celle-ci se traduit par un second pic de faible amplitude (écart de  $4^{\circ}\text{C}$ ) débutant à 3h10. Il convient de noter les épaulements traduisant une succession de processus chimiques.

Avec le dispositif (2), les essais sont effectués sur 1 g de ciment et un rapport  $l/s = 0,3$ , dans des conditions adiabatiques, quasi isothermes. La figure 2 montre les résultats obtenus, d'une part avec du SECAR 71 pur (trait plein), d'autre part avec le mélange ciment + 5 % hexacyclophosphate de sodium.

Dans le premier cas, la prise s'effectue après 5h, et la différence de température observée est  $\Delta\theta = 0,2^{\circ}\text{C}$ , ce qui correspond à une quantité de chaleur  $\Delta Q \approx 13,7 \text{ J}$  pour 1 g de ciment, valeur certainement inférieure à la réalité en raison de la fuite thermique.

Dans le second cas, une élévation de température de  $0,27^{\circ}\text{C}$  a lieu 5 mn après le gâchage ( $\Delta Q \approx 18,5 \text{ J}$  par g de matière), le pic de la prise hydraulique n'apparaissant qu'après 4h, avec  $\Delta\theta = 0,05^{\circ}\text{C}$  ( $\Delta Q \approx 3,4 \text{ J}$ ).

Ces essais qui possèdent un caractère préliminaire seront complétés par des mesures microcalorimétriques ; ils ont permis de déterminer la succession temporelle des phénomènes.

## II - Etude dans le domaine de température 100-1000°C.

a) Essais exploratoires : Dans le tableau I, sont rassemblés les résultats des essais (A), portant sur le dihydrogénomonophosphate de sodium et sur l'hexacyclophosphate de sodium, soit secs, soit gâchés avec de l'eau dans le rapport pondéral  $l/s = 0,3$ .

Il convient de noter qu'après la formation intermédiaire de diphosphate, se forme à partir de  $300^{\circ}\text{C}$ , du tricyclophosphate qui subsiste jusqu'à  $600^{\circ}\text{C}$ , quel que soit le produit de départ.

A  $700^{\circ}\text{C}$ , la C.C.M. permet de révéler la présence de polyphosphate à longue chaîne ( $> 3 \text{ P}$ ), amorphe aux rayons X.

Dans le tableau II sont présentés les résultats des essais (B) d'évolution thermique des mélanges de

SECAR 71 exempt d'alumine<sup>100%</sup>, avec CaO,  $\text{Al}_2\text{O}_3$ , dans les proportions indiquées, gâchés à l'eau ( $l/s = 0,3$ ). Dans chaque cas, les transformations et combinaisons des phosphates avec les oxydes se produisent à température relativement basse ( $\theta < 400^{\circ}\text{C}$ ).

A  $\theta > 600^{\circ}\text{C}$ , seule la tache du monophosphate apparaît sur le chromatogramme.

Dans tous les cas, la preuve d'un excès d'alumine ou

de SECAR 71 est apportée par diffraction X, de sorte que, bien que les phosphates soient en forte proportion (50 % massique), leur combinaison avec les oxydes peut se faire complètement.

Enfin, le tableau III contient les résultats des deux essais effectués sur les mélanges des monophosphates et polyphosphates avec  $Al_2O_3$  et SECAR 71, gâchés à l'eau dans un rapport  $l/s = 0,3$ .

TABLEAU III		
Mélanges T°C	DHP (1g) + $Al_2O_3$ (1g) + SECAR 71 (1g) + $H_2O$	HCP (1g) + $Al_2O_3$ (1g) + SECAR 71 (1g) + $H_2O$
100°C	CCM : MP	MP + DP

400°C à 1000°C	MP	MP RX : Secar + $Al_2O_3$ + $CaNaPO_4$

Pour  $200^\circ C < \theta < 400^\circ C$ , le chromatogramme permet de déceler un mélange de mono- et diphosphates. Au-delà de  $400^\circ C$ , ne subsiste que le monophosphate.

La transformation diphosphate + tricyclophosphate n'a donc lieu que lorsque les phosphates ne sont pas mélangés avec des oxydes. Dans le cas contraire, que ce soit avec  $Al_2O_3$  ou  $CaO$  ou le SECAR 71, il se forme directement du monophosphate.

Fig. 3 - Courbe d'évolution thermique de l'hexacyclophosphate de sodium industriel.

(1) : hexacyclophosphate de sodium seul.

(2) : hexacyclophosphate de sodium +  $H_2O$  ( $l/s = 0,3$ ).

La décomposition thermique de "l'hexacyclophosphate de sodium" industriel présente une courbe d'évolution en fonction de la température qui se caractérise par un minimum de masse à  $600^\circ C$ . Une telle courbe, donnant le pourcentage d'eau perdue en fonction de la température est tracée figure 3.

TABLEAU IV		
T°C chauffage	$NaH_2PO_4$ t°C point froid : 25°C	$(NaPO_3)_6$ t°C point froid : 25°C
150°C	$\Delta m = 0$ C.C.M. → MP	$\Delta m = 0$ C.C.M. + PP + traces TCP et TP
210°C	$\Delta m$ : perte de $1H_2O$ /mole. C.C.M. : DP + traces PP	$\Delta m = 0$
445°C	$\Delta m$ : perte de $2H_2O$ /mole. C.C.M. : TCP + traces PP	$\Delta m \approx 1,4 \% H_2O$ C.C.M. : TCP + traces PP

Le minimum coïncide avec la transformation du tricyclophosphate cristallisé, produit de décomposition de l'hexacyclophosphate à  $200^\circ C$ , en polyphosphate vitreux à longue chaîne.

b) Premiers résultats en thermogravimétrie (TG) : Les courbes de déshydratation du dihydrogénophosphate de sodium et de l'hexamétaphosphate industriel sont représentées figure 4. Les produits de décomposition sont analysés comme précédemment par C.C.M. (tableau IV).

Fig. 4 - Courbes de déshydratation, sous  $3,2 \cdot 10^3$  Pa de pression de vapeur d'eau en fonction de la température.

— : dihydrogénophosphate de sodium.

$\frac{\Delta H_2O}{n}$  : nombre de moles d'eau perdues par mole de produit.

--- : hexacyclophosphate de sodium industriel.

$\Delta m H_2O$  : pourcentage en masse d'eau perdue.

Il doit être noté que la pression de vapeur d'eau maintenue constante par la thermorégulation du "point froid" a eu peu d'influence sur le taux de déshydratation atteint à une température donnée.

Ces résultats, obtenus dans des conditions mieux définies, confirment, dans le domaine de température qu'ils ont pour le moment permis d'explorer ( $80^{\circ}\text{C} < \theta < 400^{\circ}\text{C}$ ), les conclusions tirées des essais de décomposition thermique point par point.

#### CONCLUSION .

A température ambiante, l'étude cinétique en solution à  $L/s = 10$  permet de constater que l'hexacyclophosphate de sodium met un certain temps à s'hydrolyser. Pendant cette période, la concentration en  $\text{CaO}$  dans le filtrat augmente jusqu'à un maximum de  $15.10^{-3} \text{ mol.kg}^{-1}$ . Puis une compétition entre l'hydrolyse interne de l'hexacyclophosphate de sodium et la précipitation du phosphate de calcium peut expliquer l'allure de la courbe obtenue.

Une analyse par C.C.M. du filtrat indique que les ions "phosphate" ont disparu de la solution après 4h de réaction. Pour ce même temps de réaction, la forte teneur en  $\text{Al}_2\text{O}_3$  observée peut s'expliquer par la formation d'un aluminat de sodium soluble, due aux ions  $\text{Na}^+$  apportés par le cyclophosphate. La succession des phénomènes est également traduite par la variation du pH.

Cette étude montre, qu'à la température ambiante la prise "phosphate" s'effectue avant la prise hydraulique, commence dès le gâchage avec l'eau et l'hydrolyse interne du phosphate cyclique ; ceci est confirmé également sur pâte ( $L/s = 0,3$ ) au moyen des courbes de dégagement de chaleur en fonction du temps. L'intensité de la prise hydraulique est alors affaiblie par rapport à celle du SECAR 71 pur.

En montée progressive de température, entre l'ambiante et  $1000^{\circ}\text{C}$ , les états successifs de décomposition de l'hexacyclophosphate de sodium ont été mis en évidence, notamment, la formation du tricyclophosphate entre  $300^{\circ}\text{C}$  et  $600^{\circ}\text{C}$  et celle de polyphosphates au-delà de  $600^{\circ}\text{C}$ . Par contre en présence de divers oxydes, le tricyclophosphate n'est pas formé mais la réaction évolue vers l'apparition de monophosphate dès  $600^{\circ}\text{C}$ .

Dans les expériences d'évolution à  $L/s = 10$ , et en pâte avec 5 % d'hexacyclophosphate de sodium, il n'avait pas été possible de mettre en évidence directement par analyse (rayons X, C.C.M.) le phosphate de calcium présent dans le précipité. Sa formation avait été déduite d'une part de la courbe thermique, d'autre part de la disparition des ions "phosphate" en C.C.M.

En dernière minute, nous donnons les résultats d'une expérience complémentaire qui a consisté en une simulation, par mélange de 5 g d'hexacyclophosphate de sodium dans 1 l d'eau de chaux de concentration initiale  $[\text{C}]_0 = 22,2.10^{-3} \text{ mol.kg}^{-1}$ . Ceci correspondrait sensiblement à la concentration maximale atteinte par la chaux dans l'expérience à  $L/s = 10$  avec l'hexacyclophosphate.

Dans une durée analogue (1h 45) il s'est formé un précipité blanc, amorphe en diffraction  $X_0$  (anneau de diffusion aux alentours de  $d_{hk1} = 7,3 \text{ \AA}$ , pouvant correspondre à  $\alpha\text{-Ca}_3(\text{PO}_4)_2$ ).

L'analyse par C.C.M. du précipité a montré la présence d'ions monophosphate et triphosphate.

On notera également, que l'hydrolyse interne de l'hexacyclophosphate de sodium (5g) dans 1 l d'eau sans addition de chaux, est beaucoup plus lente, puisqu'après un temps d'agitation de 15h, la C.C.M. révèle des traces de monophosphate, de tricyclophosphate, mais une proportion encore importante d'hexacyclophosphate.

\* La signification du terme "prise phosphatique" peut être contestée : certains auteurs l'appellent plutôt "liaison phosphatique".

\*\*\* Nous rappelons que le SECAR 71 est un ciment alumineux à 70 % d'alumine.

\*\*\*\*\* SECAR 71 exempt d'alumine signifie pour nous SECAR 71 sans addition supplémentaire d'alumine.

# Problème de l'utilisation des sous-produits minéraux dans la production des liants

## *Use of mineral sub-products in binder manufacturing*

P. BOJENOV, Docteur ès Sciences, Professeur, Ecole du Bâtiment, Léninegrad, U.R.S.S.,  
B. GRIGORIEV, Candidat ès Sciences, Chargé de Cours, Ecole du Bâtiment, Léninegrad, U.R.S.S.

RESUME : La fusion des métaux ferreux et non-ferreux, la combustion des combustibles et d'autres opérations sont suivies, à grande échelle, par des processus analogues à la formation des clinkers. La composition chimique de la partie minérale des minerais et des combustibles, les conditions thermiques déterminent la formation de l'orthosilicate du calcium. Les sous-produits contenant  $\beta$ - $C_2S$  sont à utiliser non seulement comme un composant des matières premières des crues de ciments, mais aussi pour la fabrication des ciments composés.

Sont proposées des méthodes d'activation des propriétés liantes des sous-produits, en utilisant le mécanisme de l'adsorption intérieure entre les cristaux et un procédé d'évaluation des propriétés liantes des sous-produits d'après les coefficients de base. Il a été constaté que le progrès dans la création de nouveaux ciments à la base de sous-produits de l'industrie est intimement lié à l'étude de leur composition chimique et de phase, et de la technologie de la fabrication du produit essentiel.

SUMMARY: The processes similar clinker formation occur under ferrous and non-ferrous metal fusion, combustion of combustible and in other branches of industry in large scale. Chemical composition of the mineral part of ores and combustibles and temperature conditions determine the calcium orthosilicate formation.

It is shown that subproducts containing  $\beta$  -  $C_2S$  are useful not only as a raw material component of cement charges but also for the separate cement fabrication.

The methods of subproduct's astringent properties activation using the mechanism of inner adsorption between crystal as well as the way of subproduct's astringent properties estimation by the bases coefficient are offered.

It is inferred that the success in the creation of new cements on the basis of industry subproducts is closely connected with their phase and chemical structure exploring, with comprehensive interference in technology of the product fabrication.

L'analyse de l'état des ressources en matières premières utilisées pour la production des liants, d'une part, la pratique du bâtiment, d'autre part, prouvent que les ciment bérites, notamment le ciment de Portland, conserveront leur rôle essentiel dans l'avenir proche et même dans l'avenir plus éloigné.

La base cristallographique pour la fabrication du ciment de Portland est la suivante: élimination de l'eau des minéraux stratifiés et stratifiés en bande; reconstruction et destruction des méthastructures; décarbonisation du carbonate de calcium et refonte de la grille de la calcite trigonale (rhomboédrique) en structure cubique de l'oxyde de calcium; combinaison postérieure de la chaux et de la silice et formation du silicate bicalcique et tricalcique. Dans ces conditions la nature de liaison entre les éléments de structures des matériaux de base change ce qui conditionne l'activité hydraulique des silicates de calcium formés. L'adaptation réciproque des éléments de tétraèdres silice-oxygène et colonettes (bandes) des octaèdres de calcium est fonction de plusieurs facteurs dont la température. Elle rend plus facile la réalisation des structures orthosilicates de calcium. Dans les conditions réelles de la production du clinker, en général, l'état d'équilibre n'est pas atteint dans le système, et les nouvelles formations surgies sont à l'état métastable.

Des processus analogues ont lieu à une grande échelle pendant la production des métaux ferreux et non ferreux, la combustion des combustibles solides ainsi que dans certaines branches de l'industrie chimique.

Le volume sommaire de la production à la base des matières premières minérales mis sur le marché mondial augmente progressivement. Ainsi, suivant des données incomplètes, au début du XX<sup>e</sup> siècle, la pro-

duction annuelle en était 140 millions de tonnes, elle a atteint près de 3 milliards en 1975, on attend pour 1980 plus de 10 milliards.

Actuellement, les entreprises faisant usage des éléments dispersés dans l'écorce terrestre se développent d'une manière intense. Pour en fabriquer 1 tonne il faut traiter des dizaines et même des centaines de tonnes de minerais.

Or, on peut supposer que le volume annuel des matières premières minérales extraites de l'écorce terrestre atteindra 150-200 milliards de tonnes vers l'année 2000.

Nombreuses sont les entreprises où les matières premières mises en oeuvre pour la fabrication du produit essentiel sont soumises à un traitement thermique à une température qui souvent ne dépasse pas 1200-1300°C. Mais, comme le rendement du produit essentiel ne fait qu'une partie insignifiante des matériaux traités, les frais principaux d'énergie, de combustible, de main-d'oeuvre sont dépensés, fait paradoxal, à la modification, l'enrichissement, le chauffage et la séparation des sous-produits.

Comme le produit essentiel ne peut être fabriqué sans ces dépenses et, d'autre part, puisque la composition chimique et les conditions thermiques de la partie minérale favorisent la formation de l'orthosilicate de calcium, on peut bien comprendre l'aspiration des spécialistes du ciment de coopérer avec les branches d'industrie produisant des sous-produits pareils.

Une intervention raisonnable dans les procédés technologique en vue d'obtenir des sous-produits d'une composition de phase et de qualité requises est devenue une nécessité vitale de notre époque. L'industrie présente des exemples concluants de la résolution de cette tâche.

Le traitement complexe de la roche

apatitonéphéline pour la production du ciment, de l'alumine, du sodium et de la potasse réalisé en URSS est rendu possible grâce à l'étude approfondie de la composition chimique et de phase des sous-produits, grâce à la modification appropriée de la technologie de production de l'alumine en vue d'augmenter le rendement de  $\beta - C_2S$ .

En théorie, il est possible de corriger la charge et mener le processus de manière à assurer la formation du silicate tricalcique en quantité égale à celle renfermée dans le ciment de Portland, c'est-à-dire, fabriquer le clinker du ciment portland sans déchets.

Mais cela aurait pour conséquence la réduction du rendement des appareils pour le produit essentiel; et la modification des paramètres techniques du fonctionnement des appareils entraîne une augmentation des pertes du produit essentiel et une consommation de combustible due à l'accroissement de la masse de la roche traitée pour le compte du calcaire complémentaire.

C'est pourquoi dans les techniques du ciment est devenue courante la méthode de la mise en oeuvre des sous-produits contenant le silicate bicalcique, des laitiers, des boues etc. comme un des composants de la charge des matières premières. Ils ont déjà passé le stade de formation de  $C_2S$  ce qui rend la formation du silicate tricalcique plus facile, réduit la consommation de combustible et d'énergie électrique à 20-50%, tout en assurant la bonne qualité du ciment de Portland (1,2).

Pourtant la formation, à la base de ces produits, des liants indépendants, ne cédant en qualité au ciment de Portland semble être plus perspectif.

L'expérience de la production, en URSS, des ciments de néphéline à la base des boues de néphéline, sous-produit de production de l'alumine, qui contient 85%

$\beta - C_2S$ , a prouvé que ces ciments peuvent avoir un usage courant pour la fabrication des pièces en béton armé et en béton cellulaires (3,4).

L'expérience prouve que les boues de néphéline de diverses entreprises, contenant à peu près la même quantité d'orthosilicate du calcium, possèdent une activité hydraulique variée. Cela résulte, évidemment, de la différente action stabilisante des additions comprises dans les matières premières traitées qui, étant adsorbées aux limites des grains, sont aptes à régler la formation de  $C_2$  dans des modifications et exercent une influence sur la dimension et la forme des cristaux. A l'aide du mécanisme de l'adsorption intérieure entre les cristaux, on peut augmenter l'activité de  $\beta - C_2S$  et du liant lui-même par une seconde cuisson à une température basse.

La faculté forte exprimée de l'orthosilicate du calcium de dissoudre des additions diverses, d'une part, l'étude approfondie de la conduite des additions dans différentes conditions, d'autre part, laissent à rechercher de nouvelles voies d'activation du silicate bicalcique. C'est ainsi que le problème de l'usage des sous-produits contenant  $C_2S$  peut avoir un autre sens. C'est pourquoi au VI Congrès à Moscou, le professeur P. Bojenov a proposé de l'examiner comme une question spéciale au Congrès futur.

Un autre problème spécial: influence de l'excédent de chaux sur la stabilisation d'une forme de l'orthosilicate de calcium, nouvelle répartition de l'oxyde de calcium en phases dans les systèmes contenant  $C_2S$  sous l'influence des ions halogènes et certains oxydes des éléments de transition.

Les essais nous ont montré qu'il est possible d'obtenir un ciment du clinker avec  $KH = 0,67$  en présence de l'oxyde de chrome et de manganèse dont l'activité est

50-55 MPa en 7 jours et 65-70 MPa en 28 jours.

On a fait usage de ce procédé pour l'accroissement de l'activité des liants à la base des sous-produits, contenant l'orthosilicate du calcium.

Une autre possibilité d'activation des propriétés liantes de tels systèmes est leur transformation en un état hydraté et un traitement thermique postérieur du produit d'hydratation à une basse pression. Le ciment ainsi fabriqué dont la composition, à côté d'autres phases, contenait  $\beta$ - $C_2S$  à l'état des cristaux fins a formé, aux conditions de durcissement normales, une pierre d'une résistance assez élevée - 40 MPa. Ce procédé de fabrication des liants n'exige pas de hautes températures, nécessaire pour le synthèse des minéraux de clinkers suivant les techniques du ciment de Portland.

L'état de l'orthosilicate de calcium en cristaux fins des sous-produits a été défini par une charge supplémentaire en chaux de certaines espèces de laitiers et par le réglage du régime de traitement thermique. Il en résultent des liants ayant l'activité de 40 à 100 MPa.

L'étude des déchets agglomérés dans les terris présente un problème spécial.

Sous l'influence des agents atmosphériques, la composition chimique et la composition de phase des déchets dans les terris se modifient. L'hydratation des compositions silicates et d'autres, leur carbonisation par l'acide carbonique de l'air ont des conséquences défavorables sur les propriétés hydrauliques des déchets. Pourtant, même alors la situation n'est pas irréversible.

C'est ainsi que l'étude de la composition de phase des fractions fines des laitiers de haut-fourneau pulvérisés, produits ensemble avec les alliages ferreux et en-

richis par l'alumine, a permis à A. Boldyrev et à ses collaborateurs de fabriquer un ciment de silicate alumineux dont les propriétés se rapproche à celles des ciments alumineux (1).

P. Bojenov, B. Grigoriev ont montré que par l'addition de NaOH,  $Na_2CO_3$ , CaCl et d'autres combinaisons est atteinte une considérable activation des laitiers qui contiennent jusqu'à 25% du carbonate de calcium sous l'aspect de vaterite et jusqu'à 15% de vollastonite.

V. Glouckovski et ses collaborateurs (5) après avoir étudié l'influence des additions sur l'activité des laitiers ont formé un ciment nouveau, substance liante en laitier alcalin dont les propriétés peuvent rivaliser et même dépasser celles des ciments portlands.

Pour apprécier les propriétés liantes (hydrauliques) des sous-produits, laitiers et cendres y compris, on fait usage comme caractéristique chimique des modules divers. Pourtant, l'étude de différents laitiers a prouvé que parfois leur activité effective ne correspond pas aux valeurs données des modules. La raison en est l'absence de logique mathématique et chimique dans la formule des modules, ce qui empêche leur emploi en qualité de caractéristique chimique de n'importe quel sous-produit silicate. A une valeur constante de module, l'activité des liants, produits à la base de diverses matières peut différer de manière sensible. P. Bojenov a proposé le "Coefficient de base" qui, contrairement aux modules, ne prévoit plus la simple somme des oxydes, mais tient compte de la succession des opérations dans les nouvelles formations du produit.

$$\text{Coef. de base} = \frac{(\text{CaO} + 0,93 \text{ MgO} + 0,6 \text{ R}_2\text{O}) - (0,55 \text{ Al}_2\text{O}_3 + 0,35 \text{ Fe}_2\text{O}_3 + 0,7 \text{ SO}_3)}{0,93 \text{ SiO}_2}$$

où  $\text{CaO}$ ,  $\text{MgO}$ ,  $\text{SiO}_2$  est la teneur globale des oxydes.

L'analyse de cette formule donne la possibilité au technologue d'estimer les matières premières dont il se sert et les corriger.

Dans notre rapport nous avons analysé quelques espèces de sous-produits contenant, en règle générale, l'orthosilicate du calcium. Cependant, l'industrie produit d'autres matériaux, notamment ceux qui comprennent le silicate  $\text{Mg}$  et dont on peut faire usage pour la production des liants.

Le développement postérieur de la production des ciments traditionaux et la création de nouveaux ciments à la base des sous-produits de l'industrie peut être assuré par l'étude de la composition de phase des sous-produits, par l'intervention raisonnable dans la technologie de la fabrication du produit essentiel, enfin, par la mise au point d'une méthode de la correction de leurs propriétés, dont l'augmentation de l'activité hydraulique.

G.V. ZAVADSKI, Ingénieur,  
B.E. YUODOVITCH, Candidat ès Sciences Techniques, NIITzement, Moscou, U.R.S.S.

RESUME : Le niveau insuffisant des résistances initiales empêche, partiellement dans le cas de  $\beta$ - $C_2S$ , (complètement pour ce qui est de  $\gamma$ - $C_2S$ ) la mise en oeuvre, en tant que composants hydrauliquement actifs, des sous-produits technogènes de l'industrie de l'alumine, notamment du  $\beta$ - $C_2S$  ou du  $\gamma$ - $C_2S$ .

Le passage dans un broyeur à jet de mélanges composés de 70 % de clinker ordinaire et de 30 % de  $\beta$ - $C_2S$  technogène, additionnés de gypse, donne un ciment dont l'activité initiale est sensiblement supérieure à celle des ciments provenant des broyeurs à boulets.

La baisse de l'énergie d'activation de l'hydratation, que l'on observe lors de la pulvérisation par jet, a pour effet un relèvement sensible du taux d'utilisation de l'énergie potentielle contenue dans  $\beta$ - $C_2S$  et le clinker de ciment Portland industriel, et permet d'organiser sur cette base une production rentable des ciments d'activités différentes.

SUMMARY : Reduced growth of strength at the early stage of hardening limits the use of technogenic by-products of alumina industry containing  $\beta$ - $C_2S$  and excludes the use of by-products containing  $\gamma$ - $C_2S$  as hydraulically active components of cement.

Jet grinding of mixture comprising 70% of ordinary clinker and 30% of technogenic  $\beta$ - $C_2S$  with gypsum renders cement with considerably increased initial activity as compared with cement crushed in a ball drum mill.

Reduction of hydration activation energy by jet grinding ensures considerable increase in the degree of utilization of the potential energy stored in the technogenic  $\beta$ - $C_2S$  and industrial portland cement clinker and provides for economic production of cements of various activity.

L'exposé (1) traite des raisons pour lesquelles il serait utile d'activer le silicate bicalcique qui se crée lors du traitement thermique des minéraux dans le système  $\text{CaO} - \text{SiO}_2$ , ou bien dans les systèmes minéraux comprenant le système sus-mentionné, notamment lors de l'extraction de l'alumine par agglomération des aluminosilicates. Les sous-produits, comprenant le silicate bicalcique en quantités toujours croissantes, ce qui est lié à l'extension de la production d'alumine, doivent être utilisés dans d'autres industries dans le cadre d'une technologie sans rejets. L'activité hydraulique du silicate bicalcique permet l'utilisation des sous-produits qui comprennent ce minéral, avant-tout, pour la production des ciments. L'introduction du silicate bicalcique technogène dans la composition du ciment, par broyage, avec un clinker portland, constituerait un procédé simple dont la réalisation est la plus facile. Cependant, l'accroissement ralenti de la résistance pendant la période initiale de durcissement (jusqu'à 72 heures) empêche l'utilisation, en tant que constituants hydrauliquement actifs, des sous-produits  $\beta - \text{C}_2\text{S}$  - partiellement, et  $\gamma - \text{C}_2\text{S}$  - partiellement dans leur totalité. Dans ce contexte, les procédés d'activation mécanique et chimique du silicate bicalcique technogène, passés en revue dans la présente communication, acquièrent une importance considérable.

#### PRINCIPES D'ACTIVATION MECANIQUE ET CHIMIQUE

Sous le nom d'activation mécano-chimique des matériaux, on comprend généralement l'élévation de leur réactivité (dans les réactions chimiques) à la suite des modifications de structure par le traitement mécanique, notamment par broyage. Le traitement mécanique peut être effectué au préalable. Dans ce cas, son effet d'activation doit se conserver, au moins, jusqu'au début de la réaction chimique intensifiée. Mais ce genre de traitement peut être également opéré pendant la réaction; cette activation est la plus efficace, quoique sensiblement plus compliquée du point de vue matériel, c'est plutôt une technologie du demain bien qu'il existe des licences, d'application pratique peu sûre, ainsi que deux ou trois solutions techniques valables.

Les modifications de la structure apparaissant lors de l'activation mécano-chimique se prêtent à la classification suivante : 1<sup>o</sup> modification statiques, c'est-à-dire qui se conservent en permanence dans la structure activée, 2<sup>o</sup> modifications dynamiques gardées pendant un certain temps et qui disparaissent spontanément, 3<sup>o</sup> modifications mixtes qui incluent à la fois les deux types de modifications précédentes.

Du point de vue de la physique du corps solide, les modifications statiques sont conditionnées par les défauts du réseau cristallin, dus au changement de place des atomes dans les noeuds et les interstices des noeuds, ainsi qu'aux variations dans le nombre et l'emplacement des lacunes. L'augmentation quantitative de ces changements peut être considérée formellement, ou liée

de fait à l'accroissement de la densité de dislocations dans le réseau cristallin de la matière jusqu'à son amorphisation complète (2,3).

Naturellement, de tels changements de la structure lors du traitement mécanique de la matière peuvent être enregistrés avec succès, par la méthode de la radiographie. Les changements dynamiques de la structure survenant au cours de l'activation mécano-chimique des matériaux sont conditionnés par les défauts, apparaissant et disparaissant, dans les enveloppes électroniques des atomes qui constituent le réseau cristallin. Il est généralement admis aujourd'hui que lors de la dispersion de la matière, une partie des électrons se trouvent séparés de leurs atomes par les interfaces apparaissantes, ce qui provoque un excès du potentiel électrostatique à la surface et entraîne des variations correspondantes du niveau Fermi, c'est-à-dire de l'énergie moyenne des électrons dans les zones extérieures du réseau cristallin (4). La valeur de cet excès du potentiel peut être stable et alors les variations de la structure engendrées par ce potentiel, peuvent être envisagées comme défauts statiques. Cependant, dans bien des cas, l'excès du potentiel Fermi, après la dispersion, a une tendance à se diminuer, par exemple à la suite de l'émission à partir de la surface des électrons excédentaires durant un certain temps qui suit la pulvérisation. Une telle émission exo-électronique a été observée pour la première fois sur le gypse par Kramer (5). C'est ce qu'on appelle aujourd'hui "effet Kramer". Parmi les autres modifications, conditionnant la baisse du niveau excédentaire du potentiel Fermi des matériaux activés, on peut citer l'adsorption des molécules de gaz, et notamment, du gaz carbonique et/ou de l'oxygène contenu dans l'air, des molécules d'eau qui constituent l'humidité naturelle, etc. Les défauts du réseau cristallin disparaissant pendant cette réaction peuvent aussi être considérés comme modifications dynamiques provoquées par l'activation. Elles sont enregistrées grâce aux procédés indirects, compte tenu des techniques modernes. En particulier, l'émission exoélectronique (effet Kramer) est observée au moyen des capteurs à pointe à rayons X, puisque l'énergie des électrons émis est assez importante (6). Jusqu'à présent, on ne trouve pas de critères théoriques de structure, qui conditionnent la présence ou l'absence de l'effet Kramer à la suite de l'activation mécano-chimique des matériaux. Aussi, le type des modifications dynamiques du réseau cristallin des matériaux activés n'est-il défini que par voie expérimentale.

#### PULVERISATION PAR JET EN TANT QUE METHODE D'ACTIVATION

On connaît toute une série de méthodes d'activation mécano-chimique des matériaux par dispersion. Le broyage en broyeurs à cylindres en est un procédé d'activation préliminaire très ancien, utilisé par l'homme pour des processus physiques et chimiques divers tels que pyrométallurgie, panification, fabrication d'objets en céramique, etc. Au XIX<sup>e</sup> siècle, ce procédé a

été en partie remplacé par broyage à tambour, notamment, dans des moulins à tubes remplis de corps broyants nécessaires à la mouture (boulets, cylpebs, etc). Dans les années cinquante de notre siècle, afin d'accroître l'efficacité de l'activation préliminaire, on recourt largement au broyage par percussion et par vibration, deux inventions datant d'une vingtaine d'années, ainsi qu'à un traitement par désintégration. De tous ces procédés relativement nouveaux, seule la mouture par vibration est utilisable dans le cas de l'activation du silicate bicalcique, les autres ne permettant que l'obtention d'un produit assez grossier par comparaison à la finesse des ciments ordinaires. Les expérimentations sur broyage par vibration du silicate bicalcique technogène, effectuées à l'Institut dans les années soixante, ont donné des résultats positifs. Cependant, elles n'ont pas trouvé d'application industrielle en raison de certaines particularités de construction du broyeur vibrant, de son faible rendement et du taux d'usure élevé de la garniture, par rapport aux moulins à tambours ordinaires. La pulvérisation par jet a été proposée, en tant que méthode d'activation mécano-chimique préliminaire des liants, par un des auteurs du présent exposé, dans les années soixante (?). Par rapport aux autres engins de broyage, le procédé en question se caractérise par un niveau plus élevé (d'un ordre de grandeur) de la consommation d'énergie par unité de volume utile, un équipement peu encombrant donc une quantité moindre de matériaux mis en oeuvre pour sa construction, l'absence de pièces mobiles, de corps broyants, de séparateurs, d'où un taux moins élevé (de deux ordres de grandeur) d'usure des organes de travail, un fonctionnement silencieux, sans parler des avantages intrinsèques résidant dans la nature physique même de cette méthode d'activation mécano-chimique. Son atout principal consiste dans une propagation à vitesse supersonique des ondes de choc et, comme corollaire, une éventualité très minime de relaxation des contraintes apparaissant dans le réseau cristallin.

Outre l'augmentation du rendement de l'énergie dépensée pour le broyage, cela garantit le taux maximum de formation des défauts statiques et le taux maximum de maintenance de défauts dynamiques provoqués pendant la pulvérisation par jet de la matière à activer. Cela assure une utilisation efficace de la pulvérisation par jet du clinker portland et de ses mélanges avec le laitier granulé de haut fourneau, en tant que méthode de la fabrication des ciments à haute résistance dont la surface spécifique est pour une résistance égale, d'environ 1000 cm<sup>2</sup>/g inférieure à celle des ciments analogues obtenus dans les broyeurs à tube (8).

**MATIERES UTILISEES PENDANT LES EXPERIENCES.**  
Clinker portland industriel,  $\beta$ -C<sub>2</sub>S technogène (boue de bélite, résidu d'extraction d'alumine à partir de néphéline) et  $\gamma$ -C<sub>2</sub>S - produit de synthèse par cuisson dans le four pilote rotatif de la cimenterie expérimentale de l'Institut. - avaient un

composé chimique illustré par le tableau I. Les analyses pétrographique et aux rayons X ont prouvé la présence dans le clinker d'alite de la série monoclinique des modifications, de  $\beta$ -C<sub>2</sub>S et de C<sub>3</sub>A tétragone; dans  $\beta$ -C<sub>2</sub>S technogène, on remarquait la présence d'impuretés ordinaires de gehlenite, de wollastonite et de minéraux alcalins, le tout avec 80% de la matière de base. Le  $\gamma$ -C<sub>2</sub>S contenait près de 20% de  $\beta$ -C<sub>2</sub>S, ce qui correspond parfaitement à la composition des rejets issus de la transformation industrielle des produits de kaolinite de la valorisation du charbon en alumine.

TABLEAU I			
Composition chimique des matériaux, en %			
Oxydes	Clinker	$\beta$ -C <sub>2</sub> S semi-produit	$\gamma$ -C <sub>2</sub> S
Pertes à la calcination	0,21	2,76	0,35
SiO <sub>2</sub>	21,56	30,52	35,00
Al <sub>2</sub> O <sub>3</sub>	4,69	2,79	0,22
Fe <sub>2</sub> O <sub>3</sub>	4,52	2,52	0,10
CaO	64,97	56,67	63,70
CaO (libre)	0,05	néant	0,40
MgO	1,46	-	traces
SO <sub>3</sub>	0,53	-	traces

**RESULTATS DES EXPERIENCES.** Chacune des matières précitées, y compris les mélanges préparés d'avance et constitués à 70% de clinker à 30 % de  $\beta$  et  $\gamma$ -C<sub>2</sub>S avec 5% de gypse ont subi une pulvérisation par jet dans un engin de la série USV-300. Les matériaux obtenus ont été analysés au sujet de la radioactivité, au moyen d'un compteur de rayons X directif d'après la méthode (9) et utilisés pour la fabrication d'échantillons conformément aux Normes GOST 310 - 76) avec du sable (rapport 3 à 1), afin d'évaluer leur activité hydraulique. L'usage, pendant la pulvérisation, de divers agents porteurs d'énergie - tels que l'air ou la vapeur d'eau - prouve que ces agents exercent un effet considérable sur l'activité hydraulique et la radioactivité des matériaux obtenus. Dans le cas, présent, on a fait usage de vapeurs d'eau.

La granulométrie des matériaux obtenus par pulvérisation par jet se distingue des matériaux de la mouture à boulets, qui ont la surface spécifique identique (déterminée d'après la méthode de la perméabilité à l'air) par la valeur légèrement supérieure de l'ascension  $n$  (tangente de l'angle d'inclinaison) de la droite - anamorphose de la répartition des particules selon leurs dimensions, dans le système Rosin-Rammler - Sperling-Bennett :  $n = 1,1-1,3$ , pour la pulvérisation par jet, et 0,7-0,9 pour le broyage à boulets.

On a établi l'existence, pendant environ 24 heures après la pulvérisation par jet, de  $\beta$ -C<sub>2</sub>S, ainsi que du clinker portland, d'une émission exo-électronique à partir de

la surface de leurs particules. Le  $\gamma$ -C<sub>2</sub>S est, paraît-il, exempt de ce phénomène. L'intensité d'émission des particules clinker est inférieure par rapport à  $\beta$ -C<sub>2</sub>S, proportionnellement au contenu de ce minéral dans le clinker; ceci permet de considérer  $\beta$ -C<sub>2</sub>S comme cause de l'émission, puisqu'il fait partie du clinker. L'activité hydraulique de  $\beta$ -C<sub>2</sub>S, et plus particulièrement, de  $\gamma$ -C<sub>2</sub>S n'est pas forte par rapport aux données assez favorables sur l'activité du mélange technogène clinker portland -  $\beta$ -C<sub>2</sub>S (tableau II).

**EXAMEN DES RESULTATS.** Les données de l'émission exo-electronique coïncident, dans leur ensemble, avec les résultats du travail (9) à la suite duquel on a constaté la présence exclusive de cette émission dans C<sub>2</sub>S ( $\beta$ -forme, à ce qu'il paraît), hormis le reste des minéraux clinker. Le diagramme X des poudres de tous les matériaux pulvérisés prouve qu'il n'y a pas lieu d'appréhender l'existence d'une multiplication des dislocations, et moins encore d'une amorphisation des particules dans les couches superficielles, en comparaison avec le broyage à boulets dans des broyeurs de laboratoire.

Au contraire, il peut y s'agir de l'intensi-

fication des pics d'analyse d'alite (51,7°), de  $\beta$ -C<sub>2</sub>S (15,5°) et de  $\gamma$ -C<sub>2</sub>S (29°) après la pulvérisation par jet, par rapport au broyage à boulets. Ceci atteste la densité moins forte des dislocations dans les matériaux pulvérisés par jet et, par conséquent, l'existence des interfaces plus planes. Les microphotos des préparations d'immersion de certaines fractions du clinker prouvent, qu'après le broyage par jet, les grains sont moins rugueux: une partie de la surface des grains est constituée, à la différence du broyage à boulets, par le plan de clivage. Mais les projections visibles sur les épreuves témoignent que, souvent après la pulvérisation par jet, se forment les grains aux angles aigus de moins de 1 rad, alors que chez les particules issues du broyage à boulets, les angles aigus ne dépassent jamais 1,4 rad et, si besoin est de former un angle aigu solide, celui-ci est créé par deux angles obtus, comme on le voit sur le schéma (Fig.1).

Fig.1; Une particule obtenue par jet (a) et par boulets (b) ayant un angle solide égal entre les faces (schéma).

La soumission de la répartition des particules selon les dimensions, pendant la pulvérisation par jet, à l'équation Rosine-Rammler-Sperling avec le coefficient d'uniformité  $n \approx 1$ , est conditionnée, (10), d'après l'analyse théorique, par l'absence de relaxation au cours de la pulvérisation, et par la domination exclusive de l'action percutante. Lors du broyage à boulets, qui constitue une combinaison des actions percutante et abrasive (11), les angles aigus, formés dans les particules après l'action percutante, deviennent obtus sous l'effet de frottement. Le phénomène des angles aigus, des particules de matériaux obtenus par jet, rend plus accessible leur volume intérieur pour les réactions chimiques hétérogènes, et accélère, on le sait (12), leur continuation dans le temps. C'est là que nous sommes enclins de voir l'effet essentiel d'activation offert par la pulvérisation par jet. L'activation du réseau cristallin n'aura d'effet sur la surface des particules qu'avec un taux de dispersion très élevé, allant jusqu'à 8000 cm<sup>2</sup>/g de  $\gamma$ -C<sub>2</sub>S. L'importance des exo-électrons pour l'acti-

tivité hydraulique est aussi prouvée. En effet, le taux de consistance de la pâte de ciment normale produite à partir du clinker fraîchement moulu avec du gypse en poudre, se réduit d'une façon exponentielle dans le temps (13); il en est de même pour la valeur d'émission exo-électronique. Cet effet n'est pas utilisé exprès pendant nos expérimentations puisque, d'une manière générale, il n'est guère réalisable que pendant la production complexe des ciments et bétons ce qui est réservé pour l'avenir. C'est pourquoi, pendant ces expériences, le gâchage hydraulique des matériaux pulvérisés par jet s'effectuait au bout des 24 heures après la pulvérisation et l'arrêt total de l'émission exo-électronique. Cependant, même dans ces conditions, la pulvérisation par jet du mélange constitué à 70% par clinker industriel et à 30% par  $\beta$ -C<sub>2</sub>S avec 5% de gypse, a permis d'obtenir un ciment à activité initiale considérablement élevée par rapport au ciment de la même composition mais pulvérisé dans un tambour broyeur à boulets. Son taux de résistance correspond au portland ordinaire, (classe 400, Normes GOST 10178-76), ou bien au ciment type 1 ASTM C-150.

Pour trouver la cause de l'accroissement accéléré de la résistance de ce ciment, en comparaison avec un ciment analogue broyé par boulets, il a fallu toute une série d'analyses (ingénieur N.V. TSOUKANOVA) qui avaient pour objectif d'étudier la vitesse d'hydratation dans un milieu dont la température variait.

Les résultats de ces expériences attestent que la pulvérisation par jet peut être considérée comme un procédé qui réduit la valeur énergétique d'activation de l'hydratation des ciments et augmente le degré d'utilisation de l'énergie potentielle accumulée dans un clinker et  $\beta$ -C<sub>2</sub>S technogène.

#### CONCLUSIONS.

La technologie rationnelle de la production des ciments qui comprennent  $\beta$ -C<sub>2</sub>B technogène, peut se baser sur la pulvérisation par jet du mélange de cette matière avec du clinker industriel et du gypse. Ce procédé permet d'obtenir des ciments à activité variable, y compris des homologues du portland ordinaire (type 1, Normes ASTM), lorsqu'ils contiennent 30% de  $\beta$ -C<sub>2</sub>S technogène environ; cela revient à la réduction de 30% des dépenses en énergie lors de sa production. Pour utiliser  $\gamma$ -C<sub>2</sub>S, il faut des efforts d'activation supplémentaires. Sont particulièrement prometteuses les possibilités qui sont tracées dans un de nos ouvrages et qui concernent l'activation des C<sub>2</sub>S par les agents énergétiques sous haute température permettant de combiner dans un même engin (broyeur à projection) les processus de pulvérisation, de séchage et du traitement thermique de haute température (14). Cela amène dans la couche superficielle deshydratée de  $\beta$ -C<sub>2</sub>S, l'apparition de zones actives du réseau cristallin qui accélèrent le processus d'hydratation. Actuellement, on

procède à la mise au point de cet engin en Union Soviétique.

RESUME : La disparition des composants initiaux et la formation des phases intermédiaires et finales des crus de ciment alumineux à base de CA ou de CA<sub>2</sub> ont été étudiées aux rayons X dans des fours de laboratoire.

On a observé que pour les ciments à base de CA, en augmentant l'intensité de la cuisson, on accroissait la proportion de CA, mais que du CA<sub>2</sub> était toujours détectable. Un composé intermédiaire C<sub>12</sub>A<sub>7</sub> est aussi formé.

Pour les ciments à base de CA<sub>2</sub>, on observe un accroissement continu du CA<sub>2</sub> et la formation de deux composés intermédiaires : CA et C<sub>12</sub>A<sub>7</sub>.

Des expérimentations, en laboratoire et en usine pilote, ont montré que, pour les ciments à base de CA, la proportion maximale de CA est obtenue par une cuisson modérée. Ce maximum coïncide avec la plus grande résistance initiale du ciment. Si l'on augmente l'intensité de la cuisson, on diminue à la fois la proportion de CA dans le ciment, et sa résistance initiale.

SUMMARY: The disappearing of the starting components as well as the formation of the intermediate and final phases of monocalcium-aluminate- and calcium-dialuminate-type raw meals were followed by X-ray investigation using heating chamber.

It was stated that at CA-composition the amount of CA increases upon increasing the burning intensity, and beside it CA<sub>2</sub> can be detected too. Intermediate C<sub>12</sub>A<sub>7</sub> is also formed.

At CA<sub>2</sub> composition the amount of CA<sub>2</sub> is continuously increasing and intermediate CA and C<sub>12</sub>A<sub>7</sub> are also formed.

Laboratory and pilot plant burning experiments also proved that in case of CA composition the maximal CA is achieved by the less intensive burning. This maximum coincides with that of the initial strength of cement. Upon increasing the burning intensity both CA and the initial strength of cement are decreasing.

The physical-mechanical properties of white high alumina cements depend on their  $\text{Al}_2\text{O}_3$  content and the way of burning.

It is known from literature that the high initial strength is mainly due to CA. Rapid hardening is caused by CA that is why the conditions of forming the maximal amount of CA in the CA and  $\text{CA}_2$  type clinkers is investigated in the following.

#### THE FORMATION OF CA AND $\text{CA}_2$

When burning raw mixtures corresponding in their composition to the above mentioned two calcium aluminates besides the basic mineral other calcium aluminates partly of intermediate, partly of constant character are formed as a function of sintering temperature and time [1,2,3].

According to recent publications on the  $\text{CaO}-\text{Al}_2\text{O}_3$  systems [1,4] CA and  $\text{CA}_2$  melt incongruently. Among the calcium aluminates of intermediate character the  $\text{C}_{12}\text{A}_7$  is formed only in the presence of moisture /the moisture being present in air is sufficient/ and in the burnt CA one can almost always find CA too, if during burning a partial melting appears for when an incongruently melting compound is crystallizing out from the melt, a perfect state of equilibrium can rarely be achieved.

For the investigation of the CA and  $\text{CA}_2$  formation a Jeol type X-ray diffractometer equipped with heating chamber was used. The maximum heating temperature of the chamber is 1773 K.

Since our aim was the definition of the conditions at which the maximal amount of CA is formed and not the determination of the absolute amount of minerals, the changes were followed by measuring the most characteristic peaks of the individual minerals.

Raw meal compositions corresponding to CA and  $\text{CA}_2$  were prepared using alumina, limestone and in some cases lime hydrate. The  $\text{CaO} + \text{Al}_2\text{O}_3$  content - referred to the loss on ignition free state - amounted to 99 %.

The raw meals were heated at a rate of  $10^\circ/\text{min}$ . Between 1173 and 1773 K the heating was interrupted at every  $100^\circ$  increase stage for 30 minutes and the material was maintained at those temperatures to have the equilibrium state being achieved and following this the X-ray patterns were made.

The experiments with CA were repeated four times: twice using limestone and twice lime hydrate as basic material while that with  $\text{CA}_2$  only once using lime hydrate.

Fig. 1. shows the average data of the four CA syntheses. On the abscisse the temperature, on the ordinate the heights of the 0,240 nm CaO, 0,208 nm  $\text{Al}_2\text{O}_3$ , 0,268 nm  $\text{C}_{12}\text{A}_7$ , 0,298 nm CA and 0,349 nm  $\text{CA}_2$  peaks are plotted.

Besides the continuous decrease of the peak characterising the initial CaO and  $\text{Al}_2\text{O}_3$ , the reflection of  $\text{C}_{12}\text{A}_7$  appears at 1173 K then, after reaching a maximum, it disappears

Fig. 1.- Formation of calcium aluminates from raw meals of CA composition as investigated by X-ray diffractometer equipped with heating chamber

at 1550 K.

The  $\text{CA}_2$  appears at 1320 K, its reflection intensity increases up to 1520 K then remains constant up to the possible maximal heating temperature - 1770 K. It may be supposed that upon a further temperature rise and subsequent cooling of the material besides CA the amount of  $\text{CA}_2$  would also decrease due to the tendency to approach the state of equilibrium.

This is confirmed by the X-ray patterns of the materials of CA composition melted in laboratory arch furnace and sintered in laboratory furnace where besides the CA peaks  $\text{CA}_2$  reflections of minor intensity can also be observed.

On the basis of these investigations it can unambiguously be stated that in the case of a composition corresponding to CA the maximal amount of CA can be obtained by elevating the temperature or by melting.

Fig. 2. shows the phase composition relations in the process of heating the mixtures with a composition corresponding to  $\text{CA}_2$ . These relations are more simple than those of CA type mixtures.

The intensity of the initial CaO and  $\text{Al}_2\text{O}_3$  reflections are continuously decreasing here, too. The peak showing CA formation appears at 1200 K. Its intensity increases up to 1400 K and thereafter begins to diminish.

The  $\text{CA}_2$  and  $\text{C}_{12}\text{A}_7$  reflections appear at 1470 K. The intensity of the  $\text{CA}_2$  peaks increases continuously with the temperature while that of the  $\text{C}_{12}\text{A}_7$  reflections decreases. Using extrapolation it seems to be probable that in the final equilibrium state only  $\text{CA}_2$  is

Fig. 2. - Formation of calcium aluminates from raw meals of  $CA_2$  composition as investigated by X-ray diffractometer equipped with heating chamber

present which is supported by other investigations, too.

In case of  $CA_2$  composition the maximal intensity of  $CA$  reflections - in contrast with the  $CA$  composition - can be observed at a relatively low temperature i.e. far away from the state of equilibrium.

#### PHYSICAL-MECHANICAL PROPERTIES OF THE CEMENT AS A FUNCTION OF THE WAY OF SINTERING

In order to investigate the relationships between the intensity of burning, the formation of crystalline  $CA$  and the strength,  $CA$  and  $CA_2$  type raw meals were burnt at 1473, 1623 and 1723 K with sintering times of 2 and 4 hours in a silite rod heated electrical laboratory furnace.

The clinkers cooled in the furnace were ground to a specific surface of 400  $m^2/kg$  and the strength tested according to the Hungarian Standard Specs. MSZ 4702/9/74 requiring the compressive strength at 3 days age to reach the minimal values as listed below:

$Al_2O_3$ content < 70 %	34,3 MPa
$Al_2O_3$ content > 70 %	24,5 MPa

The compressive strength of the products of  $CA$  composition is shown in Fig.3. while in Fig.4. the 0,298 nm peak height of the X-ray pattern, in Fig.5. the compressive strength of  $CA_2$  and in Fig.6. the 0,349 nm peak height can be seen.

Fig.3. - Change of the compressive strength as a function of burning temperature and time of  $CA$  composition cement burnt and ground in laboratory

Table I. - The free CaO content and the insoluble residue of CA and  $CA_2$  type clinkers synthesized in laboratory

Table I. shows the free CaO-content and the insoluble in hydrochloric acid residue of the cements.

The strength of the CA-type cement burnt at 1473 K for 2 hours is lowered by the large amount of free CaO. Upon increasing the temperature and sintering time the strength and - as it has been stated by the investigation of the CA forming process - the height of the 0,298 nm CA peak is also continuously increasing.

In the X-ray pattern of the product burnt at 1473 K for 4 hours the line of  $Cl_2A_7$  - even if only in traces - can be found. Moreover, in the pattern of the sample burnt at 1723 K for 2 hours the presence of  $CA_2$  can be observed.

In case of the  $CA_2$  composition the  $Al_2O_3$  being present in larger amount binds the CaO of smaller amount more rapidly thus the CA is formed quickly and at a lower temperature.

According to our investigations the maximum of the CA-peak can be observed after the burning at 1473 K for 2 hours but it may be supposed that also in case of a less intensive burning it would further increase since in Fig. 4. only the descending part of the curve can already be seen.

The strength of the with the lowest intensity burnt material is in this case, too, diminished by the free CaO but the amount of it is considerably less than in the case of

the similarly burnt CA-composition thus its strength is ten times higher than that of the former one.

The highest strength value is achieved by burning at 1473 K for 4 hours. The maximums of CA peak-intensity and strength do not coincide which is due to the larger amount of free CaO remaining after a less intensive burning.

Further on, the strength and the intensity of the CA-peak decrease continuously while the  $CA_2$  reflection increases.

The change of the strength and CA-reflections according to a maximum curve as well as the continuous increase of  $CA_2$  correspond to the tendency that was found by investigating the products of  $CA_2$  composition.

The amount of the insoluble in hydrochloric acid residue is big and as contrasted to the CA-composition mixture, it is increasing with intensified burning.

In order to prove as well as to prepare the utilization of our laboratory results a raw meal corresponding in its composition to  $CA_2$  was also burnt in the 10 meter long rotary kiln of our pilot plant.

The data of burning temperature, free CaO and the insoluble in hydrochloric acid residue are given in Table II. while in Fig. 7 the strengths, in Fig. 8. the 0,298 nm peak heights of CA and 0,349 nm ones of  $CA_2$  are shown.

Clinker mark	Burning temperature K	Free CaO %		Insoluble in hydrochloric acid %
		original	after storage	
I.	1373-1423	2,83	0,15	35,3
II.	1423-1473	1,63	0,25	39,1
III.	1473-1573	0,17	-	42,0
IV.	1573-1673	traces	-	39,0
V.	1773	0	-	41,7

The cements marked with I. and II. were stored under atmospheric conditions in order to neutralize the effect of free CaO since their strengths could not be determined due to rapid setting. In this way the strength-reducing effect of free CaO was eliminated even for the less intensively burnt material, too.

The tendencies are the same as in the laboratory experiments but the actual values show some deviation due to changes in the way of burning and the sensitivity of testing.

In case of the  $CA_2$ -composition both in laboratory experiments and in those ones made in pilot plant it can be observed that with

Fig. 7. - Change of the compressive strength as a function of burning temperature of a  $CA_2$  composition cement burnt in pilot plant and ground in laboratory

the increase of hardening time the maximum of strength is shifted towards the more intensive burning. The probable cause of this phenomenon is that here hydration of the less soluble and more slowly hardening  $CA_2$  is already beginning.

#### CONCLUSIONS

The early strength of high alumina cements is proportional with their CA-content. The conditions of maximal CA-formation were stated by comparing the characteristic peak heights measured by X-ray investigation using heating chamber.

The amount of crystalline CA in the clinker composition corresponding to CA is continuously increasing with intensified burning. Meanwhile intermediate  $C_{12}A_7$  and  $CA_2$  are also formed. The amount of  $C_{12}A_7$  changes according to a maximum curve then disappears.  $CA_2$  does not fully disappear even in melted CA supporting its nature of incongruent melting.

In the clinker composition corresponding to  $CA_2$  CA disappears after a relatively low temperature maximum. Intermediately  $C_{12}A_7$  is also formed. The amount of crystalline  $CA_2$  is continuously increasing with the intensification of burning.

Fig.8. - Change of the 0,298 nm CA and 0,349 nm  $CA_2$  peak heights as a function of burning temperature of a  $CA_2$  composition clinker burnt in pilot plant rotary kiln

Laboratory and pilot plant clinker burning experiments prove the CA-formation tendencies determined by the X-ray investigation using heating chamber as well as the relationships between CA formation and 3 days age strengths.

Consequently, clinkers of CA composition giving high strength can be produced by intensive burning or by melting. In case of  $CA_2$  composition the burning should be carried out very softly at the temperature of the maximal CA formation. Care should be taken, however, that no free CaO remains in the clinker because this would diminish the strength. According to our investigations the optimal amount of free CaO is 0,2 %.

With prolonged storing time the maximal strengths of test specimens are shifted towards the more intensive way of burning.

**RÉSUMÉ :** A la base des lois de correspondance structurale, on trouve des cations, susceptibles de stabiliser les modifications des orthosilicates de calcium à haute température. Du point de vue des idées sur l'adsorption interne entre les cristallites, il est proposé un mécanisme de stabilisation  $\beta-C_2S$  par la chaux en excès. Par la voie expérimentale, il est démontré que l'activité des ciments bélites peut être considérablement augmentée par un réglage judicieux de la distribution des additions.

Il est proposé une explication du mécanisme d'activation de l'orthosilicate du calcium obtenu dans les réactions topotaxiques de déshydratation des hydrosilicates dans le vide. Il est constaté que le silicate bicalcique est apte à former, dans les conditions normales de durcissement, une pâte durcie ayant une résistance considérable.

Il est proposé une explication de l'activation hydrothermale en présence de  $SiO_2$  et  $CO_2$ .

**SUMMARY:** On the basis of the structural accordance low the cations which can stabilize high-temperature modifications of the calcium orthosilicate were ascertained.

The stabilization mechanism of  $\beta - C_2S$  with abundant lime was proposed from the position of intercrystal interior adsorption ideas. It was shown experimentally that under regulation of additions distribution one can essentially increase an activity of belit cements.

The activation mechanism of the calcium orthosilicate as a product of topotaxic reactions of dehydration of high based hydrosilicate in vacuum was explained. There was found that double - calcium silicate obtained as a result of dehydration side by side with  $CaO$ , under normal conditions of hardening was capable to form a stone of rather high strength.

The hydrothermal activation of  $C_2S$  in the presence of  $SiO_2$  and  $CO_2$  was explained.

L'activité hydraulique des orthosilicates du calcium est fonction d'une part, de la façon complète ou incomplète de la succession des fragments structuraux des chaux et, d'autre part, de la mode de formation d'une modification de  $C_2S$ .

La succession de la structure des chaux semble être plus grande dans les modifications  $\alpha$ ,  $\alpha'$  et  $\beta$ , elle n'est que partielle dans celles de  $\gamma - C_2S$  (1).

L'analyse de la loi de correspondance structurale et l'usage des notions du dynamisme de  $SiO_2$  nous a permis de proposer un modèle théorique sur lequel ont été révélés des cations essentiels susceptibles de stabiliser des modifications  $C_2S$  aux températures élevées.

La particularité des structures avec des cations tels que  $Cr^{2+}$ ,  $Mn^{2+}$ ,  $Ca^{2+}$ ,  $Sr^{2+}$ ,  $Ba^{2+}$ ,  $Na^+$ ,  $K^+$  etc. réside dans le fait que pour assurer les conditions de la loi de correspondance structurale les tétraèdres Si doivent s'unir dans des diorthogroupes. La stachyometrie des orthosilicates anhydres ne permet pas de réaliser de telles associations, et pour assurer la commensurabilité de l'arête du tétraèdre Si avec celle du cation polyèdre, les gros cations doivent avoir une coordination supérieure à 6.

Le passage d'une partie de  $Ca^{2+}$  au polyèdre à 7 sommets permet de stabiliser  $\beta - C_2S$ .

Or, le mécanisme de cette stabilisation n'est pas encore révélé définitivement. Il y a une particularité: pour la stabilisation  $\beta - C_2S$  il est nécessaire, pour une courte durée, de chauffer une seconde fois à une température modérée ( $\sim 1000^\circ C$ ) les produits de la cuisson primaire du mélange

L'analyse du mécanisme de distribution des ions additifs dans les corps polycristallins nous a donné la possibilité de

proposer une explication du procédé de stabilisation du point de vue de l'adsorption intérieure entre les cristallites (AI) étudiée pour les systèmes métalliques par B. Archarov. (2)

La particularité de la distribution des ions additifs, compte tenu la AI, réside dans le fait que dans la réaction primaire, à la phase solide, les ions additifs, essentiellement, sont localisés dans l'espace entre les cristallites et y égalisent ainsi les maximums énergétiques. Ceux-ci sont dûs aux déformations considérables de la grille cristalline à l'endroit des joints des cristallites.

Ces ions sont appelés horophiles.

Une seconde cuisson à basse température permet d'éliminer la hétérogénéité locale des phases pour le compte de la diffusion des ions additifs au fond des cristallites (là, ils peuvent stabiliser une certaine modification).

C'est en réglant la distribution des additions dans les polycristallites qu'il est possible de modifier essentiellement les propriétés des métaux (2), des céramiques, des liants clinkers, ce qui est prouvé par les résultats des essais sur les ciments bélites (tableau 1) fabriqués des clinkers KH = 0,67 additionné de 1% d'oxyde de chrome. Le refroidissement se faisait soit par une trempe sous l'eau, soit par un lent refroidissement dans le four. Dans le premier cas reste une hétérogénéité locale des phases, dans le deuxième cas elle est partiellement évitée.

Pour créer des centres actifs d'hydratation, des cuissons de deux types ont été effectuées à une température basse: un recuit à courte durée et celui à une durée plus prolongée. Conformément à l'hypothèse de travail, les ions horophiles devaient diffuser dans la masse des cristaux

en faisant "ameublir" les zones entre les cristallites. Pendant le recuit à courte durée le processus n'est pas terminé, et la microhétérogénéité locale est conservée, elle doit disparaître au recuit plus prolongée.

De même a été effectué le recuit dans le vide. Dans ce cas la défektivité des zones entre les cristallites devait accroître, due à l'apparition des places vacantes de l'oxygène dans l'oxyde du chrome.

cates, ou bien des structures semblables à tilléites, adhérent encore de l'autre côté du mur portlandite.

Dans les réactions topotaxiques de déshydratation, des hydrosilicates à fort cuisson doivent se dégrader en CaO et  $\gamma$ -C<sub>2</sub>S (à la structure la plus stable). Mais comme la déshydratation est réalisée aux températures modérées de 500-900°, en présence des chaux à dispersion fine, le mécanisme de AI est mis en action qui

Tableau I

Activité des ciments bélites en fonction des conditions de refroidissement et du recuit des clinkers

Conditions de fabrication des clinkers		Temps de recuit min	Activité MPa	
refroidissement	cuisson		7 jours	28 jours
A l'air	A l'air	5 30	4,6 3,2	5,9 3,5
	Dans le vide	5 30	5,0 4,4	5,9 4,9
La trempe	A l'air	5 30	6,9 5,6	12,6 10,9
	Dans le vide	5 30	8,0 6,0	16,0 12,0
Une cuisson		-	5,0	8,5

Cette conception relative au comportement de CaO horophile au cours de la stabilisation  $\beta$ -C<sub>2</sub>S explique bien le fait, noté pour la première fois par Keevil, et Thorvaldson<sup>(3)</sup>, que dans certains cas c'est justement cette modification qu'on obtient pendant la déshydratation des hydrosilicates du calcium à haute base; cette conception explique aussi des données contradictoires concernant la modification obtenue de C<sub>2</sub>S après la déshydratation TSH (C<sub>2</sub>SH<sub>2</sub>).<sup>(4)</sup>

Il est connu que dans les hydrosilicates de calcium à haute base, parmi des fragments structuraux, on peut relever des murs portlandites auxquels adhèrent d'un côté ou de deux côtés des blocs orthosili-

transforme  $\gamma$ -C<sub>2</sub>S en modification.

La vitesse de cette réaction est limitée par le degré de récrystallisation de CaO, c'est-à-dire par l'impossibilité de former la solution solide  $\gamma$ -C<sub>2</sub>S + CaO. Pour obtenir des produits de la réaction topotaxique de déshydratation des hydrosilicates à haute base à l'état de dispersion fine on peut faire usage de la déshydratation dans le vide (analogue à la décarbonisation)<sup>(5)</sup>.

Afin d'obtenir de telles compositions liantes une synthèse des hydrosilicates de calcium a été réalisée dans le rapport C/S  $\gg$  2 (TSH, C<sub>2</sub>S<sub>2</sub>H et d'autres) avec leur déshydratation ultérieure à la tempé-

rature de 500-900° à l'air et dans le vide.

Les données du tableau 2 montre que le silicate bicalcique, résultat de la déshydratation, dans les conditions normales de durcissement est susceptible de former une pierre d'une résistance assez élevée. La présence de  $B - C_2S$  dans le produit de la déshydratation accroît l'activité des système liants.

cations difficiles à cerner, dans les produits hydratés, des tétraédres isolés peuvent s'unir en diorthogroupes ( $Si_2O_7$ ), puisque une partie de  $CaO$  de  $C_2S$  passe en portlandites, et la présence ( $OH^-$ ) permet de construire des combinaisons hydratés en conservant partiellement  $-C_2S$  et en formant, d'autre part, des bandes til-  
lées ( la réalisation des diorthogroupes).

Tableau II

Activité des produits de la déshydratation des hydrosilicates de calcium à hautes bases

Produits hydratés	Conditions de déshydratation °C, Pression	Contenu des phases des produits cristallins	Activité MPa	
			7 jours	28 jours
TSE	670°C atmosphère	$C_5S_2H$ , $CaO$	8,5	13,6

$C_5S_2H$	635°C atmosphère	$C_2S$ , $CaO$ , $C_5S_2H$	6,9	10,0
	vide	$B C_2S$ , $CaO$ , $C_5S_2H$	18,7	24,1
	700°C atmosphère	$C_2S$ , $CaO$	8,7	13,3
	vide	$B + R C_2S$ , $CaO$	31,6	42,3
	900°C atmosphère	$R - C_2S$ , $CaO$	6,4	8,9
	vide	$R + R C_2S$ , $CaO$	26,1	35,0
Les boues hydratés de néphéline	700°C vide	$R + R C_2S$ , $CaO$	18,5	20,0
	800°C vide	$B + R C_2S$ , $CaO$	25,6	28,3
	900°C vide	$B + R C_2S$ , $CaO$	8,8	9,6

La succession des fragments structuraux dans les réactions de déshydratation des silicates de chaux des ciments était indiquée en (6) pourtant la manifestation de la loi de coordination structurale dans des combinaisons anhydres et hydratés, selon notre avis, se réalise avec un changement du degré de dynamisme  $SiO_2$  et détermine l'accroissement des réactions d'hydratations des orthosilicates de calcium dans certaines conditions.

Cette affirmation s'explique par le fait que, si dans  $C_2S$  anhydre l'unité essentielle dynamique  $SiO_2$  (7) doit se faire correspondre aux arêtes des polyèdres de.

Exemple caractéristique: la structure du dellite stable dans des larges limites. Ainsi, dans les conditions favorisant la formation partielle de diorthogroupes la réaction d'hydratation doit s'accroître. Ces conditions sont notamment: présence des groupes  $OH^-$  ( $F^-$ ) (traitement hydrothermal) présence de  $SiO_2$  ou  $CO_2$  (ou bien des deux) pour la formation des structures. L'accroissement de la vitesse d'hydratation  $C_2S$  en présence de  $SiO_2$  ou de  $CO_2$  était enregistré expérimentalement à plusieurs reprises (8). En utilisant ces réactions à la base des boues de néphéline, nous avons obtenu des matériaux de construc-

tion qui jouissent de bonnes propriétés d'exploitation.

# Analyse de la composition granulométrique des ciments de forages pétroliers

## *Study of the grain composition of oil-well cements*

V.S. BAKCHOUTOV, Candidat ès Sciences Techniques,

KH. AL-VARDI, Candidat ès Sciences Techniques,

Tchjao PIN-KHOUAN, Candidat ès Sciences Techniques, Institut I.M. Goubkine de l'Industrie Pétrochimique et du Gaz de Moscou,

M.K. NIKOLAEVA, Candidat ès Sciences Techniques, Institut de Recherches Scientifiques de l'Information et de l'Economie, Industrie des Matériaux de l'U.R.S.S.

**RESUME :** L'analyse de la composition granulométrique de plus de 70 ciments pour forages pétroliers connus précédemment et élaborés par les auteurs, de composition et de destination différentes, a permis d'établir, pour chaque ciment, des valeurs optimales de la dimension et de la quantité des diverses fractions et de déterminer le paramètre D (dimension conventionnelle moyenne des particules) qui peut caractériser la composition granulométrique. On a obtenu des équations de régression linéaire décrivant la relation entre le paramètre D et les propriétés technologiques principales des mortiers de ciment et de la pierre de ciment à base de ces derniers, ce qui permet de les "prédire" encore au stade de broyage des ciments sans ou avant les essais techniques, et d'obtenir les matériaux ayant les propriétés requises. L'influence considérable qu'exerce la composition granulométrique sur les propriétés des ciments pour forages pétroliers et sur la structure physique du ciment durci a permis de conclure à la nécessité de son contrôle au cours du broyage du ciment. A cet effet, on a mis au point un procédé rapide de détermination de la composition granulométrique de ces ciments dans les conditions industrielles. Il a été établi que les dépendances entre le paramètre D, la perméabilité et la porosité du ciment durci ont un caractère linéaire.

**SUMMARY :** Study of over 70 different oil-well cements made it possible to establish the optimal grain size and amount of fractions and to determine parameter D, an arbitrary average size of particles which may be used to characterize grain composition. Equations of linear regression describing the relationship between parameter D and important technological properties of cement mortars and stones were obtained which enable to predict these properties at the grinding stage before or without technological tests and to obtain oil-well cements with required properties. Strong effect of grain composition on oil-well cement properties and cement stone physical structure was established. It necessitates control of grain composition during grinding. An express method for determining grain composition of oil-well cements under production conditions was developed. Linear dependence between parameter D and permeability and porosity of the cement stone was established.

On a étudié tant les ciments de colmatage ordinaires que les ciments de colmatage allégés (CCA), allégés expansifs (CCAE), expansifs (CCE) et alourdis (CCL), élaborés par les auteurs et produits par mélangeage ou broyage simultané des constituants dans un désintégrateur du modèle D-7210 ou dans un broyeur à boulets (1).

Il a été établi que un CC (ciment de colmatage) ordinaire de broyage industriel se caractérise par une basse teneur en petites fractions hydrauliquement les plus actives (de 0 à 5  $\mu\text{m}$  - 12 % ; de 5 à 40  $\mu\text{m}$  - 50 % ; jusqu'à 40  $\mu\text{m}$  - 60 %). Les auteurs ont prouvé qu'il est possible de régler la composition granulométrique des CC ordinaires en modifiant le régime du traitement par désintégration, ce qui augmente la teneur en fractions de 0 à 5  $\mu\text{m}$  de 12 à 64 % et plus, la teneur totale en fractions de 0 à 40  $\mu\text{m}$  pouvant atteindre 99 %. Ceci conduit à l'accroissement de l'activité hydraulique du liant en entier, car grâce à la présence d'une quantité considérable de petites particules de gypse, de  $\text{C}_3\text{A}$ , de  $\text{C}_2\text{S}$  et  $\text{C}_4\text{AF}$  très actifs, le processus de durcissement se trouve considérablement intensifié. Pour éclaircir la relation entre la granulométrie et les propriétés des ciments de colmatage on a introduit le paramètre D :

$$D = \frac{R_1 \Pi_1 + R_2 \Pi_2 + \dots + R_n \Pi_n}{\Pi_1 + \Pi_2 + \dots + \Pi_n} \quad \text{ou}$$

$$D = \frac{\sum R_i \Pi_i}{\sum \Pi_i} \quad (\mu\text{m}),$$

où  $R_i$  est la dimension moyenne des particules dans la gamme de mesure,  $\mu\text{m}$  ;  $\Pi_i$ , la teneur en fraction de la gamme de mesure donnée, %.

Le paramètre D caractérise la dispersité du ciment de colmatage du point de vue de sa granulométrie en général. Comme sa valeur est proche de celle de la dimension moyenne de toutes les particules du ciment, il est appelé dimension moyenne conventionnelle des particules. Lors du traitement des données obtenues par la méthode de corrélation, on a révélé une dépendance linéaire ( $y = ax + b$ ) entre les propriétés des ciments étudiés ( $y$ ) (degré d'étalement, temps de prise, temps d'épaississement, résistance à la compression et perméabilité à l'eau) et la grandeur  $D(x)$ . Le coefficient de corrélation, caractérisant le degré d'interdépendance linéaire de  $x$  et de  $y$ , s'est avéré assez élevé (0,85 à 0,99) et était calculé d'après la formule

$$r = \frac{\left[ \frac{1}{n} \sum (x_i y_i) - \bar{x} \bar{y} \right]}{\sigma_x \sigma_y},$$

où  $x = D_i$  est le paramètre caractérisant la dimension moyenne conventionnelle des particules ;  $y_i$ , le paramètre caractérisant les propriétés du ciment ( $E$  est le degré d'étalement,  $I$ , la prise initiale

et  $F$ , la prise finale,  $\sigma_{\text{comp}}$ , la résistance à la compression,  $K_{\text{perm}}$ , la perméabilité à l'eau) ;  $n$ , le nombre d'expériences (tabl. I).

Compte tenu des paramètres indiqués, l'équation de régression linéaire était ramenée à la forme

$$y = \bar{y} + r \frac{\sigma_y}{\sigma_x} (x - \bar{x}),$$

où  $\sigma_x$ ,  $\sigma_y$  sont les écarts quadratiques moyens ;

$r \frac{\sigma_y}{\sigma_x}$  est le coefficient angulaire (coefficient de régression de  $y$  par rapport à  $x$ ).

En connaissant la composition granulométrique ( $D$ ), on peut prédire, par le calcul, avec une précision assez élevée, toutes les propriétés technologiques principales des ciments de colmatage encore au stade de leur broyage, sans procéder aux essais techniques. De la même façon, mais partant cette fois des exigences concrètes sur la qualité du ciment de colmatage (par exemple la résistance), on peut déterminer pour ce dernier la valeur optimale de  $D$ , i.e. la composition granulométrique.

Il est établi que pour les CC ordinaires la valeur optimale de  $D$  se trouve dans l'intervalle de 12 à 15  $\mu\text{m}$  et pour les CC ordinaires dont le degré de dispersion est élevé, dans l'intervalle de 8 à 9  $\mu\text{m}$ . Les équations de régression pour les ciments principaux sont données dans le tableau I.

Le trait caractéristique des CCA de broyage industriel est une basse teneur en fraction de 0 à 5  $\mu\text{m}$ , qui est de 20 % ; la teneur en fraction de 40 à 210  $\mu\text{m}$  est près de 31 %. Lors du traitement par désintégration du CCA-1, on peut régler sa composition granulométrique de sorte que la teneur en fraction de 0 à 5  $\mu\text{m}$  augmente de 2 fois et plus et la teneur en fraction de 40 à 210  $\mu\text{m}$  diminue de 15 à 20 fois. Ceci augmente fortement la résistance de la pierre de ciment CC pour tous les délais de durcissement, ce qui est très important, car la résistance de la pierre de ciments allégés est habituelle faible. L'étude de la variation de résistance et de temps de prise de CCA-1 en fonction de la valeur de  $D$  a montré que pour le degré d'étalement égal à 18 cm, la composition granulométrique optimale est la suivante :  $D = 14 \mu\text{m}$  pour  $E/C = 1,1$  et  $D = 6,3 \mu\text{m}$  pour  $E/C = 1,6$ .

On a étudié dans ce travail la composition granulométrique et les propriétés des ciments de colmatage allégés expansifs, élaborés par les auteurs, avec additions de l'oxyde de calcium (CCAE-1) et de la boue de chromates (CCAE-2). Pour CC AE-1 utilisé dans l'intervalle de température de 20 à 90 °C, la valeur optimale de  $D$  se trouve dans les limites de 7 à 8  $\mu\text{m}$  pour  $E/C = 0,9$  ; de 4 à 5  $\mu\text{m}$  pour  $E/C = 1,1$ . L'augmentation de la teneur en fractions de 0 à 5  $\mu\text{m}$  de 2,5 fois conduit

à l'accroissement de 3 fois de la résistance de la pierre de ciment CCAE-2 durant les premiers deux jours, l'augmentation graduelle de la teneur en petites fractions s'accompagnant toujours d'accroissement de résistance. Pour CCAE-2 qu'on recommande d'utiliser aux températures de 90 à 120 °C, la valeur optimale de D se trouve dans les limites de 14 à 15  $\mu$ m. L'accroissement de la valeur optimale de D qui suit la hausse de la température correspond en gros aux conclusions faites auparavant pour CC ordinaire.

On a également étudié l'influence de la composition granulométrique sur les propriétés des ciments de colmatage expansifs (CCE) ayant une grande expansion (jusqu'à 6 %) à base d'oxydes (en particu-

culier, avec addition d'oxyde de calcium). L'analyse des résultats des études du CCE-1, utilisé essentiellement pour la cimentation des puits à la température jusqu'à 75 °C, montre que tant à 22 °C qu'à 75 °C on observe l'accroissement de résistance à la compression du ciment durci à mesure que la teneur en petites fractions augmente ; la tendance à l'accroissement continu de la résistance avec le temps se conserve, bien que la vitesse de cet accroissement diminue graduellement.

La valeur optimale de D pour le ciment en question avec E/C = 0,5 se trouve dans l'intervalle de 14 à 16  $\mu$ m. Une conclusion analogue a été faite pour CCE-2 avec addition de 20 % de sable, utilisé à des températures jusqu'à 90 °C, bien que ce ciment se caractérise également par une certaine diminution de résistance avec le temps lorsque la teneur en petites fractions augmente. On a procédé à des études analogues pour CCE destinés aux températures plus élevées.

On a également étudié l'influence qu'exerce la composition granulométrique sur les propriétés des ciments de colmatage alourdis (CCL) de composition différente (2). Les CCL-1 et 2 avec magnétite se caractérisent par ce que même une variation relativement petite de teneur en petites fractions de 0 à 5 et de 5 à 10  $\mu$ m, conditionnée par la technique de broyage, conduit à une augmentation notable de leur résistance. Ainsi, l'accroissement de la teneur en fractions 0-5  $\mu$ m de 12,2 à 19,6 % et en fractions 5-10  $\mu$ m de 25,5 à 31,6 % conduit à l'augmentation de résistance de 14,6 à 20,6 MPa à l'âge de deux jours, la perméabilité de la pierre de ciment diminuant de trois fois. Avec l'accroissement de la teneur en magnétite, ces dépendances restent en vigueur, bien que la résistance diminue en valeur absolue.

Le domaine de D optimal pour CCL avec magnétite se trouve, pour les rapports E/C = 0,35 et 0,38 dans l'intervalle de 20 à 22  $\mu$ m.

On a également étudié la relation entre la composition granulométrique des ciments de colmatage, la composition chimico-minéralogique des différentes fractions constitutives et la structure physique du ciment durci. Il a été admis que telles ou telles fractions du ciment se trouvent parfois surenrichies, par rapport à la teneur moyenne, en constituants de clinker déterminés. Pour vérifier cette supposition, on a divisé une série de ciments en 15 fractions (y compris en 8 fractions dans l'intervalle de 0 à 40  $\mu$ m) et en procédant à l'analyse quantitative aux rayons X, on a déterminé la teneur de chaque fraction en minéraux essentiels. Ensuite on a construit les diagrammes de variation du pourcentage de ces minéraux en fonction de la dimension moyenne des particules de ciment. L'hypothèse a été confirmée et on a établi que la teneur du ciment en chaque minéral a ses maxima et minima dans des intervalles

déterminés de dimension des particules de ciment, constants pour chaque minéral, et ceci quels que soient le type du ciment, la cimenterie et le mode de broyage. Ainsi, la quantité maximale de  $C_3S$  est contenue dans les petites particules de ciment de dimension variant de 3 à  $12\ \mu m$  et la quantité minimale, dans des particules plus grandes de dimension de 50 à  $100\ \mu m$ ; la teneur en  $C_3S$  des fractions de 0 à  $12\ \mu m$  dépasse sa teneur dans le ciment de départ de 25 à 30 %, et dans les fractions de 50 à  $100\ \mu m$  elle est 1,5 à 2 fois plus petite que dans le ciment de départ. Ceci permet d'intensifier considérablement le processus de durcissement lorsque la teneur du ciment en petites fractions augmente jusqu'à une valeur optimale déterminée pour chaque ciment (3, 4).

On a émis une hypothèse d'après laquelle la structure physique de la pierre de ciment (en particulier la micromorphologie de sa surface, la porosité et la perméabilité) est conditionnée, de façon déterminée, par sa granulométrie, surtout au cours du durcissement précoce, et peut donc être "programmée" à l'avance au stade de broyage du ciment et aisément réglée au besoin.

Les analyses de la micromorphologie du cli-vage de la pierre de ciment par la méthode de microscopie électronique à balayage ont confirmé cette hypothèse et montre qu'aux délais précoces (2 jours après le gachage) la pierre (fig. 1, c et d) se compose en général des particules d'a peu près la même dimension prédominante (D) que le ciment de départ (fig. 1, a et b), ces particules étant fixées l'une à l'autre par le "gel" des nouvelles formations hydratées. Ceci est caractéristique pour CC composé des fractions fines (fig. 1, a) et pour CC de broyage plus grossier (fig. 1, b).

Il est naturel que s'il existe une telle dépendance pour les particules de ciment formant la carcasse de la pierre de ciment, il devrait exister une dépendance analogue pour les pores formés par ces particules (5). Pour évaluer quantitativement ces phénomènes, on a pris pour base le nomogramme connu du professeur V.S. Danuchevski et du candidat es sciences techniques K.A. Djabarov, d'après lequel on peut déterminer la relation entre E (porosité totale de la pierre de ciment), R (rayon moyen des pores) et  $K_{perm}$  (perméabilité à l'eau) (fig. 2, a). Sur la base des données expérimentales disponibles sur la granulométrie et la perméabilité à l'eau du ciment durci à l'âge de deux jours, on a construit un diagramme montrant la dépendance de  $K_{perm}$  par rapport à la dimension moyenne conventionnelle D des particules de ciment. Comme il est apparu, cette dépendance a un caractère linéaire. En disposant de la valeur expérimentale de  $K_{perm}$  pour une valeur déterminée de D et de la perméabilité à l'eau  $K_{perm}$ , on déterminait d'après le nomogramme la valeur de R en construisant de cette façon le diagramme de dépendance de R par

Fig. 1 - Influence de la composition granulométrique du ciment de colmatage sur la microstructure de la pierre de ciment.  
a, c) CC de broyage fin (fractions de  $< 40\ \mu m$ )  
 $S_{sp} = 3900\ cm^2/g$ ;  $D = 8,83\ \mu m$ ; rayon moyen des pores  $R = 0,05\ \mu m$   
b, d) CC de broyage industriel  
 $S_{sp} = 2890\ cm^2/g$ ;  $D = 24,76\ \mu m$ ; rayon moyen des pores  $R = 0,16\ \mu m$

rapport à D, qui a, lui aussi, un caractère linéaire (fig. 2, b). Les dépendances linéaires établies de  $K_{perm}$  et de R de la pierre de ciment par rapport à sa composition granulométrique, qui se manifestent surtout pour les délais de durcissement précoces, témoignent d'une possibilité réelle de réglage de la microstructure de la pierre de ciments pour colmatage encore au stade de son broyage, ce qui a une grande importance pratique.

Nous avons élaboré un procédé rapide simplifié de détermination du paramètre D par l'analyse pétrographique \*) des particules de ciment en immersion, qui consiste dans la détermination de la valeur moyenne (diamètre) soit des particules de ciment elles-mêmes dans l'échantillon moyen, soit des cristaux d'alite bien visibles dans ces dernières.

Les équations de régression obtenues montrent qu'entre ces grandeurs et le paramètre D existe une dépendance linéaire (fig. 3).

\*) Ce travail était fait avec la participation du pétrographe V.I. Goussev.

Fig. 2 - Relation entre la dimension moyenne conventionnelle des particules du ciment (D) et la structure physique de la pierre de ce ciment (porosité-1 et perméabilité-2). Temperature de 75 °C, temps de durcissement de deux jours. (a - les données de V.S. Danuchevski et K.A. Djabarov);  $C_p$  - coefficient de perméabilité à l'eau, mdarcy;  $R$  - rayon moyen des pores,  $\mu m$ ; porosité totale -  $\epsilon$ ; variation de  $R$  en fonction de  $D$ ;  $D$  - dimension moyenne conventionnelle des particules de ciment,  $\mu m$ .

#### CONCLUSION

L'analyse des résultats de ce travail montre que la composition granulométrique des ciments de colmatage détermine pour beaucoup leurs principales propriétés technologiques : étallement, temps de prise et durée d'épaississement, résistance, porosité et perméabilité. En réglant la composition granulométrique au cours du broyage du ciment, on peut régler par la même les propriétés indiquées, en les choisissant pour la résolution de tel ou tel problème concret. Ceci permet de conclure sur la nécessité, lors du broyage des ciments de colmatage, du contrôle de leur composition granulométrique afin d'en optimiser le degré de finesse et les propriétés technologiques.

Fig. 3 - Variation de dimension moyenne des cristaux d'alite  $d_1(I)$  et des particules de ciment  $d_2(2)$  en fonction de la dimension moyenne conventionnelle des particules  $D$  ( $d_1$  et  $d_2$  sont déterminés pétrographiquement,  $D$  est déterminé par le calcul d'après les données de l'analyse de la composition granulométrique du ciment;  $d_c$  -  $d$  calculé).

**RESUME :** On a étudié dans ce travail le mécanisme et la cinétique de la cristallisation ainsi que la structure cristalline des monocristaux d'hydrosilicates et d'hydroaluminates de calcium de composition différente, qui se forment lors du durcissement des ciments pour forages pétroliers, dans les conditions spécifiques des forages (de  $-10^{\circ}\text{C}$  jusqu'à  $+300^{\circ}\text{C}$  et des pressions allant jusqu'à 150 MPa) en contact avec les milieux salins concentrés (jusqu'à 80 % par rapport à la saturation), etc.

On a établi que les réactions d'hydratation, au cours desquelles le type et la structure des phases hydratées se constituent, peuvent se produire en solution ou de façon topotactique. Les cristaux hydratés stables qui se forment dans les pâtes de ces ciments sont principalement constitués de formations régulières des types suivants : enchevêtrement, interpénétration, concrétion. Le développement de ces dernières formations cristallines, dans la pâte durcissante, dès le début de l'hydratation, grâce au choix de la composition stoechiométrique du clinker et au choix de la composition du liquide, est le principe essentiel qui permet de contrôler la cristallogénie de ces sortes de ciment, et d'accroître leur efficacité.

**SUMMARY :** The work investigates the mechanism, kinetics of crystallization and crystalline structure of monocrystals of calcium hydrosilicates and hydroaluminates of different composition which are formed at hardening of oil-well cements under the specific conditions of the wells ( $-10^{\circ}\text{C}$   $+300^{\circ}\text{C}$ , pressures up to 150 MPa) and on contact with concentrated salt media (up to 80 % saturation), etc.

It has been found out that the hydration reactions wherein the type and structure of the hydrate phases are formed can take place both through the solution and topotactically. The main form of stable existence of hydrate crystals in the oil-well cement stone are regular concretions of the following main types : intergrowth, interpenetration and combinations thereof. Increase of their number for a given crystalline phase within the volume of the hardening system at the beginning of hydration, either by introduction from the outside or by formation in the bulk of the hardening system owing to selection of the composition and stoichiometry of the solid (binder) and liquid (mixing medium) phases, is the main principle of crystallochemical control of the oil-well cement hardening processes with a view to intensifying the latter.

Les processus d'interaction cristallogénique des phases hydratées apparues entre elles et avec les minéraux du liant de départ, i.e. les processus de concrétion des cristaux, jouent un rôle essentiel dans la formation de la structure résistante de la pierre.

Les particularités cristallogéniques de la structure des phases hydratées principales (parmi celles présentes dans les systèmes durcissants de ciments de colmatage), à savoir les hydrosilicates de calcium (HSC), de composition différente et de formule générale :

où  $x, y, z > 0, m, n > 0$ , et les hydroaluminates de calcium et les complexes formés à leur base de composition différente et de formule générale :

où  $x, y, z > 0; m, n, p, q > 0, \text{R} = \text{O}^{2-}, (\text{OH})^-, \text{Cl}^-, (\text{SO}_4)^{2-}$ , etc., se forment encore au stade de leur état préembryonnaire. Une vraie solution moléculaire qui apparaît au cours de la dissolution des constituants de départ du liant, se compose d'abord de complexes séparés, ayant une organisation structurale déterminée, de trois types: les complexes de solvates ordinaires du type  $[\text{CaO} \cdot \text{H}_2\text{O}]$ ,  $[\text{SiO}_2 \cdot \text{H}_2\text{O}]$  et  $[\text{Al}_2\text{O}_3 \cdot \text{H}_2\text{O}]$  ayant la structure de la phase initiale, les complexes des nouvelles formations du type  $[x\text{CaO} \cdot y\text{SiO}_2 \cdot z\text{H}_2\text{O}]$  et  $[x\text{CaO} \cdot y\text{Al}_2\text{O}_3 \cdot z\text{H}_2\text{O}]$  apparaissant de façon épitaxiale-topotactique et ayant la structure du constituant de départ, et les complexes dits "de transport" - par exemple pour les hydrosilicates de calcium, ce sont les complexes du type  $[(\text{Ca}-\text{Si})\text{R}_z] \cdot (\text{H}_2\text{O})_m \cdot (\text{OH})_n$ , où R est un ion alcalin dit "de transport" ( $\text{Na}^+, \text{K}^+, \text{Li}^+$ ).

Dans ce cas, la formation des phases hydratées (par exemple, des hydrosilicates de calcium) a lieu lorsque les ions de transport substituent, encore en solution, de façon isomorphe l'ion  $\text{Ca}^{2+}$  dans ses complexes, ce qui entraîne la diminution de leurs dimensions (vu que le nombre de coordination, par exemple  $\text{Na}^+$ , est de deux fois inférieur à  $\text{Ca}^{2+}$ ), la diminution de la masse et l'accroissement de leur mobilité. De plus, on assiste en même temps à la substitution aux atomes de O dans les chaînes (Si-O) des groupes (OH)- qui, pour un volume identique à celui des atomes de O, ont une charge ionique deux fois moindre. Ceci conduit à la rupture de longues chaînes (Si-O), ce qui augmente la disposition des éléments de la solution pour l'association régulière.

Avec l'accroissement de sursaturation, la quantité de ces complexes de transport et de leurs associés par unité de volume augmente et lorsqu'ils sont proches l'un de

l'autre, les forces d'attraction mutuelle les réunissent en groupements construits en présence des éléments de régularité spatiale. Ce sont justement la structure et la quantité de ces groupements qui prédominent la structure du germe et son type.

Dans ce travail on a posé le problème d'élaboration et d'étude des monocristaux de certaines phases de HSC et de leurs agrégats, des conditions de leur apparition et de détermination des frontières des champs de stabilité dans une large gamme des conditions initiales (1-3).

La cristallisation hydrothermale dans le système  $\text{CaO}-\text{SiO}_2-\text{ROH}$  ( $\text{R}=\text{Na}, \text{K}, \text{Li}$ ) était réalisée dans l'intervalle de températures de  $200^\circ$  à  $700^\circ$  et de pressions de 100 à 300 MPa, imitant les conditions des puits profonds, d'après la méthode connue, avec variations du rapport  $\text{CaO}/\text{SiO}_2$  (pond.) = 0,25 à 5,0 et celles de la concentration de l'alcali de 0 à 60 %.

Au cours de la cristallisation hydrothermale se manifesta le rôle "catalytique" de  $\text{Na}^+$  qui est proche, du point de vue cristallogénique, du cation "matriciel" des hydrosilicates, à savoir  $\text{Ca}^{2+}$ : les produits principaux de la synthèse étaient des monocristaux de différents HSC de 10 mm environ de longueur et de près de 3 mm de diamètre (fig. 1); dans certains cas (synthèse dirigée), on a obtenu des monocristaux de composition mixte ( $\text{Na}, \text{Ca}$ ).

Fig. 1 - Monocristal de Ca-chondrodite de composition  $\text{C}_5\text{S}_2\text{H}$  (lumière passante,  $\times 100$ )

L'analyse cristallogénique des processus de synthèse des HSC de telle ou telle structure a montré que la formation et la croissance des HSC sont dues à l'aptitude de Ca à construire des incréments de structure caractéristiques de telles ou telles conditions concrètes, lorsque le matériau

de construction "non calcique" est disposé dans les chambres et les couloirs de la cage principale en Ca (4). La silice est une "charge" principale ; selon N.V. Bélov (4), la molécule neutre de  $\text{SiO}_2$  à deux liaisons potentielles Si-O et de configuration "angulaire" (exigée par la chimie quantique) ( $\text{O-Si-O} \sim 109^\circ$ ) est une unité dynamique sous forme de laquelle la silice passe d'une construction à l'autre ; c'est justement cette molécule "angulaire"  $\text{SiO}_2$  qui forme dans les structures de HSC l'unité statique, le tétraèdre de Si. Les exigences énergétiques de réalisation des liaisons potentielles de la molécule "angulaire" de  $\text{SiO}_2$  lors de la formation de l'ossature structurale de tel ou tel HSC s'expriment par le postulat cristallographique sur la conformité dimensionnelle des arêtes des polyèdres de Ca et des tétraèdres de Si. Les motifs silico-oxygénés qui se fixent dans les structures des HSC : tétraèdres isolés, diorthogroupes, triorthogroupes, rubans, gaufres, etc., suivent entièrement les aires de croissance primaires en polyèdres de Ca. Ainsi, pour les HSC faiblement basiques et hautement polymérisés de type xonotlite-hillebrandite-tobermorite de faciès fibreux, les éléments structuraux principaux silico-oxygénés - les rubans à anneaux octogonaux  $[\text{Si}_6\text{O}_{17}]^{10-}$  ou les gaufres  $[\text{Si}_{12}\text{O}_{31}]^{14-}$  - à base de ces rubans - correspondent aux colonnes triples ou (dans la hillebrandite et les tobermorites) aux couches d'octaèdres de Ca en cas d'une correspondance complète des périodes de répétition des éléments structuraux indiqués le long de l'axe "b" ; pour les éléments  $[\text{Si-O}]$  cette période est égale à  $n \cdot 7,3 \text{ \AA}$ , pour les éléments  $[\text{Ca-O}]$  à  $2n \cdot 3,65 \text{ \AA}$ . Dans ce cas, dans xonotlite  $\text{Ca}_6[\text{Si}_6\text{O}_{17}] \cdot (\text{OH})_2$  les parois (couches d'octaèdres de Ca alternants) sont "fixées" entre elles par les rubans  $[\text{Si}_6\text{O}_{17}]^{10-}$ , dans la hillebrandite  $\text{Ca}_{12}[\text{Si}_6\text{O}_{17}] \cdot (\text{OH})_4 \cdot 12\text{Ca}(\text{OH})_2$  les unités structurales "de xonotlite" sous-mentionnées "s'alternent" en quelque sorte avec les couches de portlandite  $\text{Ca}(\text{OH})_2$ , et, dans la tobermorite  $\text{Ca}_{10}[\text{Si}_{12}\text{O}_{31}] \cdot (\text{OH})_6 \cdot n\text{H}_2\text{O}$  ( $n = 3, 8, 18$ ), le motif cristallin est un réseau gaufré formé lors de la condensation et du "chevauchement" mutuel des mêmes rubans  $[\text{Si}_6\text{O}_{17}]^{10-}$  ; ce fait témoigne avant tout de la similitude cristallographique des éléments principaux de la structure résistante du ciment durci.

Du point de vue cristallographique, l'hydratation du liant peut suivre deux voies - celle de solution et topotactique. Dans les deux cas, au début, a lieu l'interaction des ions  $\text{H}^+$ ,  $(\text{OH})^-$ , des dipôles d'eau avec le cristal du minéral de départ, ce qui fait que sa couche superficielle (de la couche monomoléculaire jusqu'aux milliers de couches atomiques) se trouve déformée et détruite par la suite.

Au début de l'hydratation, lorsque le système contient beaucoup de phase liquide et le degré de polymérisation des radicaux  $[\text{Si}_2\text{O}_5]^{2-}$  et  $[\text{Al}_2\text{O}_5]^{2-}$  est peu élevé, la cristallisation se fait essentiellement

moyennant la solution, car, dans ces conditions, il est plus facile d'ordonner des éléments structuraux relativement petits des hydrates en réseau cristallin. A ce stade il apparaît habituellement beaucoup d'hydrates différents faiblement polymérisés. Mais par la suite commence à prédominer la voie topotactique de formation des phases hydratées. Si l'on considère, par exemple, l'hydratation des minéraux principaux (siliceux) des ciments de colmatage, on voit se former deux groupes d'hydrates : à base de la structure de  $\beta$  - ou  $\gamma$  -  $\text{C}_2\text{S}$  se forment la chondrodite calcique  $\text{Ca}_5[\text{SiO}_4] \cdot (\text{OH})_2$  ou  $2\text{C}_2\text{S} \cdot \text{CH}$ , la dellaïte (phase Y)  $\text{Ca}_6[\text{Si}_2\text{O}_7] \cdot [\text{SiO}_4] (\text{OH})_2$ , l'afwillite  $3\text{CaO} \cdot 2\text{SiO}_2 \cdot 3\text{H}_2\text{O}$  faiblement polymérisés fortement basiques ; sur la base de la structure de la wollastonite  $\beta$  -  $\text{CaO} \cdot \text{SiO}_2$  se forment la xonotlite  $\text{Ca}_6[\text{Si}_6\text{O}_{17}] \cdot (\text{OH})_2$ , la hillebrandite  $\text{Ca}_{12}[\text{Si}_6\text{O}_{17}]_2 \cdot (\text{OH})_4 \cdot 12\text{Ca}(\text{OH})_2$  ou  $\text{C}_2\text{SH(B)}$ , les phases de tobermorite du type  $\text{Ca}_{10}[\text{Si}_{12}\text{O}_{31}] \cdot (\text{OH})_6 \cdot n\text{H}_2\text{O}$  et d'autres HSC faiblement basiques hautement polymérisés.

La structure résistante de la pierre de ciments de colmatage est formée par des agrégats réguliers (prédominants) et des agrégats irréguliers des cristaux (5) (fig. 2). Les germes des agrégats réguliers se forment principalement avec des sursaturations élevées par déposition, sur la face conventionnelle du cristal primaire, de l'association des atomes ou des ions en position maclée (le plus souvent antiparallèle).

Fig. 2 - Agrégats de cristaux de HSC du groupe de la chondrodite (lumière passante, avec analyseur,  $\times 10$ )

A partir des associés "maclés" ainsi apparus il se forme des agrégats réguliers : la plupart des HSC fortement basiques sont maclés d'après les lois périclinique et de Manebach (fig. 3) ; les HSC faiblement basiques se caractérisent par le maclage et la formation des agrégats parallèles dans la direction parallèle à l'axe d'allongement du cristal, ce qui est dû à leur fa-

ciès fibreux-filiforme. Il convient de noter que seuls les cristaux analogues sur le plan structural et chimique présentent en règle générale des agrégats réguliers.

Fig. 3 - Diagrammes de Laue de la zone de contact (C) des agrégats de cristaux de HSC du groupe de la chondrodite (structures d'enchevêtrement)

La concrétion de ces cristaux se réalise par l'accrolement des éléments identiques de leur structure : pour HSC par exemple ce sont les couches octaédriques de portlandite et les radicaux de degré de polymérisation voisin. Dans le premier cas a lieu une concrétion "classique" d'après des lois déterminées : de maillage polysynthétique, périclinique, de Manebach, etc., et dans le deuxième cas, une "couture" de polymérisation avec la formation des structures résistantes spatiales de durcissement (5). La concrétion régulière des cristaux de composition différente peut avoir lieu d'après le schéma de Royer-Friedel avec une correspondance relative de leurs paramètres réticulaires dans la zone des contacts. Les agrégats de ce type sont caractéristiques d'une grande classe de cristaux hexagonaux lamellaires des aluminates hydratés de calcium et de composés complexes à base de ces derniers.

Les agrégats réguliers se forment au stade de germination lorsque la probabilité d'apparition de la zone de contact à peu de défauts est maximale. D'après nos données, la dimension des microcristaux qui forment intensément des macles au stade de germination ne dépasse pas  $10^{-5}$  cm et leur particularité caractéristique est une aptitude

manifeste à la croissance ultérieure.

Les cristaux mal orientés d'un même type structural et les cristaux de types structuraux différents donnent des agrégats irréguliers.

Ainsi donc, la structure cristalline résistante de la pierre de ciment de colmatage est une carcasse formée par des agrégats réguliers relativement grands (jusqu'à  $10^{-2}$  cm), des cristaux individuels des phases hydratées et leurs agrégats (textures) basés dans l'espace intergranulaire et sur les grains en cours d'hydratation du liant de départ, "fixée", aux points de contacts, par le "gel" des nouvelles formations hydratées (6) qui est également représenté par les microgermes des agrégats réguliers, des cristaux individuels et de leurs agrégats dont la dimension est inférieure à  $10^{-5}$  cm.

En mettant en évidence les régularités de l'interaction cristallochimique des cristaux des minéraux composant la pierre de ciments de colmatage, on a réussi à formuler un procédé de réglage cristallochimique des processus de leur durcissement (dans le but d'intensification) grâce à l'augmentation de la quantité de phase cristalline stable (agrégats et cristaux individuels) dans le volume du système durcissant aux stades d'hydratation précoces (7, 8). On peut l'atteindre par deux voies : soit par "renforcement mécanique" du système en y introduisant des HSC "prêts" et/ou leurs constituants, soit par "autorenforcement" du système en créant les conditions pour l'apparition spontanée de ces phases hydratées (dites intensificateurs cristallochimiques de durcissement - ICD) grâce au choix de la composition et de la stoechiométrie des phases solide et liquide.

Les exigences principales envers ICD sont les suivantes : ils doivent être analogues du point de vue chimique et structural à la masse principale des cristaux d'hydrates qui sont stables dans des conditions concrètes données ; les cristaux de ICD doivent avoir une dimension de  $10^{-6}$  à  $10^{-5}$  cm, le faciès de préférence filiforme et l'aptitude à une croissance ultérieure intense, i.e. à l'accrolement avec leurs semblables et la matrice de ciment. Les ICD contribuent à l'apparition spontanée d'un grand nombre d'agrégats stables des hydrates au stade précoce de durcissement, remplissent les fonctions de supports d'orientation pour les hydrates apparaissant dans le système principale, augmentent la concentration totale de la phase cristalline aux stades d'hydratation précoces, accélèrent chimiquement les réactions d'hydratation grâce à l'évacuation des nouvelles formations (ions, complexes) des zones de réaction et "renforcent" de façon purement mécanique le système en cours de durcissement, ce qui entraîne une amélioration notable de sa structure physique et des propriétés de résistance (fig. 4).

Fig. 4 - Zone de contact des ICD de renforcement avec la matrice de ciment (réplique de platine-carbone,  $\times 10000$ )

L'introduction dans le système durcissant des ICD du type de HSC de composition, structure, dimension, degré de perfection, etc., différents qui représentent les phases métastables synthétisées lors de l'interaction des solutions aqueuses saturées de la chaux et de l'acide silicique, en quantité de 1 à 3 % par rapport à la masse du ciment conduit à l'accroissement de résistance de la pierre de ciment d'une valeur allant jusqu'à 60 % (7, 8).

Des résultats positifs furent également obtenus par introduction simultanée dans le système du ciment durcissant de colmatage des constituants individuels de HSC-CaO ou de  $\text{Ca}(\text{OH})_2$  avec des formes différentes de  $\text{SiO}_2$ .

L'utilisation en tant que ICD, dans les solutions allégées, de la chaux anhydre qui, en combinaison avec le constituant siliceux très fin hydrauliquement actif, (gaize), permet d'augmenter considérablement la quantité de HSC aux délais de durcissement précoces, a permis d'obtenir, pour la densité de la solution de l'ordre de  $1,5 \text{ g/cm}^3$ , un ciment durci avec  $\sigma_{\text{flex}}$  après deux jours de durcissement à  $75^\circ\text{C}$ , de l'ordre de 2,0 à 2,5 MPa et  $\sigma_{\text{comp}}$  de l'ordre de 7,0 MPa, i.e. dépassant de plus de deux fois les ciments ordinaires de ce type.

On a élaboré par un procédé analogue une série de ciments de colmatage expansifs (CCE) de grande expansion, utilisant en tant que constituants des ICD les oxydes de calcium et de magnésium cuits à des températures différentes en combinaison avec le sable quartzueux (9,10).

Comme un exemple de réalisation pratique de l'"autoreinforcement", on peut citer la solution alcaline de potassium (SAP) pour colmatage qui sert à la cimentation des puits à des températures positives peu élevées et négatives (11,12). Le problème principal, à savoir l'accroissement de résistance de la pierre à  $+5$  à  $-10^\circ\text{C}$ , fut résolu par application en qualité de

liquide de gâchage d'une phase liquide spéciale qui ne gèle pas à  $t < 0^\circ\text{C}$  et sert d'intensificateur des processus de durcissement ; lors du durcissement il se forme des ICD, phases hydratées supplémentaires donnant un agrégat cristallin normal et stable dans ces conditions.

#### CONCLUSION

L'application des méthodes de modification cristallochimique des processus de durcissement des solutions pour colmatage à base de liants minéraux permet d'élever rapidement et avec les dépenses minimales la vitesse de durcissement et la résistance du ciment durci ainsi que d'améliorer sa microstructure. La reproductibilité des résultats est alors très élevée, ce qui permet de considérer comme très avantageuse la méthode cristallochimique de réglage des processus de durcissement des ciments de colmatage ayant pour but leur intensification.

# Application of activated calcium aluminate clinker to quick hardening cement

## *Utilisation d'une pouzzolane artificielle alumino-calcique dans la fabrication d'un ciment à durcissement rapide*

K. ISOZAKI, Research Chemist,

S. SAKAMAKI, Assistant to Research Manager,

K. NAKAGAWA, Senior Research Manager, Denki Kagaku Kogyo Co., Ltd., R and D Department of Omi-Plant, Japan.

**RESUME.** On a étudié la relation entre la résistance et le processus d'hydratation d'un ciment spécial préparé en mélangeant du clinker de ciment portland avec 20 % de sulfate de calcium et d'un aluminat de calcium activé; ce dernier était obtenu par fusion au four électrique, puis refroidissement brusque, d'un cru approprié. Des mélanges de cette sorte sont utilisés industriellement dans la fabrication des ciments expansifs du type M et dans celle des ciments à haute résistance initiale.

En faisant varier le rapport C/A de cette pouzzolane artificielle et sa proportion dans le ciment, on peut obtenir diverses sortes de ciments à prise rapide. L'augmentation de ce rapport C/A peut accroître les résistances à 1 heure, 7 jours et 28 jours, mais la prise peut devenir trop rapide pour pouvoir être contrôlée. En augmentant l'addition du gypse, les résistances à 3 et 24 heures augmentent, et le ciment devient plus maniable.

Il a été établi que les propriétés de ces ciments dépendent de la vitesse de la formation de l'ettringite et de l'hydratation du  $C_3S$ , et que l'on peut maîtriser ces facteurs par réglage du mélange. Une optimisation de ces ciments à prise rapide est possible.

**SUMMARY:** The relation between the strength and hydration process of the special cement which was prepared by admixing ordinary portland cement with 20%(wt.) of the admixture consisting of calcium sulfate and calcium aluminate clinkers made by quenching after electric melting thereof was examined. The admixtures of this kind are industrially applied to the M-type expansive cement, quick hardening cement and high strength cement.

Various kinds of quick hardening cements can be obtained by varying the C/A ratio of clinker. When the C/A ratio is raised, the strength can be improved per 1 hour, 7 days, and 28 days. but the setting is so rapid that in most cases the control of setting time is difficult. When anhydrite content is increased, there is a tendency that the 3 hour and 24 hour strengths can be increased, and the workability can be also improved.

We have made it clear that the characteristics of quick hardening cement can be determined by the yield and formation timing of ettringite and hydration of  $C_3S$ , and these factors can be controlled by said admixtures. Whereby it has been made possible to plan ideal quick hardening cement.

## 1. INTRODUCTION

We have already reported a part of the method for producing electrically melted calcium aluminate clinker (1) and the application thereof to expansive cement (1,2), quick hardening cement (2), and high strength cement (3,4). The present report discusses more in detail on the basic properties of said calcium aluminate clinker when applied to the quick hardening cement. And, there are reported the hydration process of the cements added with the admixtures prepared by changing C/A ratio of clinker and anhydrite (Type II-calcium sulphate) content, the structures of cement stone, morphology of hydrates and the effects given to the mechanical strength, and such like basic data which become the guidelines for planning ideal quick hardening cement.

## 2. PREPARATION of SAMPLES

The samples which were prepared by mixing calcium oxide and bauxite at predetermined blending ratios were melted at a temperature in the range of from 1500°C to 1700°C for about one hour and blown by air to quickly cool off. Regarding the calcium aluminate clinkers which were used in this test, the following three kinds of compositions are given below. (Table I)

TABLE I Chemical composition of clinkers (wt%)						
Name of clinker	C/A	CaO	Al <sub>2</sub> O <sub>3</sub>	SiO <sub>2</sub>	f-CaO	blaine (cm <sup>2</sup> /g)
A	1.10	48.7	44.1	2.5	0.3	5720
B	0.92	43.9	47.7	3.4	0.1	5530
C	0.65	36.1	55.5	3.8	0.1	5540

TABLE II Chemical composition of admixtures			
Name of admixture	C/A	clinker/ II-CaSO <sub>4</sub> (SO <sub>3</sub> /Al <sub>2</sub> O <sub>3</sub> )	S/A
A <sub>1</sub>	1.10	1/1	1.33
A <sub>2</sub>	1.10	1/1.5	2.00
A <sub>3</sub>	1.10	1/2	2.66
B <sub>1</sub>	0.92	1/1	1.23
B <sub>2</sub>	0.92	1/1.5	1.84
B <sub>3</sub>	0.92	1/2	2.46
C <sub>1</sub>	0.65	1/1	1.06
C <sub>2</sub>	0.65	1/1.5	1.59
C <sub>3</sub>	0.65	1/2	2.11

Table II shows the compositions of 9 kinds of admixtures prepared by adding anhydrite to calcium aluminate clinker. Table III shows the chemical composition of ordinary portland cement.

TABLE III Chemical Composition of ordinary portland cement (wt%)						
ig.loss	insol.	SiO <sub>2</sub>	Al <sub>2</sub> O <sub>3</sub>	Fe <sub>2</sub> O <sub>3</sub>	CaO	
0.7	0.3	22.0	4.8	3.2	64.9	
MgO	SO <sub>3</sub> <sup>*</sup>	Na <sub>2</sub> O	K <sub>2</sub> O	f-CaO	blaine (cm <sup>2</sup> /g)	
1.9	1.9	0.40	0.44	0.7	3110	

## 3. EXPERIMENTAL

The quick hardening cement was prepared by mixing 20% by weight of admixture with 80% by weight of ordinary portland cement. The ratio of water and the cement was 0.41. As the retarder, 0.8% by weight of the mixture of citric acid and potassium carbonate in the ratio of 1:3 to the cement was added. The mixing was carried out in such a manner that water was poured into a vessel to dissolve the retarder, and the quick hardening cement was added thereto and stirred. The curing was carried out at 20°C. 80%rh.

The paste specimen having arrived at the predetermined age was crushed into particles whose particle sizes were respectively from 5.0mm to 2.5mm, and below 1.7mm and the sample whose particle size was from 5.0mm to 2.5mm was subjected to D-drying treatment for two days, and was used as the sample for measuring evaporable water, non-evaporable water (1000°C, 1 hr), pore volume (mercury pressure porosimeter) and observation by scanning electron microscope (SEM). The sample whose particle size was below 1.7mm was washed with ethanol for terminating hydration, and was subjected to the measurement of X-ray diffraction. The heat liberation curve of hydration was obtained by conduction calorimeter, and the compressive strength test was carried out by using 1:2 mortar (4x4x16 cm beam).

## 4. RESULTS AND DISCUSSION

## 4-1 HYDRATION PROCESS

The hydration of C<sub>3</sub>S is remarkably affected by the C/A ratio of clinker. There is a tendency that the hydration of C<sub>3</sub>S is more retarded as the C/A ratio is lower. This tendency holds true not only in the case of early stage of age but also in the case of 28 day age. The effect of anhydrite content is differed more or less by the composition of clinker. (Fig. 2)

Regarding the formation of ettringite, the effect of the C/A ratio is great. In Series A ( $C/A=1.10$ ), the abrupt formation of ettringite started right after the pouring of water, and the yield arrived slowly at the maximum in 14 days. The formation of ettringite was milder in Series B ( $C/A=0.92$ ) than in Series A, but the yield of ettringite became constant around one day age, and after the 14th day, the yield thereof became lowered. In Series C ( $C/A=0.65$ ), the ettringite formation reaction in early age was milder and the vigorous reaction was brought about from 2 to 12 hours, and the yield arrived at the maximum in about one day, and thereafter the

yield is abruptly reduced. When the C/A ratio is low and anhydrite content is high, the reaction in the early age is retarded. When the C/A ratio is low and anhydrite content is low, the formation timing of calcium aluminate monosulfate hydrate is accelerated and the yield becomes increased.

The retarding mechanism of hydration of  $C_3S$  is considered as follows. While the ettringite producing reaction is vigorously carried out, the crystalline nucleation for  $C_3S$  hydration to enter into acceleration period cannot be sufficiently carried out (5).

Therefore, it is considered that as the C/A ratio is lower, the delayed period is prolonged.

The reaction between calcium aluminate clinker and anhydrite has the tendency to be more delayed as the C/A ratio is lower, and this can be explained by the protective coating film forming mechanism which controls ion dissolution. It can be confirmed that by the SEM photograph that the clinker enriched more with  $Al_2O_3$ , the crystal growing reaction of fine ettringite is more delayed, and this phenomenon is also considered to be related to the concentration of Ca ion.

Fig. 1 - Hydration of  $C_3S$  and formations of ettringite (Ett) and calcium aluminate monosulfate (Mono).

Fig. 2 - Rate of heat liberation.

Fig. 3 - Morphology of hydrates (by SEM).

The above described hydration process can be vouched by the heat liberation curve of hydration. The height of the first peak of Series A is about 6 times that of Series C, and is deeply related to the yield of ettringite.

On the other hand, as the anhydrite content becomes larger, the position of the first peaks of Series A, B, and C are delayed, and the heights thereof are lower, and the lower the C/A ratio is, the greater the above mentioned tendency is. The appearance of the second peak in Series C is caused by the delay of ettringite producing reaction... The second peaks of Series A and B are overlapped with the first peaks, and therefore the second peaks are not present. (Fig. 2) The size of heat liberation peak caused by C<sub>3</sub>S hydration is almost identical with the results of X-ray diffraction.

Fig. 3 shows the morphology of the hydrates by means of SEM. The diameter of ettringite crystal grows in the range of from 0.2 to 0.4  $\mu$  and the length thereof in the range of from 3 to 4  $\mu$  within 2 hour age in Series A and B and there is not so much difference from those of the sample of 28 day age. In Series C, the sample of 3 hour age, ettringite takes on such a morphology as fine and wide rectangular form and covers the surface of the calcium aluminate particles, said ettringite is also turned into the same morphology and size as in the case of Series A and B in several hours. Calcium aluminate monosulfate hydrates take on remarkably hexagonal morphology before 24 hour age.

#### 4-2 HYDRATE STRUCTURE AND HYDRATION DEGREE

Fig. 4 shows the relation between the non-evaporable water of cement stone and  $\text{SO}_3/\text{Al}_2\text{O}_3$  (S/A) of the admixture. Throughout all the ages Series B shows high values regardless of anhydrite content, and above all, B<sub>2</sub> shows the highest value and little pore volume. (Fig. 5) In Series B, it is remarkable that pore volume ranging from 1000 to 10000 Å which belongs to capillary pore is less than Series A and C. In Series A and B, pore volume from 2000 to 4000 Å is abruptly reduced in 3 hour to one day age, and the pore volume in Series C ranging from 3000 to 9000 Å is reduced over the 3 hour age to one day age, but the pore volume ranging from 1000 to 2500 Å remains unchanged. This is considered to have been caused partially by the morphological change of ettringite in the early stage of the reaction. The C/A ratio rather than anhydrite content overwhelmingly affects non-evaporable water, pore volume and pore size distribution.

Fig. 6 shows the relation thereof to the heat of hydration and Series A takes extremely high value in one hour age, and Series A and B take almost the same values in 3 hour age.

In 24 hour age, there is a tendency that when the C/A ratio is higher, heat of hydration become higher, but the increase in the heat of hydration of  $B_3$  is great.

Regarding the relation between the degree of hydration and the structure of hydrates, not only the kind, morphology and quantity of hydrate are important factors, but also the hydration process is a very important factor.

Fig. 4 - Relation between non-evaporable water and  $\bar{S}/A$  of admixture.

Fig. 5 - Relation between total pore volume (75-75000 Å) and  $\bar{S}/A$  of admixture.

Fig. 6 - Relation between heat of hydration and  $\bar{S}/A$  of admixture.

#### 4-3 STRENGTH DEVELOPMENT AND SETTING TIME

The production of ettringite contributes much to the development of primary strength as is apparent in jet cement (5) and it is considered that the hydration of  $C_3S$  affects the development of long period strength. In regard to the strength development against unit heat of hydration, up to 24 hour age, Series C is the highest when compared with Series A and B, but the hydration of  $C_3S$  is considered to have contributed not so much to the strength development, and in a long period age, no strength development can be observed when the hydration of  $C_3S$  has been carried out. This phenomenon is considered to have been caused by the structural change of the conversion of ettringite to calcium aluminate monosulfate hydrate and the carbonation. On the contrary, when the C/A ratio is high, the dependability on  $C_3S$  hydration is increased. (Fig. 7, 8) Therefore, not only the yield of ettringite, but also hydration process become an important factor.

As the important characters of quick hardening cement, workability, strength development in the early stage of the reaction, and the stability in long period age can be given, but the degree of importance of said factors can be, of course, varied in accordance with the applications thereof. As is shown in Fig. 9, when much handling time is desired to be taken, there are three ways to solve the problem; i.e., (i) the C/A ratio be controlled lower (ii) the amount of anhydrite be increased; and (iii) the amount of retarder be increased.

When quick setting is desired, the opposite ways are recommended to be taken. Generally speaking, it is not clever to use a large amount of retarder, and when the C/A ratio is controlled to be too low, the strength development becomes poor.

Fig. 7 - Relation between compressive strength and  $\bar{S}/A$  of admixture.

For example, when quick setting is more desired, A ( $C/A=1.10$ ,  $S/A=1.33$ ) is appropriate, and this is applied to the chemical grout. On the other hand, when the development of 2-3 hour strength and 7-28 day strength are desired by taking a proper handling time, B<sub>3</sub> ( $C/A=0.92$ ,  $S/A=2.46$ ) composition is appropriate, and this composition is now being applied to urgent repair.

Fig. 8 - Relation between compressive strength and degree of  $C_3S$  hydration.

Fig. 9 - Relation between setting time and  $S/A$  of admixture (the retarder 0.8% by weight to cement).

## 5. CONCLUSION

The hydration process, strength and workability of the special cement which was prepared by adding ordinary portland cement to 20% of the various kinds of admixtures prepared by changing the composition of the electrically melted calcium aluminate clinker and anhydrite content were examined, and the following facts have been made clear;

The  $C/A$  ratio affects more to the hydration of silicate phase and ettringite producing reaction than anhydrite content, and brings about strength development and determines the structure of cement stone.

There is a tendency that when the  $C/A$  ratio is raised, quicker hardening property can be attained, and when the amount of anhydrite to be added is increased, hardening become slowed down, but the effect of the  $C/A$  ratio is overwhelming.

When the  $C/A$  ratio is lowered too much, handling time can be taken sufficiently, but it is impossible to expect the high strength development. In the neighbourhood of  $C/A=0.9$ , excellent workability can be attained when the anhydrite content is high, and strength development can be expected, and cement stone of high quality can be obtained, and therefore, the cement whose  $C/A$  ratio is in the neighbourhood of 0.9, having high anhydrite content is considered to be appropriate as quick hardening cement for general constructions.

# Role of Expansive additive CaO in expansive cement

## *Rôle d'une addition de CaO expansive dans les ciments expansifs*

U. YAMAZAKI, H. KAMIKA and S. KOBAYASHI, Japan.

RESUME : Les auteurs ont effectué des recherches sur le comportement des pâtes et mortiers de ciments expansifs, lorsqu'on leur ajoute séparément ou ensemble les composés expansifs suivants :  $\text{CaO}$  -  $\text{CaSO}_4$  -  $\text{C}_4\text{A}_3\text{S}$  et CA. Ils ont étudié tout d'abord l'addition de  $\text{CaO}$ .

L'expansion des éprouvettes de mortier de ciment expansif additionné de  $\text{CaO}$  expansif commence dès que la résistance à la compression de ces éprouvettes atteint quelques  $\text{kgf/cm}^2$ . Elle est due à la formation massive de  $\text{Ca(OH)}_2$  à partir de  $\text{CaO}$  non hydraté.

Si, en plus de  $\text{CaO}$ , on ajoute  $\text{CaSO}_4$ , l'expansion est augmentée. Ceci semble dû à l'effet retardateur de  $\text{CaSO}_4$  sur l'hydratation de  $\text{CaO}$ .

SUMMARY : This paper describes the results of investigations on the behaviors of the expanding additive  $\text{CaO}$  in cement paste and mortar specimens, as one of the studies on the roles of the expanding additives.  $\text{CaO}$ ,  $\text{C}_4\text{A}_3\text{S}$  and  $\text{CaSO}_4$  in expansive cement.

The expansion of expansive cement mortar specimen with expansive additive  $\text{CaO}$  starts at the time when the compressive strength of the mortar reached to several  $\text{kgf/cm}^2$ . This expansion is caused and increased by the successive formation of massive  $\text{Ca(OH)}_2$  formed from the unhydrated  $\text{CaO}$ .

The expansion of expansive cement mortar specimen with  $\text{CaO}$  is promoted by the additional  $\text{CaSO}_4$  because the amounts of the unhydrated  $\text{CaO}$  is increased by the retarding effect of  $\text{CaSO}_4$  on the hydration of  $\text{CaO}$ .

### Introduction

Many studies of the mechanism of the expansion of expansive cement have been reported. There are some hypotheses of the expansion mechanism, for example, the crystallization 1) 2) the dusting 3) and the swelling 4).

In order to make clear the role of expansive additive CaO in expansive cement, the behaviors of hydration of CaO in expansive cement were investigated in this study. The expansion of mortar specimen was continuously observed from the early stage of hydration by the Automatically Restraining Apparatus (ARA).<sup>5)</sup> The processes of hydration studied by employing Scanning Electron Microscopy (SEM), conduction calorimeter, X-ray diffraction techniques.

### Experimental procedure

Cements used are listed in Table I. CaO was calcinated in electric furnace at 1500°C. CaO calcinated was ground to 10 % residue on 170 mesh sieve.

CaSO<sub>4</sub> was ground to 8000 cm<sup>2</sup>/gr. Blaine.

Table I. Mix proportion of ordinary portland cement and expansive components

	Proportion			
	CaO	CaSO <sub>4</sub>	C <sub>4</sub> A <sub>3</sub> S	Ordinary portland cement
A	0	0	0	100
B	3	0	0	97
C	3	3	0	94
D	3	6	0	91
E	0	6	0	94
F	2	5	2	91

1) The length changes of the mortar specimens (cement:sand:water=1:2:0.6) under the restrained condition were measured by the ARA. The loading equipment of the ARA is shown in Fig. 1. The mortar specimen cured at 20°C was demoulded at 7 hours after casting. The demoulded specimen was wrapped with polyethylene sheet and was set on the loading stage. The expansion of the specimen was continuously measured from 7 hours after casting.

The expansion of mortar specimen which was "remoulded" by the following methods at 7 hours after casting was also measured with the ARA.

- a mortar specimen of ordinary portland cement premixed with 0.5-3.0% CaO was demoulded at 7 hours and was crushed into pieces and was moulded again to keep the initial size (50 x 10 cm) by a press.
- Ordinary portland cement mortar demoulded at 7 hours was crushed into pieces by the same way as (a) mixed with 0.5-3.0% CaO and then moulded again by the same way as (a).

Fig.1. Schematic diagram of the load stage equipment for uniaxial restraining of specimen

- The amounts of CaO and CaSO<sub>4</sub> in expansive cement pastes were determined with the XRD by the internal standard method. The paste sample was mixed with the standard MgO in cyclohexanol.<sup>6)</sup>
- The rate of heat liberation was measured with the conduction calorimeter.
- The structure of hardened expansive cement paste was observed by SEM and EPMA.

### Results

- The linear expansion curves of the specimens (A-F) are shown in Fig. 2. The expansion of each specimen started at about 7 hours after casting, and reached to the maximum by 3 days. The expansions of the specimens (B,C,D and F) were more than  $5 \times 10^{-4}$ , while the expansion of the specimen E with CaSO<sub>4</sub> only was very small.

Fig.2. Expansion curves of cement (A-F)

- Expansion curves of the remoulded mortars by the method, (a) and (b) are shown in Fig. 3. Fig. 4 shows the relations between the added contents of CaO and the expansion of the remoulded mortar specimens at 3 days. In each case, the more CaO was added, the larger the expansion of the specimen became.

Fig. 3. Expansion curves of mortars added CaO 1% and 3%

(a) premixed  
(b) mixed at 7 hours after casting

3) As a result of XRD analysis, it was recognized that one-third of added CaO remained at the age of 7 hours in the specimen B with 3 % CaO, while a half of both CaO and  $\text{CaSO}_4$  remained in the specimen D with CaO 3 % and  $\text{CaSO}_4$  6 % at the same age.

4) The amounts of unhydrated CaO in  $\text{CaO-H}_2\text{O}$  system and in  $\text{CaO-CaSO}_4\text{-H}_2\text{O}$  system were calculated from the measurement of the heat of hydration of the systems. The results obtained show that the hydration of CaO in  $\text{CaO-CaSO}_4\text{-H}_2\text{O}$  system was retarded by  $\text{CaSO}_4$  (Fig. 5).

(ii)  $\text{CaO-CaSO}_4\text{-H}_2\text{O}$  system  
(CaO: $\text{CaSO}_4$ =1:1)

5) In Fig. 6 are shown the typical figures of the massive reaction products observed only in the expanded paste specimens B, C, D and F. These reaction products were recognized to be  $\text{Ca(OH)}_2$  by EPMA.

#### Discussion

The typical relations between the expansion curve of the mortar specimen D and the reaction processes of the corresponding expansive cement are shown in Fig. 7. Though it was suggested from the rate of

heat liberation, the amounts of  $\text{Ca(OH)}_2$  and the decrease of expanding additives  $\text{CaO}$  and  $\text{CaSO}_4$  of the specimen D that the hydration reaction of expansive cement D proceeded in 7 hours, and that the expansive components reacted in 7 hours. The expansion of this specimen was detected just after the age of 7 hours, when the compressive strength of this specimen attained to about 3 kgf/cm<sup>2</sup>.

Fig.7. Typical patterns of the rate of heat liberation curve in cement paste, expansion curve in mortar and contents of  $\text{CaO}$ ,  $\text{CaSO}_4$  and produced  $\text{CH}$  in paste, in case of expansive cement D  
(  $\text{CH}=\text{Ca(OH)}_2$  )

When more than 1 %  $\text{CaO}$  remains in the expansive cement mortar at 7 hours, as plotted in (b), Fig.4, the mortar shows considerable expansion.

Though a half of  $\text{CaO}$  hydrated before the age of 7 hours, however, the expansion of mortar specimen was not observed as shown in Fig.7. This is for the reason that as cement gel is movable to fill up the space of water consumed in hydration of  $\text{CaO}$  at the earlier age, the structure of mortar specimen absorbs the expanding force originated from the hydration of  $\text{CaO}$ . In other words, while  $\text{CaO}$  grains increase their volume 1.8 times by hydration, the total volume ratio of  $\text{Ca(OH)}_2/\text{CaO}$  and  $\text{H}_2\text{O}$  decreases to 90 % as a whole structure. Therefore the mortar specimen shows no expansion, when the cement gel is movable.

After 7 hours, it is not easy for cement gel to fill up the space of  $\text{H}_2\text{O}$  because the matrix possesses some rigidity. And  $\text{Ca(OH)}_2$  as shown in Fig. 6 produced from unhydrated  $\text{CaO}$ . In this case, the hydration of unhydrated  $\text{CaO}$  to  $\text{Ca(OH)}_2$  brings out the change of volume by about 1.8 times as a whole. Therefore, the mortar specimen shows expansion. When  $\text{CaSO}_4$  coexists in the expansive cement including  $\text{CaO}$ , the hydration of  $\text{CaO}$  is restrained as observed in  $\text{CaO-CaSO}_4\text{-H}_2\text{O}$  system with conduction calorimeter. This retarding effect of  $\text{CaSO}_4$  in hydration of  $\text{CaO}$  is caused because the solubility of  $\text{Ca(OH)}_2$  is decreased by dissolution of  $\text{CaSO}_4$  and because the surface of  $\text{CaO}$  is covered with the tighter film layer of  $\text{Ca(OH)}_2$  which was recognized by means of optical microscopic observation by the authors.

This phenomenon is also recognized in the expansion reaction of expansive cement specimen with additional  $\text{CaO}$  and  $\text{CaSO}_4$ . The expansion of expansive cement mortar specimen with  $\text{CaO}$  is promoted by the additional  $\text{CaSO}_4$  because the amounts of the unhydrated  $\text{CaO}$  is increased by the retarding effect of  $\text{CaSO}_4$  on the hydration of  $\text{CaO}$ .

#### Conclusion

- 1) The expansion of expansive cement mortar specimen with expansive additive  $\text{CaO}$  starts at the time when the compressive strength of the mortar reached to several kgf/cm<sup>2</sup>. This expansion is caused and increased by the successive formation of massive  $\text{Ca(OH)}_2$  formed from the unhydrated  $\text{CaO}$ .
- 2) The expansion of expansive cement mortar specimen with  $\text{CaO}$  is promoted by the additional  $\text{CaSO}_4$  because the amounts of the unhydrated  $\text{CaO}$  is increased by the retarding effect of  $\text{CaSO}_4$  on the hydration of  $\text{CaO}$ .
- 3) In many cases, the massive  $\text{Ca(OH)}_2$  formed the hydration of the unhydrated  $\text{CaO}$  is observed in the expanded specimen with expansive additive  $\text{CaO}$ .

## INTRODUCTION

Les propriétés des pâtes fraîches de ciment portland, présentent un grand intérêt, car les propriétés des bétons en découlent. Cet intérêt est très général en ce qui concerne les caractéristiques du ciment qui influent sur la consistance, la maniabilité et la prise du béton. La maîtrise des propriétés rhéologiques du béton frais doit avoir des conséquences importantes, sur le choix de la composition du béton et sur les moyens de malaxage et de mise en oeuvre.

Les examens au microscope des coupes de béton normalement durci, montrent que chaque grain de l'agrégat est enrobé dans une matrice de pâte de ciment durcie, des films de cette pâte séparant complètement ces grains les uns des autres. Le béton frais doit acquiescer cette sorte de structure, dans la période de repos qui précède la prise. Cependant, durant le malaxage et la mise en oeuvre du béton, les grains de sable ou ceux du gros agrégat, auront fréquemment entre eux des contacts directs. Ces contacts directs, créeront des forces de frottement; les effets sur les divers grains interféreront et s'ajouteront pour réduire la fluidité de la pâte de ciment elle-même.

Bien que des progrès aient été faits dans la connaissance des phénomènes et l'établissement de relations entre la rhéologie du béton et celle de la pâte de ciment (1-5), la plupart des essais standardisés sur les ciments, les mortiers et les bétons sont purement empiriques; et les résultats de ces divers essais semblent difficilement comparables. Par exemple, un ciment très finement broyé, peut exiger dans une pâte pure plus d'eau de malaxage et avoir une consistance plus raide, qu'un ciment plus grossièrement broyé; mais il faut aussi exiger moins d'eau de malaxage (ou avoir une plus grande fluidité) s'il est essayé dans un mortier plastique, par suite de la diminution du nombre des contacts des plus gros grains de ciment avec les grains du sable, dans le mortier.

Les essais de détermination de la consistance du béton ou du mortier, consistent à mesurer leur déformation sous l'action de la gravité, ou la progression de leur déformation (ou le temps nécessaire pour obtenir une déformation donnée) sous l'action d'impacts répétés, ou de vibrations et de la granité. De tels essais donnent des résultats numériques, relevant d'échelles arbitraires, qui n'ont aucun rapport simple avec les propriétés physiques, bien définies, telles que la viscosité ou le seuil de rigidité (contrainte minimum de cisaillement provoquant l'écoulement). Le "slump test" est considéré comme mesurant la consistance du béton frais, et le facteur de compactage; alors que le "V.B. test", mesure la viscosité apparente (6). Cependant, il a été constaté qu'aucun essai ponctuel, comme ceux-ci ne pouvait fournir une mesure valable de la fluidité et de la maniabilité des bétons dans toute la gamme des conditions possibles (3, 7). La raison en est, qu'il y a une grande différence entre l'état de la pâte, avant et après le début de l'écoulement. Il est de pratique courante d'utiliser la vibration pour fluidifier les bétons frais trop raides, et permettre leur mise en oeuvre dans les moules. Les structures faibles dans la pâte sont alors détruites par des cisaillements énergiques ou par la vibration. La pâte est dite avoir alors la consistance fluide. La consistance du béton, lors de sa mise en place par vibration est due, au moins en partie, aux caractéristiques rhéologiques de sa pâte de ciment, dans son état

fluidisé (1). La résistance du béton frais à la déformation et à l'écoulement, dans l'état statique, doit aussi être liée, au moins en partie, au seuil de cisaillement de la pâte de ciment.

La résistance de la pâte de ciment portland au cisaillement, dépend, à la fois, du temps et de la vitesse de la déformation. Elle dépend aussi de la durée du malaxage et de son intensité. Les pâtes de ciment sont normalement thixotropiques, c'est-à-dire que leur résistance au cisaillement s'amointrit lors de l'écoulement de la pâte, par suite de la rupture progressive, des liaisons de floculation entre particules. L'hydratation du ciment a des effets à court terme (prise rapide, fausse prise), aussi bien qu'un raidissement normal progressif. Le comportement à l'écoulement peut cependant être très complexe, même pour un seul ciment, et les comparaisons entre divers ciments peuvent être fortement affectées par des variations des méthodes d'essais ou de l'appareillage utilisé.

Les propriétés des pâtes fraîches de ciment portland, sont aussi intéressantes, dans les recherches sur les autres caractéristiques du ciment. Par exemple, l'étude des propriétés des pâtes fraîches est utilisée, pour déterminer l'influence de la distribution granulométrique du ciment, ou pour mesurer l'action, sur les réactions d'hydratation initiales, des teneurs plus ou moins fortes en gypse ou en autres additifs. Dès le début du mélange eau ciment, le processus de la dissolution et de la formation des hydrates, provoque des changements progressifs dans la structure et les propriétés rhéologiques de la pâte.

## STRUCTURE DE LA PATE FRAICHE

Les ciments portland modernes sont moulus en poudre fine, qui n'a qu'un très faible pourcentage de grains supérieurs à 74 microns ou inférieurs à 1 micron. La taille des grains, est le résultat de nombreuses factures aléatoires, qui se produisent à la fin du broyage, et tendent à transformer certains grains arrondis en grains anguleux. La distribution granulométrique rapportée à des grains sphériques de diamètre équivalent, en se basant soit sur la vitesse de sédimentation, soit sur la surface spécifique, donne une bonne approximation.

Les ciments modernes ont généralement des surfaces spécifiques de l'ordre de 300 à 500 m<sup>2</sup>/kg (soit 3000 à 5000 cm<sup>2</sup>/gr), mesurées par la perméabilité à l'air à l'aide de méthodes telles que celle de Lea et Nurse, ou celle de Blaine (ASTM C. 204). Certaines méthodes, telles que l'A.S.T.M. C 115 utilisant le turbidimètre de Wagner, conduisent à des valeurs beaucoup plus faibles, parce que la teneur en particules les plus fines est sous estimée. Certaines autres méthodes sédimentométriques mesurent la teneur des ciments en fines particules, en bon accord avec les méthodes de perméabilité à l'air. Par contre, les valeurs des surfaces spécifiques mesurées par adsorption d'azote (méthode BET), sont bien plus grandes, que celles mesurées par perméabilité à l'air, parce que l'adsorption mesure aussi la surface des hydrates, et celle d'autres petites particules collées à la surface des grains de ciment, aussi bien que celles des fissures et peut être même celle de certains pores du ciment. Il semble que la surface spécifique mesurée par la méthode Blaine, soit mieux appropriée à l'étude de l'écoulement ou de la sédimentation,

que celle mesurée par la méthode B.E.T., parce que l'eau enrobe les grains de ciment d'une couche lisse, qui supprime l'influence des petites irrégularités de la surface des grains.

Les pâtes fraîches de ciment sont initialement une suspension épaisse de grains de ciment dans l'eau de malaxage. La structure de cette suspension dépend du rapport eau ciment, et de la distribution granulométrique du ciment. Elle dépend aussi des forces qui s'exercent entre particules, et des forces d'attraction de l'eau à la surface des grains solides, qui à leur tour, dépendent de l'ionisation et de la concentration des solutions. Dans les solutions diluées, les grains de ciment doivent normalement flocculer, c'est-à-dire s'agglomérer en amas distincts appelés flocons, qui sédimentent rapidement. Les flocons ainsi formés, à partir de ciment ordinaire, dans les solutions diluées, ont un rapport eau ciment d'environ : 0,4. Dans les suspensions épaisses, que sont les pâtes de ciment, les flocons isolés sont amalgamés, à l'état statique dans un grand flocculant continue unique. Les grains ne sont pas uniformément répartis dans une telle structure; Certains flocons réunissent plus de grains que la concentration moyenne, mais laissent entre eux des intervalles remplis d'eau. A l'intérieur de ces flocons les grains tendent à réduire les intervalles entre particules, de façon à réduire l'énergie potentielle. Powers a appelé ceci l'état flocculé (1).

Pendant le malaxage, les grains de ciment tendent à se disperser plus uniformément dans l'eau; et il y a une rupture généralisée des liaisons entre flocons; ceci est la cause de la thixotropie (chute de la résistance au cisaillement) des pâtes de ciment. Si l'on opère à vitesse de cisaillement constante, un équilibre structurel (peut être résultant de la distribution granulométrique des flocons) est atteint au bout de quelques minutes, produisant une viscosité apparente constante. Il y a aussi un processus de neutralisation empêchant la structure de se reconstituer. Lorsque le malaxage est arrêté, la structure flocculée statique se reforme graduellement. Bien que la pâte soit fluide durant le malaxage, elle prend, dans son état statique, une structure flocculée, correspondant à un état faiblement solide, mais ayant un seuil de cisaillement défini.

Certains additifs organiques (réducteurs d'eau) sont utilisés pour accroître la fluidité des bétons, ou pour réduire leur teneur en eau, pour une même fluidité. L'examen au microscope, montre que pour des teneurs en additifs suffisantes les grains de ciment sont tous séparés, au lieu d'être flocculés. Il y a lieu de penser, que ceci résulte de l'adsorption de l'additif à la surface des grains de ciment, qui provoque ainsi une neutralisation des charges, et la création, entre grains de ciment, de forces répulsives.

Un tel concept peut être utilisé pour visualiser la structure d'une pâte fraîche de ciment, comme indiqué, à titre de modèle simple sur la figure (1). Les frais y sont représentés sous forme de sphères, de diamètres équivalents correspondant à la distribution granulométrique d'un ciment de 430 m<sup>2</sup>/kg de surface spécifique. La grande demi-sphère du fond, représente un grain de 30 microns de diamètre. Les intervalles entre grains sont remplis par de l'eau et par des grains plus petits. La figure correspond à un rapport

Fig. 1 - Modèle simple de grains sphériques dispersés, dans la structure d'une pâte fraîche de ciment, pour un rapport eau ciment de 0,5 et un ciment de 430 m<sup>2</sup>/kg (8)

eau ciment de : 0,5. Lorsque l'eau est fortement attirée à la surface des grains, chacun de ces grains est enrobé d'un film d'eau continu; si le ciment est dispersé par un vigoureux malaxage, ou si l'on utilise un additif réducteur d'eau, l'épaisseur de ces films tend à s'uniformiser. Une première approximation de cette épaisseur est donnée par le rayon hydraulique : le volume de l'eau de malaxage divisé par la surface spécifique. Pour le ciment et la teneur en eau de la fig. 1, cette épaisseur est d'environ : 1,2 microns, soit à peu près le dixième du diamètre moyen des grains de ciment. Bien que ce modèle soit plus proche d'une solution dispersée que d'une pâte de ciment, l'épaisseur du film d'eau reste la même. Une seconde approximation peut être obtenue en tenant compte de l'eau contenue dans les grands interstices entre grains(2,9). Les réactions d'hydratation initiales peuvent aussi être considérées, selon un modèle plus réaliste de la structure de la pâte fraîche. La dissolution rapide du gypse et des alcalis, dans l'eau de malaxage, produit des hydroxydes et des sulfates de sodium, de potassium et de calcium. Grâce au gypse destiné à régulariser l'hydratation de l'aluminate tricalcique, un enrobage de sulfo-aluminate se forme sur les grains d'aluminate tricalcique, ce qui arrête leur réaction d'hydratation initialement très rapide. Environ 10 % du C<sub>3</sub>A peut être hydraté dans les dix premières minutes(10); après quoi la réaction d'hydratation du C<sub>3</sub>A est beaucoup plus lente, jusqu'à épuisement du gypse, ce qui ne se produit généralement qu'à la fin de la prise. La profondeur de l'attaque dans le C<sub>3</sub>A, au début (10 %) de la réaction peut être estimée à : 0,1 micron. Si le produit de la réaction est de

l'ettringite très compacte, la surface du C.A est enrobée d'une couche épaisse d'environ : 0,8 micron. Rapidement, la moitié du gypse est consommée dans cette réaction initiale; si le gypse a une surface spécifique initiale d'environ 800 m<sup>2</sup>/kg, et si chaque grain de gypse se dissout sur une même épaisseur, cette épaisseur est de 0,5 micron environ. Après cette réaction initiale la surface spécifique de particules de gypse résiduelles est inférieure à la moitié de cette valeur, et la surface spécifique du ciment est diminuée de 30 m<sup>2</sup>/kg environ. Cependant, la surface spécifique mesurée au B.E.T. augmente par suite de la formation des produits de l'hydratation; si ces hydrates se forment à la surface des grains de ciment, ils peuvent avoir un effet négatif sur la fluidité à ce moment. La formation de l'ettringite peut, elle-même, réduire la teneur en eau libre de la pâte de ciment d'environ : 0,02 g/g de ciment, pendant cette même période (10 %) de l'hydratation.

Tous ces processus initiaux influent sur la surface spécifique, et sur la teneur en eau libre, donc sur l'épaisseur du film d'eau d'enrobage, pendant la période de latence. La réaction initiale d'hydratation des silicates peut avoir un petit effet, sur la structure des pâtes fraîches de ciment, à moins qu'un vigoureux malaxage soit poursuivi, découpant continuellement les hydrates à la surface des grains. Après cette période de latence, des cristaux de chaux hydratée commencent à se former dans la solution; ceci accélère l'hydratation des silicates, et des cristaux de silicate de calcium hydraté se forment sur la surface correspondante des grains solides, et croissent sous forme d'aiguilles. La prise normale se produit alors, résultant de l'entrecroisement de ces hydrates; la recristallisation de l'ettringite peut aussi contribuer à la prise (10).

#### DEFORMATION ET COMPORTEMENT FLUIDE

La consistance des pâtes fraîches de ciment, après cette période de prise, varie si fortement, avec la composition du ciment et avec le temps, qu'un seul appareil de mesure ne peut suffire à en couvrir toute l'étendue. Les viscosimètres, spécialement les viscosimètres à cylindres coaxiaux, sont généralement utilisés avec les pâtes les plus fluides, dont le seuil de cisaillement va jusqu'à 200 Pa (2000 dynes/cm<sup>2</sup>) et dont la viscosité apparente, va jusqu'à plusieurs milliers mPa/s (= centipoises). Récemment un mini slup test, a été jugé très pratique, pour comparer les fluidités de pâtes de diverses compositions (11). Dans cet essai, un petit cône est rempli avec la pâte à essayer, puis soulevé de façon que la pâte s'écoule et forme un pâtre; l'aire de ce pâtre, donne la mesure de la consistance. Pour des pâtes plus rigides, des essais de pénétration, tels que l'aiguille de Vicat, sont mieux adaptés à la mesure de la teneur en eau qui donne la consistance normale, ainsi qu'à la mesure du début et de la fin de la prise. Un appareil automatique, le rhéographe décrit par Bombléd (12 - 13), mesure les seuils de cisaillement par des essais de pénétration, sur un large éventail de pâtes à résistances très variées, depuis environ 30 jusqu'à plus de 1,5 x 10<sup>5</sup> Pa. Il recouvre donc tout le domaine, depuis l'extrémité des mesures faites au viscosimètre à cylindres coaxiaux, jusqu'aux valeurs de début et de fin de prise mesurées à l'aiguille de Vicat, qui correspondent approximativement respectivement à : 2 x 10<sup>4</sup> et 1 x 10<sup>5</sup> Pa.

La figure 2 donne des exemples de courbes mesurées au rhéographe, sur des pâtes de ciment de rapport eau ciment égal à 0,25, avec des ciments de différentes finesses (13). Les seuils de rigidité (résistance au cisaillement) sont calculés, pour des forces nécessaires pour produire une pénétration de 20 mm, à l'aide d'une ou de plusieurs sondes, dont les diamètres varient de 1 à 12 mm. Les valeurs initiales du seuil de rigidité sont, parfois, plus grandes par suite de la faiblesse du rapport eau ciment. La consistance normale des pâtes correspond approximativement à un seuil de rigidité de 2000 Pa. Deux de ces pâtes étaient plus raides que la consistance normale. Ces courbes peuvent être utilisées pour définir et calculer les divers paramètres qui interviennent dans la prise du ciment; début et fin de prise, vitesse de prise, durée de la période de latence, pendant laquelle le seuil de rigidité est pratiquement constant. A des teneurs en eau plus fortes, le début de ces courbes est presque horizontal.

Malgré le fait que de tels essais statiques montrent clairement l'existence de seuils de rigidité dans les pâtes de ciment ordinaires, les résultats obtenus avec les viscosimètres dynamiques ne donnent souvent pas de valeurs bien définies de ces seuils. La vitesse de déformation par cisaillement en fonction de la contrainte de cisaillement, peut être représentée par des courbes; lorsque ces mesures sont faites à l'aide de viscosimètre rotatifs (voir fig. 3), on constate que les résultats dépendent considérablement de l'histoire de la déformation des pâtes et du type d'appareil utilisé.

Le comportement des pâtes de ciment, lors de cette déformation, peut, suivant la nature des pâtes et le type d'appareil utilisé, être classé en quatre catégories. 1) newtonien, 2) Binghamien, 3) pseudo-plastique et 4) dilatant. En outre les courbes peuvent présenter un comportement réversible, entre thixotropique (chute de seuil de cisaillement) et anti-thixotropique (augmentation du seuil de cisaillement). Le comportement antithixotropique semble être du à un processus de retour de thixotropie, qui doit, cependant, être distingué de la dilatace, qui elle aussi, provient d'une augmentation du seuil de cisaillement mais pour d'autres raisons.

#### ÉCOULEMENT NEWTONIEN ET BINGHAMIEN

Quand la vitesse de cisaillement  $\dot{\gamma}$ , est proportionnelle à la contrainte de cisaillement  $\tau$ , l'écoulement est dit newtonien, ou à viscosité constante.

Les pâtes de ciment ne sont normalement pas newtoniennes, mais peuvent le devenir très rapidement, en y ajoutant des quantités suffisantes de certains additifs réducteurs d'eau (14 - 17). Les pâtes de ciment ont approximativement le comportement d'un solide plastique de Bingham, avec un seuil de rigidité  $E$ , et une viscosité  $U$ , de telle façon que :

$$\dot{\gamma} = \frac{1}{U} (\tau - E) \quad (1)$$

Les résultats des mesures rhéologiques faites sur les pâtes de ciment, sont souvent représentés graphiquement (comme sur la fig. 3), en portant en abscisse la résistance au cisaillement (ou le couple de torsion du viscosimètre rotatif), et en ordonnée la vitesse de cisaillement (ou la vitesse de rotation) (2).

Fig. 2 - Courbes relevées au rhéographe, sur des pâtes (clinker broyé plus 5 % de gypse, à un rapport E/C de 0,25) pour des ciments de finesses variées : 1) 201 m<sup>2</sup>/kg; 2) 248,5 m<sup>2</sup>/kg; 3) 307 m<sup>2</sup>/kg; 4) 403 m<sup>2</sup>/kg; 5) 511 m<sup>2</sup>/kg (13).

Dans de tels diagrammes, les fluides newtoniens sont représentés par une ligne droite passant par l'origine ( $E=0$  dans l'équation : 1). Les solides plastiques de Bingham sont aussi représentés par une droite, mais ne passant plus par l'origine, dans ces cas, la pente de la droite est égale à l'inverse de la viscosité plastique; la viscosité apparente est  $\frac{\tau}{\dot{\gamma}}$ , c'est-à-dire l'inverse de la pente de la droite qui relie l'origine à un point de la courbe. Donc, même si la viscosité plastique est constante, la viscosité apparente dépend de la vitesse de cisaillement, et peut être beaucoup plus grande que la viscosité plastique, aux faibles valeurs de la vitesse de cisaillement, par suite de l'existence d'un seuil de rigidité non nul.

Fig. 3 - Courbes relevées au viscosimètre rotatif pour diverses pâtes de ciment : 1) E/C = 0,4; 2) E/C = 0,25, à vitesse constante et à l'équilibre; 3 et 4) E/C = 0,32; 3 immédiatement après malaxage; 4 immédiatement après la première mesure (2)

#### PSEUDOPLASTICITE

Les seuils de rupture mesurés au viscosimètre sur les pâtes de ciment, réelles, ne sont pas définis aussi nettement que dans le modèle plastique de Bingham. Au lieu d'une droite, les couples de valeurs mesurées : vitesse de cisaillement vs, contrainte de cisaillement, peuvent figurer une courbe graduellement croissante depuis l'axe des contraintes pour tendre vers une droite (fig. 3), ce comportement est appelé : pseudo-plastique ou plastique thixotropique. La portion droite de cette courbe, peut être utilisée, en la prolongeant vers les vitesses de cisaillement décroissantes, pour obtenir par extrapolation la valeur du seuil de rigidité. La partie courbe peut résulter de la combinaison d'un écoulement non uniforme de l'échantillon, et de la nature thixotropique du matériau, notamment si le viscosimètre comporte un espace trop large entre les deux cylindres coaxiaux (1).

Dans l'essai des pâtes de ciment dans les viscosimètres à cylindres coaxiaux, l'écoulement peut ne pas devenir immédiatement uniforme. Ainsi, quelques glissements peuvent se produire, à la surface des cylindres, des parties de la pâte étant décollées des parois, et s'écoulant, alors que d'autres y restent adhérentes. La vitesse de cisaillement des parties décollées, donc en mouvement, est alors bien plus grande que celle indiquée par la vitesse de rotation relative des cylindres. Parfois la totalité de la pâte glisse d'une façon apparemment uniforme. Ces phénomènes ont

été étudiés en détail, en utilisant des cylindres lisses et des cylindres cannelés, et en faisant varier la vitesse de cisaillement et la nature des pâtes (18).

Dans une approche différente, Legrand (19), utilise un viscosimètre comportant une série de pales radiales, plongeant dans un grand volume d'échantillon. La variation du couple de torsion en fonction du temps, pendant la période d'écoulement non uniforme, a été analysée, pour déterminer le seuil de rigidité, la contrainte de cisaillement, et la vitesse de cisaillement, pour diverses valeurs constantes de la vitesse de rotation.

#### DILATANCE

Il y a un passage progressif entre les propriétés de l'écoulement plastique thixotropique et le comportement dilatant (réduisant la résistance au cisaillement), lorsque le volume des solides augmente dans les mortiers et les ciments (19). Quand la proportion de ces volumes solides dépasse environ 0,6, la résistance au cisaillement augmente avec la vitesse de cisaillement, et une augmentation du volume se produit alors. La courbe est alors concave vers l'axe des déformations, au lieu d'être convexe comme dans le cas de la fig. 3. Ces effets résultent de modifications dans l'arrangement mutuel des grains de ciment, de façon à permettre le mouvement relatif de ces grains, le long des surfaces de rupture. Il en résulte une augmentation moyenne des interstices entre grains dans la direction perpendiculaire à la direction du cisaillement. L'eau est alors amenée à pénétrer dans ces interstices élargis, et la résistance au cisaillement dépend, par conséquent, de la vitesse du cisaillement et de la perméabilité du matériau. D'autre part, du fait que l'eau et les solides sont peu compressibles, un peu d'air tend à pénétrer dans le matériau. Cet air ainsi piégé, fournit l'espace d'expansion, sans exiger d'écoulement d'eau supplémentaire.

Ces interactions entre grains produisent un accroissement rapide du seuil de rigidité et de la viscosité apparente, lorsque la proportion en volume des solides dépasse environ 0,6 et lorsque le matériau n'est pas vibré. Lorsque le matériau est vibré, le comportement à l'écoulement est transformé, et cette transition vers la dilatance se produit alors seulement lorsque la proportion en volume des solides est un peu supérieure (0,62).

Les mêmes considérations s'appliquent aussi aux pâtes de ciment à très faible rapport eau ciment. Une concentration en volume de ciment de 0,6 (40 % en eau du volume total), correspond à un rapport eau ciment en poids de 0,21. Des courbes typiques de dilatance ont été obtenues, pour des rapports eau ciment de cet ordre, avec des pâtes de clinker broyé, fluidifiées avec des additions de lignosulfonate et de carbonate soluble (17, 20).

#### THIXOTROPIE

Il a été démontré (3, 18, 21, 22), que dans des conditions expérimentales appropriées (vitesse de cisaillement constante, écoulement uniforme), le couple de torsion  $T_0$ , mesuré dans un viscosimètre à cylindres coaxiaux, variait exponentiellement avec le temps depuis la valeur  $T_0$ , jusqu'à une valeur d'équilibre  $T_E$ , selon la formule :

$$T = T_E + (T_0 - T_E)e^{-Bt} \quad (2)$$

où B est une constante qui dépend de la vitesse de cisaillement (ou de la vitesse angulaire) et des propriétés de la pâte. Les valeurs de B sont de l'ordre de  $0,04 \text{ s}^{-1}$ . L'équilibre est atteint en 1 ou 2 minutes. Depuis  $T_0$  jusqu'aux diverses valeurs de  $T_E$ , la forme des courbes peut varier considérablement, en ce qui concerne les vitesses de cisaillement (déformations et contraintes), selon la durée des augmentations (courbes croissantes) ou des diminutions (courbes descendantes) de ces vitesses de cisaillement (méthode de Green). La fig. 3 montre des exemples de comportements thixotropiques des pâtes de ciment, au cours de tels essais (2). On y distingue quatre manifestations de la thixotropie apparente :

1. La courbure des courbes ascendantes, indique une diminution de la viscosité lorsque la vitesse de cisaillement augmente.
2. Les courbes ascendantes correspondent à des contraintes de cisaillement plus fortes (pour des vitesses de cisaillement identiques) que celles des courbes descendantes.
3. La courbe 2 montre la diminution de la contrainte de cisaillement pour une vitesse de rotation du viscosimètre constante.
4. La courbe 4 montre des contraintes de cisaillement plus faibles, lorsque l'on recommence immédiatement l'essai de la courbe 3.

Non seulement, la boucle d'hystérésis de la courbe 4 est déplacée vers les contraintes de cisaillement les plus faibles (et les viscosités plastiques les plus faibles) mais encore la boucle 3 est plus grande que la boucle 4; ce qui implique qu'il y ait davantage de ruptures de liaisons dans le premier cycle que dans le second. Dans des conditions d'essai standardisées, les aires de ces boucles d'hystérésis, ont été utilisées pour mesurer la proportion des ruptures des liaisons thixotropiques. Des tentatives ont aussi été faites pour déterminer quantitativement l'énergie nécessaire, par unité de volume pour produire ces ruptures des liaisons thixotropiques lorsqu'on opère à vitesse de cisaillement constante (3, 22).

Une autre manifestation de la thixotropie a été observée, dans des essais, où la vitesse de cisaillement maximum augmentait avec le nombre de cycles. Dans ce cas les boucles aussi évoluent vers des contraintes et des viscosités plastiques plus faibles, ce qui implique qu'il y ait davantage de ruptures de liaison aux vitesses de cisaillement élevées (3).

#### ANTI-THIXOTROPIE ET EFFETS DU MALAXAGE

Des résultats obtenus dans des viscosimètres à cylindres coaxiaux, ont montré, des seuils de rigidité bien définis, et des viscosités plus faibles, pour des faibles vitesses de cisaillement; ceci dépendait du degré de dispersion des grains de ciment par un malaxage approprié et du type de viscosimètre employé, et notamment de l'étroitesse de l'espace entre cylindres. Bien que Greenberg et Meyer (24) ait publié en 1963 que pour obtenir un écoulement uniforme, il leur avait été nécessaire de réduire cet espace à 1,0 mm environ,

la plupart des résultats publiés depuis, ont été obtenus avec des espaces trop larges pour éviter cet effet instrumental. Un autre facteur peut être la douceur de marche de la machine, et l'absence de vibrations de l'appareil, les vibrations et les chocs peuvent provoquer des écoulements non uniformes aux faibles valeurs des seuils de résistance. Roy et Asaga (15) ont récemment publié des résultats obtenus avec un viscosimètre de 0,7 mm d'espace entre cylindres, dans lesquelles les courbes croissantes sont remarquablement linéaires, avec des seuils de rigidité bien définis, c'est-à-dire un comportement presque Binghamien (voir fig. 4). Par contre, des viscosimètres comportant des espaces plus larges entre cylindres (4 mm et plus) ont montré un comportement pseudo-plastique sans seuils de rigidité bien définis (2, 22, 25). Il y a lieu de noter que les courbes d'hystérésis de la fig. 4 sont très différentes de celles des autres publications. Non seulement, elles montrent des seuils de rigidité bien définis, pour des contraintes de cisaillement croissantes, mais aussi des boucles d'hystérésis comportant une importante antithixotropie ou réduction de la résistance au cisaillement; notamment, des contraintes plus élevées se produisent sur les courbes descendantes que sur les courbes ascendantes, pour une même vitesse de cisaillement. Le viscosimètre et les méthodes utilisés par Roy et Asaga ont donné des résultats entièrement dépourvus de comportement plastique-thixotropique. D'autre part, l'une des raisons de la grande surface des boucles d'hystérésis antithixotropique, semble être la très faible vitesse des essais (15 minutes par cycle) alors qu'habituellement ces cycles ne durent que quelques minutes. Désormais, une durée plus longue doit être attribuée à la fois aux ruptures de liaisons thixotropiques et à la recouvrance.

Plusieurs expérimentateurs ont observé à la fois des comportements thixotropiques et antithixotropiques sur les mêmes pâtes (23, 24, 25) essayées, à différents âges après malaxage. Des courbes pseudoplastiques ont été obtenues à des vitesses plus rapides (cycles de 2 à 3 minutes) que celles utilisées par Roy et Asaga. Les vitesses d'essai plus rapides laissent moins de temps pour la recouvrance thixotropique des pâtes fraîches. Même, les résultats obtenus ont montré que peu de temps après le malaxage, les pâtes étaient habituellement légèrement antithixotropiques, mais qu'après quelque temps de repos (30 à 45 minutes) elles devenaient thixotropiques. Cependant, quand après un certain temps de repos, la pâte était agitée, par des essais répétés, la courbe évoluait de la forme thixotropique, à la forme antithixotropique. Après un temps de repos plus long (2 à 3 heures) la pâte devenait très fortement thixotropique à l'approche de la prise, sauf si elle était continuellement agitée. Cette action de l'agitation conduit à penser que l'intensité du malaxage initial doit aussi influencer sur la fluidité de la pâte, ce qui est bien connu, depuis déjà quelque temps.

Les malaxeurs mécaniques capables de produire un malaxage énergétique et uniforme sont habituellement utilisés, peut être par intermittence, pour produire des pâtes de meilleure fluidité, après un malaxage assez long (5 à 10 minutes). Si la pâte est malaxée pendant 30 secondes, au moins, elle subira une prise rapide, qui est due, pense-t-on, à un collage des grains entre eux, par suite des produits de la réaction initiale avec l'eau, formés à leur surface. Bien qu'un temps de malaxage de 1 minute puisse être assez long

Fig. 4 - Courbes relevées au viscosimètre rotatif, pour des pâtes malaxées suivant six méthodes différentes, mais avec un même E/C = 0,40 (15)

pour supprimer cette prise rapide, il peut ne pas être suffisant, pour produire une dispersion correcte, ou pour éliminer la fausse prise due à la formation de gypse, à partir de semi-hydrate qui pouvait être présent dans le ciment. Ces cristaux de gypse forment une structure faible, qui peut être brisée par un malaxage ou un remalaxage.

Un malaxage énergétique continu, peut aussi briser les structures de floculation des grains de ciment, qui sont responsables du comportement thixotropique. Des mesures, telles que celles indiquées sur la figure 3, pour diverses séries de malaxage d'une durée de 5 minutes chacune, dans un malaxeur planétaire, ont montré, qu'en augmentant la vitesse de malaxage de 150 tours/minute à 450 tours/minute, on abaissait les boucles d'hystérésis à des contraintes de cisaillement plus faibles, et qu'on rétrécissait ces boucles vers un comportement plastique presque réversible, du type Bingham (non thixotropique). Des résultats analogues ont été obtenus lorsque les temps de malaxage, à la vitesse de 250 tours/minute étaient portés de 3 à 20 minutes. Dans toutes ces mesures, faites avec des pâtes ayant un rapport eau ciment de 0,35, on a constaté que la viscoplasticité, indiquée par la courbe décroissante, diminuait progressivement avec l'intensité et la durée du malaxage. Cependant, pour un rapport E/C de 0,25, on atteignait le seuil de rigidité après environ 5 minutes de malaxage (2).

Une étude des effets du malaxage à haute intensité, sur des pâtes ayant un rapport eau ciment de 0,45, ont montré que la viscoplasticité passait par un minimum, mais que les seuils de rigidité augmentaient progressivement avec la durée du malaxage depuis 10 jusqu'à 50 Pa (2). Un malaxage énergétique semble briser très rapidement la thixotropie et améliorer la fluidité, mais si ce malaxage est prolongé l'abrasion des grains augmentera le seuil de rigidité et la viscoplasticité.

En utilisant des mélangeurs à grande vitesse, pour malaxer des pâtes de E/C égal à 0,5, on a trouvé que le seuil de rigidité initial (à 15 minutes) augmentait progressivement de 22 à 52 Pa, et que les viscoplasticités diminuaient de 21 à 47 mPa/s, lorsque la durée du malaxage passait de 1 à 10 minutes (23). La température finale du mélange était de 25°C. Après une hydratation de 3 heures, la température augmentait quand la durée du malaxage croissait, ce qui dénote la persistance des effets de la durée du malaxage. En outre, les pâtes malaxées pendant une minute étaient thixotropiques, et le devenaient encore plus, avec la durée de l'hydratation, tandis que les pâtes malaxées pendant 10 minutes étaient initialement antithixotropiques, mais devenaient, après deux heures d'hydratation, encore plus thixotropiques que les pâtes malaxées pendant 1 minute. Un malaxage à très grande vitesse (10 000 tours/minute), comportant un refroidissement externe, a été utilisé pour produire des pâtes à faible ressuage (26). On pense que son principal effet, a été de remanier les minces couches d'hydrates formés à la surface des grains de ciment, et de les disperser dans la pâte, qui a ainsi atteint une consistance épaisse.

Les résultats inscrits sur la figure 4, ont été obtenus principalement pour déterminer l'influence de l'intensité du malaxage sur les courbes d'écoulement. Il n'a pas été procédé à des variations de la durée de ce malaxage énergétique, mais on constate cependant de grandes variations dans les propriétés rhéologiques. Six sortes de malaxage, d'intensité croissante, ont été essayées. Le processus AS est celui de la méthode ASTM C 305, utilisant un malaxeur planétaire Hobart à faible (140 tours/minute) ou à moyenne (280 tours/minute) vitesse. Le processus A 20 comporte le malaxage pendant 20 minutes à faible vitesse. Le processus B 20 est celui du standard API utilisant un mélangeur à grande vitesse pendant 1 minute à titre de malaxage préliminaire, suivi d'un malaxage de 20 minutes à faible vitesse dans un gobelet B, Bl et Bh sont d'autres variantes du processus de malaxage dans un mélangeur à grande vitesse, comportant des malaxages à faible (3 500 tours/minute) et grande (17 000 tours/minute) vitesse, mais sans dépasser un temps de malaxage de 1 minute. De telles variations dans l'intensité du malaxage n'ont qu'une incidence mineure sur la fluidité. La fig. 4 montre que les seuils de rigidité et les viscoplasticités, de toutes ces pâtes mélangées et malaxées sont sensiblement plus faibles que celles des pâtes malaxées moins énergiquement. Cependant, après addition de 1 % du poids du ciment, d'un additif superplastifiant formé d'un condensat de sulfonate de formaldéhyde de  $\beta$  naphtalène (additionné d'un retardateur de prise), ces variations ont été pratiquement supprimées, notamment les seuils de rigidité sont alors voisins de zéro. Les boucles d'hystérésis sont beaucoup plus minces que celles de la figure 4; les pentes de ces courbes sont à peu près les mêmes que celles obtenues avec des pâtes sans additif malaxées très énergiquement.

Plusieurs des divers types de comportement fluide, obtenus par divers expérimentateurs peuvent être expliqués qualitativement par des ruptures de liaisons thixotropiques et une certaine recouvrance, se produisant pendant et après les divers malaxages et les processus d'essais. Dans cet esprit, il est utile de considérer que la force et le nombre des liaisons intergranulaires, dans les structures floculées,

sont des fonctions du temps. Le développement des ruptures thixotropiques et de la recouvrance peut être exprimé dans de tels termes (3), qui permettent aussi de définir un degré de floculation. Bombled et d'autres ont attribué la thixotropie à des variations du degré de floculation, qu'ils ont défini de façon mesurable, par le rapport entre la dimension moyenne des agglomérats floculés et la dimension moyenne des grains (2). Cette définition ne peut pas donner une mesure exacte de la résistance au cisaillement de la structure floculée, mais elle permet d'expliquer les comportements complexes qui ont été observés. Pour ce faire, on admet que le degré de floculation peut être représenté qualitativement en fonction du temps, pendant et après le malaxage comme indiqué sur la fig. 5.

Deux courbes sont présentées : 1) La courbe L-LR correspond à un malaxage à faible intensité pendant un temps M, puis à une recouvrance le long de la courbe LR si la pâte est laissée au repos, 2) La courbe H-HR qui correspond à une pâte malaxée énergiquement (mais pas assez longtemps pour produire d'autres effets) et sa recouvrance. Une décroissance exponentielle des courbes est observée, à la fois pour la période des ruptures et celle de la recouvrance; mais la durée constante de la recouvrance semble être au moins dix fois plus grande que la période des ruptures. Ceci est cohérent avec des durées des périodes de rupture de l'ordre de 1 minute (3, 21), et des durées de la recouvrance, indiquées par le changement de l'écoulement antithixotropique en écoulement thixotropique, de 30 à 45 minutes (23, 25). Un point important est que ces pâtes à cause de leur haut degré de floculation, ou à cause d'un malaxage et d'une recouvrance insuffisants, donneront lieu à davantage de ruptures thixotropiques, que les pâtes plus complètement dispersées par un malaxage énergétique.

Les pâtes plus complètement dispersées subiront une recouvrance plus rapide après malaxage, et tendront vers un comportement antithixotropique si le processus de la recouvrance se superpose aux modifications imposées par l'essai de mesure. Cependant si la pâte malaxée énergiquement est laissée au repos après le malaxage, le degré de floculation retrouvera le même niveau que celui de la pâte malaxée à faible intensité pendant quelque temps P, comme montré sur la fig. 5.

Les variations du degré de floculation provoquées par l'essai lui-même apparaissent, pour un seul cycle, sur la fig. 6, les courbes du haut et du bas ayant été obtenues à l'aide d'un viscosimètre, en maintenant constantes les vitesses des variations de vitesse du cisaillement, comme indiqué sur la partie basse de la figure. La courbe en forme de S, montre les variations du degré de floculation de la pâte, lorsque la vitesse croît lentement au début de l'essai. Pendant l'essai, le degré de floculation diminue lentement, seulement aux faibles vitesses de cisaillement initiales; mais décroît plus rapidement pour les plus grandes vitesses de cisaillement, puis de nouveau, plus lentement, pour les faibles vitesses de cisaillement de la fin de l'essai. D'autre part, si la pâte au repos a récupéré sa recouvrance, à une vitesse appréciable, comme indiqué sur la courbe de recouvrance R, la courbe obtenue résulte de la superposition de deux effets qui ressemblent à ceux de la courbe T. La courbe T peut varier entre les positions

Fig. 5 - Variations du degré de floculation des grains de ciment dans des pâtes, pendant un malaxage à haute intensité H, ou à faible intensité L, et pendant la recouvrance, la pâte étant mise au repos après le malaxage

extrêmes S et R, selon les conditions de l'essai, et peut être considérée comme thixotropique ou antithixotropique selon l'effet qui prédominera au cours de l'essai.

#### FACTEURS INFLUANT SUR LA FLUIDITE

La finesse du ciment et le rapport eau ciment de la pâte fraîche sont les deux principaux facteurs qui influent sur la fluidité. Ces deux facteurs commandent ensemble l'épaisseur moyenne des films d'eau d'enrobage des grains et l'espacement intergranulaire. Malgré le fait que les pâtes normales de ciment sont dans l'état floculé dès qu'elles sont au repos, le concept de l'épaisseur moyenne des films d'eau, semble être assez valable pour caractériser les propriétés rhéologiques. Pour déterminer les effets de la teneur en eau, de la finesse et d'autres facteurs plus ou moins simples, Legrand a étudié systématiquement le comportement fluide des pâtes et mortiers confectionnés avec des poudres fines de calcite ou d'autres matériaux (19). Des essais analogues mais moins complets ont été effectués avec des ciments. La valeur maximum du seuil de rigidité de telles pâtes au repos,  $E_0$ , avant les ruptures thixotropiques provoquées par l'essai, est étroitement liée à la concentration en volumes solides  $C$ , suivant la formule :

$$E_0 = Ae^{a(C - 0,5)} \quad (3)$$

dans laquelle  $A$  et  $a$  sont des paramètres déterminés par l'expérience. Quand les pâtes sont vibrées, les seuils de rigidité sont nuls. Les valeurs de  $C$  s'évaluent de 0,475 à 0,677 pour les ciments portland; ce qui correspond à des valeurs du rapport eau ciment variant de 0,15 à 0,35. Bien que le comportement de

ces pâtes, passe, pour ces valeurs de  $C$ , par une transition entre l'état plastique thixotropique et l'état dilatatant, l'équation (3) représente bien les résultats obtenus pour toutes ces valeurs de  $C$ .

Fig. 6 - Variations du degré de floculation des grains de ciment, dans des pâtes pendant leur essai au viscosimètre rotatif, au cours d'un seul cycle. La courbe S correspond à une pâte à recouvrance lente après malaxage. La courbe R correspond à une pâte à recouvrance rapide. La courbe T montre la superposition de ces deux effets S et R.

Les valeurs de  $a$  dans l'équation (3) dépendent de la nature et de la forme des grains, mais sont indépendantes de la surface spécifique et de la distribution granulométrique du matériau; les valeurs de  $a$  s'évaluent entre 23 et 48 selon que les grains sont sphériques ou anguleux. La valeur de  $A$  augmente rapidement avec la surface spécifique du ciment, jusqu'à dépasser environ 100 Pa.

Une relation analogue, a été trouvée, entre la concentration en volumes solides  $C$  et la contrainte de cisaillement  $\tau$ , mesurée à des vitesses constantes de la déformation par cisaillement, pendant que la pâte est vibrée :

$$\tau = Be^{b(C - 0,5)} \quad (4)$$

dans laquelle  $B$  et  $b$  sont des paramètres déterminés par l'expérience. Cette relation est applicable aux valeurs de  $C$  inférieures à la transition entre comportement dilatatant et comportement pseudoplastique. Dans ce cas,  $b$  dépend de la vitesse du cisaillement, de la nature du matériau et de la forme des grains,

mais est indépendant de la surface spécifique et de la distribution granulométrique.  $b$  atteint un maximum d'environ 26 pour une vitesse de déformation de  $40 \text{ s}^{-1}$ . La valeur de  $B$  croît aussi avec la vitesse de cisaillement et la surface spécifique, atteignant plusieurs centaines de Pa pour les ciments finement broyés.

Les formules (3) et (4) représentant les résultats expérimentaux sont utiles, parce qu'elles permettent d'identifier certains facteurs qui peuvent influencer sur la fluidité dans les systèmes les plus simples; la formule (4) est aussi vérifiée pour les pâtes de ciment portland pendant leur vibration. Les résultats obtenus avec des pâtes de ciment portland non vibrées, ont aussi été étudiés, dans le but de déterminer les véritables relations fonctionnelles et de mieux comprendre le rôle des facteurs qui influencent la fluidité. Les résultats obtenus au viscosimètre et indiqués sur la fig. 3, montrent la diminution des seuils de rigidité et des viscosités quand la teneur en eau augmente. Une série d'essais, effectués sur des pâtes de ciment portland ordinaire d'une finesse Blaine de  $447 \text{ m}^2/\text{kg}$ , avec des rapports eau ciment très variés, ont donné les résultats exposés au tableau I.

TABLEAU I		
Rapport E/C en poids g/g	Seuil de rigidité (Pa)	Viscoplasticité en mPa.s
0,4	81	39
0,45	39	22
0,5	25	16
0,6	9	12
0,7	6,4	8,5
0,8	1,6	5,8

Des résultats correspondant à des rapports E/C plus faibles sont donnés sur le tableau II, qui comportent à la fois des mesures faites au viscosimètre et au rhéographe (2)

Bien que l'on ait employé différents ciments et diverses méthodes de malaxage, ces deux ensembles de résultats donnent des valeurs analogues pour le seuil de rigidité en fonction de la teneur en eau.

TABLEAU II	
Rapport E/C en poids g/g	Seuil de rigidité Pa
0,24	1900
0,32	130
0,36	65
0,40	30
0,50	8,5

Les résultats de la fig. 2, montrent l'influence des variations de la surface spécifique du ciment, sur les valeurs initiales du seuil de rigidité, pour des pâtes ayant un rapport E/C de 0,25; ils montrent aussi comment ces valeurs évoluent pendant la prise. L'effet de la finesse du ciment est aussi montré sur le tableau III, pour des pâtes à rapport E/C 0,4, et aussi pour d'autres pâtes dont le rapport E/C a été fixé par la condition d'avoir pour ces pâtes un même seuil de rigidité (2)

TABLEAU III			
Surface spécifique $\text{m}^2/\text{kg}$	Seuil de rigidité pour E/C = 0,4 (Pa)	E/C en poids pour E = 30 Pa	Distance entre grains en microns *
235	14,0	0,35	2,0
278	26,5	0,44	2,3
329	75,0	0,475	2,2
442	165,5	0,55	1,9
560	>250,0	0,58	1,6

\* distance calculée à l'aide de la formule (5) en fonction de la surface spécifique.

Comme on peut s'y attendre, en considérant l'épaisseur des films d'eau et les distances intergranulaires, l'augmentation de la surface spécifique, augmente progressivement le seuil de rigidité pour une même teneur en eau. De même, la teneur en eau nécessaire pour obtenir un seuil de rigidité de 30 Pa augmente systématiquement avec la surface spécifique. Bombled pense que les distances intergranulaires restent approximativement constantes, si la teneur en eau augmente avec la surface spécifique, de façon à maintenir constant le seuil de rigidité (2). La distance intergranulaire (2 fois l'épaisseur du film en microns) est donnée par la formule :

$$d = 2 \times 10^3 \frac{E/C - 0,12}{S} \quad (5)$$

où E/C est le rapport eau ciment, S la surface spécifique du ciment, et 0,12 la proportion de l'eau intersticielle, qui ne contribue ni à l'épaisseur des films ni aux espaces intergranulaires, comme indiqué sur la fig. 1. On voit sur le tableau III que les valeurs de  $d$  sont approximativement constantes.

En plus des formes fonctionnelles (3) et (4), des équations ont été élaborées pour représenter la relation entre la fluidité du ciment et sa finesse. Les résultats du tableau II, ont été utilisés pour établir la formule suivante, valable pour S constante.

$$E_0 = \frac{0,124}{(E/C - 0,15)^{3,97}} \quad (6)$$

Cette formule a été obtenue par la méthode des moindres carrés. Pour obtenir le meilleur ajustement, la teneur en eau qui ne contribue pas à l'écoulement, doit être prise égale à 0,15. Les résultats du tableau III, ont été tracés sur un diagramme logarithmique, dont la pente a permis d'obtenir la formule

$$E_0 = 4,47 \times 10^{-9} S^{4,01} \quad (7)$$

Le fait que les exposants dans les deux formules (6) et (7) soient pratiquement égaux, montre à nouveau, que le seuil de rigidité est étroitement lié à la surface spécifique et à la teneur en eau. Toutefois, ces données semblent donner aussi de bons ajustements pour d'autres exposants, et d'autres relations, par suite du faible nombre et de la faible précision de ces données.

La relation fonctionnelle entre la viscoplasticité apparente, la teneur en eau et la surface spécifique devient plus compliquée. Dans une étude (9), la viscosité apparente a été trouvée égale à :

$$\eta = 13(d')^{-0,6} - 1 \quad (8)$$

où  $d'$  est un paramètre utilisé pour mesurer l'espace intergranulaire; il s'exprime en microns par la formule :

$$d' = \frac{(E - E_0)^2}{S} \cdot 10^3 \quad (9)$$

dans laquelle les teneurs en eau  $E$  et  $E_0$ , ainsi que la surface spécifique  $S$ , sont calculées par unité de pieds du ciment. La valeur de  $E_0$ , la teneur en eau imposée par l'essai standard, est d'environ 0,3. Ceci conduit à penser que les relations fonctionnelles entre la viscosité et la teneur en eau, peuvent différer considérablement de celles correspondants aux seuils de rigidité pour le ciment portland.

#### ADDITIFS REDUCTEURS D'EAU

Les observations au microscope ont, maintes fois, confirmé que les grains de ciment étaient dispersés par les additifs réducteurs d'eau (2). On a longtemps pensé que cette dispersion était le résultat de la neutralisation des charges superficielles et de la réduction des forces attractives intergranulaires. Les additifs assez récents appelés "super réducteurs d'eau", tels que le formaldéhyde melamine sulfoné (type M) ou le formaldéhyde naphthalène sulfoné (type N), sous forme de condensats ne créent pas de retards importants à l'hydratation. Ils peuvent toutefois, être employés à des concentrations beaucoup plus fortes (plus de 1 % en poids de ciment) que celles que l'on utilisait habituellement avec les additifs aux lignosulfonates. Ce dernier type d'additif provoque habituellement des retards importants à des concentrations quelque peu supérieures à 0,1 %, que cet additif contienne ou non du sucre (27).

Daimon et Roy (28) ont mesuré la loi d'adsorption du condensat de formaldéhyde naphthalène sulfoné par les grains de ciment dans l'eau, ils ont trouvé que celle-ci correspondait à une isotherme de Langmuir. Ils ont aussi montré qu'avec le ciment utilisé (393 m<sup>2</sup>/kg) et

avec des proportions d'additifs d'environ 1,5 %, presque tout le composant actif était adsorbé (environ 20 % n'était pas adsorbable); mais quand on augmentait fortement cette proportion d'additif, une part rapidement croissante, restait en solution. Les mesures du potentiel zéta des grains les plus fins du ciment, ont montré que ses variations en fonction de la proportion d'additif suivait une isotherme d'adsorption de Langmuir, atteignant des valeurs d'environ 50 mV, au maximum de l'adsorption (29). Des essais d'écoulement des mortiers ont aussi montré un accroissement similaire en fonction de la proportion d'additif. Des mesures faites au viscosimètre rotatif ont montré que les seuils de rigidité initiaux, qui variaient de 40 à 100 Pa (selon l'énergie du malaxage) pour la pâte pure à 0,4 d'eau, diminuaient jusqu'à zéro pour une proportion d'additif de 1 %. La viscosité apparente, diminuait aussi de 500 environ à 200 mPa/s environ, si la pâte était malaxée peu énergiquement (ASTM); mais cette diminution était très faible si la pâte était malaxée très énergiquement (API), comme indiqué dans la discussion de la figure 4.

L'adsorption de deux additifs du type N et de deux polymères du système à haut poids moléculaire, par les ciments, a pu être portée (30) jusqu'à 0,5 % du poids du ciment. Pour les additifs du type N, la loi d'adsorption était du type isotherme de Langmuir; pour le polymère du styrène elle a été du type H (forte affinité). Les mesures de vitesse de sédimentation, avec des additifs du type N, de suspensions diluées de ciment dans l'eau (3 g dans 28,5 ml) ont montré la bonne séparation des grains; car la vitesse de sédimentation diminuait quand on ajoutait l'additif jusqu'à une proportion de 0,4 % en poids du ciment.

Petri (14) a mesuré la viscosité apparente des pâtes de ciment, à l'aide du viscosimètre rotatif de Brookfield, avec ou sans ajout d'additifs divers. Ces ajouts ont atteint 1,6 % du poids du ciment. On a constaté, en accroissant l'ajout d'additifs du type N, une diminution progressive du seuil de rigidité, de la viscosité et de l'aire des boucles d'hystérésis, par augmentation et diminution de la vitesse de cisaillement, jusqu'à ce qu'un comportement newtonien soit obtenu, pour une proportion de 1,2 % d'additif. Un autre additif essayé par Petri l'hexamétaphosphate de sodium, a produit son effet maximum pour une proportion d'environ 0,5 %.

Petri a aussi tenté de déterminer la relation fonctionnelle, autre la viscosité apparente  $\eta$  de la pâte de ciment, et la concentration en volumes solides  $C$ . Les résultats concernant les pâtes de ciment sans additif n'ont satisfait aucune des nombreuses équations théoriques de l'électroviscosité. Ceci n'est pas surprenant, car ces équations ont été établies dans l'hypothèse d'un comportement newtonien. Cependant, Petri, a trouvé que pour les pâtes contenant 1 % d'additif du type N, les mesures faites sur les suspensions correspondaient remarquablement au modèle théorique de sphères, de dimensions égales, et sans attractions mutuelles, dans une suspension très concentrée; dans ce cas on a :

$$\eta = \eta_0 (1 - 1,35 C)^{-2,5} \quad (10)$$

Les recherches continuent sur l'emploi de lignosulfonate comme additif réducteur d'eau, particulièrement

dans les pâtes à faible rapport eau ciment. On y ajoute du carbonate soluble pour éviter un retard de prise excessif. Odler et coll. (17) ont étudié les propriétés rhéologiques des pâtes de ciment portland (à 6 % de gypse), avec ou sans lignosulfonate de sodium additionné de carbonate de soude, et des pâtes de clinker pulvérisé, avec les mêmes additions. Il fut ajouté jusqu'à 1,25 % de chacun de ces deux additifs, et quand ils étaient tous les deux ajoutés on a observé un effet fluidifiant et régulateur de prise. La finesse variait de 340 à 850 m<sup>2</sup>/kg. Lorsque le ciment était gypsé, le temps de prise était réduit, mais sur les produits non gypsés ces additifs produisaient un comportement normal à la prise et un durcissement accéléré. Les mélanges à rapport eau ciment aussi bas que 0,225 étaient suffisamment fluides pour pouvoir être essayés au viscosimètre rotatif. Comme indiqué précédemment, on observa un comportement avec épaississement de ces pâtes. Dans une autre étude (31), utilisant du lignosulfonate de calcium, et du carbonate de potassium, des difficultés apparurent au-dessous d'un rapport eau ciment de 0,25, pour l'essai de ces pâtes dans un viscosimètre rotatif. Ces pâtes sont décrites comme ayant une consistance caoutchouteuse. D'autres expérimentateurs ont utilisé des lignosulfonates avec NaHCO<sub>3</sub>, pour produire des pâtes, ayant des rapports eau ciment variant de 0,22 à 0,24, qui se sont montrées "automontantes", mais qui avaient des propriétés rhéologiques très complexes; elles semblaient avoir des propriétés élastoplastiques, difficilement caractérisables en termes normaux (20).

#### COMPOSITION DES CEMENTS ET HYDRATATION

Pour les ciments dont les premières réactions d'hydratation ont été correctement contrôlées, les propriétés rhéologiques, pendant la période de latence, ne dépendaient pas beaucoup de la composition de ces ciments. Une étude portant sur douze ciments de divers types, a conclu, que, sauf pour un ciment à prise régularisée, la composition chimique et minéralogique du ciment, avait peu d'influence, sur le comportement rhéologique, comparativement à l'influence de la teneur en eau et de la finesse du ciment (25). Cependant, l'eau nécessaire à rendre fluide une pâte, augmente d'une façon significative avec la proportion de C<sub>2</sub>A et d'alcalis; elle en dépend autant que de la distribution granulométrique (32). En outre, le sulfate de calcium doit être sous une forme convenable, pour contrôler les réactions initiales des aluminates et empêcher la fausse prise (24 - 33). Cependant, si les mesures au viscosimètre sont poursuivies assez longtemps au cours de l'hydratation, l'effet de la teneur en C<sub>2</sub>A devient progressivement plus important. Des mesures faites sur des ciments contenant des teneurs en C<sub>2</sub>A variant de 0 à 14 %, ont montré une faible variation du seuil de rigidité, de la viscoplasticité ou de l'aire des boucles d'hystérésis, pendant les 45 minutes suivant le malaxage (23). Cependant, deux heures après malaxage, la thixotropie, représentée par l'aire des boucles d'hystérésis, augmentait fortement quand la teneur en C<sub>2</sub>A dépassait 2 %. Le seuil de rigidité, lui aussi commençait à croître avec la teneur en C<sub>2</sub>A après 2 heures. La viscoplasticité n'a, cependant, pas sensiblement présenté le même effet même après 3 heures.

Wittmann (34) a étudié l'effet d'un additif du type M, sur la viscosité des pâtes de ciment, ayant un rapport eau ciment de 0,6, à des âges supérieurs à 7 heures. Pour les pâtes sans additif, les courbes

de la viscosité en fonction du temps, ont montré, pour différentes vitesses de rotation du viscosimètre, une augmentation du temps d'hydratation plus grande que celle obtenue au rhéographe (fig. 2). Pour une vitesse de rotation de 80 tours/minute, la viscosité apparente augmentait d'environ 2000 à l'origine jusqu'à plus de 20000 mPa/s, après environ 4 heures. Ces valeurs paraissent extraordinairement élevées. Avec 1,5 % d'additif, la viscosité initiale tombe à une valeur d'environ 50 mPa/s, et montre au bout d'une heure ou deux, un comportement très proche du comportement newtonien idéal. Après environ 3 heures, la viscosité n'est plus newtonienne, et la vitesse de cisaillement augmente jusqu'à près de 20000 mPa/s, à 80 tours minute, après environ 7 heures. Des études entreprises sur plusieurs ciments différents ont donné des résultats analogues, sauf pour un ciment du type PZ 550, qui exige un plus fort pourcentage d'additif pour retarder l'augmentation de la viscosité. Ceux-ci, et bien d'autres résultats, comme ceux indiqués sur la fig. 2, montrent que le raidissement de la pâte au cours de la prise, suit, normalement, un processus progressif. Ce processus résulte des réactions d'hydratation initiales, et il est affecté par certains facteurs qui accélèrent ou retardent l'hydratation.

#### CONCLUSION ET DISCUSSION

Il apparaît à la lecture de la littérature disponible, qu'il y a encore d'importantes lacunes dans notre connaissance de la rhéologie des pâtes fraîches de ciment. On a tenté, avec difficulté, d'exprimer quantitativement les résultats en fonction des propriétés des matériaux, et d'établir des relations entre la concentration et les propriétés du ciment. Un résultat, au moins partiel, est le suivant : le processus de malaxage des pâtes de ciment, et les méthodes de mesure de leurs propriétés rhéologiques, influent sur les propriétés à mesurer. Il semble souhaitable d'étudier la rhéologie des pâtes de ciment, dans un état de dispersion des grains dans l'eau, comparable à celui qui existe dans les pâtes du béton. Pour cette raison T.C. Powers préconise l'emploi de mélanges à grande vitesse, parce qu'il pense que les vitesses de cisaillement des pâtes de ciment dans les malaxeurs à béton, sont au moins aussi énergiques, que dans les malaxeurs de pâte à ciment des laboratoires. Nous avons vu récemment des résultats qui montrent des différences sensibles entre les malaxeurs de chantier et les malaxeurs des essais normalisés. Il serait alors prudent, si cela n'a pas encore été fait, de commencer par définir l'intensité du malaxage désirée; ensuite on pourrait concentrer nos efforts sur les pâtes ainsi malaxées. Des considérations, analogues peuvent intervenir, en ce qui concerne les types très variés de viscosimètres rotatifs. Des expérimentations très soignées ont, d'autre part, été entreprises, sur les appareils de mesure, dont la conception et les dispositions constructives, peuvent empêcher des mesures quantitatives, car ne créant pas un malaxage uniforme et régulier, ou provoquant des ruptures de l'écoulement. Il apparaît que ce problème a été bien perçu par certains expérimentateurs, et que plusieurs méthodes valables vont apparaître permettant de réaliser des essais reproductifs. Peut être, on pourrait mettre au point des méthodes valables de comparaison des divers essais rhéologiques, soit en choisissant un ciment standardisé bien défini servant d'étalon, soit en utilisant un matériau inerte ayant des propriétés rhéologiques proches de celles du ciment.

En ce qui concerne les interprétations théoriques, la situation pouvait aussi, être sensiblement améliorée. Petri (14) considère la théorie des suspensions fluides, de grains chargés électriquement par un électrolyte, c'est-à-dire l'électroviscosité. Les équations complexes qui représentent la viscosité de telles suspensions, font appel aux paramètres électriques des potentiels de double couche, aussi bien qu'à la concentration en volumes solides  $C$ , et à la viscosité du liquide. Sous leur forme réduite, la plus simple, ces équations donnent :

$$\eta = \eta_0 (1 + kC) \quad (11)$$

qui, pour  $k = 2,5$  donne l'équation bien connue d'Einstein. Ceci met en évidence une imperfection flagrante de la théorie, lorsqu'on l'applique aux systèmes, tels que les pâtes de ciment, dans lesquels les forces intergranulaires provoquent une floculation et la formation d'une structure, ayant un seuil de rigidité non nulle, dépendant de la vitesse de déformation, et une thixotropie, c'est-à-dire un comportement non newtonien.

Néanmoins, les recherches sont parvenues à nous fournir une compréhension qualitative et parfois même semi-qualitative du comportement complexe des pâtes fraîches de ciment. Plusieurs formules empiriques, donnant semble-t-il satisfaction, ont été établies pour relier les propriétés rhéologiques des pâtes fraîches, à la surface spécifique du ciment, et à sa concentration dans l'eau. Cette matière semble mériter des recherches complémentaires, l'objectif étant de pouvoir prévoir à l'avance, de façon sûre, les propriétés rhéologiques des pâtes fraîches de ciment, en fonction de la composition du ciment et de ses propriétés physiques.

Le développement rapide de l'emploi de réducteurs d'eau organiques et d'autres additifs dans le béton, et l'apparition de nouveaux additifs, a provoqué maintes recherches sur leur action sur les propriétés rhéologiques des pâtes de ciment. De telles recherches ont généralement pour but de connaître l'efficacité d'additifs particuliers. Cependant, puisque le comportement rhéologique des pâtes de ciment contenant des additifs est plus simple que celui des pâtes sans additif, il doit être possible d'établir les véritables relations fonctionnelles qui commandent l'état dispersé, puis, ensuite, s'attaquer aux problèmes des pâtes floculées à divers degrés.

\* This communication constitutes the principal report of sub-theme VI-0 which was received too late to be published in the volume 1 "Principal Reports".

## INTRODUCTION

The properties of fresh portland cement pastes are of interest primarily because of their relationship to the properties of concrete. Of universal interest are the characteristics of cements that influence the consistency, workability, and setting characteristics of the concrete. Understanding how to control the rheological properties of fresh concrete is important for the economical proportioning of concrete mixtures and the proper mixing and placement of concrete.

Microscopic examinations of sections of normal hardened concrete show each aggregate particle to be suspended in a matrix of hardened cement paste with films of paste completely separating the particles. Hence, the fresh concrete must have had this kind of structure in the quiescent state at the time of setting. However, during the mixing and placement of the concrete, the coarse aggregate and sand particles must come into frequent direct contact. Such direct contact between aggregate particles results in frictional forces and particle interference effects in addition to the resistance to flow of the cement paste itself.

Although progress in the development of an understanding of the relationship between the rheology of concrete and cement paste has been made (1-5), most standard testing procedures for cements, mortars, and concretes are purely empirical and results obtained by different tests may appear to be inconsistent. For example, a more finely ground cement may have a higher water requirement or a stiffer consistency than a coarser cement in a cement-water paste, but may have a lower water requirement (or greater flow) when tested in a plastic mortar because of a smaller amount of interference by the largest cement particles to the motion of sand particles in the mortar.

Tests to measure concrete or mortar consistencies include those that measure deformation due to the force of gravity, and the cumulative deformation (or time to a given deformation) under repeated impact or vibrational and gravitational forces. Such tests yield numerical results on arbitrary scales which have no simple relationship to any well defined physical properties such as yield value (minimum shear stress for flow) or viscosity. The slump test has been shown to be a measure of the yield value of fresh concrete, and the compacting factor and Vebe tests are measures of the apparent viscosity (6). However, it has been shown that no single-point test provides an adequate measure of the flow properties and workability of concretes under various conditions (3,7). One reason for this is that there is an important difference between the state of the paste before and after it has begun to

flow. It is common practice to use vibration to cause stiff fresh concrete mixtures to flow readily into place in the forms. Weak structures in the paste are broken down by steady shear or by vibration. The paste is then said to be in the fluidized state. The consistency of concrete while it is being placed by vibration is due, at least in part, to the rheological characteristics of its paste component in the fluidized state (1). The resistance of fresh concrete to deformation and flow when in the static state must also be due, at least in part, to the yield value of the cement paste.

The resistance of portland cement paste to shear is both time and shear strain rate dependent. It also depends upon mixing time and intensity. Cement pastes are normally thixotropic, or shear thinning, as a result of progressive breakdown of the flocculent structure of the particles as the paste is forced to flow. Hydration of the cement has some short term effects (brief mix set, false set) as well as the normal progressive stiffening. The flow behavior can therefore be very complex for even a single cement and comparisons between cements can be strongly affected by variations in methods of test and equipment employed.

The properties of fresh portland cement paste are also of interest relative to research on other characteristics of cements. For example, study of the properties of fresh pastes is useful in determining how cement particle size distributions might be improved, or how the gypsum content and other additions can be varied to obtain proper control of the early hydration reactions. From the time of initial mixing of the cement with water, the processes of solution and formation of hydrates cause progressive changes of the structure and rheological properties of the paste.

## FRESH PASTE STRUCTURE

Modern portland cements are ground to a fine powder in which only a few percent of the cement is coarser than 74  $\mu\text{m}$ , or finer than 1  $\mu\text{m}$ . The particle shapes are the result of random multiple fracturing of the polymineralic clinker during finish grinding and tend to vary in shape from somewhat rounded to more angular grains. Hence, particle size distributions using equivalent spherical diameters for equal sedimentation velocities or surface areas should be good approximations.

Modern cements commonly have specific surface areas of 300-500  $\text{m}^2/\text{kg}$  (3000-5000  $\text{cm}^2/\text{g}$ ), as measured by air permeability methods such as those due to Lea and Nurse or Blaine (ASTM C204). Some methods, such as the ASTM C115 Wagner Turbidimeter method, yield much lower values because the amounts of the finest particles are

underestimated. Certain other sedimentation methods determine amounts of fine cement particles that yield specific surface areas in close agreement with air permeability methods. By contrast, the values of the specific surface areas of cement as determined by nitrogen adsorption (BET method) are much larger than the air permeability values because adsorption methods determine the surface areas of the hydrates and other very small particles adhering to the surfaces of the cement particles, as well as the cracks, fissures and perhaps some of the pores in the clinker particles. It appears that the Blaine surface areas are more appropriate for use in the consideration of flow or sedimentation than the BET values because the water flow around the particles defines a smooth cement particle - water interface and does not detect minor irregularities of the particle surfaces.

Fresh cement pastes are initially a thick suspension of the cement particles in the mixing water. The structure of this suspension depends upon the water-cement ratio and the particle size distribution of the cement. It also depends upon the interparticle forces and attraction of the water to the solid surfaces, which in turn depends upon surface charges, ionic species and concentrations in solution, and sorption from solution. In dilute suspensions cement particles normally will flocculate, forming separate clusters of particles called flocs; these settle rapidly. Flocs formed from ordinary cement in dilute suspensions have a water-cement ratio of about 0.4. In the thick suspensions we call cement pastes, the separate flocs in the static state merge into a single continuous large floc. The particles are not uniformly distributed in such a structure; there are aggregations of higher than average particle concentrations between which are water-filled interstices. Within these aggregations the particles tend to have smaller interparticle separations corresponding to minimum potential energy configurations. Powers has called this the flocculent state (1).

During mixing, the cement particles tend instead to become more uniformly dispersed in the water. There is a continuous breaking down of the structure during mixing; this is the origin of the thixotropic, or shear-thinning, behavior of cement pastes. At any constant rate of shear an equilibrium structure (perhaps floc size distribution) is reached within several minutes, resulting in a constant apparent viscosity. There is also a counteracting process of structure reformation. When the mixing is stopped, the static floc structure gradually forms again. Although the paste is a fluid during mixing, the floc structure is a weak solid, with a finite yield value, in the static state.

Certain organic (water-reducing) admixtures are used in concrete to improve its flow properties or reduce the water requirement for flow. Microscopic examinations show that when suitable amounts of such admixtures are used, the cement particles are completely dispersed in the water instead of being in the flocculent state. This is believed to be a result of adsorption of the admixture molecules on the cement particle surfaces, neutralization of charges, and the development of static repulsive forces between cement particles.

Some of these concepts can be used to visualize the structure of fresh cement pastes in terms of a simple model (8) as depicted in Fig. 1. The particles are represented

Fig. 1 - Simple dispersed spherical particle model of the structure of fresh cement paste of 0.5 water-cement ratio; 430 kg/cm<sup>2</sup> cement (8).

as spheres of sizes given by the equivalent spherical diameters of the particle size distribution curve typical of a cement of 430 m<sup>2</sup>/kg specific surface area. The large half-sphere at the bottom represents a 30  $\mu$ m particle. The spaces between large particles are filled with smaller particles and water. The figure is drawn for a paste with a water-cement ratio of 0.5. Because the water is strongly attracted to the particle surfaces, each particle is shown with a continuous film of water; if the cement is dispersed by vigorous mixing or with the use of a water-reducing admixture, the thicknesses of these films will tend to equalize as much as possible. A first approximation to the average thickness of these films is given by the hydraulic radius: the volume of water divided by the specific surface area of the cement. For this cement and water-cement ratio, the average film thickness is about 1.2  $\mu$ m, only about one-tenth of the mass median particle diameter. Although the model is better suited to dispersed cements than

for pastes in the flocculent state, the average value of the film thicknesses will be the same. Second approximations have been proposed which consider the interstitial water outside of the films (2,9).

The early hydration reactions of the cement must also be considered in more realistic models of fresh paste structure. The initial rapid solution of the gypsum and alkali phases in the cement results in an aqueous solution of the hydroxides and sulfates of sodium, potassium, and calcium. With proper gypsum control of the hydration of the tricalcium aluminate, a sulfoaluminate coating is formed which almost stops the  $C_3A$  hydration after the rapid initial reaction. About 10% of the  $C_3A$  may hydrate in the first few minutes (10), after which the  $C_3A$  hydration is very slow until the gypsum is depleted, which usually occurs after final set. The depth of the reaction into the  $C_3A$  during the initial (10%) reaction can be estimated to be about 0.1  $\mu\text{m}$ . If the reaction product is densely packed ettringite, these  $C_3A$  surfaces would be coated with a layer of about 0.8  $\mu\text{m}$ . Nearly half of the gypsum would be consumed in this initial reaction; if the gypsum had an initial specific surface area of about 800  $\text{m}^2/\text{kg}$  and if each gypsum particle dissolved to equal depths, the depth would be about 0.5  $\mu\text{m}$ . After this reaction the specific surface area of the remaining gypsum particles would be less than half this value, so that the specific surface area of the cement would be reduced by about 30  $\text{m}^2/\text{kg}$ . However, the BET surface area would be increased by formation of hydration products; if these hydrates form on the cement particle surfaces, they should not have any adverse effect on flow at this stage. Ettringite formation would by itself reduce the free water content of the paste by about 0.02 g/g cement for the same (10%) reaction.

All of these initial processes affect the specific surface area, free water content and, therefore, the water film thicknesses during the dormant period. The initial hydration reaction of the silicate surfaces should have little effect on the fresh paste structure unless vigorous mixing is continued so that the hydrates are continuously abraded from the surface. After the induction period, crystals of calcium hydroxide begin to form out of solution; this accelerates the hydration of the silicates and the formation of calcium silicate hydrate in acicular growths over all of the available solid surfaces. Normal setting occurs as a result of the intergrowth of these hydrates; ettringite recrystallization may also contribute to the setting (10).

#### DEFORMATION AND FLOW BEHAVIOR

The consistencies of fresh cement pastes up to the time of set vary so widely with composition and time that no single method of

measurement suffices for the entire range. Viscometers, especially coaxial cylinders viscometers, are commonly used for the more fluid pastes with yield stress values up to about 200 Pa (2000 dynes/cm<sup>2</sup>) and apparent viscosities of up to several thousand mPa·s (= centipoise). Recently, a mini-slump cone test has also been found useful for comparing flow properties of cement pastes of different compositions (11). In this test a small cone filled with paste is lifted so that the paste flows out to form a pat; the area of the pat is used as a measure of the consistency. For stiffer pastes, penetration tests such as Vicat needles are more suitable for the determination of the water content for normal consistency and the initial and final set times. A versatile automatic instrument, the rheograph described by Bombléd (12,13), measures the yield value by penetration tests over a very wide range of paste shear strengths, from about 30 to more than  $1.5 \times 10^5$  Pa. It therefore somewhat overlaps the upper part of the range of coaxial cylinders viscometers and extends the range beyond the Vicat initial and final set yield values, which were found to correspond to shear strengths of  $2 \times 10^4$  and  $1 \times 10^5$  Pa, respectively.

Figure 2 gives five examples of rheograph curves for cement pastes made at water-cement ratios of 0.25 with cements of different finenesses (13). The yield values (shear strengths) are calculated from the force required to produce a penetration of 20 mm by one of several probes ranging in diameter from 1 to 12 mm. The initial yield values are, in these cases, rather high because of the low water-cement ratio. Normal consistency pastes have initial yield values of about 2000 Pa. Two of these pastes were stiffer than normal consistency. These curves can be used to define and calculate various parameters useful in characterizing the setting of cements, such as the initial and final set times, the rate of setting, and a time period analogous to the dormant period, during which the yield value is approximately constant. At higher water contents, the early part of the curve is nearly horizontal.

Despite the fact that such static tests clearly show the existence of a yield value for ordinary cement pastes, the results obtained dynamically with viscometers often do not indicate well defined yield values. The shear strain rate versus shear stress curves obtained with rotational viscometers (see Fig. 3) depend strongly on the flow history of the pastes and also on the apparatus used. Depending on the paste composition and testing conditions, cement pastes exhibit flow behavior approximating any of four main types: 1) Newtonian, 2) Binghamian, 3) pseudoplastic, and 4) dilatant. In addition, the

Fig. 2 - Rheograph curves for cement pastes (ground clinker plus 5% gypsum at 0.25 water-cement ratio) for cements of various finenesses. 1) 201 m<sup>2</sup>/kg; 2) 248.5 m<sup>2</sup>/kg; 3) 307 m<sup>2</sup>/kg; 4) 403 m<sup>2</sup>/kg; 5) 511 m<sup>2</sup>/kg (13).

curves may indicate reversible, or thixotropic (shear thinning), or antithixotropic (shear thickening) behavior. Antithixotropy seems to be a manifestation of the thixotropic recovery process, which should, therefore, be distinguished from dilatancy, which is also shear thickening but for other reasons.

**NEWTONIAN AND BINGHAMIAN FLOW.** When the rate of shear strain,  $\dot{\gamma}$ , is directly proportional to the shear stress,  $\tau$ , a fluid is said to be Newtonian with a constant coefficient of viscosity.

Cement pastes are not normally Newtonian but can become very nearly so with additions of sufficient amounts of certain water-reducing admixtures (14-17). Cement

Fig. 3 - Rotational viscometer curves for several cement pastes. 1) w/c = 0.4; 2) w/c = 0.35, held at constant speed for equilibration; 3,4) w/c = 0.32; 3 immediately after mixing; 4 immediately after the first measurement (2).

pastes often approximate a Bingham plastic solid with a finite yield value,  $f$ , and plastic viscosity,  $U$ , so that:

$$\dot{\gamma} = \frac{1}{U} (\tau - f) \quad (1)$$

Results of rheological measurements on cement pastes are often presented graphically (as in Fig. 3) with the shear stress (or torque in a rotational viscometer) as the abscissa and the shear strain rate (or rotational speed) as the ordinate (2). In such plots, Newtonian fluids yield straight lines through the origin ( $f = 0$  in Eq. 1). Bingham plastic solids yield straight lines with an intercept at  $f$ ; in this case the slope of the straight line is the reciprocal of the plastic viscosity; the apparent viscosity is  $\tau/\dot{\gamma}$ , i.e., the reciprocal of the slope of a line through the origin to any point along the line of Eq. 1. Hence, even if the plastic viscosity is constant, the apparent viscosity is shear rate dependent and may be very much higher than the plastic viscosity at low shear rates because of the finite yield value.

**PSEUDOPLASTICITY.** The yield values indicated in viscometer tests of cement pastes are not as sharply defined as in the Bingham plastic model. Instead; plots of shear rate vs shear stress may curve gradually upward from the stress axis to an approximately linear portion (Fig. 3) and are

termed pseudoplastic or plastic-thixotropic. This linear portion, or the reverse at decreasing shear rates, may then be used to estimate the yield value by extrapolation. The curved portion may be a result of the combination of non-uniform flow of the sample and the thixotropic nature of the material in instruments in which the gap between the cup and bob in the viscometer is too wide (1).

During testing of cement pastes in coaxial cylinders viscometers, uniform flow may not be immediately achieved. Instead, some slippage occurs, with a portion of the paste flowing and a portion remaining as a plug. The shear rate in the flowing portion is then much higher than indicated by the speed of rotation and the gap width. Eventually the entire volume of paste flows apparently uniformly. These phenomena have been investigated in some detail using both smooth and serrated cylinders in connection with time and shear rate dependence studies of cement pastes (18).

In a different approach, Legrand (19) used a viscometer with a set of radial blades immersed in a much larger cup of sample. The variation of the torque with time through the non-uniform flow period was analyzed to determine the yield value, the shear stress and shear strain rate at constant rotor speeds.

**DILATANCY.** There is a progressive transition of flow properties from plastic-thixotropic to dilatant (shear thickening) behavior as the volume concentration of solids is increased in mortars of cement fineness (19). When the volume fraction of solids exceeds about 0.6, the resistance to shear increases with shear rate and volume expansion occurs during shear. The curve is then concave to the shear stress axis instead of convex as for the curves in Fig. 3. These effects are a result of changes in the packing of the particles that are required to permit the particles to move past one another along shear surfaces. The result is increased average separations of particles in the direction perpendicular to the direction of shear. The water is then required to flow into the enlarged separations and the resistance to shear, therefore, depends upon the shear rate and the permeability of the material to such flow. Also, since water and the solids have small compressibilities, some air will tend to be drawn into the mixture to provide the necessary dilatancy during shearing during mixing. This entrapped air provides the capacity for dilation without requiring as much water flow.

These particle interference effects produce rapid increases in the yield value and apparent viscosity as the volume concentration of solids exceeds about 0.60 when the material is not vibrated. When the material is vibrated the flow behavior is altered, but this transition to dilatancy

occurs at only slightly higher (0.62) volume concentration of solids.

These same considerations also apply to the cement paste itself at very low water-cement ratios. A volume concentration of cement in water of 0.6 (40% water by volume) corresponds to a water-cement ratio of 0.21. Dilatant type curves have been obtained at water-cement ratios in this range in ground clinker pastes fluidized with lignosulfonate and soluble carbonate additions (17,20).

**THIXOTROPY.** It has been shown (3, 18, 21-22) that under proper experimental conditions (constant rate of shear, uniform flow) in a coaxial cylinders viscometer the initial torque,  $T_0$ , decays exponentially with time,  $t$ , to an equilibrium value  $T_E$  according to:

$$T = T_E + (T_0 - T_E)e^{-Bt} \quad (2)$$

where  $B$  is a breakdown constant which depends upon the shear strain rate (or angular speed) and properties of the paste. Values of  $B$  are of the order of  $0.04 \text{ s}^{-1}$ . The breakdown process reaches essential equilibrium in 1 or 2 minutes. Since  $T_0$  may be several times  $T_E$ , this process may have a considerable effect on the shapes of shear rate vs shear stress curves obtained, depending on the time allowed for each point at increasing (up curve) and then decreasing (down curve) rates of shear (Green's method). Figure 3 shows examples of the thixotropic behavior of cement pastes in such tests (2). There are four manifestations of the apparent thixotropy shown.

1. The curvature of the up curve indicates decreasing viscosities with increasing shear strain rates.
2. The up curves have higher shear stresses (at equal shear rates) than the down curves.
3. Curve 2 shows the decrease in shear stress while the paste is mixed in the viscometer at constant speeds.
4. Curve 4 shows lower shear stresses upon immediately repeating the curve 3 test.

The hysteresis loop 4 is not only shifted to lower shear stresses, (and lower plastic viscosities) but loop 3 was also larger than loop 4, indicating more breakdown during the first cycle than during the second cycle. For standard test conditions the areas of the hysteresis loops so formed have been used as a measure of the amount of breakdown of the thixotropic structure (23). Attempts have also been made to determine quantitatively the energy per unit volume required for the

thixotropic breakdown process from constant rate of shear tests as with Eq. 2 (3,22).

Another manifestation of thixotropy is shown in tests in which the maximum shear rate is increased in successive cycles. When that is done the loops also shift to lower stresses and lower plastic viscosities, indicating more breakdown at higher shear rates (3).

**ANTITHIXOTROPY AND THE EFFECTS OF MIXING.** Obtaining results with coaxial cylinders viscometers that show well defined yield values and lower viscosities at low shear rates seem to depend upon the degree of dispersion of the cement particles by adequate mixing and use of viscometers with very narrow gap widths. Although Greenberg and Meyer (24) reported in 1963 that to obtain uniform flow it was necessary for them to use a gap width of about 1.0 mm, much of the published data has been obtained with gaps too wide to avoid instrumental effects. Another factor may be the smoothness of operation and freedom from vibration of the equipment; vibration or shocks may initiate non-uniform flow at low yield stresses. Recently published data obtained by Roy and Asaga (15) using an improved viscometer with a 0.7 mm gap showed remarkably linear up curves with distinctly indicated yield values, i.e., nearly Binghamian behavior (see Fig. 4). By contrast, viscometers with larger (4 mm or more) gaps give results indicating pseudoplastic behavior with no distinct yield value (2,22,25). It should be noted that the hysteresis curves in Fig. 4 are considerably different from most other published data. Not only do they show distinct yield values at increasing shear stress, but the hysteresis loops show considerable antithixotropy or shear thickening, that is, higher stresses occurred on the down curves than on the up curves at equal shear rates. The viscometer and procedures used by Roy and Asaga yielded results largely free of the plastic-thixotropic behavior often observed. Also, one reason for the large area of the antithixotropic hysteresis loop appears to be that the test was conducted more slowly (15 minutes/cycle) than in the usual few minutes. Hence, more time was allowed for both the thixotropic breakdown and recovery processes.

Several workers have observed both thixotropic and antithixotropic behavior of the same pastes (23,24,25) at different times after mixing. Pseudoplastic curves were obtained at faster rates (2-3 minutes/cycle) than used by Roy and Asaga. The faster testing rate allows less time for thixotropic recovery of freshly mixed pastes. Even so, their results showed that shortly after mixing the pastes were usually slightly antithixotropic, but after some time at rest (30-45 minutes) became thixotropic. However, when the paste after

Fig. 4 - Rotational viscometer curves for pastes mixed by six different methods, w/c = 0.40 (15).

being at rest was agitated by repeated testing, the type of flow curve changed from thixotropic to antithixotropic. At rest for longer times (2-3 hours), the pastes became very strongly thixotropic as setting approached unless continuously agitated. These effects of agitation suggest that the initial mixing intensity should also affect the paste flow properties, and this has been known for some time.

Mechanical mixers capable of producing a uniformly and vigorously mixed paste are normally used, perhaps intermittently, for long enough time periods (5 - 10 minutes) to produce pastes of the best flow properties. Inadequate or excessive mixing increases the paste stiffness. If the paste is mixed for only 30 seconds or less, it will suffer brief-mix-set, thought to be caused by cementing together of the grains by the reaction products formed on their surfaces by the rapid initial reactions with water. Although a mixing time of 1 minute may be long enough to eliminate brief-mix-set, it may not be long enough to effect adequate dispersion or to eliminate false-set due to the formation of gypsum from hemihydrate that may be present in the cement. These gypsum crystals form a weak structure which can be broken down by continued mixing or remixing.

Continuous vigorous mixing also breaks down the flocculent structure of the cement particles responsible for the thixotropic behavior. Measurements like those shown in Fig. 3 for different batches mixed 5 minutes each in a planetary mixer showed that increasing the mixing speed from 150 rpm to 450 rpm shifted the hysteresis

loops to lower shear stresses, and narrowed the loops to a nearly reversible (nonthixotropic) Bingham plastic type behavior. Similar results were obtained when the mixing time at 250 rpm was increased from 3 to 20 minutes. In both of these sets of measurements, made with pastes at a water-cement ratio of 0.35, the plastic viscosity indicated by the down curves decreased progressively with mixing time and intensity. However, at a w/c of 0.25, the yield values reached a minimum after about 5 minutes of mixing (2).

A study of the effects of high intensity mixing of 0.45 water-cement ratio pastes showed that a minimum was reached for the plastic viscosity, but that the yield values increased progressively with mixing time from 10 to 50 Pa (2). Intense mixing appears to produce very rapid thixotropic breakdown and improved flow, but if it is prolonged, abrasion of the particles will increase the yield value and plastic viscosity.

When high speed blenders were used to mix pastes at a w/c of 0.5, it was found that the initial (15 minute) yield values increased progressively from 22 to 52 Pa and the plastic viscosities increased from 21 to 47 mPa-s as the mixing time increased from 1 to 10 minutes (23). The final temperature of the mixes was 25°C. At hydration times up to 3 hours, these increases with mixing time became even greater, indicating a persistent effect of these differences in mixing times. In addition, the pastes mixed for 1 minute were thixotropic and became more so with hydration time, whereas the pastes mixed 10 minutes were antithixotropic initially, but became even more thixotropic after 2 hours than the 1 minute pastes. High speed (10,000 rpm) mixing with external cooling has been employed to produce pastes with reduced bleeding (26). It is believed that the main effect was that the mixing removed thin layers of hydrates formed on the cement grains and dispersed these in the paste to produce a thick consistency.

The results in Fig. 4 were obtained primarily to determine the effect of mixing intensity on the flow curves. They do not include prolonged high intensity mixing, but still show wide variations in the rheological properties. Six different mixing procedures of increasing intensities were used. Procedure AS was the ASTM C305 procedure using a Hobart planetary mixer at low (140 rpm) and medium (280 rpm) speed. Procedure A20 was mixing for 20 minutes at low speed. Procedure B20 was the API standard procedure using a high-speed blender for 1 minute after preliminary mixing, followed by 20 minutes of low speed mixing in a beaker. B, B1 and B<sub>h</sub> are other variations of procedures with the high-speed blender including blending

at low (3,500 rpm) and high (17,000 rpm) speed, but for not more than 1 minute. Such variations in mixing intensity with the high-speed blender had only minor effects on the flow behavior. Fig. 4 shows that the yield values and plastic viscosities of all the blender-mixed pastes were substantially less than the less intensively mixed pastes. However, with the addition of 1 percent by weight of the cement of a superplasticizing admixture of the  $\beta$ -naphthalene sulfonate formaldehyde condensate (with added retarding component), such variations in mixing procedures had no appreciable effect; with the admixture the yield values were all nearly zero. The hysteresis loops were much thinner than those of Fig. 4, with slopes for the up curves about the same as the most intensively mixed pastes without the admixture.

Many of the different types of flow behavior obtained by different research workers can be qualitatively understood in terms of the thixotropic breakdown and recovery processes that occur during and after different mixing and testing procedures. For conceptual purposes it is useful to consider the strength and number of bonds between particles in the floc structure as a function of time. The extent of the thixotropic breakdown or recovery can then be expressed in such terms (3), which could also be used to define a degree of flocculation. Bombled and others have attributed the thixotropy to changes in the degree of flocculation, which he defined in terms of measurable quantities, the ratio of the median size of the agglomerates of particles to the mass median particle size (2). This definition may not be an exact measure of the structurally related resistance to shear, but it provides a conceptual basis for explaining the complex behavior observed. To do this it is assumed that the degree of flocculation can be qualitatively represented as a function of time during and after mixing as shown in Fig. 5. Two curves are shown: 1) curve L-LR which corresponds to low intensity mixing for a time M, and recovery if left undisturbed along the curve LR, and 2) curve H-HR which corresponds to a paste mixed at high intensity (but not for so long as to produce other effects) and its recovery. Exponential decay curves are assumed for both the breakdown and recovery curves, but the time constant for recovery is assumed to be at least ten times that of the breakdown curve. This is consistent with a comparison of breakdown time constants of the order of one minute (3,21) with recovery times indicated by changes from antithixotropic to thixotropic flow curves in 30 to 45 minutes (23,25). The important point is that pastes with a high degree of flocculation, either because of inadequate mixing or subsequent recovery, will be subject to more thixotropic breakdown during the test than pastes more completely dispersed by intense mixing.

The more completely dispersed pastes will undergo more rapid recovery after mixing and will tend to show antithixotropic behavior if this recovery process is superimposed upon the changes caused by the test itself. However, if the paste mixed at high intensity is allowed to stand before testing, the degree of flocculation will have recovered to the same level as that of the paste mixed at low intensity at some time  $P$  shown in Fig. 5.

Fig. 5 - Changes of the degree of flocculation of particles in cement pastes during mixing at high intensity H, and low intensity L, and recovery while at rest after mixing HR and LR.

The changes in degree of flocculation caused by the test itself are sketched in Fig. 6 for a single cycle, up curve and down curve in a viscometer, at constant rates of change of rate of shear as shown in the lower part of the figure. The S shaped dashed curve, S, indicates the changes in the degree of flocculation of a paste that was increasing relatively slowly when the flow test began. During the test the degree of flocculation decreases only slowly at the initial low rates of shear, but decreases more rapidly at the highest shear rate, and then more slowly again at the low rates of shear at the end of the test. If, on the other hand, the undisturbed paste would have been recovering at an appreciable rate as shown by the recovery curve R, the curve obtained as a result of superposition of the two effects should resemble curve T. The position of curve T will vary between the extremes S

and R, depending upon the testing conditions, and would be referred to as thixotropic or antithixotropic depending on which effect predominates during the test.

Fig. 6 - Changes of the degree of flocculation of particles in cement pastes during testing in a rotational viscometer during a single up-curve, down-curve cycle. S: curve for changes during test of paste that was recovering slowly after mixing, R: recovery curve of paste recovering rapidly after mixing, T: superposition of the two effects.

## FACTORS AFFECTING FLOW

The fineness of the cement and the water-cement ratio of the fresh paste are two of the most important factors affecting flow. These two factors together determine the average water-film thicknesses and inter-particle spacings. Despite the fact that normal cement pastes are in a flocculent state when at rest, the average water-film thickness concept appears to have some validity in determining their rheological properties. To determine the effects of water content, fineness, and other factors uncomplicated by the effects of cement hydration, Legrand systematically studied the flow behavior of pastes and mortars made with fine powders of calcite and other materials (19). Similar but less complete results were obtained with cements (5). The maximum yield value of such pastes at rest,  $f_0$ , before any thixotropic breakdown during the test, was found to depend on the volume concentration of solids,  $C$ , according to:

$$f_0 = Ae^{a(C - 0.5)} \quad (3)$$

in which A and a are parameters determined from the data. When the pastes were vibrated, the yield values were essentially zero. C values ranged from 0.475 to 0.677; for portland cements these volume concentrations would correspond to a range of water-cement ratios from 0.15 to 0.35. Although the flow behavior of these pastes went through a transition from plastic-thixotropic to dilatant behavior in this range, Eq. 3 applied over this entire range of solids concentrations.

The value of a in Eq. 3 depends on the material and shape of the particles, but is independent of the specific surface area or particle size distribution; values ranged from 23 to 48 for spherical to angular particles. The value of A increases rapidly with the specific surface area for powders of cement finenesses up to values of about 100 Pa.

A similar dependence on the volume concentration of solids was found for the shear stress,  $\tau$ , measured at constant rates of shear strain while the paste was vibrated:

$$\tau = Be^{b(C - 0.5)} \quad (4)$$
