/10/ it results that in the stretching vibration range should be observed three  $A_1$ -type vibrations from the fully symmetric stretching vibration of the isolated  $SiO_4$  tetrahedron and six vibrations /  $3A_1 + 3E$  / from the remained stretching vibrations. This quantity of the bands in the spectrum of the low-temperature  $C_{3v}S$  modifications is observed. In the spectra of highly symmetric modifications the mean of these bands is observed and as the result for the rhombohedral modification three weak separated bands are observed; for fully symmetric vibration at about  $840\text{ cm}^{-1}$  and for remained vibrations two bands :  $890$  and  $930\text{ cm}^{-1}$ . In the high-temperature modifications the splitting in the correlation field for  $SiO_4$  tetrahedron is not observed, and the observed splitting in the crystal field /activation of the  $A_1$  vibration and reduction of the degeneration of  $F_2$  vibration to E and  $A_1$ / show the position symmetry of the  $SiO_4$  tetrahedra in the crystal structure accordingly to Jeffery -  $C_{3v}$ . These conclusions are confirmed by the Raman spectra for the same samples. The Raman spectra have been obtained in the Si-O stretching vibration range / $800 - 1050\text{ cm}^{-1}$ /, in the remained range there are no characteristic bands for the  $C_{3v}S$ . The weak intensity and broadening of these bands increases strongly with the quantity of the admixed stabilizer. On this base it is possible to conclude that in the FIR range the spectra of the high-temperature modifications are similar to the spectra of amorphous state. The position of the peaks of the complexed  $800-950\text{ cm}^{-1}$  band are almost the same like the bands in the IR spectrum and the same changes of the band shape during the increase of the stabilizer concentration are observed /fig.3/. For the rhombohedral modification only three weak separated bands are observed, similar to the IR spectrum.

Figure 3. Raman spectra in the  $700 - 1000\text{ cm}^{-1}$  range of the  $C_{3v}S$  polymorphic modifications stabilized by ZnO.

## DISCUSSION AND CONCLUSIONS

On the base of the IR and Raman spectra the following conclusions can be drawn :

- the symmetry of the tetrahedra in the structure of all polymorphic modifications is close to  $C_{3v}$  symmetry and during the phase transitions the tetrahedron does not deform and its dimensions are almost the same,
- in the stabilized crystallochemically structures of the high-temperature modifications higher symmetry is obtained by the reduction of the oxygen sublattice order,
- the disorder of the oxygen sublattice is a consequence of the orientation disorder of the  $SiO_4$  tetrahedra in the  $C_{3v}S$  structure /no splitting in the correlation field/.

In the paper /10/ we have put forward a hypothesis on the real structure of  $C_{3v}S$ ,

which can be now extended to explain the complicate polymorphism of the  $C_{3v}S$ . According to our hypothesis the base symmetry of the short range order in the  $C_{3v}S$  crystals is the same or very close to the rhombohedral symmetry /high-temperature form/ and the crystal is of "sandwich" structure with the layer by turn : silicate of  $C_{2v}S$  and oxide of  $CaO$ .

The dicalcium silicate layer is probably of  $\alpha$ - $C_{2v}S$  structure in the rhombohedral modifications and in the low-temperature modifications  $\alpha'$ - and  $\beta$ - $C_{2v}S$ . About the symmetry of the whole crystal and about the size of the unit-cell in the  $C_{3v}S$  polymorphic modifications decides mutual arrangement of the oxide layer respecting to the silicate one.

During the polymorphic transition cycle of  $C_{3v}S$  the positions of oxygen ions are at first a little displaced what is the result of tetrahedra reorientation. This mechanism could be explanation of the small thermal effect of  $R \leftrightarrow M_{III}$  transition and rapid reduction symmetry from  $C_{3v}$  to  $C_s$  with practically unchanged parameters of the unit-cell. It is necessary to suppose that during this transition calcium and silicon cations do not displace.

The  $M_{III} \leftrightarrow M_I$  transition is of similar character and as a result the new tetrahedra orientation is established. During the further  $M_I \leftrightarrow T_{III}$  transition the cations are displaced what can be presented as a shift of the silicate layer respecting to the oxide layer. The consequence is the increase of the unit-cell parameter of  $T_{III}$  form.

Now is clear the significant thermal effect of this transition.

During the  $T_{III} \leftrightarrow T_{II}$  transition the significant structural changes do not occur. During last  $T_{II} \leftrightarrow T_I$  transition occurs again the change of sequence of silicate and oxide

de layers causing further increase of the unit-cell dimensions and considerable thermal effect.

On the basis of our hypothesis we can distinguish two kinds of the transitions during the polymorphic transition cycle of the  $C_3S$  :

- with little only reorientation of  $SiO_4$  tetrahedra
- with the change of the mutual positions of the silicate and oxide layer being the structure elements of  $C_3S$ .

The transitions of second type are :

$M_{II} \leftrightarrow T_{III}$  and  $T_{II} \leftrightarrow T_I$ . Noting double layer  $C_2S$  and  $CaO$  by letters we can illustrate  $R^2$ ,  $M_I$  and  $M_{II}$  forms like : AAA...;  $T_{III}$  and  $T_{II}$  forms like : ABAB..; and  $T_I$  form :

ABCABC....

Supporting on this hypothesis it is possible to explain the mechanism of the stabilizing operation such ions like  $Zn^{2+}$ ,  $Mg^{2+}$  and  $Al^{3+}$ . Stabilizing  $Zn^{2+}$  and  $Mg^{2+}$  ions substitute larger  $Ca^{2+}$  ions in the  $C_3S$  lattice causing loosening of the structure. Because substituted is mainly calcium from the oxide layer, admixed ions cause change of the oxide layer orientation respecting to neighbouring silicate layer. The kind of the layer arrangement depends on the admixture concentration.

More complicate is character of  $Al^{3+}$  ions in the  $C_3S$  structure what is a subject of our another paper /10/.

It is necessary to remark that the stabilization mechanism of the  $C_3S$  forms is different from the stabilization mechanism of the  $C_2S$  modifications. There is a correctness that the ions stabilizing for  $C_3S$  are destabilizing for  $C_2S$  and vice versa.

**RESUME:** Dans le but de produire le clinker de ciment Portland on a procédé à de nombreuses expériences sur des accélérateurs d'électrons de types divers. On décrit la méthode utilisée ainsi que les installations montées au laboratoire. Pour une puissance de dose retenue de 20 à 40 Mrad/s et une pression atmosphérique normale la décomposition totale du carbonate de calcium et, pratiquement, le développement complet de la réaction de synthèse du clinker de ciment de Portland n'ont exigé qu'environ 10 s. Les mesures de l'énergie consommée avec ce procédé ont donné  $3300 \pm 300$  J ou  $800 \pm 70$  cal/g ce qui est d'environ 100 cal/g inférieur à la consommation avec le procédé purement thermique. On a déterminé les caractéristiques de résistance du ciment (50 MPa ou 500 kgf/cm<sup>2</sup> et plus) ainsi que le caractère extrême du rapport entre la résistance et la grandeur de la dose retenue. On a étudié les caractéristiques physiques et chimiques du clinker obtenu par le procédé radiatif. On a détecté une importante irrégularité de phases, un contenu superstoichiométrique et une cristallisation fine de l'alite. On a émis une hypothèse sur le mécanisme des transformations engendrées dans le mélange par un grand flux d'électrons accélérés.

**SUMMARY:** A plurality of experiments for obtaining a portland-cement clinker have been conducted at electron accelerators of various types. A technique with description of laboratory installations is presented. At an absorbed dose power of 20-40 Mrad/s and normal atmospheric pressure, total decomposition of calcium carbonate and substantially complete synthesis of the portlandcement clinker take about 10 s. The energy consumption measured at this method was  $3300 \pm 300$  J, or  $800 \pm 70$  cal/g, which is about 100 cal/g as low as in case of a purely thermal method. The strength characteristics of the cement (50 MPa or 500 kgf/cm<sup>2</sup> and above) and the extreme nature of strength-to-absorbed dose relationship have been discovered. The physical and chemical features of the clinker obtained by the radiation method have been studied. Considerable non-uniformity of phases, superstoichiometric composition and fine crystallization of alite have been detected. Suppositions of the mechanism of transfers caused in the mixture by a powerful flux of accelerated electrons have been put forward.

Dès qu'on a commencé à produire le clinker de ciment Portland son développement technique se base exclusivement sur le procédé thermique et consiste au perfectionnement de la technologie et des équipements. Quant à l'utilisation de la méthode de haute intensité telle que le procédé radiatif, considéré d'un grand avenir dans nombre de domaines de la technologie chimique, on la jugeait impossible pour les processus exigeant beaucoup d'énergie. Pourtant la nécessité de l'intensification de la technologie du ciment Portland, de l'abaissement capital des dépenses en combustible naturel de haute qualité pour sa production ainsi que des prescriptions écologiques ont incité à une reconsidération minutieuse des arguments avancés.

En abordant l'étude des possibilités d'obtenir le clinker de ciment Portland au moyen du procédé radiatif on s'est basé sur certains succès de la technologie radiative en matière de l'utilisation du flux d'électrons accélérés et de la possibilité de leur introduction condensée dans le système de réaction.

De nombreuses expériences sur des accélérateurs d'électrons de types divers assurant une puissance de dose retenue de 20 à 40 Mrad/s, ont montré que l'irradiation du mélange brut de ciment de Portland permet d'aboutir à la formation du clinker pendant quelques secondes ou, au cas de flux d'électrons moins puissants - en quelques dizaines de seconde. Le processus s'achève à une température d'environ 200°C inférieure à l'ordinaire. Cela se solde par une diminution de l'énergie dépensée. Des mesures réalisées dans des conditions quasi-adiabatiques ont permis de l'estimer à 3300±300 J/g ou 800±70 cal/g.

Par une voie analogue on a obtenu des silicates tri et bi-calciques purs. On a également synthétisé une série d'aluminates composant les agglomérés d'alumine de l'industrie d'aluminium.

La technologie radiative utilisée pour la production du clinker de ciment Portland exige une préparation de la matière première par la voie sèche. On peut soumettre à l'irradiation soit la farine brute, soit le mélange brut granulé. Ayant étudié un grand nombre d'échantillons de clinker en laboratoire, on a obtenu les résultats suivants.

Les paramètres de résistance du ciment sont suffisamment élevés: résistance du ciment durci 50 MPa et plus; l'accroissement de résistance au cours du durcissement suit le rythme commun au ciment Portland ordinaire (fig.1). La dépendance des indices de résistance du ciment de la dose retenue (fig.2) a un caractère extrême. La surabondance comme l'insuffisance des doses retenues au cours de la formation du clinker se traduit par des indices de résistance du ciment inférieurs à ceux obtenus pour le clinker fabriqué avec des doses optimales. Le palier des doses optimales est toutefois suffisamment large et ne présente pas de difficultés technologiques.

Le clinker obtenu par synthèse radiative est proche de celui du ciment Portland par sa composition en phases et ses caractéristiques physico-chimiques. Toutefois, la vitesse assez grande des transformations chimiques au sein du matériau soumis à l'action d'un flux puissant d'électrons accélérés entraîne une série de caractéristiques physico-chimiques du clinker obtenu. S'y rapporte le déséquilibre des phases du clinker, la teneur superstoechiométrique en alite, la quantité insuffisante du composant intermédiaire comprenant parmi d'autres aluminates à basse basicité.

Fig.1. Cinétique du durcissement du ciment obtenu à partir du clinker par le procédé radiatif pour des valeurs différentes de CaO libre

Fig.2. Variation des indices de résistance du clinker du ciment Portland en fonction de la variation de la dose retenue (y compris les pertes en chaleur):

—○— FS = 0,91    n = 2,0    p = 1,0  
 —●— FS = 0,86    n = 5,7    p = 2,3

On observe souvent une structure cristalline hétérogène (sur une seule coupe mince on peut enregistrer des secteurs de cristallisation très fine peu prononcée à côté de secteurs de grands cristaux aiguillés de l'alite). La cristallisation de l'alite comme du belite est très fine (de 3 à 7 jusqu'à 10 à 15  $\mu\text{m}$ , rarement de 20  $\mu\text{m}$ ), l'alite ayant les cristaux en prismes allongés, on rencontre des cristaux de forme isométrique, irrégulière et en prismes courts.

Le clinker obtenu dans le flux d'électrons accélérés a une broyabilité plus élevée.

Le mécanisme des transformations chimiques de haute température engendrées par les radiations propres aux flux puissants amorcés au sein du corps solide est aujourd'hui insuffisamment connue; les méthodes d'étude expérimentale de ces flux sont loin d'être parfaites. Aussi ne peut-on faire que des hypothèses sur le mécanisme de développement des processus physico-chimiques au cours de la formation du clinker par la voie radiative. Selon l'une de ces hypothèses on peut supposer qu'à côté des processus d'ionisation et d'excitation ainsi que de formation d'une quantité assez grande de défauts de radiation dans le matériau irradié on voit de nombreuses zones submicroscopiques de surchauffage local en forme de coins et d'avalanches thermiques. L'énergie de chaque coin thermique se disperse presque instantanément dans le microvolume du matériau environnant et n'entraîne pas d'élévation de la température moyenne (pour des doses de 250 à 300 Mrad on n'a jamais enregistré de températures dépassant 1300°C). Cependant en chacune de ces zones il se crée des conditions très favorables à la décomposition ultra-rapide de la matière première ainsi qu'à la synthèse également très rapide de phases de hautes températures (vraisemblablement sous forme de germe ou de prémice de germe). Ainsi que la formation du clinker dans un grand flux d'électrons accélérés doit sembler-il être interprétée comme un phénomène de radiation thermique dont l'originalité réside en une transformation très efficace de l'énergie de radiation en énergie des transformations chimiques avec pertes minimales (devant les processus purement thermiques) d'énergie dans le milieu environnant. Un tel complexe de phénomènes assure le transfert direct de l'énergie du flux d'électrons au matériau irradié; les phénomènes purement thermiques ne jouant qu'un rôle subsidiaire. C'est la raison qui nous autorise de soutenir la thèse que la voie radiative d'obtention du clinker de ciment Portland présente non seulement du point de vue cinétique mais également énergétique un procédé de fabrication du clinker dont le rendement est en principe supérieur à celui basé sur des procédés d'utilisation directe de l'énergie électrique. Ses principaux avantages sont:

- absence de besoin d'utiliser le combustible organique naturel au cours du processus technologique, ce qui est particulièrement

important eu égard à l'orientation actuelle du développement des techniques des courants forts;

- coïncidence dans le temps des différents stades de formation du clinker, ainsi qu'une vitesse très grande de déroulement du processus, qui l'intensifie dans son ensemble et crée des conditions favorables à la diminution des gabarits et des besoins en métal du matériel;

- possibilité de limiter l'empoussiérage au cours de la fabrication du clinker et, par tant, l'abaissement très important de poussière et de produits nocifs évacués dans l'atmosphère.

Le niveau actuel et les tendances de la technique des accélérateurs autorisent à croire que le problème de la mise au point d'accélérateurs surpuissants pour des applications techniques sera résolu dans un proche avenir. Pour un rendement de la chaîne de fabrication de 1800 à 3000 t de clinker par jour il est nécessaire de disposer d'un complexe d'accélérateurs de puissance de 60 à 90 MW composé de 7 accélérateurs d'une puissance de 10 à 15 MW chacun (un accélérateur est en réserve).

Les orientations principales des études de fabrication du clinker par la voie radiative se concentrent actuellement sur la mise au point de l'équipement technologique du processus.

Nous croyons que la première chaîne industrielle de fabrication du clinker par la voie radiative qui correspondrait aux exigences énergétiques et écologiques actuelles pourrait voir le jour dans les années 90 du siècle courant.

# Modèles mathématiques et leur application à des fins d'optimisation des processus de broyage et d'élévation de la qualité du produit,

## *Mathematic models and their application for optimizing crushing processes and improving quality of products*

V.V. KAFAROV, membre de l'Académie des Sciences de l'U.R.S.S., chef de chaire de la cybernétique des processus chimico-techniques de l'Institut chimico-technique Mendéléev de Moscou,  
M.A. VERDIAN, candidat ès sciences techniques, chef de laboratoire de simulation mathématique du "NII Tzement", Moscou, U.R.S.S.

**RESUME :** On étudie au niveau macrocinétique les processus de broyage des corps solides. Toutes les études sont réalisées au moyen de calculateurs électroniques permettant ainsi de ne traiter que les variantes optimales d'organisation du processus qui garantissent une haute activité aux produits de broyage ainsi que des dépenses en énergie minimales.

On a mis au point des modèles mathématiques types de moulins à tambour ; les broyeurs variés et les processus de broyage qui s'y déroulent ont été classés d'après les formes de leurs modèles mathématiques.

En conformité avec les nouveaux principes d'analyse et de calcul des processus et des broyeurs de corps solides la répartition des particules suivant la dimension est considérée comme l'aboutissement d'une interaction compliquée entre la cinétique de la mouture et la structure hydrodynamique du courant de matériau dans le broyeur, c'est-à-dire comme la distribution du temps de séjour des particules du matériau broyé.

On montre la liaison naturelle et continue existant entre la distribution des particules du matériau en temps de séjour et en dimensions. D'où la possibilité d'appréciation qualitative et de prévision de la granulométrie du produit broyé d'après l'arrangement dans les broyeurs de la structure hydrodynamique du courant de matériau.

**SUMMARY :** The macrokinetic level of solid crushing processes investigations is considered. All the investigations are carried out with the use of computers, which provides for optimizing the variants of the process organization with high activity of crushed products and minimum power consumption.

Typical mathematical models of the drum mills have been developed and the diversity of mills and crushing processes occurring therein have been classified with respect to their mathematical models.

In accordance with novel principles of analysis and calculations of the solid crushing processes and apparatuses, distribution of particles in size is considered as a result of intricate correlation of crushing kinetics with hydrodynamic structure of the material flow in the mill, i.e. with distribution of the exposure time of the crushed material flow particles.

The natural interrelation and inseparability of distribution of material particles by the exposure time and size is shown. This provides for qualitatively estimating and forecasting the grain composition of the crushed product depending on the organization of the material flow hydrodynamic structure in the mill.

L'élévation de la qualité des produits industriels sur la base d'agréats de grande puissance unitaire est un trait caractéristique du fonctionnement des entreprises de ciments modernes. On sait quelle importance a acquis du point de vue pratique et théorique le degré de dispersion du produit broyé dans la production du ciment ainsi que son rôle déterminant dans l'élévation de l'activité des produits moulus et l'abaissement des frais en énergie dépensés à leur production. Sur l'élucidation de la nature de cette interdépendance repose en grande partie l'efficacité du processus technologique dont l'élévation est en rapport avec l'organisation maximale de ce dernier ce qui exige des conditions optimales pour la marche du processus les frais d'établissement demeurant constants et les dépenses en travail mis en oeuvre, pour atteindre le but posé, restant minimales.

Pour une grande part cette interdépendance a été établie dans la première phase en laboratoire au niveau appelé conventionnellement études microcinétiques et à un moindre degré dans seconde phase, lors des études macrocinétiques sur des unités industrielles d'essai et des complexes industriels mis en oeuvre. Il est évident qu'en pratique la mise en oeuvre du processus dans les conditions établies au cours de la première phase d'études s'avère difficile et le travail qu'il est nécessaire de dépenser pour le développement du processus est de beaucoup plus grand que celui du processus idéal. Il est donc bien entendu que plus le processus réel est proche du processus idéal moins grande est l'énergie qu'il faut dépenser à sa réalisation. C'est sur ces prescriptions qu'on s'est appuyé dans des études entreprises dans seconde phase.

Les études macrocinétiques incluent le choix de la dimension du broyeur et de son modèle mathématique. Toutes les études sont menées également avec l'aide de calculateurs électroniques ce qui permet de ne faire intervenir que des variantes optimales garantissant la production du ciment avec un produit broyé d'une haute activité et pour une dépense d'énergie minimale.

Les études théoriques et expérimentales du processus de broyage des corps solides en recourant à la nouvelle méthodologie de leur analyse (1) ont permis de déterminer les traits caractéristiques des processus se déroulant dans les broyeurs à grande puissance unitaire (2). S'y rapporte la réalisation du broyage dans des broyeurs dont le rapport de leur longueur au diamètre est différent de la valeur optimale ; l'aggravation des conditions cinétiques et hydrodynamiques de la marche du processus ; l'introduction d'un recyclage afin d'élever l'efficacité du broyage, mesure nécessaire, mais insuffisante ; le besoin impérieux de recourir aux systèmes automatiques de réglage et exigences élevées envers ces systèmes.

Il va de soi que même de petits écarts du régime de fonctionnement optimal

ou de la construction optimale d'agréats de broyage de grands diamètres entraînent des pertes sensibles et abaissent les paramètres techniques et économiques de leur travail.

Un rôle important dans l'optimisation du processus de broyage et dans l'élévation de la qualité du produit des broyeurs de grande puissance revient à la mise au point de modèles mathématiques de broyeurs types (1, 3).

Le fondement de la description mathématique du processus technologique du broyage se compose des équations concernant l'hydrodynamique des courants (3). Le mouvement du courant de matériau broyé dans les moulins à tambours utilisés dans l'industrie du ciment est très compliqué. Les différents éléments du courant se déplacent suivant des trajectoires variées. La direction de leur mouvement devient même quelquefois opposée à celle du mouvement principal du courant. Il s'ensuit que certains éléments du courant peuvent traverser le broyeur très rapidement. Le séjour de ces éléments dans le broyeur est très restreint et inférieur au séjour moyen des éléments du courant dans le broyeur. Pour les particules du matériau traversant le plus vite le broyeur le temps de séjour dans ce dernier est insuffisant pour acquérir le degré de broyage nécessaire. En cas de présence dans le courant d'un grand nombre de ces éléments une partie de volume utile proportionnelle à la fraction de ces éléments dans le courant total est utilisée de façon inefficace.

Le temps de séjour de certains éléments du courant dans le broyeur peut dépasser de plusieurs fois celui de séjour moyen et abaisser également l'efficacité du broyeur.

Ainsi donc la méconnaissance dans les calculs des broyeurs industriels de la structure réelle du courant qui les parcourt peut être la cause d'importantes erreurs aussi bien dans le calcul du rendement que dans celui du degré de broyage.

Les études expérimentales de la nature du mouvement des matériaux broyés dans les broyeurs de dimensions diverses (1, 3) ont établi que les broyeurs industriels constituent des installations (des systèmes) se caractérisant par une hétérogénéité nettement exprimée de la distribution du temps moyen de séjour du matériau. On a défini les causes de cette hétérogénéité de distribution du temps de séjour du matériau dans les broyeurs. En leur nombre citons : l'existence au sein du courant de régions de stagnation ; des courants de by-pass ; le transport d'une partie du matériau dans le sens opposé au mouvement général de ce dernier ; la diffusion turbulente ; le profil irrégulier des vitesses du matériau. Les causes mentionnées se manifestant en diverses combinaisons dans les broyeurs conditionnent la spécificité de l'irrégularité dans chaque cas particulier.

Les études réalisées pratiquement pour toute la classe des moulins à tambours,

ont permis de mettre au point des modèles mathématiques types de la structure hydrodynamique des courants de matériaux broyés. Ces modèles traduisent l'essence physique des processus de broyage ainsi que les traits spécifiques de ces derniers au cours de l'utilisation pour le broyage de broyeurs de dimensions variées. Les modèles mathématiques types de la structure du courant dans les moulins à tambours comprennent (3) :

- le modèle de déplacement idéal ;
- le modèle de malaxage idéal ;
- le modèle de diffusion ;
- le modèle de maillage ;
- le modèle de déplacement idéal avec zone de stagnation ;
- le modèle de déplacement idéal parallèlement à la zone de malaxage idéal ;
- le modèle de malaxage idéal suivi de la zone de déplacement idéal ;
- le modèle de déplacement idéal avec by-pass ;
- le modèle de déplacement idéal avec recyclage interne ;
- le modèle de malaxage idéal avec zone de stagnation ;
- le modèle de malaxage idéal avec contre-courant et zone de stagnation ;
- le modèle de malaxage idéal avec by-pass ;
- le modèle de malaxage idéal suivi de la zone de déplacement idéal connectant avec la zone de stagnation ;
- le modèle de malaxage idéal avec zone de stagnation et celle de déplacement idéal ;
- le modèle de malaxage idéal avec zone de stagnation, suivi de celle de déplacement idéal, soumises au by-pass ;
- le modèle de malaxage idéal suivi de la zone de déplacement idéal, connectant à la zone de stagnation et soumis au by-pass ;
- le modèle du maillage avec zones de stagnation ;
- le modèle du maillage avec contre-courants ;
- le modèle du maillage avec by-pass et zones de stagnation.

Au cours de la mise au point de modèles mathématiques du processus de broyage dans les moulins à tambours on s'est appuyé sur les modèles hydrodynamiques de la structure des courants passés en revue plus haut. Le processus de transformation du matériau brut en un produit broyé est étudié sous l'angle pseudochimique, la cinétique du broyage constituant une réaction du premier ordre :

$$\frac{dR}{dt} = -kR,$$

où  $k$  est une constante de la vitesse de transformation,

$R$ , la dispersité caractérisée par la teneur en grosses particules (refus sur le tamis).

Le domaine d'application de modèles passés plus haut en revue est fonction du broyeur type mis en oeuvre, de sa géométrie, des propriétés du matériau utilisé et des ré-

gimes de fonctionnement de l'installation de broyage. Les études ont montré que pour les broyeurs tubulaires on peut recourir aux modèles de déplacement idéal et à leurs combinaisons, le modèle de diffusion, le modèle du maillage et ses modifications. Pour les installations à autobroyage - le modèle de malaxage idéal et ses combinaisons, le modèle du maillage et ses modifications. Pour l'établissement du schéma technologique de broyage on construit le modèle mathématique général en accord avec le schéma structural sur la base des modèles types de ses éléments constitutants.

C'est ainsi qu'après des études de plusieurs années des structures de courants hydrodynamiques de moulins à tambours industriels on a mis au point et classé les modèles mathématiques types des processus de broyage des corps solides susceptibles de perfectionner la technologie et de promouvoir des installations de grande puissance unitaire. L'application concrète de modèles consiste dans la simulation de schémas technologiques de broyage permettant ainsi de démontrer le rôle de différents facteurs variables et de déterminer les meilleures variantes de structure des schémas ; dans l'élaboration de projets optimisés de moulins à tambours à grande puissance unitaire, ainsi que de systèmes technologiques de broyage sur la base du fonctionnement d'installations pilotes ; dans l'étude de l'efficacité et de mise au point de système de contrôle du processus de broyage (1, 3).

On examine plus loin une des applications pratiques des modèles mathématiques consistant dans le calcul du degré de dispersion du produit fini (4).

Le problème se pose de la façon suivante : les propriétés du matériau brut étant connues si l'on connaît la géométrie et les conditions de fonctionnement de l'unité de broyage déterminer la dispersité du produit  $R_{sor}$  à la sortie du broyeur. On utilise les modèles de malaxage idéal (1), de déplacement (2), de diffusion (3) et du maillage (4) dont les équations prennent la forme :

$$R_{sor} = R_{en} \frac{1}{1 + k\tau} \quad (1)$$

$$R_{sor} = R_{en} \cdot e^{-k\tau} \quad (2)$$

$$R_{sor} = R_{en} \frac{4a \cdot \exp\left(-\frac{Pe}{2}\right)}{(1+a)^2 \exp\left(\frac{a}{2} \cdot Pe\right) - (1-a)^2 \cdot \exp\left(-\frac{a}{2} \cdot Pe\right)} \quad (3)$$

$$\text{où } a = \sqrt{1 + 4k\tau/Pe}$$

$$R_{sor} = R_{en} \cdot \frac{1}{\left(1 + \frac{k\tau}{N}\right)^N} \quad (4)$$

Les paramètres des modèles mathématiques mentionnés nécessaires au calcul de la dispersion du produit sont : le temps moyen de séjour dans le broyeur  $\bar{t}$  ; le nombre  $Pe$ , caractérisant le degré de malaxage longitudinal du matériau dans le broyeur ; la constante de la vitesse de broyage  $k$  et le nombre de maille  $N$ . Les valeurs quantitatives de ces paramètres ont été obtenues par l'expérience ou le calcul dans des conditions de fonctionnement concret des broyeurs industriels.

La technique de calcul de la finesse de mouture du matériau à l'aide de modèles mathématiques (1, 4) a été vérifiée sur les broyeurs de matériau brut de voie humide de dimensions  $7,0 \times 2,3$  ;  $4,0 \times 5,5$  ;  $4,0 \times 13,5$  ;  $3,0 \times 14,0$  et  $2,6 \times 13,0$  m et les broyeurs à ciment de dimensions  $2,6 \times 13,0$  ;  $3,0 \times 14,0$  et  $4,0 \times 13,5$  m. L'erreur de calcul maximal ne dépasse pas 9 % ce qui constitue une précision suffisante pour des calculs d'ingénieurs. Cette technique à la différence de la technique courante (5) est plus souple (le type de modèle utilisé est fonction de celui de l'appareil et des conditions de son fonctionnement exigées par la précision du calcul) et universelle (s'applique à tous les broyeurs à tambours), aussi est-elle typique (4).

En accord avec les nouveaux principes d'analyse et le calcul des processus et des installations de broyage de corps solides la distribution des particules en dimension (DPD) est étudiée comme un résultat compliqué d'interaction de la cinétique de broyage et de la structure hydrodynamique du courant de matériau dans le broyeur, c'est-à-dire de la distribution du temps de séjour (DTS) des particules du courant de matériau broyé.

Si l'on admet dans le cas général que dans les broyeurs différents est moulu un matériau aux propriétés identiques ou très proches, c'est-à-dire si l'on pose pour hypothèse que la cinétique de broyage demeure toujours identique ce qui est très vraisemblable, alors il devient évident qu'un rapport naturel et continu s'établit entre la DTS et la DPD.

Cela autorise de juger de la DPD du produit fini obtenu sur la base de modèles mathématiques de la structure hydrodynamique de courants de broyeurs concrets, c'est-à-dire d'après la DTS. Il est évident que dans ce cas la DPD sera pour l'essentiel fonction du type de broyeur, de ses paramètres géométriques et de régimes, vu que tous ces paramètres peuvent en règle générale être présentés sous forme de différentes fonctions d'une même grandeur, la DTS des particules au sein du broyeur.

Ce qui vient d'être dit reçoit une confirmation d'autant plus évidente si l'on tient compte du fait que les courbes de densité de distribution des particules en dimension et en temps de séjour pour des degrés de malaxage des particules variés présentent une nature stochastique identique, obéis-

sent à certaines lois de probabilité identiques et, partant, sont analogues. Cela signifie qu'entre les paramètres de ces courbes de distribution, par exemple, les dimensions caractéristiques des particules du produit et la dispersion de la distribution d'une part, et le temps moyen de séjour et le malaxage longitudinal d'autre part, il existe un rapport univoque.

La dimension moyenne des particules du produit fini est fonction du temps moyen de séjour du matériau dans le broyeur, tandis que la dispersion de la distribution de la granulométrie l'est de la grandeur du coefficient de malaxage longitudinal.

Il s'ensuit la possibilité d'appréciation qualitative et de prévision d'obtention d'une granulométrie voulue dans des broyeurs de dimensions différentes d'après l'arrangement dans ces derniers de la structure hydrodynamique du courant de matériau. C'est d'autant plus important que jusqu'à présent on manquait de classification de broyeurs suivant la forme de leurs courbes de distribution des particules en dimension.

La mise au point de modèles mathématiques types de structures hydrodynamiques de courants et leur concrétisation pour les moulins à tambours rendent possible une telle systématisation, la solution du problème devenant ainsi suffisamment générale et rigoureuse. Vu la continuité de la liaison entre DTS et DPD, le domaine d'application de modèles mathématiques, les dépendances de leurs paramètres des caractéristiques géométriques et des régimes des broyeurs déterminent les dimensions des broyeurs dans lesquels on s'entend à obtenir la DPD, ainsi que la liaison entre les caractéristiques du broyeur et les paramètres de la DPD. Donc le spectre de distribution des dimensions de particules le plus large correspond aux broyeurs de malaxage idéal, tandis que le spectre le plus étroit à celui de broyeurs de déplacement idéal.

En conséquence à ce cas limite de réalisation du broyage dans des broyeurs de déplacement et de malaxage idéaux correspondent des cas limites de distribution de particules en dimension, bref, toutes les particules sont dans le premier cas d'une même dimension et dans le second la teneur en toutes les particules est la même. Les résultats obtenus sont confirmés par les publications de données théoriques et expérimentales (5-8). Il semble évident que l'utilisation complexe et l'apport mutuel de la méthode traditionnelle et de la nouvelle méthode d'analyse de la DPD renferment de grandes possibilités d'élévation de l'efficacité de la solution du problème fondamental de la production du ciment : l'obtention du produit broyé d'activité désirée avec une dépense minimale en énergie.

# Cristallisation du périclase et constance du volume des ciments

## *Crystallization of periclase and soundness of cements*

Y.V. NIKIFOROV, chef de laboratoire, candidat ès sciences techniques,

R.A. ZOSOLIA, collaborateur scientifique en chef, candidat ès sciences techniques, Institut d'Etat de recherches scientifiques de l'industrie du ciment de l'U.R.S.S., "Giprotzement".

**RESUME:** De nombreuses études (Sérov V.V., Boudnikov P.P., Roiak S.M., Schmitt-Henco C., etc.) ont établi qu'il existe une série de mesures qui permettent d'atténuer fortement l'influence nocive du magnésium dans le clinker.

Un des facteurs conditionnant la constance du volume des ciments magnésifères est le mode de cristallisation du périclase. Il a été établi qu'avec un périclase finement dispersé (1 à 7  $\mu$ m) et régulièrement réparti la teneur limite en MgO dans le clinker peut être élevée jusqu'à 8,5%. Une telle cristallisation s'observe lorsqu'on utilise en qualité de matière première des laitiers magnésifères de haut fourneau ainsi que des matériaux divers contenant du silicate de magnésium.

**SUMMARY:** Numerous investigations (by Serov V.V., Budnikov P.P., Royak S.M., Schmitt-Henco C., etc.) have proved that there are a number of measures which considerably decrease detrimental influence of magnesia in clinker.

One of the principal factors dictating the soundness of magnesium-containing cements is the nature of periclase crystallization. It has been found out that when periclase is finely dispersed (1-7 microns) and uniformly distributed in the mix, maximum content of MgO in the clinker may be increased to 8,5%. Such a crystallization of periclase is observed when using magnesium blast furnace slags and various magnesium silicate containing materials as a raw material ingredient.

Les déformations volumétriques des ciments conditionnées par l'hydratation du périclase se sont essentiellement fonction de la dimension de ses grains et de la nature de leur distribution (1,2). Aussi en utilisant des procédés technologiques assurant une dispersité élevée du périclase peut-on accroître la limite admissible de la teneur en oxyde de magnésium dans le ciment sans altération de sa qualité. C'est ainsi, par exemple, que les ciments, obtenus à partir des clinkers fondus présentant des cristaux de périclase de dimension de 1 à 5  $\mu\text{m}$ , supportent des essais en autoclave sous 2 MN/m<sup>2</sup> pour une teneur en oxyde de magnésium de 7 à 8% (3,4).

Habituellement dans les clinkers industriels à concentration élevée en oxyde de magnésium le périclase se présente sous forme de grains isolés de dimension de 15 à 20  $\mu\text{m}$  formant des accumulations compactes et constituant des pseudomorphoses sur des cristaux de dolomite du mélange brut (5,6).

On a montré que la dispersion du périclase et, partant, l'accroissement de la teneur admissible en MgO dans le clinker au cas de l'utilisation comme composant du mélange brut du calcaire dolomitique sont favorisés par son broyage plus fin (7), ainsi que par la diminution de la valeur du module d'alumine dans le clinker (8,9). Le ciment Portland magnésifère contenant jusqu'à 10% d'oxyde de magnésium (dans le clinker) et dont la production a été mise en oeuvre dans l'usine de ciment de Podolsk sur proposition de V.V.Serov (10,11) possède également un bas module d'alumine (0,6-0,9). Le ciment a résisté aux essais en autoclave sous une pression de 0,8 et 1,4 MN/m<sup>2</sup>. Sur la base de cette méthode technologique l'usine de ciment citée a produit pendant longtemps un ciment Portland magnésifère ainsi qu'un ciment Portland au laitier avec 10% d'oxyde de magnésium dans le clinker.

Les études ultérieures, réalisées par "Giprotsement" ont été orientées vers la recherche de voies d'atténuation de l'influence nocive du périclase sur la variation régulière du volume. On a établi que les composés fluorés (en particulier, CaF<sub>2</sub>, Na<sub>2</sub>SiF<sub>6</sub>) une fois introduit en quantité dosée dans le mélange brut contribuent à diminuer les dimensions moyennes de cristaux du périclase et, partant, les ciments (sans adjuvants minéraux actifs) arrivent à supporter l'essai en autoclave (pression 2 MN/m<sup>2</sup>) pour une teneur en MgO jusqu'à 6% (2).

Toutefois ni l'introduction dans la matière brute de composés de fluor, ni l'abaissement (dans les limites indiquées) du module de l'alumine ne s'opposent à la possibilité d'accumulation du périclase (par suite de la dissolubilité limitée de l'oxyde de magnésium dans la fusion de clinker) et ne permettent donc pas d'élever la teneur en oxyde de magnésium dans le clinker au-dessus de 6%.

Mais la cristallisation devient de nature toute différente au cas d'utilisation en qualité de composants magnésifères de base des laitiers magnésiens de haut fourneau.

Le périclase dans ces clinkers se répartit régulièrement sur toute la coupe mince sous forme des grains de dimension de 1 à 7  $\mu\text{m}$ . Rien que 20 à 30% de tout le périclase possèdent des grains de dimension de 7 à 15  $\mu\text{m}$ . Les accumulations de cristaux (de 80  $\mu\text{m}$  et plus) si communes aux clinkers formés de calcaires dolomitiques et d'argiles ne s'y observent pas. La nature de la cristallisation mentionnée du périclase peut avoir pour cause deux circonstances. Tout d'abord, en utilisant des laitiers magnésiens l'oxyde de magnésium libre se forme par interaction de CaO avec les minéraux magnésifères du laitier de haut fourneau à des températures relativement élevées - 1200-1400°C et, par suite, la période de recristallisation du périclase se raccourcit fortement. Ensuite, la concentration en ions de magnésium dans les minéraux des laitiers de haut fourneau est inférieure à celle rencontrée dans les minéraux de carbonates (dolomite).

Il s'ensuit que pour la même teneur en oxyde de magnésium dans les mélanges bruts le volume des minéraux magnésifères est de beaucoup supérieur lorsqu'on utilise dans la matière crue des laitiers magnésiens au lieu du calcaire dolomitique. C'est la raison de la répartition régulière des grains de périclase parmi les granules du clinker.

La haute dispersité de la cristallisation du périclase dans le clinker à base de laitiers magnésiens de haut fourneau ainsi que sa répartition régulière permet d'accroître sensiblement la teneur admissible en MgO sans entraîner des changements irréguliers dans le volume du ciment. Au cours de nos expériences les ciments à base de ces clinkers ont bien résisté au traitement en autoclave (sous 2 MN/m<sup>2</sup>) pour une teneur en oxyde de magnésium ne dépassant pas 8,5%, se sont avérés satisfaisants. Tandis que le ciment à base de clinker contenant 6,65% MgO et fabriqué à partir du calcaire dolomitique et de l'argile n'a pas résisté aux épreuves de régularité de la variation de volume (Tabl.I).

Tableau I			
Dénomination du composant argileux	MgO dans le clinker en %	Dilatation linéaire, %	
		Bouillissage	Traitement en autoclave
Laitier N.1	7,02	0,04	0,19
Laitier N.2	8,00	0,04	0,29
Laitier N.3	11,2	0,04	~14
Laitier N.4	6,82	0,02	0,16
Laitier N.6	7,53	0,04	0,23
Laitier N.7	7,70	0,02	0,15
Laitier N.9	9,30	0,04	5,4
Laitier N.10	6,94	0,06	0,41
Laitier N.11	7,85	0,03	0,57
Argile	6,65	0,02	~11

Donc la limite admissible de la teneur en oxyde de magnésium dans les clinkers à base de laitiers magnésiens de haut fourneau peut être élevée par rapport aux normes existantes sans altération de la qualité du ciment en ce qui concerne la régularité de variation du volume.

# Activation mécanique des matières premières pour la fabrication du ciment

## *Mechanical activation of cement raw materials*

M.E. NOUDEL, candidat ès sciences techniques, collaborateur scientifique,

G.S. KRYKHTINE, candidat ès sciences techniques, chef de laboratoire, NIITzement, Moscou, U.R.S.S

**RESUME:** Les auteurs exposent les résultats des recherches qui avaient pour but de mettre au point les principes de la rationalisation du procédé de préparation des matières brutes à la cuisson. Ces principes sont fondés sur l'étude des propriétés des matières premières, propriétés qui peuvent être modifiées par fragmentation de ces matières et exercer une influence considérable sur leur transformation ultérieure, en réduisant la consommation du combustible pour la cuisson et en augmentant l'activité du clinker. Par fragmentation on entend la dispersion et l'activation mécanique, c'est-à-dire, l'accroissement du nombre de défauts cristallins (destruction). On décrit les trois stades principaux de modification de la réactivité des matières premières pendant leur broyage, on établit les limites conventionnelles de ces stades et la possibilité de leur réalisation, on donne les formules pour déterminer le degré et l'efficacité de l'activation mécanique des matières premières. On donne la définition des notions de "degré" et d'"efficacité" de l'activation mécanique. On expose succinctement les principes de fonctionnement d'un activateur destiné à augmenter les défauts de la structure et la surface de contact des grains des matières broyées.

**SUMMARY:** The work deals with development of a systematic approach to rationalizing the technology of preparation of cement raw materials for calcination. It is based on study of properties of raw materials which may be changed during crushing and exert a considerable effect on further processing, on reduction of fuel consumption for calcination and increase of clinker activity. Crushing is considered as a process of dispersing and mechanical activation - increase of the number of defects in the crystalline structure (destruction). Three main stages of conversion of reaction capacity of the cement production raw materials during crushing are described, conventional boundaries of these stages and the possibility of their achievement are given, formulae for determining the degree and efficiency of mechanical activation of raw materials are given. The notions of "degree" and "efficiency" of mechanical activation are defined. The operating principles of the activator intended to increase defects in the structure and contact surface of the raw mix grains are briefly discussed.

L'efficacité, la qualité et la stabilité de la fabrication du ciment dépendent pour beaucoup de la manière dont on prépare les matières premières à la cuisson. La présente communication a pour objet l'étude des propriétés des matières premières, lesquelles peuvent être modifiées au cours de la fragmentation de ces dernières et exercer une influence considérable sur le processus de traitement thermique des produits broyés. La connaissance de ces propriétés et des lois qui régissent leur modification au cours de la fragmentation des matières premières permettront de choisir les procédés les plus efficaces de préparation de celles-ci à la cuisson avec utilisation du matériel tant existant qu'inédit.

Nos recherches ont porté sur l'argile kaolinique et les calcaires de composition chimique voisine: un calcaire compact à gros cristaux, un calcaire poreux à gros cristaux et un calcaire compact à cristaux fins. Les calcaires ont subi la réduction séparément et conjointement avec l'argile dans un broyeur à boulets de laboratoire à fonctionnement discontinu. Les produits du broyage ont été soumis aux analyses granulométrique, thermique différentielle, calorimétrique, aux rayons X, chimique et microscopique. A partir des résultats des analyses, on a calculé: la taille caractéristique des particules des matières broyées ( $\bar{D}_{36,8}$ ); l'énergie d'activation pour la décarbonation des calcaires ( $E$ ); les effets thermiques globaux de la clinkérisation du mélange brut ( $Q_c$ ) et de la dissolution dans l'eau de l'oxyde de calcium résultant de la décarbonation des calcaires ( $Q_{CaO}$ ); le rapport de la hauteur à la largeur (dans leur partie située à mi-hauteur) des pics représentant, sur les radiogrammes, la structure de la calcite ( $\beta_{CaCO_3}$ ) et de l'oxyde de calcium ( $\beta_{CaO}$ ) pour des quantités invariables de ceux-ci.

La figure 1 représente graphiquement, en coordonnées sans dimensions, les relations généralisées entre les variations des grandeurs  $\bar{D}_{36,8}$ ,  $E$  et  $Q_c$  et la durée de la réduction des calcaires et de leurs mélanges avec de l'argile. Il ressort de ces courbes que la vitesse maximale des décroissements de la taille caractéristique des particules est observée pendant les premières minutes de leur réduction (le premier stade conventionnel de fragmentation). Ensuite, la vitesse de la variation du degré de dispersion commence à baisser (c'est le deuxième stade conventionnel) et, enfin, il arrive un moment (le début du troisième stade conventionnel) où une réduction prolongée ne provoque aucun accroissement appréciable du degré de dispersion des produits à broyer.

La vitesse minimale de la variation des grandeurs  $E$  et  $Q_c$ , qui traduisent respectivement la réactivité des calcaires et des constituants de base lors de leur traitement thermique, est observée au premier stade de fragmentation, et la vitesse maximale, au deuxième. L'accroissement de la durée de réduction des matières au troisième stade favorise la variation des grandeurs  $E$  et  $Q_c$ , bien que la dispersité des produits broyés

Fig.1. Variations, au cours de la réduction des matières premières, de l'effet thermique global de la clinkérisation (1), de l'énergie d'activation du processus de décarbonation (2) et de la taille caractéristique des particules (3).

reste pratiquement inchangée. Il existe donc une certaine disproportion entre les variations de la dispersité et de la réactivité des matières premières au cours de leur réduction.

Pour pouvoir expliquer ce phénomène, nous avons étudié la variation de la réactivité des matières premières au cours de la réduction, leur dispersité restant invariée. On a prélevé dans le broyeur des prises d'essai du calcaire, en faisant varier la durée de la réduction de celui-ci. On a achevé le broyage pendant un court laps de temps (30 s) dans un broyeur de porcelaine en présence de 50% d'eau, ce qui entraîne, comme il ressort de l'analyse microscopique, la désaggrégation d'agglomérations secondaires constituées de particules très fines. Les prises d'essai ainsi désagrégées ont été divisées par tamisage en fractions qui ont été ensuite mélangées dans une proportion assurant une distribution logarithmique de la composition granulométrique avec un coefficient d'uniformité de 0,7 et une taille caractéristique  $\bar{D}_{36,8} = 30$  microns. On a ainsi obtenu une série de prises d'essai des calcaires, ayant des compositions granulométriques voisines mais ayant subi un broyage de durées différentes.

Comme il ressort des courbes 1 à 3 (Fig.2), l'accroissement de la durée de réduction des calcaires au premier stade conventionnel aboutit à l'obtention de produits qui présentent une valeur accrue de  $E$  à condition de maintenir invariable la dispersité. Cette baisse de la réactivité des calcaires peut être attribuée au décroissement, au cours de leur réduction à ce stade, du nombre de défauts des particules ayant des degrés de dispersion égaux. Ce décroissement est dû au fait qu'au premier stade de réduction il se produit essentiellement une dégradation fragile de la matière par suite de l'ouver-

Fig.2. Variations des valeurs de  $E$ , de  $\beta_{CaCO_3}$ , de  $\beta_{CaO}$  et de  $Q_{CaO}$  des échantillons de calcaire obtenus à la suite des fragmentations de différentes durées, le degré de dispersion restant invarié.

ture des défauts volumiques naturels de sa structure (pores, fissures, etc.), sans qu'il y ait une formation appréciable de défauts nouveaux. Cette hypothèse est étayée par l'accroissement relatif maximal, parmi les calcaires examinés, de la valeur  $E$  du calcaire poreux (de plus de 3 kcal/mole), ainsi que par l'accroissement, au premier stade de réduction, de la valeur  $\beta_{CaCO_3}$  (Fig.2, courbes 4 à 6).

La diminution du degré de destruction des calcaires favorise la formation, à l'issue de leur décarbonation, d'un oxyde de calcium présentant lui aussi une structure plus ordonnée (Fig.2, courbes 7 à 9). Ce phénomène est, à son tour, responsable de la diminution de la réactivité de l'oxyde de calcium, ce dont témoigne, d'une manière indirecte, le décroissement de sa chaleur unitaire de dissolution dans l'eau (Fig.2, courbes 10 à 12).

La vitesse de la fragmentation au deuxième stade se voit baisser par suite du décroissement, au sein de la matière, du nombre de défauts volumiques qui ne sont autres que des "fissures de destruction" résultant des

contraintes de déformation créées dans le broyeur. La dégradation des particules à ce stade s'effectue en deux étapes: l'apparition de la fissure (par suite de la déformation plastique) et la propagation de celle-ci. Les divers défauts (dislocations, hémotropies, etc.) qui apparaissent et se déplacent lors de la déformation plastique d'un solide n'y donnent des "fissures de destruction" qu'en partie, à cause d'une redistribution non uniforme des contraintes au sein du solide. C'est pourquoi au deuxième stade de fragmentation des calcaires on constate un décroissement de la grandeur  $\beta_{CaCO_3}$ . Au cours du deuxième stade de fragmentation il se forme un grand nombre de particules dont la taille est inférieure à celle des grains cristallins constituant la roche. S'agissant des calcaires étudiés, la solidité des liaisons intracristallines est supérieure à celle des liaisons intercristallines. Aussi, au cours du deuxième stade de fragmentation, y a-t-il rupture de liaisons plus solides qu'au cours du premier. Il en résulte un accroissement de la réserve d'énergie libre des surfaces en cours de formation, tandis qu'une tendance à sa diminution a pour effet un déplacement plus intensif des atomes superficiels vers l'intérieur, c'est-à-dire une destruction plus forte de la matière. L'intensification de la destruction des calcaires accentue leur réactivité, ce dont témoignent les variations correspondantes des valeurs  $E$  et  $Q_{CaO}$ , constatées en cas de prises d'essai aux degrés de dispersion voisine au cours du deuxième stade de fragmentation.

Au troisième stade de fragmentation intervient un équilibre entre la formation d'aggrégations de petites particules et leurs désaggrégation, aussi un prolongement de l'action des effets sollicitant la matière n'entraîne-t-il pas de changements de son degré de dispersion. Toutefois, la destruction de la matière résultant essentiellement de la déformation plastique des particules dans les zones adjacentes aux endroits de leurs contacts superficiels continue à s'accroître, ce qui entraîne un accroissement de la réactivité des calcaires réduits à ce stade avec l'augmentation de la durée de leur broyage (Fig.2).

En partant des données ainsi obtenus, on peut calculer qu'au premier stade de fragmentation l'accroissement de la réactivité résulte totalement de l'augmentation du degré de dispersion des calcaires et se voit freiner pour 20 à 40% par la diminution du degré de leur destruction. Au deuxième stade de fragmentation, l'accroissement du degré de dispersion des calcaires donne 35 à 60% de la contribution totale à l'augmentation de leur réactivité, le reste résultant de la destruction. L'accentuation de 85 à 90% de l'activité des calcaires avec l'accroissement de la durée de fragmentation au troisième stade est due à l'augmentation du degré de destruction des produits broyés.

En conséquence, la fragmentation des constituants de base doit être considérée non

point comme une modification de leur degré de dispersion mais comme une opération d'activation mécanique. Pour l'étude de ce phénomène, nous recommandons de faire usage des indices de degré ( $I_d$ ) et d'efficacité ( $I_e$ ) de l'activation mécanique des matières premières, qui peuvent être calculés d'après les formules suivantes:

$$I_d = \frac{Q'_c - Q_c}{Q'_c} \cdot 100 \quad (1)$$

$$I_e = \frac{1,16 (Q'_c - Q_c)}{E} \quad (2)$$

où  $Q'_c$  et  $Q_c$  sont les effets thermiques globaux de clinkerisation, déterminés pour la matière de charge, respectivement avant et après sa réduction; cal/g;

$E$  représente les dépenses d'énergie pour la réduction de la matière de charge, kWh/t.

L'indice  $I_d$  indique la part qui revient à l'activation mécanique dans l'abaissement de la consommation unitaire de chaleur pour la clinkerisation lors du traitement thermique des matières premières, alors que l'indice  $I_e$  montre l'efficacité avec laquelle s'effectue cette opération dans l'unité considérée. Pour déterminer les valeurs de  $I_d$  et de  $I_e$  on prépare plusieurs échantillons obtenus à différentes dépenses d'énergie unitaires pour la réduction, on les soumet à une analyse thermique différentielle et on calcule les valeurs correspondantes de  $Q_c$ . En mettant les valeurs de  $Q_c$  et de  $E$  dans l'équation suivante, qui traduit le phénomène d'activation mécanique, on peut déterminer la valeur de  $Q'_c$ :

$$Q_c = Q'_c \exp \left( - \frac{K_1 E}{K_2 + E} \right) \quad (3)$$

Etant donné que les indices  $I_d$  et  $I_e$  traduisent bien les principales transformations utiles intervenant au cours de l'activation mécanique des matières premières, la mise en œuvre de ces indices permet de mener à bien avec plus de certitude les principaux problèmes de rationalisation du procédé de préparation à la cuisson des matières premières, par rapport à l'utilisation des caractéristiques liées au degré de dispersion. Une meilleure précision est notamment obtenue quand il s'agit de déterminer le degré de réduction optimal de la matière de charge ou bien de choisir le matériel le plus efficace et le schéma technologique le plus rationnel. En outre, en faisant varier le degré d'activation mécanique par modification des paramètres de fonctionnement des broyeurs, on parvient à obtenir à leur sortie un produit avec une valeur constante de  $Q_c$ .

Une analyse du fonctionnement des unités de broyage actuellement en usage a montré qu'elles ne fonctionnent efficacement ( $I_e = 1$ ) qu'au premier et au deuxième stades conventionnels et n'atteignent pas de ce fait le degré limite d'activation mécanique. C'est pourquoi nous avons mis au point un dispositif spécial dans lequel la matière issue des deux premières stades de fragmentation subit une destruction intensive sans donner lieu à une variation du degré de dispersion. Dans ce dispositif, les matières premières broyées subissent des chocs qui ne désagregent point les particules mais les déforment seulement d'une manière plastique aux endroits des contacts superficiels. Il en résulte une augmentation brusque (de presque 100 fois) de la surface de contact des particules et leur destruction considérable. La matière sort de l'activateur sous forme de granules secs de 0,5 à 5,00 mm.

L'accroissement du nombre de défauts de structure et de la surface de contact des particules dans l'activateur permet d'augmenter de 20 à 30% l'activité mécanique des matières broyées. L'indice d'efficacité  $I_e$  est d'ailleurs 12 à 15 fois plus grand qu'avec le même degré d'activation mécanique des matières premières dans un broyeur à boulets à fonctionnement discontinu, alors que réaliser ce niveau d'activation mécanique dans les broyeurs à boulets à fonctionnement continu est tout à fait impossible. L'activation plastique sous l'effet de coups, subie par les matières premières broyées, contribue à augmenter l'activité hydraulique du ciment fabrique à partir de celles-ci, ce qui est dû à un déroulement plus complet des réactions de formation d'alite et à une structure particulière des minéraux constituant le clinker.

La mise en œuvre de la farine brute sous forme de granules actifs secs offre la possibilité d'augmenter l'intensité de combustion dans le four et de réduire la quantité du mélange pulvérulent de ciment et de matières premières qui circule dans le système "four - échangeur de chaleur". Tout cela contribue à accroître considérablement le rendement de l'unité, à stabiliser et améliorer la qualité du clinker, de le ciment Portland et à réduire les émanations de poussières rejetées à l'atmosphère.

On voit donc que l'accroissement de l'activité mécanique des matières premières n'est pas proportionnel à l'augmentation de leur degré de dispersion dans tout l'intervalle possible de variation de ce dernier. Plus développée est la surface du mélange brut, plus grande est l'efficacité qui peut être atteinte dans l'augmentation de la reactivité par destruction de ses particules, et moindre est celle qui s'obtient par accroissement ultérieur de leur degré de dispersion. Des lors, il existe des limites de l'activation mécanique des matières premières qu'on a intérêt à atteindre dans les unités qui dispersent efficacement la matière. L'activation ultérieure peut être avantageusement effectuée dans des unités

dont la fonction principale est une destruction intensive des matières divisées. Les limites de l'utilisation de ces unités dépendent de leur conception, des propriétés et des particularités technologiques du traitement thermique ultérieur des matières premières. Ces limites peuvent être mises en évidence avec recours aux indices de degré et d'efficacité de l'activation mécanique.

# Etude thermodynamique de la cinétique de la formation de l'alite

## *Thermodynamic studies of alite formation kinetics*

A.V. BESSMERTNYKH, collaborateur scientifique,

V.K. KHOKHLOV, chef de section,

V.V. CHELOUDKO, chef de laboratoire, "NIITzement", Moscou, U.R.S.S.

**RESUME:** On analyse la cinétique de la formation du silicate tricalcique en présence de la phase liquide par des méthodes thermodynamiques de processus irréversibles. Les équations cinétiques sont présentées sous forme d'équations linéaires d'Onsager pour les différents domaines de déroulement de la réaction: la réaction est limitée a) par la vitesse de dissolution des deux composants de base en phase liquide, b) par la vitesse de la réaction en phase liquide, c) par la vitesse de cristallisation à partir de la fusion, d) par la vitesse de dissolution d'un des composants de base. Dans ce dernier cas les équations d'Onsager sont bilinéaires et possèdent des coefficients phénoménologiques croisés négatifs. On analyse les conditions de dominance de la saturation par la chaux en phases solide ou liquide du silicate bicalcique.

**SUMMARY:** The kinetics of formation of tricalcium silicate in the presence of a liquid phase have been analyzed by the irreversible process thermodynamics methods. The kinetic equations are presented in the form of linear Onsager equations for different reaction regions; the reaction is limited; (a) by the rate of dissolving of both starting substances in the liquid phase; (b) by the rate of the liquid phase reaction; (c) by the rate of crystallization from the melt; (d) by the rate of dissolving of one of the starting substances. In the latter case the Onsager equations are bilinear and feature negative cross-coupling phenomenological coefficient. The conditions of prevailing solid- or liquid-phase saturation of bicalcium silicate with lime have been analyzed.

Le processus complexe de formation du silicate tricalcique en phase liquide (fusion de silicate) peut se subdiviser en une série de processus élémentaires se déroulant simultanément, parmi lesquels on dégagera les processus suivants:

- dissolution de  $C_2S$  et de  $CaO$  de base en phase liquide,
- réaction de formation du  $C_3S$  en phase liquide,
- cristallisation de  $C_3S$  à partir de la fusion.

Ces processus interagissant mutuellement, aussi juge-t-on utile d'en donner une description simultanée. La liaison entre deux ou plusieurs processus en marche peut être établie sous l'angle de la thermodynamique des processus irréversibles (TPI), dont les méthodes seront fréquemment mises en œuvre plus loin.

Soit un système isothermique hétérogène ferme comprenant des phases solide (s) et liquide (l) ainsi que des phases de l'alite cristallin. Vu qu'entre les phases il se produit des phénomènes d'échange de masse, ces dernières seront considérées comme ouvertes.

Les principes généraux de la description cinetico-thermodynamique de ces systèmes sont, en particulier, exposés dans (1).

En se servant de l'équation fondamentale de Gibbs pour chaque phase du système, en tenant compte du bilan massique et énergétique, ainsi que de la propriété d'additivité de l'entropie, on peut montrer que la fonction dissipative du système considéré prend la forme

$$\begin{aligned} \theta = & \frac{d_1 S}{dT} T = -(\mu_{CaO}^s \frac{dn_{CaO}}{dT} - \mu_{C_2S}^s \cdot \\ & \cdot \frac{dn_{C_2S}}{dT} + \mu_{CaO}^l \frac{dn_{CaO}}{dT} + \mu_{C_2S}^l \frac{dn_{C_2S}}{dT} - \\ & - \mu_{CaO}^l \frac{d\xi_l}{dT} - \mu_{C_2S}^l \frac{d\xi_l}{dT} + \mu_{C_3S}^l \cdot \\ & \cdot \frac{d\xi_l}{dT} - \mu_{C_3S}^l \frac{dn_{C_3S}}{dT} + \mu_{C_3S}^s \frac{dn_{C_3S}}{dT}) = \\ & = \Delta \mu_{CaO} W_{CaO} + \Delta \mu_{C_2S} W_{C_2S} + A_l W_l + \\ & + \Delta \mu_{C_3S} W_{C_3S} \end{aligned} \quad (1)$$

Analysons l'équation (1) pour différents domaines de déroulement de la réaction de formation du  $C_3S$  cristallin, avec la prise en compte des limitations imposées à sa cinétique.

A. La vitesse de la réaction est limitée par celle de la dissolution des substances de base, les vitesses molaires de dissolution constituant un rapport des proportions stoechiométriques :

$$\frac{dn_{CaO}}{dT} = \frac{dn_{C_2S}}{dT}$$

Dans ce cas

$$\begin{aligned} \frac{dn_{C_3S}}{dT} &= \frac{d\xi_l}{dT} = \frac{dn_{CaO}}{dT} = \\ &= \frac{dn_{C_2S}}{dT} \quad \text{soit,} \end{aligned}$$

$W_{CaO} = W_{C_2S} = W_l = W$  et l'équation (1) prend la forme:

$$\theta = W(\Delta \mu_{CaO} + \mu_{C_2S} + A_l + \mu_{C_3S}) = W A_s \quad (2)$$

où

$$A_s = \mu_{CaO}^s + \mu_{C_2S}^s - \mu_{C_3S}^s \quad \text{qui est}$$

l'affinité pour la réaction en phase solide. Les méthodes TPI montrent que la fonction dissipative a toujours la forme:

$$\theta = \sum X_i Y_i \quad (3)$$

en outre, entre les flux généralisés et les forces généralisées on retrouve, avec l'application de la méthode linéaire TPI, la relation linéaire uniforme d'Onsager:

$$Y_i = \sum_{j=1}^m L_{ij} X_j \quad (i = 1, 2 \dots m) \quad (4)$$

Les données expérimentales accumulées autorisent d'admettre que dans la grande majorité des cas les phénomènes de transfert (conductibilité thermique, diffusion, phénomènes électrocinétiques, etc.) peuvent être décrits avec un haut degré de précision par les équations du type (4). Au cas de réactions chimiques soumises à la loi d'action des masses l'application des méthodes linéaires TPI se limite au domaine de la réalisation approchée de l'égalité:

$$1 - e^{-\frac{A}{RT}} = \frac{A}{RT} - \frac{1}{2!} \left(\frac{A}{RT}\right)^2 + \frac{1}{3!} \left(\frac{A}{RT}\right)^3 - \dots \approx \frac{A}{RT} \quad (5)$$

$A$  étant l'affinité maximale pour l'une des réactions élémentaires.

D'après les données fournies par (2) il est possible de calculer l'affinité pour la ré-

action

$$A = -\Delta Z = 3939 \text{ cal/mol}$$

Les données thermochimiques de base pour le calcul de l'affinité pour les réactions élémentaires manquant, en posant ces dernières égales l'une à l'autre, on obtient  $A = 1313 \text{ cal/mol}$ .

Donc, en tenant compte de deux premiers termes dans le développement en série de la fonction exponentielle, il est possible de décrire la vitesse de la réaction par des relations linéaires dans le domaine de températures posées avec une précision allant jusqu'à 7,5%.

En revenant à (2) écrivons la relation linéaire

$$W = LA_s \quad (6)$$

Dans l'équation cinétique on ne trouve pas sous une forme explicite les termes marquant l'influence de la phase liquide. Cette relation, comme la fonction dissipative qui lui correspond, est analogue par sa forme aux équations décrivant la cinétique de la saturation par la chaux en phase solide du silicate bicalcique, autrement dit la phase liquide se manifeste par une action purement catalytique que traduit la grandeur du coefficient phénoménologique à propos duquel on peut remarquer ce qui suit:

si la réaction résultante

la relation linéaire étant  $W = LA$ , se déroule à des stades quelque peu élémentaires

$$(W_1 = L_1 A_1)$$

$$(W_2 = L_2 A_2)$$

alors on a entre les coefficients la relation

$$\frac{1}{L} = \frac{1}{L_1} + \frac{1}{L_2} + \frac{1}{L_3} \quad (7)$$

Les termes additionnés dans le second membre, par analogie avec les résistances thermique et de diffusion, peuvent être appelés résistances chimiques des réactions élémentaires. Si l'on peut, par rapport à l'une quelconque des résistances, négliger autres résistances, il est possible de tirer de (7), en posant, par exemple,  $L_2 \gg L_1$  et  $L_3 \gg L_1$ , que  $L = L_1$ . Dans l'étude des réactions en phases solides sans la

phase liquide la résistance principale est la résistance à la diffusion des réactifs à travers la couche du produit qui est de beaucoup supérieure à celle s'opposant à la dissolution. Aussi la vitesse de la réaction en présence de la phase liquide est-elle supérieure à celle des réactions dans des phases solides.

B. La vitesse de la réaction est limitée par celle de la dissolution de l'un des réactifs (par exemple, CaO):

$$\frac{dn_{\text{CaO}}}{dt} < \frac{dn_{\text{C}_2\text{S}}}{dt}$$

Dans ce cas, on obtient de l'équation (1):

$$\begin{aligned} \theta = W(\Delta \mu_{\text{CaO}} + A_1 + \Delta \mu_{\text{C}_3\text{S}} + \Delta \mu_{\text{C}_2\text{S}}) + \\ + \Delta W \Delta \mu_{\text{C}_2\text{S}} \end{aligned} \quad (8)$$

Les équations linéaires correspondantes compte tenu de la relation de réciprocity d'Onsager sont:

$$\left. \begin{aligned} W &= L_{11} A_s + L_{12} \Delta \mu_{\text{C}_2\text{S}} \\ \Delta W &= L_{21} A_s + L_{22} \Delta \mu_{\text{C}_2\text{S}} \end{aligned} \right\} \quad L_{12} = L_{21} \quad (9)$$

Dans les relations (8) et (9)

$\Delta W$  est la différence des vitesses de dissolution des substances de base en phase liquide.

Donc la vitesse de la réaction est dans ce cas une fonction bilinéaire, c'est-à-dire qu'il se produit une superposition d'influences de forces thermodynamiques généralisées - de l'affinité chimique et de l'affinité pour la dissolution de la substance de base dont la vitesse stoechiométrique molaire de dissolution est la plus grande. Il est en outre important de souligner que les deux forces thermodynamiques constituent des tenseurs d'ordre zero, c'est-à-dire des scalaires.

Pour l'utilisation pratique de la relation (9) il est important d'établir le signe du coefficient croisé  $L_{21} = L_{12}$ . Il est connu que les coefficients directeurs des relations linéaires d'Onsager sont toujours positifs. Quant aux coefficients croisés ils ne possèdent pas, en général, de signe déterminé et il est nécessaire de le déterminer dans chaque cas concret.

Pour établir le signe du coefficient croisé dans le système (9), rapportons-nous au mécanisme de la marche de la réaction aboutissant à la formation de  $\text{C}_3\text{S}$ . La signification physique de  $\Delta W$  est la vitesse du cumul de  $\text{C}_3\text{S}$  en phase liquide. Si la phase liquide est prise pour une solution diluée obéissant à la loi de Henry, on peut affirmer que l'affinité pour la dissolution

$$\Delta \mu_{C_2S} = -RT \ln \frac{C_{C_2S}}{C_{C_2S}^{Sat}} \quad (10)$$

où  $C_{C_2S}^{Sat}$  est la concentration de saturation.

Donc, à mesure de l'accumulation dans la phase liquide du composant a dissolution plus rapide, son affinité pour la dissolution diminue et, partant, sa vitesse de dissolution s'abaisse: le système évolue vers un état (appelons-le stationnaire) pour lequel  $\Delta W \rightarrow 0$ . Mais dans ce cas il est important qu'on ait:

$$\Delta \mu_{C_2S} = \Delta \mu_{C_2S}^{st} > 0.$$

En profitant de l'indépendance des coefficients phénoménologiques de la grandeur de l'affinité, on tire de la seconde équation du système (9):

$$L_{21} = -L_{22} \frac{\Delta \mu_{C_2S}^{st}}{A_s} < 0 \quad (11)$$

En portant (11) dans la première équation du système (compte tenu de la relation de réciprocity), il vient:

$$W = L_{11}A_s - L_{22} \frac{\Delta \mu_{C_2S}^{st} \cdot \Delta \mu_{C_2S}}{A_s} \quad (12)$$

Notons l'importance de cette équation pour l'appréciation de l'influence de la quantité de la phase liquide sur la cinétique de la formation de  $C_3S$ . En laissant tomber les détails indiquons que l'équation (12) se caractérise par l'existence d'un maximum de la fonction

$$W = f\left(\sum_1 N_i\right)$$

pour une valeur optimale de la quantité de la phase liquide  $\sum N_i$ ; avec l'accroissement subséquent de cette dernière la vitesse de formation de  $C_3S$  diminue.

C. La réaction se déroule dans un domaine cinétique, autrement dit est limitée par la vitesse de la réaction dont tous les participants sont en phase liquide. Vraisemblablement ce cas se présente pour un cuison ultrarapide, se traduisant par la formation d'un oxyde de calcium et de silicates en état métastable qui se dissolvent rapidement. Le système de relations linéaires qui s'y rapporte est:

$$\left. \begin{aligned} W &= L_{11}A_s + L_{12}\Delta \mu_{CaO} + L_{13}\Delta \mu_{C_2S} \\ \Delta W_{CaO} &= L_{21}A_s + L_{22}\Delta \mu_{CaO} + L_{23}\Delta \mu_{C_2S} \\ \Delta W_{C_2S} &= L_{31}A_s + L_{32}\Delta \mu_{CaO} + L_{33}\Delta \mu_{C_2S} \end{aligned} \right\} \quad (13)$$

$$L_{12} = L_{21}, L_{23} = L_{32}, L_{31} = L_{13}$$

On peut également montrer que ce système tend vers un certain état stationnaire correspondant à la vitesse minimale de l'apparition de l'entropie.

La première équation peut également être étudiée en rapport avec l'extrémum.

D. La réaction est limitée par la vitesse de cristallisation de la substance produite. Dans ce cas il y a plusieurs variantes de rapports entre les vitesses des processus élémentaires. Par exemple, pour

$$W < W_{CaO} = W_1 < W_{C_2S}$$

le système d'équations linéaires prend la forme:

$$\left. \begin{aligned} W &= L_{11}A_s + L_{12}A_{s1} + L_{13}\Delta \mu_{C_2S} \\ \Delta W_1 &= L_{21}A_s + L_{22}A_{s1} + L_{23}\Delta \mu_{C_2S} \\ \Delta W_2 &= L_{31}A_s + L_{32}A_{s1} + L_{33}\Delta \mu_{C_2S} \end{aligned} \right\} \quad (14)$$

où

$$A_{s1} = \mu_{CaO}^s + \mu_{C_2S}^s - \mu_{C_3S}^l \text{ est l'affinité}$$

pour la formation de  $C_3S$  en phase liquide à partir de  $CaO$  et  $C_2S$  solides. Au cours des raisonnements précédents on a admis l'existence d'un modèle de saturation en chaux à l'état liquide. On peut alors sur la base de considérations thermodynamiques générales affirmer qu'il se cristallise à partir de la fusion une certaine modification stable de  $C_3S$  (appelons la modification  $\cdot x$ ).

Toutefois dans le système  $C_2S - CaO$ , pour des conditions thermodynamiques appropriées, il peut y avoir lieu à formation d'une autre modification  $\cdot y$  par réaction de saturation en phase solide. En présence de la fusion la modification  $\cdot y$  est métastable, car elle doit se dissoudre rapidement dans la fusion pour cristalliser ensuite à partir de cette dernière en une modification  $\cdot x$  stable.

Il est connu que la dissolution de la phase métastable est de beaucoup supérieure à celle de la phase solide (3), assurant ainsi continuellement le rétablissement des surfaces réagissant suivant le mode de la phases solides de  $CaO$  et  $C_2S$ . En posant que la marche

des réactions élémentaires s'écoule sous la forme

on peut montrer que dans ce cas l'équation cinétique est analogue par la forme à l'équation (6):

$$W' = L' A_s \quad (15)$$

Toutefois le coefficient  $L'$  est différent de  $L$  et se détermine au moyen de la relation

$$\frac{1}{L'} = \frac{1}{L'_1} + \frac{1}{L'_2} + \frac{1}{L'_3}$$

Donc la question de dominance de la saturation, en phase liquide ou solide se réduit à l'établissement du rapport entre les vitesses de dissolution de  $\text{CaO}$ ,  $\text{C}_2\text{S}$  et  $\gamma - \text{C}_3\text{S}$  dans la fusion. Ce rapport est en premier lieu fonction du régime de cuisson, du mélange de composants de base et, dans chaque cas concret, peut amener la dominance de l'un des mécanismes de saturation.

#### CONCLUSION

L'application des méthodes TPI à l'étude de la cinétique de la réaction hétérogène de formation du  $\text{C}_3\text{S}$  peut conduire à de nouveaux résultats fort importants. La vitesse de formation du  $\text{C}_3\text{S}$  peut être décrite par des relations linéaires de forme très simple dont l'aspect varie suivant le domaine de déroulement de la réaction. On admet généralement que si la vitesse est limitée par celle de la dissolution de l'un des composants, la vitesse de dissolution de l'autre composant (et, partant, l'affinité pour cette dissolution) n'exerce pas d'influence sur la cinétique de la réaction. Or l'analyse par les méthodes TPI montre que ce point de vue est en principe faux. Cet analyse permet également d'établir les conditions de dominance du mécanisme de saturation par la chaux de  $\text{C}_2\text{S}$  en phase liquide ou bien solide.

#### SIGNES SPECIAUX:

$$\frac{d_i S}{dT} - \text{entropie dégagée;}$$

$$\Delta \mu - \text{affinité pour la dissolution (cristallisation);}$$

$$x_i, y_i - \text{forces et flux thermodynamiques généralisées;}$$

$$A - \text{affinités pour les réactions selon Donder;}$$

$$W = \frac{dn}{dt} - \text{vitesses de dissolution ou de cristallisation;}$$

$$n - \text{nombres de moles;}$$

$$\xi - \text{variable chimique;}$$

$$L_{ij} - \text{coefficients phénoménologiques.}$$

# L'oxyde ferreux dans le clinker

## *Ferrous iron in clinker*

M.G. TOLOTCHKOVA, candidat ès sciences techniques,  
 V.P. RIASINE, candidat ès sciences techniques,  
 K.G. KOLENOVA, candidat ès sciences techniques,  
 V.N. SERGUEEV, ingénieur NIITzement, Moscou, U.R.S.S.

**RESUME :** Il s'est avéré que des clinkers du même type, à teneur en oxyde ferreux identique, présentent une activité hydraulique différente. Dans nombre de cas la présence de 0,6 à 0,8% de FeO n'impliquait pas l'altération de propriétés des clinkers de cuisson industrielle.

Des études ont été menées pour définir la composition quantitative et qualitative des phases du clinker avec la variation de la teneur en FeO de 0 à 1,8%. On a montré, en particulier, comment varie la composition de la phase aluminoferrite sous l'angle du rapport A/F et la présence dans cette dernière du FeO. Les résultats obtenus sont mis en rapport avec les conditions de formation du  $Fe^{2+}$  au cours de la synthèse du clinker dans un milieu gazeux oxydant.

On a avancé une hypothèse sur l'influence de la formation du fer bivalent et de sa répartition en phases du clinker caractérisée par le rapport  $FeO_{total}/FeO_{alite}$  sur les propriétés des clinkers contenant de l'oxyde ferreux.

**SUMMARY :** It has been found out that single-type clinkers comprising equal amounts of ferrous iron are characterised by different hydraulic activity. In a number of cases with 0.6-0.8% of FeO present, no deterioration of plant-calculated clinker properties has been detected.

Investigations of qualitative and quantitative composition of clinker phases have been performed with FeO content changing from 0 to 1.8%. Changes in the composition of the aluminoferrite phase are in particular shown, said phases being characterised by the A to F ratio and presence of FeO therein. The results obtained are correlated with the conditions of formation of  $Fe^{2+}$  in the process of clinker synthesis in oxidizing gas medium.

A supposition is made on the influence of the bivalent iron formation and distribution thereof among clinker phases, characterised by the  $FeO_{total}$  to  $FeO_{alite}$  ratio, on the properties of the FeO-containing clinkers.

On attribue souvent à la présence d'oxyde ferreux l'altération de la résistance limite du clinker. Cependant les teneurs limites recommandées en  $\text{FeO}$  (0,3 à 0,4%) ne sont pas toujours suffisamment argumentées. Le mécanisme de formation du  $\text{Fe}^{2+}$ , sa teneur quantitative ainsi que les propriétés des clinkers contenant du  $\text{FeO}$  sont fonction de la composition et des propriétés de la matière première, du régime et du milieu dans lequel s'effectue la cuisson et le refroidissement du clinker.

Au cours de la synthèse du clinker l'oxyde ferreux peut se former dans le milieu réducteur de la cuisson ainsi que par transformation à hautes températures des composés ferrugineux. Le  $\text{FeO}$  peut également se former par oxydation incomplète du fer métallique introduit avec la matière première. Le wustite introduit avec les minéraux de la matière première ou formé au cours de leur destruction exerce une influence favorable sur la réactivité du mélange brut en accélérant la dissociation des carbonates et les réactions topochimiques (1). La réduction de l'oxyde ferrique par dissociation thermique s'effectue suivant le principe des transformations successives en passant par des stades intermédiaires

La décomposition de la modification paramagnétique  $\alpha$  de  $\text{Fe}_2\text{O}_3$ , la plus stable, se réalise aux températures de 1350-1500 °C et pratiquement  $\text{Fe}^{2+}$  est identifié en présence d'une phase gazeuse neutre et même oxydante. La formation du fer métallique dans ces conditions est peu probable, vu que  $\text{FeO}$  n'est dissocié qu'à des températures beaucoup plus élevées (2500 °C).

Pratiquement la dissociation thermique à cause de la nécessité d'augmenter l'intensité de combustion dans la zone de cuisson s'observe souvent avec l'utilisation de matières premières de basse réactivité, avec la composition de mélanges crus à cuisson difficile, au cas d'une préparation insuffisante du matériau à la cuisson, de même que lors d'un long séjour du matériau dans la zone de cuisson, où il est mis en contact avec la flamme des chalumeaux.

L'accroissement de l'intensité de combustion au stade de la cuisson active entraîne l'élévation de la teneur en  $\text{FeO}$  ainsi que l'accentuation de l'influence négative sur les propriétés du clinker par suite de l'abaissement de l'activité hydraulique des silicates de calcium comprenant dans leur structure  $\text{Fe}^{2+}$  sous forme d'impureté isomorphe (2-4). La phase  $\text{C}_6\text{A}_{x,y}$  s'appauvrit en fer.

L'accroissement de  $\text{FeO}$  dans les clinkers industriels jusqu'à 1,8% s'accompagnait d'une variation du rapport molaire A/F dans la composition des aluminoferrites de calcium de 0,96-1,05 à 1,45-1,76 (fig.1). Pour des teneurs en  $\text{Fe}^{2+}$  maximales la phase aluminoferrite possède les compositions suivantes :

Fig.1. Influence de  $\text{FeO}$  sur la composition réelle du clinker : 1 - dans les fours rotatifs de longueur 185 m; 2 - dans les fours rotatifs de longueur 150 m (production par la voie humide).

$C_6A_{1,75-1,77}F_{0,94-1,09}O_{10-0,13}$  x)

Pour une teneur en FeO égale dans le clinker à 1% on observait la divergence maximale entre la composition théorique (selon Bogue) et expérimentale (obtenue par analyse aux rayons X) de  $C_6A_{1,75-1,77}F_{0,94-1,09}O_{10-0,13}$ , atteignant 3,8-5,5%.

L'ion du fer bivalent en pénétrant dans la structure des silicates vient se placer en position octaédrique (4,5). Avec un lent refroidissement du clinker  $Fe^{2+}$  est capable de détruire la structure de l'alite en formant jusqu'à 3-8% de  $C_2S$ . Toutefois, dans nombre de cas, surtout avec la présence dans le clinker de FeO pour 0,6-0,8% la teneur en alite au lieu de diminuer augmentait quelque peu (fig.1). Ce fait est à ce qu'il paraît un témoignage de l'existence de conditions dans lesquelles FeO ne fait qu'amorcer la clinkérisation (en abaissant la viscosité de la phase liquide) et joue le rôle de modificateur des compositions de phases de bélite, d'aluminate et d'alumoferrite.

Il y a également formation de FeO au cas d'utilisation d'un combustible de bas pouvoir calorifique. La combustion incomplète du combustible est décrite par l'équation connue de Boudoire selon laquelle le transport dans la couche du matériau du système  $CO-CO_2$  à travers la phase gazeuse au cours de la cuisson favorise la formation d'oxydes inférieurs. La réduction de  $Fe^{3+}$  par le carbone solide ou les produits de combustion incomplète présente un caractère local.

En présence de clinker fondu on assiste à la réduction de l'oxyde ferrique dit "actif" qui modifie de façon efficace la composition en phases du clinker. En contact avec les agglomérats de clinker suffisamment formés (par exemple, avec du charbon à partir du chalu-meau) la réduction s'effectue principalement à partir de la surface des granules. Plus la dimension des granules est petite, plus grande est la surface de contact avec le réducteur et partant, plus grand est le degré de réduction. Le transfert  $Fe^{3+} \rightarrow Fe^{2+}$  s'effectue alors au sein des phases déjà formées et contenant l'oxyde ferrique dissous. Plus les granules sont grosses moins grande est l'intensité de la réduction nocive de  $Fe_2O_3$  dans l'alite.

Dans les clinkers où dominent des grosses granules de  $Fe^{2+}$  on n'observe pas en général d'abaissement de la quantité d'alite ainsi que de l'activité même pour des teneurs en FeO de 0,8-1,0%. D'un autre côté plus la quantité totale d'oxyde ferreux est importante plus on a de chance de le trouver dans les petites granules du clinker.

Les essais sur les clinkers industriels à teneur en FeO de 0 à 1,8% ont montré la nature variable de l'influence de  $Fe^{2+}$  sur les paramètres de résistance (Tabl.1). C'est ainsi que l'abaissement de la résistance limite pouvait s'observer même pour une teneur en FeO dans le clinker de 0,3-0,6%, la présence de 0,6-0,8% de FeO étant souvent

sans effet sur les propriétés des produits cuits. L'apparition d'une quantité de FeO supérieure à 1% se traduisait toujours par une chute de résistance. Vraisemblablement selon les conditions de formation de FeO et, partant le mode de distribution de  $Fe^{2+}$  suivant les phases du clinker, l'influence de l'oxyde ferreux sur les propriétés du clinker se modifiait.

La teneur en FeO dans la partie non siliceuse des clinkers étudiés est à peu près la même et constitue 0,18 à 0,25%. La présence de  $Fe^{2+}$  dans la phase d'aluminate et d'alumoferrite ne peut pas être rangée parmi les facteurs négatifs, de même que sa détection dans la phase du bélite au cas où il ne se produit pas, de déstabilisation de la forme  $\beta$ . L'ion  $Fe^{2+}$  devient le plus nocif dans la phase de l'alite (5,6). En admettant que FeO se dissout de préférence dans  $C_2S$  (selon (7) jusqu'à 0,8-1,2%) et tenant compte de sa présence obligatoire dans la phase intermédiaire (0,2-0,3%), on peut supposer qu'avec l'observation de conditions déterminées de synthèse seule une petite fraction

x) Symbole f - FeO

de la quantité totale de l'oxyde ferreux sera contenu dans  $C_2S$ . Autrement dit on est autorisé à supposer qu'au moins jusqu'à 1% de  $FeO$  peut se trouver dans le clinker hors la phase de l'alite.

D'après les données fournies par l'expérience, en raison de cette (ou très proche) distribution de  $FeO$  dans les phases de clinker une teneur en  $FeO$  de 0,6-0,8% n'altérerait pas l'activité du produit. Par contre une sensible baisse de l'activité pour de petites (0,2-0,4%) teneurs en oxyde ferreux est conditionnée à ce qu'il paraît, par le fait que dans ce cas  $Fe^{2+}$  entre dans la structure de l'alite non pas par suite de la distribution en phase (à partir de la fusion) mais en qualité de produit de réduction de  $Fe^{2+}$  dissous dans l'alite.

La possibilité de fixer  $FeO$  dans la phase vitreuse inerte (5) ou sous forme de magnétite (3, 5) change également nos idées sur l'interdépendance entre l'activité hydraulique et la teneur en oxyde ferreux dans le clinker. Le  $FeO$  s'écartant du composé stoechiométrique par un manque d'ions métalliques peut être représenté sous forme d'un système, où coexistent des ions de fer bi- et trivalents :

où  $\square$  est la lacune anionique,  $x$  - la concentration de lacunes dans le sous-réseau métallique (8). Plus encore la similitude de liaison chimique (liaison ionique), le rapprochement de dimensions des mailles élémentaires et des rayons ioniques conditionnent la solubilité réciproque et l'apparition d'isomorphisme dans les solutions solides non limitées (substitution) entre  $FeO$  et les oxydes de métaux bivalents. Aussi l'assimilation du composé  $FeO$  à une phase de wustite peut-elle être admise que de façon toute conventionnelle. Donc le mécanisme de formation du fer bivalent ainsi que sa distribution en phases du clinker (et avant tout la valeur du rapport  $f_{total}/f_{alite}$ ) sont les facteurs qui déterminent les propriétés des clinkers contenant  $FeO$ .

# Sur les solutions solides dérivant du $C_2F$ par remplacement des atomes Fe par Mn et Al

## *Researches on the phase originated from $C_2F$ by substitution of iron atoms with Mn and Al*

C. BRISI, professeur, et B. DE BENEDETTI, professeur assistant, Istituto di Chemica Generale e Applicata e di Metallurgia del Politecnico di Torino, Italie.

RESUME : On a étudié l'étendue de la phase qu'on peut obtenir à partir du ferrite bicalcique par remplacement des atomes de fer par des atomes de manganèse et d'aluminium. Cela dans le but de vérifier la possibilité d'avoir dans le clinker des phases du type de l'aluminoferrite, riches en manganèse.

Dans les solides obtenus par trempe dans l'air, à partir de  $1300^{\circ}C$ , le remplacement du fer par le manganèse se borne seulement au 25% atomique, celui par l'aluminium au 70%. Il est cependant possible d'obtenir des solutions solides dans lesquelles tous les atomes de fer du  $C_2F$  sont remplacés en partie par l'aluminium et en partie par le manganèse; dans ces solutions solides, le pourcentage atomique de manganèse, en relation au total Mn+Al, se situe entre 32 et 44%.

Le manganèse introduit dans le réseau cristallin du  $C_2F$  présente toujours, dans les solides trempés dans l'air, un degré d'oxydation moyen supérieur à trois.

SUMMARY: The stability field of the phase obtainable from dicalcium ferrite by substitution of iron atoms with manganese and aluminium was studied. This with the aim to verify the possibility to obtain in the clinker phases of the aluminoferrite type rich in manganese.

In the solids quenched in air from  $1300^{\circ}C$ , the replacement of iron with manganese alone is limited to 25% atomic, while the replacement with aluminium is limited to 70%. It is, however, possible to obtain mixed crystals in which all the iron atoms of  $C_2F$  are partly replaced by aluminium and partly by manganese; in these solid solutions the atomic percentage of manganese in relation with the total Mn+Al ranges from 32 to 44%.

The manganese introduced in the crystal lattice of  $C_2F$  always presents, in the solids quenched in air, a mean number of oxidation higher than three.

La phase ferritique, c'est à dire la série de solutions solides  $2\text{CaO} \cdot (\text{Fe}, \text{Al})_2\text{O}_3$  qui dérivent du ferrite bicalcique par remplacement partiel des atomes de fer par des atomes d'aluminium, représente un des constituants principaux du clinker de ciment portland.

En réalité celle écrite ci-dessus est seulement une formule idéale parce que dans le système très complexe correspondant au clinker une petite partie des atomes de calcium, fer et aluminium peut être remplacée par d'autres éléments. Dans cette communication nous étudierons la possibilité d'introduire dans le réseau cristallin de la phase ferritique des atomes de manganèse, même en proportions bien plus élevées que celles qu'on peut rencontrer dans les matières premières employées pour la fabrication du ciment portland.

Quelques indications isolées sur ce problème sont déjà contenues dans la littérature scientifique.

Au cours du troisième symposium sur la chimie du ciment Parker (1) a signalé l'existence d'une phase de formule  $4\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{Mn}_2\text{O}_3$  qui dériverait de l'ainsi-dite brownmillerite ( $4\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{Fe}_2\text{O}_3$ ) par remplacement complet des atomes de fer par des atomes de manganèse. Entre cette phase et la brownmillerite on aurait, toujours selon Parker, une série continue de solutions solides. Parker ne fournit aucune donnée sur la structure cristalline du  $4\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{Mn}_2\text{O}_3$  duquel il donne cependant un diagramme de poudres aux rayons X.

Les résultats auxquels parvient Parker ne sont cependant pas en accord avec ceux d'une recherche antérieure conduite par Guttman et Gille (2), selon laquelle en partant de la brownmillerite le remplacement du fer par le manganèse serait limité à la composition  $4\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot 0,4\text{Fe}_2\text{O}_3 \cdot 0,6\text{Mn}_2\text{O}_3$ .

A la même conclusion semblent parvenir aussi Okorov et Peskina (3) qui eux aussi affirment que la formule  $4\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot 0,4\text{Fe}_2\text{O}_3 \cdot 0,6\text{Mn}_2\text{O}_3$  correspond à un solide monophase.

Une phase de composition  $4\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{Mn}_2\text{O}_3$  a été au contraire à nouveau signalée par Gharpurey et Pai (4) qui l'auraient obtenue par chauffage à 1310-1330°C de mélanges de  $\text{CaO}$ ,  $\text{Al}_2\text{O}_3$  et  $\text{MnO}_2$ . Pour cette phase ils donnent les paramètres réticulaires  $a_0=5,23$ ,  $b_0=14,68$  et  $c_0=5,44$  Å; il n'est pas toutefois clair si ces valeurs ont été mesurées directement par les auteurs ou ont été calculées en prenant pour base le diagramme de poudres donné par Parker.

A côté des travaux cités au dessus on doit signaler deux autres notes concernant les solutions solides qu'on peut obtenir du ferrite bicalcique par remplacement des atomes de fer par des atomes de manganèse en absence d'aluminium.

Selon Coates et McMillan (5), qui ont travaillé sur des solides chauffés à l'air à 1350°C, un tel remplacement serait possible jusqu'à une limite maximale du 25% atomique. Les produits ainsi obtenus présentent un excès d'oxygène en comparaison de celui demandé par un

degré d'oxydation égal à trois soit pour le fer soit pour le manganèse. La solution solide limite, en particulier, prend la composition  $2\text{CaO} \cdot \text{Fe}_{1,5}\text{Mn}_{0,5}\text{O}_{3,13}$ . Pour cette phase on donne les paramètres réticulaires  $a_0=5,40$ ,  $b_0=14,97$ ,  $c_0=5,54$  Å; en comparaison du ferrite bicalcique on a ainsi une augmentation de  $b_0$  et une diminution de  $a_0$  et  $c_0$ .

Les résultats obtenus par Coates et McMillan ont été confirmés plus récemment par Bando et coll. (6), qui trouvent la même limite de solubilité et une même variation des paramètres réticulaires, mais qui ne donnent aucune indication sur le degré d'oxydation du manganèse.

Tous les solides examinés ont été obtenus à partir de mélanges de carbonate de calcium, sesquioxyde de manganèse, hydroxyde d'aluminium et sesquioxyde de fer purs pour analyse. Le rapport atomique  $\text{Ca}/(\text{Fe}+\text{Mn}+\text{Al})$  a été maintenu toujours constant et égal à 1, tandis qu'ont été modifiés les pourcentages relatifs de fer, manganèse et aluminium.

Les mélanges, broyés par voie humide en présence d'alcool éthylique absolu, ont été échauffés à l'air à 1300°C.

la réalisation des conditions d'équilibre a été plutôt lente, surtout pour les produits plus riches en oxyde d'aluminium; pour cette raison l'échauffement a été prolongé pour des temps allant de 300 à 600 heures. A la fin de la cuisson les solides étaient soumis à trempe en l'air. On passait ensuite à la détermination par voie analytique du degré d'oxydation moyen du manganèse. Dans ce but 0,2 grammes de substance étaient dissous dans une solution aqueuse d'acide perchlorique et d'acide oxalique, en titulant après avec permanganate de potassium l'excès du dernier acide.

On a examiné d'abord les produits obtenus par échauffement de mélanges de carbonate de calcium, sesquioxyde de fer et sesquioxyde de manganèse.

Les résultats de l'analyse aux rayons X (diagrammes de poudres, radiation  $\text{FeK}\alpha$ ) sont en accord avec les indications de Coates et McMillan. Les solides avec un pourcentage atomique de manganèse (à l'égard de la somme  $\text{Fe}+\text{Mn}$ ) situé entre zéro et 25 sont constitués par une seule phase à symétrie romatique semblable à celle du ferrite bicalcique, on a ensuite une zone biphasée et après, entre 50 et 100% de manganèse, une deuxième zone monophasée dans laquelle on rencontre une solution solide  $\text{Ca}(\text{Mn}, \text{Fe})\text{O}_{3-x}$  avec une structure du type perovskite, qui dérive du composé de formule idéale  $\text{CaMnO}_3$  par remplacement partiel des atomes de manganèse par des atomes de fer.

Pour la solution solide romatique de composition limite on a mesuré les paramètres réticulaires suivants:  $a_0=5,38$ ,  $b_0=15,03$ ,  $c_0=5,54$  Å.

L'analyse chimique a donné un degré d'oxydation moyen de fer et manganèse égal à 3,14. Puisque on peut supposer que tous les atomes de fer maintiennent le degré d'oxydation trois, cela entraîne un degré d'oxydation moyen du manganèse égal à 3,56. La composition du produit trempé de 1300°C correspond ainsi à la formule  $2\text{CaO} \cdot \text{Fe}_{1,5}\text{Mn}_{0,5}\text{O}_{3,14}$ .

On pourrait penser qu'un tel degré d'oxydation pour le manganèse soit lié à la présence de lacunes dans le réseau des ions trivalents, c'est à dire à la formation d'une phase du type  $2\text{CaO} \cdot (\text{Fe}, \text{Mn})_{2-x}\text{O}_3$ ; cela paraît toutefois à exclure parce que dans ce cas, avec la composition des mélanges de départ, on devrait constater dans les produits examinés la présence de quantités pas négligeables d'autres phases à rapport  $(\text{Ca}/\text{Fe}+\text{Mn})$  inférieur à 1, phases qui n'ont pas été remarquées à l'examen aux rayons X.

D'autre part la structure du ferrite bicalcique, qui correspond à celle d'une perovskite déformée avec des lacunes anioniques ordonnées (7) n'exclut pas la possibilité d'introduire dans le réseau cristallin des ions tétravalents. On a en effet récemment signalé (8) des phases du type  $\text{Ca}_2\text{Fe}_{2-x}\text{Ti}_x\text{O}_{5+0,5x}$  dans lesquelles, au moins pour des pourcentages de titane pas trop élevés, les paramètres réticulaires changent régulièrement avec l'augmentation de la fraction d'ions fer remplacés par des ions titane.

L'examen des solides obtenus par échauffement de mélanges renfermant (en plus du carbonate de calcium et de deux sesquioxyde de fer et

Fig. 1 - Domaine de stabilité des solutions solides provenant du ferrite bicalcique en fonction des pourcentages relatifs de fer, manganèse et aluminium.

de manganèse) aussi de l'hydroxyde d'aluminium a montré que la solution solide à symétrie romique provenant du ferrite bicalcique peut admettre le remplacement simultané des atomes de fer par atomes d'aluminium et atomes de manganèse. On a ainsi des solides monophasés représentés par la formule  $2\text{CaO} \cdot (\text{Fe}, \text{Al}, \text{Mn})_2\text{O}_{3+x}$ .

L'étendue de la zone de stabilité de cette phase, toujours pour solides trempés à l'air à partir de 1300°C, est représentée dans la figure 1.

La zone de stabilité des solutions solides provenant du ferrite bicalcique occupe la partie centrale du diagramme. Les produits plus riches en manganèse sont formés par un mélange mécanique de ces solutions solides avec la phase  $\text{Ca}(\text{Mn}, \text{Fe})\text{O}_{3+x}$ , tandis que celles plus riches en oxyde d'aluminium correspondent à des mélanges triphasés de  $2\text{CaO} \cdot (\text{Fe}, \text{Al}, \text{Mn})_2\text{O}_{3+x}$ ,  $3\text{CaO} \cdot \text{Al}_2\text{O}_3$  et  $12\text{CaO} \cdot 7\text{Al}_2\text{O}_3$ .

Le remplacement dans le ferrite bicalcique des atomes de fer par des atomes de manganèse entraîne, comme déjà dit, une augmentation du paramètre  $b_0$  et une diminution de  $a_0$  et  $c_0$ ; un phénomène tout à fait analogue arrive aussi en présence d'atomes d'aluminium, comme on peut bien voir dans le graphique de la fig. 2 où sont montrés les paramètres réticulaires des solides à pourcentage constant d'aluminium.

Fig. 2 - Paramètres réticulaires des solutions solides  $2\text{CaO} \cdot (\text{Fe}, \text{Al}, \text{Mn})_2\text{O}_{3+x}$  à pourcentage fixe d'aluminium:  $\text{Al}/(\text{Fe}+\text{Al}+\text{Mn})=65\%$ .

L'introduction d'atomes d'aluminium à la place des atomes de fer entraîne au contraire une diminution de tous les paramètres réticulaires, soit lorsque elle a lieu à partir du ferrite bicalcique pur, comme l'on connaît bien des nombreuses études sur les solutions solides  $2\text{CaO} \cdot (\text{Fe}, \text{Al})_2\text{O}_3$  (9,10,11,12), soit

lorsque un tel remplacement a lieu en présence d'atomes de manganèse, comme l'on voit sur le graphique de la fig.3, qui montre les paramètres réticulaires mesurés sur des produits dans lesquels on maintenait constant le pourcentage atomique de manganèse.

Fig. 3 - Paramètres réticulaires de solutions solides  $2\text{CaO} \cdot (\text{Fe}, \text{Al}, \text{Mn})_2\text{O}_3$  à pourcentage fixe de manganèse:  $\text{Mn}/(\text{Fe} + \text{Al} + \text{Mn}) = 25\%$ .

Le remplacement des atomes d'aluminium par des atomes de manganèse entraîne à son tour une augmentation assez marquée du paramètre  $b_0$ , tandis que  $a_0$  et  $c_0$  demeurent pratiquement inchangés.

Le degré d'oxydation du manganèse va graduellement en diminuant avec l'augmentation du pourcentage d'atomes de fer remplacés par l'aluminium. On passe en effet de la valeur déjà indiquée de 3,56 pour  $2\text{CaO} \cdot \text{Fe}_2\text{Mn}_2\text{O}_3$  jusqu'à des valeurs pas beaucoup plus élevées que trois pour les produits complètement dépourvus de fer. En maintenant constant le rapport entre atomes de fer et atomes d'aluminium, le degré d'oxydation du manganèse montre au contraire une augmentation avec l'accroissement du pourcentage de manganèse.

En regardant le graphique de la fig.1 on peut observer qu'il est possible d'obtenir des solutions solides avec une structure semblable à celle du ferrite bicalcique dans lesquelles tous les atomes de fer ont été remplacés par des atomes d'aluminium et de manganèse. Ce fait est assez remarquable puisque un composé  $2\text{CaO} \cdot \text{Mn}_2\text{O}_3$  n'est pas connu; l'aluminate bicalcique  $2\text{CaO} \cdot \text{Al}_2\text{O}_3$ , du même type structural du ferrite bicalcique, a été préparé récemment (13), il a été toutefois obtenu en travaillant sous une pression de 25.000 bar. L'échauffement à pression ordinaire de mélan-

ges  $2\text{CaO} + \text{Al}_2\text{O}_3$ , au contraire, donne naissance, comme il est bien connu, à un mélange mécanique de  $3\text{CaO} \cdot \text{Al}_2\text{O}_3$  et de  $12\text{CaO} \cdot 7\text{Al}_2\text{O}_3$ .

Le domaine d'existence des solutions solides rombiges  $2\text{CaO} \cdot (\text{Al}, \text{Mn})_2\text{O}_3$  est très limité. Dans les produits trempés à l'air de  $1300^\circ\text{C}$  il s'étend environ de 32 à 44% de manganèse à l'égard de la somme  $\text{Al} + \text{Mn}$ .

Pour des teneurs en manganèse plus élevés la solution solide limite est en équilibre avec la phase  $\text{CaMnO}_{3-x}$ , pour des teneurs plus petites avec  $3\text{CaO} \cdot \text{Al}_2\text{O}_3$  et  $12\text{CaO} \cdot 7\text{Al}_2\text{O}_3$ . La solution solide en équilibre avec  $\text{CaMnO}_{3-x}$  présente les paramètres réticulaires  $a_0 = 5,25$ ,  $b_0 = 14,96$ ,  $c_0 = 5,47$  Å; la solution solide en équilibre avec les aluminates présente les paramètres  $a_0 = 5,24$ ,  $b_0 = 14,81$ ,  $c_0 = 5,46$  Å.

Des données rapportées ci-dessus on voit bien que, au contraire des indications de Parker et de Gharpurey et Pai, il ne nous a pas été possible d'obtenir le remplacement complet dans la brownmillerite des atomes de fer par des atomes de manganèse. L'échauffement des mélanges de carbonate de calcium, sesquioxyde de manganèse et hydroxyde d'aluminium avec un rapport  $\text{Mn}/\text{Al}$  égal à 1 a en effet toujours amené à la formation de mélanges mécaniques de  $\text{CaMnO}_{3-x}$  avec la solution solide limite. Les mêmes résultats ont été obtenus aussi conduisant l'échauffement à  $1350$  et  $1400^\circ\text{C}$ .

## CONCLUSIONS

On peut obtenir des phases dérivant du ferrite bicalcique par remplacement total des atomes de fer par des atomes de manganèse et d'aluminium.

Lorsque le manganèse remplace le fer dans le  $\text{C}_2\text{F}$  il présente toujours, dans les solides trempés dans l'air, un degré d'oxydation moyen supérieur à trois.

# Granularity Influence of Limestone and Quartz on the Reactivity of Cement Raw Material

## *Influence de la finesse de broyage du calcaire et du quartz sur la réactivité du cru*

S. CHROMY, RNDr, CSc, Research Institute of Building Materials, Brno, CSSR (Tchécoslovaquie).

**RESUME :** On a utilisé une méthode cinétique basée sur l'analyse microscopique des phases de clinkers cuits isothermiquement à la température de 1400°C et de farines de matière première ne différant que par la teneur en grains de calcite ou de quartz plus grands que 40  $\mu$  m. On a montré la dépendance linéaire de la réactivité avec la valeur inverse du carré du rayon de la particule moyenne de calcite, en définissant cette valeur moyenne, comme celle qui a 25 % de grains plus gros. On a déterminé une dépendance analogue pour la grandeur médiane de la particule de quartz contenu dans la farine de matière première. Seuls les grains de calcite les plus grands donnent naissance aux amas de grains de CaO libre; et d'une matière analogue, les grains de quartz les plus grands donnent naissance aux amas des grains de bélite.

Aux corrélations ci-dessus correspond la similitude géométrique de la réaction des amas de CaO et de bélite libres dans le processus de formation de l'alite, qui joue un rôle décisif du point de vue de la réactivité. Pour les farines de matière première de même composition chimique, et dans lesquelles tous le SiO<sub>2</sub> se trouve sous forme de quartz, la réactivité est inversement proportionnelle au produit des rayons médians de calcite et de quartz.

**SUMMARY :** The reactivity of a series of raw meals, differing only in the calcite or quartz grain contents larger than 40  $\mu$ m, was determined by a kinetic method based on quantitative microscopic phase analyses of clinkers isothermally fired at 1400°C. It was shown that there exists a linear relationship between the reactivity and the reciprocal value of the square of the average calcite particle radius, if the size of the average particle is determined employing 25% of the coarsest calcite particles. An analogical dependence was determined for the average particle size of all the quartz in the raw meal. Only from the larger calcite grains there are formed agglomerations of free CaO grains and similarly the agglomerations of belite grains are formed from larger quartz grains. To the above relationship corresponds a geometrical similarity of the reactions of the free CaO and belite agglomerations in the process of alite formation which is decisive from the point of view of reactivity. For raw meals of the same chemical composition, in which all the SiO<sub>2</sub> is in the form of quartz, the reactivity varies linearly with the reciprocal value of the product of average diameter squares of calcite and quartz.

## INTRODUCTION

Large limestone and quartz grains are the source of chemical inhomogeneity in the clinker formation process and therefore their size is one of the main factors of the raw meal reactivity. On rapid heating there occurs simultaneously with the formation of the liquid clinker phase at a high rate the formation of belite, during which there are reacted the fine fractions of free CaO and all the SiO<sub>2</sub>. Out of the larger quartz grains there are formed belite agglomerations with the increased contents of more acidic interstitial melt. The agglomerations of free CaO grains left for the reaction of alite formation are formed from the originally largest limestone grains (1,2). The following reaction  $C + C_2S = C_3S$  is a slow process of free CaO and belite dissolution and alite crystallization, controlled by the diffusion of CaO in the liquid phase, and its rate can be described by the modified Kondo and Choi equation (3,4)

$$\left(1 - \sqrt[3]{1 - \alpha}\right)^2 = \frac{2D \cdot \Delta C \cdot y}{r_0^2} = Kt = F(\alpha) / 1/$$

where  $\alpha$  = degree of conversion of free CaO in the reaction  $C + C_2S = C_3S$

$D$  = diffusion coefficient of CaO in the liquid clinker phase

$\Delta C$  = CaO concentration gradient in the reaction zone

$y$  = liquid phase quantity in the clinker

$r_0$  = radius of average sized free CaO agglomeration in the reaction  $C + C_2S = C_3S$

$K$  = rate constant of the reaction

$t$  = duration of isothermal firing

With regard to the great difference in the rate of the two following processes, the raw meal reactivity (Rm) can be determined as the relative value of the rate constant of the kinetic description of the second reaction (3)

$$Rm = \frac{K^*}{K_s} \quad /2/$$

where  $K^*$  = rate constant of the reference raw meal. After the elimination of the influences of the liquid phase quantity and lime saturation onto the rate constant (3), it is possible to determine simultaneously also the "reactivity of the raw materials source" (Rq)

$$Rq = \frac{K^* r_{0C}^2}{K_s^* r_{0S}^2} \quad /3/$$

where  $K_s^*$  = rate constant of the reference raw meal

$r_{0C}$  = radius of an average sized CaCO<sub>3</sub> particle for the reaction  $C + C_2S = C_3S$  (approx. 25% of the coarsest particles)

$r_{0S}$  = analogically for the reference raw meal.

Through a change in raw meal granulometry there is changed the rate of clinker formation (Rm), but the value Rq does not change, as long as jointly ground identical raw components are employed. The above kinetic methods for the determination of the reactivities can be utilized for an objective influence assessment of the size of limestone and quartz particles onto Rm. The information obtained represents a pre-condition for a simplified reactivity assessment and can be utilized also for influencing the reactivity of cement raw materials.

## RAW MEALS

As raw components there were employed coarse-grained natural calcite, quartz, Al<sub>2</sub>O<sub>3</sub> and Fe<sub>2</sub>O<sub>3</sub>. All raw meals had an identical chemical (Table I) as well as mineralogical composition, and differed only in their contents of calcite (C 1-C 6) or quartz (S 1-S 6) particles larger than 40  $\mu$ m (Table II). The CS raw meal was prepared only from components that passed through the 40  $\mu$ m sieve.

TABLE I Chemical composition of raw meals

Ignition loss	SiO <sub>2</sub>	Al <sub>2</sub> O <sub>3</sub>	Fe <sub>2</sub> O <sub>3</sub>	TiO <sub>2</sub>
34,61	13,86	3,97	2,33	0,01
Ignition loss	CaO	MgO	K <sub>2</sub> O	Na <sub>2</sub> O
34,61	43,66	1,32	0,02	0,06

The granulometric composition of the fractions was determined, with the exception of the 90-200  $\mu$ m fraction, by the Coulter Counter Method and the average particle sizes (Table III) were calculated as the geometrical mean value from the relationship

$$\log d_v = \sum p_i \cdot \log d_i \quad /4/$$

where  $d$  = cross section of particle  
 $p$  = mass of fraction.

For the 90-200  $\mu$ m fraction was carried out a partial sieve analysis and for the average grain size of the individual fractions was taken the arithmetic mean of the marginal values.

TABLE III Average grain sizes of the calcite and quartz fractions

Fraction ( $\mu$ m)	0-40	40-63	63-90	90-200
d - calcite	20,03	54,65	72,61	67,00
d - quartz	20,33	51,37	74,42	68,00

The average raw meal grain sizes were computed from the values listed in Table III and from the cumulative curves of fractions according to equation /4/ on the basis of values in Table II.

TABLE II Contents of limestone and quartz sieve fractions in the raw meals

Fraction( $\mu$ m)	C A L C I T E						Q U A R T Z					
	C 1	C 2	C 3	C 4	C 5	C 6	S 1	S 2	S 3	S 4	S 5	S 6
0 - 40	71,22	71,22	71,22	76,22	66,22	61,22	7,65	7,65	7,65	9,65	2,65	-
40 - 63	10						5					
63 - 90		10		5	15	20		5		3	10	12,65
90 - 200			10						5			

#### RESULTS

In accordance with the methods for the determination of reactivities (3), from each raw meal clinkers were fired with an effective isothermal holding period at 1400°C of 1.6 and 5.6 minutes. The clinkers were subjected to a quantitative microscopic analysis (5) and the reactivities listed in Table IV were computed.

TABLE IV Reactivity ( $R_m$ ), conversion ( $\alpha = \frac{C_3 S}{C_3 S_{\max}}$ ) of experimental firings and ratio of average calcite ( $r_{oC}$ ) and quartz ( $r_{oQ}$ ) particles in raw meals

	CS	C 1	C 2	C 3	C 4	C 5	C 6	CS	S 1	S 2	S 3	S 4	S 5	S 6
$R_m$	3,03	2,44	2,00	1,34	2,37	1,61	1,29	3,03	1,92	1,01	0,74	1,81	0,41	0,25
$R_q$	0,46	0,47	0,50	0,47	0,43	0,53	0,55	0,46	0,40	0,24	0,21	0,38	0,13	0,10
1.6	0,668	0,649	0,591	0,586	0,644	0,591	0,578	0,668	0,525	0,508	0,451	0,598	0,344	0,244
5.6	0,883	0,850	0,806	0,751	0,845	0,776	0,743	0,883	0,779	0,681	0,614	0,794	0,489	0,384
$r_{oC}(\mu$ m)	18,38	20,66	23,47	28,13	20,2	27,11	30,91							
$r_{oQ}(\mu$ m)								10,16	14,67	16,97	21,53	13,82	28,33	37,20

The dependence of the reaction grade ( $\alpha$ ) expressed as the ratio of the alite quantity in the clinker to its maximum possible quantity is shown in Fig. 1, and the dependence of  $R_m$  on the average particle sizes in Fig. 2.

A satisfactory linearity of the dependence of the raw meal reactivity ( $R_m$ ) on  $1/r_o^2$ , assumed from equation /1/, was obtained for the determination of the average particle size from 25% of the coarsest particles of the raw meals C 1-C 6, and for the raw meal series S 1-S 6 for the determination of the average particle size of all the quartz in the raw meal (Table IV, Fig. 2). The elimination of granulometric differences in raw meals with coarser calcite is therefore effective and for considerable differences in the  $R_m$  values, the differences in the raw materials source reactivities ( $R_q$ ) are slight (Table IV). The quartz granulometry is a factor of the raw materials source reactivity and therefore both reactivity values in raw meals with coarser quartz particles are changing concurrently. An analogy

of the dependence of  $R_m$  on the size of calcite and quartz particles (Figs. 1, 2) points to a geometrical analogy of the belitic agglomerations degrading process with the dissolution of free CaO agglomerations. A different slope of dependence lines in Fig. 1 may be caused by a different size of the belite and free CaO agglomerations formed from equally large calcite and quartz grains. Microscopic studies have shown that in the reaction course of the isothermal alite formation in the clinkers C 1-C 6 there is formed rapidly a homogenous belitic environment, in which the free CaO agglomerations are reacting (Fig. 3). This corresponds to the geometrical model of equation /1/, the free CaO grain agglomerations being somewhat smaller than the original calcite particles. On the contrary, on heating the raw meals of the S 1-S 6 series are formed very rapidly belite agglomerations after larger quartz grains, whereas the free CaO is uniformly scattered (Fig. 4). The degradation process of these agglomerations through an internal CaO diffusion is a geometrical analogy of

Fig. 1 - Conversion change with the quantity of coarse  $\text{CaCO}_3$  (O) and quartz (□) particles, isothermal firing of raw meals C 4-C 6 and S 4-S 6, 1400 °C, 1.6 and 5.6 minutes.

Fig. 2 - Change of reactivity ( $R_m$ ) with the size of the average calcite and quartz particle. ● -CS, C 1-C 6, ■ -CS, S 1-S 6.

the Jander and Ginstling-Eronstein model, and for the description of its rate for lower conversions there can also be employed equation /1/. The volume of the belitic agglomerations is more than three times as large as the original quartz grains and the largest agglomerations are only being partially reacted, since they represent the source of residual belite, especially in clinkers with a lower lime saturation.

From Fig. 5 can clearly be seen the linear dependence of  $R_m$  on the reciprocal value of the products of squares of average

Fig. 3 - Free  $\text{CaC}$  agglomerations in C 2 clinker, firing at 1400 °C, 1 minute. Phases according to blackening of photograph: Interstitial mass, free  $\text{CaO}$ , alite, belite. Large homogenous area - epoxide. ( $\text{CH}_3\text{COOH}$  vapour)

Fig. 4 - Belite agglomerations in S 5 clinker, firing at 1400 °C, 1 minute. Phases same as in Fig. 3.

limestone and quartz particle radii that have been determined as described above. This dependence holds true only for raw meals of identical chemical composition in which all the  $\text{SiO}_2$  is in the form of quartz. Since in industrial raw meals the ratio  $\text{SiO}_2/\text{quartz}$  is always  $> 1$ , it is necessary to take into account for the practical utilization of the above findings also the influence of the quartz quantity onto the rate of clinker formation. The raw meal reactivity can be influenced only by the quartz grains which cause the formation of such local  $\text{SiO}_2$  concentrations in the belitic clinker that hinder the following alite formation process. With intensive heating, this effect of the smallest quartz particles is suppressed already in the course of the formation of the liquid phase, and therefore there exists a critical size, below which all forms of  $\text{SiO}_2$  can for practical purposes be considered as approximately identically reactive. This fact has been established already in previous investigations and the critical size can be found closely below 40 μm (6,7). Since the reaction mechanism of larger silica grains as well as their influence onto the reactivity is analogous to quartz, it is possible to propose a

Fig. 5 - Change of reactivity with the size of the average calcite and quartz particle. simplified method for the determination of the raw meal reactivity on the basis of sieve analyses of the raw meal, the insoluble residue and the chemical composition :

$$R_m' = \frac{L}{r_{0C}^2 \cdot r_{0Q}^2 \cdot C_3S_{max}} \cdot \frac{1}{S} \quad /5/$$

where  $L$  = computed liquid phase quantity in the clinker

$C_3S_{max}$  = computed equilibrium  $C_3S$  content in the clinker

$r_{0C}$  = average particle radius out of 25% of the coarsest raw meal particles

$r_{0Q}$  = average particle radius of the insoluble residue of the raw meal in HCl

$S$  = expression value in the brackets of the equation /5/, computed for the reference raw meal.

The influences of the liquid phase quantity in the clinker and of  $C_3S_{max}$  onto the reactivity of the raw meal are well known (8, 3), and in the course of the assessment of the insoluble residue the average grain size is determined experimentally only for the rest on the 40  $\mu m$  sieve, and for the computation of  $r_{0Q}$  there is assumed an average grain size of the remaining  $SiO_2$   $d_{0-40} = 20 \mu m$ . The proposed method for determining the reactivities of raw meals neglects the influence of side admixtures and is loaded with the systematic error of the differences between the actual and calculated contents of alite and the liquid phase and the simplified assessment of the insoluble residue. It is therefore suitable especially for investigating the reactivity of raw meals prepared from components out the same

locality, i.e. for solving the problems of a cement plant, in the laboratory of which it can easily be realized.

#### CONCLUSION

The reactivity of the cement raw meal decreases linearly with the reciprocal value of the product of the squares of the average calcite and quartz grains. This relationship, together with certain findings concerning the mechanism of clinker formation, have made it possible to present a simplified method for the operational determination of reactivity which can be realized in cement plant laboratory. The reactivity is determined from the chemical composition of the raw meal, its sieve analysis and the sieve analysis of the insoluble residue.

# Thermodynamics of closed systems applied to the annealing of clinker

## *Thermodynamique des systèmes clos appliquée à la cuisson du clinker*

M. SHULTZ, Academician, Institute of Silicate Chemistry of the Academy of Sciences of the USSR, Leningrad, U.R.S.S.

**RESUME :** En thermodynamique, il a été convenu d'appeler "clos" des systèmes dans lesquels les processus se développent sans échange de matière avec le milieu extérieur; c'est à dire dans des conditions d'isolation matérielle. Dans la cuisson du clinker de ciment, il y a des stades appropriés qui, quoique approximativement, peuvent être assimilés aux processus ayant lieu dans les systèmes clos. Nous voulons parler des réactions de formation des minéraux et des processus de redistribution de matière entre les phases qui continuent de se développer après l'achèvement de la déshydratation et de la décarbonisation, suivant les variations de la température dans chacune des zones du four.

Malgré le fait que, dans les conditions réelles, les états d'équilibre ne sont pas atteints, une considération thermodynamique permet de mettre en évidence les directions essentielles les plus probables de développement des processus à la cuisson du clinker.

Dans cette communication deux questions corrélées sont considérées. En se basant sur des concepts thermodynamiques généraux, il a été montré comment les changements de température influencent les compositions des phases du clinker (les phases liquides et solides), pour une composition atomique donnée du système, et en cas d'isolation matérielle.

Dans la deuxième partie de la communication une étude est faite, par la méthode des "séries isomolaires" sur la stabilité relative des combinaisons des systèmes  $\text{CaO-SiO}_2$ ,  $\text{CaO-Al}_2\text{O}_3$ ,  $\text{MgO-SiO}_2$ , dans des conditions isothermiques et isobariques, les oxydes dont sont constitués les clinkers étaient, dans cette étude, dans les mêmes proportions que dans les diagrammes de phase habituels bien connus.

**SUMMARY :** In thermodynamics it is customary to call "closed" the systems in which the processes develop without exchange of material with the outer medium, i.e. under conditions of material isolation. During the annealing of cement clinker there are appropriate stages which, although approximately, can be attributed to the processes taking place in the closed systems. We mean concretely the formation reactions of minerals and the redistribution processes of the material between phases which continue to develop also after the completion of dehydration and decarbonization in accordance with changing temperature in each zone of the cement kiln.

Despite the fact that under real conditions the equilibrium states are not attained, a thermodynamic consideration permits to reveal the most probable basic directions of the development of processes during annealing the clinker.

Two interrelated questions are dealt with in the present paper. When solving one of these questions on the basis of general thermodynamic concepts, we tried to show how the temperature changes influence the compositions of the coexisting clinker phases (liquid and solid solutions) at a given brutto-composition of the system, what corresponds to the conditions of material isolation.

In the second part of the paper a consideration is given, using the method of "isomolar series", of the relative stability of compounds in the systems  $\text{CaO-SiO}_2$ ,  $\text{CaO-Al}_2\text{O}_3$ ,  $\text{MgO-SiO}_2$  under isothermal-isobaric conditions and at either but at a given mass correlation of the constituent oxides of clinker minerals with respect to the known phase diagrams.

# INFLUENCE OF TEMPERATURE ON PHASE RELATIONS IN THE CLOSED SYSTEMS

A thermodynamic consideration of the heterogeneous systems includes as a base, along with the principles of equilibrium and conditions of its stability, the concept of phase as combination of complexes of bodies the equilibrium properties of which can be described by the general thermodynamic equation - an equation of phase. By Gibbs, the latter can be represented as follows:

$$S^r dT - v^r dp + \sum_{i=1}^n m_i^r dM_i = 0 \quad (1)$$

where  $S^r$  and  $v^r$  are the entropy and the volume of the phase;  $m_i^r$  is the mass of each of the components of phase  $V_r$ ;  $T, p, M_i$  are the temperature, the pressure and the chemical potentials, respectively;  $r$  is the index of phase. By solving the system of equations (1) for two phases, the generalized differential Van-der-Waals equation is obtained which is considered in detail in /2/ and written as follows:

$$Q^{12} dT - v^{12} dp + \sum_{k=1}^{n-1} \sum_{i=1}^{n-1} (x_i^2 - x_i^1) G_{ik}^1 dx_i^1 = 0 \quad (2)$$

where  $Q^{12}$  and  $v^{12}$  are the thermal and volume effects of phase transformation;  $x_i^1$  and  $x_i^2$  are the mole fractions of  $i$ -components in the solid and liquid phases, respectively;

$G_{ik}^1 = \left( \frac{\partial^2 G}{\partial x_i \partial x_k} \right)^1$  is the second derivative of the Gibbs free energy by mole fractions of components in the phase. The symbols of phases  $V_1$  and  $V_2$  are then introduced.

Equation (2) is written in the variables of the composition of phase  $V_1$ ; analogous equation can be written in the variables of phase  $V_2$ .

At full description of the equilibrium processes in the heterogeneous systems, the following equalities are also taken into consideration /2/:

$$d \left( \frac{\partial G^1}{\partial x_i^1} \right)_{T, p, x_j} = d \left( \frac{\partial G^2}{\partial x_i^2} \right)_{T, p, x_j} \quad (3)$$

(  $i = 1, \dots, n-1$  )

which are reduced to the form

$$\begin{aligned} - \left( \frac{\partial S^1}{\partial x_i^1} \right) dT + \left( \frac{\partial v^1}{\partial x_i^1} \right) dp + \sum_{k=1}^{n-1} G_{ik}^1 dx_k^1 = \\ = - \left( \frac{\partial S^2}{\partial x_i^2} \right) dT + \left( \frac{\partial v^2}{\partial x_i^2} \right) dp + \sum_{k=1}^{n-1} G_{ik}^2 dx_k^2 \end{aligned} \quad (4)$$

The total number of independent equations from system (4) together with equation (2) is established using the phase rule and is equal to " $n$ ". For the closed systems, equations (2) and (4) are complemented by conditions of material isolation, e.g., in the following form:

$$\begin{aligned} x_i^1 m^1 + x_i^2 m^2 = m_i^0 = \text{const} \\ m^1 + m^2 = m^0 = \text{const} \end{aligned} \quad (i=1, \dots, n) \quad (5)$$

where  $m^1$  and  $m^2$  are the masses of phases  $V_1$  and  $V_2$ ;  $m_i^0$  is the full mass of  $i$ -component;  $m^0$  is the full mass of the system.

Differentiation of the system of equations (5) leads to the following expressions:

$$m^1 dx_i^1 + m^2 dx_i^2 = (x_i^2 - x_i^1) dm^1 \quad (i=1, \dots, n) \quad (6)$$

A consideration of combination of equations (2), (4), (6) often leads to rather bulky and difficult for interpretation expressions. However, as it follows from the works of Filippov /3/, the representation of the appropriate systems of equations in the form of vector expressions permits to easily draw rather clear and visual conclusions. To this purpose, vectors of phase compositions (or generalized vectors of the directions of changes in phase composition),  $dx_i$ , are introduced as well as vectors of tie-lines  $(x_i^2 - x_i^1)$  connecting the figurative points of the coexisting phases  $V_1$  and  $V_2$ . The concentration space is represented in the metrics of Gibbs free energy; operators  $G_1$  and  $G_2$  are introduced to which the matrices  $|G_{ik}|^r$  ( $r=1,2$ ) correspond; and finally, use is made of the general expressions for the concentration gradients of the entropies of phases  $\nabla S^1$  and  $\nabla S^2$ . This results, as discussed in detail in /3-6/, in the following expressions for isobaric conditions:

$$m^1 d\bar{x}_1 + m^2 d\bar{x}_2 = (\bar{x}_2 - \bar{x}_1) dm^1 \quad (7)^*$$

$$G_1 d\bar{x}_1 - \nabla S^1 dT = G_2 d\bar{x}_2 - \nabla S^2 dT \quad (8)$$

$$(\bar{x}_2 - \bar{x}_1) G_1 d\bar{x}_1 = [s^1 - s^2 - (\bar{x}_2 - \bar{x}_1) \nabla S^1] dT \quad (9)$$

After making several transformations of the system of equations (7)-(9) and after introducing the additional term - the concentration gradient of the entropy of the heterogeneous system as a whole,  $\nabla S$ , (the proper entropy of the heterogeneous system is expressed as  $S = S^1 m^1 + S^2 m^2$ ) one obtains, as shown in /4-6/, the following expression characterizing the influence of temperature on the composition of one of the coexisting phases, e.g., of the phase  $V_1$ :

$$G_1 \frac{d\bar{x}_1}{dT} = \nabla S^1 - \nabla S \quad (10)$$

Scalar product of equation (10) by the vector  $\bar{e}_1$  lying at the tangent to the isotherm-isobar of phase  $V_1$  (the straight line  $T_1(V_1 - V_2)$  in Figure 1) gives

$$\bar{e}_1 G_1 \frac{d\bar{x}_1}{dT} = \bar{e}_1 (\nabla S^1 - \nabla S) \quad (11)$$

The left part of equation (11) is a projection of vector  $\frac{d\bar{x}_1}{dT}$  against the tangential

\*With vector values the phase index stands below

vector  $\vec{e}_1$  and characterizes the shift of the composition of phase  $V_1$  in relation to the primary position or, in other words, the motion of the end of the tie-line (or its turn) with the isobaric change of temperature (Figure 1).

Fig. 1 - Change in position of the isotherm-isobar and of the tie-line in the closed system  $V_1$ - $V_2$  with changing temperature.

As seen from equation (11), the direction of the vector of the tie-line turn at the fixed brutto-composition of the system is determined by the correlation of projections (in a common sense) of the entropy gradients of phase  $V_1$  and of the system  $V_1$ - $V_2$  against vector  $\vec{e}_1 \in T_1(V_1-V_2)$  or, what is the same, by the correlation of the corresponding concentration derivatives. Actually, it can be shown that

$$\vec{e}_1(\nabla S^1 - \nabla S) = \left( \frac{\partial S^1}{\partial x_1^1} \right)_{\vec{e}_1} - \left( \frac{\partial S^2}{\partial x_1^2} \right)_{\vec{e}_1} \vec{e}_1 \quad (12)$$

where  $x_1^1$  is the mole fraction of i-component in the phase  $V_1$  and  $x_1^2$  is the brutto-mole fraction. The following general conclusion can be formulated: If the difference of the derivatives characterizing the entropy change of the phase  $V_1$  and of the system  $V_1$ - $V_2$  in the direction of vector  $\vec{e}_1 \in T_1(V_1-V_2)$  tangential to the isotherm-isobar is positive, then with isobaric increase in temperature of the system the shift of composition of phase  $V_1$  and consequently the turn of the tie-line will occur in the direction of vector  $\vec{e}_1$ , and on the opposite.

Let us note that in a particular case when the tangents and the isotherms-isobars of the coexisting phases are parallel (such a case will be dealt with somewhat later), the following equation can be obtained:

$$\vec{e}_1(\nabla S^1 - \nabla S) = m^2 \left[ \left( \frac{\partial S^1}{\partial x_1^1} \right)_{\vec{e}_1} - \left( \frac{\partial S^2}{\partial x_1^2} \right)_{\vec{e}_1} \right] \vec{e}_1 \quad (13)$$

Due to the equilibrium conditions which are, in particular, expressed by equality (3), the differences of the entropy derivatives in equations (12) and (13) can be replaced accordingly by those of the enthalpy derivatives by concentration attributed to the absolute temperatures. The correlations considered here are of special interest for such cases when the coexisting phases are of variable composition. During the annealing of

clinker one often deals with the cases when many phases of variable composition enter into interaction as the clinker phases represent different solid solutions. However, there is a paucity of concrete data on the compositions of coexisting phases.

As it follows from [7], two equilibrium solid solutions,  $(\text{MgO}, \text{FeO})\text{SiO}_2$  and  $(\text{MgO}, \text{FeO})_2\text{SiO}_2$ , form in the  $\text{MgO}$ - $\text{FeO}$ - $\text{SiO}_2$  system for which, although schematically, the positions of tie-lines are given for different temperatures. Based on these data to illustrate consequences (12) and (13), we show in Figure 2 how the temperature influences the position of one of the tie-lines connecting the figurative points of two solid solutions  $(\text{MgO}, \text{FeO})\text{SiO}_2$  - phase  $V_1$  and  $(\text{MgO}, \text{FeO})_2\text{SiO}_2$  - phase  $V_2$ .

Fig. 2 - Positions of tie-lines of two-phase equilibria of the solid solutions  $(\text{MgO}, \text{FeO})\text{SiO}_2$  and  $(\text{MgO}, \text{FeO})_2\text{SiO}_2$  in the  $\text{MgO}$ - $\text{FeO}$ - $\text{SiO}_2$  system at 955° and 1250°C.

As follows from Figure 2 and equations (12) and (13), the entropy and enthalpy derivatives by concentration in the equilibrium phases are larger for phase  $V_1$  than for phase  $V_2$ , but they are probably rather close in value.

It should be noted that the results given above are first of all of practical significance serving as strict (precise) thermodynamic criteria of the reliability of experimental data. It is obvious that such criteria are quite necessary for experimental investigations of the systems of refractory oxides. This will be evidenced, in particular, by the material to be discussed in the next paragraph.

#### RELATIVE STABILITY OF COMPOUNDS FORMING THE MINERALS OF CEMENT CLINKER

One of the main questions of the thermodynamic consideration of the formation processes of clinker is that concerning the most probable reactions of mineral formation under given particular conditions. This question is often answered by comparing the values of the Gibbs free energy decrease for different reactions and by asserting that the process with the greatest decrease of this function will be most probable. However, the mass correlations of the participants of the process should also be taken into consideration, as shown on many examples by Mchedlov-Tetrossian et al [8/.

Long ago Shchukarev /9/ came to the conclusion that if in a system of two different elements a series of compounds is formed, then the thermal effects of compounds formation calculated per one gram-atom (in the total), represented graphically as a function of composition, should be described by smooth curves without sharp inflections. This concept was illustrated by many examples; for oxide systems they are given in /10/. The analysis of the above-mentioned generalization of experimental data leads to the conclusion that under certain conditions these data can be regarded as consequences of the principle of equilibrium stability developed in the most complete and strict form by Gibbs /1/, if the concept mentioned is related not to enthalpy but to free energy /11/. We shall not concern here the details of the known conceptions but remind only of the following. In the most general form the conditions of equilibrium stability are expressed by the inequality

$$(\Delta E)_{s,v,m_1,\dots,m_n} > Q \quad (14)$$

where  $\Delta E$  is the internal energy of the system;  $s$  is the entropy;  $v$  is the volume;  $m_1, \dots, m_n$  are the masses of components.

The fulfillment of inequality (14) is a necessary and sufficient condition for equilibrium stability with respect to any arbitrary changes of the state. This inequality means that under indicated conditions (at a given mass of components included), if the system is in the state of stable equilibrium, any change of the state which disturbs the equilibrium should be accompanied by an increase of internal energy. For the isothermal-isobaric conditions, analogous concept is applicable to the standard Gibbs free energy, i.e. under given conditions for a system being in the equilibrium state, the following inequality should be fulfilled

$$(\Delta G)_{T,p,m_1,\dots,m_n} > 0 \quad (15)$$

at all changes which disturb the equilibrium of the system. Getting off the point let us note that inequality (15) can be used to derive the following requirement for the states of stable equilibrium:

$$\left[ d^2 G(x_1, \dots, x_{n-1}) \right]_{T,p} \gg 0 \quad (16)$$

(if the composition is expressed in mole fractions).

For the states of stable equilibrium, inequalities (15) and (16) require that in graphic representation the surface of the free energy would be prominent in relation to the coordinate axes of the system composition. This principle is widely used in the study of solutions, i.e. at a continuous change of composition. In the form of inequality (15) it can also apply to the series of compounds formed by the same substances which enter into interaction in the different proportions. The only peculiarity is that in this case a comparison of states discontinuous in composition is made, as

shown schematically in Figure 3 /11/.

Fig. 3 - Free energies of formation of stable compounds in the system A-B. Composition is given in mole fractions of B ( $x_B$ ).

This figure is drawn in such a way that each compound is stable with respect to the decomposition into any other compounds being formed in the system. The point is in what concentration range the brutto-composition of the mixture lies: in one range some pairs of compounds are stable, in the other the different ones. This principle extends also to more complex systems where the number of coexisting stable compounds is determined by the phase rule. Without drawing such a diagram or without an appropriate numeric calculation one cannot be sure that the experimental or calculated data are consistent with thermodynamic requirement of stability. Recently, for example, analogous diagrams were used to the same purpose in /12/. Graphic representation is not always convenient but it can be replaced by appropriate calculations. Any complex compound which can be composed of "n" less complex compounds or simple substances will not decompose into them, if the following inequality is fulfilled:

$$\left[ \sum_{i=1}^n x_i \Delta G_i^* - \Delta G^* \right]_{T,p} > 0 \quad (17)$$

where  $x_i$  is the fraction of the compound chosen as component of the complex compound;  $\Delta G_i^*$  is the free energy of the component (or of the compound);  $\Delta G^*$  is analogous value for the complex compound calculated per one mole of the total amount of interacting substances. In all cases the values  $\Delta G_i^*$  and  $\Delta G^*$  are obtained by dividing the molar free energies of compounds formation by the total number of particles forming the compound ( $\Delta G_i^* = \frac{\Delta G_i}{n_i}$ ;  $\Delta G^* = \frac{\Delta G}{n}$ ).

Let us turn our attention to several particular examples and consider first of all the data for one of the major systems of interest to the technology of cement, namely for the CaO-SiO<sub>2</sub> system. Several compounds

form in this system:  $C_3S$ ,  $C_2S$ ,  $C_3S_2$ ,  $CS$ , the thermodynamic data for which are reported in /8/ and presented in the well-known phase diagrams /13, p.33/. The thermodynamic data were used to draw Figure 4 which shows the composition dependence (in mole fraction of  $SiO_2$  ( $X_S$ )) of the free energy of compounds formation calculated per one mole of the total oxides ( $\Delta G^*$ ).

Fig. 4 - Free energies of formation of the oxide compounds in the  $CaO-SiO_2$  system as a function of mole fraction of  $SiO_2$ . The temperatures are 298K, 1300K, 1700K.

As seen from Figure 4, only two compounds,  $C_2S$  and  $CS$ , show consistency with requirements of stable equilibrium given by inequalities (15) and (16). At all temperatures indicated in the figure the compounds  $C_3S$  and  $C_3S_2$  must decompose into pairs of compounds adjoining in composition. The compound  $C_3S$  must decompose into  $CaO$  and  $C_2S$ , and  $C_3S_2$  into  $C_2S$  and  $CS$ . However, the compound  $C_3S$  owing to the small difference effect of the free energy decrease according to equation (17), which apparently lies within the limits of experimental error, is probably located somewhere at the stability boundary as regards the process of decomposition into phases  $CaO$  and  $(CaO)_2SiO_2$ . It should be noted that we have no data which would permit to attribute the phases  $C_3S$  and  $C_3S_2$  to metastable phases. To this end, it would be necessary to obtain and study the stability of solid solutions based on  $C_2S$  and  $C_3S_2$  at variable contents of  $CaO$  and  $SiO_2$  in them.

If one turns attention to the corresponding phase diagram for the  $CaO-SiO_2$ , it will be possible to attribute all compounds shown in

Figure 4 to equilibrium compounds and assume that all of them should coexist in equilibrium with the adjoining in composition compounds without decomposition over the temperature range studied, except for  $C_2S$  below 1250°C. It ought to be concluded that thermodynamic data for this system do not agree fully with the phase diagram. Further checking of thermodynamic data and probably a more critical evaluation of results given in the phase diagram are needed.

The slowing down of the processes in solid bodies is probably responsible for the formation of unstable compounds which are presented in the diagram along with stable compounds. However, to draw final conclusions, further precision of the experimental data discussed here is needed.

Analogous conception can be related to another system of importance for the technology of cement:  $CaO-Al_2O_3$ . Figure 5 which was drawn using data of paper /8/ shows the dependence of the free energy of formation of the calcium aluminates calculated per one mole of the total oxides on the mole fraction of  $Al_2O_3$  in the compound.

Fig. 5 - Free energies of formation of the oxide compounds in the  $CaO-Al_2O_3$  system as a function of mole fraction of  $Al_2O_3$ . The temperatures are 1000K, 1500K, 1800K.

As it is obvious from Figure 5 and condition (15), the compound  $CA$  is unstable with respect to the process of decomposition into compounds  $CA_2$  and  $C_{12}A_7$  adjoining in composition at temperatures of 1500 and 1800K. But if we turn our attention to the corresponding well-known phase diagram /13, p.210/, we shall see that in the temperature range considered in Figure 5 all the compounds

shown are equilibrium in themselves and can coexist with the adjoining compounds. Obviously, there is also some contradiction here.

Finally, to complement the picture under discussion, data on the  $\text{MgO-SiO}_2$  system are presented in Figure 6. Here also in contradiction to the appropriate phase diagram [13, p.28], the compound  $\text{MS}$  is unstable.

Fig. 6 - Free energies of formation of the oxide compounds in the  $\text{MgO-SiO}_2$  system as a function of mole fraction of  $\text{SiO}_2$ . The temperatures are 1500 and 1800K

Many examples could be given to illustrate the point when the phases are presented in the diagrams as equilibrium whereas by thermodynamic properties they should be attributed to unstable phases. The indicated facts, firstly, set the task of a simultaneous study of phase diagrams and thermodynamic functions of formation of the compounds and solid solutions. Together with this, it is apparently of great scientific interest and of practical significance to develop concrete quantitative characteristics of the thermodynamic non-equilibrium "frozen" solid phases and to study the factors of stabilization of the non-equilibrium states.

#### CONCLUSIONS

Further development of the physico-chemical bases of cement technology implies the deepening of concepts in the field of thermodynamics of the heterogeneous processes and accumulation of appropriate data. It also sets the task of a critical analysis of thermodynamic data on the compounds formation in cement clinker and of the appropriate phase diagrams. It is necessary to coordinate both data with respect to the equilibrium stability of the phases of cement clinker.

# Fonction généralisée de clinkérabilité

## *Generalized clinkerability function*

P. GOMA, docteur ès sciences chimiques. Laboratoire de zone de Catalogne, Asland S.A., Espagne.

RESUME : On a établi une méthode pour déterminer les températures de clinkérisation des crus de clinker portland à partir des courbes de l'abaissement de la teneur en chaux libre en fonction de l'augmentation de température jusqu'à 1.600°C dans une calcination dans des conditions contrôlées proches de celles d'un four réel.

Cette méthode, qui a déjà été employée par des auteurs précédents, est associée ici, pour la première fois, à une nouvelle méthode d'analyse chimique absolue due à l'auteur. Elle élimine les erreurs encore inconnues dans le procédé gravimétrique traditionnel pour la détermination de la silice ou dans ses variantes.

L'exactitude et la reproductivité ainsi obtenues ont permis de voir l'influence quantitative des variables qui influent sur la température maximum nécessaire pour la clinkérisation des crus industriels.

On établit une fonction généralisée qui donne le degré de clinkérabilité des crus.

Son application aux crus, dans un processus concret, permet de connaître indirectement, en fonction de la chaux libre obtenue, la température maximum équivalente qu'a atteint le matériau dans la zone de clinkérisation et d'évaluer indirectement le degré de concentration de la combustion obtenue, équivalent à la valeur de l'échange "flamme-clinker".

SUMMARY: We establish a method which can be used to determine the clinkerability temperatures of portland clinker raw mixes from the curves corresponding to the lowering of the free lime value depending on the temperature up to 1.600°C by means of burnability under controlled conditions similar to those of a given kiln.

The base of the method, which has been used by other former authors, is combined here for the first time with a new method of absolute chemical analysis for the gravimetric determination of silica due to the author which avoids errors which are still unknown in the traditional gravimetric process or its variants.

The accuracy and reproducibility obtained in this way have allowed us to see the quantitative influence of the variants which affect the burning temperature maximum that it is necessary for clinkerizing the industrial raw mixes.

Its application on the raw mixes in a concrete process allow to determine indirectly, in relation with the free lime obtained, the maximum equivalent temperature reached by the material in the zone of clinkerization and to know indirectly the concentration degree of flame reached, equivalent to the "flame-clinker" interchange value.

# I- Difficultés à surmonter pour connaître le degré d'optimisation énergétique d'une installation de clinkérisation.

L'utilisation énergétique d'une installation dépend de deux facteurs importants: de la valeur des pertes de chaleur de l'ensemble de l'installation et de la valeur obtenue au moyen des transmissions de chaleur au matériel au cours de ses trois étapes principales, celle de l'échangeur, et dans le four, celle des zones de calcination et clinkérisation, étant cette dernière celle qui permettra d'obtenir, selon sa valeur, un niveau de qualité suffisant pour une production donnée et de laquelle nous parlerons dans ce travail.

La valeur globale de ces facteurs est déterminée d'habitude par les bilans thermiques basés sur des mesures thermodynamiques et physiques, mais ces mesures ne suffisent pas pour évaluer sans interférence la valeur de l'échange entre la flamme et le produit synthétisant dans la zone de clinkérisation que nous appelons échange "flamme-clinker".

Le degré de cet échange serait obtenu en connaissant la valeur de la température du matériel dans la zone de clinkérisation en fonction du temps. Cela n'est pas possible dans la technologie actuelle, mais nous essaierons d'expliquer comment on peut déterminer la valeur de cet échange en fonction de la température maximum qui est mesurée indirectement à partir de ce qu'on appelle les courbes de combinabilité obtenues dans le laboratoire dans des conditions déterminées.

La température maximum du clinker dépend- en quantité de combustible constante- du degré de concentration de la zone de combustion obtenu dans le four, qui permet d'augmenter le nombre de calories et d'énergie de radiation par unité de surface intérieure de la zone.

Le degré de concentration de la combustion dépend des paramètres de la combustion dans le procédé et de la stabilité de son équilibre thermique.

Dans la pratique du proces industriel, ces variantes se cachent et interfèrent de manière qu'il n'est pas possible de connaître avec certitude, de façon systématique, quel est le cru le plus approprié à une installation, quand il y a des conditions forcées, quel est le facteur qui limite la production dans chaque cas ou si celui-ci dépend des conditions chimiques du cru ou physico-mécaniques de l'installation. Ces difficultés empêchent l'ajustement énergétique des installations industrielles.

Nous croyons qu'il est possible de connaître, dans des conditions déterminées que nous essaierons d'expliquer, le degré de clinkérisabilité d'un cru de façon suffisamment exacte et reproductible et que nous pouvons déduire de celui-ci la température maximum équivalente que doit atteindre le cru dans la zone en un temps constant pour obtenir sa clinkérisation correcte avec une faible teneur en chaux libre et que cette température est, à son tour, une mesure de sa demande d'énergie.

La connaissance de ces points permet de repérer le facteur qui limite la production dans chaque cas et trouver le chemin pour réussir à l'augmenter.

Nous nous basons dans le fait que le temps de clinkérisation soit sensiblement constant pendant le proces en équilibre et que des petites variations de sa valeur dans le laboratoire ne parviennent pas à varier ou diminuer remarquablement le taux de chaux libre et si, au contraire, l'augmentation sensible de la "température maximum atteinte dans le matériel" nous a

permis de prendre comme variante principale cette température pour les mesures que nous prenons au cours de l'analyse du proces.

## II- Jugement analytique des antécédents

Parmi les premiers travaux systématiques se trouve celui de HEILMANN (1) fondé sur la détermination de la teneur en chaux libre en fonction de la température. Les températures employées ont été de 1400 à 1500 °C ce qui amené l'obtention d'une chaux libre inférieure à 2%. BLAISE (2) emploie des cycles de température entre 1000 et 1450 °C et mesure l'aptitude à la calcination comme l'inverse de l'intégrale de la courbe de chaux libre en fonction de la température. SU-LIKOWSKI (4) utilise des températures entre 900 et 1400°C et définit la calcinabilité par des paramètres arbitraires. KOCH (5) avec des températures de 1350-1450 °C propose un modèle d'analyse statistique pour déduire la valeur de chaux libre en fonction de dix variantes. LUDWIG et RUCKENSTEINER (6) emploient une température de 1350 °C et expriment la chaux libre au moyen d'une fonction exponentielle. CRISTENSEN (7) établit par calcination à 1400°C une fonction pour déduire la chaux libre à cette température. KONDO (3) a utilisé des températures entre 1100 et 1450°C et a déterminé le comportement de différentes matières premières et RAUSCHENFELS (8) a résumé une étude comparative de procédés.

Les températures employées dans tous les travaux précédents sont remarquablement basses par rapport à celles qu'on a réellement "dans le matériel" dans les zones de clinkérisation des fours avec les crus d'aujourd'hui.

Dans notre travail nous employons des températures plus hautes jusqu'à 1600°C du même ordre des réelles.

Les réactions, en l'absence de phase liquide, ont une cinétique de réaction différente à celle qu'on a dans la cristallisation par le refroidissement de la phase liquide selon les études à partir des diagrammes de phase, et les composés formés, avant son apparition, sont modifiés en fonction de la température maximum atteinte.

L'influence de la composition chimique sur le degré de clinkérisabilité est la plus importante et dans sa détermination on n'a pas tenu compte de l'influence, que les méthodes choisies pour l'analyse ont sur les résultats, à cause de ses limitations et d'erreurs encore inconnues aux quelles nous nous rapporterons.

La solution d'avoir recours à l'analyse mathématique par régression renfermera tous ces inconvénients parmi d'autres dont nous n'avons pas tenu compte, puis-que nous ne croyons pas qu'ils puissent fournir, d'eux-mêmes, de nouvelles connaissances sur la physico-chimie du proces.

Nous n'avons remarqué aucune fonction qui rapporte le degré de clinkérisation à la température maximum réelle atteinte par le matériel, mais nous croyons qu'il est beaucoup plus intéressant se référer de la valeur de la clinkérisabilité à cette température pour-quoi nous croyons que ceci permet d'évaluer indirectement le degré de l'échange "flamme-clinker".

## III- Conditions pour réussir à ce que la température de clinkérisabilité soit reproductible et corresponde à la composition chimique du cru.

Le procédé que nous proposons essaie de mesurer le degré de clinkérisabilité par la température que le cru a besoin d'atteindre, pendant 25 minutes, pour réussir la valeur de sa chaux libre à 2% (déterminée par la méthode au glycol).

Le figure n°1 ci-dessous illustre la diminution de la chaux libre en fonction de la température maximum

a temps constant sur des crus à différent degré de clinkérabilité. Les courbes ci-dessous ont été obtenues en laboratoire par calcination à différentes températures jusqu'à 1.600°C

Fig. n°1 Variation de la valeur de la chaux libre en fonction de la température du matériel pour crus à différentes températures de clinkérabilité

Les courbes expérimentales suivent une fonction exponentielle de type général :

$$\text{CaO libre\%} = A \cdot e^{\frac{1450-t}{a}} \quad [1]$$

où les paramètres A et a dépendent du degré de clinkérabilité dans des marges étroites. Leurs valeurs déterminées s'expriment dans le tableau I

TABEAU I

T°C	1450	1500	1550	1600	1650	1700
a	80	92	104	116	130	140
A	2,0	3,4	5,2	7,4	9,5	12,0

#### 1- Exactitude et précision dans la détermination de la composition chimique.

Il faut choisir les procédés d'analyse par le fait connu que différentes méthodes d'analyse mènent à des résultats différents sur une même échantillon homogénéisé. CHALMERS (9). Quand il s'agit de la détermination de la silice, cette dispersion est encore plus grande, à la suite de l'existence d'erreurs encore inconnues dans la méthode classique traditionnelle ou méthode de référence. GOMA (10) et (11).

L'auteur a étudié cette méthode de façon systématique ainsi que le comportement des gels de silice analytiques et a fait apparaître les variantes qui produisent le passage de silice au filtrage qui sont: l'insécurité de l'insolubilisation et la température haute pendant l'extraction (d'usage répandu et généralisé); la basse concentration d'acide et le volume élevé en elle-même et pendant les lavages, tous s'emploient couramment. Par contre, l'extraction doit être faite en froid avec acide ClH 1:1, le volume minimum et lavage à eau froide seulement. L'insolubilisation avec anhydride acétique et évaporation à 160 ± 5°C. La teneur de la silice qui passe au filtrage, selon cette méthode se mesure en fonction du contenu en SiO<sub>2</sub>.

L'emploi de ce procédé; celui de méthodes d'analyse pour l'aluminium dont le résultat ne soit pas altéré par des impuretés d'autres sesquioxides, silice phosphore, etc comme par exemple la complexométrie par retour avec pyridine-azo-naphtol et l'emploi de la complexométrie pour la détermination de la CaO et MgO, permettent d'obtenir les paramètres Lsf, Ms, et Mf (Lsf-facteur de saturation en chaux, Ms-module de silicates, Mf-module de fondants) avec l'exactitude, précision et reproductibilité exigées pour déterminer le degré de clinkérabilité. L'écart standard obtenu dans les résultats des oxydes majoritaires est de 0,04 et sa repercussion dans la détermination des paramètres du cru donne lieu aux variations suivantes Lsf: 0,8; Ms: 0,07; Mf: 0,07.

#### 2- Conditions de l'homogénéisation

Dans les études de l'auteur mentionnées (10) il en est arrivé à la conclusion qu'il est indispensable d'employer une capsule vibratoire pour la préparation des crus

#### 3- Conditions fondamentales pour obtenir les courbes de clinkérabilité

Le four employé a été électrique à élément de chauffage vertical de SiC de 44 mm de Ø intérieur, 58 mm Ø extérieur et une longueur de 400 mm. Muni de relais de réglage automatique de température. On mesure la température avec un pyromètre Pt/Rh-Pt en contact avec le matériel et la température vérifiée par moyen de substances de point de fusion connu CaSO<sub>4</sub>, Pd.

Une quantité constante de 10g. de cru comprimée en forme de pastilles est clinkérisée dans un creuset de Pt selon les courbes standard établies dans le fig.-2. La pression à utiliser doit être entre 50-100 Kp/cm<sup>2</sup>

Fig. n°2 Courbes standard de température et pentes des courbes de refroidissement en fonction du temps pour obtenir les clinkérisations en laboratoire à différentes températures maximum

Après avoir refroidi, on détermine la valeur de la chaux libre dans un échantillon représentatif par la méthode de l'éthylenglycol - après broyage manuel à finesse extrême

#### IV- La fonction de la clinkérabilité

Dépend de nombreuses variantes parmi lesquelles les plus importantes sont: la composition chimique, la granulométrie de l'ensemble et de chaque composant,

la composition minéralogique et la présence ou non de substances fondantes, etc. D'autres qui n'ont pas été mentionnées comme par exemple, la quantité de phase liquide est déjà implicite dans le module de silicates Ms et, sa viscosité, dans le module de fondants.

Les oxides étrangers au système  $\text{SiO}_2\text{-Al}_2\text{O}_3\text{-Fe}_2\text{O}_3\text{-CaO}$  modifient ces dernières et nous en tenons compte comme variante par la somme de leurs pourcentages comme F.

$$F = (\text{MgO}, \text{K}_2\text{O}, \text{Na}_2\text{O}, \text{SO}_3, \text{MnO}, \text{P}_2\text{O}_5) \% \quad [2]$$

Grâce à l'étude des crus au cours de cette dernière décade nous avons pu en arriver à la conclusion qu'il est possible, à notre avis, de généraliser une fonction à six variantes comme influences plus importantes qui ont un effet "sensible" sur le degré de clinkétabilité. En plus, par les raisons ci-dessus, nous croyons d'intérêt technique la mesure du degré de clinkétabilité par la température maximum, Tc, dont le cru a besoin pour sa transformation en clinker.

$$T_c = T_i + (\text{Lsf}, \text{Ms}, \text{Mf}, \text{F}, R_{92\mu}, R_{200\mu}) \quad [3]$$

si  $R_{92\mu}$  et  $R_{200\mu}$  sont pourcentages des particules supérieures aux respectifs  $\phi$  en microns

La généralisation de cette fonction se fonde sur les points suivants:

- sur le fait que les matières premières employées à tous les essais pour la détermination de celles-ci ont été naturelles parmi les calcaires et silicates habituels dans les exploitations et en l'absence d'agents d'addition comme les silicates artificiels, fluorures ou d'autres dont l'effet pourra être déterminé, a posteriori, par le même procédé que nous proposons.
- sur le fait que l'application est pour crus en Portland gris à composition variable dans de limites étroites des compositions habituelles: Lsf=90-100%, Ms=2,0-3,5, Mf=1,5-3,0, F=1-5%,  $R_{92\mu}$ =5-25% et  $R_{200\mu}$ =0-2%
- sur le fait que dans cette zone de compositions restreinte, l'influence des fonctions partielles de chaque variante apparaît pratiquement comme linéaire et uniquement l'effet de la finesse, se rattachant au rejet de dimensions plus grandes de  $92\mu$ , se montre de type exponentiel
- et que dans ces conditions l'influence de la composition minéralogique est beaucoup plus petite que celle de la composition chimique

D'après nos recherches, nous avons déduit, par le procédé que nous décrivons dans III, que les températures maximum équivalentes atteintes par le clinker dans des différentes lignes de procès à fuel et, avec ou sans précalcination, qui avaient un degré de concentration de flamme optimisé, sont comprises entre 1550 et 1650°C. Nous avons constaté que quand la Tc est très proche de 1600 °C on obtient un déroulement de procès régulier et en équilibre thermique stable et cette régulation devient difficile pour des températures plus hautes ce qui détériore fortement les réfractaires.

Nous avons pris cette valeur comme point de repère et avons constaté que les compositions de crus les plus courantes ayant cette Tc sont très proches à la suivante ou sont iso-combinables avec elles:

$$\text{Lsf}=95\%, \text{Ms}=2,5, \text{Mf}=2,2, \text{F}=2,1, R_{92\mu}=18\%, R_{200\mu}=0 \quad [4]$$

Dans une série de crus obtenus en laboratoire avec des matières premières naturelles et avec des courbes granulométriques analogues à celles des crus obtenus dans les circuits fermés usuels, on a modifié chacune de ces variantes tout en gardant toutes les autres constantes, dans les marges établies, pour obtenir les

quotiens des accroissements partiels finis correspondant à chaque variante.

Les valeurs moyennes obtenues à partir d'un grand nombre d'essais sont exposées sur le tableau II

TABLEAU II

$\frac{\Delta T_c}{\Delta \text{Lsf}}$	$\frac{\Delta T_c}{\Delta \text{Ms}}$	$\frac{\Delta T_c}{\Delta \text{Mf}}$	$\frac{\Delta T_c}{\Delta R_{92}}$	$\frac{\Delta T_c}{\Delta R_{200}}$	$\frac{\Delta T_c}{\Delta F}$
+10,9	+113	+50	+6,7	+31,6	-41,0

si  $R_{92\mu}$  est la valeur moyen pour l'intervalle considéré.

Le sens du terme indépendant Ti est la valeur de température de clinkétabilité Tc qui correspond à un cru aux caractéristiques données sur [4], obtenu à partir d'oxydes purs, cas dans lesquels tous les autres termes de la fonction donnée sont annulés puisque F est pratiquement zéro.

Un cru avec ces caractéristiques [4], avec des substances pures naturelles, a été obtenu en laboratoire. Il est composé d'un quartz de 99,8% avec une granulométrie continue dont la grandeur maximum est de 30 microns, une calcite du 99,7% avec une distribution granulométrique continue et dont la grandeur maximum est de 200 microns et un rejet sur tamis de particules supérieures à 92 microns de 18%, une gamme alumine et une sidérite, très pures aussi, dont la grandeur maximum est de 10 microns.

La valeur de sa température de clinkétabilité a été de 1.655°C, valeur moyenne de plusieurs déterminations, que nous avons prise comme valeur de Ti (terme indépendant).

L'application des coefficients partiels de chaque variable (Tableau II) qui a de l'influence sur la valeur de Tc trouvée dans les crus que nous avons étudiés et la valeur du terme indépendant trouvée expérimentalement, nous a permis d'établir la fonction polynomique ci-dessous:

$$T_c = 1655 + (\text{Lsf}-95) \cdot 10,9 + (\text{Ms}-2,5) \cdot 113 + (\text{Mf}-2,2) \cdot 50 + (R_{92\mu}-18) \cdot R^{0,65} + 31,6 \cdot \alpha \cdot R_{200\mu} - 41,0 \cdot F \quad [5]$$

L'application de cette fonction à des crus différents, obtenus à partir de matières premières naturelles à différente nature dont les paramètres ont été obtenus à partir des analyses chimiques faites par moyen des procédés décrits dans ce travail, donne les valeurs de leurs respectives températures de clinkétabilité Tc. Celles-ci sont comparées avec celles obtenues par le procédé sur III et sont exprimées sur la Tableau III ci-dessous:

Les numéros des courbes de la fig.n°1 correspondent aux crus du même n° dans le tableau III.

TABLEAU III

Crus ref.	1	2	3	4	5
Lsf	90,2	91,7	95,4	91,1	98,5
Ms	2,84	2,56	3,00	2,27	2,60
Mf	2,52	2,33	2,20	2,21	1,51
R <sub>&gt;92μ</sub> %	14,2	18,3	6,9	19,9	18,0
R <sub>&gt;200μ</sub> %	1,6	2,5	0	2,2	0
F %	0,9	0,9	-	0,9	-
F %	4,1	2,8	3,2	2,3	3,4
T <sub>C</sub> calculée en °C	1507	1596	1545	1565	1565
T <sub>C</sub> Trouvée " "	1500	1571	1526	1545	1582
Dif. en °C	+7	+25	-19	-20	+17

Fig. n° 3. A- Courbe de la diminution de la chaux libre du cru avec  $R_{>200\mu}$  et  $T = 1.450^{\circ}\text{C}$  en fonction de la température.

B- Courbe de la diminution de la chaux libre du cru avec  $R_{>200\mu} = 0$  en fonction de la température.

De ces résultats on peut déduire que quand la température atteinte par le clinker dans une installation mesurée par le procédé proposé, est plus grande que  $1.550^{\circ}\text{C}$ , le  $R_{>200\mu}$  du cru peut être relativement haut ce qui confirme les résultats de Heilmann (1).

La valeur de l'accroissement de  $\Delta T_C$  du à la valeur de  $R_{>200\mu}$  quand le calcaire qui la compose a  $>90\%$  en  $\text{CO}_3\text{Ca}$  peut être exprimée à peu près par la fonction suivante:

$$T_C = 31,6 \cdot R_{>200\mu} \cdot \alpha \cdot \left[ 1 - (T_m - 1450) \cdot 6 \cdot 10^{-3} \right] \quad [6]$$

Etant  $\alpha$  la fraction du calcaire exprimé à tant pour 1, et  $T_m$  la température du matériel.

V - Evaluation de la température maximum équivalente atteinte par le clinker dans un four donné.

Malgré tout les limitations qu'il y a pour trouver cette température nous croyons qu'il existe une énergie thermique qui peut être mesurée uniquement à travers la chaux libre résiduelle, qui est équivalente à celle donnée dans l'essai en laboratoire et que nous rapportons à la température maximum atteinte à temps constant.

Nous avons pris comme composition chimique de référence celle qui correspond au clinker obtenu parce qu'elle est la plus proche de celle de la clinkérisation et aussi de sa teneur en fondants. Quant à la composition granulométrique nous avons pris comme point de repère celle du cru à son entrée dans l'échangeur. Ceci bien que n'étant pas rigoureusement exact, est techniquement utile.

La séquence d'opérations à effectuer, en somme, pour évaluer quelle est la température maximum équivalente dans une ligne de proces est la suivante:

- Une fois obtenu un régime de marche en équilibre et stable dans le proces, on extrait un échantillon représentatif du cru (A) qui entre dans l'échangeur (moyenne de plusieurs intervalles pendant une demi-heure). On y détermine la composition chimique par moyen des méthodes indiquées, les pourcentages de  $R_{>92}$  microns,  $R_{>200}$  microns et sa fraction de chaux soluble en acide et la courbe de clinkérisabilité sur trois points  $T^{\circ}$  1500, 1550 et 1600°C.

L'application de cette fonction à des procédés avec des paramètres connus et fixes permet de la ramener à un nombre de variables plus petit selon les circonstances.

Quand la valeur de  $R_{>200\mu}$  est plus grande que 2%, nous avons essayé de déterminer comment réagit sa fraction calcaire  $R_{>200\mu}$  quand le calcaire qui la compose est à haut titre (supérieur à 90%).

En introduisant un 5% de particules de calcaire du 95% plus grandes que 200 microns à un cru aux caractéristiques suivantes Lsf = 90% Ms = 2,3, Mf = 2,0 et F = 2,5% avec une  $T_C$  de  $1.450^{\circ}\text{C}$ , il a été clinkérisé à différentes températures. La valeur de la chaux libre résiduelle en fonction de la  $T^{\circ}$  est exprimé sur la figura n° 3.

- Au bout du temps pendant lequel ce matériel a été clinkérisé, on extrait un échantillon représentatif du clinker obtenu (B) et on détermine sa composition chimique et sa chaux libre par moyen des mêmes méthodes et on déduit les valeurs: Lsf, Ms, Mf et le somme de fondants F. On déduit sa température de clinkérabilité par moyen de la fonction polynômique que nous avons rapportée avec les valeurs  $R > 92\mu$  et  $R > 200\mu$  correspondantes au cru (A) et on déduit les valeurs de CaO à différentes températures au moyen de l'équation [1] avec les paramètres correspondants donnés dans le tableau I et on obtient le diagramme de la figure n° 4.

Fig. n° 4 B- Courbe de clinkérabilité du cru qui a la composition chimique du clinker et les valeurs de  $R > 92\mu$  et  $R > 200\mu$  qui correspondent au cru qui entre dans l'échangeur.  
A- Courbe de clinkérabilité qui correspond au cru qui entre dans l'échangeur.  
Tm- Température équivalente atteinte par le clinker/ dans la zone de clinkérabilité du four industriel.  
La déviation standard pour la mesure de la température Tc est de  $\pm 20^\circ\text{C}$ .

Celui-ci permet de déduire la valeur de la température maximum équivalente en interpolant la valeur de sa chaux libre dans sa courbe correspondante.

Expérimentalement on en est arrivé à la conclusion que la concentration de flamme optimum est obtenue quand la température maximum équivalente est proche à  $1.600^\circ\text{C}$ . Le dépassement de cette température comportera conditions de marche forcée.

#### VI - Conclusions.

1- On établit les conditions et les méthodes d'analyse pour obtenir l'exactitude et la reproductibilité convenables spécialement à la détermination de la silice par la méthode gravimétrique classique modifiée par l'auteur.

2- On a trouvé une fonction généralisée pour déduire la valeur de la température de clinkérabilité des crus dans les marges des compositions usuelles avec une erreur de  $\pm 20^\circ\text{C}$  et une fonction exponentielle pour déduire la teneur en chaux libre en fonction de la température du matériel et de la température de clinkérabilité du cru.

3- Il est possible de déterminer la valeur d'une température maximum équivalente atteinte par le clinker dans la zone d'une installation donnée. Cette connaissance ainsi que celle de la température du clinker permet l'analyse du processus: évaluer indirectement le degré de concentration de la combustion, la valeur de l'échange "flamme-clinker" et la température de clinkérabilité maximum possible du cru pour tirer le plus grand profit de l'énergie en jeu.

Je suis reconnaissant à Asland S.A pour l'aide qu'elle a bien voulu m'apporter.

# The pore structure and the grindability of clinkers

## *La structure poreuse et la broyabilité des clinkers*

I.F. PETERSEN, F.L. Smidth & Co. A/S Vigerslev Alle 77, DK-2500 Valby Copenhagen, Denmark.

RESUME : On a recherché l'influence de la structure poreuse des clinkers sur leur broyabilité, les essais ayant porté sur des clinkers sans poussières. Des mesures quantitatives au microscope et des mesures de la broyabilité ont été utilisées. Pour un broyage à 3000 Blaine, on a observé une réduction de l'énergie de broyage, lorsque la surface spécifique des pores augmente.

En utilisant un modèle basé sur la physique capillaire, on a montré que la structure des pores des clinkers dépendait de l'importance de la phase liquide, de la finesse des cristaux de  $C_3S$  et de  $C_2S$ , et des espaces intercrystallins. Des expériences faites pour confirmer le modèle ont décélé une cause supplémentaire : la coalescence des cristaux de  $C_3S$ . Ces effets sont, dans une large mesure, commandés par la composition chimique et minéralogique du cru, et par sa finesse de broyage.

L'influence de la poussière des clinkers a aussi été examinée.

SUMMARY: The relationship between clinker pore structure and grindability has been investigated, for clinker that do not contain clinker dust. Quantitative microscopy and grindability determinations were the techniques employed. A decrease in the specific power requirement for grinding clinker to 3000 Blaine was observed when the specific surface area of the clinker pore system increased.

Using a model based on capillary physics, it is possible to attribute changes in the clinker pore system to a combination of changes in melt content, fineness of  $C_3S$  and  $C_2S$  crystals and space between these crystals. Experiments associated with the model indicate an additional effect, caused by a coalescence of  $C_3S$  crystals. These effects are to a large extent dependent on chemical and mineralogical composition together with fineness of the raw mix.

The effect of the content of clinker dust on grindability is also discussed.

## INTRODUCTION

Clinker grindability is a relative measure of the ability of a given clinker to resist grinding forces. Previous investigations by Gouda (1) and by Butt et al (2) have emphasized the importance to clinker grindability of melt content, clinker microstructure and especially clinker pore structure.

In this study the relationship of the pore structure of industrial clinker nodules to their grindability is investigated microscopically by determination of the specific surface of the pore system.

The clinker pore system results from the processes within the burning zone, where the charge, consisting of crystals and melt, is agglomerated. Therefore, factors affecting the specific surface of the clinker pore system are conveniently elucidated by a model which considers the clinker nodules as agglomerates in which the liquid phase has been frozen.

## EXPERIMENTAL

The grindability index used here is the specific power requirement (kWh/t) for grinding the clinkers to a specific surface of 3000 Blaine in a standardized grinding test. This test consists of grinding a batch of 20 kg clinker in a tumbling mill, using three different charges of grinding media simulating three chambers. Two ball charges and one cylpebs charge are employed. The first ball charge is used until 85 wt % of the ground material is finer than 0.5 mm; the second ball charge is then used until 85 wt % of the ground material is finer than 0.25 mm, and finally the cylpebs charge is used until the desired fineness is attained.

The specific surface area of the clinker pore system is determined microscopically in clinker polished section. Two measurements are carried out: A point count of the porosity  $\epsilon$ , and a measurement of  $N_L$  ( $\text{mm}^{-1}$ ), where  $N_L$  is the number of intersections of the pore surface with a random test line of unit length. According to DeHoff and Rhines (3) the specific pore surface area  $O_s$  ( $\text{mm}^2/\text{mm}^3$ ) equals:

$$O_s = \frac{2 N_L}{1 - \epsilon} \quad (1)$$

Seven industrial clinker samples ranging from ordinary Portland clinkers to special types including white clinkers were investigated by grindability testing and microscopy. These clinker samples consisted of pure clinker nodules and contained no clinker dust finer than 0.5 mm.

Fig. 1 shows the results. A decrease in the specific power consumption for grinding to 3000 Blaine is observed with increasing specific clinker pore surface.

Fig. 1 - Power consumption for grinding clinkers to 3000 Blaine versus specific pore surface of clinkers.

## PORE SYSTEM MODEL

To identify parameters influencing the specific pore surface of clinkers, it is appropriate to consider a model. The basic assumption in this model is that the pore system in the cooled clinker nodules can reflect the pore system at high temperature in the burning zone. At high temperature, the clinker nodules may be considered as agglomerates consisting of solid particles ( $\text{CaO}$ ,  $\text{C}_2\text{S}$  and  $\text{C}_3\text{S}$  crystals) and melt phase, where the melt more or less fills out the void volume between these crystals.

Microscopic investigations of clinkers indicate that the melt is effective in wetting the crystals. It is, therefore, appropriate to analyse the specific pore surface in an agglomerate consisting of solid particles and a wetting liquid. In such an agglomerate there will exist a difference in pressure between the surrounding gas phase and the liquid, and the pressure will be lowest within the liquid itself. Provided that changes in liquid volume can be carried out reversibly, isothermally, and without compression, the following equation is a consequence of the first law of thermodynamics, as shown by Morrow (4).

$$-P_C \cdot dV_L = \gamma_{LV} \cdot d(A_{LV} + \cos\theta \cdot A_{PV}) \quad (2)$$

$P_C$ , the capillary pressure, is the difference in pressure between gas and liquid phase,  $V_L$  is the liquid volume,  $\gamma_{LV}$  is the specific surface energy of the liquid-gas

surface,  $A_{lv}$  is the area of the liquid-gas surface,  $A_{pv}$  is the area of the solid-gas surface,  $\theta$  is the contact angle of the liquid against the solid and  $d$  denotes differential change.

The liquid volume  $V_l$  within the agglomerate is appropriately expressed by means of the liquid saturation  $S_l$ , defined as the fraction of the void volume between the solid particles occupied by the liquid.

$$V_l = V_p \cdot \frac{\phi}{1-\phi} \cdot S_l \quad (3)$$

$V_p$  is the volume of solid particles and  $\phi$  is the void fraction in the packing of the solid particles.

Within an agglomerate with a low liquid saturation the liquid is found in discrete liquid bridges between the particles. In this case, changes in liquid volume cannot be considered reversible. At a certain liquid saturation  $S_l^*$ , termed the irreducible liquid saturation, the liquid phase within the agglomerate becomes continuous. From  $S_l^*$  up to a liquid saturation close to unity, it is realistic, at least to a first approximation, to consider changes in the liquid volume as reversible and thus to use expression (2). Within this range of liquid saturation, the capillary pressure varies little with liquid saturation, and may be considered constant (cf. for example measurements by Dodds and Lloyd (5)). According to Rumpf (6), the capillary pressure may be calculated:

$$P_c = \gamma_{lv} \cdot \frac{1-\phi}{\phi} \cdot \frac{A_p}{V_p} \cdot \cos \theta \quad (4)$$

$A_p$  is the surface area of the solid particles; thus  $A_p/V_p$  becomes the specific surface area of the solid particles.

Since clinker melt wets the crystals effectively, the contact angle  $\theta$  must be small; thus  $\cos \theta$  must be close to unity. Use of this value of  $\cos \theta$  and substitution of expressions (3) and (4) into (2) give:

$$-A_p \cdot dS_l = d(A_{lv} + A_{pv}) \quad (5)$$

The quantity  $(A_{lv} + A_{pv})$  is the surface area of the pore system, and can be obtained by integration of (5) using  $S_l^*$  and the corresponding surface area  $(A_{lv}^* + A_{pv}^*)$  as lower limits. Integration gives after rearrangement:

$$\frac{A_{lv} + A_{pv}}{A_p} = K - S_l \quad (6)$$

Where  $K$  is given by:

$$K = \frac{A_{lv}^* + A_{pv}^*}{A_p} + S_l^* \quad (7)$$

Equation (6) describes the ratio of the pore surface to the surface of solid particles, as a function of the liquid saturation.

The magnitude of the dimensionless quantity  $K$  has been estimated by simple calculations. The system considered consists of equally-sized spheres, varying in packing between the two extremes: Three-dimensional close packing and simple cubic packing as described by Mayer and Stowe (7). In these packings, liquid bridges corresponding to the irreducible liquid saturation have been introduced at particle contacts, using the circle approximation for the form of the liquid bridges as described by Pietsch and Rumpf (8). The calculated values of  $K$ , between 0.84 and 0.88, indicate that  $K$ , at least to a first approximation, may be considered constant.

#### EXPERIMENTS ASSOCIATED WITH MODEL

In order to investigate the model, six industrial raw meals produced for the manufacture of Portland cement clinkers were burned at 1400°C for 30 minutes in the laboratory. The surface of the pore system, and that of the  $\text{CaO}$ ,  $\text{C}_2\text{S}$  and  $\text{C}_3\text{S}$  crystals considered as single crystals, were measured using the line-intercept method previously mentioned. These measurements make it possible to calculate the ratio of the pore surface to the surface of the crystals. The liquid saturation was determined based on point counting of interstitial phase and pores. A plot of the pore surface relative to the surface of the crystals is shown in fig. 2.

Fig. 2 - Ratio of pore surface to crystal surface versus liquid saturation.

A linear regression analysis on the data in fig. 2 gave the following expression with correlation coefficient 0.93:

$$\frac{A_{lv} + A_{pv}}{A_p} = 0.52 \cdot (0.79 - S_l) \quad (8)$$

The relationship of this result to the corresponding expression (6) from the model may be interpreted in the following way: The ratio of the pore surface to the surface of the crystals is a linear function of the liquid saturation, as predicted by the model, but the derivative with respect to  $S_l$  is found to be -0.52 and not -1. This can be explained as a result of a coalescence of crystals within the clinker, reducing the surface area of these crystals. This sintering effect appears to be especially important for  $C_3S$ -crystals. This is supported by numerous observations from clinker polished sections showing  $C_3S$  areas of irregular shape, indicating that a growing-together of several individual  $C_3S$  crystals has occurred. Finally the quantity 0.79 in expression (8) is close to the values of  $K$  found in the simple model calculations.

Now it is possible to obtain an expression for the specific surface of the clinker pore system. The total condensed volume within a clinker nodule is the sum of the volumes of solid crystals  $V_p$  and of melt phase. Using expression (3) this sum becomes:

$$V_p + V_l = V_p \cdot (1 + \frac{\phi}{1-\phi} \cdot S_l) \quad (9)$$

By multiplication by  $A_p$  on both sides of equation (8) followed by division by expression (9), the specific surface of the pore system  $O_s$  becomes:

$$O_s = \frac{A_{lv} + A_{pv}}{V_p + V_l} = 0.52 \cdot \frac{A_p \cdot (0.79 - S_l)}{V_p \cdot (1 + \frac{\phi}{1-\phi} \cdot S_l)} \quad (10)$$

From expression (10) it is apparent that the specific surface of the clinker pore system is influenced by the specific surface of the crystals  $A_p/V_p$ , the liquid saturation  $S_l$  and the void fraction  $\phi$  between the crystals.

The more common quantities clinker porosity ( $\epsilon$ ) and wt%(L) of melt phase can be introduced by the following relations:

$$\epsilon = \phi \cdot (1 - S_l) \quad (11)$$

$$S_l = 1.16 \cdot \frac{1-\phi}{\phi} \cdot \frac{L}{100-L} \quad (12)$$

In equation (12) a density of  $2.8 \text{ g/cm}^3$  for clinker melt and an average density for  $3.25 \text{ g/cm}^3$  for the crystals is assumed.

#### DISCUSSION

Data given by Butt et al (2) show that an increase in clinker porosity occurs when the amount of melt is reduced. Using the value 0.43 for  $\phi$  found from these data and a

combination of equation (10) and (12), it is possible to calculate expected values for the specific surface of the clinker pore system as a function of the amount of clinker melt and of the fineness of the crystals. By means of the data given in fig. 1, results from these calculations can be used as an aid in the prediction of clinker grindability (fig. 3).

Fig. 3 - Expected specific pore surface and grindability of clinker as function of wt % melt for various crystal finenesses.

The various values for the specific surface of crystals  $A_p/V_p$  (300, 200 and  $150 \text{ mm}^2/\text{mm}^3$ ) used in fig. 3 are in accordance with microscopic investigations of ordinary Portland cement clinkers, and correspond to Sauter mean diameters of 20, 30 and  $40 \mu\text{m}$  respectively. The range of melt contents corresponds to values obtained with Lea and Parkers formulae (9) using compositions corresponding to ordinary Portland cement clinkers.

The crystal fineness has the strongest influence on the specific surface of the clinker pore system and thereby on grindability.

An increase in specific crystal surface increases the specific pore surface and reduces the power requirement for grinding. A reduction in the amount of melt has a similar, but less marked, effect.

It seems reasonable to expect finer crystals within the clinker when the fineness of the raw mix is increased. Very small  $C_3S$  and  $C_2S$  crystals are obtained in special-type clinkers with silica ratio about 10, for

which the raw mix has to be ground extremely fine in order to compensate for the otherwise difficultly burnable material.

The mineralogy of the raw mix also influences the specific surface of clinker crystals. The finest crystals are in general obtained by burning of a marl-type raw mix, which nature has provided with a high degree of homogeneity in distribution of the components. In the investigation from which fig. 2 was derived, the specific surface of clinker crystals decreased from  $200 \text{ mm}^2/\text{mm}^3$  to  $150 \text{ mm}^2/\text{mm}^3$  when the raw mix changed from a marl- to a sandy type.

The amount of melt formed is influenced mainly by the chemical composition of the raw mix, with the silica ratio as the most important parameter. When the silica ratio increases, the amount of melt decreases and according to fig. 3 the power consumption for clinker grinding decreases. However, burnability and kiln operation considerations set a limit to the benefit obtainable from this effect, because decreasing the amount of melt without simultaneously ensuring fine crystals will increase the chance of a dusty clinker product.

Hitherto, the investigations and the discussion concerning clinker grindability have dealt with nodule clinkers, which contain no clinker dust finer than 0.5 mm. However, when clinker becomes dusty, grindability will suffer. For the first stage grinding with large-size balls, the fine clinker actually requires less energy than does coarse clinker, as the normal criteria for transferring the material to final stage grinding are based on coarse sieve residues. However, as a consequence of the reduced extent of grinding in the first and second chambers, the material leaving the second chamber actually becomes coarser, with larger residues on sieves finer than, for instance, 0.25 mm; as a result the power consumption in the third chamber, for grinding to 3000 Blaine, increases. Table I, which summarizes the results obtained in separate grinding tests of two size fractions of the same clinker, shows that the total power consumption for grinding to 3000 Blaine is about 25% higher for the fine clinker fraction than for the coarse one.

TABLE I

Size fraction, mm	-8 +0.5	-0.5
kWh/t in chamber I+II	10.0	2.6
% residue on 0.045 mm after chamber II	53	87
kWh/t in chamber III	24.9	41.4
Total kWh/t to 3000 Blaine	35.0	44.0

As long as the amount of clinker dust is modest, the increase in total specific power requirement for grinding to 3000 Blaine is not great, because the decrease in power requirement in the first stage of grinding partially counterbalances the increase in the third chamber. However, with high dust content a drastic increase in total power requirement is to be expected. Particularly at plants with major variations in content of clinker dust, the specific power consumption in the cement mills will increase, as in this case it is not possible consistently to take advantage of a low specific power consumption in the first chamber.

#### CONCLUSIONS

The fineness of  $\text{C}_3\text{S}$  and  $\text{C}_2\text{S}$  crystals in well-burned nodule clinker, together with the amount of melt phase, are important parameters for the structure of the clinker pore system and hence for the power requirement for clinker grinding. To optimize clinker grindability, it is essential to avoid too large an amount of fine-grained clinker dust.

# Producing Portland cement clinker using blast-furnace barric-manganese slag

## *Utilisation de laitiers contenant BaO et MnO, dans la fabrication du clinker de ciment Portland*

I.S. VALKOVA, Senior Research, Associate, Master of Science, Institute for Scientific Researches of Construction Materials, Sofia, Bulgaria.

R.G. DOGANDZHIEVA, Senior Research Associate, Institute for Scientific Researches of Construction Materials, Sofia, Bulgaria.

**SUMMARY :** The investigations conducted show that slags containing basic oxides necessary to form portland cement clinker -  $\text{CaO}$ ,  $\text{Al}_2\text{O}_3$ ,  $\text{SiO}_2$ ,  $\text{Fe}_2\text{O}_3$  and in some cases also alloying oxides  $\text{BaO}$  and  $\text{Mn}_2\text{O}_3$ , are valuable raw material for portland cement clinker.

The high-temperature treatment at which the slags have been subjected permits the same to be equalized with the raw cement mixture at temperature  $1000-1100^\circ\text{C}$ , i.e. when the interaction in the solid phase is already completed with formation low-basic clinker minerals.

It is proved that, introducing of slags both in vitreous, or in crystalline state, intensifies clinker formation and in the same time the processes of lime saturation are accelerated and the formation of clinker minerals is relieved. The presence of  $\text{BaO}$  and  $\text{MnO}$  in the slag contributes for the increase and modification of alite crystals, which leads to increased strength values of the cement.

**RESUME :** Des essais ont montré que des laitiers contenant les oxydes de base nécessaires à la fabrication du clinker de ciment portland ( $\text{CaO}$ ,  $\text{Al}_2\text{O}_3$ ,  $\text{SiO}_2$  et  $\text{Fe}_2\text{O}_3$ ) et dans certains cas contenant aussi des mélanges des oxydes de Baryum et de Manganèse, peuvent être utilisés comme crus des ciments Portland.

La haute température à laquelle les laitiers ont été soumis, au cours de leur fabrication, les rend équivalents aux crus chauffés à la température de  $1000$  à  $1100^\circ\text{C}$ ; notamment lorsque les interactions entre phases solides sont déjà achevées, avec formation d'un clinker faiblement basique.

Il a été montré qu'en utilisant du laitier à l'état vitreux, ou à l'état cristallisé, la formation du clinker était activée et qu'en même temps le processus de la saturation en chaux était accéléré et la formation des composants minéraux du clinker aidée. La présence de  $\text{BaO}$  et de  $\text{MnO}$  dans le laitier augmente et modifie la cristallisation de l'alite, ce qui conduit à une augmentation des résistances du ciment.

One of the effective directions, ensuring considerable economy of the consumption of fuel (solid or liquid) and electric power for the portland cement production and increase of the rotary furnace activity, is the use of slags as raw-material for the portland cement clinker production, by feeding directly the cold end of the furnaces.

The insuflation of the grinded slag (used in pure form or as a mixture) in the hot end of the furnace, which method (way of feeding) has been patented in Germany as early as 1929, and the first realization is put into practice in 1944, in the cement plant in Maastricht - Holland. On account of a number of difficulties this method had not been applied to very great extent.

In USSR, the additional feeding of the furnaces has been applied first in Giprocement by E.I. Tsivileva (1), and at this, the additional component having been fed at the upper end of the furnace. Later, this practice was developed in the scientific works of I.V. Kravtchenko and coll. (2, 3). Their method treats the additional feeding of the furnaces, beginning from their cold end, in case of wet production way.

The aim of our investigations was the study of the processes of the clinkerforming, in case of additional feeding of the furnaces, beginning from the cold end, with blast furnace slag, using the dry method for portland cement production.

At the time of the slag feeding, at the cold end of the furnace, the joint baking of the materials is being effected, which are not been homogenized in advance, and differ by their chemical composition, in connection of which the following factors have been studied:

- The influence of the phase and chemical composition of the blast furnace slag on the processes of the clinkerforming;
- The influence of the fed quantity of slag on the processes at the moment of the baking of the portland cement clinker and the properties of the portland cement clinker.

For the carrying out of the experimental work are used blast furnace granulated and non-granulated slag with varied make-up, limestone, marl and pyrites slags, the characteristics of which are given on TABLE 1.

Blast furnace slags differ in chemical as well as in phasal composition. Thus, furnace slag-1 contains BaO and MnO, but slag-2 does not contain these oxides. The petrographical analysis of slags shows the following:

Blast furnace granular slag-1. The predominant component of the slag, in quantity 89-93 per cent, represents glass of homoge-

neous composition - compact sometimes porous with N - 1,68;

Blast-furnace non-granular slag-1. By contrast with the granular slag, here the crystal phase is much more and gets to 40-45 per cent. Predominant mineral here are bicalcium silicate and olchamide in dendritic form and size to 100 microns. Granules of melilite and alabandite are observed in some places.

Blast-furnace granular slag-2. By contrast with slag-1, slag-2 contains a great part of crystal phase 25-30 per cent. It is presented predominantly by melilite. The glass phase is homogeneous.

Blast-furnace non-granular slag-2. By contrast with non-granular slag-1, blast-furnace non-granular slag-2 consists predominantly of crystal phase, the quantity of which gets to 60-70 per cent. The basic mineral which it contains are: ochermanite and gelenite, in the form of rectangular and square tablets with light-blue interference colouring. Dendrites of oldhamite and larnite crystals are observed in some places.

Some raw compounds characterized by the same chemical composition and the following module characteristics: KH = 0,921, n = 2,70, p = 1,60 were prepared in order to investigate the influence of the phasal and chemical composition of the blast-furnace slag on its interaction into the portland cement raw materials.

The mixture was ground in a laboratory ball mill until 10% residuum on sieve with 4900 mesh/cm<sup>2</sup> was obtained. Then was added to it slag in quantity 10 per cent of the weight of the raw flour. Some briquettes were made out of the mixture obtained and they were baked in a laboratory supercantal furnace at 1100; 1200; 1300; 1400 and 1450°C and an isothermic delay of two hours.

It is known that the reactivity of the raw material mixture depends on a number of factors, mostly on the physicochemical nature of the initial raw material; the dispersion of the blend, the raw material mixture; on the temperature and duration of baking; on account of which, all enumerated factors, during the experiments carried out, were equal except the chemical and phasal composition of the feeding slag. Table 2 shows the kinetics of the combined calcium oxide, depending of the kind of feeding slags, the chemical composition of which is shown in Table 1.

From the data in Table 2 it can be seen that, when introducing the blast-furnace slags into the raw material mixture, the kinetics of the clinkerforming is accelerated and a considerable difference is observed in the annealing of the calcium oxide.

In the raw material mixtures containing slags, the quantity of the free CaO varies

TABLE I

Chemical composition of the starting materials in %										
Materials	Ign. loss	SiO <sub>2</sub>	Fe <sub>2</sub> O <sub>3</sub>	Al <sub>2</sub> O <sub>3</sub>	CaO	MgO	BaO	MnO	SO <sub>3</sub>	Na <sub>2</sub> O K <sub>2</sub> O

Pyrite dross	2,38	18,28	60,27	5,69	1,32	1,00	-	-	9,81	0,45 0,80
Bl.furn.sl.gr.-1	-	34,19	0,30	8,94	40,08	2,48	5,66	2,9	3,9	0,86 0,67
Bl.furn.sl.gr.-2	-	34,46	1,96	8,70	42,69	4,55	-	-	4,17	0,79 0,82
Bl.furn.sl.nongr.-1	-	35,80	0,60	8,79	40,67	2,29	4,8	1,17	3,9	1,29 0,70
Bl.furn.sl.nongr.-2	-	32,60	1,81	9,28	42,84	5,71	-	-	5,48	0,72 0,48

between the limits of 18,23 to 15,90 per cent. Simultaneously, the raw material mixtures not containing slags, have a content of free CaO, getting to 23,67 per cent, which can be explained by the fact that the slag melting temperature, and especially that of slag-1, is considerably lower (850-900°C) than that of the raw material mixture. From the data in Table 2 it can be seen that this regularity is kept with the further increase of temperature.

The phasal composition of the slags used does not exert a particular influence on the kinetics of clinkerforming. The combining of the free CaO is almost equal when introducing granular as well as crystal slags (Table 2).

The chemical composition of the slags used exerts considerable influence on the combining quickness of CaO. Thus, in a raw material mixture containing slag-1, the combining of CaO passer faster than in mixtures containing slag-2, which can be explained

TABLE II

Assimilation of the CaO according to the art the slag

4.Bl.furn.sl.gr.-2	10	24,70	18,23	14,01	0,82	trace
5.Bl.furn.sl.nongr.-2	10	24,73	18,15	13,90	0,88	trace

with the lower melting temperature of slag-1 in comparison with the melting temperature of slag-2 (1000-1100°C), which brings an earlier appearance of a liquid phase and accounts for the acceleration of clinker forming.

Comparing the results of the petrographic investigations, one sees that the produced clinkers from mixture containing slag-1, are characterized by a more clearly expressed crystallization of the alite and the belite, the crystals of which are with regular crystallographic outlines. Crystals with the size of about 40-60 microns predominate.

The physical and mechanical testings of the cements obtained after grinding of the clinkers, with an addition of 5 per cent gypsum stone and a specific surface 4000 cm<sup>2</sup>/g show that, according to their characteristics, they are almost identical

The results of the testing of the specimens

from the cement flour with density according to norm and sizes  $2 \times 2 \times 2$  cm are given on Table 3.

TABLE III Physical and mechanical characteristics of the cement									
No.	Specific surface $\text{cm}^2/\text{g}$	Norm density %	Regime of preserving				Strength of the pressure, $\text{kg}/\text{cm}^2$ , after		
			under water	under water	after steaming		1 day	28 days	4 months
							3 days	7 days	28 days
1.	4020	28,5	470	650	720	900	1290	1310	1400
2.	4050	29,0	485	667	790	920	1294	1340	1450
3.	4060	30,0	478	665	790	950	1300	1350	1470
4.	4040	29,0	475	657	713	880	1280	1318	1445
5.	4010	30,0	469	630	700	893	1250	1313	1400

REMARK: The numbers in this Table correspond to those in Table II.

From the data in Table 3, one can see that the cements on the basis of clinkers with utilization of slag-1, show higher strength of pressure than these utilizing slag-2. Probably that is due on the influence of the introduced with slag-1 oxides:  $\text{Mn}_2\text{O}_3$  and  $\text{BaO}$ , which, at liquid phase baking, contribute to the increase of the alite phase quantity of a clinker with increased activity.

In such a manner, the investigations carried out show that blast furnace granulated slags represent a valuable raw material for the portland cement clinker production and their utilization will permit the increase of the activeness of his production thanks to the intensification of the processes of the baking. The introduction of the complex of oxides  $\text{BaO}$  and  $\text{Mn}_2\text{O}_3$  in the raw material mixture, corresponds to the increasing of the alite quantity in the

clinker, the enlarging of its crystals and increasing of the strength indices of the cement.

At the examining the influence of the introduced slag on the processes of the forming of the clinkers and the characteristics of the portland cement clinker, are utilized the same raw materials (Table 1). The blast-furnace slag - 1 is introduced in quantities 5, 10, 15 and 20 per cent. The raw material mixture was prepared from the following modulus characteristics:  $\text{KH} = 0,92$ ;  $n = 2,80$ ;  $p = 1,65$ . The methods for the preparation of the raw material mixture and the baking of the clinker, are as described here above.

On Table 4 are given the data of the kinetics at the time of the combining the free calcium oxide. It is seen that with the increase of the slag from 5 to 20%, the speed of the  $\text{CaO}$  increases and at  $1400^\circ\text{C}$ , in the mixture containing slag, the free  $\text{CaO}$  is almost absent.

TABLE IV Kinetics for the combining of free $\text{CaO}$					
No.	Quantity of slag %	free $\text{CaO}$ - %			
		$1300^\circ\text{C}$	$1350^\circ\text{C}$	$1400^\circ\text{C}$	$1450^\circ\text{C}$
1.	0	16,42	7,22	2,42	0,70
2.	5	10,67	3,43	0,85	0,35
3.	10	8,91	3,09	0,68	0,28
4.	15	7,80	3,00	0,42	-
5.	20	7,63	2,85	0,20	-

The petrographic analysis of the clinker obtained shows that the samples of clinker No. 1 (without slag) is of a non-uniform, granular structure, with mostly alite crystallization. The alite crystals are of an irregular form and sizes of 60 to 70 microns, average 40-50 microns. In almost all grains there are belite inclusions. The belite is found foremostly as inclusion and rarely as separate grains. The intermediate mass is about 15%, with the aluminoferrite sensibly predominating.

Clinker No. 2 (with 5% slag). In comparison with sample No. 1, a crystallization with bigger crystals is watched (average 60-65 microns) and better formed crystals.

Clinker No. 3 (with 10% slag). It is identical to sample No. 2, with still larger crystallization.

Clinkers No. 4 and 5 (with 15 and 20% slag) are almost equal, with large crystallization, almost of alite type. The alite crystals with hypidiomorphic form and sizes to 120 microns. In some of them there are belite inclusions. The belite is presented in separate grains also, with sizes to 60 microns. Many pores.

From the petrographic analysis is seen that at introduction of slag the process of formation of clinkers is considerably intensified and the alite synthesis is accelerated. Apart of that, an enlargement of the alite and belite crystals is observed.

The activity of the clinkers, which are obtained through using slag, in comparison with the common clinkers, is almost equal (table 5).

- full assimilation of the slag introduced;
- increase of the productivity of furnaces;
- considerable decrease of the specific consumption of fuel and electric power;
- bettering the structure and increase the hydraulic activity of the clinker.

#### CONCLUSIONS

1. It has been proved that the blast-furnace slags, containing the basic oxides necessary for the forming of the portland cement clinker -  $\text{CaO}$ ,  $\text{Al}_2\text{O}_3$ ,  $\text{SiO}_2$ ,  $\text{Fe}_2\text{O}_3$ , and, in individual cases also alloying oxides  $\text{BaO}$  and  $\text{Mn}_2\text{O}_3$ , represent valuable raw material for the production of portland cement clinker.

2. The introduction of the slag in the raw material mixture through additional feeding of the furnace, makes possible the intensification of the processes of the clinker formation; in order to increase the furnace productivity and to lower considerably the specific expenses of fuel and electric power for the portland cement production.

The intensifying influence of the slags at the time of the forming of the clinkers was examined in industrial conditions of plants working according to the dry and semidry ways, among which which, the furnaces with cyclone heat-exchangers, type "Humboldt", "Polysius" and "Lepold". The high furnaces were consequently fed with different quantities of slag - from 5 to 25 per cent, as regards the clinker.

In plant conditions was established:

# Clinker-Raw Meal-Coal Interrelations in some Indian Cement Plants

## *Corrélations entre clinker, cru et charbon dans certaines cimenteries indiennes*

A.K. CHATTERJEE, V.K. ARORA, T.N. VERMA, D.V. RAMANA RAO et D. GHOSH, Cement Research Institute of India, New Delhi, India.

**RESUME :** Une série de recherches sur les corrélations entre clinker, cru et charbon dans certaines cimenteries indiennes est expliquée à l'aide de résultats obtenus dans deux fours à pré-chauffeurs, d'une capacité de 600 tonnes par jour et de 900 tonnes par jour dans un four Lepol d'une capacité de 1000 tonnes par jour et dans deux fours à voie humide d'une capacité de 600 tonnes par jour (l'un avec des chaînes et l'autre avec un concentrateur). On a essayé de corréliser les variations de la composition chimico-minéralogique des crus, leur finesse et les caractéristiques des cendres du charbon avec les caractéristiques principales du clinker telles que la distribution des phases, la composition et la microstructure. On a démontré que la qualité du clinker obtenu dans de tels fours, utilisant des charbons riches en cendres (cendre 21-29 %, MV 25-36 %) peut être représentée sous l'angle des microstructures par une combinaison d'indices quantitatifs tels que l'indice chimico-minéralogique, l'indice de grain et l'indice d'agglomération.

On a également démontré que, dans les conditions ci-dessus, la qualité du clinker, telle qu'évaluée à l'aide des indices indiqués ci-dessus, pouvait être prévue, avec une bonne probabilité, en utilisant un autre indice, basé empiriquement sur le cru; cet indice est calculé en tenant compte de la composition du cru, après calcination, de l'influence des cendres du charbon, de sa teneur potentielle en liquide et de sa fraction retenue sur le tamis de 150 microns.

**SUMMARY :** A course of investigations on CLINKER-RAW MEAL-COAL INTERRELATIONS in some Indian Cement plants has been illustrated with the help of results obtained from two suspension preheater kilns of 600 TPD and 900 TPD capacity, one lepol kiln of 1000 TPD capacity and two wet kilns of 600 TPD capacity (one with chains and another with concentrator). Attempts have been made to interrelate the variations in chemico-mineralogical composition of the raw meals, their fineness, coal ash characteristics, and ash influence with the major clinker characteristics such as phase assemblage, composition and microstructure. It has been demonstrated that the quality of clinker that is obtained from such kiln systems, using high ash coals (ash 21-29 %, MV 25-36 %) can be represented by a combination of quantitative indices such as Chemico-mineralogical Index (CMI), Grain Index (GI), Clustering Index (CI) alongwith the micro-structural features.

It has been further shown that under the given conditions, the acceptable quality of clinker, as assessed by the above indices can be forecast with an element of certainty with the help of an empirical raw meal index (RMI) derived from the composition of ignited raw mixes with coal ash influence, together with its potential liquid content and fraction retained on 150  $\mu$ m.

## INTRODUCTION

Within about six decades of its existence and development, the Indian cement industry today has 56 production units with an installed capacity of 22.75 million tonnes. The production comes from a wide variety of kiln systems that differ from one another in their processes, designs and rated outputs. In addition, the industry has of necessity to use hard crystalline or sedimentary limestones—often quartzose or siliceous—in most of the plants along with high-ash coal. In an average cement plant the relative shares of raw materials and fuel (including power) in the aggregate cost structure obtain at 26.2 and 38.6 percentage (1). Therefore, one of the immediate needs of the industry is to optimise clinker quality and output by balancing the inputs of coal and raw meal.

The present communication is based on a systematic investigation undertaken in this regard. Although the data and results presented below relate to five selected plants, the generalisations, reported here, have been arrived at from a wider set of data which have been excluded for the sake of brevity.

## PLANT CHARACTERISTICS

The kiln, raw meal, fuel, and clinker characteristics of the plants in question are presented in Tables I & II. The plants were chosen on the following considerations:

To cover the three major processes of raw meal preparation.

The kiln capacity range to represent the general run i.e. 600–1000 tonnes per day (tpd), which indeed is the range of 50 percent of the operating kilns.

The limestone characteristics to represent a cross section of the material used. Thus plants A, D and E make use of coarse grained quartzose limestone with a host of accessory minerals, while plant B utilises a compact crypto-crystalline fine-grained siliceous limestone, and plant C depends on a high-grade micritic limestone. Further, while plants A, D and E make use of limestones of the same geological horizon, they differ in their raw meal preparation and preheating systems.

To represent different additives and correctives used (Plant A, sandstone 6%, clay 2%; Plant B, bauxite 1%, laterite 4%; Plant C, clay 20%; Plant D, bauxite 2%, iron ore 2%, and Plant E, lime sludge 5%, red mud 2%).

CLINKER QUALITY:

From the phenomenological inter-relations of phase composition, microstructure, quality, and burning of portland cement clinkers (2) it is known that in addition to their chemical composition, the quality of clinker is defined by the optimum proportions of the major phases, grain size of clinker minerals and overall microstructural characteristics. However, no quantitative indices correlating the above parameters have yet been established. Nevertheless from a study of a fairly large number of Indian plant clinkers it has been observed that the overall quality can be represented by the combination of the following parameters.

Chemico-Mineralogical Index (CMI)

$$CMI = 60(0.05 - K) - (BI_{Exp} - 3) \quad (1)$$

where

$$K = \frac{1 - 3/\sqrt{1-x}}{T}$$

$$x = \frac{CaO - CaO_f}{CaO}$$

T = burning time taken as 20 min

$$BI_{Exp} = \frac{C_3S\%}{C_3A\% + C_4A\%} \text{ as determined experimentally, for example by XRD.}$$

With high-ash coal firing in Indian plants, the chemico-mineralogical quality of a clinker appears to be acceptable so long as CMI lies within  $\pm 0.5$  with the  $BI_{Exp}$  ratio limited to 3.5. Any value of CMI beyond the above range indicates either high free lime, or low alite content, or disproportionate presence of the nonsilicate phase or their combination.

Grain Index (GI)

$$GI = \frac{C_3S \cdot XP + C_2S \cdot XQ}{80} \quad (2)$$

Where P and Q refer respectively to the proportion of alite and belite grains lying in the range 21-40 micron.

The closer the index to unity, the better is the clinker quality, when other quality indices are the same.

Clustering Index (CI)

The clustering index is given by the cluster size and frequency. The cluster size is given in millimeters by their average length of linear intercepts obtained from a larger number of traverses across polished sections of clinker samples under the microscope with the help of an integrating stage. Parallely the cluster frequency can be denoted by the number of clusters per millimeter. The higher the intercept length or the lower the frequency, the poorer is the quality. With high-ash coal firing, clustering phenomenon appears to be very common in the plant clinkers and, hence, the significance of this index.

Microstructure

The microstructural characteristics are presented in qualitative and relative terms to cover the grain shape and outline, inclusions within grains, rimming, zoning and twinning. Under Indian conditions, Type I monodolastic microstructure is rarely achieved and the clinkers generally display Type II monodolastic and Type III glomerolastic features (2).

The above quality indices of the clinkers produced by the five plants are illustrated in Table III. For better comprehension, the crystal size distribution of alite and belite as well as the nature of clustering in the above clinkers are presented in Fig 1 and 2. From Table III and Fig 1 and 2, one may conclude that the clinker of plant B is of the best quality with the only deficiency that the grain growth is not entirely satisfactory. In an overall grading of clinker quality plant B is followed by plants E, A, C and D although on the basis of CMI one may observe that the clinkers of plants A, C and D are below the acceptable limits, which is also corroborated by the facts that the free lime in clinker A is high, in clinker C very high and the alite content in clinker D is very low.

RAW MEAL COMPOSITION AND COAL ASH INFLUENCE

The raw meal characteristics of the five plants in terms of moduli values, burnability factor and potential liquid content are presented in Table IV, which also shows the average ash absorption in

Fig.1. ALITE AND BELITE SIZE DISTRIBUTION

TABLE III  
Clinker Quality

Plant	A	B	C	D	E
CMI	1.29	0.29	1.96	2.22	0.46
GI	0.32	0.22	0.41	0.72	0.64

Cluster Frequency (Av)	1.68	-	2.97	1.12	1.17
Description of Microstructure					
Plant A : Irregular grains of alite with profuse inclusions of belite. Belite grains twinned and zoned. Rims of belite around alite present.					
Plant B : Well developed alite and belite. No zoning or twinning of belite. Rims of belite around alite and inclusions of belite within alite rare.					
Plant C : Regular grains of alite and belite. Belite better developed than alite. Belite rims around alite present. Some alite have irregular margins. Twinning and zoning rare. Inclusions of belite within alite not very frequent.					
Plant D : Alite grains with wavy outline and inclusions of belite. Two generations of belite noticed, one regular and moderately coarse grained and another irregular and fine grained. Twinning in belite present. Rims of belite around alite rare.					
Plant E : Alite with irregular outline and inclusions of belite. Belite better developed with twinning.					

clinker produced through the given kiln systems. The average ash absorption has been derived from the plant records of specific heat consumption in clinkerisation, compositional differences between raw meal and clinkers, and ash compositions for long periods of plant operation.

The effective changes in all the parameters due to ash absorption are also shown in Table IV. For an additional indirect assessment of the relative burnability of the raw mixes, the theoretical heat requirement ( $H_{TH}$  in K Cal/Kg) for clinkerisation with and without coal ash influence has also been carried out following the methods of Strassen (3).

It is obvious from Table IV that the relative burnability of the raw meals cannot be clearly assessed from the set of data individually or in combination. The data is still more confusing if one tries to correlate them with the quality of clinker produced by the plants as summarised in Table III. For example, the relatively inferior quality of clinkers of plants C and D can hardly be envisaged from these indirect burnability indices. This led to the study of granulometry of raw mixes.

TABLE IV  
Raw Meal Composition and Coal Ash Influence

#### RAW MIX GRANULOMETRY

The broad pattern of granulometry of the raw mixes of different plants including the five selected was studied by finding out the slopes of lines from the log-log plots of cumulative weight fractions retained on different sieves (Table V) and correlating the slopes with fraction retained on 150, 90 and 53 micron sieves on a semi-log scale (Fig 3). It is evident from Fig 3 that there is a break in the slope of lines beyond ~5% retention on 150 micron sieve and corresponding to ~14% and ~37% retentions on 90 and 53 micron sieves respectively—all against a slope factor range of about 2. But the break in the case of 150 micron is smoother than in the other cases with a detectable trend of approaching a linear relation.

TABLE V  
Raw Meal Particle Size Distribution

Plant	A	B	C	D	E
In Microns					
+150	3.05	4.70	3.90	8.49	3.26
-150+ 90	10.85	8.30	8.79	12.46	9.14
- 90+ 75	5.80	4.10	5.86	6.83	6.84
- 75+ 53	40.81	19.40	14.50	27.37	49.94
- 53	59.43	63.50	66.95	44.85	30.82

Further, since modern trends of granulometric studies of raw mixes (4,5) have revealed that the size fractions retained in the 125-150 micron range have an appreciable effect on burnability, the mineral constitution of the coarser fractions of the raw meals and their effect on burnability were separately studied.

The mineral phases present in the +90 and +150 micron sieve fractions in their order of abundance as well as the relative concentrations of calcite

and quartz in these size fractions are presented in Table VI. It is evident that the patterns of mineral concentration in both the coarse fractions are more or less identical but in certain cases there is some increase in the concentration of calcite grains in the +150 micron fraction. Therefore, the effect of increase in the coarsest fraction i.e. +150 micron range on residual free lime was further investigated, the results of which have been reported later in this paper.

# CLINKER-RAW MEAL-COAL INTER-RELATION BASED ON AN EMPIRICAL RAW MEAL INDEX

Since the normally adopted moduli values on the burnability factor derived from them did not yield an acceptable approach to envisage clinker quality and relative burnability as highlighted earlier in this paper, attempts were made to study the Indian plant raw mixes so as to establish the equivalence in terms of the burnability effect of moduli values vis-a-vis potential liquid of raw meals with coal ash influence, on the one hand, and vis-a-vis raw mix fraction retained on 150 micron sieve on the other. In the context of such equivalence studies it was revealed that for the type and range of kiln systems under investigation the normally favourably working ranges of potential liquid and size fraction retained on 150 micron sieve are about 22.5-27.5% and 0-5% respectively. The disturbance in burnability with potential liquid exceeding the limiting values is such that no equivalence can be established while the effect on account of the higher proportion of coarser fraction is regular and additive. Based on such observations a raw meal index could be derived which is given below:

$$\text{RMI} = 100 \text{ LSF} + 10\text{SM} - (L_c - 25) - 2(5 - R) \quad (3)$$

Where LSF and SM are derived from the ignited raw mix with average coal ash influence,  $L_c$  is the potential liquid content of that raw mix with coal ash (lying in the range 22.5-27.5) and R is the fraction retained on 150 micron sieve.

It has been further observed that so long as this index lies between 105 and 110 approximately, a fairly acceptable quality of clinker that is achievable with high-ash coal firing can be ensured with CMI lying in the range of  $\pm 0.5$ . The raw meal indices of the five selected plants are given in Table VII.

TABLE VII

## Raw Meal Indices

Plant	A	B	C	D	E
RMI	107.2	105.3	115.2	130.5	109.7

It may be worthwhile to mention here that so far as plant A is concerned, although RMI=107.2, CMI is not favourable. This is explained by the fact that the raw mix of this particular plant contains an appreciable amount of manganese oxide in addition to magnesia and iron oxide. If now LSF is recalculated in accordance with Spohn's formula taking into account the magnesia content, it increases substantially (from 83 to 91) and if manganese oxide is added with iron oxide to obtain the other moduli value, then the potential liquid of this raw mix becomes almost 29%, as a result of which Equation (3) becomes untenable for this raw mix and consequently, the difficulty in obtaining a clinker of acceptable quality can be forecast.

## CONCLUSIONS

With the type of raw materials and fuel used in Indian cement plants of 600-1000 tpd capacity, the quality of clinkers produced can be characterised by a combination of four parameters: Chemico-mineralogical Index (CMI), Grain Index (GI), clustering size and frequency, and microstructural features. A CMI range of  $\pm 0.5$  with high GI, low clustering, the Type II/III microstructural variety normally indicates an acceptable quality of clinker. Such prognostication of clinker quality cannot always be envisaged with certainty from the conventional moduli values, burnability factors and potential liquid contents, either independently or in combination. The plant raw mixes generally contain an appreciable proportion of fraction retained on 150 micron sieve, which, as expected, has a strong bearing on the overall burnability of raw mixes. From experimental and plant data an equivalent effect of chemical composition and potential liquid content of ignited raw meals with coal ash influence as well as of the raw meal fraction retained on 150 micron sieve, a raw meal index (RMI) has been worked out with certain limiting conditions. It has been observed that when the index lies within the range 105 to 110, an acceptable quality can be achieved for the clinkers under the given conditions.

## ACKNOWLEDGEMENT

The work reported here is part of the R & D programme of the Institute and the report is being communicated with the permission of the Director General, Cement Research Institute of India, New Delhi.

## Influence des microadditions d'oxyde de chrome (III) sur la composition chimique et minéralogique des clinkers de ciment portland

*The influence of chromium sesquioxide microadditions on the  
chemical and mineralogical composition of portland cement clinkers*

I. TEOREANU, H. BALASOIU, C. RADOVICI et D. CIOMARTAN, Roumanie.

**RESUME :** Le travail est une analyse de la façon dont la composition chimique et minéralogique des clinkers de ciment portland est influencée par des microadditions d'oxyde de chrome (III) (jusqu'à 3 %). Les auteurs ont examiné les modifications de la composition chimique des constituants majeurs du clinker, par suite de la solubilisation du chrome (III) et de la variation des proportions d'autres oxydes inclus dans les réseaux de base, et donnent des solutions solides complexes. La distribution du chrome (III) entre les phases cristallines du clinker, en fonction de sa solubilité dans chaque phase, est aussi analysée. On décrit la façon dont la présence du chrome (III) influence la texture des clinkers et le polymorphisme de leurs constituants silicates.

**ABSTRACT:**

In the present work is analyzed the way the addition of variable amounts of chromium sesquioxide (as microadditions up to 3 wt.%) exerts an influence on the chemical and mineralogical composition of portland cement clinkers. The changes in the chemical composition of the main components of clinker as a consequence both of the chromium(III) dissolution and of the variations in the amount of other ions inclusion in the basic lattices, resulting in complex solid solutions formation, are examined. The distribution of chromium(III) in the crystalline phases of clinker as a function of its solubility in each phase is analyzed. The way in which the chromium(III) presence influences the clinker texture and the polymorphism of the silicate constituents in clinker is examined, too.

## A. INTRODUCTION

Dans une publication précédente /1/ ont été examinées les conséquences de la présence des ions de chrome(III) sur la formation et la stabilité des phases silicatiques dans le clinker de ciment portland. Des modifications assez importantes peuvent avoir lieu dans la composition chimique des phases majeures du clinker par suite de la distribution différente des ions de chrome(III) et par les modifications de la solubilité des autres ions dans ces phases. La structure du clinker en général et la structure de ses phases minéralogiques en particulier, peuvent aussi subir des modifications notables.

Le but de ce travail est d'apporter des informations nouvelles en ce que concerne les questions indiquées plus haut, étant donné que des modifications chimiques et structurales du clinker et de ses constituants peuvent engendrer des variations importantes des propriétés liantes des ciments respectifs.

## B. PARTIE EXPERIMENTALE

Afin d'obtenir ces informations (s'ajoutant à celles déjà présentes dans la littérature) ont été utilisées comme matières premières pour les clinkers à contenu en oxyde de chrome(III) variable (c'est à dire 0; 0,5; 3 % en poids) carbonate de calcium, bioxyde de silicium, oxyde d'aluminium, oxyde de fer(III) et oxyde de chrome(III) de pureté chimique (réactifs Merck). Les paramètres modulaires des clinkers synthétisés sont suivants :  $S_K=0,96$ ;  $MSI=2,2$ ;  $MAI=2$ . Les mélanges brutes, sont caractérisés par des surfaces spécifiques élevées, résultat des dimensions granulaires réduites des matières premières (le résidu sur le tamis de 0,063 mm est nul). La cuisson a été effectuée dans un four électrique à 1350°C, pour 30 minutes.

L'analyse qualitative de la composition minéralogique des clinkers a été faite par la diffraction des rayons X, à la température ambiante et aussi par diffractométrie à haute température, entre 500-1200°C, pour chaque hausse de 100°C de la température. Ont été utilisés un appareil de type DRON-2,0 à un goniomètre horizontal GUR-5 (USSR) et une chambre de hautes températures de type GPVT(USSR). Dans tous les cas on a travaillé avec la radiation  $CuK_{\alpha}$ .

L'analyse chimique des échantillons a été faite par la fluorescence des rayons X, avec un appareil de type VRA-2 (Freiberger Präzisionsmechanik-R.D.A.). Pour identifier Ca, Fe, Cr on a travaillé avec un tube de W; le cristal analyseur a été de LiF. Pour identifier Al et Si on a utilisé le tube de Cr, et cristal analyseur de pentaerythritol. Pour éliminer l'instabilité à court terme de l'appareil, on a utilisé un système de mesure à moniteur. Pour éliminer les erreurs à long terme, on a remplacé pour l'étalonnage et les mesures, le nombre des impulsions correspondant au maximum du peak analytique, par le rapport entre le nombre des impulsions au

sommet du peak et le nombre des impulsions au fond du même peak ( $I_T/I_F$ ). Pour chaque système ont été préparées cinq pastilles étalon et pour compenser les effets matriciaux, les concentrations des éléments dans chaque pastille ont été calculées jusqu'à 100 % utilisant un programme de calcul adéquat.

Les résultats des analyses par fluorescence des rayons X ont été vérifiés et complétés par analyse chimique.

La co-existence des quatre phases cristallines et de la phase vitreuse rend très difficile l'analyse chimique quantitative des constituants minéralogiques du clinker. Pour écarter en partie au moins ces obstacles, les constituants minéralogiques du clinker, ont été séparés par attaque chimique sélectif. On a utilisé une solution d'acide salicylique en alcool éthylique qui rend solubles les phases silicatiques, les phases célitique et vitreuse restant insolubles. Les phases silicatiques ont été reprécipitées par ébullition à sec. Les réseaux cristallins attaqués ou labilisés par l'attaque chimique, et surtout les phases reprécipitées, deviennent susceptibles de réagir (se carbonater, etc.), avec l'environnement. Pour éviter les erreurs produits par ces réactions, les produits résultant après l'attaque chimique ont été soumis à une cuisson supplémentaire, à 1350°C pour 2 heures.

Ont été aussi effectuées des analyses semiquantitatives avec une microsonde électronique Jeol de type JXA-3A.

Pour obtenir des informations concernant la texture des clinkers à contenu variable en oxyde de chrome(III) ont été effectuées des mesures de porosité pour toute la gamme des clinkers synthétisés, utilisant un microscope analyseur d'images Quantimet 720.

## C. RESULTATS ET DISCUSSIONS

Les analyses diffractométriques ont mis en évidence la diminution jusqu'à une disparition quasi-totale de l'alite dans les échantillons à 3 % oxyde de chrome(III) (résultat qu'on attendait d'ailleurs d'après /1/), la phase béliitique étant la plus importante; dans les clinkers exempts d'oxyde de chrome(III) ou à 0,5 % d'oxyde de chrome(III) la phase alitique est la plus abondante.

Les résultats des investigations de diffractométrie à haute température ont montré que l'inclusion du chrome(III) dans les réseaux des minéraux du clinker, n'implique pas des différences essentielles dans leur comportement envers les variations de température, comparées à celles des minéraux du clinker étalon (exempts de Cr); on a remarqué l'abaissement de la température de transition polymorphique  $\beta \rightarrow \alpha$  du bélite par rapport à l'orthosilicate de calcium pur (mais ce phénomène est déterminé pas seulement par l'inclusion dans le réseau de l'orthosilicate de calcium des ions de chrome(III), mais aussi des ions d'aluminium et de fer(III)).

Les compositions oxydiques des phases séparées et analysées par la fluorescence des rayons X et par la voie chimique (tableau I), montrent que le chrome (calculé comme oxyde de chrome(III)) est distribué surtout dans les phases alitique et béli-

tique. Le contenu en chrome est presque double dans les phases déjà mentionnées par rapport à celui déterminé dans les phases célitique et vitreuse.

La distribution préférentielle des ions chrome(III) dans les phases alitique et bélite est aussi démontrée par les images obtenus à l'aide de la microsonde électronique; dans la figure 1 (a et b) sont présentées les distributions des ions de silicium, aluminium, fer(III) et chrome(III), correspondant aux clinkers à 0,5 et 3 % oxyde de chrome(III) respectivement.

L'inclusion du chrome dans le réseaux des minéraux silicatiques entraîne des modifications dans les rapports établis entre les oxydes qui les composent, c'est à dire les oxyde de base (oxydes de silicium et de calcium) et les oxydes solubilisés dans les minéraux de base, formant des solutions solides (oxyde d'aluminium et oxyde de fer(III)) en fonction des modifications de la stabilité des ces minéraux.

Dans le cas du clinker à 0,5 % oxyde de chrome(III), l'inclusion d'une quantité relativement importante de chrome dans les réseaux des silicates dicalcique et tricalcique ne modifie pas essentiellement le rapport gravimétrique entre les oxydes de calcium et de silicium, mais détermine une diminution importante de la quantité des oxydes d'aluminium et de fer(III) solubilisés dans les constituants silicatiques du clinker de ciment portland.

Dans le clinker à 3 % oxyde de chrome(III) on a déterminé une diminution nette du rapport gravimétrique des oxydes de chrome et de silicium, dans les conditions d'une diminution de la quantité d'oxyde de calcium et d'une augmentation visible du contenu en oxydes d'aluminium et de fer(III), allant jusqu'à 3,37 % en poids, par rapport à 2,19 % en poids dans le cas du clinker sans chrome; le contenu en chrome (déterminé comme oxyde de chrome(III)) atteint 3,94 % en poids. Par conséquent, le rapport gravimétrique entre l'oxyde de calcium et les oxydes acides diminue, par rapport au clinker étalon, de 2,21 jusqu'à 2.

Les modifications des rapport oxydiques dans les minéraux silicatiques du clinker, lorsque le contenu en oxyde de chrome(III) est variable, sont certainement corrélées avec les changements de la composition minéralogique des phases silicatiques. Les modifications, bien que peu importantes par rapport à l'étalon pour le cas du clinker à 0,5 % oxyde de chrome(III), deviennent importantes pour les clinkers à 3 % oxyde de chrome(III) (dans ce cas, on ne trouve pratiquement pas d'alite).

Pour la composition des phases célitique et vitreuse (phases interstitielles) des clinkers obtenus à partir d'un mélange brut (sans microadditions d'oxyde du chrome) un contenu élevé en oxyde de calcium est caractéristique, probablement par suite de la solubilisation de cet oxyde dans la phase liquide du clinker (qu'on retrouve après la solidification comme phase vitreuse).

Figure 1 - La distribution élémentaire des atomes de silicium, aluminium, fer et chrome dans deux sortes de clinker: a) à 0,5% en poids oxyde de chrome(III); b) à 3% en poids oxyde de chrome (III).

Les clinkers à additions d'oxyde de chrome (III) se distinguent par un contenu plus bas en oxyde de calcium dans les phases interstitielles, surtout dans le cas du clinker à 0,5% oxyde de chrome(III). Cette constatation est en accord avec le fait que le contenu en phases silicatiques dans ce clinker est plus grand /1/. Dans les phases interstitielles du clinker à chrome on observe aussi un abaissement du contenu en oxyde de silicium. En même temps, on observe une aug-

mentation du contenu en oxyde de fer(III) et surtout, en oxyde d'aluminium. L'oxyde de fer(III) se trouve dans les phases interstitielles dans une proportion plus grande que dans le clinker étalon, seulement dans le cas du clinker à 0,5% oxyde de chrome. Quand le contenu en oxyde de chrome(III) dans le mélange brut atteint 3% les pourcentages des oxydes de fer(III) et d'aluminium dans les phases interstitielles sont plus bas par rapport aux phases interstitielles des clinkers à 0,5% oxyde de chrome(III). La somme des pourcentages des oxydes de fer et d'aluminium incorporés est pourtant plus grande que dans le cas des clinkers étalon; ceci peut être attribué au contenu relativement élevé en chrome(2,39% en poids, calculé comme oxyde de chrome(III)).

On peut conclure que les variations des proportions des phases célitique et vitreuse dans les clinkers sont directement influencées par les processus ayant lieu dans les phases silicatiques à l'incorporation de proportions variables en oxyde de Cr (III), et par la tendance de solubiliser, notée dans le cas des phases interstitielles surtout dans le ferrite-aluminate de calcium /2,3/.

Les additions en oxyde de chrome(III) conduisent aux changements importants de la texture résultant des modifications de la composition et des influences sur les processus physiques et chimiques pendant la formation du clinker de ciment portland. Les résultats des mesures de porosité effectuées sur les clinkers à contenu variable en chrome, utilisant le microscope-analyseur des images, confirment les suppositions annoncées plus haut, et en même temps, sont en accord avec les modifications dans la composition minéralogique et dans la morphologie des minéraux des clinkers /1/.

Tableau II - Mesures de porosité pour les clinkers étudiés

Les propriétés examinées	Clinkers à:		
	0% Cr <sub>2</sub> O <sub>3</sub> en poids	0,5% Cr <sub>2</sub> O <sub>3</sub> en poids	3% Cr <sub>2</sub> O <sub>3</sub> en poids
La répartition volumique des pores (%vol.)	20,56	14,09	12,31
Le diamètre moyen des pores(mm)	0,0169	0,0085	0,0096

Les données présentées dans le tableau II montrent que la présence du chrome conduit à une vitrification assez importante des clinkers. Ceci est en bonne concordance avec les conclusions occasionnées par les mesures de la composition oxydique des phases majeures du clinker. En même temps avec l'abaissement de la porosité totale a lieu une modification de la distribution des dimensions des pores (tableau III): la

proportion en petits pores augmente.

**Tableau III** - La distribution des pores pour les clinkers étudiés

Distribution du nombre des pores ayant le diamètre compris dans l'intervalle (% du nombre total des pores)	Clinkers à:		
	0% Cr <sub>2</sub> O <sub>3</sub> en poids	0,5% Cr <sub>2</sub> O <sub>3</sub> en poids	3% Cr <sub>2</sub> O <sub>3</sub> en poids
0 - 3 $\mu$ m	30,12	64,93	26,47

50 - 80 $\mu$ m	4,88	1,08	1,54
plus de 80 $\mu$ m	1,76	0,43	0,32
nombre total des pores/mm <sup>2</sup>	575	1079	961

#### D. CONCLUSIONS

La présence du chrome dans le clinker entraîne des modifications de la composition minérale des clinkers et aussi des modifications notables de la composition chimique des phases majeures; ces modifications peuvent être corrélées avec celles qui sont observées dans la composition minéralogique des clinkers, intéressant surtout les phases silicatiques. Ces modifications sont plus importantes quand l'oxyde de Cr(III) est incorporé dans des proportions supérieures à 0,5% en poids. Lorsque cette proportion augmente, la phase alitique diminue, jusqu'à une disparition quasi-totale dans les clinkers à 3% oxyde de chrome(III). Les modifications dans les proportions relatives des phases silicatiques et dans leur composition chimique impliquent des modifications dans la composition et les propriétés des phases silicatiques.

La présence du chrome dans les clinkers détermine une vitrification plus intense; à l'augmentation du contenu en oxyde de chrome(III) correspondent un abaissement de la porosité totale et une modification de la distribution des pores (les petits pores deviennent beaucoup plus nombreux).

# Common influence of BaO and $Mn_2O_3$ on the obtaining and the properties of the portland cement

## *Influence des additions de BaO et $Mn_2O_3$ sur la fabrication et les propriétés des ciments Portland*

RESUME : Pour étudier l'influence de BaO et  $Mn_2O_3$  sur les processus de formation du clinker et les propriétés du ciment, on a fabriqué et étudié des mélanges de matériaux à partir de ces composés chimiques et de matières premières naturelles.

Il a été établi que BaO et  $Mn_2O_3$  accélèrent la calcination de la pierre à chaux, améliorent la structure cristalline du clinker et augmentent leur teneur en alites.

Le clinker obtenu se caractérise par une mouture améliorée et par une activité chimique et hydraulique augmentée. Les ciments portland contenant une addition de baryum-manganèse ont un durcissement plus rapide et une résistance plus grande de 80 à 120 kg/cm<sup>2</sup> que les ciments sans cette addition.

Cette addition exerce une action complexe sur la formation des composants du ciment et leur minéralisation.

SUMMARY : For the investigation of the common influence of BaO and  $Mn_2O_3$  on the clinker-forming processes and the properties of the cement obtained, raw material mixtures of chemical reactivities and natural materials are made up and studied.

It is established that BaO and  $Mn_2O_3$  accelerate the lime absorption, better improve the crystal structure of the clinker and increase the alite contents in it.

The clinker obtained is characterized by a bettered grinding ability, increased chemical and hydraulic activity. The portland cements containing a baryum-manganese addition harden faster and must strength by 80-120 kg/cm<sup>2</sup> higher higher in comparison with cements without addition.

The addition has a complex, alloying and mineralizing action.

The utilization of the alloying and mineralizing additions increases very much the possibilities of accelerating the processes of the mineralforming and regulation the structure of the portland cement clinker and its products. (1, 2). The action of BaO and  $Mn_2O_3$  is of particular interest and each one of them has contradictory data (3-6).

In the present communication brief data will be given concerning the simultaneous action of  $BaO + Mn_2O_3$ , the use of which becomes real especially when utilizing different natural raw materials or industrial wastes. The action of the addition is studied in laboratory, semi-industrial and industrial conditions.

The oxide of barium is introduced as  $BaSO_4$  (baryte or concentrate of baryte), the  $Mn_2O_3$  as  $MnCO_3$ , manganese containing ore or wastes. Additions containing 0,5 + 2,0% BaO and 0,4 + 2,0%  $Mn_2O_3$  in different correlation, have been studied.

#### I. OBTAINING AND STRUCTURE OF THE PORTLAND CEMENT CLINKER

In the Portland cement constituents the dissociation of  $BaSO_4$  takes place at lower temperatures in comparison with the clean salt, and practically comes to his end at  $1400^\circ C$ . The acid oxides  $SiO_2$ ,  $Al_2O_3$  and  $Fe_2O_3$  (7) contribute for this. The separating barium oxide has alkaline comportment and appears as analogous to CaO. The manganese compounds most often fully pass into  $Mn_2O_3$ , which replaces  $Fe_2O_3$  in the constituents of the Portland cement clinker. This fact was accounted for at constituting the raw material mixtures and the calculation the mineral constituent of the clinker.

In the presence of  $BaO + Mn_2O_3$  accelerated annealing of the calcium lime (CaO) was observed. In clinkers with different constituent (KH = 0,85-0,95 - according to Kind-Yong,  $n = 1,7-3,2$  and  $p = 1-2,5$ ), the full absorption of the lime terminates at temperature by 20-40°C lower in comparison with the samples without addition.

In industrial conditions the obtaining of clinker is carried out without any deviation from the technological regime. More uniform and granulometrical clinker constituent is established, with absence of fine and most coarse fractions. The clinker obtained is of a decreased strength and increased Brittleness and with ~ 30% ameliorated grind capacity.

The microscopic observations in laboratory and industrial clinkers show that the in the presence of  $BaO + Mn_2O_3$ : the porosity of the clinker increases; improves the crystallization of the basic phases - of alites and belites (Fig. 1 and 2). Often the alite crystals show additional sectility, some admixtures are included in them, or alteration of their surface is observed. The quantity of the alite phase is by 3 to 8% bigger.

Microphotography of clinkers, containing BaO and  $Mn_2O_3$ , obtained in laboratory conditions (reflected light, Magnitude 90 x)

Fig. 1

Microphotography of clinkers, containing BaO and  $Mn_2O_3$ , obtained in factory conditions (reflected light, Magnitude 90 x)

Fig. 2

The observations with microtester bear witness of practically uniform distribution of BaO in the Portland cement clinker structure, while  $Mn_2O_3$  remain mainly in the constituent of the interstitial substance which surrounds the alite and belite crystals.

It is obvious that the action of the addition  $BaO + Mn_2O_3$  begins as early as the reactions of the solid phases, with a partially formed aluminate of barium and a manganate of barium and calcium.

However, its presence in the clinker melt is the determining factor, the quantity and the activity of which is increasing, while the viscosity decreases (8, 9). For this contributes the increased components of the system and the specific modifying influence of  $Ba^{2+}$ ,  $Mn^{2+}$  and  $SO_4^{2-}$ . (1)

The presence of BaO concerns, to the utmost

degree, the balite phase and contributes for the stabilization of  $\beta$ , while increased concentrations of  $\alpha$ - $\text{C}_2\text{S}$  also, a fact confirming the data of (10).

The manganese, before all, forms a complex alluminium-ferro-manganese phase, but some though very small part of it, is to be found in the alite and belite phases, something confirmed by data of microtester.

## 2. HYDRATATION AND HARDENING OF THE CEMENTS CONTAINING $\text{BaO}+\text{Mn}_2\text{O}_3$ IN THE CLINKER

The increased defectiveness of clinker silicate phases, as well as the increased quantity of alite, are a prerequisite for an increased hydraulic activity. This is also favoured by the chemically more active varium ion, especially that from the surface areas of the clinker particles.

An established fact is the increase of the degree of hydration of cements containing  $\text{BaO}+\text{Mn}_2\text{O}_3$  in comparison with cements without addition, including the three month term of hydration in grout with norm density. This is also accompanied by an increase of the activity of the liquid phase, which in our estimation, activates the hardening.

The laboratory data concerning clinker cements of different constituents (KH, n and p) and different content of  $\text{BaO}+\text{Mn}_2\text{O}_3$  show an increase both of the initial (1-7 day) and the later strength. In single instances, the difference ranges from 80 to 160  $\text{kg}/\text{cm}^2$ .

The best strength of cements is obtained when the content of BaO is from 0,5 to 1,5% and for  $\text{Mn}_2\text{O}_3$  - from 0,4 to 1,6%. The data were confirmed with obtaining clinker in semi-plant furnace (0,7 x 8,0 m) working with liquid fuel.

The positive influence of  $\text{BaO}+\text{Mn}_2\text{O}_3$  is manifested both in trials of grout and in reference solutions. This contributes to increasing the adhesive and cohesive properties.

The laboratory and semi-plant trials have been carried out in different cement plants including those working by the dry, semi-dry and aqueous method with liquid or hard fuel.

The necessary quantity of BaO and  $\text{Mn}_2\text{O}_3$  is introduced with the help of an appropriate industrial waste matter, obtained when dressing the ironstone (11, 12)

When calculating the raw material mixtures, the content of  $\text{Mn}_2\text{O}_3$  was equalized to that of  $\text{Fe}_2\text{O}_3$ , while that of BaO - to CaO.

The strength standard determinations show an increase of the hydraulic activity towards the 28th day with an amount of 80 to 120  $\text{kg}/\text{cm}^2$  (Table 1).

These data were confirmed by the corresponding tests of concretes with various compo-

sitions.

+ The testings according to the Bulgarian State Railways (for short = BST) correspond to the Instructions of ISO.

## CONCLUSIONS

The introduction of  $\text{BaO}+\text{Mn}_2\text{O}_3$  in the composition of the portland cement raw material mixtures gives us the possibility to conduct the process of the clinkerformation.

The addition has complex, alloying and

mineralizing action, through which a clinker with a better crystallization and with an increased contents of alite, is achieved.

The clinker is characterized by an increased chemical and hydraulic activity.

# Formation and Stability of $C_3S$ and Alites

## *La formation et la stabilité du $C_3S$ et des alites*

Udo LUDWIG and Albrecht WOLTER, Institut für Gesteinshüttenkunde, RWTH Aachen, R.F.A.

RESUME : La synthèse du  $C_3S$  d'une haute pureté a été réalisée pour la première fois au-dessous de  $1300^\circ\text{C}$  par l'application de nouveaux modes de préparation, comme le séchage au pétrole chaud (HPT), la synthèse hydrothermale (HTS) et le séchage avec pulvérisation (SPR).

De plus, une technique de cuisson a été mise au point, permettant, non seulement de chauffer très rapidement et de maintenir la température constante pendant un très long temps, à un niveau prédéterminé, mais aussi de faire varier cette température d'une façon programmée. C'est ainsi que la température de stabilité du  $C_3S$  pur, en présence de  $C_2S$  et de chaux libre, a pu être déterminée à  $1264 \pm 3^\circ\text{C}$ .

Ensuite des solutions solides courantes de  $C_3S$  ont été essayées. Ce que l'on appelle l'alite normale est une solution solide dans le  $C_3S$ , d' $Al_2O_3$ , de  $Fe_2O_3$  et de  $MgO$ . La réaction solide qui produit cette alite à partir de  $C_2S$ , de  $CaO$ , de  $MgO$  et de  $C_4AF$  se produit à environ  $1200^\circ\text{C}$  et est beaucoup plus rapide que celle qui produit le  $C_3S$  pur. L'addition de phosphate de zinc et de sulfate de baryum à l'alite normale n'a qu'une faible influence sur la température de formation de l'alite et sur la vitesse de la réaction. Mais l'addition de 2 % de  $MnF_3$  à l'alite normale abaisse cette température à  $1100^\circ\text{C}$ .

La formation de l'alite a aussi été étudiée dans des crus industriels de ciment Portland. Dans ces matériaux, la température limite de formation du  $C_3S$  est inférieure de quelques degrés à  $1200^\circ\text{C}$ . Il n'y a que de faibles différences dans la formation du  $C_3S$ , selon le taux de saturation en chaux du cru.

Ces résultats montrent l'intérêt technique d'utiliser des crus très actifs. Une résistance comparable à celle des ciments Portland peut être obtenue même à une température relativement basse de cuisson et un cru faiblement dosé en chaux. Des économies d'énergie peuvent aussi être faites dans le broyage du clinker.

SUMMARY: The synthesis of very pure  $C_3S$  was made for the first time in the temperature range below  $1300^\circ\text{C}$  by using new preparation techniques such as "hot kerosene drying" (HPT), "hydrothermal synthesis" (HTS) and "spray drying" (SPR). In addition a burning technique was developed, which allowed not only to heat up very rapidly and keep the temperature constant at a prefixed point for a very long time, but also to change the sample temperature for distinct amounts. In this way the stability temperature of pure  $C_3S$  from  $C_2S$  plus free lime could be determined as  $1264 \pm 3^\circ\text{C}$ .

After that some common solid solutions of  $C_3S$  were investigated. A so-called "normal alite" represents the solid solution limit of  $C_3S$  with  $Al_2O_3$ ,  $Fe_2O_3$  and  $MgO$ . The solid state reaction of this alite from  $C_2S$ ,  $CaO$ ,  $MgO$  and  $C_4AF$  occurs at about  $1200^\circ\text{C}$  and proceeds much faster than the formation of pure  $C_3S$ . Admixtures of zinc phosphate and bariumsulphate to the normal alite had only a small influence on the formation temperature and reaction rate of alite. But the addition of 2 %  $MnF_3$  to normal alite reduced the formation temperature to  $1100^\circ\text{C}$ .

In specially prepared technical Portland cement raw mixes the alite formation was investigated too. In these materials the temperature limit for  $C_3S$ -Formation was some degrees lower than  $1200^\circ\text{C}$ . There were only small differences between  $C_3S$ -formation in a raw mix with a high and a low lime saturation factor.

These results point out the technical importance of the use of high active raw mixes. A strength similar to Portland cement is attained in spite of a lower burning temperature and a lower lime dosage. Additionally energy can be saved in the clinker milling.

## INTRODUCTION

The system  $\text{CaO}-\text{SiO}_2$  is well known by work carried out by RANKIN and WRIGHT (1), LEA and PARKER (2), WELCH and GUTT (3) and many other authors. In the past with a high lime content of this system the calcium oxide (C) coexists with dicalcium silicate ( $\text{C}_2\text{S}$ ). At higher temperatures the tricalcium silicate is formed from these phases (see Fig. 1).

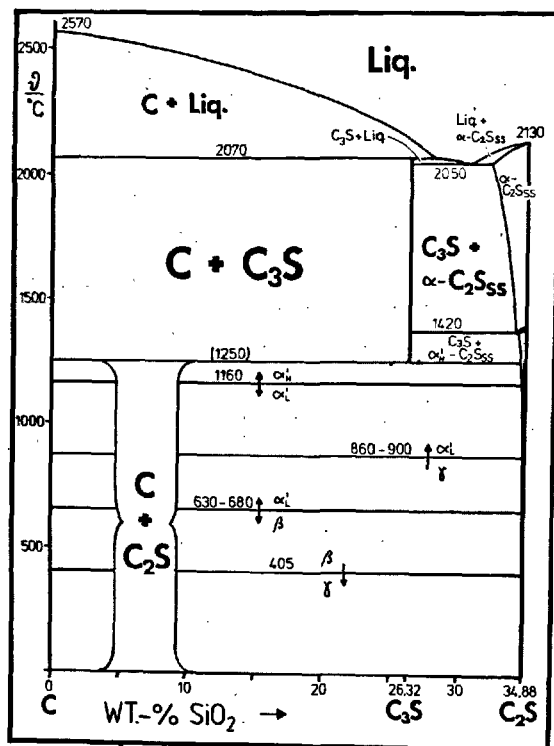

Fig. 1 The subsystem C- $\text{C}_2\text{S}$  of the system  $\text{CaO}-\text{SiO}_2$

Much research work was done to determine the lower stability limit of  $\text{C}_3\text{S}$  (2,4,5). They all synthesized pure or doped  $\text{C}_3\text{S}$  at temperatures between 1450 and 1600°C and observed the decomposition of  $\text{C}_3\text{S}$  to  $\text{C}_2\text{S}$  and free lime in the temperature range from 1300 to 1000°C. In this way, 1250°C could be extrapolated from the decomposition rate at lower temperatures, but there has not as yet been an exact determination of the stability temperature of  $\text{C}_3\text{S}$ .

The main difficulty the investigations of  $\text{C}_3\text{S}$ -formation come up against is the very low free energy ( $\Delta G$ ) of the reaction  $\text{C} + \text{C}_2\text{S} \rightleftharpoons \text{C}_3\text{S}$  of about 8 to 13 kJ/mol at room temperature to circa - 4 to - 10 kJ/mol at 1800°C.

Figure 2 shows the free energy over the temperature (6,7,8,9). It is easy to see that the tolerances of the thermodynamical data do not allow a good calculation of the stability range of  $\text{C}_3\text{S}$ .

Fig. 2 Free energy ( $\Delta G$ ) for the reaction  $\text{C}_2\text{S} + \text{C} \rightarrow \text{C}_3\text{S}$  (starting with  $\beta\text{-C}_2\text{S}$ )

Another difficulty is created by the strong influence of impurities on the  $\text{C}_3\text{S}$ -reaction rate. Only a few authors gave information about the purities of their starting materials for  $\text{C}_3\text{S}$ -synthesis. But nobody did report on the purity of his synthesized  $\text{C}_3\text{S}$ .

The affinity of  $\text{Al}_2\text{O}_3$ ,  $\text{Fe}_2\text{O}_3$  and  $\text{MgO}$  to  $\text{C}_3\text{S}$  in the form of solid solutions ("alites") is well known (10,11,12). The solution limit is about 2 wt-% of  $\text{MgO}$ , 1 wt-% of  $\text{Al}_2\text{O}_3$  and 1 wt-% of  $\text{Fe}_2\text{O}_3$  in  $\text{C}_3\text{S}$ . This alite we call "normal alite".

In technical Portland cement clinker there are a lot of other minor compounds such as alkalis (Na, K), heavy metal oxides ( $\text{TiO}_2$ ,  $\text{Cr}_2\text{O}_3$ ,  $\text{Mn}_2\text{O}_3$ ,  $\text{ZnO}$ ,  $\text{NiO}$ ,  $\text{PbO}$  etc.) and anion groups ( $\text{F}$ ,  $\text{Cl}$ ,  $\text{SO}_4$ ,  $\text{P}_2\text{O}_5$  etc.) present.

To investigate the special influences of these compounds on alite formation we took the following scheme (Fig. 3):

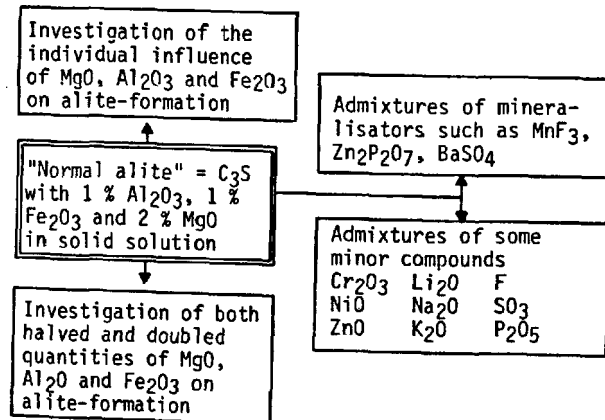

Fig. 3 Working scheme for qualitative investigations on alite-formation

At first the stability temperature of normal alite was examined. The second part concerns the influence of the minor compounds, single and in combinations, on the alite formation temperature, reaction rate and sintering mechanisms in normal alite. To complete this research work, alite formation was observed in homogenized technical Portland cement clinker too. In the literature there is only one piece of information, that  $\text{Fe}^{++}$ -rich alite decomposes spontaneously at 1173°C (13).

#### EXPERIMENTAL

For the comparison of common preparation techniques such as homogenisation of heterogeneous compounds by milling and the new ones such as "hot kerosene drying" (HPT), "hydrothermal syntheses" (HTS) and "spray drying" (SPR) a series of samples was taken all with the same  $\text{CaO}/\text{SiO}_2$ -ratio = 3/1:

Preparation	$\text{SiO}_2$ - part	$\text{CaO}$ - part	specific surface (BET) $\text{m}^2/\text{g}$
Milling	Quartz	$\text{CaCO}_3$	1,3
Milling	Aerosil	$\text{Ca}(\text{OH})_2$	24,5
Milling	$\beta\text{-C}_2\text{S}$	$\text{CaCO}_3$	1,9
HPT	Ethylsilicate	$\text{Ca}(\text{CH}_3\text{COO})_2$	41,6 +) 20,3 ++)
SPR	Aerosil	$\text{Ca}(\text{CH}_3\text{COO})_2$	24,3 +) 32,2 ++)
HTS	$\text{C}_3\text{SH}$		17,1

+ ) 200°C - dried - material  
++ ) 450°C - treated - material

The values of specific surface (BET) from 1.3 to 41.6  $\text{m}^2/\text{g}$  indicate distinct activities of these mixtures, but it is not the sole characteristic of the activity, as the reaction rates in the temperature range from 1200-1300°C show (see Fig. 4).

The worst activity can be seen in the mixture of quartz with  $\text{CaCO}_3$ . The best "mixture" is the tricalcium silicate hydrate ( $\text{C}_3\text{SH}$ ). But as it was not possible, to make really pure  $\text{C}_3\text{SH}$ , the HPT-material was used for the determination of the  $\text{C}_3\text{S}$ -stability temperature. The low activity of the Aerosil- $\text{Ca}(\text{OH})_2$ -mixture in response to its high specific surface is attributed to big inhomogeneities between Ca- and Si-distribution in the mixture.

For the very fast heating of the pressings to the prefixed temperature in 2 or 5 min, a new burning procedure, was developed for samples with a volume of 1  $\text{cm}^3$  which also facilitated the temperature change in the gradient of a chamber kiln with tubes. After burning the samples were quenched in air and examined for the free lime content according to the FRANKE-method and also for the phase-composition with x-ray-analyses. The reaction grade (UGR) was calculated from free lime value ( $C_{\text{free}}$ ) according to the formula:

$$\text{UGR} = \frac{100 - (C_{\text{free}} \times 4.072)}{100}$$

Fig. 4 Reactivity of various lime silica mixtures

and from the x-ray intensities of  $\text{C}_3\text{S}$ ,  $\text{C}_2\text{S}$  and C by using a computer programme.

For the investigations of alite formation in technical Portland cement clinker two technical cement raw mixes with Kalkstandard III (KSt) = 100 and 107 were calcined at 900°C and homogenized by hydrothermal treatment in water suspension at 310°C/100 bar for 5 hours. After drying at 160°C a very homogeneous and fine-grained mixture of tricalciumsilicatehydrate, hydrogarnet and calcium hydroxide with small amounts of brucite was left behind. All materials were pressed into small compacts with 1  $\text{cm}^3$  volume.

#### RESULTS AND DISCUSSION

After a burning period of 20 minutes at a temperature of 1300°C the reaction degree of pure  $\text{C}_3\text{S}$  was 0.54. After the 20 minutes the sample was rearranged to a temperature of between 1220 and 1300°C. Figure 5 shows the increase or decrease in the reaction rate with the square root of time.

The stability temperature lies between 1260°C and 1270°C. The exact temperature value of 1264,2°C can be extrapolated from the formation- and decomposition-rate over the temperature (Fig. 6). The error margin of this value is  $\pm 3^\circ\text{C}$ , produced by the uncertainties of the thermocouple, the temperature measurement and the positioning of the sample in the temperature gradient.

The reason why the gradient of the increasing reaction rate is much higher than that of the decreasing reaction rate lies in the difference in the density of  $\text{C}_2\text{S} + \text{C}$  and  $\text{C}_3\text{S}$ . The  $\text{C}_3\text{S}$ -decomposition produces

Fig. 5 Degree of  $C_3S$ -conversion as a function of burning period and temperature

Fig. 7 Reaction degree of normal alite at various temperatures (HPT)

Fig. 6 Temperature dependence of the rate of formation and of decomposition of pure  $C_3S$

Fig. 8 Influence of low lime-dosage and of mineralisators on formation of normal alite (SPR)

more dense phases and so micro-fractures are originated, at which the solid state diffusion stops. On the other hand the newly formed  $C_3S$  occupies a greater volume than the starting phases and so  $C_3S$ -formation proceeds faster than  $C_3S$ -decomposition.

On the basis of 1264,20°C as the lower stability limit of  $C_3S$ , the free energy of  $C_3S$ -formation from  $B-C_2S+C$  at normal temperature in air was calculated to be 8.32 kJ·mol<sup>-1</sup>.

The formation of alite could be observed without a temperature change programme, because the alite formation is sharply accelerated as opposed to pure  $C_3S$ . The synthesis of normal alite was carried out at temperatures of 1100 to 1280°C (Fig. 7).

Up to 1200°C the alite forms metastably and decomposes after some 10-100 h again. At 1220°C a stable alite is formed. So, the stability temperature should be something higher than 1200°C.

Both halved and doubled quantities of the admixtures of  $Al_2O_3$ ,  $Fe_2O_3$  and  $MgO$  had no effect on the stability temperature.

Figure 8 shows the influence of a lower lime dosage (alite : belite = 50 : 50) and of some mineralisators on the alite formation in the temperature range of 1000°C to 1350°C. The burning period in each case was 16 minutes. A lower lime content retards the alite formation. 3 wt.-% barium sulfate accelerates the formation rate, but raises the formation temperatures by about 10°C. 2 wt.-% zinc phosphite also accelerates the formation rate, but it lowers the formation by about 20°C. The biggest influence was observed by addition of 2 wt.-%  $MnF_3$ . The stability limit of this fluor-bearing alite is short under 1100°C. At lower temperatures a "pseudo-alite" is formed, which gives x-ray patterns similar to the  $3C_3S \cdot CaF_2$ -phase. At temperatures higher than 1100°C a solid solution of alite and pseudo-alite phase develops.

The alite synthesis in homogenized technical cement raw mix (KSt = 100) was carried out in the temperature range of 1185 - 1250°C. Figure 9 shows the reaction grade against burning time.

Fig. 9 Reaction degree of hydrothermal homogenized industrial Portland cement raw mix (KSt = 100)

The reaction proceeds in a clearly logarithmic fashion:

$$\text{UGR} = a + b \ln t \quad \left| \quad 0 \leq \text{UGR} \leq 0.95 \right. \\ \left. t \geq 1 \text{ min} \right.$$

with the temperature depending constants  $a$  for the initial alite content after heating + 1 min burning time and  $b$  for the materials activity. That is to say alite formation in a very homogeneous mixture proceeds like a chemical reaction. The error margin of the above equation in the technical cement burning process is attributed to the comparatively high heterogeneity of the compounds in normal cement raw mixes (14,15,16).

For the 1250°C series a material with lower activity than for the other temperatures was used. The stability temperature of technical alite is determined by the very strong difference in reaction between 1200 and 1192°C. The alite formation in the second technical raw mix with KSt = 107 was very similar to the former raw mix. This result is in good correspondence to the behaviour of synthetic normal alite.

#### ACKNOWLEDGEMENTS

We thank the government of the Nordrhein-Westfalen country for the sponsoring of this research work.

# Dispersing and Plasticizing admixtures to cements

## *Des ajouts disperseurs et plastifiants des ciments*

**RESUME :** On a cherché à obtenir du ciment plastifié par addition de tanins synthétiques et de lignosulfonate du magnésium technique. Ces ciments plastifiés possèdent de hautes propriétés physico-mécaniques et constructives.

L'addition de 0,15-0,5 % de ces plastifiants abaisse l'eau de mouillage nécessaire de 14 à 30 %. La résistance des ciments plastifiés au gel et au sulfate est respectivement 0,93-0,96 et 0,94-1,00. Les processus d'hydratation sont étudiés par les méthodes de radiographie, de thermographie, de spectrographie infrarouge et d'analyse chimique. On a constaté la régularité de l'hydratation des ciments en présence des ajouts indiqués. Les additions de lignosulfonate de magnésium et de syntane améliorent la broyabilité des clinkers.

On a étudié des ajouts de triéthanolamine, de diéthanolamine et monoéthanolamine comme agents de broyage des clinkers. On a constaté que le diéthanolamine et le monoéthanolamine (qui sont des homologues de la triéthanolamine) sont des ajouts disperseurs très actifs. Nous avons étudié l'adsorption des additifs par les différents ciments et son influence sur la broyabilité. En ajoutant 0,3 à 0,5 de triéthanolamine à des ciments différents par leur composition chimico-minéralogique, nous avons obtenu des ciments pour le bétonnage sans coffrage. Le ciment pour le bétonnage sans coffrage peut aussi être obtenu avec du ciment sursulfaté normal et du ciment super-blanc. On peut l'utiliser pour la consolidation des excavations et pour la décoration des bâtiments. La durée de prise de ces ciments est 8 à 15 minutes, leur résistance à la compression est de 2,0 à 2,3 MPa au bout de 2 heures et de 25,2 à 36,3 MPa au bout de 28 jours.

**SUMMARY :** Possibility of plasticized cement obtaining at the base of synthetic tannic acids and technical magnesium lignin sulfonate admixtures is studied. Plasticized cements possess high physical, mechanical, building and technical properties.

Introduction of plasticized admixtures (0,15 - 0,5%) lowers the water requirement of cements by 14 - 30%, it increases the strength of cement solutions by 17 - 20%. Plasticized cements freeze and sulfate resistance is respectively 0,93 - 0,96 and 0,94 - 1,00. Processes of hydration are studied by X-ray method, thermographical method, method of infrared spectroscopy and by chemical analysis. Regularities of cement hydration in the presence of mentioned admixtures are established. Magnesium lignin sulfonate and sytan admixtures improve clinker grindability.

Triethanolamine, diethanolamine and monoethanolamine admixtures as intensifiers of clinker grinding process are studied. Triethanolamine homologs-diethanolamine and monoethanolamine are established to be very effective dispersing admixtures. Adsorptive activity of mixtures is studied on different cements, its influence upon the dispersity of powders is also studied. Possibility of cement obtaining for the tubbingless cementation by introducing 0,3 - 0,5 triethanolamine admixtures into the different (according to their chemical-mineralogical composition) cements is established. Cement for the tubbingless cementation can be produced at the base of normal sulfate resistant white cement, it can be used for the rock manufactures strengthening and for the building decoration. Cement setting is 8-15 minutes, strength at compression in 2 hours of solidification is 2,0-2,3 MPa in 28 days - 25,2 - 36,3 MPa.

It is possible to obtain special plasticized cements and intensify clinker grinding process with a help of organic surfactants. Some scientists decided to divide the organic surfactants according to their water affinity and their influence upon cement and cement stone surface properties into two big groups: water-retaining surfactants and water-repellent surfactants(I)

The first group consists of sulfite-cellulose liquor, sulphite yeast converter mash and their derivatives, which increase the cement water affinity. The second group consists of the additives of silicone liquids compositions, fatty naphthenic acids, resin acids and their alkali salts. Adsorption of these substances is accompanied by chemical fixation of additive polar groups with formation of unsoluble calcium soaps at the cement particle surfaces. Water-repellent additives act as plasticizers in the solution and concrete mixtures.

Besides, superplasticizing and superdiluting additives are widely used. Sulfonated melamine-formaldehyde and naphthalene-formaldehyde resins, modified and purified lignin sulphates, polybenzene aromatic and other compounds are used.

Plasticizing surfactants improve the cement mixtures and concrete properties. High plasticity and packing increase the concrete quality and its ageing.

We used synthetic tannic acids (syntan), SPS and technical magnesium lignin sulfonate as surfactant for obtaining plasticized cement. Plasticized capacity of additives and cement solution water requirement lowering was studied. Tests were carried out according to GOST 310-60. The results are shown in table I.

TABLE I

Admixture	Admixture quantity, %	Deliquescence pyrocone	Water requirement lowering
Without admixture	0	105	0
Syntan	0,1	123	10
	0,15	130	14
	0,20	145	20
	0,5	206	30
Magnesium lignin sulfonate	0,1	114	7,5
	0,15	120	10
	0,25	130	14
	0,5	187	25

In the studied concentrations of surfactants the cement solutions plasticity increases permanently. Syntan plasticizing capacity

is higher than it is with sulphite-cellulose liquor and technical magnesium lignin sulfonate. To obtain plasticizing Portland cement with deliquescence pyrocone of no less than 125mm it is necessary to use 0,15% SPS or 0,25% magnesium lignin sulfonate. The best surface activity of syntan SPS in comparison with magnesium lignin sulfonate is proved by the data of determination of surfactant aqueous solutions surface tension.

Water-requirement lowering of plasticizing cements was determined according to the degree of decreasing the normal density value. Syntan SPS additive is the most effective. If SPS concentration is 0,1-0,2-0,5% the lowering of Portland cement solution water requirements is 10,20,30% and that of magnesium lignin sulfonate is 7,5-12,5-25% respectively. The admixtures used did not increase the plasticity and didn't low the water requirement of high aluminous white cement.

Process of solidification of plasticized cement hydration were studied. Cement strength and the degree of hydration according to the content of  $\text{Ca(OH)}_2$  and water in solid solution content are determined. Results are shown in table II.

TABLE II

Admixture	Strength of compression			$\text{Ca(OH)}_2$ , % in 28 days
	I	7	28	
Without admixture	6,9	41,4	60,7	8,22
Syntan SPS	5,2	44,6	69,0	9,15
Magnesium lignin sulfonate	2,8	36,8	63,8	8,71

Plasticized cement strength and the degree of its hydration in a day is less than that of the control cement. In the course of further cement solidification the velocity of  $\text{Ca(OH)}_2$  liberation and its strength increase and in 7-28 days they will surpass the control samples by 5-14%. It is in good agreement with X-ray, thermographic and infrared spectroscopic analyses data  $\text{Ca(OH)}_2$  peaks intensity of the X-ray patterns (4,90Å), end-effect surface of the thermogram (480-500°C) and adsorption lines intensity on the spectra (3648cm) of the plasticized cements in a day of solidification is lower than that of control samples.

Strength of the plasticized cement-sand solutions in 28 days is higher by 17-20% than that of the control samples.

Strength of the plasticized cement-sand solutions in 28 days is higher by 17-20% than that of control samples.

Slowing of hydrolysis reaction and of plasticized cement hydration at the beginning of setting is explained by the surfactant absorption film formation on the surface of cement particles and new formations. This film makes water combination with cement granules difficult. This slowing of plasticized cements hydration with the age increase of samples is compensated by higher hydration process velocity during this period.

It was also determined that plasticized cements with sytan SPS and MLS admixtures are highly freeze and sulfate resistant. Thus, they may be used in the strict exploitation conditions. Plasticized cement freeze resistance coefficient is 0,93-0,96 (control sample - 0,67-0,80), firmness coefficient in the aggressive media 0,94-1,00 (control sample - 0,64-0,78).

Sytan SPS and magnesium lignin sulfonate admixtures intensify clinker grinding process. Of grinding time is the same, plasticized cement residue on the control sieves is 3-5%, while control cement residue is 10%, specific surface increases by 300 - 400 cm<sup>2</sup>/g.

Different surfactants as clinker grinding process intensifiers were studied. Amino alcohols-monoethanolamine (MEA), diethanolamine (DEA) and triethanolamine (TEA) were used as surfactants. Cement powder dispersity is determined by percentage residue on the control sieve, by the specific surface and by granule composition. Results of surfactants influence upon cement residue on the control sieves are given in table III.

TABLE III		
Admixture	Admixture quantity	Residue on sieve 008, %
Without admixture	0	10
Monoethanolamine (MEA)	0,025	4,50
	0,05	4,75
	0,10	5,00
	0,20	5,50
Diethanolamine (DEA)	0,025	3,75
	0,05	4,00
	0,10	4,25
	0,20	6,00
Triethanolamine (TEA)	0,025	4,00
	0,05	4,25
	0,10	4,50
	0,20	4,75

According to their intensifying influence on grinding process, surfactants may be arranged as follows: MEA, DEA, TEA. If we take into account the adsorption activity value of these amino alcohols their arrangement will be the same: MEA, DEA, TEA.

Aminoalcohols usage in a certain quantity also promotes the increasing of grinding product specific surface. However, dispersity increasing determined by specific surface quantity, is much lower than that of the value by the residue on the sieve 008. Dispersity increasing of grinding products with surfactants additives, is obviously connected with the adsorption of strength and with the disaggregation of the surfactants.

Thus, triethanolamine analog-monoethanolamine and diethanolamine highly intensify the clinker grinding process, that's why they can be used for cement mills intensification.

Possibility of obtaining the special cement for tubingless cementation with triethanolamine admixture was determined. Sulfate resistant, normal and white cements were the initial substances for the tubingless cementation. Triethanolamine admixtures were added into the make up water of the cement paste with water-cement ratio of 0,40

Triethanolamine considerably accelerates cement setting time. Admixture optimal quantities for cement obtaining are: for the sulfate resistant and white Portland-cement - 0,3% TEA, for normal - 0,5. Here setting time is 8-15 minutes, it meets the technical condition requirements. Beams (4x4x16 cm) were formed from cement paste with water-cement ratio of 0,40, with triethanolamine admixture 0,3 - 0,5%. Tests were carried out according to GOST 310-60. Results are given in table IV.

TABLE IV				
Cements	Strength of samples (water-cement ratio - 0,40), MPa			
	at bending in...		at compression	
	2 hours	28 days	2 hours	28 days
Sulfate resistant	0,9	4,41	2,5	25,2
Normal	1,01	4,48	2,2	36,3
White	0,95	4,05	2,3	30,8

The results of physico-mechanical tests showed that the strength of sulfate-resistant, normal and white cements with respective quantities of triethanolamine met the requirements of conditions for the tubbingless cementation. Thus, the strength of compression of sulfate resistant cement samples (triethanolamine optimal concentration is 0,3%) in two hours of solidification is 2,0 MPa, and in 28 days - 25,2 MPa that of normal and white Portlandcement samples in 2 hours of setting is 2,2 and 2,3 MPa, and in 28 days - 36,3 and 30,8 MPa (4,5). Cement for tubbingless cementation can be manufactured directly at the cement mills by introducing triethanolamine while clinker grinding.

#### CONCLUSIONS

Our studies showed that plasticized cements with syhtan SPS and magnesium lignin sulfonate admixtures had high physico-mechanical, building and technical properties. The admixtures surfactants studied favourably influence the hydration and cement setting process.

Triethanolamine analogs-monoethanolamine and diethanolamine are very effective intensifiers of clinker grinding process.

Possibility of cement manufacturing for the tubbingless cementation by using higher triethanolamine admixtures for different cements was determined.

## Comminution and Dissociation characteristics of Indian limestones

### *Broyabilité et décarbonatation des calcaires indiens*

S.K. SINHA, S.K. HANDOO et A.K. CHATTERJEE, Cement Research Institute of India, New Delhi, India.

**RESUME :** Etant donné que l'industrie indienne du ciment utilise des calcaires de presque tous les âges géologiques, depuis la période Précambrienne jusqu'à la période Pléistocène, des échantillons représentant des horizons géologiques caractéristiques des différents âges ont été rassemblés dans différentes cimenteries indiennes pour une étude systématique. La présente communication rend compte de la variation de la résistance au concassage, de l'aptitude au concassage, de la broyabilité et des caractéristiques de désintégration de la calcite et du quartz libre en fonction de leur assemblage minéral et de leur répartition granulométrique. Tout en essayant de corréler les paramètres ci-dessus mentionnés, on a étudié et on a comparé la réactivité de différents calcaires après leur désintégration, et les causes de leurs variations ont été établies.

**SUMMARY :** Since the Indian cement industry has been using limestones of almost all the geological ages starting from Precambrian to Pleistocene period, representative samples of typical geological horizons of different ages were collected from various Indian cement plants for a systematic study. The present paper reports the variation in the crushing strength, crushability, grindability, and dissociation characteristics vis-à-vis their mineral assemblage and grain size distribution of calcite and free quartz. While attempts have been made to interrelate the above parameters, the reactivity of different limestones after dissociation has been investigated and compared, causes for the variations established.

## INTRODUCTION

The total reserves of cement-grade limestones in India, estimated at more than 59000 million tonnes are distributed in geological time scale from pre-cambrian to recent times. At present, the contributions of precambrian and postcambrian limestones in cement production are estimated at about 78% and 22% respectively but the future expansion programme of the industry is likely to increase the utilization factor of postcambrian limestones to some extent. Because of this changing pattern of utilization of limestones of different geological ages as well as to ascertain the degree of intrinsic difference in the process response of limestones having different characteristics, a systematic investigation had been undertaken to establish the basic relationship between the property and characteristics of different limestones. Some of the significant trends of results obtained are illustrated with the help of eight varieties of limestones belonging to different geological ages and horizons.

## LIMESTONE CHARACTERISTICS

## Chemical Composition

The composition of the limestones is presented in Table I. The compositional variability of these limestones is reflected in the ratios of CaO to SiO<sub>2</sub> (C/S), (CaO + SiO<sub>2</sub>) to (Al<sub>2</sub>O<sub>3</sub> + Fe<sub>2</sub>O<sub>3</sub>), and (CaO + SiO<sub>2</sub> + Al<sub>2</sub>O<sub>3</sub> + Fe<sub>2</sub>O<sub>3</sub>) designated as  $\epsilon$ ,  $\epsilon_2$ , to (100 -  $\epsilon$ ) denoted as B. The C/S ratio varied from about 3 to 30, C+S/A+F ratio from 13.5 to 21.5, and  $\epsilon$ /B from 13.7 to 47.1. However, no specific correlation could be established either amongst the above three ratios or individually between the ratios and the geological age of the limestone horizons.

## Mineral Constituents

The major and minor minerals detected in the limestones by X-ray diffractometry and optical microscopy are listed in Table II. Apart from calcite, which is predominantly present, quartz and dolomite constitute the other important phases. The contribution of feldspathic, micaceous and clay minerals to the total composition of the limestones if of minor significance and more or less comparable in all the varieties. The quartz accounts for the major proportion of silica present in the limestones while the magnesia present in limestone S(5-8) comes mostly from dolomite and in S(1-4) from clay minerals.

## Textural Features

The significance of crystal size of calcite and quartz in limestones has been fairly well established (1). The grain size ranges of calcite and quartz in the limestones under study along with their average size, determined from the frequency of grains occurring in different size-ranges, are given in Table II. Depending on the average size of calcite grains (1) and comparing the grain size of calcite and quartz the limestones under reference can be classified as follows:

- S 7 : Medium-grained (0.5-0.25mm) inequigranular
- A S 8 : Medium-grained equigranular
- S 2 : Fine-grained (0.25-0.10mm) equigranular
- B S 4 : Fine-grained inequigranular
- S 1 : Very fine-grained (0.10-0.01mm)
- C S 3 : equigranular
- S 6 : equigranular
- D S 5 : Microcrystalline (<0.01 mm) equigranular

Limestone S1 and S5 display poor compaction.

## CRUSHABILITY AND GRINDABILITY

The crushing strength of the limestone and their relative grindability (with respect to a standard clinker) are presented in Table III. The difficulties of correlating these parameters with the composition or textural characteristics of limestones have been indicated earlier. Nevertheless, in the present situation for the given set of limestones, a qualitative relation between grain size plus C/S ratio on the other, was observed.

So far as the crushing strength is concerned, it increased with decrease in grain size in the range of medium to very fine grain size. The anomalously low strength obtained for the very fine-grained and cryptocrystalline limestones S1 and S5 could be explained by the degree of weathering and poorer compaction. Within each range of the empirical crushing strength scale the limestones with inequigranular distribution of calcite and quartz showed lower strengths than those with equigranular texture.

The relative grindability factor (2) of the limestones, in which the easier grindability is denoted by higher indices, appears to have a joint relationship with the grain size and silica content. The coarser and less quartzose limestones displayed easier grindability (for example, S-7 and S-5). No quantitative relation could be established as the individual effects of grain size and C/S ratio on the grindability were apparently interactive and not additive.

## DISSOCIATION CHARACTERISTICS\*

The dissociation characteristics of the limestones were investigated by differential thermal analysis carried out with the help of a Hungarian MDM Derivatograph. In order to study the effect of particle size on the dissociation phenomena, each limestone was ground separately to three different finenesses (-45  $\mu$ m, -150  $\mu$ m, and - 250  $\mu$ m) and the samples of each fineness were subject to thermal decomposition separately. The rate, temperature maximum (T max) and temperature range of decarbonisation of the limestones ground to different

finenesses are presented in Table IV. From the table it is evident that: (i) no double stage decomposition (3) was observed even in the case of coarsely ground medium-grained limestones, and (ii) there was no consistent trend of increase in T max or decrease in the decarbonisation rate with decrease in the fineness of the limestones. The highest rates of decarbonisation or the lowest T max did not necessarily tally with the finest grinding. In a large number of cases the limestones ground to 150  $\mu$ m and sometimes to 250  $\mu$ m shows relatively lower temperature of decarbonisation or higher rates of decomposition.

## Activation Energy of Dissociation

It has been reported (4) that activation energy of limestone dissociation has a strong effect on the activation energy of clinker mineral formation. The lime combination at 1300°-1400°C was observed to be higher in those cases where the activation energy of carbonate dissociation was lower.

Following the method of Imlach (5) the activation energies (E<sub>a</sub>) of dissociation of the limestone samples under investigation were determined (Table V). As reported by Imlach for the plant raw mixes, a two-stage decomposition with different values of E<sub>a</sub> for the lower and upper stages could be obtained for most of the limestones. The ultimate activation energies of all the limestones lay within the range of 30-60 kcal/mole as reported by Petrosyan (4). But at the same time, no well defined relationship could be observed

between  $E_a$  and impurity alone. However, a similar interactive effect of grain size and impurity, as observed in the case of grindability, was apparent in the case of activation energy as well. The finer the grain size and the more impure a limestone, the lower is the activation energy of dissociation. Further, barring a few exceptions, which could not be readily explained, an apparent relation could be seen between  $E_a$ - $T_{max}$  and  $E_a$ -decomposition rate (Fig.1)

TABLE IV

FIG.1 ACTIVATION ENERGY  $E_a$  VS RATE OF DECOMPOSITION (—, ●) AND PEAK TEMPERATURE  $T_{max}$  (---, ○)

## HIGH-TEMPERATURE REACTIVITY

In order to establish the intrinsic reactivity of the limestones, samples of each variety ground to a fineness of  $-150\mu m$ , were fired at temperatures ranging from  $600^{\circ}$  to  $1100^{\circ}C$  at intervals of  $100^{\circ}C$  and the phase changes taking place at different temperature were studied by X-ray diffractometry (Table VI and Fig. 2).

It is evident from this investigation that the early formation of  $C_2S$  is favoured by relatively lower

activation energy of carbonate dissociation simultaneously with the presence of fluxes along with silica. With higher activation energy the appearance of  $C_2S$  takes place at higher temperatures. In the absence of fluxes the  $C_2S$  formation is pushed to high temperatures and the released lime crystals after dissociation tend to grow with loss of reactivity.

The new mineral formation was detected, as a rule, at temperatures above 800°C and depending on the limestone characteristics the first phases detected were  $C_2F$ ,  $C_2AS$ ,  $C_2S$  and  $C_3A$ . The presence of dolomite did not show any significant effect on the kinetics of dissociation and mineral formation.

## CONCLUSIONS

A wide variety of limestones belonging to different geological ages and horizons as well as differing in their chemico-mineralogical and textural characteristics showed that, although no direct correlation of reactivity and dissociation characteristics of limestone is possible with their geological age and genesis, they can be linked up with their chemico-mineralogical and textural features. For the given set of limestones the crushing strength and grindability have displayed an apparent relation with grain size and impurities present in limestone.

These two parameters also appear to have a significant effect on the activation energy of carbonate dissociation. The formation of dicalcium silicate at relatively lower temperature is favoured in limestones with lower activation energy of dissociation and simultaneous presence of fluxing oxides; otherwise the new phases that form are  $C_2F$ ,  $C_2AS$  and  $C_3A$ , depending on the limestone characteristics. For the given limestone the first appearance of new phases was a temperature above 800°C. The dolomite did not show any

FIG. 2 CHANGES IN PHASE COMPOSITION OF LIMESTONE WITH TEMPERATURE

significant effect on the dissociation or reaction kinetics. On the whole, the grain size jointly with the impurities present in limestones controls their process response.

#### ACKNOWLEDGEMENT

The work reported here is part of the R&D programme of the Institute and the report is being communicated with the permission of the Director-General, Cement Research Institute of India.

# Burnability of industrial Portland cement raw mixes

## *Cuisabilité des crus du ciment de Portland industriel*

U. LUDWIG, Institut für Gesteinshüttenkunde, RWTH Aachen, Allemagne Fédérale,  
S.E. IBRAHIM, Bagdad.

RESUME : La cuisabilité de 14 crus granulés industriels a été déterminée pour des températures comprises entre 1340 et 1420°C.

La cuisabilité, pour une certaine température, a été définie comme étant le temps de cuisson en minutes qui est nécessaire pour obtenir une teneur de la chaux libre de 2m-%.

Pour une température de cuisson de 1360°C

- l'hétérogénéité du cru élève ce temps de 19 à 525 minutes, soit en moyenne 100 minutes,
- la teneur en chaux le monte de 34 à 109 minutes, soit en moyenne 65 minutes, et
- la teneur en liquidus l'élève de 22 à 78 minutes, soit en moyenne 50 minutes.

L'élévation de la température de cuisson de 1360°C à 1420°C effectue une réduction du temps de cuisson de moitié.

La cuisson des farines non granulées cause des états actifs près de la température de déshydratation et de calcination, et par là la formation spontanée de dépôts adhérent aux réfractaires et la formation de grenailles.

A notre avis, ces états actifs sont la cause des dépôts adhérents, et des anneaux dans les fours.

SUMMARY: The burnability of 14 different granulated industrial raw mixes was measured in the temperature range between 1340 and 1420°C. The burnability is the required burning period in minutes at a given burning temperature to reach a free lime content of 2 wt.-%.

At a given burning temperature of 1360°C

- the influence of the heterogeneity of the provided mixes amounts to between 19 and 525 minutes, 100 minutes on average
- the influence of the standard lime amounts to between 34 and 109, 65 minutes on average and
- the influence of the melt content amounts to between 22 and 78 minutes, 50 minutes on average.

The increase in the burning temperature from 1360 to 1420°C effects a lowering of the burning period by half.

The burning of non-granulated powder leads in the temperature range of dehydration and decarbonization to active states and thereby to spontaneous formation of adhesions on the lining of the kiln and to the formation of granules. In our opinion they are the cause of adhesions and ringformation in the technical kiln process.

## INTRODUCTION

The prediction of the burnability of a technical raw mix and of the factors influencing it is for the design and the management of cement plants of great technical and economical importance.

For determination of the burning behaviour of a raw mix the residue of free lime after a given burning period (1, 2) or the required period to achieve a given content in free lime is normally measured (3,4,5). In a paper which has just been published (6) the authors proposed to measure the ratio between the lime combined in the clinker minerals and the total lime of the mix in relation to a temperature-range of 800 to 1450°C.

Mostly the burnability is valued only qualitatively. Quantitative valuations have existed for several years for calculating the residue of free lime or the required burning time at a given temperature from the different characteristics of a raw mix. A formula which has been used for some time in our work group (4) for the prediction of burnability was improved (7). Here the burnability again is marked as the burning period needed to achieve a residue in free lime of 2 wt.-%.

## EXPERIMENTAL

Mainly the burning experiments were performed in a discontinuous working electrically heated laboratory rotary kiln. The heating was achieved by a partially sawn through coal bar inside the burning room of the kiln. The kiln is designed with a speed control. Mainly the raw mix feeding was done through the non-rotating stopper of the front wall. The stopper contains a second bore hole for temperature measurement. The depletion was done through a lateral opening. With 600 g raw mix pellets the required period to reach the desired burning temperature amounts to 9 minutes. The burning of granulated material did not give rise to difficulties. The output was nearly 100 % of the theoretical.

Most of the raw mixes were well burned at 1360°C within 10 to 120 minutes. Mixes that needed a longer period of burning later on were put into an electrical chamber furnace for long term burning.

Besides the measurement of free lime in the well burned clinkers, the content of alkali-, sulphate- and calcium-aluminate-ferrite phases were determined.

More details of the experimental equipment and procedure is given in (7).

Up to now we have not succeeded in burning powdered raw mix in the above-mentioned rotary kiln. The formation of active states within the raw mixes during dehydration of clay minerals and much more during decarbonization of limestone leads to raw mix deposits on the lining of the laboratory kiln. In practice the crust and ring formation in the preheater system and in the rotary kiln respectively are caused primarily in the same way. In addition we directly watched the formation of loose pellets after decarbonization at 1050°C (fig. 1).

Fig. 1 - Loose raw mix pellets formed at 1050°C in the laboratory rotary kiln

## RESULTS

### Chemical data

For the 14 examined technical raw mixes the following variations were derived from the chemical analysis:

lime standard III	94,3 - 107,6
silica ratio	2,1 - 4,7
alumina ratio	0,55 - 3,8
calculated melt content at 1360°C according to Dahl	15,0 - 28,4 wt.-%

By thermo-chemical measurement the melt formation was found to be in the range between 1270 and 1345°C. The latter value was found only at low alumina ratio and low impurity content.

### Granulometrical data

The deviations in granulometric data are shown in fig. 2. A good characterisation is achieved by the gradient  $n$  and the most frequent grain diameter  $d'$  from the Rosin-Rammler-Sperling-Bennet (RRSB) diagram. -

Here as a new value the ratio between hete-

Fig. 2 - Data derived from granulometric measurement

rogenous  $H_R$  and total coarse grain content  $R$  is introduced as heterogeneity ratio  $HG$ .  $HG$  in this paper is assumed to be constant for the coarse grain fractions. For better valuation of the influence of  $HG$  raw mixes with 50 wt.-% and totally pulverized coarse fraction  $>90 \mu m$  were prepared. In the table they are designated as "1:1" and " $<90 \mu m$ ". The residues  $R_{200 \mu m}$  and  $R_{90 \mu m}$  which are used in practice are directly readable from the RRSB-diagram.

#### Burnability data

Burnability data are derived from free lime determination dependent on the time. Four typical graphs show the time dependent decrease in free lime at several burning temperatures and also contents of coarse raw mix.

It is impossible to get raw mix A well burned within 13 hours because of the high standard lime of c. 108. Experimental work with this raw mix shows that maximum standard lime could be c. 104 to get well burned clinker ( $\bar{c}$  2 wt.-% free lime).

A burning period of 2 1/2 hours at  $1360^\circ C$  was needed to get raw mix B with standard lime of 103 and the heterogenous portion  $>90 \mu m$  ( $H_{R90}$ ) of 7,6 wt.-% well burned. The additional milling of the coarse fraction  $>90 \mu m$  leads to a reduction of the burning period to 70 minutes.

Raw mix  $G_S$  with the lowest alumina ratio of 0,55 was less burnable at  $1340^\circ C$  because of the formation of the clinker melt at higher temperature. That was also established with thermo-chemical analyses.

Improved burnability was measured with raw mix C because of its favourable chemical and granulometric data.

Fig. 3 - Typical free lime - time - curves at several temperatures and  $H_{R90}$ -contents

The temperature dependent inter- and extra-polated practical burnability  $B_T$  derived from the free lime - time - slopes follow an exponential equation:

$$B_T = B_{1360} e^{0.0126(1360-T)}$$

The correlation coefficient between the measured data and the data calculated from the above equation amounts to 0,95.

Fig. 4 shows a parabolic slope of the practical measured burnability as function of the

heterogeneity  $H_{R90}$ . On the other hand from the values of the burnability of 5 raw mixes with additional milling of grain fraction  $>25 \mu\text{m}$  the conclusion can be drawn that there is a marked influence of heterogeneous particles up to this small grain size.

Fig. 4 - Practical burnability as function of the heterogeneity

With a constant heterogeneity ratio HG the sum of the heterogeneity influences  $\Sigma$  HE are put together by HG, the gradient  $n$ , the most frequent grain diameter  $d'$  and the value of the maximum grain diameter  $d_{\text{max}}$  from RRSB-diagram.

A total prediction of the burnability of the raw mixes by computation shows besides the influences from heterogeneity an increase in the needed burning period with the square of the standard lime and a decrease with the square of the melt content. The coefficient of correlation between the experimental data and the data calculated from the raw mix amounts to 0,96.

For all the burnability series together with the coefficient of temperature the connection represented in fig. 5 was found. The coefficient of correlation amounts to 0,94. Excluding the series with a burning temperature of 1340°C with incomplete melt formation the correlation coefficient was 0,96.

Fig. 5 - Practical and theoretical burnability

#### CONCLUSIONS

The time dependent measured practical burnability  $B_{pr}$  in the range of 1340 to 1420°C of 14 technical Portland cement raw mixes was set in relation to their chemical and granulometric characteristics. This results in the possibility of the prediction of a theoretical burnability  $B_{cal}$ .

The time dependent free lime content at a given burning temperature and the thereof derived  $B_{pr}$  are of great importance for the design and the operation of cement kilns. In contrast the measurement of the chemical and granulometric characteristics shows the separate influences of the heterogeneity, the lime standard, and of the melt content of a given raw mix on the burnability. This can help to optimize the composition of raw mixes.

#### ACKNOWLEDGMENT

The authors want to express their thanks to A. Wolter for his help in questions of mineralogical and mathematical content. - The work was supported by some cement plants that delivered the raw mixes and by the Deutsche Forschungsgemeinschaft that financed the project.

# A comparative study of the effect of heating rate in 2-stage and 4-stage suspension preheater kiln installations

*Etude comparée de l'influence de la vitesse de chauffe  
dans les fours avec préchauffeurs à deux et à quatre étages*

M.V. RANGA RAO and KAMAL KUMAR, Cement Research Institute of India, New Delhi, India.

**RESUME :** Des résultats expérimentaux, obtenus sur des fours à préchauffeurs à deux et à quatre étages, installés en Inde, ont été analysés, compte tenu du traitement thermique du cru. Cette analyse a mis en évidence l'effet de la vitesse de chauffe du cru sur la structure et les propriétés du clinker produit. Après avoir tenu compte de l'effet important de la composition chimique du cru sur la structure et les propriétés du clinker produit dans ces usines (utilisant du charbon pulvérisé de qualité plus ou moins constante), on a pu identifier l'effet de la vitesse de chauffe, considérée isolément. On a constaté qu'en plus de l'effet sur la porosité et la texture, une vitesse de chauffe élevée permettait d'obtenir les principaux constituants du clinker sous la forme de cristaux très petits, ce qui a une influence favorable sur la cinétique de formation du  $C_2S$ ; il en résulte aussi une productivité plus grande.

**SUMMARY :** Operational data obtained from one 2-stage suspension preheater kiln system and two 4-stage suspension preheater kiln systems in India have been analyzed with respect to the thermal treatment received by the raw meal in these systems. The analysis highlights the effect of the different rates of heating of the raw meal on the structure and properties of the clinker produced. After giving due weightage to the effect of differences in chemical characteristics of raw meal on the structure and properties of clinker produced in these installations (using pulverised coal of more or less similar characteristics) the effect of heating rate alone on these properties has been identified. It is observed that, besides the effect on porosity, texture, etc., higher heating rate gives rise to relatively small size crystals of the major minerals and has a favourable influence on the kinetics of  $C_2S$  formation, thus resulting in relatively higher productivity.

## INTRODUCTION

The formation and properties of Portland Cement clinker in rotary kilns are influenced by a number of parameters such as (i) Raw Meal chemical composition, its particle size distribution and homogeneity, (ii) Rate of heating of the Meal and the temperature at the time of occurrence of reactions, (iii) Fuel type and quality and (iv) Ash composition and absorption in the case of solid fuels containing inorganic mineral matter. Of the above (ii) is an inbuilt feature of System Design largely dependent on the type of fuel. With solid fuels of the grade mentioned in the text, reactions have proved to be more complex and any attempt to analyse data obtained from such systems is likely to lead to conflicting conclusions. Nevertheless an attempt is made in this paper to analyse the effect of the parameter on the microstructure of clinkers obtained from 3 different dry process suspension preheater kiln systems one of which has a 2 stage preheater kiln. All these systems used semi-Bituminous coal as fuel.

## SYSTEM DETAILS

The system details of the 3 plants are given in Table I. The two 4 stage SP installations are herein designated as  $S_I$ ,  $S_{II}$  and the two stage SP installation is designated as  $S_{III}$ . These three units have different rated capacities and these range from 300 tpd to 900 tpd. The clinker samples examined for this paper were taken when the operation was stable.

TABLE I				
Kiln System Details				
Sl. No.	Parameter	Systems		
		I	II	III
1.	$L/D_E^*$	15.69	16.62	23.95

## OPERATIONAL DATA

The operational data relating to the three installations  $S_I$ ,  $S_{II}$  and  $S_{III}$  are reproduced in Table IV.

# EFFECT OF RAW MEAL CHARACTER AND ASH ABSORPTION ALONE ON CLINKER STRUCTURE

It may be seen from Table II that the characteristic Moduli values of the raw material and the corresponding clinkers do not follow the same trend as is normally to be expected provided the operational parameters and coal quality, ash composition and fusion point System Design, are similar. The chemical characteristics of clinker, would not alone reflect how much of ash might have been absorbed in them. As such it may not be correct to infer that the effect of differences in the Moduli values of meal in these systems has not been any significant in respect of ash absorption and thereby the clinker structure. Thus the effect of differences in the characteristic values, viz. LSF, SM, AM of the rawmeal on the texture and

porosity of the clinkers produced could be attributed to differences in the system design and operational parameters and could be delineated as follows:

- a) On the basis of SM values, the size of alite crystals formed from  $RM_{III}$  would be larger than those from  $RM_I$  and smaller than those of  $RM_{II}$
- b) On the basis of AM values, the size of alite crystals formed from  $RM_{III}$  would be larger than those of both  $RM_I$  and  $RM_{II}$
- c) On the basis of LSF also, the size of alite crystals from  $RM_{III}$  would be larger than those of  $RM_I$  &  $RM_{II}$ . The nett deduction of a, b, & c would thus be that much larger sized alite crystals would have been formed in  $S_{III}$  than in  $S_{II}$  &  $S_I$ .

TABLE IV  
Operational Data

Sl No	Parameter	Systems		
		I	II	III

	ii) Transition Zone	36.3	19.6	15.9

## ACTUAL OBSERVATIONS

On the otherhand from microscopic observations of the clinker from these systems under an optical microscope it was seen that the relative sizes of the alite and belite crystals in different clinkers revealed that clinkers from  $S_{III}$  are smaller in size than those from  $S_I$  &  $S_{II}$ . The photo micrographs of the 3 clinkers are shown in Figures 1, 2 and 3 respectively.

Fig. 1

Fig. 2

Fig. 3

## INFERENCE

One may infer from the above that operational parameters such as the heating rate of meal have predominantly influenced the rate of growth of alite and belite grains and thereby the clinker's structure, porosity and to some extent texture also. How this could have happened is discussed in next section.

## DISCUSSION

The deviation from the expected behaviour as derived from the chemical character of the mixes in the different systems may be summed up as follows:

Effect of operational parameters and mechanical condition of the equipment in the systems:

The parameters that influence all the rotary kiln reactions are:

- i) Velocity of flue gases
- ii) Temperature and Partial pressures of radiant gases.
- iii) Residence time of the meal as derived from the rates of heat transfer.

The effect of above parameters on the course of the reactions in the kiln are discussed in the following sub sections.

## Velocity of Gases

Due to the counter-current flow of gas and meal, the relatively higher velocity of gas entrains the solid particles, the quantity of particles entrained depending on the physical characteristics such as shape, density and texture. The density of calcium oxide being greater than silicon dioxide, sometimes it remains in the mass of meal as  $SiO_2$  is lifted up due to the turbulent action of the gas stream in the loosely packed surface of the mass of meal exposed to it. Another parameter which is of great significance and importance is the origin of  $SiO_2$ . If it is present as free  $\alpha$ -quartz, its particle size, shape and texture being different from silica obtained from in-situ dissociation of argillaceous components in the meal is not so easily carried by the gas except for the finer fractions.

## Temperature and Partial Pressure of the Gases

Although partial pressure of  $CO_2$  &  $H_2O$  in the gases suppress the calcining reaction as it progressively increases unstream of the kiln and then upto the 2nd stage of the preheater. The retardation in the decarbonation reaction is made up by the increase in radiant heat supplied to the meal by  $CO_2$  and  $H_2O$  in the gas stream along with  $SO_2$  and other diatomic gases. (Stefan-Boltzman's law still forms a basis for all radiant heat exchange calculations. Although the view factor & the product of absorptivity and emissivity explain the mechanism of radiant heat transfer, certain hitherto uninvestigated phenomena, which in our view account for the differences in the crystal sizes of  $C_3S$  and  $C_2S$ , are promoted by relatively higher temperature prevailing in the sintering zone.)

In  $S_I$ ,  $p_{CO_2}$  at the boundary of Tr I and calcining zone was less than in  $S_{II}$  &  $S_{III}$  whereas at kiln inlet the gases in  $S_{III}$  had comparatively a higher value. The  $PH_2O$  values were more or less the same

at the corresponding points in the systems.

#### CONCLUSION

##### Reactions occurring in the kiln

The sequence of reactions in the burning zone finally alter the grain sizes and boundaries depending on the operating sintering zone temperature. The quantum of heat transfer in the zone depends on the  $\text{CO}_2$  and water vapour partial pressure in the combustion products. The thermodynamics of combustion of coal are in turn responsible for the changes in the values of partial pressure in the zones specially of  $\text{CO}_2$ . The thermodynamics of combustion in turn depends on the quality of coal, fineness and ash content. Coal fineness seems to play a vital role in the clinkerisation process. What comes into the sintering zone viz.  $\text{C}_4\text{AF}$ ,  $\text{C}_3\text{A}$  and  $\text{C}_2\text{S}$ ,  $\text{CaO}$  (uncombined) forms the nucleus for further reactions in the zone. The two fluxing compounds melt and along with  $\text{CaO}$  form the vehicle for the remaining mineral  $\text{C}_2\text{S}$  to react with the balance unsatisfied  $\text{CaO}$  both in the liquid and solid states. The differences in the reaction times of the partially combined oxides of  $\text{CaO}$ ,  $\text{Al}_2\text{O}_3$  and  $\text{Fe}_2\text{O}_3$  on one hand and the complete combination of  $\text{SiO}_2$  with the  $\text{CaO}$  already liberated in the calcining zone on the other, obviously explain the differences observed in the microstructure of the clinkers obtained in the sintering zones of the respective systems produced as a result of disintegration/dissociation phenomena occurring in the transition zone with the  $\text{C}_2\text{S}$  transformation to  $\text{C}_3\text{S}$  being promoted at the relatively higher temperatures prevailing in the sintering zone.

From the heating rates, as can be deduced from the temperature and pressure conditions at the boundaries of the reaction zone, it is to be inferred that low heating rates prevailed in calcining and burning zones and thus allowed the formation of more number of nuclei which ultimately result in smaller sized grains of  $\text{C}_2\text{S}$  and  $\text{C}_3\text{S}$  as is evident from the photomicrograph in Fig.3.

#### ACKNOWLEDGEMENT

The work reported here is part of the R&D programme of the Institute and the report is being communicated with the permission of the Director General, Cement Research Institute of India, New Delhi.

# Effect of $\text{Na}_2\text{O}$ on the stability of calcium aluminoferrite under the reducing atmosphere

## *Effet du $\text{Na}_2\text{O}$ sur la stabilité de l'aluminoferrite de calcium sous atmosphère réductrice*

M. ONO, Senior Research Engineer, Research and Development Laboratory,  
M. AKITA, Research Engineer, Mitsubishi Ming and Cement Co., Ltd.,  
K. HIKITA, Research Engineer, Tokyo, Japan.

RESUME : La phase aluminatée contenue dans le clinker de ciment portland, produit dans des fours à atmosphère réductrice, augmente avec la réduction de la phase ferrite. Pour en comprendre le mécanisme, la stabilité de l'aluminoferrite de calcium ( $\text{C}_4\text{AF}$ ), avec ou sans  $\text{Na}_2\text{O}$ , a été étudiée à  $1420^\circ\text{C}$  dans l'air et dans différentes atmosphères réductrices.

Sans  $\text{Na}_2\text{O}$  dans le système, l'aluminatée tricalcique se forme à partir de la ferrite quand la pression partielle de l'oxygène est maintenue à moins de  $10^{-4}$  atm. En présence de  $\text{Na}_2\text{O}$  l'aluminatée se sépare de la ferrite dans n'importe quelle condition de cuisson, sans relation avec la pression partielle d'oxygène, mais la quantité d'aluminatée formée augmente avec la diminution de la pression partielle d'oxygène.

Les phases cubique, orthorhombique et monoclinique de l'aluminatée sont formées à partir de la ferrite suivant la quantité de  $\text{Na}_2\text{O}$  contenue dans le système.

On détermine également la solubilité solide du fer dans cette phase aluminatée.

SUMMARY : Aluminate phase content in portland cement clinker increases with the reduction of ferrite phase burning under the reducing atmosphere. To clarify the mechanism, the stability of calcium aluminoferrite ( $\text{C}_4\text{AF}$ ) with or without  $\text{Na}_2\text{O}$  was investigated at  $1420^\circ\text{C}$  in air and several reducing conditions.

Without  $\text{Na}_2\text{O}$  in the system, tricalcium aluminate phase is formed from ferrite phase when the partial pressure of oxygen is kept less than  $10^{-4}$  atm. In the presence of  $\text{Na}_2\text{O}$ , aluminate is separated from ferrite in all heating conditions having no connection with the oxygen partial pressure, but the amount of aluminate formed increases with lower oxygen partial pressure.

Cubic, orthorhombic and monoclinic phases of aluminate is formed from ferrite depending upon the  $\text{Na}_2\text{O}$  content in the system.

The solid solubility of iron in these aluminate phase is also determined.

## INTRODUCTION

It is very important for the cement technology to make clear the atmospheric effect on the formation of clinker minerals. Most of the investigations which have been carried out in this field are as for the silicate phases, and only a few investigations, on the contrary, have been done to the interstitial materials. Some workers reported that the quantitative ratio of the dark and light interstitial materials was changed in accordance with the oxygen partial pressure (1),(2),(3). J.A. Imlach and F.P. Glasser gave many investigations in regard to the effect of oxygen partial pressure on the formation of the clinker minerals in  $\text{CaO-Al}_2\text{O}_3\text{-FeO-Fe}_2\text{O}_3$  system under  $10^{-5}$  and  $10^{-8}$  atm. of the oxygen partial pressure (4). In this report, the stability of ferrite phase with  $\text{Na}_2\text{O}$  at the elevated temperature under 0.21,  $10^{-4}$ ,  $10^{-7}$  and  $10^{-9}$  atm. of the oxygen partial pressure is discussed from some experimental results.

## EXPERIMENT

$\text{C}_4\text{AF}$  burned at  $1380^\circ\text{C}$  in air and  $\text{Na}_2\text{O}$  (as  $\text{Na}_2\text{CO}_3$ ) were mixed in various ratios and reheated under 0.21 (in air),  $10^{-4}$  (in dry  $\text{N}_2$ ),  $10^{-7}$  and  $10^{-9}$  (in  $\text{CO/CO}_2$  mixture) atm. of the oxygen partial pressure ( $P_{\text{O}_2}$ ).

Samples were kept 30 min. at  $1420^\circ\text{C}$  in the platinum crucibles put into the alumina tube furnace (50 mm $\phi$ ). The fused samples were cooled to  $900^\circ\text{C}$  at the rate of  $5^\circ\text{C/min.}$  and then allowed to cool to room temperature. The total gas flow rate was 400ml/min.. The samples were subjected to the examinations by X-ray powder diffraction, electron probe microanalysis, microscopic observation and chemical analysis.

## RESULTS

It is shown for the X-ray powder diffraction that any phase except ferrite can not be detected from the sample without  $\text{Na}_2\text{O}$  which

is burned under 0.21 and  $10^{-4}$  atm.  $P_{\text{O}_2}$ . However in the presence of  $\text{Na}_2\text{O}$ , orthorhombic  $\text{C}_3\text{A}$  is formed from  $\text{C}_4\text{AF}$ . In proportion as  $\text{Na}_2\text{O}$  content the quantity of  $\text{C}_3\text{A}$  increases and its crystal system changes from orthorhombic to monoclinic. If  $\text{Na}_2\text{O}$  content of the samples reaches over 2.8%,  $\text{C}_3\text{A}$  formed from  $\text{C}_4\text{AF}$  is decomposed into free  $\text{CaO}$  and  $\beta\text{-NaAlO}_2$ . When the samples without  $\text{Na}_2\text{O}$  are burned under the condition of  $10^{-7}$  atm.  $P_{\text{O}_2}$ , cubic  $\text{C}_3\text{A}$  is formed from the ferrite phase. In this case, free  $\text{CaO}$  and  $\kappa\text{-Fe}$  are also detected. However burning  $\text{C}_4\text{AF}$  with  $\text{Na}_2\text{O}$  under the same condition, the quantity of  $\text{C}_3\text{A}$  increases and its crystal system changes from cubic to monoclinic through orthorhombic in proportion as  $\text{Na}_2\text{O}$  content in the system. Under the condition of  $10^{-9}$  atm.  $P_{\text{O}_2}$ ,  $\text{FeO}$  is detected having no connection with  $\text{Na}_2\text{O}$  content in addition to the minerals described above.

Small amount of the  $\text{C}_3\text{A}$  phase which is not detected by X-ray diffraction, is observed in the samples burned under  $10^{-4}$  atm.  $P_{\text{O}_2}$  by reflective microscopy. It is shown in Fig.1 that the parameter  $P$  of the residual ferrite phase ( $\text{C}_2\text{AF}_{1-P}$ ) decreases with lower  $P_{\text{O}_2}$  at the reheating condition and the analytical value of the reheated sample. As shown in Fig.2 and Fig.3, the content of

Fig.1 Relation between the residual ferrite phase composition ( $\text{C}_2\text{AF}_{1-P}$ ) and  $\text{Na}_2\text{O}$  content in the reheated sample.

$\text{Na}_2\text{O}$  and  $\text{Fe}_2\text{O}_3$  in the  $\text{C}_3\text{A}$  phase formed from the initial  $\text{C}_3\text{AF}$  are related to the quantity of  $\text{Na}_2\text{O}$  in the reheating sample and  $\text{Po}_2$  at the reheating condition. In the case of  $\text{Po}_2$  above  $10^{-9}$  atm.,  $\text{Na}_2\text{O}$  content of the  $\text{C}_3\text{A}$  phase reaches the maximum value of 6.2% when  $\text{Na}_2\text{O}$  is included more than 2.8% in the reheated sample.

Fig.2 Relation between  $\text{Na}_2\text{O}$  content of  $\text{C}_3\text{A}$  and the quantity of  $\text{Na}_2\text{O}$  in the reheated sample.

Fig.3 Relation between  $\text{Fe}_2\text{O}_3$  content of  $\text{C}_3\text{A}$  phase and the quantity of  $\text{Na}_2\text{O}$  in the reheated sample.

It can be read off from Fig.4 that linear relationship exists between  $\text{Na}_2\text{O}$  and  $\text{Fe}_2\text{O}_3$  content of the  $\text{C}_3\text{A}$  phase under every  $\text{Po}_2$  except 0.21 atm., and its slope decreases with the lower  $\text{Po}_2$ .

Fig.4 Relation between  $\text{Fe}_2\text{O}_3$  content and  $\text{Na}_2\text{O}$  content of the  $\text{C}_3\text{A}$  phase.

#### DISCUSSION

Ferrite phase is unstable under the reducing atmosphere. Therefore, without  $\text{Na}_2\text{O}$  it begins to decompose under  $10^{-4}$  atm. and  $\text{C}_3\text{A}$ , free  $\text{CaO}$ ,  $\alpha\text{-Fe}$  and  $\text{FeO}$  phase are formed below  $10^{-7}$  atm.  $\text{Po}_2$ . In the presence of  $\text{Na}_2\text{O}$ , the formation of  $\text{C}_3\text{A}$  from ferrite phase is promoted and the composition of the residual ferrite phase shifts to higher Fe composition. The  $\text{C}_3\text{A}$  phase formed from the initial ferrite phase contains  $\text{Fe}_2\text{O}_3$  and its quantity changes linearly depending upon the  $\text{Na}_2\text{O}$  content which is included in the  $\text{C}_3\text{A}$  phase simultaneously. G. Yamaguchi et al.(5) estimated that the distribution of  $\text{Fe}^{3+}$  ion extend to the  $\text{Al}^{3+}$  sites as well as the  $\text{Ca}^{2+}$  sites in cubic  $\text{C}_3\text{A}$ . Therefore the results of the present study are sufficient to understand that the substitution of  $\text{Fe}^{3+}$  by  $\text{Ca}^{2+}$  ion in the  $\text{C}_3\text{A}$  phase obeys following equation in the presence of  $\text{Na}^+$  ion.

If the above substitution could occur  $\text{Fe}_2\text{O}_3$  content might be increased in proportion as the content of  $\text{Na}_2\text{O}$  in the  $\text{C}_3\text{A}$  phase.

## CONCLUSION

The stability of  $C_4AF$  with or without  $Na_2O$  was investigated at the elevated temperature in air and several reducing conditions. The ferrite phase without  $Na_2O$  begins to decompose under  $10^{-4}$  atm.  $PO_2$  and  $C_3A$ , free  $CaO$ ,  $-Fe$  and  $FeO$  phase are formed below  $10^{-7}$  atm..

In the presence of  $Na_2O$ , the formation of  $C_3A$  phase from ferrite phase is promoted in all heating condition having no connection with  $PO_2$ . The  $C_3A$  phase formed from the initial ferrite phase contains  $Fe_2O_3$  and its quantity changes lineally depending upon the  $Na_2O$  content which is included in the  $C_3A$  phase simultaneously.

# Aging of cement through long term storage

## *Vieillessement du ciment lors du stockage à longue durée*

Dr. M. MAULTZSCH, M. GIERLOFF and Dr. P. SCHIMMELWITZ, Federal Institute for Testing Materials  
(Bundesanstalt für Materialprüfung (BAM) Berlin, R.F.A.

RESUME : Jusqu'à présent, on n'a étudié la stockabilité du ciment que pendant des durées de 3 à 12 mois. On communique ici des recherches effectuées sur des ciments stockés de 7 à 15 ans. Des ciments ayant été stockés en sacs de papier revêtus furent légèrement hydratés de façons variées. D'analyses de phases par thermogravimétrie, il ressort qu'il s'était formé pendant le stockage, avant tout, des silicates hydratés de calcium, de l'ettringite et de la syngénite. Dans des zones marginales solidifiées du contenu des sacs, apparurent, de façon importante, du silicate hydraté de calcium et de la calcite. On a pu considérer la teneur en eau évaporable jusqu'à 180°C (par des analyses thermogravimétriques) comme mesure du degré d'hydratation des ciments stockés. Ce paramètre fut mis en relation avec le développement de la résistance mécanique; il a servi aussi pour la représentation de la répartition locale de l'eau de hydrate dans des sacs de ciment individuels. Comparée avec des ciments frais, l'évolution de l'hydratation des ciments de stockage est caractérisée par une portion moins importante de silicates hydratés de calcium et d'ettringite nouvellement formés durant les premières heures après le gâchage et par la formation initiale de gypse secondaire. Là se trouve la raison de valeurs de résistance amoindries, spécialement dans la phase initiale. Cependant, on a pu constater clairement que des ciments stockés pour une durée de 15 ans atteignent aussi des résistances finales encore satisfaisantes.

SUMMARY: The storage possibility of cement was tested till now only for the period of 3 to 12 months, whereas here tests were made on cement stored for a period of 7 to 15 years. The cements, stored in laminated paper bags were differently pre-hydrated. Thermogravimetric phase determinations showed that principally calcium silicate hydrate, ettringite and syngenite were formed during the storage, Calcium silicate hydrate and calcite could be found especially in the hardened exterior parts of the bags. Through the thermogravimetric analysis the water content was defined as reference for the hydration degree, as the water evaporable up to 180 °C. This reference unit can be related to the strength development; as well the unit serves to describe the space distribution of the hydration water in various cement bags. In comparison to fresh cements the process of hydration of stored cement is characterized by smaller contents of new-formed calcium silicate hydrate and ettringite during the first hours after the addition of water and an initial formation of secondary gypsum. Herein lays the reason for the partially lower values of the strength, especially of early strength. Nevertheless it was established definitely that 15 years long stored cement reaches a satisfactory final strength.

## INTRODUCTION

It is well known that the storage of cement may impair its most important property, the strengthening of mortar and concrete. The extent of strength reduction depends on the type of the cement, the condition and the duration of storage. For cements in silos or in bags, stored for 3 months in a dry shed, the loss of strength may be about 10 % (1), in another study values of 10 - 20 % are mentioned for 3 months storage and 20 - 30 % for 6 months storage (2).

Some of the earliest investigations on the aging of cements are those of Gary and Burchartz (3,4), carried out in the former Royal Office for Testing Materials, now Federal Institute for Testing Materials (BAM) in Berlin. The cements, spread out on the floor or filled in paper bags, were exposed to laboratory atmosphere for three or six months. They showed retardation of setting, lower hydration heat development and lower density than the samples of fresh cements, and they contained lumps. The strength values after 28 d hardening were up to 40 % but after 5 years hardening only about 15 % lower than those of fresh cements. In other studies cement bags were stored for 12 months. The early strength development was reduced by 30 %, while the reduction in strength after 28 d and 2 years was only 22 % and 15 % respectively (5). Favorable to strength development is to screen out the lumps (6). Later on cement in 5-ply paper bags was exposed to a rather humid climate. The strength values decreased by nearly 30 %, but only by 12 % if the bags were wrapped in polyvinyl cloth (7). There are only few studies on long term storage. One of these was carried out for up to 4 years. The 28-d strength of the cements stored in paper bags in rather humid climate came up to only 30 % compared to that of fresh cement samples (8). Most of strength reduction occurred in the early period of storage. In general the authors hardly enter into the reasons for strength reduction.

## INVESTIGATIONS ON CEMENTS STORED FOR LONG TERMS

During the last years the Federal Institute for Testing Materials (BAM) in Berlin had the chance to test cements stored for at least 7 years, but mostly for 10 - 15 years. The cements in 5-ply paper bags, one ply covered with bitumen or polyethylene, were piled up to 40 bags in height in large sheds. More than 300 samples were at this investigation's disposal (9).

Many thermogravimetric analyses were made to answer the question whether the stored cements were partially hydrated or not. For example Fig. 1 (bottom) shows the differential thermogravimetric (d.t.g.) curves for samples of a 15 years old cement, taken from the outer and the inner zones of the bag. The peaks appearing with rising temperature mark the portions of adsorbed water (H), calcium silicate hydrates (C-S-H), ettringite (E), gypsum ( $\text{Cs} \cdot \text{H}_2$ ),

calcium aluminate hydrates (C-A-H), syngenite (Sy), calcium hydroxide (CH), and calcium carbonate (Cc). Fig. 1 (top) includes the corresponding curves for fresh portland cement in

Fig. 1 - Differential thermogravimetric curves of fresh portland cement (top) and stored cement (bottom).

unhydrated and partially hydrated state. The resemblance to the curves for the partially hydrated sample and for the stored cement is evident. Related to fresh cements the stored cement contains increased portions of calcium hydroxide and ettringite, probably a certain portion of such calcium silicate hydrates too which dehydrate at the same temperatures as ettringite, though tobermorite phases dehydrating at about 700 °C do not increase in general. Aluminate hydrates could not be identified definitely. In the outer zones of the bags above all such phases which dehydrate up to 180 °C occur in higher amounts, moreover a strong carbonation is significant. Furthermore the potassium calcium sulphate "syngenite" was found in quantities of 1,1 - 1,4 % by mass, sporadically up to 4 % by mass, in all stored cements. The mineral syngenite is held responsible for the formation of lumps and for the false set (10, 11, 12). In this investigation increased portions of syngenite were found mostly in lumps. As it crystallizes in needles similar to the ettringite the syngenite may cause a certain consolidation of the cement. The strengthening or hardening of the cement in the outer zones of the bag, however, should be attributed to beginning hydration, especially the formation of ettringite, and to carbonation, as the dotted line in fig. 1 (bottom) shows. Furthermore long term stored cements may be compacted by the pressure due to the high piles of bags.

The thermogravimetric analyses of the stored cements showed essential differences for all samples in the behaviour of dehydration up to 180 °C. The weight loss in this temperature

range includes the loss of adsorbed water, the partial dehydration of C-S-H phases (and slightly of a C-A-H phases too) and of ettringite, also the complete dehydration of gypsum. Provided that each cement has a nearly constant content of gypsum due to the manufacturing process, the loss of weight at 180 °C may be seen as a measure for the degree of hydration. For simplification it is called "water content" in the following.

The "water content" of nearly 100 samples taken from two different cement types here called A and B were determined by drying at 180 °C. In fig. 2 the "water content" values of the cements stored for various terms are compared with the compressive strength after 2 and 28 days respectively. There is a good reciprocal correlation between the values, especially with regard to the 2-d-strength. A minimum value for the "water content" of about 0,4 % by weight may be recognized, referring to the original gypsum content of the cements. If reference values are available it seems possible to infer the strength development by this simple method.

Fig. 2 - Correlation of "water content" to compressive strength after 2 and 28 days respectively, plotted for the cements "A" and "B".

It was mentioned already that the outer zones of the cement bags were partially more hydrated than the inner zones. By determining the "water content" the hydration degree of cements was examined depending on the location in the bags. Fig. 3 shows the distribution of the "water content" values in longitudinal sections of three bags piles one upon another, stored for 15 years. The maximum hydration degrees were found near the ends of the bags, above all at the filling valves on the right side of the figure. Besides the "water content" increases if the air could not circulate because of the adjacent piles of bags. In this case the probability is greater that moisture from the air would con-

densate on the paper bags and water diffusion would take place.

Fig. 3 - Distribution of the 180 °C-evaporable "water content" of cement in bags stored for 15 years (longitudinal section).

The cement bags shown in longitudinal section were stored in a shed that was not heated and badly ventilated. Thus the cement was exposed to a relatively humid climate at least for some time, and to alternating temperatures. Other bags stored in a rather dry, heated shed for 15 years too were examined in the same manner. High "water contents" were found in this case only in narrow zones at the edges of the bags. Consequently the storage conditions are very important for quality decrease of long term stored cements.

A simple test ascertained the amount of time that moisture needs to penetrate the 5-ply bitumen coated paper bags and to impair the quality of cement. Samples of fresh portland cement PZ 35 F was wrapped in original paper bag material and then exposed to an ambient humidity of 95 % at 22 °C. The relative humidity inside the test bags was measured continuously (fig. 4 top). It rose quickly, and it came up to 80 % r.h. within 10 days and to more than 90 % r.h. within 40 days. That means that the protective effect of this packing is small with regard to penetration of moisture.

At the same time the density of the cement samples decreased continuously from 3,06 g/cm³ to 3,01 g/cm³ within 10 weeks, as was also stated in other investigations (3, 4, 13). Furthermore samples were taken after 6, 20, 71 d respectively for tests on strength development (central part of fig. 4). In relation to the strength values of the original cement the 2-d-strength values decreased to 40 - 60 %. The 28-d-values were not reduced before a longer period of storage; after 10 weeks the reduction was about 20 %. Alterations of mineral phases of the same cement samples were examined thermogravimetrically.

Fig. 4 - Tests by artificial storage: development in time of relative humidity inside the bag, strength values, and mineral phases expressed as weight loss (determined by thermogravimetric method)

The weight loss found by these analyses correlates to the portions of the phases, thus only the weight loss values for certain phases are taken for fig. 4 bottom. Syngenite content increases while gypsum content decreases. The beginning of hydration is shown by formation of more and more ettringite and silicate hydrates dehydrating in the same temperature range. Aluminate hydrates increase slowly. The results found after a rather short

but unfavorable storage agree qualitatively with those of long term stored cements.

Alterations of mineral phases by long term storage of cements affect the process of hydration, especially during the initial period. In general the hydration process of stored cements will be retarded. In fig. 5 the contents (as weight loss by thermogravimetric analyses) of gypsum and ettringite with C-S-H respectively in various cement pastes are shown in relation to the time of hydration. The fresh portland cement is continuously forming C-S-H phases and ettringite combining gypsum at the same time. Depending on the various types of cements, the extent and the velocity of the formation of new hydrates in long term stored cements are lower. The content of gypsum even increases slightly in the beginning, probably by redissolution of some ettringite and syngenite in the mixing water. This may cause "false set" in some cases. The slow hydration proceeding within the first hours after mixing with water presumably is responsible for the lower strength values of stored cements, particularly for the early strength development.

Fig. 5 - Thermogravimetrically determined weight loss  $\Delta G$  referred to gypsum (top) and to C-S-H and ettringite (bottom) dependent on time of hydration.

Strength values of cements stored for 7 - 15 are spread over a large range. Classified by the age in years, the frequency of 2-d- and 28-d-compressive strength values is plotted in fig. 6. It is conspicuous that a greater number of strength values for the 11 - 15 years old cements fall below the minimum values required for comparable fresh cements. On the other hand many samples of this age reach a rather high compressive strength. Cements stored up to 10 years altogether show a higher strength than the older ones. One of the reasons may be the packing. For the younger cements one ply of the 5-ply paper bags was coated with polyethylene instead of bitumen. The moisture permeability of this material seems to be lower than that of the bitumen coated paper.

Fig. 6 - Frequency of compressive strength after 2 d and 28 d. Number of values separately plotted for the different ages of the stored cements.

The test on strength were made with unsieved samples. Further 300 partially lumpy samples recently taken from the same stores were passed through the 1-mm-sieve. In this case all values of strength exceeded the minima of 10 N/mm<sup>2</sup> after 2 d and 35 N/mm<sup>2</sup> after 28 d. Besides it is possible to obtain better strength development by adding chemical reagents or regrinding the stored cements (9).

During the storage period strength development of the cements could only be observed insufficiently because sampling by statistical point of view was impossible. The number of bags in each store amounted to 20'000 - 100.000, and the storage conditions were various and mostly undefined. Another cause

is the change of the method of test according to the German standard in 1970. Nevertheless, based on all the present values one may estimate the annual reduction of the 28-d-compressive strength to 1 N/mm<sup>2</sup> or 2 % on an average with regard to long term storage in 5-ply paper bags.

#### CONCLUSIONS

If cements packed in coated paper bags are stored for a long term their quality will be less seriously affected than presumed on the basis of short time investigations. Even 15 years old cements are useable. In this case, however, it is recommended to screen out the lumps. Long term storage affects hydration on cement particle surfaces and formation of syngenite and ettringite. The loss of reactivity by partial hydration and particularly the changes in sulphate compounds affects a more or less retarded hydration within the first hours after mixing with water. This results in reduction of strength, especially of early strength. One of the most important factors for preservation of quality is the storage condition. Air humidity should be low, and the stores should be provided with good ventilation.

# Mécanisme de la stabilisation dans la transformation polymorphique beta-gamma $C_2S$

## *Polymorphic Phase change of beta-gamma $Ca_2SiO_4$*

A. DERDACKA - GRZYMEK

J. GRZYMEK, Pologne.

**RÉSUMÉ :** Dans cette communication, on présente les résultats des recherches faites sur l'influence de microquantités de cations étrangers et de grandes quantités d'aluminate de calcium à l'état vitreux sur le mécanisme de stabilisation du  $\beta$  orthosilicate de calcium. En se basant sur des résultats expérimentaux, on a proposé une formule pour estimer l'abaissement de la température de l'autodésintégration de l'orthosilicate de calcium.

La discussion des résultats a démontré que l'activité des cations dans le mécanisme de stabilisation dépend de l'intensité du champ ( $e/\pi r^2$ ), de l'électronégativité de la configuration des électrons de valence et du nombre de charges positives des cations. Les cations qui stabilisent la modification  $\beta C_2S$  ont été subdivisés en deux groupes. Au premier appartiennent les cations qui stabilisent la modification  $\beta C_2S$  au-dessous de 0,5 % mol. par gmole  $C_2S$ . Au second appartiennent les cations dont l'effet stabilisant est observé au-dessous de 1 % mol/gmole  $C_2S$ . Les auteurs en concluent que la stabilisation résulte des surtensions dans l'intérieur des cristaux sous l'influence du champ électrostatique à cause du phénomène de la polarisation, et même de l'influence de la pression extérieure exercée sur les cristaux du  $\beta C_2S$ .

Le plus grand effet thermique sur les transformations polymorphiques du  $C_2S$  a été observé dans le cas de la transformation  $\alpha = \alpha'_{II}$  (3,28 kcal/mole). La transformation la plus rapide est celle de  $\beta \rightarrow \gamma$  (0,22 kcal/gmole). L'autodésintégration est accompagnée d'un effet thermique de 1,2 kcal/gmole. Si pendant la transformation polymorphique on élève, puis on abaisse la température, le  $C_2S$  peut perdre 25 % de son énergie interne. Les auteurs ont constaté que l'énergie interne du réseau de  $C_2S$  atteint 4700 kcal/gmole.

**SUMMARY:** In this paper study of the influence of microamounts of foreign cations and of larger amounts of the glassy calcium-aluminate phase on the stabilization of calcium orthosilicate was performed. Basing on experimental results and theoretical considerations an empirical formula has been proposed for the quantitative evaluation of the decrease of the temperature of self-disintegration of calcium orthosilicate.

The discussion on the results shows that the activity of cations in the stabilization is primarily dependent from the force of the cation field ( $e/\pi r^2$ ), electronegativity and valences. The stabilizing cations have been divided into two groups. To the first belong cations which stabilize totally the  $\beta - Ca_2SiO_4$  in amounts up to 0.5% mol/gmol. To the second belong cations in case of which a stabilizing effect is observed only after addition of amounts above 1% mol/gmol  $Ca_2SiO_4$ .

Authors suggest that the directly reason of stabilizing effect are rising the strains under the effect of increasing electrostatic field inside the crystals as well as an external influence of pressure on crystals of  $\beta$  calcium orthosilicate phase. The network energy of calcium orthosilicate amounts about 4700 kcal/gmol.

In the paper, that the most heat effect among of the polymorphic processes of investigated  $Ca_2SiO_4$ , mark out, the two-way process of polymorphic transformation of  $\alpha \rightleftharpoons \alpha'_{II}$  /3.28 kcal/gmol/ itself was determine. The shortest one is polymorphic transformation of  $\beta \rightarrow \gamma$  /0.22 kcal/gmol/. The emission of 1.2 kcal/gmol heat during self-disintegration phenomena is the consequence of polymorphic transformation. When reheating and recooling, during the polymorphic transformation, calcium orthosilicate loses about 25% heat energy emission.

Le grand intérêt auprès de polymorphisme de  $\text{Ca}_2\text{SiO}_4$ , dont la preuve sont de nombreux travaux de recherche, résulte certainement d'une grande importance de ce problème pour la pratique industrielle. Les travaux de Bredig /1/ sur fluoroberylene de sodium modèle sont des premiers dans ce domaine.

L'existence des différentes formes polymorphes  $\alpha$ - $\alpha_H$ - $\alpha_L$ - $\beta$ - $\gamma$  qui cristallisent sous structures; romboédrique, monoclinique et hexagonale dans le ciment portland, le laitier de haut fourneau et aussi dans les matériaux réfractaires de dolomite stabilisés est d'une importance exceptionnelle de point de vue des propriétés de ces matériaux. Ce problème est surtout relié au phénomène connu depuis plusieurs années sous le nom de "décomposition calcique" qui se produit à la transition de la phase  $\beta$  en forme polymorphe basse température  $\gamma$   $\text{Ca}_2\text{SiO}_4$ . Ce phénomène est accompagné d'une abaissement de poids spécifique et d'une transition de la symétrie monoclinique de cristal  $\beta$  à la symétrie romboédrique de la phase  $\gamma$  avec une réduction simultanée de nombre de coordination d'atomes de calcium.

Le phénomène d'autopulvérisation de l'orthosilicate de calcium en grains d'une taille de quelques ou plusieurs microns comme le résultat de la transition polymorphique  $\beta$  en  $\gamma$  est d'une importance élémentaire si ce phénomène soit utilisé pour la méthode complexe de production d'alumine et des ciments portland à haute teneur d'alites à partir de matériaux à la base des aluminosilicates. Le principe de ce procédé élaboré en Pologne /2, 3, 4, 5/ se traduit par la clinkerisation de calcaire broyée en présence d'aluminosilicates afin d'obtenir un aggloméré aluminifère contenant l'orthosilicate de calcium et des aluminates de calcium. On fait l'extraction de l'oxyde d'aluminium de l'aggloméré refroidi et décomposé en poudre avec des solutions diluées de carbonate de sodium. Le résidu de l'extraction, obtenu au cours de la production de l'alumina, contenant principalement  $\text{Ca}_2\text{SiO}_4$  sous la forme  $\gamma$  est le matériau première pour la cuisson du clinker portland après l'addition de carbonate de calcium broyé. A partir de solution de l'aluminate de sodium on obtient l'hydroxide d'aluminium, qui après la carbonisation devient l'oxyde d'aluminium de haute qualité pour l'industrie métallurgique.

On a profité de ce phénomène d'autopulvérisation de  $\text{Ca}_2\text{SiO}_4$  pour le développement des méthodes de production des sables de moulage et des ciments colorés de revêtement /brevets polonais no. 62637 et 62386/. Ce sont des exemples uniques dans le monde entier de "broyage cristallochimique des matériaux" en utilisant dans ce but l'énergie déclenchée par la transformation polymorphe de phase.

Il est évident, que non seulement pour des besoins scientifiques mais également pratiques, la connaissance du mécanisme de la stabilisation de la phase  $\beta$  et l'examination de la cinétique de transformation de la phase  $\beta$  en  $\gamma$   $\text{Ca}_2\text{SiO}_4$  sont d'une importance considérable.

En années cinquantiennes nous avons commencé en cimenterie Groszowice des recherches de retardation ou même d'arrêt de la formation des germes stables de la forme polymorphe  $\gamma$  dans la phase  $\beta$ . Les efforts étaient basés sur l'introduction des quantités limitées des oxydes étrangers dans l'orthosilicate de calcium synthétisé pendant la clinkerisation à la température  $1450^\circ\text{C}$ . Ces additifs peuvent avoir même une influence sur certains changements structuraux de la phase  $\beta$  dont la preuve sont postérieures travaux de Goerlich /6/ portants sur des propriétés thermodynamiques de cette structure ou des autres changements existants dans cette phase de l'orthosilicate de calcium. En utilisant le microscope à chauffage équipé d'échelle de température, nous avons réussi de saisir à l'aide de photographies continues des moments caractéristiques du processus d'autopulvérisation superficielle se produisant sous l'influence de transformation  $\beta$  en  $\gamma$   $\text{Ca}_2\text{SiO}_4$ .

Le caractère du type de nucléation de changement de phase polymorphe  $\beta$  en  $\gamma$   $\text{Ca}_2\text{SiO}_4$  relié à l'autopulvérisation de la phase  $\gamma$  a été examiné par Bethke et Grzymek /7/, Bielański et Nedoma /8/. L'affirmation du caractère du type de nucléation des transformations de phase mentionnés et la détermination de la vitesse de ces changements avait une importance considérable pour l'explication du mécanisme de ces transformations de phase.

Dans nos expériences nous avons observé que des oxydes introduits dans l'orthosilicate de calcium synthétisé - en tenant compte de leur influence sur la marche du processus d'autopulvérisation - peuvent être classés en deux groupes. Le premier comprend les oxydes ayant des cations avec le potentiel ionique plus élevé et plus électronégatifs. Ces oxydes provoquent la réduction de la température d'autopulvérisation de l'orthosilicate de calcium de  $525^\circ\text{C}$  à la température inférieure de  $400^\circ\text{C}$ . L'autre groupe comprends les oxydes contenant des cations avec des potentiels ioniques sensiblement plus faibles et moins électronégatifs. Les cations appartenant à ce groupe ont une moindre influence sur l'abaissement de la température d'autopulvérisation de l'orthosilicate de calcium, qui est comprise dans ce cas entre  $525^\circ\text{C}$  et  $400^\circ\text{C}$ .

Nous avons cependant constaté la discontinuité de la fonction entre l'abaissement de la température de l'autopulvérisation et le potentiel ionique et l'électronégativité des cations introduits pour la synthèse de  $\text{Ca}_2\text{SiO}_4$ . Dans cette situation nous avons essayé de dériver la formule mathématique empirique, qui dans la manière plus précise permettrait de trouver une relation continue entre les propriétés des cations utilisés et l'abaissement de la température d'autopulvérisation de l'orthosilicate de calcium. Pour des calculs des éléments supplémentaires ont été introduits, en tenant compte de la structure des cations considérés. La formule prend également en considération le coefficient

d'activité reliée à l'action des charges positives sur les niveaux energetiques individuels. Avec une formule mathématique ainsi élaborée il est possible d'évaluer quantitativement l'influence des cations utilisés sur l'abaissement de la température  $\Delta m$  d'auto-pulvérisation de l'orthosilicate de calcium.

$$\Delta m = E[W_n \cdot \Phi_n \cdot (e_s + e_p + e_d)] + \frac{2}{\sqrt{W_{(n-1)} \cdot \Phi_{(n-1)} (e_s + e_p + e_d)}} \cdot \frac{e}{n-1} \cdot \frac{1}{\pi r^2}$$

$E$  = électronégativité du cation,

$W_n$  = nombre quantique principal de cation stabilisant correspondant à sa couche électronique,

$W_{(n-1)}$  = nombre quantique correspondant au niveau energetique interieur voisin de la couche électronique du cation considéré,

$\Phi$  = coefficient d'activité relative des charges élémentaires positives placées sur des niveaux energetiques respectifs,

$\Phi_n$  = coefficient d'activité relative des charges élémentaires positives localisées sur la couche électronique déterminée par le nombre quantique principal  $W_n$  /,

$\Phi_{(n-1)}$  = coefficient d'activité relative des charges élémentaires positives localisées au niveau energetique le plus proche à la couche électronique du cation  $W_{(n-1)}$  /.

Dans l'évaluation de l'activité des charges élémentaires positives qui dépend de la répartition aux niveaux energetiques respectifs, nous avons pris pour l'activité des charges positives dans la couche L une valeur de 0,8.

Cette activité relative correspond à celle de charges positives disposées sur la couche du cation  $B^{+2}$ , qui dans notre cas, possède le nombre quantique principal le plus bas = 2. Afin de déterminer des activités relatives des charges élémentaires positives localisées

aux niveaux energetiques consecutifs, nous avons pris un multiple de nombre 0,3. Or, conformément à l'hypothese acceptée, suivant des resultats experimentaux, l'activité relative des charges positives localisées aux niveaux energetiques respectifs des cations étudiés, doit correspondre pour la couche K etant la plus proche du noyau d'atome à une valeur;

pour la couche K	$K = \Phi_{(1)} = 0,5 \cdot 0,3 \times 0 = 0,5$
" " "	$L = \Phi_{(2)} = 0,5 \cdot 0,3 \times 1 = 0,8$
" " "	$M = \Phi_{(3)} = 0,8 \cdot 0,3 \times 2 = 1,4$
" " "	$N = \Phi_{(4)} = 1,4 \cdot 0,3 \times 3 = 2,3$
" " "	$O = \Phi_{(5)} = 2,3 \cdot 0,3 \times 4 = 3,5$
" " "	$P = \Phi_{(6)} = 3,5 \cdot 0,3 \times 5 = 5,0$

r - rayon de cation en Å,

e - valence de cation = somme de charges positives localisées dans les cages sur la couche electronique  $W(n)$  et de charges positives localisées au niveau energetique  $W(n-1)$  voisin à la couche electro-

$$e = (e_s + e_p + e_d) \cdot n + (e_s + e_p + e_d) \cdot n - 1$$

$t_d$  - température du debut d'autopulverisation de l'orthosilicate de calcium, déterminée experimentale, en °C,

$t_m$  - température d'autopulverisation de  $Ca_2SiO_4$ , calculée à l'aide de la formule mathématique dérivée en °C,

$\frac{e}{\pi r^2}$  - expression pour le potentiel de la surface ionique, introduits par les auteurs.

Tableau I resume les resultats experimentaux sur l'abaissement de la température d'autopulverisation de l'orthosilicate de calcium au - dessous de 525°C en présence de cations stabilisants introduits en quantité 0,3 % mole/gramme mole  $Ca_2SiO_4$  au aggloméré synthetisé à 1450°C. A partir des résultats présentés dans le tableau ci-dessus, le caractère stabilisant la forme  $\beta$   $Ca_2SiO_4$  possèdent les cations ayant à la même fois des valeurs élevées de potentiel de surface ionique, électronégativité et surtout les cations se caractérisant d'un nombre de charges positives plus élevé, localisés sur les couches électroniques avec le nombre quantique plus élevé. Outre cela, ces cations doivent en même temps se caractériser d'une stabilité thermique au cours de leur synthèse en présence de l'orthosilicate de calcium aux températures atteignant 1500°C.

Le cation  $As^{+5}$  est un exemple d'une activité stabilisante considerable. Ce cation possède en même temps une stabilité thermique importante, électronégativité exceptionnellement élevée = 2,2 et le potentiel de surface de section ionique élevé = 7,5 e/Å<sup>2</sup>. En même temps la couche électronique localisée dans ce cation et correspondante à un nombre quantique élevé = 4 est privée de 5 electrons, ce qui implique à ce cation le rôle d'un stabilisateur le plus fort parmi tous examinés. Malgré une stabilité thermique exceptionnelle et le nombre quantique élevé = 6 de cation  $Ba^{+2}$ , l'oxyde de baryum a prouvé des propriétés stabilisantes relativement faibles. L'abaissement de l'activité stabilisante de BaO est l'effet de sa électronégativité

basse  $E = 0,89$  et du potentiel de surface de section ionique exceptionnellement faible 0,354 e/Å<sup>2</sup>. En plus, le nombre des charges élémentaires positives limité, situées sur la couche électronique extérieure exclue l'activité stabilisante plus étendue. Les plus faibles ou pratiquement sans aucune influence sur l'abaissement de la température d'autopulverisation de l'orthosilicate de calcium, sont des cations  $Na^+$  et  $K^+$ . On peut expliquer cette faible activité de sodium et de potassium par leur électronégativité la plus faible  $E = 0,82$  et 0,93 respectivement. Ce caractère est en plus dû au potentiel de surface de section ionique faible de 0,179 à 0,338 e/Å<sup>2</sup> avec le minimum, soit une seule charge élémentaire positive située dans la couche électronique de ces cations. En outre, nous avons constaté, que tous les plus forts stabilisateurs pour le processus d'autopulverisation polymorphe de  $Ca_2SiO_4$ , qui sont selon nous les suivants, classés dans l'ordre d'activité diminuant:  $As^{+5}$ ,  $P^{+5}$ ,  $B^{+3}$ ,  $V^{+5}$ ,  $Cr^{+6}$ , perdent ces propriétés après que leur valence ionique est réduite.

Les cations  $As^{+3}$ ,  $P^{+3}$ ,  $V^{+3}$ ,  $B^{+1}$ ,  $Cr^{+3}$  obtenues par la réduction chimique avec le charbon introduit au cours de la cuisson de l'aggloméré de l'orthosilicate de calcium en limitant en l'air, perdent leur propriétés de l'abaissement de la température d'autopulverisation.

On peut expliquer ce phénomène à partir de la formule mathématique dérivée. Or, à cause de réduction chimique des oxydes ayant le degré d'oxydation plus élevé, le nombre de charges élémentaires positives situées sur les couches électroniques de ces cations est réduit. La réduction des oxydes de ces cations augmente en même temps leur taille, ce qui possède une influence sur l'abaissement de leur potentiel de surface de section ionique. La réduction du potentiel de surface de section ionique, conformément à la formule dérivée, provoque l'augmentation de la température d'autopulverisation de l'orthosilicate de calcium plus sensiblement en présence des oxydes ayant le degré d'oxydation plus faible qu'en cas de présence des oxydes des mêmes cations mais avec le degré d'oxydation plus élevé. On peut conclure alors, que dans les procédés industriels il faut maintenir pendant la clinkerisation l'atmosphère reductrice afin d'obtenir une l'autopulverisation complète des agglomérés aluminifères contenant l'orthosilicate de calcium.

Afin d'obtenir une évaluation quantitative, qui pourrai nous indiquer plus précisément le mécanisme de changements de phase dans l'orthosilicate de calcium, on a utilisé l'analyse derivatographique des phénomènes qui accompagnent les changements de phase polymorphes à l'aide de l'analyseur "Setaram". Les effets calorifiques obtenus - au cours de la synthèse et de refroidissement de l'orthosilicate de calcium échantillons à 1 gramme mole de l'échantillon examiné de  $Ca_2SiO_4$  ont été présentés dans le tableau II.

Réchauffement au total					33,0	-42180	
Refroidissement au total					50,5	+ 5170	
Grand total					83,5	- 37010	

$T_1$  - température /°C/ d'initiation de l'effet calorifique de processus qui se produit dans l'échantillon étudié dans le temps  $t_1$

$T_2$  - température /°C/ finale de l'effet calorifique de processus qui se produit dans l'échantillon étudié dans le temps  $t_2$

$T_m$  - température /°C/ correspondante à l'intensité maximum de processus qui se produit pendant réchauffement et refroidissement de l'échantillon

$t = t_2 - t_1$  duré /exprimé en minutes/ de processus qui se produit dans l'échantillon étudié entre température  $T_1$  et  $T_2$

$\Delta C$  - effets calorifiques /exprimés en calories/gramme mole/ de minéraux individuels présents dans des proportions déterminées dans l'échantillon étudié, se produisant au cours de réchauffement ou refroidissement de l'échantillon

$\Delta Q$  - effet calorifique unitaire /exprimé en calories/ résultant au cours de réchauffement et refroidissement de l'échantillon, converti pour 1 gramme mole des des composants minéraux individuels compris dans l'échantillon.

L'échantillon a été soumis à la température de 1500°C pendant 60 minutes. Vitesse d'échauffement ou de refroidissement 10°C/min.

Les observations et conclusions qui se posent en tenant compte des données comparatives du tableau II annexé des différences observées qu'on a obtenues entre effets calorifiques et intervalles de température dans lesquels se produisent ces effets pendant réchauffement et refroidissement de l'échantillon étudié. L'effet calorifique le plus important se produit pendant le processus même de la synthèse de l'orthosilicate de calcium et il atteint 12230 cal/gramme mole du  $\text{Ca}_2\text{SiO}_4$ . Ce processus a lieu pendant réchauffement de l'échantillon dans l'intervalle étroit de 1430 à 1478°C. Cette synthèse parcourt avec une intensité importante et se caractérise

d'une vitesse relativement élevée du dégagement du chaleur égale à 2445 cal/gramme mole/minute. Le plus lents parmi des processus polymorphes ayant en même temps les effets calorifiques les plus faibles par l'unité de temps sont des changements de phase bidirectionnels  $\alpha_H \rightleftharpoons \alpha_L$ . Le processus de changement de phase bidirectionnel  $\alpha \rightleftharpoons \alpha_H$  est un processus rapide, ayant l'effet calorifique le plus élevé des processus polymorphes. Le changement polymorphe unidirectionnel  $\beta \rightarrow \gamma$ , isolé par nous, est un processus de changement de phase d'une durée la plus courte. Les transformations polymorphes bidirectionnelles dans l'orthosilicate de calcium pur, sans additions stabilisantes, se produisent rapidement /dans un intervalle de 1,5 à 6 minutes/. Cependant cette observation ne s'applique pas au changement de phase de longue durée  $\alpha_L \rightleftharpoons \alpha_H$  /qui dure 24 minutes/, ce qui mantrait, qu'il faudrait reviser les données de la littérature portant sur des changements de structure qui accompagnent cette transformation polymorphe. Les transformations de phase polymorphes endothermiques unidirectionnelles sont d'une durée longue et se caractérisent d'une marche plus modérée se traduisant par un degré d'intensité plus faible.

A partir de nos données expérimentales, nous avons calculé, en utilisant la formule de Kapustyński et la valeur de  $e_k$  de A.E.Fersman, l'énergie de réseau des cristaux de l'orthosilicate de calcium

$$E = E_1 + E_2 + E_3$$

$E_1$  - énergie de réseau du  $\text{SiO}_2$

$E_2$  - énergie de réseau du  $\text{CaO}$

$E_3 = \Delta Q$  = calories dégagées au cours de la synthèse  $2\text{CaO} + \text{SiO}_2 = 12,23$  kcal/gramme mole du  $\text{Ca}_2\text{SiO}_4$  - évaluées par nous.

La valeur moyenne de l'énergie de réseau calculée selon le deux méthodes pour un gramme mole du  $\text{Ca}_2\text{SiO}_4$  est égale à 4696,53 kcal.

En appliquant pour A dans la formule de Born Mayer une valeur de 4,439 pour  $\beta$  quartz et en assumant  $B = 9$  pour tous les combinaisons

binaires - l'énergie de réseau pour  $\beta$  quartz calculée selon la formule de Born Mayer est égale à  $E_1 = 3042 \text{ kcal/mole SiO}_2$ . D'où la valeur de l'énergie de réseau;

$$E = 12,23 + 3042 + 2 \times 825,15 = 4704,53 \text{ kcal/gramme mole du Ca}_2\text{SiO}_4.$$

En considérant ces calculs on peut assumer que l'énergie de réseau moyenne des cristaux de l'orthosilicate de calcium doit être environ 4700 kcal/gramme mole du  $\text{Ca}_2\text{SiO}_4$ . A partir de ces données on peut conclure, que les transformations  $\Delta Q$  se produisant dans l'ensemble de l'énergie de réseau  $E$  et résultant du phénomène de changement de phase polymorphe  $\beta \rightarrow \gamma \text{ Ca}_2\text{SiO}_4$  qui provoque une désintégration totale des cristaux de l'orthosilicate de calcium, sont très faibles par rapport à l'énergie de réseau totale des cristaux de l'orthosilicate de calcium, car ils ne dépassent pas une valeur de 1,5 kcal/gramme mole. Néanmoins ces changements ont une influence importante sur auto-désintégration de ces cristaux. Il faut expliquer cette efficacité considérable des changements énergétiques relativement faibles par le degré exceptionnellenent élevé de l'intensité de la marche des changements de phase polymorphes se produisant dans un système fortement sursaturé résultant de surfusion considérable de la phase  $\beta$  par rapport à la phase  $\gamma \text{ Ca}_2\text{SiO}_4$ . L'autodésintégration totale du  $\beta$  orthosilicate de calcium conduisant aux grains d'une taille moyenne de  $20 \mu\text{m}$  est provoquée par une réduction de l'énergie de réseau totale de 0,032 % seulement. D'où vient que la quantité de l'énergie de réseau nécessaire pour désintégrer une tonne d'un mineral composé de  $\beta \text{ Ca}_2\text{SiO}_4$  sous la forme des grains d'une taille de 30 mm environ au cours de son transformation en poussière /taille moyenne de  $20 \mu\text{m}$ / est 8720 kcal.

Si l'on compare cette énergie à l'énergie consommée par des installations mécaniques /broyeurs à boulets rotatifs/ où il est nécessaire d'assurer 200 kilowattheures par tonne, ce qui est équivalent à 172 000 kcal, on voit bien qu'il est possible de faire des économies de l'énergie d'un facteur de 20 environ grâce à l'utilisation du phénomène de polymorphisme dans les opérations de broyage.

**RESUME :** L'objet de l'étude a été l'analyse des principaux aspects théoriques de l'intensification de la cuisson du clinker dans les fours rotatifs. Le recours aux flux dispersifs au stade préparatoire de décarbonatation du matériau modifie le mécanisme des réactions en phase solide. Il a été établi par l'expérience que pour des échanges de chaleur et de masse poussés la vitesse de dissociation des carbonates est de beaucoup supérieure à celle de la fixation de la chaux par les oxydes acides. L'accroissement de la concentration du  $\text{CaO}_{\text{lib}}$  actif au cours du traitement thermique ultérieur en couche contribue à l'intensification du processus d'interaction des oxydes. Au stade final, à une température de 1623°K, on peut obtenir un clinker de structure perturbée avec une certaine quantité de  $\text{CaO}_{\text{lib}}$  et de grande activité hydraulique.

**SUMMARY :** Theoretical fundamentals of intensification of clinker burning in rotary furnaces are considered. Use of disperse flows at the stage of preparation of material for decarbonization changes the mechanism of solid-phase reactions. It has been determined experimentally that at high heat and mass exchange the rate of dissociation of carbonates considerably exceeds the rate of binding of lime with acid oxides. Increase of concentration of active  $\text{CaO}_{\text{free}}$  at further thermal treatment in the bed intensifies the reaction of oxides. At the final stage at a temperature of 1623°K, clinker with distorted structure may be obtained, this clinker includes a certain amount of  $\text{CaO}_{\text{free}}$  and features high hydraulic activity.

Une organisation rationnelle des processus physico-chimiques de clinkérisation dans le four est la condition essentielle de l'intensification de la cuisson et de l'abaissement des dépenses spécifiques d'énergie en production du clinker. Dans les fours modernes on utilise au stade préliminaire la préparation de la matière le procédé de flux dispersifs assurant une vitesse maximale à l'apport de chaleur et l'utilisation de cette dernière avec un haut rendement. Un rôle particulièrement important revient aux procédés technologiques et physico-chimiques d'action aux stades suivants de clinkérisation. L'addition au mélange brut de composants capables d'abaisser la chaleur théorique de clinkérisation ainsi que le mode d'amenée de la chaleur exercent une influence sur l'ordre et la séquence des réactions en phases solide et liquide, ce qui au cas d'une cuisson dans des fours rotatifs, se répercute de façon imminente sur la résistance limite du ciment.

Le nombre de réactions dont il faut tenir compte dans le système chimique - mélange brut - le nombre de phases engagées et l'orientation d'interaction entre les phases, peuvent être déterminés par la règle des phases. Toutefois, en cas de la cuisson rapide le rôle décisif appartient aux particularités de la cinétique chimique.

Il est connu que la vitesse de transformation des matières dans les systèmes se trouvant en phase solide est fonction de la surface de contact des phases, de la concentration des agents chimiques, c.-à-d.:

$$\frac{dq}{dt} = K C_1^m C_2^n \cdot F_1 \cdot F_2, \quad (1)$$

où  $m, n$  sont les ordres des réactions;  $F_1, F_2$  - la surface des particules;  $C_1, C_2$  - la concentration des agents chimiques.

L'ordre apparent des réactions peut varier en fonction de l'activité catalytique de l'un des constituants, tandis que les substances gazeuses intermédiaires permettent d'améliorer l'échange de matière entre les phases.

La haute valeur de la constante de vitesse de décarbonatation aboutit à ce que la vitesse de transformation du constituant calcique se trouve limitée par la vitesse de l'apport de chaleur.

Les calculs ont établi que le temps de réchauffement des particules de matière première servant à la production du ciment et ayant les propriétés d'un corps fin, pour un diamètre équivalent à 0,00025; 0,0005; 0,0001 m et une température dans le four de 1273, 1373, 1473°K, se mesure en centièmes de seconde.

La vitesse de synthèse des composés du calcium avec les oxydes acides est de plusieurs degrés inférieure à celle de la dissociation du  $\text{CaCO}_3$ , ce qui au stade préparatoire de clinkérisation dans les courants dispersifs

des fours industriels implique une haute teneur en  $\text{CaO}_{\text{lib}}$  dans le matériau. De plus, dans ce cas, le constituant argileux s'avère convenablement préparé à l'interaction subséquente avec la chaux.

Les produits finement dispersés ainsi obtenus possèdent de grandes réserves d'énergie interne et, vraisemblablement, sont susceptibles d'influencer la marche des réactions en phase solide au cas d'un réchauffement dans la couche roulante du four rotatif, où la surface de contact des phases entrant en réaction est grande.

Après l'apparition du bain fondu eutectique la clinkérisation se poursuit suivant l'équation des réactions hétérogènes

$$W = \frac{D \cdot S}{V} \cdot \frac{dC}{dx} \quad (2)$$

où  $S$  est la surface;  $V$  - le volume du liquide;  $C$  - la concentration,  $D$  - le coefficient de diffusion,  $x$  - la distance.

On peut admettre que la concentration poussée de chaux formée aux dépens d'une rapide dissociation de  $\text{CaCO}_3$  et une intensification de son interaction avec les oxydes acides peut également engendrer un écartement sensible du processus équilibré de formation des minéraux à des températures plus basses.

La vitesse de croissance des cristaux (période de recristallisation accumulative) est une fonction exponentielle de la température, aussi faut-il s'attendre à une élévation de l'activité hydraulique des phases générant le clinker-portland, y compris celle de la chaux libre.

A des fins de vérification de l'hypothèse formulée, on a utilisé, dans des conditions de laboratoire, un mélange brut à deux constituants avec un facteur de saturation 0,85;  $n = 3,3$ ;  $p = 1,8$ . Le mélange cru était broyé jusqu'à la traversée complète du tamis à 5476 mailles/cm<sup>2</sup>. Ensuite, on préparait des pastilles de 10 mm de hauteur et de 8 mm de diamètre qui étaient chauffées jusqu'à 1473°K. Les éprouvettes obtenues étaient de nouveau broyées puis passées à travers un tamis de 5476 mailles/cm<sup>2</sup> et pressées en pastilles. Les pastilles étaient placées dans un four de platine chauffé jusqu'à 1473°K et y étaient réchauffées jusqu'à 1623°K au rythme de 12°/mn. Les constituants du mélange cru étaient également soumis à la cuisson séparément jusqu'à la température de 1473°K, puis broyés, passés au tamis de 5476 mailles/cm<sup>2</sup> et servaient à la confection de pastilles de composition chimique identique au premier mélange cru. Ces pastilles étaient, elles aussi, cuites jusqu'à la température de 1623°K. Les résultats des déterminations en éprouvettes du  $\text{CaO}_{\text{lib}}$  avec l'alcoole et glycérat sont donnés au tableau I.

Il découle du tableau que la vitesse absolue de l'assimilation de la chaux est supérieure dans les éprouvettes se caractérisant

par leur teneur en chaux plus élevée dans les échantillons de départ. L'accélération de l'assimilation de la chaux est due à l'augmentation de la différence entre sa concentration dans les phases en interaction. La teneur absolue en  $\text{CaO}_{\text{lib}}$  est plus grande dans les éprouvettes dont les constituants étaient cuits séparément. Toutefois, à la température de cuisson de  $1673^\circ\text{K}$  la chaux est totalement assimilée indépendamment de la teneur en  $\text{CaO}_{\text{lib}}$  à des stades intermédiaires.

Les analyses aux rayons X, comme les études pétrographiques d'éprouvettes cuites, ont montré que l'alite se forme à des températures plus basses dans des matériaux à teneur élevée en chaux libre.

Afin d'élucider les raisons possibles de l'apparition précoce de l'alite dans les éprouvettes, on a procédé à la comparaison d'échantillons cuits à des températures s'élevant jusqu'à  $1573^\circ\text{K}$ . Il s'est avéré que la bélite, principal minéral formé à ce stade de cuisson, apparaît dans le mélange homogène sous une seule forme et dans le mélange comprenant des constituants cuits séparément, sous deux formes (Fig.1).

La variante commune pour les deux types d'éprouvettes est la bélite à "faible" relief. La bélite à "fort" relief n'apparaît

Fig.1 La bélite dans des éprouvettes du mélange cru homogène (a) et du mélange cru formé à partir de constituants cuits séparément (b) I - bélite à "fort" relief. II - bélite à "faible" relief (500 x).

que dans les éprouvettes obtenues par cuisson séparée des constituants. Vraisemblablement, à en juger par la texture des éprouvettes cuites à  $1623^\circ\text{K}$  (Fig.2) la bélite à relief fort constitue une source d'alite.

Il est typique que dans les éprouvettes en mélange homogène la bélite à fort relief n'apparaît qu'une fois atteinte la température de  $1623^\circ\text{K}$ .

Des recherches pilotes ont été réalisées dont le schéma comprend un four rotatif de 1 m de diamètre et long de 15 m, une installation de décarbonatation à cyclone de 1,25 m de diamètre et d'une capacité de  $1,1 \text{ m}^3$ , un précipitateur de 1,45 m de diamètre, deux étages d'échangeurs de chaleur à cyclones, un dispositif de dépoussiérage et un refroidisseur à tambours. L'installation de décarbonatation est munie de quatre brûleurs à gaz. La matière destinée à la décarbonatation est transportée par le courant d'air utilisé

Fig.2. Alite (1) des éprouvettes en mélange formé de constituants cuits, séparément à 1623°K (grossissement 500x).

pour la combustion.

La matière, après avoir traversé le système d'échangeurs de chaleur, est dirigée vers l'installation de décarbonatation, d'où la partie précipitée du mélange cru passe par le conduit à gaz du four rotatif pour rentrer au précipitateur, tandis que la partie restante est, elle aussi, emportée par les fumées vers le précipitateur; ensuite, toute la matière, après avoir subi un traitement thermique préalable, est introduite dans le four rotatif. L'installation d'essai ne prévoit pas de cycle complet d'utilisation de la chaleur. Les études étaient menées sur des mélanges de matières premières dont le facteur de saturation oscillait entre 1,0 et 1,13 à des températures de décarbonatation de 1123 à 1323°K; la consommation en mélange cru étant de 960-1788 kg/h.

L'accroissement du facteur de saturation est dû à un entraînement sélectif du constituant calcique. Le module silicique variait de 3,2 à 3,3 et celui d'alumine, de 1,55 à 1,8. Le degré de décarbonatation atteint sur cette installation après cuisson se montait à 80%.

Le processus de clinkérisation a été étudié sur l'installation d'essai en recourant aux méthodes d'analyse chimique, aux rayons X et aux déterminations pétrographiques.

Les valeurs moyennes de déterminations chimiques sont rapportées sur le graphique de la figure 3. Les données fournies montrent que la clinkérisation sur l'installation utilisée diffère du processus se déroulant dans le four rotatif courant par une décarbonatation accélérée.

Le  $\text{CaO}_{\text{lib}}$  apparaît aussitôt que commence la décarbonatation puis, à mesure que le processus se poursuit, la quantité de  $\text{CaO}_{\text{lib}}$  augmente proportionnellement au degré de décarbonatation, tant que ce dernier monte

Fig.3. La marche de la clinkérisation.

jusqu'à 80%. Ensuite, on observe une brusque chute de la quantité de  $\text{CaO}_{\text{lib}}$  dans le matériau cuit. Le point d'inflexion de la courbe de variation de  $\text{CaO}_{\text{lib}}$  correspond au déplacement du mélange cru vers le four rotatif court, marquant ainsi la fin du traitement thermique du matériau en suspension et le début de cuisson en couche. L'aspect des courbes de la figure 3 implique qu'au cours de la décarbonatation en suspension les processus en phase solide sont quelque peu ralentis par rapport à ceux observés lors de la cuisson en couche.

La diminution sensible des résidus indissolubles est constatée simultanément au début de la baisse de la teneur en  $\text{CaO}_{\text{lib}}$ .

Les données d'analyse aux rayons X et des déterminations pétrographiques sont en accord complet avec les résultats d'analyse chimique.

Donc, les études à l'échelle industrielle ont confirmé qu'à l'état de suspension la décarbonatation s'effectue de façon intense: quant aux réactions en phase solide entre  $\text{CaO}$  et les constituants argileux elles n'ont pas le temps de se produire.

La concentration, de beaucoup plus grande qu'au cas d'une cuisson ordinaire, de  $\text{CaO}_{\text{lib}}$  et des produits de transformation des constituants argileux ayant subi un traitement thermique préalable est le facteur qui augmente la vitesse de marche des processus en phase solide dans le tronçon court du four rotatif.

Au cours de l'élévation subséquente de la température jusqu'à 1573°K, la concentration

des masses en réaction étant grande et les transformations structurales se poursuivant, on observe d'intenses interactions entre les constituants, ce que confirment les données de déterminations physico-chimiques.

Il est intéressant que les formations nouvelles, comme le confirment les diagrammes radiographiques, contiennent à côté de la bélite d'importantes quantités d'alite avant même l'apparition de la phase liquide.

Les clinkers ainsi obtenus se caractérisent par une activité hydraulique élevée (500-600 kgf/cm<sup>2</sup>) quoiqu'ils contiennent une petite quantité de CaO<sub>lib</sub> (tableau II).

Comme il s'ensuit du tableau II, malgré une certaine teneur en CaO<sub>lib</sub> à la température de 1623°K le clinker obtenu possède une grande activité hydraulique dont la raison, d'après les diverses méthodes d'étude, tient à l'irrégularité de la structure perturbée des minéraux du clinker.

Il faut noter qu'avant on obtenait également des ciments d'une résistance limite élevée à base de clinkers à haute teneur en CaO<sub>lib</sub> en abaissant la température de cuisson dans la zone d'agglomération. Mais ces clinkers exigeaient une mouture beaucoup plus fine.

### CONCLUSION

Les études entreprises montrent que l'intensification de la décarbonatation est le résultat d'accélération, dans les courants dispersifs, des échanges de chaleur et de masse, engendrant une haute teneur en chaux libre dans la matière cuite.

En continuant d'élever la température de la masse fluide dans le four rotatif, on arrive à accélérer la clinkérisation à tous les stades suivants du processus grâce à la grande concentration de CaO<sub>lib</sub> et aux transformations des matériaux argileux.

Au stade final, à la température de 1623°K, on peut obtenir un clinker de structure désordonnée contenant une certaine quantité de CaO<sub>lib</sub> et dont l'activité hydraulique est très grande.

# Bases physico-chimiques de la formation des granules du clinker

## *Physical and chemical grounds for granulation of clinker*

B.S. ALBATS, candidat ès sciences techniques, chef de laboratoire,

L.S. FILIPPOVA, collaborateur scientifique, NIITZement,

Y.R. KRIVOBORODOV, collaborateur scientifique, Institut Chimico-Technique, Mendéléiev,  
Moscou, U.R.S.S.

**RESUME :** Le processus de formation des granules du clinker repose sur les lois d'agglomération en phase liquide des poudres et avant tout sur la relation entre la quantité, la tension superficielle, la viscosité de la matière fondue, son pouvoir mouillant, la dimension initiale des particules et le retrait linéaire relatif.

L'accroissement de la dimension des particules de la matière à l'entrée de la zone de cuisson et la variation de tension superficielle et de viscosité des matières fondues exercent l'influence la plus efficace sur le processus de formation des granules.

L'accroissement de la tension superficielle des matières fondues dans le système  $\text{CaO-Al}_2\text{O}_3\text{-Fe}_2\text{O}_3\text{-SiO}_2$ , jusqu'à  $540\text{-}580 \cdot 10^{-3}$  N/m pour les valeurs de la viscosité de  $1,2$  à  $1,6 \cdot 10^{-1}$  Pa.s, dû à l'introduction des oxydes de titane, d'aluminium, de magnésium, de cadmium, de nickel et de manganèse, entraîne l'augmentation de la dimension des granules du clinker. Les relations quantitatives obtenues permettent de régler la composition granulométrique du clinker des fours rotatifs par variation de la composition chimique du mélange cru et du traitement thermique.

**SUMMARY :** The process of clinker granulation is determined by conditions of liquid-phase sintering of powders and, first of all, interrelation between the amount, surface tension, viscosity of the melt, its wettability, initial particle size and relative linear shrinkage.

The most effective method of controlling the granulation process is increase of the size of the material particles before the sintering zone and variation of surface tension and viscosity of the melt.

The surface tension of the melts in the  $\text{CaO-Al}_2\text{O}_3\text{-Fe}_2\text{O}_3\text{-SiO}_2$  system is increased to  $540\text{-}580 \cdot 10^{-3}$  N/m at a viscosity of  $1,2\text{-}1,6 \cdot 10^{-1}$  Pa.s by introduction of oxides of titanium, aluminium, magnesium, cadmium, nickel, manganese resulting in increase of dimensions of the clinker granules. The quantitative relationship obtained make it possible to regulate the granulometric composition of clinker in rotary furnaces by changing the chemical composition of the raw mix and thermal parameters in the furnace.

Actuellement la masse principale du clinker portland est soumise à la cuisson dans les fours puissants avec une large gamme de réglage des paramètres thermotechniques et technologiques. Cela permet de combiner de façon rationnelle le niveau de température de la cuisson avec la composition chimico-minéralogique du mélange cru pour obtenir le clinker ayant la composition et les propriétés optimales. Dans ce cas c'est la stabilité du fonctionnement des fours qui est la plus importante; elle dépend fortement de la composition granulométrique du clinker car la présence dans le clinker d'une grande quantité de fines particules (de la poussière de clinker) et de grands agglomérés provoque les perturbations dans le fonctionnement de l'équipement et la déstabilisation de la cuisson. C'est pour cette raison que l'étude de la formation des granules du clinker présente un grand intérêt scientifique et pratique.

Le processus de formation des granules du clinker repose sur les lois d'agglomération en phase liquide des poudres et avant tout sur la relation entre la quantité, la tension superficielle, la viscosité de la matière fondue, son pouvoir mouillant, la dimension des particules de départ et le retrait linéaire relatif. Les paramètres indiqués déterminent la dimension finale des grains du clinker et la vitesse du processus d'aggrégation.

Nous avons montré précédemment [1] que la dimension des grains du clinker dans les fours rotatifs se détermine par le rapport de deux forces: la force serrant les particules de la matière soumise à la cuisson (F) et la force de pesanteur (P), sous la forme suivante:

$$\frac{F}{P} = \frac{3 \cdot \sigma}{4r^2 \cdot \gamma \cdot g} \left\{ \sin^2 \gamma \left[ \frac{\cos(\gamma + \theta)}{1 - \cos \gamma} - \frac{1}{\sin \gamma \cdot \frac{(1 - \cos \gamma) [1 - \sin(\gamma + \theta)]}{\cos(\gamma + \theta)}} \right] + 2 \sin \gamma \cdot \sin(\gamma + \theta) \right\}, \quad (1)$$

où  $\sigma$  est la tension superficielle de la matière fondue, N/m;

$r$  - le rayon des particules, m;

$\gamma$  - la densité des particules, kg/m<sup>3</sup>;

$g$  - l'accélération de la force de pesanteur, m/s<sup>2</sup>;

$\theta$  - l'angle de mouillage, degrés;

$\gamma$  - l'angle dépendant de la quantité de la phase liquide, degrés.

On prend la grandeur F/P pour paramètre d'aggrégation sans dimension.

Il est évident que les particules cessent d'être agrégées dans les cas où  $F < P$  et le paramètre d'aggrégation  $F/P < 1$ . Cette valeur du paramètre est critique [2];

La vitesse du processus d'aggrégation peut être exprimée en fonction de la vitesse de retrait du conglomerat des particules en cours d'agglomération:

$$\frac{\Delta l/l_0}{\tau} = \frac{\sigma}{\eta \cdot r} \left\{ \left[ \frac{\cos(\gamma + \theta)}{1 - \cos \gamma} - \frac{1}{\sin \gamma \cdot \frac{(1 - \cos \gamma) [1 - \sin(\gamma + \theta)]}{\cos(\gamma + \theta)}} \right] + 2 \frac{\sin(\gamma + \theta)}{\sin \gamma} \right\} \quad (2)$$

où  $\Delta l/l_0$  est le retrait linéaire relatif;

$\tau_0$  - le temps, s;

$\eta$  - la viscosité, Pa.s.

Lors du passage de la matière par la zone de préclinkérisation, plusieurs variantes du processus d'aggrégation, dépendant de la valeur initiale (avant l'agglomération) du paramètre d'aggrégation et de la vitesse d'aggrégation, sont possibles. Pour évaluer la grandeur F/P et la vitesse d'aggrégation nous avons utilisé les valeurs expérimentales de la tension superficielle et de la viscosité des matières fondues modèles, préparées sur la base de la matière fondue de composition suivante: CaO - 57,0; SiO<sub>2</sub> - 7,5; Al<sub>2</sub>O<sub>3</sub> - 22,6 et Fe<sub>2</sub>O<sub>3</sub> - 12,9% en masse, avec additions des différents oxydes. Les données expérimentales sont obtenues avec la participation de A.Ossokin et S.Ivachtchenko et citées dans le tableau.

Tableau

Addition, % en masse	Viscosité, Pa.s.10 <sup>-1</sup>	Tension superficielle, N/m.10 <sup>-3</sup>
Matière fondue	1,6	580
1,0 de K <sub>2</sub> O	1,8	455
2,0 de K <sub>2</sub> O	2,4	350
2,5 de SO <sub>3</sub>	0,7	350
1,9 de SO <sub>3</sub> + 3,0 de K <sub>2</sub> O	1,6	150
1,0 de MoO <sub>3</sub>	1,2	490
1,0 de BaO	1,7	565
1,0 de CaO	1,6	577
1,0 de MgO	1,5	573
1,0 de Al <sub>2</sub> O <sub>3</sub>	1,5	565
2,0 de Na <sub>2</sub> O	2,2	457
1,0 de Na <sub>2</sub> O	1,7	555
1,0 de Ni <sub>2</sub> O	1,4	560
1,0 de Fe <sub>2</sub> O <sub>3</sub>	1,3	577
1,0 de Mn <sub>2</sub> O <sub>3</sub>	1,3	560
1,0 de B <sub>2</sub> O <sub>3</sub>	1,6	570
1,0 de TiO <sub>2</sub>	1,3	577

Envisageons les variantes possibles du processus d'agglomération.

1. La grandeur F/P atteint la valeur critique à l'entrée de la zone de préclinkérisation, quand le processus commence et la dimension des granules est faible. Cela est possible lorsque la tension superficielle de la matière fondue est très basse (150 à 350.10<sup>-3</sup> N/m) et la valeur de F/P est de 1,5 à 4, par exemple si le bain fondu contient 2,5% en masse de SO<sub>3</sub> ou 1,9 % en masse de SO<sub>3</sub> + 3% en masse de K<sub>2</sub>O et la vitesse d'aggrégation est grande (pour la viscosité du bain fondu de 0,7 à 1,2.10<sup>-1</sup> Pa.s). Dans ce cas l'aggrégation s'achève à peine commencée et la matière passe toute la zone de cuisson sous forme d'une masse finement dispersée.

2. La grandeur F devient égale à P au milieu de la zone de cuisson, lorsque le processus

d'agrégation est assez développé et les granules formés atteignent la valeur commensurable avec la dimension des granules du produit fini (de 8 à 10 mm). Cette variante du processus d'agrégation a lieu si la tension superficielle des matières fondues est de 540 à  $580 \cdot 10^{-3}$  N/m et le paramètre d'agrégation est égal à 6-9, par exemple en présence des oxydes de Ti, Mg, Ba, Al, et la vitesse d'agrégation est assez élevée (pour les valeurs de la viscosité de la matière fondue de 1,2 à  $1,6 \cdot 10^{-1}$  Pa.s). Les granules ainsi formés seront compactés pendant un temps assez long en présence de phase liquide, par suite de quoi il se forme le clinker de composition granulométrique serrée (sans particules fines).

3. La grandeur F/P devient égale à l'unité dans la deuxième moitié de la zone de préclinkérisation, lorsque le processus de cristallisation des minéraux à partir du bain fondu est intense. Cette situation apparaît si la tension superficielle des matières fondues est assez élevée (390 à  $520 \cdot 10^{-3}$  N/m), le paramètre d'agrégation est de 4,5 à 6, par exemple en présence de 1 à 2 % en masse de  $K_2O$  ou de  $Na_2O$ , et la vitesse d'agrégation est petite (pour les valeurs de la viscosité de 1,6 à  $2,6 \cdot 10^{-1}$  Pa.s). Dans ce cas le processus d'agrégation ne s'achève que vers la sortie de la zone de préclinkérisation, lorsque la teneur en phase liquide de la matière baisse brusquement. Par suite, les grains ainsi formés se trouvent sous l'action des tensions thermomécaniques.

On peut influencer sur le processus d'agrégation, en déplaçant son achèvement vers le milieu de la zone de préclinkérisation, à l'aide de la variation des paramètres entrant dans les équations (1) et (2). Nos recherches ont permis d'analyser l'influence des paramètres indiqués et de choisir les paramètres les plus efficaces pour la commande du processus d'agrégation.

Influence de la quantité de la matière fondue. Les valeurs de l'angle  $\varphi$ , caractérisant la quantité de la matière fondue dans le système de préclinkérisation, étaient calculées d'après sa tangente qui, à son tour, était déterminée d'après le rapport de la longueur de l'isthme entre deux granules, agglomérés au cours de la cuisson, au diamètre du granule. Les mesures des grandeurs mentionnées étaient effectuées pour les granules des mélanges de composition chimique différente (avec la teneur en phase liquide de 11 à 35 % en volume). Ainsi on a établi que les angles mesurés ne dépassent pas 40 degrés. Comme le montrent les calculs d'après l'équation (1), la variation des angles  $\varphi$  dans l'intervalle de 10 à 40° conduit à la diminution du paramètre d'agrégation de 18-25 % (Fig.1).

Influence de l'angle de mouillage. Des angles de mouillage, formés par les bains fondus de clinker de composition différente sur les surfaces des agglomérés denses de  $CaO$  et  $C_2S$ , ne dépassent pas 30° [3].

Les calculs faits d'après l'équation (1)

montrent que la grandeur F/P diminue de

Fig.1; Influence des caractéristiques du système de frittage sur le paramètre d'agrégation

20-25 % lors de la variation de  $\theta$  de 0 à 30° (Fig.1). Dans les conditions réelles les angles de mouillage peuvent être sensiblement inférieurs aux angles mesurés ou même égaux à zéro grâce à la rugosité de la surface des particules dispersées solides et à l'interaction chimique des phases solide et liquide, ce qui conduit à la diminution de l'influence de l'angle de mouillage sur le paramètre d'agrégation.

Influence de la tension superficielle. La tension superficielle des matières fondues dépend fortement du type et de la quantité des additions et peut varier de 150 à  $580 \cdot 10^{-3}$  N/m à la température de 1723°K (voir le tableau). La valeur du paramètre d'agrégation est proportionnelle à la tension superficielle (équation (1)) et si cette dernière varie dans les limites indiquées, elle augmente d'environ 75 % (Fig.1).

Influence de la dimension des particules. L'influence principale sur le paramètre d'agrégation est exercée par la dimension des particules, car la grandeur F/P est inversement proportionnelle au carré de leur rayon. La variation de 2 à 6 mm entraîne la diminution du paramètre d'agrégation d'environ 95% (Fig.1). Pour une dimension "maximale" déterminée des particules en amont de la zone de préclinkérisation (près de 10 mm), elles ne forment pas d'aggrégats.

Influence de la viscosité. La viscosité de la matière fondue influe sur la vitesse du processus d'agrégation (équation (2)) et en fin de compte sur la dimension des granules du clinker. Les grandes vitesses d'aggrégation

tion sont dues aux petites valeurs de la viscosité des matières fondues ( $0,7$  à  $1,2 \cdot 10^{-1}$  Pa.s) et les petites vitesses, aux valeurs élevées de la viscosité ( $1,7$  à  $2,6 \cdot 10^{-1}$  Pa.s).

L'analyse effectuée montre que le procédé le plus efficace d'action sur le processus de formation des granules consiste dans la variation de la tension superficielle, de la viscosité des matières fondues et de la dimension des particules de la matière en amont de la zone de cuisson.

Il est préférable d'utiliser les matières fondues ayant une tension superficielle élevée qui assure de grandes valeurs initiales du paramètre d'aggrégation ( $6$  à  $9$ ) pour pouvoir déplacer la fin du processus d'aggrégation vers le milieu de la zone de préclinkérisation en faisant varier sa vitesse. La variation de la dimension des granules du clinker en fonction de la tension superficielle des matières fondues est représentée sur la figure 2.

Fig.2. Variation de la dimension des grains du clinker en fonction de la tension superficielle

On peut accroître la vitesse d'aggrégation par l'introduction complémentaire dans le mélange cru de  $Fe_2O_3$  (le module alumine diminue) ainsi que des oxydes de titane et de manganèse en quantité de  $1\%$  en masse (en recalculant pour la matière fondue). Des résultats analogues peuvent être obtenus en augmentant la quantité de matière fondue.

On peut diminuer la vitesse d'aggrégation en augmentant le module alumine par l'introduction dans le mélange cru d'une quantité supplémentaire d' $Al_2O_3$  ou des oxydes de magnésium, de cadmium, de nickel en proportion de  $1\%$  en masse.

Dans les conditions industrielles, on a contrôlé expérimentalement l'influence des additions d' $Al_2O_3$ ,  $SO_3$ ,  $Fe_2O_3$ ,  $MgO$ ,  $Na_2O + K_2O$ ,  $MnO$  sur la composition granulométrique du clinker. La teneur élevée en  $SO_3$  et  $R_2O$ , les

autres conditions étant égales, empire la granulation du clinker; par contre la teneur élevée en  $Al_2O_3$ ,  $Fe_2O_3$ ,  $MnO$ ,  $MgO$  améliore la granulation.

En plus de l'augmentation de la plasticité du mélange cru, on peut influencer sur la dimension des particules de la matière en amont de la zone de préclinkérisation en faisant varier la position et la longueur de cette zone. Ainsi, si la zone de préclinkérisation est courte, la température de la matière diminue dans la zone de calcination tandis que la dimension des particules augmente (Fig.3).

Fig.3. Variation de dimension des particules en fonction de la température dans la zone de calcination.

La composition granulométrique du clinker se trouve donc bien améliorée. Les compositions granulométriques des clinkers obtenues pour la zone de préclinkérisation courte (courbe 2) et longue (courbe 1) sont représentées sur la figure 4.

La commande du processus de formation des granules du clinker n'est pas seulement importante du point de vue de la stabilité du fonctionnement du four mais aussi du point de vue de l'accroissement de l'activité du clinker.

Les recherches effectuées dans plusieurs cimenteries ont permis d'établir les dépendances extrêmes entre la température théorique du courant gazeux dans la zone de préclinkérisation d'une part et la dimension dominante des granules du clinker et son activité à l'âge de 28 jours d'autre part (Fig.5).

Le caractère des courbes témoigne de la dépendance proportionnelle entre la composition granulométrique du clinker et son activité.

Fig. 4. Courbes de répartition granulométrique du clinker.

T - Température calculée du courant gazeux dans la zone de cuisson du four rotatif, °K

d - Dimensions prédominantes des grains du clinker, mm

$R_{comp}^{28}$  - activité du clinker, MPa

Fig. 5. Variation de la dimension dominante des granules du clinker (courbe 1) et son activité (courbe 2) en fonction de la température théorique du courant gazeux

Aux températures abaissées du courant gazeux dans la zone de préclinkérisation, on obtient un clinker qui a une grande teneur en particules fines et dont l'activité est généralement peu importante par suite du caractère inachevé des processus de forma-

tion des minéraux. En plus d'un grand pourcentage de petites particules dans le clinker aux températures élevées, on observe de gros boules. L'activité de ce clinker est également peu importante, ce qui est lié à la décomposition de l'alite (d'après les données de l'analyse des phases aux rayons X).

Enfin, il existe le domaine optimal de températures qui correspond aux grains de clinker relativement gros (la dimension prépondérante étant de 10 à 15 mm) à granulométrie serrée. C'est justement ce clinker qui présente l'activité maximale.

#### CONCLUSIONS

La commande du processus de formation des granules du clinker peut être réalisée sur la base des dépendances quantitatives obtenues, par modification de la composition chimique des mélanges crus et des paramètres thermotechniques du fonctionnement des fours rotatifs. L'action dirigée sur la formation des granules assure des caractéristiques techniques et économiques élevées du fonctionnement des fours et le clinker ainsi obtenu est de haute qualité.

Les recherches théoriques effectuées sont confirmées dans les conditions industrielles lors de la production des clinkers portlands dans les fours rotatifs puissants.

Kleem

RÉSUMÉ: On a déterminé les effets de minéralisateurs et de fondants contenant du fluor sur l'aptitude à la cuisson d'une série de mélanges crus, allant du système quaternaire  $\text{CaO-Al}_2\text{O}_3\text{-Fe}_2\text{O}_3\text{-SiO}_2$  à des mélanges plus complexes et industriels. On a trouvé de nouveaux indices qui montrent que les additifs contenant du fluor ont une influence importante sur la composition de la phase liquide, laquelle accélère la formation des silicates entre 1200°C et 1300°C.  $\text{MgO}$  et  $\text{K}_2\text{SO}_4$  influencent la répartition du fluor entre les phases silicate et interstitielle. Le processus de cristallisation de  $\text{C}_3\text{S}$  entraîne un départ de fluor des phases interstitielles, ce qui provoque un changement de composition de  $\text{C}_{11}\text{A}_7\text{-CaF}_2$  à  $\text{C}_3\text{A}$ . Les résultats expérimentaux montrent les interactions entre le pourcentage de fluor, la température de clinkérisation, le rapport  $\text{Al}_2\text{O}_3/\text{Fe}_2\text{O}_3$  et les vitesses de réaction. On a mis en évidence les facteurs qui influencent l'hydratation et le développement des résistances. Ces résultats ont des implications directes sur la production du clinker et la conservation de l'énergie.

SUMMARY: The effects of fluorine-containing mineralizers and fluxes on the burnability of a series of raw mixes, ranging from the quaternary system  $\text{CaO-Al}_2\text{O}_3\text{-Fe}_2\text{O}_3\text{-SiO}_2$  to more complex mixtures and industrial mixes, were determined. New evidence has been found to show that fluorine-containing additives have a major influence on the composition of the liquid phase which, in turn, accelerates silicate mineral formation between 1200° and 1300°C.  $\text{MgO}$  and  $\text{K}_2\text{SO}_4$  influence the partitioning of fluorine between silicate and interstitial phases. The  $\text{C}_3\text{S}$  crystallization process results in removal of fluorine from the interstitial phases, and causes a compositional shift from  $\text{C}_{11}\text{A}_7\text{-CaF}_2$  to  $\text{C}_3\text{A}$ . Data are given which show the relationships between fluorine content, clinkering temperature,  $\text{Al}_2\text{O}_3/\text{Fe}_2\text{O}_3$  ratio, and rates of reaction. Factors that influence hydration and strength development are shown. These results have direct implications on commercial clinker production and energy conservation.

## INTRODUCTION

A potentially attractive approach to energy conservation in the cement industry is through the addition of mineralizers and fluxes to the cement raw feed to enhance its burnability. This could result either in a decrease of the required kiln temperature or in an increase of the clinker production rate. Although for many years substantial efforts have been devoted to various aspects of this problem, most, for one reason or another, have been peripheral to gaining a fundamental understanding of the effects of mineralizers and fluxes on clinker formation (1).

The purpose of this present work was to establish the fundamental relationships and relative importance of fluorine-containing substances and minor oxides on mineral formation and clinkering reaction mechanisms. This was approached by starting with the basic quaternary system,  $\text{CaO-Al}_2\text{O}_3\text{-SiO}_2\text{-Fe}_2\text{O}_3$ , and progressing to more complex compositions, including industrial raw mixes, to determine the reaction kinetics of liquid and compound formation under dynamic or nonequilibrium conditions.

## EXPERIMENTAL

Reagent-grade calcium carbonate, silicic acid, aluminum oxide, and ferric oxide were used to prepare three experimental quaternary compositions. The total of  $\text{Al}_2\text{O}_3 + \text{Fe}_2\text{O}_3$  was held at 10% in each composition, but the ratio  $\text{Al}_2\text{O}_3/\text{Fe}_2\text{O}_3$  was varied, as shown in Table I, along with the potential amounts of  $\text{C}_{11}\text{A}_7\cdot\text{CaF}_2$  that could be formed if sufficient fluorine were available.

TABLE I

Quaternary Composition	$\text{CaO/SiO}_2$	$\text{Al}_2\text{O}_3/\text{Fe}_2\text{O}_3$	% Potential $\text{C}_{11}\text{A}_7\cdot\text{CaF}_2$
A	3	0.67	0.36
B	3	1.50	6.82
C	3	4.00	13.28

Further additions to each experimental composition, on a loss-free clinkered basis, were made with reagent-grade magnesium oxide and potassium sulfate. Calcium fluoride and calcium fluosilicate dihydrate were used as mineralizers for the above synthetic raw mixes, whereas fluosilicic acid was used for an industrial raw mix. Free  $\text{CaO}$ ,  $\text{C}_3\text{S}$ , and  $\text{C}_{11}\text{A}_7\cdot\text{CaF}_2$  contents in clinker were determined by a quantitative X-ray diffraction procedure (2). The silicate phases were removed from the clinker by the selective dissolution of interstitial compounds with a hot aqueous KOH-

sugar solution (3). The fluorine contents of both the original clinker and the separated silicate phases were determined by a method based on an initial lithium metaborate fusion, followed by dissolution in dilute  $\text{HNO}_3$  and measurement with a fluoride-specific ion electrode (4).

## RESULTS AND DISCUSSION

The most readily observed improvement from adding fluorine to a cement raw mix is due to its interaction with the liquid phase during the clinkering process. The importance of this liquid phase on clinker burnability has been discussed in detail in recent publications (5,6). The fluorine-containing liquid, which after solidification usually contains  $\text{C}_{11}\text{A}_7\cdot\text{CaF}_2$ , is formed at a lower temperature and exhibits a lower viscosity, thus permitting the more rapid diffusion of reactive species and the accelerated formation of  $\text{C}_3\text{S}$ .

**Clinkering Kinetics.** Previous clinkering studies (7) on the three basic quaternary compositions containing 0.5% F<sup>-</sup> as  $\text{CaF}_2$  and  $\text{CaSiF}_6$ , at 1200° and 1300°C, established that as the ratio A/F was decreased, the clinker burnability was somewhat improved. Furthermore, at the same level of fluorine,  $\text{CaF}_2$  appeared to be a slightly more effective mineralizer than  $\text{CaSiF}_6$ . Using either the progressive decrease in free  $\text{CaO}$ , or the corresponding increase in  $\text{C}_3\text{S}$  in the clinker, as an indicator of the clinkering reaction, it was found that the reaction rate of mineralized compositions at 1300°C was generally comparable to compositions without mineralizer additions at 1450°C. These findings are supported by Johansen and Christensen (8), who studied the kinetics of the reaction ( $\text{C} + \text{C}_2\text{S} \rightarrow \text{C}_3\text{S}$ ) in the presence of  $\text{CaF}_2$ , by means of diffusion-couple experiments.

To determine the effectiveness of mineralizers on more complex mixtures, minor oxide additions were made to the basic quaternary compositions. The effects of  $\text{CaF}_2$  and 1% additions of  $\text{MgO}$  and  $\text{SO}_3$  (as  $\text{K}_2\text{SO}_4$ ) on the burnability of composition B are shown in Figure 1.

In the absence of a mineralizing additive, essentially no  $\text{C}_3\text{S}$  is formed at temperatures as low as 1200°C, and only a small amount is formed at 1300°C. The addition of minor oxides to a non-mineralized composition produces two different effects.  $\text{MgO}$  functions as a flux because it lowers the temperature of liquid formation and significantly increases the rate of  $\text{C}_3\text{S}$  formation at 1300°C. A comparable addition of  $\text{K}_2\text{SO}_4$  decreased the rate of  $\text{C}_3\text{S}$  formation to below that of the basic composition.

Mineralization with  $\text{CaF}_2$  (0.5% F<sup>-</sup>) greatly accelerated the clinkering reaction, and permitted the rapid formation of  $\text{C}_3\text{S}$  at 1200°C, a temperature well below the usual stability range of 1300° to 1800°C for  $\text{C}_3\text{S}$ . This is in agreement with work by Mukherji (9), who reported that in the presence of  $\text{CaF}_2$  the lower limit of decomposition of  $\text{C}_3\text{S}$  is reduced from 1000°-1300°C to

800°-1030°C. Roy and Sarkar (10) also observed  $C_3S$  formation at 1200°C in the presence of  $CaSiF_6$ , and have shown the enlargement of the  $C_3S$  primary phase field in the fluorine-containing ternary system  $CaO-Al_2O_3-SiO_2$ .

Figure 1. Rates of  $C_3S$  formation in composition B.

The previously observed negative effect of  $SO_3$  additions on the clinkering reaction rate is not apparent with the mineralized compositions. Minor oxide additions, particularly at 1300°C, seem to have a further fluxing effect and give a slightly higher  $C_3S$  content than the composition with only  $CaF_2$ . In every case, however, mineralized compositions exhibit a very rapid initial reaction rate during the first 10-30 minutes, followed by a greatly reduced rate of  $C_3S$  formation. Selected clinkering tests conducted for up to four hours duration indicated that the  $C_3S$  content leveled off to about the same amount for each burning temperature. Approximately 40%  $C_3S$  was formed at 1200°C, and 60%  $C_3S$  formed at 1300°C.

**Fluorine Partitioning.** The finding of limits to maximum  $C_3S$  content obtained at a given clinkering temperature raises the question of whether the limits are due to a chemical constraint such as a change in melt composition or depletion of a reacting species, or perhaps a physical constraint such as inhomogeneities within the raw mix and localized regions of melt formation, which could restrict the diffusion processes.

To minimize burnability problems resulting from poor raw mix homogeneity, three samples of composition B, all containing  $CaF_2$  (0.5% F<sup>-</sup>), 1%  $MgO$ , and 1%  $SO_3$  (as  $K_2SO_4$ ), were burned for 30 minutes, ground, and subsequently reburned for an additional 15 minutes, one each at 1100°, 1200°, and 1300°C. The resulting analyses of major clinker phases and fluoride contents of the total clinker as well as the separated silicate phases, are shown in Table II.

TABLE II			
	Burning Temperature (C°)		
	1100	1200	1300
Free CaO (%)	16.8	5.8	0.7
$C_3S$ (%)	9	42	59
$C_{11}A_7 \cdot CaF_2^*$	+++	++	0
F <sup>-</sup> in Clinker (%)	0.48	0.44	0.39
F <sup>-</sup> in Silicates (%)	0.08	0.14	0.35
Fluorine Loss (%)	4	12	22

\* Amounts are relative; 0 = none, + = detectable, ++ = moderate, +++ = substantial.

Again, although a steady-state condition was reached more rapidly, the  $C_3S$  content was limited to about 40% at 1200°C and 60% at 1300°C. Furthermore, the amount of  $C_{11}A_7 \cdot CaF_2$  which was originally formed at 1100°C, decreased at 1200°C, and could not be detected at 1300°C. At this higher temperature, X-ray diffraction showed that  $C_3A$  was the only aluminate phase present. The loss of  $C_{11}A_7 \cdot CaF_2$  was accompanied by an increase of fluorine in the silicate phases. Additionally, as has been reported by other researchers (8,11), about 20% of the fluorine appears to have volatilized.

Based on the observed partitioning of fluorine between the interstitial and silicate phases, the following reaction sequence was proposed (12) to clarify the clinkering process in the presence of fluorine-containing mineralizers:

- 1) Fluorine (as  $CaF_2$  or  $CaSiF_6$ ) reacts with the raw mix components to form a ferrite and aluminate liquid phase below 1200°C.
- 2) The clinker liquid phase is required for low temperature formation of  $C_3S$ . Accordingly,  $C_3S$  rapidly forms at temperatures below 1200°C. As  $C_3S$  crystallizes from the melt, it continuously removes with it a small quantity of fluorine.
- 3) Depletion of fluorine results in a change of the liquid phase composition, quali-

tatively depicted as ( $F_{ss} + C_{11}A_7 \cdot CaF_2 + F_{ss} + C_3A$ ). Such a change in melt composition varies with initial fluorine content and clinkering temperature, and may limit the amount of  $C_3S$  that will form at a given temperature.

- 4) At higher temperatures (e.g., 1300°C), sufficient fluorine may be removed from the clinker liquid to result in the complete decomposition of  $C_{11}A_7 \cdot CaF_2$  and formation of  $C_3A$ .

**Calcium Fluosilicate and Minor Oxides.** The effect of changes in interstitial phase composition on clinker burnability and on the effectiveness of mineralization was determined on quaternary compositions A, B, and C. The three compositions, representing alumina ratios of 0.67, 1.50, and 4.00, were prepared with minor oxide additions of 1% MgO, 1%  $SO_3$  (as  $K_2SO_4$ ), and a combination of MgO and  $SO_3$ . Each mixture contained  $CaSiF_6$  (0.5%  $F^-$ ) as the mineralizing agent. For comparison, the most complex mixture, containing both MgO and  $SO_3$ , was prepared with  $CaF_2$  (0.5%  $F^-$ ). After burning each for 30 minutes at 1300°C, the clinkered products were analyzed, and the results are given in Table III.

The amount of free CaO remaining after clinkering may be used as an index of the progress of the clinkering reactions and, therefore, the relative burnability. It appears that the compositions burn with somewhat more difficulty as the alumina content is increased. In all cases, however, the addition of minor oxides results in an improvement of burnability, and the combination of MgO and  $SO_3$  gives the lowest free CaO contents. A comparison with those compositions contain-

ing  $CaF_2$ , suggests that, at equivalent fluorine concentrations,  $CaSiF_6$  is the more effective mineralizing agent. This is the opposite of what had been previously found in the absence of minor oxide additions.

An analysis of the clinkers for total fluorine content indicates that the amount of fluorine found in the basic quaternary compositions A, B, and C are essentially the same, and that about a 20% loss occurs during the clinkering process. Those samples containing MgO alone seem to have retained slightly more fluorine, and those containing  $SO_3$  have somewhat less. This could perhaps be attributed to the influence of  $K_2O$  on fluorine volatilization.

Some interesting effects were observed in the partitioning of fluorine between the silicate and interstitial phases in the clinker. MgO additions tend to increase the amount of fluorine passing into the silicate phases, whereas  $SO_3$  additions have a negative influence on the process. In the absence of  $SO_3$ , the higher alumina ratio compositions also exhibit less fluorine in the calcium silicate minerals.

There is a poor correlation between the amount of fluorine that can be calculated as being in the interstitial phase and the  $C_{11}A_7 \cdot CaF_2$  content estimated from X-ray diffraction measurements. This is particularly true with composition A, which is capable of forming only a very small quantity of  $C_{11}A_7 \cdot CaF_2$ . A substantial amount of fluorine is clearly associated with the predominate ferrite phase. In composition B, partitioning of fluorine seems to occur between the aluminate and ferrite phases, as well as the silicate phases. Little has been done to charac-

TABLE III

Composition	Clinker				Silicate Phase
	Free CaO (%)	$C_3S$ (%)	$C_{11}A_7 \cdot CaF_2^*$	$F^-$ (%)	$F^-$ (%)
A + $CaSiF_6$	4.8	50	+	0.39	0.31
A + MgO + $CaSiF_6$	3.4	55	+	0.42	0.38
A + $SO_3$ + $CaSiF_6$	3.0	55	+	0.36	0.21
A + MgO + $SO_3$ + $CaSiF_6$	2.8	52	+	0.41	0.23
A + MgO + $SO_3$ + $CaF_2$	3.7	55	+	0.36	0.23
B + $CaSiF_6$	7.2	52	++	0.40	0.23
B + MgO + $CaSiF_6$	3.8	52	++	0.41	0.30
B + $SO_3$ + $CaSiF_6$	4.2	57	+	0.37	0.19
B + MgO + $SO_3$ + $CaSiF_6$	3.0	52	+	0.37	0.23
B + MgO + $SO_3$ + $CaF_2$	4.0	30	+	0.37	0.24
C + $CaSiF_6$	7.4	56	++	0.39	0.21
C + MgO + $CaSiF_6$	5.2	53	+++	0.41	0.24
C + $SO_3$ + $CaSiF_6$	5.2	63	++	0.34	0.19
C + MgO + $SO_3$ + $CaSiF_6$	3.6	54	++	0.37	0.20
C + MgO + $SO_3$ + $CaF_2$	7.2	33	++	0.38	0.18

\* Amounts are relative; 0 = none, + = detectable, ++ = moderate, +++ = substantial.

terize these fluorine-containing Fss phases, but Yamaguchi and co-workers (13) have reported that in a high calcium fluoroaluminate clinker, the ferrite phase approaches the alumina-rich end of the solid solution series and contains about 1% fluorine.

**Industrial Raw Mixes.** An industrial portland cement raw mix was chosen for study that broadly resembled composition B. The chemical composition is given in Table IV.

TABLE IV	
Oxide	%
SiO <sub>2</sub>	13.88
Al <sub>2</sub> O <sub>3</sub>	3.27
Fe <sub>2</sub> O <sub>3</sub>	1.42
CaO	42.67
MgO	2.03
SO <sub>3</sub>	0.70
K <sub>2</sub> O	0.67
Na <sub>2</sub> O	0.16
Ignition loss	35.52
	100.32

It has been reported (14) that improved burnability is achieved when the fluorine-containing mineralizing agent is added to the raw mix as a free mineral acid rather than as a salt. Therefore, all fluosilicate additions were made in the form of H<sub>2</sub>SiF<sub>6</sub> as a 24% aqueous solution. This was accomplished in two ways. First, the acid solution was added to a slurry of the raw material, which was subsequently dried and identified as raw mix I. In the second way, the acid solution was well mixed with the dry powdered raw material, which was called raw mix II. The fluorine contents of both raw mixes were 0.30 and 0.60%. Each mix composition was burned for one hour at 1300°C. The amounts of free CaO and C<sub>3</sub>S in the clinker were determined by X-ray diffraction, and are shown in Table V.

TABLE V			
Composition	H <sub>2</sub> SiF <sub>6</sub> Addition (% F <sup>-</sup> )	Free CaO (%)	C <sub>3</sub> S (%)
Raw Mix I (slurry)	0.30	2.3	58
	0.60	1.5	58
Raw Mix II (powder)	0.30	4.2	48
	0.60	2.3	52

Both raw mixes had good burnability characteristics, with the actual free CaO content depending upon the amount of fluosilicic acid originally used for mineralization. When compared with raw mix II containing the same amounts of fluorine, raw mix I had lower free CaO contents, and higher amounts of C<sub>3</sub>S formed, which are attributed to the greatly improved homogeneity brought about by slurry mixing. This

has permitted the same degree of clinkering to be achieved with 0.3% F<sup>-</sup> in a slurry-derived mix as could be achieved with 0.6% F<sup>-</sup> in a mix prepared as a powder.

**Hydration and Strength Development.** It has been established that portland cement clinker can be produced at temperatures of 1300°C, if fluorine-containing additives are used as mineralizing agents. Furthermore, fluorine will partition between the interstitial and the silicate phases during clinker formation. The effect this will have on the subsequent hydration and strength development of cement produced from such clinkers is, therefore, of great importance. Welch and Gutt (15) and Nurse and co-workers (16) showed that the increasing fluorine content in C<sub>3</sub>S resulted in reduced strength and rates of strength development. However, this work was conducted on pure C<sub>3</sub>S preparations, and the effect of fluorine on C<sub>3</sub>S produced in normal clinker at lower temperatures had not been determined.

Cement from selected compositions was prepared with laboratory-burned clinkers and 5% gypsum, and ground to a Blaine fineness of about 3500 cm<sup>2</sup>/g. These clinkers consisted of compositions A, B, and C, all containing 1% additions of MgO and SO<sub>3</sub> (as K<sub>2</sub>SO<sub>4</sub>), and burned for 30 minutes at 1450°C. Similar compositions, mineralized with CaF<sub>2</sub> (0.5% F<sup>-</sup>), were burned for 30 minutes at 1300°C. Industrial raw mix I, mineralized with H<sub>2</sub>SiF<sub>6</sub> (0.3% F<sup>-</sup>), and raw mix II, mineralized with H<sub>2</sub>SiF<sub>6</sub> (0.6% F<sup>-</sup>), were each burned for 60 minutes at 1300°C.

Mortar cubes, prepared according to ASTM C109 procedures were made from all cements. Twelve 25-mm cubes were produced with cements containing compositions A, B, and C, and four each were subsequently tested at 1, 7, and 28 days. Similarly, nine 50-mm cubes were produced with the cements made from the two industrial raw mixes, and three each were tested at 1, 7, and 28 days. The results of these compressive strength tests are given in Table VI.

TABLE VI			
Composition	Compressive Strength (MPa)		
	1 day	7 days	28 days
A + MgO + SO <sub>3</sub>	6.2	23.1	31.6
A + MgO + SO <sub>3</sub> + CaF <sub>2</sub>	10.1	29.2	34.8
B + MgO + SO <sub>3</sub>	7.3	22.6	33.6
B + MgO + SO <sub>3</sub> + CaF <sub>2</sub>	9.1	26.7	38.4
C + MgO + SO <sub>3</sub>	5.6	28.1	38.3
C + MgO + SO <sub>3</sub> + CaF <sub>2</sub>	1.2	20.8	32.5
Raw Mix I + H <sub>2</sub> SiF <sub>6</sub> (0.3% F <sup>-</sup> )	10.8	31.1	35.6
Raw Mix II + H <sub>2</sub> SiF <sub>6</sub> (0.6% F <sup>-</sup> )	6.3	28.1	33.6

Compared to the nonmineralized cements, compositions A and B exhibit significant strength increases, particularly at 1 day. Composition C, however, which has the highest alumina ratio and the most  $C_{11}A_7 \cdot CaF_2$ , is highly retarded at 1 day, and also remains below the rate of strength development of the control samples at 7 and 28 days.

The two cements made from industrial raw mixes mineralized with fluosilicic acid also show good strength development characteristics. The effect of fluorine level, however, is evident in that the composition containing 0.6% F- is somewhat retarded at 1 day compared to the composition containing 0.3% F-.

#### CONCLUSIONS

Fluorine-containing mineralizers greatly accelerate the clinkering reaction, permitting  $C_3S$  formation at temperatures below the usual stability range for  $C_3S$ . Minor oxide additions such as  $MgO$ ,  $K_2O$ , and  $SO_3$  have a further fluxing effect. Clinker burnability is also somewhat improved as the  $Al_2O_3/Fe_2O_3$  ratio is decreased.

Mineralizers have a major influence on the liquid phase of the clinker. At about  $1100^\circ C$ , the liquid phase contains a significant amount of  $C_{11}A_7 \cdot CaF_2$ , which subsequently transforms to  $C_3A$  at  $1300^\circ C$  as a major portion of fluorine is preferentially taken up by the silicate phase. The fluorine loss due to volatilization is about 20%. The presence of  $MgO$  seems to favor the partitioning of fluorine into the silicate phase, whereas  $K_2SO_4$  seems to increase its volatilization. Studies of the interstitial phase further indicate that partitioning of fluorine also takes place between the aluminate and ferrite phases.

Cement produced with mineralizers show, in some cases, significant increases in compressive strength as compared to nonmineralized cements. This was found to be true for both synthetic and industrial raw mixes. The results, therefore, indicate the possibility of producing clinker at lower temperatures with compressive strengths comparable to ordinary portland cements.

## Problèmes physico-chimiques du broyage du clinker-portland

### *Physico-chemical problems of grinding of portland cement clinker*

V.Z. PIROTSKI, candidat ès sciences techniques, NIITzement, Moscou, U.R.S.S.

**RESUME :** Le processus de broyage du clinker-portland s'accompagne d'effets physico-chimiques et se caractérise par la variation par stades de la constante de la vitesse de broyage et des propriétés physiques de la poudre, ce qui est dû à l'hétérogénéité macro et microscopique de la structure du clinker et aux interactions superficielles. L'efficacité du processus et la distribution granulométrique du ciment sont déterminées par l'interaction et l'influence mutuelle des propriétés physico-chimiques du clinker, des conditions thermiques d'humidité et d'adsorption. On a établi des relations qualitatives et quantitatives entre les indices de cinétique du broyage et la distribution granulométrique et les propriétés de cohésion des clinkers-portlands; ceux-ci se différencient par leurs caractéristiques minéralogiques et structurales, notamment si l'on utilise un agent de mouture. On a établi une possibilité de principe de contrôler les caractéristiques de dispersion et les propriétés du ciment en utilisant comme agents de mouture des surfactifs, qui se distinguent par leur action sélective sur les constituants. L'accroissement de l'efficacité des méthodes physico-chimiques d'intensification des processus doit être fondé sur l'optimisation du régime énergétique et hydrodynamique relativement aux propriétés du matériau et du milieu.

**SUMMARY :** The process of portland cement clinker grinding is accompanied by various physico-chemical effects and is characterized by stepwise variation of the grinding rate constant and of physical properties of the powder due to macro- and micro- inhomogeneities in the clinker structure and to surface interactions. The effectiveness of the process and the granular distribution of cement are determined by the interaction and interdependence of physico-chemical properties of clinker, heat-moisture and adsorption conditions. Qualitative and quantitative dependences of grinding kinetics, of granular distribution, adhesive-autohesive properties were determined for portland cement clinkers with different mineralogical and structural characteristics, including grinding in the presence of surface-active compositions.

The possibility of controlling dispersion characteristics and properties of cements by using surface-active compositions with selective action of the components is established. Increase of the effectiveness of physico-chemical methods of intensifying processes should be based on optimization of the energy and hydrodynamic conditions in relation to properties of the material and medium.

Le broyage du clinker-portland s'accompagne d'effets profonds et variés des interactions superficielles, qui sont caractéristiques des processus physico-chimiques et influent sensiblement sur les indices énergétiques, les caractéristiques de dispersion et sur l'activité du ciment. Ces effets consistent dans :

l'adhésion et l'autoadhésion dues à l'interaction des particules de clinker entre elles et avec les surfaces de broyage ;

la diminution de résistance d'adsorption (résistance au broyage) et la désagrégation dues à l'interaction entre les particules de clinker et le milieu actif adsorbant ;

la déformation plastique de la structure cristalline de la couche superficielle (destruction) et les réactions mécano-chimiques qui se manifestent en cas de dispersion très profonde.

La valeur et la contribution des effets sont déterminées par les propriétés physico-chimiques du clinker et des additions, les paramètres technologiques et les caractéristiques de régime ainsi que par les conditions thermiques et d'humidité et d'adsorption (1 à 6). Les procédés physico-chimiques d'intensification du processus, fondés sur la création du milieu actif adsorbant dans le broyeur par addition de surfactifs, et sur le réglage de la température du processus donnent dans les conditions réelles un effet de 15 à 20 %. Théoriquement et expérimentalement cet effet est évalué à 30-60 % et est obtenu par optimisation des paramètres et des régimes du processus relativement aux propriétés du clinker et du milieu (1, 3, 6). Dans cette optique, l'étude de la cinétique du broyage et de la distribution des grains acquiert une importance primordiale. On a montré auparavant (6, 7) que pour la plupart des clinkers, la dépendance des dépenses d'énergie spécifiques par rapport à la dispersion  $E = f(S)$  se caractérise par des stades consécutifs : broyage grossier ( $<1500 \text{ cm}^2/\text{g}$ ), moyen ( $1500 \text{ à } 2500 \text{ cm}^2/\text{g}$ ) et fin ( $>2500 \text{ cm}^2/\text{g}$ ). La grandeur  $E/S$  déterminant l'efficacité du processus est respectivement de  $(6 \text{ à } 10) \cdot 10^{-9}$ ,  $(10 \text{ à } 14) \cdot 10^{-9}$  et  $(14 \text{ à } 40) \cdot 10^{-9} \text{ kWh/cm}^2$  (6).

Au cours des études de la cinétique du broyage et de la distribution granulométrique de 10 clinkers industriels, qui se distinguent par la composition minéralogique ( $C_2S \approx 50 \pm 5\%$  ;  $C_3S \approx 24 \pm 6\%$  ;  $C_4A \approx 9 \pm 5\%$  ;  $C_4AF \approx 10 \pm 3\%$ ) et la microstructure, on a révélé la variation par stades de la constante de vitesse de broyage relative ( $K$ ) dans l'équation de la cinétique du broyage :

$$R_t = R_0 \cdot e^{-Kt^m} \quad (1)$$

La fonction  $K = f(\tau)$  se caractérise par une courbe à trois portions : accroissement, constance relative et diminution des valeurs de  $K$  (fig. 1). La valeur du rapport

$\frac{K_{\max}}{K_{\min}}$  est de 1,15 à 1,22. Les valeurs de dispersion des points caractéristiques de la courbe  $K = f(\tau)$  coïncident avec les points correspondants de la fonction  $E = f(S)$ .

Durée de broyage -  $\tau$ , mn

Fig. 1 - Variation de la constante de vitesse  $K$ , du coefficient d'uniformité  $n$ , de l'angle de talus naturel  $\alpha^\circ$  et de la valeur d'adhésion  $G_a$  en fonction de la durée de broyage

La valeur relative de  $G_a$  (%) et la cinétique de l'adhésion  $G_a = f(\tau)$  dépendent des particularités chimico-minéralogiques et structurales du clinker. Toutefois, on n'a pas réussi à suivre l'interdépendance entre le contenu de certaines phases de clinker et la grandeur  $G_a$ . D'après la valeur de  $G_a$  on a identifié trois groupes de clinkers : à valeur maximale, moyenne et minimale, respectivement de  $>0,6$  ;  $0,6 \text{ à } 0,4$  et  $<0,4\%$  (par rapport à la masse des corps broyeurs). D'après la cinétique, on a également établi trois groupes, caractérisés par la courbe exponentielle, la courbe de "maximum saturé" (fig. 1) et la courbe d'accroissement par gradins.

En fonction de la classe granulométrique, la grandeur  $K$  varie (fig. 2) non seulement de façon absolue mais aussi de façon relative. Dans le domaine de la fraction de

20 à 40  $\mu\text{m}$  a lieu une brusque diminution de  $K$  et la "redistribution" de ses valeurs par rapport aux classes de 40  $\mu\text{m}$ , ce qui est lié au début du broyage des minéraux-silicates dont la dimension prépondérante correspond à cette gamme, et aux différentes propriétés mécaniques des phases de clinker (résistance et fragilité), ainsi qu'à l'influence des phénomènes d'adhésion et d'autohésion.

Le caractère par stades des processus se voit également dans la variation de densité apparente  $\gamma_v$  ( $\text{g}/\text{cm}^3$ ).

La relation  $\alpha^0 = f(\tau)$ , qui traduit les propriétés "rhéologiques" de la poudre et caractérise indirectement sa fluidité (mobilité) présente un intérêt particulier. On a identifié trois groupes de clinkers : à allure de variations graduelle, par sauts (fig. 1), ou extrême (fig. 3) de  $\alpha = f(\tau)$ .

Fig. 2 - Dépendance de la constante de vitesse de broyage  $K$  de la classe granulométrique. 1 à 9 - clinkers-portlands.

Le coefficient d'uniformité de distribution granulométrique  $n$  dans l'équation RRB

$$R_d = R_0 e^{-\left(\frac{d}{d^*}\right)^n} \quad (2)$$

varie dans la plupart des cas à peu près de la même façon que  $\alpha^0$ , mais les points extrêmes sont d'une orientation opposée. La coïncidence des valeurs extrêmes du coefficient d'uniformité  $n$ , caractérisant

indirectement la capacité d'agrégation, avec la grandeur  $\alpha^0$  ainsi que l'accroissement du degré d'adhésion  $G_a$  au voisinage de ces valeurs témoignent de l'interdépendance entre la distribution granulométrique et les propriétés d'adhésion et d'autohésion du ciment, ce qui est en accord avec les données de Beke, Opoczky et Mrakovitchne (4, 8). Notons que les dépendances généralisées citées dans (9) n'épuisent pas toute la diversité des régularités de broyage  $n$  et  $\alpha^0$  au fur et à mesure de la dispersion.

Il est tout à fait évident que la variation par stades de la constante de vitesse, l'influence des propriétés d'adhésion et d'autohésion sur les caractéristiques de dispersion et l'efficacité du processus commandent d'en tenir compte lors de la simulation et l'optimisation du processus.

Relativement aux stades établis, l'influence de la température s'exprime par un accroissement du degré d'adhésion et d'agrégation (6, 7). L'optimum de température se situe entre 90 et 110  $^{\circ}\text{C}$ . L'influence de l'humidité s'exprime par une baisse de la fluidité (mobilité) aux premiers stades et une diminution du degré d'adhésion et d'agrégation au dernier stade. L'optimum d'humidité est alors égal à 0,5-1,0 % (6, 7).

L'intensification du processus dans les conditions du milieu actif du point de vue de l'adsorption est liée aux effets de diminution de la résistance, qui se manifestent aux stades initiaux ainsi qu'aux effets de réduction de l'adhésion et de l'agrégation au stade de broyage fin (3, 7) et d'accroissement de la fluidité (mobilité) du ciment.

En présence de surfactifs, le caractère de  $\alpha^0 = f(\tau)$  et  $n = f(\tau)$  est plus calme et la courbe ne présente pas de variations par sauts de  $\alpha^0$  et  $n$  (fig. 3), ce qui est dû à la diminution de l'agrégation.

L'efficacité des surfactifs devient plus importante lors du broyage des clinkers ayant une défectuosité élevée ; elle baisse lors de broyage simultané avec des additions poreuses faciles à broyer ainsi qu'avec des additions minérales à propriétés antiadhésives (sable, tripoli, laitiers, etc.) lorsque l'humidité devient supérieure à 1,5-2 %. Le dosage optimal des agents tensio-actifs est de 0,01 à 0,03 % (par rapport à la masse du ciment).

Pour le dosage de 0,05 à 0,1 %, l'efficacité du processus soit ne varie pas soit diminue ; pour le dosage  $> 0,1$  %, l'efficacité baisse brusquement dans la plupart des cas, ce qui est lié aux conditions empirées du processus (diminution du coefficient de frottement, accroissement de la vitesse de mouvement du matériaux, etc.).

L'interaction des surfactifs avec les particules de clinker et le milieu broyeur influe sensiblement sur la cinétique du processus et la composition granulométrique du ciment, ce qui s'exprime par va-

Durée de broyage -  $T$ , mn

Fig. 3 - Variation de la constante de vitesse de broyage  $K$ , du coefficient d'uniformité  $n$  et d'angle de talus naturel  $\alpha^0$  en fonction de la durée de broyage en présence de surfactifs (a - LST ; b - TEA + LST ; 1:1)

riation des constantes  $K$  et  $n$  (fig. 1 à 3).

Sous cet angle, l'étude des compositions de surfactifs présente un intérêt certain; il s'agit avant tout des compositions à base de triéthanolamine et de lignosulfonate technique (TEA + LST), dans lesquelles, à côté de l'évaluation des dépenses d'énergie spécifiques, des propriétés de résistance et de dispersion du ciment, on a étudié l'influence sur les indices  $K$ ,  $n$ ,  $d'$ ,  $\alpha^0$  et  $\gamma_v$  (Tableau I).

On a établi la sélectivité d'action des surfactifs complexes (leur quantité est de 0,025 % de la masse du ciment) par rapport aux paramètres de la cinétique du broyage et de la distribution granulométrique.

Ainsi, lors du broyage du clinker sans addition de surfactifs, la valeur de  $n$  et de  $d'$  est égale respectivement à 1,2 et  $34 \mu\text{m}$ , avec TEA à 1,38 et 23, avec LST à 1,51 et 34. Lors du broyage avec surfactif complexe (TEA + LST), ces indices sont de 1,6 à 1,7 et de 35 à 40. Lorsque la part de LST dans la composition augmente, les valeurs de  $n$

TABLEAU I

Influence des surfactifs sur la cinétique du broyage et la distribution granulométrique du ciment

Indice	Sans surfactifs	TEA	LST	Compositions de surfactifs			
				1:1	1:5	1:10	1:25
$K \cdot 10^{-2}$	6,41	2,87	5,15	4,15	4,52	4,73	5,58
$\gamma_v$	1,20	1,45	1,23	1,25	1,22	1,23	1,24
$\alpha^0$	48	60	53	49	46	57	53
$n$	1,23	1,38	1,51	1,71	1,62	1,62	1,62
$d'$	34	28	34	38	45	45	40
$E_R$							
$R_{comp28} \cdot 10^{-1}$	1,06	0,85	1,04	0,82	0,83	0,83	0,84

et  $d'$  s'élèvent. La sélectivité d'action des agents tensio-actifs se manifeste par un rapport différent des dépenses d'énergie spécifiques lors de l'évaluation de la dispersion d'après la teneur en grosse classe et la surface spécifique. Lors du broyage avec TEA, ce rapport est plus bas et avec LST plus élevé que lors du broyage sans surfactifs. La même régularité est caractéristique de  $\alpha^0$  et  $\gamma_v$ . Les valeurs maximales de  $\alpha^0$  et de  $\gamma_v$  correspondent aux ciments broyés avec TEA et atteignent  $60^\circ$  et  $1,45 \text{ g/cm}^3$ . Pour les ciments avec LST, elles sont respectivement égales à  $53^\circ$  et à 1,25. Lors du broyage avec TEA + LST en différentes proportions, ces indices s'expriment pour la plupart des compositions par des valeurs intermédiaires.

L'évaluation complexe de l'action de la composition de surfactifs sur les indices énergétiques et de résistance,  $E_R/R_{comp28}$ , a montré leur efficacité dans le domaine des rapports TEA + LST de 1:5 à 1:25.

Ainsi on a établi une possibilité de principe de contrôler le processus, les caractéristiques de dispersion et les propriétés du ciment sur la base des surfactifs complexes dont les constituants ont une action sélective par rapport au pouvoir dispersif et aux propriétés du ciment. Outre les propriétés du matériau et les paramètres du procédé (type, dosage, distribution des agents tensio-actifs), l'efficacité des procédés d'intensification physico-chimiques dépend aussi des régimes énergétique et hydrodynamique.

En partant de la conception de l'influence dominante des propriétés physiques, physico-chimiques du matériau et du milieu, la mise en étude, le contrôle et l'intensification du processus doivent être fondés sur une "adaptation" des régimes énergétique et hydrodynamique ainsi que des conditions thermiques et d'humidité et d'adsorption aux particularités de la cinétique du broyage et de la distribution granulométrique.

que. Les paramètres des régimes énergétique et hydrodynamique doivent être établis de manière à assurer à chaque stade une densité énergétique optimale exprimée par le rapport de l'énergie des actions broyantes à l'unité de volume du matériau :

$$q = \frac{E'}{V_m}, \text{ kWh/m}^3.$$

Le niveau de la densité énergétique est déterminé par les dimensions du boulet et de la particule, le diamètre du broyeur et le régime de vitesse de la charge broyante ainsi que par la vitesse et le caractère du mouvement du matériau (régime hydrodynamique), définissant la concentration du matériau dans le volume libre de l'espace utile. On a formulé les principes d'optimisation du processus :

l'énergie, la fréquence et le type des actions broyantes doivent être optimisés par rapport à la grosseur, à la broyabilité et aux propriétés d'adhésion du clinker ;

les résistances hydraulique et aérodynamique de la charge broyante et des diaphragmes doivent assurer une concentration et une vitesse de mouvement du matériau optimales, compte tenu des propriétés physiques, d'adhésion et d'autohéssion et de la distribution granulométrique requise ;

les caractéristiques d'adsorption ainsi que celles de température et d'humidité du milieu doivent assurer une manifestation optimale des effets de diminution de la résistance et de la désagrégation.

La réalisation du premier principe est possible par les procédés suivants : utilisation des schémas de broyage en plusieurs stades dans les cycles ouvert et fermé ; maintien du régime différentiel de vitesse et de la classification des corps broyants sur la base du blindage à coefficient d'adhérence variable (12) ; application au stade de broyage fin de corps broyants de petites dimensions (système "Minipebs").

La réalisation du deuxième principe consiste dans l'application des sections efficaces et rationnelles de diaphragmes des broyeurs, un rapport optimal entre longueurs des chambres et degrés de remplissage  $L_1/L_2$  et  $\varphi_1/\varphi_2$  ; le choix judicieux de la valeur  $L/D$ , de l'intensité d'aspiration et de la composition granulométrique des corps broyants. La valabilité d'une telle conception est confirmée par le travail (10) où l'on a proposé une méthode de calcul des broyeurs, compte tenu de la cinétique du broyage et de la distribution granulométrique. Les travaux (11), où l'hydrodynamique du processus a été étudiée de façon minutieuse, donnent des résultats théoriques et pratiques importants.

Enfin, le troisième principe se réalise par l'introduction des compositions de surfactifs-intensificateurs du broyage et par le maintien de la température du processus dans les limites de 90 à 140 °C.

L'optimisation des conditions physico-chimiques est surtout d'actualité pour les broyeurs de grande capacité dans lesquels la puissance et le débit augmentent proportionnellement à  $D^{2,5}$  et à  $D^{2,7}$  et l'intensité d'aspiration, proportionnellement à  $D^2$ . A côté d'une énergie élevée de l'action unitaire, aux dernières étapes du broyage ceci entraîne une élévation de la température du processus et conduit à l'accroissement du degré d'adhésion et d'agrégation et à la diminution de l'efficacité du processus.

# L'influence du traitement thermique sur la transmission $\beta \rightarrow \gamma$ -C<sub>2</sub>S

## *Influence of thermal treatment on the transition $\beta \rightarrow \gamma$ -C<sub>2</sub>S*

M. GAWLICKI, docteur, L'Académie de Mines et de Métallurgie, Cracovie, Pologne  
et W. NOCUN-WCZELIK, ingénieur.

**RESUME :** L'importance particulière de la transition polymorphique du  $\beta$ -C<sub>2</sub>S en  $\gamma$ -C<sub>2</sub>S consiste dans le fait que cette transition, outre l'augmentation du volume spécifique, provoque la perte des propriétés hydrauliques du C<sub>2</sub>S. Cette transition peut être arrêtée par un traitement thermique convenable qui limite la croissance des cristaux du  $\beta$ -C<sub>2</sub>S aux dimensions auxquelles la nucléation et la croissance des germes du  $\gamma$ -C<sub>2</sub>S n'est plus possible. La synthèse du  $\gamma$ -C<sub>2</sub>S à la température au-dessous de 1150°C ainsi que la cuisson du C<sub>2</sub>S à grains fins aux températures au-dessous de 1400°C assurent les conditions convenables de la stabilisation du  $\beta$ -C<sub>2</sub>S. Le dépassement, pendant la synthèse du C<sub>2</sub>S, de la température de la transition  $\alpha' \rightleftharpoons \alpha$  /1420-1450°C/ joue un rôle particulier dans le processus de la transition du  $\beta$ -C<sub>2</sub>S en  $\gamma$ . Aux températures 1420-1450°C le frittage du C<sub>2</sub>S est rapidement accéléré et les grains du C<sub>2</sub>S atteignent les dimensions si grandes que pendant le refroidissement suffisamment lent on obtient de grands cristaux de  $\beta$ -C<sub>2</sub>S qui se transforment facilement en  $\gamma$ . Simultanément le refroidissement rapide des échantillons du C<sub>2</sub>S cuits aux températures supérieures à 1450°C provoque la formation d'un grand nombre des cristaux du  $\alpha'$ -C<sub>2</sub>S très fins et conséquemment des cristaux du  $\beta$ -C<sub>2</sub>S également fins dans lesquels la probabilité de la formation et de la croissance des germes de  $\gamma$ -C<sub>2</sub>S est faible. La microstructure spécifique des agrégats des grains du  $\gamma$ -C<sub>2</sub>S composés d'un grand nombre des paillettes et des aiguilles couvertes d'un réseau des profondes fissures permet de supposer que la dimension critique des cristaux du  $\beta$ -C<sub>2</sub>S qui peuvent conserver la stabilité relative dans les conditions normales peut être estimée à 0,2-0,3  $\mu$ m.

**SUMMARY :** The polymorphic transition of  $\beta$ -C<sub>2</sub>S to  $\gamma$  form involving the great increase of specific volume and the loss of hydraulic properties of C<sub>2</sub>S is of particular importance in the polymorphism of C<sub>2</sub>S. One of the ways of suppressing this transition is by limiting the growth of  $\beta$ -C<sub>2</sub>S crystals. It can be realized by proper thermal treatment  $\beta$ -C<sub>2</sub>S can be stabilized when synthesis from oxides is performed at temperatures up to 1150°C or when finely ground  $\gamma$ -C<sub>2</sub>S is fired for a short time at temperatures below 1400°C. When the temperature corresponding the transition  $\alpha' \rightleftharpoons \alpha$ -C<sub>2</sub>S /1420-1450°C/ is exceeded, processes of sintering and crystal growth are rapidly accelerated. If, then, the cooling proceeds slowly,  $\beta$ -C<sub>2</sub>S forms thin crystals which easily invert to  $\gamma$ -C<sub>2</sub>S. The rapid cooling of the C<sub>2</sub>S samples from temperatures higher than the transition temperature, that is 1420-1450°C, results in the material which has large proportion of very small crystals of  $\alpha'$ -C<sub>2</sub>S. These crystals transform to  $\beta$  form on cooling. The probability of the transition of small  $\beta$ -C<sub>2</sub>S crystals to  $\gamma$  crystals is negligible. The aggregated  $\gamma$ -C<sub>2</sub>S grains are composed of numerous needle - and platelike crystals. The smallest dimension of these crystals can be estimated as to be equal to 0.2-0.3  $\mu$ m. It suggests that the dimension of the  $\beta$ -C<sub>2</sub>S crystals which can be transformed to  $\gamma$ -C<sub>2</sub>S crystals should be at least some about 0.3  $\mu$ m.

La transformation polymorphique de  $\beta$ -C<sub>2</sub>S en  $\gamma$ -C<sub>2</sub>S est une transition monotrope de la phase métastable en phase thermodynamiquement stable. Le traitement thermique, c'est-à-dire la température et le temps de la cuisson aux températures déterminées ainsi que la vitesse du refroidissement des échantillons du C<sub>2</sub>S joue un rôle important dans ce processus. L'analyse des publications consacrées au problème du polymorphisme de C<sub>2</sub>S [1-6] suggère la nécessité des études de l'influence du traitement thermique ainsi que de la composition granulométrique des matériaux examinés sur la transition  $\beta \rightarrow \gamma$ -C<sub>2</sub>S. Le problème de la granulométrie est dans ce cas particulièrement compliqué car  $\gamma$ -C<sub>2</sub>S forme des agrégats très caractéristiques, composés des aiguilles et des paillettes très minces, couvertes d'un réseau des fissures (figure 1).

Fig. 1 - Microscope à balayage.  $\gamma$ -C<sub>2</sub>S synthétisé à 1500°

Cette microstructure de  $\gamma$ -C<sub>2</sub>S ainsi que la cohésion assez faible entre les parts des agrégats rend pratiquement impossible la détermination de la composition granulométrique des échantillons et des produits de frittage et d'autopulvérisation. Pour cette raison les données comprises dans ce travail sont limitées aux fractions granulométriques prédominantes dans les échantillons analysés.

Dans la majorité des études effectuées on a utilisé, comme la matière de départ, la  $\gamma$ -modification orthosilicate de calcium très pure. La concentration du  $\beta$ -C<sub>2</sub>S dans le matériau analysé a été déterminée pour 1-2% au microscope.

Dans la première série des études on a déterminé les températures de l'autopulvérisation ainsi que la composition minéralogique des échantillons du C<sub>2</sub>S cuits aux températures différentes et dans les temps variables. Les observations étaient effectuées à l'aide du microscope aux températures élevées et la composition minéralogique était déterminée après le refroidissement par la diffraction aux rayons X en utilisant la méthode d'étalon externe  $d_p = 3,01 \text{ \AA}$ . Dans les études on a

utilisé C<sub>2</sub>S des grains de moins de 60  $\mu\text{m}$ . La fraction prépondérante était celle de 10-30  $\mu\text{m}$ .

Pour les observations au microscope aux températures élevées on a formé les petits cubes à partir du C<sub>2</sub>S sous la pression constante. La vitesse de l'échauffement et du refroidissement était constante - 10°/min. Les données obtenues sont montrées dans les tableaux I, II.

TABLEAU I

Température de la cuisson du C <sub>2</sub> S °C	Température de l'autopulvérisation en fonction du temps de la cuisson:				
	10'	30'	60'	120'	180'
1500	480	480	480	500	500
1450	460	460	470	470	480
1400	370	380	380	400	400
1350	360	380	380	390	390
1300	320	330	360	380	380
1250	300	320	320	360	360
1200	280	300	330	340	340
1150	Les échantillons ne s'autopulvérisaient pas.				
1100					

TABLEAU II

Température de la cuisson du C <sub>2</sub> S °C	% $\gamma$ -C <sub>2</sub> S après le refroidissement. Temps de la cuisson:				
	10'	30'	60'	120'	180'
1500	100	100	100	100	100
1450	100	100	100	100	100
1400	78	80	82	83	85
1350	75	75	78	80	80
1300	60	65	70	75	80
1250	60	60	65	70	75
1200	55	55	60	60	65
1150	40	45	45	46	47
1100	40	40	45	45	45

Des données placées dans les tableaux I, II résulte, que la température de l'autopulvérisation des échantillons et leur composition minéralogique sont liées avec la température de la cuisson ainsi qu'avec le temps de la cuisson à la température établie. Dans tous les échantillons cuits à la température 1450°C et 1500°C on n'a constaté, après le refroidissement, que la phase  $\gamma$ -C<sub>2</sub>S. L'abaissement de la température du traitement provoquait l'abaissement de la température de l'autopulvérisation des échantillons et de la teneur en  $\gamma$ -C<sub>2</sub>S des produits obtenus. Ces variations n'étaient pas proportionnelles à l'abaissement de la température du traitement, les plus grandes différences ont été constatées pour la variation de la température de 1450°C à 1400°C. En même temps il faut remarquer que la température d'autopulvérisation, déterminée par l'observation au microscope n'est qu'une mesure de la vitesse

de la transition  $\beta \rightarrow \gamma$ -C<sub>2</sub>S et ne peut pas être considérée comme la température du commencement de cette transition. Les températures du commencement de la transition  $\beta \rightarrow \gamma$ -C<sub>2</sub>S enregistrées aux thermogrammes d'ATD ne dépendaient que faiblement de la température du traitement du C<sub>2</sub>S, n'atteignant que 15° de différence pour les échantillons cuits à 1200°C et à 1500°C.

Les variations des températures de l'autopulvérisation du C<sub>2</sub>S et de sa composition minéralogique sont liées avec le degré du frittage des échantillons examinés. On a établi, que la contraction des préparations observée au microscope aux températures élevées pendant l'échauffement peut servir de la mesure de ce processus /figure 2/.

Fig. 2 - Les changements de surface de l'échantillon du C<sub>2</sub>S observés au microscope thermique.  $\Delta F = F_2 - F_1$ .  $F_1$  - la surface de l'échantillon de départ,  $F_2$  - la surface de l'échantillon à la température établie

Les résultats présentés montraient la contraction rapide au voisinage de la température de l'inversion  $\beta \rightarrow \gamma$ -C<sub>2</sub>S et s'accordaient avec ceux de S. Chroby /4/. Les études au microscope à la température élevée ne montraient pas au-dessous de 900°C des changements remarquables bien que l'augmentation de la masse spécifique accompagne la transition  $\gamma \rightarrow \alpha$ -C<sub>2</sub>S /7/. Les études effectuées dans le même intervalle de température à l'aide du microscope à balayage à la température élevée ont montré, que les contractions des fibres conduisaient à la diminution de son adhésion mutuelle et au lâchage de la microstructure fibreuse des agrégats des grains du C<sub>2</sub>S sans augmentation des dimensions de ces agrégats. Ces changements n'étaient pas décelable au microscope à la température élevée à cause de la considérable porosité des échantillons examinés. On pouvait remarquer quand même, que les échantillons du C<sub>2</sub>S cuits à 700-900°C étaient considérablement moins cohérents que ceux de départ.

La composition granulométrique du matériau de départ exerçait l'influence sur le degré de

la transition  $\beta \rightarrow \gamma$ -C<sub>2</sub>S particulièrement quand l'échantillon était cuit à une température au-dessous de 1450°C. L'augmentation du degré de dispersion provoquait l'abaissement de la température de l'autopulvérisation ainsi que l'abaissement de la teneur en  $\gamma$ -C<sub>2</sub>S du matériau refroidi. Les différences étaient plus poussées pour les températures de traitement du C<sub>2</sub>S plus basses. Les résultats des études effectués à 1300°C et à 1500°C /2 heures de la cuisson, refroidissement lent/ sont groupés au tableau III.

No.	Fraction prédominante > 70% μm	%γ-C <sub>2</sub> S après le refroidissement. Température de la cuisson du C <sub>2</sub> S:	
		1500°C	1300°C
1	60 - 80	100	87
2	10 - 30	100	85
3	5 - 10	93	35
4	2 - 5	84	10
5	< 2	72	-

La désintégration des agrégats des grains du  $\gamma$ -C<sub>2</sub>S de départ en petits fragments rend le processus du frittage et de la recristallisation du C<sub>2</sub>S difficile. Pendant le refroidissement un grand nombre de petits cristaux de  $\beta$ -C<sub>2</sub>S se forme et dans cette masse les germes de la phase  $\gamma$ -C<sub>2</sub>S ne peuvent ni se produire ni se développer. Par contre si les agrégats des grains du  $\gamma$ -C<sub>2</sub>S de départ ne furent pas désintégrés les grains peuvent se friter et recristalliser pendant l'échauffement, surtout dans les régions des agrégats. Les grandes surfaces d'adhésion des fibres et des paillettes ainsi que la concordance de l'orientation de leur structure favorisent ce processus. La phase qui paraît en train de refroidissement se compose des cristaux suffisamment grands qu'elle peut se transformer en  $\gamma$ . Pendant la cuisson du C<sub>2</sub>S à la température supérieure de 1450°C le processus du frittage comprend des espaces plus grandes que l'ensemble des fibres et des paillettes appartenant aux mêmes agrégats et il est favorisé par la transition de  $\alpha_H$  en  $\alpha$ -C<sub>2</sub>S à 1420°C. Si le temps du traitement à une température élevée est suffisamment long, on obtient pendant le refroidissement les cristaux du  $\beta$ -C<sub>2</sub>S tellement grands, qu'aussi bien la nucléation que la croissance des germes du  $\gamma$ -C<sub>2</sub>S en sont possibles.

Prenant en considération des résultats obtenus jusqu'au présent il faut admettre que la répétition des cycles "cuisson - refroidissement" du C<sub>2</sub>S conduit à la désintégration des agrégats des grains et en conséquence à l'augmentation de la teneur en  $\beta$ -C<sub>2</sub>S et à l'arrêt de l'autopulvérisation à condition que la température de la cuisson soit suffisamment basse. Cette hypothèse a été confirmée par la répétition des cycles "cuisson - refroidissement" du C<sub>2</sub>S dans les intervalles de température les suivants: 20° - 1200° - 20°, 20° - 1300° - 20°, 20° - 1400° - 20°C.

Les études au microscope, par la diffraction aux rayons X et par l'ATD ont montré, qu'après avoir répété les cycles "cuisson - refroidissement" la teneur en  $\beta$ - $C_2S$  du matériau refroidi systématiquement augmentait et l'autopulvérisation était arrêtée tandis que la teneur en  $\gamma$ - $C_2S$  ne dépassait pas 40%. Le nombre des cycles "cuisson - refroidissement" nécessaires pour arrêter l'autopulvérisation dépendait de la température et du temps de la cuisson et il avait valeurs les suivantes: 1200°/2h - 2, 1300°/2h - 3, 1400°/2h - 7. La répétition des cycles "cuisson - refroidissement" aux températures 1450°C et 1500°C ne provoquait pas des variations de la température de l'autopulvérisation et de la composition minéralogique.

Les synthèses du  $C_2S$  effectuées en partant du mélange de silicagel et de  $CaCO_3$  ainsi que de silicagel et de  $Ca(OH)_2$  ont confirmé l'influence du degré de frittage et de la recristallisation du  $C_2S$  sur sa composition minéralogique.

TABLEAU IV		
Temp. de la synthèse du $C_2S$ °C	% $\gamma$ - $C_2S$ après le refroidissement. Matériaux de départ utilisés dans la synthèse:	
	$CaCO_3 + SiO_2 \cdot nH_2O$	$Ca(OH)_2 + SiO_2 \cdot nH_2O$
1500	100	100
1400	85	83
1300	80	75
1200	65	60
1180	45	35
1160	15	5
1140	5	-
1120	-	-
1100	La synthèse du $C_2S$ de $CaCO_3$ et de silicagel n'a pas été effectuée aux 800° - 1000°C	-
1000		-
900		-
800		-

Le temps de la cuisson a été établi en fonction de la teneur en  $CaO$  libre et allait de 48 jusqu'à 150h.

La série suivante des études a montré que la vitesse du refroidissement à la température de l'inversion de  $\alpha$ - $C_2S$  en  $\alpha'$  avait de l'influence importante sur l'autopulvérisation ainsi que sur la composition minéralogique après le refroidissement d'un échantillon. On a obtenu les conditions du refroidissement rapide en immergeant des échantillons cuits au nitrogène liquide, ce qui a donné les produits composés des cristaux du  $\beta$ - $C_2S$  si fines que la probabilité du développement dans cette masse des germes stables du  $\gamma$ - $C_2S$  était très faible. La cuisson des échantillons à la température supérieure à 1450°C, le refroidissement lent jusqu'à la température 1400°C et puis le refroidissement rapide dans le nitrogène liquide ne provoquaient pas de stabilisation du  $\beta$ - $C_2S$  mais conduisaient à l'obtention du mélange du  $\beta$  et  $\gamma$ - $C_2S$ .

Les relations entre les conditions du traitement thermique et la stabilisation du  $\beta$ - $C_2S$  présentées dans le travail permettent de déterminer les conditions dans lesquelles les cristaux du  $\beta$ - $C_2S$  n'atteignent pas de dimension critique, ce qui rend possible la nucléation ainsi que la croissance des germes du  $\gamma$ - $C_2S$ . Les données présentées indiquent, que cette dimension doit être au-dessous de 2  $\mu m$ . Cette estimation coïncide avec des observations de l'autopulvérisation du  $C_2S$  dans les agglomérés contenant à côté de  $C_2S$  des aluminates de calcium /figures 3, 4/.

Fig. 3 - Microscope à balayage. Les formes du  $\gamma$ - $C_2S$  très caractéristiques pour les agglomérés contenant les aluminates de calcium à côté du  $C_2S$

Fig. 4 - Fragment de la figure 3

L'épaisseur des paillettes du  $\gamma$ - $C_2S$  dans ces échantillons, et par cela même les plus petites dimensions des grains du  $\beta$ - $C_2S$ , va de 0,2 à 0,3  $\mu m$ . On peut confirmer cette hypothèse en déterminant les dimensions des cri-

stallites du  $\beta$ -C<sub>2</sub>S stabilisé par l'addition de bore, d'arsenic ou de phosphore, par la méthode de la diffraction des rayons X. Ces dimensions, rapprochés à la limite d'utilité de cette méthode atteignent les valeurs 0,2-0,3  $\mu$ m.

# Particularités cristallochimiques et propriétés des phases du clinker de ciment portland en fonction des conditions de cuisson et de refroidissement

## *Crystal chemical peculiarities and phase properties of portland cement clinker depending on the conditions of burning and cooling*

I.F. PONOMAREV, professeur, docteur ès sciences techniques,

P.O. GAYDJOUROV, candidat ès sciences techniques,

A.P. ZOUBEKHINE, candidat ès sciences techniques,

V.V. KITAEV, ingénieur, Institut Polytechnique de Novotcherkassk, U.R.S.S.

**RESUME :** On a examiné des particularités cristallochimiques et des propriétés des phases essentielles de clinker des solutions ferriques solides et leur composition en fonction du moyen de cuisson et de refroidissement du clinker. On a établi, par effet Mössbauer, la position des ions de fer  $Fe^{3+}$  et  $Fe^{2+}$  dans la structure de  $C_3S$  et  $C_2S$ , leur coordination, les limites de la solubilité et la distribution par phases en fonction de la vitesse de refroidissement. Le caractère fortement désordonné de la structure de l'alite et l'augmentation de son activité hydraulique sont conditionnés par l'introduction, dans les limites de solubilité, de l'oxyde ferreux dans  $C_3S$ . Mais une quantité élevée de  $FeO$  conduit à la destruction de l'alite ainsi qu'à une forte diminution de la résistance du ciment. La dissolution des oxydes de fer dans les silicates, dans les conditions d'une cristallisation en équilibre instable lors d'un brusque refroidissement du clinker, est examinée. Les composés ferreux sont fixés dans la phase vitreuse, ce qui contribue à l'élévation de la qualité du ciment.

**SUMMARY :** Crystal chemical peculiarities and properties of the main clinker phases, ferri-ferrous solid solutions and their composition have been studied depending on the method of burning and clinker cooling. Crystal chemical sites of ions  $Fe^{3+}$  and  $Fe^{2+}$  in the structure of  $C_3S$  and  $C_2S$ , their coordination, limit solubility and phase distribution depending on the cooling rate have been established by Mössbauer spectroscopy. The introduction of ferrous oxide into  $C_3S$  within the solubility range accounts for a high disorder of alite structure and the increase of its hydraulic activity. However the increased amount of  $FeO$  results in destruction of alite and significant decrease of cement strength. On rapid cooling of clinker non-equilibrium phase crystallization prevents the solution of ferrous oxides in silicate minerals while ferri-ferrous compounds are fixed in the vitreous phase which promotes the increase of cement quality.

Les phases ferrifères déterminent dans une grande mesure le processus de la clinkérisation et exercent une influence importante sur les propriétés du ciment portland, en fonction de leurs quantités, conditions de cuisson et de refroidissement. On a étudié des particularités cristallochimiques des phases de clinker contenant les oxydes de fer au cours de la formation des ciments portlands à faible teneur en fer (blanc) et ordinaire. On a mis en évidence, par effet Mössbauer, que la formation des phases ferrifères au cours de la cuisson du mélange brut à faible teneur en fer (fig. 1b) diffère au plus haut degré de leur formation dans le mélange ordinaire (fig. 1a).

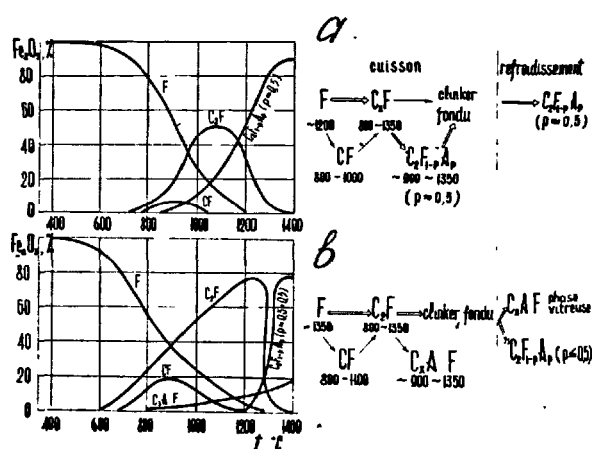

Fig. 1 - Répartition de fer par phases et schémas de formation des phases ferrifères au cours de la cuisson du clinker de ciment portland ordinaire (a) et blanc (b).

L'absence de la phase aluminoferrite dans la charge en cuisson, au cours de la formation du ciment portland blanc et l'existence séparée de  $C_2Fe$  et de la solution solide  $C_2A:F$  sont une des causes de la formation de la phase fondue de clinker aux températures élevées et du ralentissement de la formation des minéraux du clinker blanc. La composition des phases ferreuses est, dans ce cas, fonction du mode de refroidissement. Dans le cas de refroidissement lent par air, quelque 50 à 60 % des oxydes de fer entrent dans la composition de la solution solide  $C_2A:F$  et de la phase vitreuse (dissolution des quantités microscopiques de  $Fe_2O_3$  dans  $C_2S$  et  $C_2F$  n'est pas exclue), alors que le reste de  $Fe_2O_3$  forme une phase aluminoferrite indépendante dont la composition est voisine de  $C_2AF$  (fig. 2b). Par contre, en cas de refroidissement rapide par eau, l'oxyde ferrique se fixe essentiellement (90-100 %) dans la composition de la phase vitreuse et de la solution solide  $C_2A:F$  (fig. 2a). La fixation des oxydes de fer dans la composition de la phase

vitreuse ou dans  $C_2A$  conditionne l'augmentation de la blancheur du clinker de 10 à 20 % en fonction de la quantité d'oxyde ferrique dans le mélange.

Fig. 2 - Spectres Mössbauer du clinker de ciment portland blanc au refroidissement par eau (a) et par air (b).

Les conditions de cuisson réductrice du clinker à faible teneur en fer (blanc), lorsque se forment les ions  $Fe^{2+}$ , exercent un effet positif sur la rapidité de la formation des minéraux et sur les propriétés du clinker (blancheur, résistance) dans les conditions de refroidissement rapide par eau.

Quant à l'influence de  $FeO$  se formant dans le clinker de ciment portland ordinaire pendant la cuisson réductrice dans des fours industriels, elle dépend essentiellement de sa quantité et sa répartition par phases.

Nous avons établi les particularités de la formation du clinker et mis en évidence les conditions prévenant une action négative de  $FeO$  sur la résistance du ciment. En l'absence de la phase liquide, l'oxyde ferreux pénètre à  $C_2S$  et  $C_2F$  et compose des solutions solides de substitution du type :

Il a été établi, par effet Mössbauer, que la limite de la solubilité de  $FeO$  dans  $C_2S$  ne dépasse pas 1,0 %. C'est que, malgré la présence d'isomorphisme isovalent, les paramètres cristallochimiques des ions  $Ca^{2+}$  et  $Fe^{2+}$  sont essentiellement différents, en particulier leurs rayons, leur charge négative et leur potentiel polarisant qui présentent pour  $Ca^{2+}$  et  $Fe^{2+}$  respectivement

1,04 et 0,80 Å ; 1,04 et 1,70 eV ; 0,66 et 0,89.

Lors de la pénétration d'une quantité de FeO supérieure à 1,0 %, l'oxyde détruit  $C_2S$  et il se forme des phases indépendantes : triferriite  $CaO \cdot FeO \cdot Fe_2O_3$  et la composition  $0,54CaO \cdot 1,46FeO \cdot SiO_2$  (fig. 3).

Fig. 3 - Radiogrammes des échantillons  $C_2S$  cuits dans un milieu réducteur et refroidis (1-3 - lentement, 4 - vite) : 1 -  $C_2S$  ; 2 -  $C_2S$  + 1 % FeO ; 3, 4 -  $C_2S$  + 3 % FeO.

Le chimisme du processus destructif peut être représenté par l'équation :

Lorsque la teneur en FeO est excédentaire, la destruction de  $C_2S$  peut s'expliquer par les particularités de sa structure composée selon N.V. Bélov (1, 2), des couches d'octaédres  $CaO_6$  ou d'unités structurales à sept sommets  $CaO_7$ , reliés entre eux et aux tétraédres  $SiO_4$  par leurs arêtes et plans.

Lorsqu'on substitue  $Fe^{2+}$  à  $Ca^{2+}$ , sensiblement différents par leur charge négative et leur potentiel polarisant, il se produit des changements importants du type de la liaison et des déformations du réseau cristallin ce qui conduit, en fin de compte, à la destruction de la structure.

$C_2S$  est plus stable que  $C_3S$  lorsqu'il y a pénétration de FeO. La limite de la solubilité de FeO dans  $C_2S$  est de 3 %. Du fait de

la structure en flots de  $C_2S$ , composée de tétraédres isolés  $SiO_4$  et de polyèdres  $CaO_6$  ou  $CaO_7$ ,  $C_2S$  possède une plus grande capacité de déformation et modification du réseau cristallin. Ceci rend possible la pénétration d'une plus grande quantité de FeO sans destruction du réseau cristallin de  $C_2S$ .

La présence de la fusion de clinker modifie substantiellement l'effet de FeO sur les minéraux-silicates. Dans ce cas, la solubilité de l'oxyde ferreux étant limitée dans le minéral siliceux  $C_2S$  cristallisant, en premier lieu, à des températures élevées, il se produit une redistribution de FeO par phases dans la fusion de clinker. L'oxyde ferreux est essentiellement fixé dans la phase vitreuse. La vitesse de refroidissement y joue un rôle très important : plus est grande la vitesse de refroidissement du clinker à partir des températures les plus élevées possible et plus est élevé le degré de solubilité de FeO dans la phase vitreuse. Lors de la fixation de l'oxyde ferreux dans la phase vitreuse la pénétration de FeO dans l'alite peut être limitée et même nulle ce qui prévient l'effet négatif de l'oxyde ferreux sur la résistance de la pierre de ciment.

Des essais physico-mécaniques des minéraux siliceux ferrifères (tableau I) ont montré que l'introduction jusqu'à 1 % de FeO dans  $C_2S$  et  $C_3S$  augmente la résistance de la pierre de ciment de 25 % à 30 % du fait de la formation de la structure déficiente chimiquement plus active. Si l'on augmente la quantité de FeO dans les conditions de refroidissement lent, il se produit un décroissement de la résistance de  $C_2S$  et de  $C_3S$  ; elle est plus forte chez  $C_2S$  du fait de la destruction de sa structure.

TABEAU I

Dépendance de la résistance de  $C_2S$  et  $C_3S$  de la teneur en FeO et de la vitesse de refroidissement au cours de la cuisson réductrice

Minéral	Teneur en FeO, %	Refroidissement	Limite de la résistance à la compression (kgf/cm <sup>2</sup> ) après, jours			
			3	7	28	90
$C_3S$	sans addition	lent	146	304	315	319
"	1	"	185	401	406	404
"	3	"	98	180	193	189
"	5	"	0	0	15	37
$C_3S$	sans addition	rapide	167	325	340	343
"	1	"	192	418	435	437
"	3	"	165	389	395	403
"	5	"	150	366	378	387
$C_2S$	sans addition	lent	8	16	54	260
"	1	"	20	38	97	318

1	2	3	4	5	6	7
C <sub>2</sub> S	3	lent	18	29	80	305
"	5	"	16	26	85	306
C <sub>2</sub> S	sans ad- dition	rapide	10	22	69	287
"	1	"	25	56	112	335
"	3	"	23	50	108	330
"	5	"	17	45	97	318

Par contre dans les conditions de refroidissement rapide, on n'observe pas de diminution de la résistance ce qui est lié à la fixation de FeO dans la fusion et, par conséquent, l'effet négatif d'oxyde ferreux ne se produit pas. Ceci est bien confirmé dans le cas des clinkers industriels obtenus lors des essais dans les fours rotatifs 4,5x170 m dans les conditions de cuisson réductrice est oxydante (tableau II).

TABLEAU II								
Relation entre la résistance des clinkers industriels et les conditions de cuisson et de refroidissement								
Condi- tions de cuisson	Refroi- disse- ment	Te- neur en FeO, %	Limite de résistance (kgf/cm <sup>2</sup> ) après, jours					
			à la fle- xion			à la com- pression		
			3	7	28	3	7	28
oxydante	par air	0,07	49	51	59	265	310	470
oxydan- te	par air- eau	0,07	52	57	68	296	347	528
réduc- trice	par air	1,30	45	47	54	239	278	422
réduc- trice	par air- eau	1,37	48	52	58	300	345	530

Comme il apparaît du tableau II, le refroidissement lent du clinker de cuisson réductrice, diminue la résistance de 10 %. Par contre dans le cas de refroidissement rapide la résistance est loin de baisser et même elle augmente un peu.

#### CONCLUSIONS

1.- On a établi les particularités cristallographiques des phases ferrifères, la composition et la structure des clinkers à faible teneur en fer et des clinkers ordinaires dans les cas de cuisson réductrice et oxydante.

2.- L'introduction de l'oxyde ferreux dans C<sub>2</sub>S, dans les limites de solubilité (moins de 1 %), conditionne une forte perturbation de la structure de l'alite et une élévation de son activité hydraulique. L'augmentation de la quantité de FeO au-delà de la limite de solubilité conduit à la destruction de l'alite et à une diminution sensible de la résistance de la pierre de ciment.

3.- Le refroidissement rapide du clinker fixe une composition optimale des phases ferreuses, détermine une répartition voulue des oxydes de fer par phases et prévient un effet négatif de l'oxyde ferrifères sur la résistance du ciment.

# On particle size distribution in cement hydration

## *L'effet de la granulométrie sur l'hydratation du ciment*

Torben KNUDSEN, Technical University of Denmark, Lyngby, Denmark.

RESUME : Le temps que met une pâte d'un ciment Portland pour arriver à un degré d'hydratation donné, dépend de sa finesse. Par cette publication, nous désirons démontrer que la forme de la courbe du degré d'hydratation-temps du ciment Portland est étroitement liée à la granulométrie du matériau. Les détails de la cinétique de base (laquelle détermine la réaction chimique) ont moins d'importance. Il est capital de comprendre ce fait quand on veut essayer d'interpréter des essais d'hydratation du ciment Portland du point de vue cinétique, car la large granulométrie de ce matériau ne permet pas d'obtenir des informations détaillées sur la cinétique des réactions. Par des exemples numériques et des déductions mathématiques, nous cherchons à établir une base qui explique l'influence de la granulométrie sur l'hydratation du ciment Portland. Une équation sous une forme analytique simple, de l'hydratation-temps, dérivée de la transformation de Laplace, se conforme bien aux résultats expérimentaux et peut avoir une importance dans la pratique.

SUMMARY : The time for a Portland cement paste to reach a certain degree of hydration is a function of its fineness. We tend to show in the present paper that the form of the hydration degree-time curve for Portland cement is closely related to the form of the particle size distribution for this material. The detailed form of the underlying kinetics governing the reaction of the single particles is of minor importance. Recognition of this fact is important, when trying to interpret hydration experiments with Portland cement in terms of reaction kinetics. Detailed information about reaction kinetics is prohibited by the broad particle size distribution of this material. By numerical examples and mathematical derivations we attempt to establish a foundation for the understanding of the influence of particle size distribution on hydration-time behaviour of Portland cement. A hydration-time equation of a simple analytical form, derived from a Laplace transformation formulation of the problem, compares favorably with experimental data, and may prove to be of practical value.

## INTRODUCTION

Specific surface has generally been used as the practical measure of the fineness of Portland cement. Further parameters for a more detailed representation of the particle size distribution (p.s.d.) have not found technical recognition. Recently however, the approach has been broadened. Locher et al (1) and Frigione et al (2) have studied the influence of p.s.d. on compressive strength. Cements with various p.s.d.'s, but the same specific surface were tested, and the narrow distributions were found to result in higher strength. Frigione et al explain this observation by showing, that the narrower the distribution the higher the degree of hydration, and thus the higher the strength.

In the Tokyo symposium 1968 on the chemistry of cement John H. Taplin presented work on hydration kinetics of various hydraulic cements (3). In the quantitative evaluations of the data he included explicitly the influence of the p.s.d.. In his discussions of the works of other authors in the field of hydration he stressed the importance of p.s.d. in the interpretation of kinetic experiments (4).

The aim of the present investigation is to establish the general relation between p.s.d. and the hydration-time curve for Portland cement. The numerical examples and formal derivations presented in this paper will show, that the form of the broad p.s.d. of a Portland cement is very dominating in its influence on the form of the hydration-time curve. The form of the kinetic equation governing the reaction of the single particle is of comparatively smaller influence. Only the fundamental characteristics of the kinetic equation, i.e. whether of linear or parabolic form (3) is not effectively blurred by the influence of the broad p.s.d..

As an introductory illustration of the kind of relations we shall deal with in this paper, consider Table I. Measured values of the degree of hydration of a rapid hardening Portland cement at 20°C is given as a function of time. To compare with these values the cumulative p.s.d. of the same cement is presented in the last row. Values of the p.s.d. have been chosen such that 1 hour corresponds to 0.4 μm, i.e. time is multiplied by 0.4 μm/h to give the corresponding grain size. The cumulative p.s.d., when subjected to this simple transformation from grain size to time, is seen to predict the hydration-time curve with fair approximation.

Table I. Degree of hydration of a rapid hardening Portland cement at 20°C compared with the cumulative p.s.d. of the cement. Time and size values are in constant proportions.

Time, hours	5	10	20	30	40	60	80	160
Degree of hydration, %	5	21	46	58	66	75	81	90
Fraction passing, w%	10	20	37	50	60	73	83	98
Grain size, μm	2	4	8	12	16	24	32	64

## THEORETICAL PART

## Formulae for p.s.d. of Portland cement

Many formulae relating to p.s.d. of tube milled products have been suggested in the literature (5). Some have an empirical nature, some are derived from theoretical considerations. In this work we shall make use of the Rosin and Rammler's law (6) in the form:

$$W(r) = B \exp(-Br) ; C(r) = 1 - \exp(-Br) \quad (1)$$

where  $r$  is the grain size,  $B$  a constant,  $C(r)$  is the cumulative weight distribution, which is the integrated form of  $W(r)$ . We shall also make use of an extension of eq.(1) originally suggested by Gille (7), but here in a modified form:

$$W(r) = \frac{BC}{C-B} \{ \exp(-Br) - \exp(-Cr) \} \quad (2)$$

$$C(r) = 1 - \frac{C}{C-B} \exp(-Br) + \frac{B}{C-B} \exp(-Cr)$$

Experimental data for p.s.d. for normal and rapid hardening Portland cement from ref.(5) were used to test eq.(1) and (2). Eq.(1) was found to be accurate down to  $r \approx 1 \mu m$ , whereas eq.(2) gave a perfect fit down to  $r \approx 0.1 \mu m$ . This is verified in Fig.1.

Fig.1. Particle size distribution of a normal and a rapid hardening Portland cement, from ref.(5). Lines representing eq.(2), with constants:  $B=0.0297$ ,  $C=5.05$  for normal, and  $B=0.0595$ ,  $C=1.28$  for rapid hardening cement.

A formula for specific surface  $S$  can be derived from eq.(2):

$$S = \frac{6}{\rho} \int_0^{\infty} \frac{W(r)}{r} dr = \frac{6}{\rho} \frac{BC}{C-B} \ln \frac{B}{C} \quad (3)$$

Here we have adopted the definition of  $r$  used in ref. (5): particle shape is a cube, with edge length  $r$ .  $\rho$  is density. Inserting the constants found in Fig.1 we get for the specific surface of the normal and rapid hardening Portland cement respectively:  $2950 \text{ cm}^2/\text{g}$  and  $3830 \text{ cm}^2/\text{g}$ . These values are close to the blaine values for the two cements.

## Kinetics of hydration

In his work on hydration kinetics of hydraulic cements, Taplin (3) tested his experiments against the kinetic equations:

$$1 - (1 - \alpha_1)^{1/3} = \frac{kt}{r} ; \alpha_1 = 1 \text{ for } \frac{kt}{r} > 1 \quad (4a)$$

$$3 - 3(1 - \alpha_2)^{2/3} - 2\alpha_2 = \frac{kt}{r^2} ; \alpha_2 = 1 \text{ for } \frac{kt}{r^2} > 1 \quad (4b)$$

where  $\alpha_i$  ( $i=1,2$ ) is the degree of reaction,  $t$  the reaction time and  $k$  a reaction constant. Both equations can be derived from a shrinking core model (8), eq. (4a) by assuming the resistance to be in the chemical

reaction at the reaction boundary and eq.(4b) by assuming the diffusion through the inner product to be the rate controlling factor.

By writing eqs.(4) in the form:

$$\alpha_i(k,t,r) = \alpha_i(kt/r^i) ; (i=1,2) \quad (5)$$

we do not confine ourselves to any specific form of the kinetic equation, but merely state the function  $\alpha_i$  to be a function of the single variable  $kt/r^i$ . In accordance with Taplin we shall designate the cases  $i = 1$  and  $2$  linear and parabolic kinetics respectively, although we use this designation in a somewhat broader sense, as no explicit form is given to  $\alpha_i$ . The case  $i = 1$  will be of special importance to us since Portland cement, according to our findings hydrate according to linear kinetics. It should be noted, that reaction time  $t$  is measured from the end of the dormant period.

#### Combining kinetics and p.s.d.

We shall in the following make use of the basic equation:

$$\alpha_i(k,t) = \int_0^\infty \alpha_i(k,t,r)W(r)dr \quad (6)$$

which relates the degree of hydration for the total system  $\alpha_i(k,t)$  to the degree of hydration for the single particle  $\alpha_i(k,t,r)$  and the weight distribution function  $W(r)$ . Eq.(6) is based on at least two basic assumptions about the hydration of the total particulate system:

- Particles react independently.
- Particles need be classified only according to their size  $r$ .

Assumption a) are expected to be violated for very low water/cement ratios. Assumption b) excludes the influence of factors such as particles having different chemical compositions.

#### Numerical example of the use of eq.(6)

In the numerical example of the use of eq.(6) to follow, the particle system was divided into 127 size classes, with size range  $1\mu m$ , and weight fractions according to the p.s.d.:  $W(r) = 0.03\exp(-0.03r)$ . This p.s.d., as shown earlier, is typical of normal hardening Portland cement.

We wanted to see the effect of the analytical form of eq.(5) on the hydration behaviour of the total system. Therefore we included several different kinetic equations in our calculations. These kinetic equations are shown in Fig.2. Kin.1-4 were primarily chosen so as to cover a broad range of functional forms. Only kin.2 and 3 have an obvious physical meaning. They are all examples of linear kinetics.

The results of the calculation is shown in Fig.3. The constants in kin.1-4 was chosen so as to make the curves cross at  $\alpha_1 = 0.5$ . The small differences between the curves are striking from this calculation. Especially curve 2 and 3 are hardly different on the graph, and yet they correspond to two distinctly different forms of kinetics. This is a numerical demonstration of hydration behaviour of Portland cement being insensitive to the form of kinetics of the single grains. The broad p.s.d. of Portland cement blurs the kinetic details. Parabolic kinetics can be differed from linear, as demonstrated on Fig.4.

Fig.2. Kinetic equations used in the numerical example of calculation of eq.(6).

Fig.3. Results of calculations using eq.(6), the kinetic equations from Fig.2 and  $W(r) = 0.03\exp(-0.03r)$ . Log scale on abscissa axis.

In Fig.3 curve 1 and 4 are of special interest to us. Curve 1, as will be proved later, is conformal with the cumulative p.s.d. curve. Curve 4 can be given exact analytical form, which will prove of practical value in the numerical representation of hydration data for Portland cement.

Fig.4. Approximate areas for linear and parabolic kinetics of ordinary Portland cement.

### Convolution theorem

In the following we shall derive a general relationship of formal and conceptual significance for the understanding of the influence of the form of the p.s.d. on reaction degree-time curves. We have called it the convolution theorem. We start from the basic eq.(6) and assume that particle kinetics obey eq.(5):

$$\alpha_i(\tau) = \int_0^\infty \alpha_i(\tau/r) W(r) dr \quad (7)$$

where  $\tau \equiv kt^{1/i}$ , ( $i=1,2$ ). Using the relation between weight distribution  $W(r)$  and cumulative weight distribution  $C(r)$ :  $dC(r) = W(r)dr$ , and integrating by parts we get:

$$\alpha_i(\tau) = \alpha_i(\tau/r)C(r)|_0^\infty - \int_0^\infty C(r) d\alpha_i(\tau/r) \quad (8)$$

By virtue of  $C(0) = 0$  and  $\alpha_i(0) = 0$  this reduces to:

$$\alpha_i(\tau) = -\int_0^\infty C(r) d\alpha_i(\tau/r)$$

The differential of  $\alpha_i$  can be written:

$$\frac{d\alpha_i(\tau/r)}{d(\tau/r)} \frac{\partial(\tau/r)}{\partial r} dr = -\alpha_i'(\tau/r) \frac{1}{r} \frac{dr}{r} \quad (9)$$

where:

$$\alpha_i'(\tau/r) \equiv \frac{d\alpha_i(\tau/r)}{d(\tau/r)}$$

and by insertion into eq.(9) we get:

$$\alpha_i(\tau) = \int_0^\infty C(r) \alpha_i'(\tau/r) \frac{1}{r} \frac{dr}{r} \quad (10)$$

Changing now the variable of integration,  $r$  to  $\ln r$  we finally arrive at:

$$\alpha_i(\ln \tau) = \int_{-\infty}^{\infty} C(\ln r) \alpha_i'(\ln \tau - \ln r) \exp(\ln \tau - \ln r) d \ln r \quad (11)$$

It should be noted, that changing the independent variables should result in a corresponding change of the functions. For the sake of physical clarity we do not make a change of function symbols, as the physical meaning of the functions are unchanged.

This final relation has the form of a convolution integral:

$$f(y) = \int_{-\infty}^{\infty} h(x) g(y-x) dx \quad (12)$$

with  $y$  corresponding to  $\ln \tau$  and  $x$  to  $\ln r$ .

It should be noted, that:

$$\alpha_i'(\ln \tau - \ln r) \exp(\ln \tau - \ln r) \rightarrow 0 \text{ for } \ln r \rightarrow +\infty \quad (13)$$

which of course is a necessary condition for the integral in eq.(11) to have meaning.

The content of eq.(11) may be stated in words: When the cumulative weight distribution function is plotted against  $\ln r$  the degree of hydration- $\ln \tau$  function can be derived from this function by convolution with  $\alpha_i'(x) \exp(x)$ , a function depending solely on the single particle reaction kinetics. This convolution formalism illustrates the relation between the three fundamental curves:  $\alpha_i(k, t)$ ,  $\alpha_i(k, t, r)$  and  $C(r)$  in a illuminative way, and its only condition is, that particle kinetics should obey eq.(5).

The change in shape from  $C(\ln r)$  to  $\alpha_i(\ln \tau)$  accomplished by convolution according to eq.(11) depends mainly on the width of the convolution function  $\alpha_i'(\ln \tau - \ln r) \exp(\ln \tau - \ln r)$  relative to the width of the cumulative weight distribution  $C(\ln r)$ . A small relative width of the convolution function will result in a small change of shape and vice versa. In the extreme case of  $\ln 1$  in Fig.2 the convolution function is infinitely narrow, as it is the first derivative of a step function. In this case the  $C(\ln r)$  is not changed in shape by convolution according to eq.(11), but  $\alpha_i(\ln \tau)$  is merely a replica of this function, in the new variable  $\ln \tau$ . This proves our earlier postulate, that curve 1 in Fig.3 was the cumulative p.s.d. after the change of variables  $t$  to  $r$ . Thus for Portland cement the change in shape from  $C(\ln r)$  to  $\alpha_i(\ln \tau)$  can be seen in Fig.3, namely the change in shape from curve 1 to curves 2-4, as the latter three represents more realistic approaches to the particle kinetics.

Increasing the width of the p.s.d. tends to decrease the difference between  $C(\ln r)$  and  $\alpha_i(\ln \tau)$  which means, that the kinetic information tends to be lost.

In closing this paragraph it should be mentioned, that when we use the independent variable  $\ln \tau$ , the position of the  $\alpha_i$  function along the  $\ln \tau$ -axis is determined by eq.(11). The position along the  $\ln \tau$ -axis depends on the value of  $k$ .

### The Laplace transformation formalism

In the preceding paragraph the derivation of the convolution theorem assumed single particle kinetics to obey eq.(5). In the derivation of the Laplace transformation formalism we shall further assume the p.s.d. to be of the form:  $W(r) = B \exp(-Br)$ , i.e. a form typical of Portland cement.

With this additional assumption our basic eq.(6) can be written:

$$\alpha_i(B, \tau) = \int_0^\infty \alpha_i(\tau/r) B \exp(-Br) dr \quad (14)$$

Changing the integration variable we get:

$$\alpha_i(B\tau) = \int_0^\infty \alpha_i(r/\tau) B \tau \exp(-B\tau(r/\tau)) d(r/\tau) \quad (15)$$

The integral on the R.H.S. is the Laplace integral with the dummy variable  $r/\tau$ . With the accepted notation for this integral:

$$L\{F(x)\} \equiv \int_0^\infty F(x) \exp(-yx) dx \quad (16)$$

we finally arrive at:

$$\alpha_i(B\tau) = B\tau L\{\alpha_i(r/\tau)\} \quad (17)$$

Formula (17) is convenient, as it puts the problem of finding the influence of the p.s.d. of Portland cement on hydration measurements into a solid mathematical framework. Consider the way the variables  $B$ ,  $k$  and  $t$  enter into the equation. They enter as factors in the variable  $Bkt^{1/i}$ , which means, that the material variables  $B$  and  $k$  have the same influence on the  $\alpha_i(B\tau)$ -curve. This explains the often made observation, that a change of fineness and a change in temperature ( $k$  is a function of temperature) has the same effect on the  $\alpha_i(B\tau)$ -curve. This can be more clearly seen by a change of variables:

$$\alpha_i(B\tau) = \alpha_i(\exp(\ln B + \ln k + (1/i) \ln t)) \quad (18)$$

Now it is apparent, that a change of  $B$  and  $k$  works in the same direction, i.e. it translates the  $\alpha_i(B\tau)$ -curve along the  $\ln\tau$ -axis without a change in the shape of the curve.

#### Exact solutions to the Laplace transform

The importance of the Laplace transformation formalism presented by eq.(17) lies in the fact, that it represents a well-known mathematical problem with well-established methods of solution.

Consider for instance kin.1 in Fig.2. This is a step function having the properties:

$$\begin{aligned}\alpha_i(r/\tau) &= 0 \text{ for } r/\tau > 1 \\ \alpha_i(r/\tau) &= 1 \text{ for } r/\tau < 1\end{aligned}\quad (19)$$

In tables of Laplace transforms the solution to eq.(17) for this function can be found, giving a hydration-time curve of the form:

$$\alpha_i(B\tau) = 1 - \exp(-B\tau) \quad (20)$$

As expected from our earlier results, for this limiting case of kinetics the hydration-time curve is identical to the p.s.d., except for a change of variables  $\tau$  to  $r$ .

Of a more practical value is the fact, that we can find an exact solution to kin.4. This form of a kinetic equation has realistic features, and does not give rise to a hydration-time curve deviating much from kin.2 or 3 as seen from our numerical example. The solution of eq.(17) applying kin.4 is given by:

$$\alpha_i(B\tau) = \frac{B\tau}{B\tau + 1} \quad (21)$$

This equation is of an attractive simple mathematical form, which makes it useful in practice as will be shown in the following paragraph.

#### Properties of eq.(21)

We shall start by rewriting eq.(21), using  $i = 1$  in the definition of  $\tau$ :

$$\alpha_1(t_R) = \frac{1}{1+t_R} \quad (22)$$

where  $t_R \equiv t/t_{1/2}$  and  $t_{1/2} \equiv 1/Bk$  is the time to reach 50% hydration.  $t_R$  is called reduced time.

According to eq.(22) a plot of  $\alpha_1$  versus  $t_R$  for hydration experiments with Portland cements of different finenesses and carried out at different temperatures should fall on the same curve, if Portland cement hydrates according to linear kinetics. This is seen to be the case for the examples given in Fig.5. The data presented on this figure comprises different kinds of measurements of  $\alpha$ , different temperatures and different finenesses.  $\alpha_1$  has been calculated in all cases by dividing the property by the value of this property after infinite time, thus  $\alpha_1 \equiv P/P_\infty$ . Reaction time is measured from the end of the dormant period  $t_0$ , such that  $t_M = t + t_0$ , where  $t_M$  is reaction time from the mixing with water.

Fig.5. Degree of hydration versus reduced time in a single log diagram for 5 different hydration experiments. The line represents eq.(22). Data are from refs.(9,10) and our own unpublished results.

As the correct determination of the measured property at infinite time  $P_\infty$  and the duration of the dormant period  $t_0$  is important for the success of the plot in Fig.5, we shall go through the use of eq.(22) to fit experimental data. We insert  $P_\infty$  and  $t_0$  into eq.(22) and get:

$$P = P_\infty \frac{t_M - t_0}{t_M - t_0 + t_{1/2}} \quad (23)$$

For  $t_M \gg t_0$  we neglect  $t_0$  and eq.(23) can be written:

$$\frac{1}{P} = \frac{t_{1/2}}{P_\infty} \frac{1}{t_M} + \frac{1}{P_\infty} \quad (24)$$

Thus a plot of  $1/P$  against  $1/t_M$  will give a straight line, and the extrapolation  $t_M \rightarrow \infty$  will give  $1/P_\infty$ . A plot of this kind is shown in Fig.6.

Fig.6. Degree of hydration from calorimetric measurements (ref.(9)) plotted versus time in a double reciprocal diagram. Line is representing eq.(24).

Calculating values of  $\alpha$  and rewriting eq.(23) we get:

$$\frac{\alpha_1}{1-\alpha_1} = \frac{t_M}{t_{1/2}} - \frac{t_0}{t_{1/2}} \quad (25)$$

Thus a plot of  $\alpha/(1-\alpha)$  against  $t_M$  gives a straight line, and the extrapolation to  $\alpha = 0$  will give  $t_0$ .  $t_{1/2}$  can be found by employing either eq.(24) or eq.(25).

Considering again the results in Fig.5, it should be mentioned, that water/cement ratios for some of these experiments were as low as 0.4. This seems to imply, that the independent particle model of reaction is not seriously violated at these low water/cement ratios.

#### CONCLUSION

We have examined the role played by the particle size distribution in the development of hydration of Portland cement.

Systems treated were restricted by the following requirements:

- a) Particles react independently
- b) and need only be classified according to their size.

With the further restriction, that:

- c) Particle kinetics obey eq.(5)

we derived the convolution theorem connecting the degree of reaction of the total particulate system to the degree of reaction of the single particles and the particle size distribution. This theorem was useful since it provided an understanding of why the hydration curve of a material with a broad particle size distribution, as in Portland cement, is insensitive to details in the particle kinetics. This point was further elucidated by a numerical example.

Ordinary Portland cement was found to have a:

- d) particle size distribution conformal with eq.(1)

and when this further restriction was introduced we derived the Laplace transformation formulation stating, that the Laplace transform of the reaction curve for the single particle yields the reaction curve for the total system.

By means of the Laplace transformation formulation we derived an equation which fitted experimental hydration data for Portland cement quite accurately:

$$\alpha_1(t_R) = \frac{1}{1+t_R^{-1}}$$

where  $t_R$  is  $Bkt$ ,  $k$  a reaction constant,  $B$  a constant depending on particle size distribution, and  $t$  reaction time measured from the end of the dormant period. This showed ordinary Portland cement to react according to linear kinetics.

# Influence des basaltes sur la clinkerisation et les propriétés des ciments

## *Basalt influence on the clinker formation processes and cement properties*

A. PACHTCHENKO, membre-correspondant de l'Académie des Sciences d'Ukraine, chef de Chaire  
des Ciments à l'Institut Polytechnique de Kiev,

G. BAKLANOV, docteur ès sciences techniques, U.R.S.S.

**RESUME:** L'utilisation de la roche volcanique la plus répandue - du basalte à titre de composant du mélange cru pour le ciment portland contribue à l'apparition d'eutectiques fusibles, ce qui augmente l'activité chimique des constituants et rend possible l'achèvement de la clinkerisation aux températures 1350 - 1420°C.

On a étudié les processus de la décarbonatation et les réactions en phase solide dans les mélanges de basaltes et de carbonates, le mode de distribution des oxydes alcalins dans les phases du clinker et les particularités physico-chimiques de la formation des minéraux du clinker dans les mélanges contenant du basalte en fonction du degré de saturation en chaux.

On a examiné l'aptitude de ces ciments à s'hydrater et la composition de phase.

**SUMMARY:** Utilization of the vast volcanic - basalt - as a component of the raw portland-cement mixture provides formation of easily meltable eutectics which positively influence upon the raw mixture reactivity and favour clinker forming completion in the temperature range 1350 - 1420°C.

Decarbonizing processes and solid phase reactions in basalt - carbonaceous mixtures has been explored. Alkali oxides distribution nature according to clinker phases and physical-chemical peculiarities of the main clinker minerals formation in the raw basalt mixture depending on the lime saturate has been established.

Hydrolicity of basalt cement, hydrated phase composition and their lifetime stability has been investigated.

Une méthode intéressante d'intensification du processus de cuisson du clinker de ciment portland pourrait être conçue, si on trouvait certains composants du mélange de matières premières agissant de manière que la phase liquide fasse son apparition en quantité élevée et aux températures plus basses, que dans le cas des matières premières traditionnelles. L'utilisation du basalte dans ce but donne une nouvelle solution à ce problème. Le basalte est une des roches effusives les plus répandues de l'écorce terrestre. Il constitue plus de 20 % des roches magmatiques. Par la teneur en silice et autres oxydes, les basaltes correspondent aux roches basiques. Ce qui est très caractéristique, c'est la constance de leur composition chimique et minéralogique, surtout dans un même gisement, ce qui assure la stabilité des procédés technologiques et des propriétés du produit fini. Les variations de composition chimique sont présentées dans le tableau I (1). Pour un même gisement ces variations sont encore moins prononcées.

TABLEAU I

Variations de compositions chimiques des basaltes

Teneur en oxydes ( en poids, % )					
SiO <sub>2</sub>	Al <sub>2</sub> O <sub>3</sub>	Fe <sub>2</sub> O <sub>3</sub>	CaO	MgO	Na <sub>2</sub> O
45,41- 55,90	14,60- 21,80	8,96- 16,55	4,50- 13,05	1,60- 11,80	2,18- 5,60

Une particularité caractéristique des basaltes est la présence des oxydes de titane, vanadium, barium, ainsi que d'autres micro-éléments. Le fer est présent sous forme d'oxydes ferrique et ferreux. Selon la composition minéralogique, les basaltes sont des roches polyminérales, contenant des plagioclases, des minéraux melanocrates, du verre volcanique, des minéraux accessoires (magnétite, ilménite, apatite). Etant une roche effusive, le basalte contient beaucoup de phase vitreuse. En général, les basaltes se distinguent des matières pre-

mières traditionnelles. Ils sont facilement fusibles. La fusion s'opère à une température inférieure à 1250°C. Au moment de l'apparition de la phase liquide dans le mélange des matières premières ordinaires du ciment portland tout le basalte serait à l'état fondu. La viscosité du basalte fondu dépend dans une grande mesure de la composition chimique. A la température de 1250°C elle peut varier entre 8,9 et 81 kg/m.s. Lors de l'échauffement ultérieur la viscosité diminue sensiblement et à la température de 1400°C constitue 5,1 - 9,1 kg/m.s (2,3). Les températures de la limite supérieure de cristallisation des basaltes fondus se situent entre 1215° C et 1250°C (3). La dévitrification du basalte, analogue à celle du laitier, décrite par les auteurs (4), doit s'accompagner d'échauffements locaux par suite du dégagement de chaleur de cristallisation, ce qui peut contribuer à la diminution de la viscosité.

Le facteur le plus important déterminant les propriétés technologiques des matières soumises à la cuisson ainsi que la vitesse des processus physico-chimiques est la quantité de phase liquide qui détermine le domaine de réaction, son type et, en fin de compte, la cinétique des transitions de phases et des transferts de masse. La quantité de phase liquide, évaluée (d'après F.M. LEA et T.W. PARKER) dans le clinker, obtenu d'un mélange binaire de basalte et de calcaire, correspondant au coefficient de saturation 0,98, dépasse 31 %, ce qui est bien suffisant pour la formation des silicates hautement basiques. La viscosité de la phase liquide du clinker est faible et s'abaisse linéairement avec le module alumino-ferrique, atteignant 0,168 kg/m.s pour la valeur 0,81 de celui-ci. à la température de 1400°C.

Les particularités de la clinkérisation ont été étudiées sur 18 mélanges, préparés à base de basaltes de différente composition. A titre d'exemple nous citons le mélange ayant un coefficient de saturation en chaux

égal à 0,93 (5). On a montré que la fixation intense de chaux dans les mélanges pulvérulents à base de basaltes a eu lieu par réaction en phase solide (figure 1).

Fig. 1 - Variations de teneur en chaux carbonatée(1), libre(2) et combinée(3) dans le mélange basalte-calcaire.

La vitesse de cette réaction est assez grande. A la température de 1200°C la chaux est fixée à 70 - 98 % selon la composition du basalte utilisé. Lors de l'augmentation ultérieure de la température les oxydes de magnésium et de fer contribuent à l'apparition d'une phase liquide peu visqueuse, ce qui accélère considérablement le processus de formation des minéraux de clinker. Il faut dire que la présence d'ions  $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Mg}^{2+}$  dans la phase liquide aboutit à l'affaiblissement de l'armature anionique, à la diminution du frottement interne et à la fixation plus rapide de la chaux libre. L'analyse aux rayons X montre (figure 2), qu'au cours de la cuisson du mélange le bélite fait son apparition aux températures assez basses, cependant l'intensité de ses raies est faible. L'augmentation de la température de cuisson contribue à une cristallisation plus prononcée des silicates de calcium. A la température de 1200°C on constate l'apparition des raies de l'alite. Leur intensité croît avec la température de cuisson.

La cristallisation des minéraux dans le clinker ainsi obtenu est nette dans tous

Fig. 2 - Diagrammes X du mélange basalte-calcaire cru (courbe 1) et cuit aux températures 800, 1000, 1200, 1300 et 1400°C (courbes 2 - 6 respectivement).

les cas. La répartition des cristaux est régulière. L'alite se présente généralement sous forme de prismes hexagonaux et tabulaires. Le bélite apparaît sous forme de cristaux arrondis. La substance intermédiaire est constituée par les aluminoferrites de calcium de diverse composition: ( $\text{C}_6\text{A}_2\text{F}$ ,  $\text{C}_4\text{AF}$ ,  $\text{C}_3\text{AF}_2$ ) ainsi que par une faible quantité d'aluminate tricalcique, de ferrite bicalcique et de verre enrichi en oxyde de fer. Les études par microsonde et analyse chimique ont mis en évidence la présence du fer principalement dans la phase aluminoferritique et en très faible quantité dans les silicates. Les résultats de l'étude de la répartition des alcalis dans les phases du clinker sont donnés dans le tableau II.

Remarque. Au numérateur - la teneur en alcalis en % pondéraux du clinker, au dénominateur, - la teneur en alcalis dans la phase considérée, en % de leur teneur totale dans le clinker.

L'oxyde de potassium fait partie de la phase constituée d'aluminates, forme des solutions solides avec le silicate bicalcique et peut se trouver dans les aluminoferrites de calcium ainsi que dans la phase vitreuse du clinker. L'oxyde de sodium fait partie de toutes les phases principales du clinker. L'oxyde de magnésium forme de préférence des solutions solides avec les phases principales du clinker. Ce n'est qu'une partie insignifiante du  $MgO$  qui cristallise sous forme de périclase (à peu près 20 % de la quantité totale), qui n'a pas d'influence sur la stabilité de volume et d'autres propriétés des ciments.

A partir des mélanges basalte-calcaire nous avons préparé les ciments de trois compositions: bélique(1), moyennement saturé(2) et alitique(3) (tableau III). L'une des particularités de la composition minéralogique des ciments portlands basaltiques est la proportion élevée d'aluminoferrites de calcium. L'étude de l'hydratation permet de constater, que lorsque ces ciments sont mis au contact de l'eau il y a d'abord une période dite d'induction. Lors de cette période

ce sont essentiellement les phases anhydres (2,60; 2,74; 2,77  $\text{\AA}^*$ ) que mettent en évidence les diagrammes de diffraction des rayons X, l'intensité des raies des hydrates demeurant relativement faible (2,63; 4,92  $\text{\AA}^*$ ). Avec le temps le processus de durcissement se développe assez vite et l'intensité des raies des hydrates croît rapidement. On peut constater l'accumulation dans le système d'hydrosilicates proches de la tobermorite, qui confèrent la résistance mécanique.

Lors de l'hydratation des ciments durant le délai compris entre 3 jours et 2 ans, on constate sur les courbes d'ATD les inflexions endothermiques aux températures 190 - 210°C (figure 3, le cas du ciment avec  $CS=0,92$ ), caractérisant plusieurs processus, à savoir: le départ de l'eau libre et de l'eau liée dans les hydrosilicates du type de la tobermorite, le début de la déshydratation de l'aluminate de calcium hydraté hexagonal et cubique, de l'hydroferrite de composition analogue, ou de la solution solide  $C_3(A,F)H_6$ , de l'hydrosulfoaluminate et du sulfoferrite ou de leur solution solide, ainsi que la déshydratation de la fraction

TABLEAU III  
Composition minéralogique et propriétés du clinker

Composition	Température de cuisson, °C	CaO libre, en poids, %	Densité, $Kg/m^3$	Coef. de saturation en chaux (CS)	Module silicique	Module aluminoferrique	Teneur en % pondéraux de:			
							$C_3S$	$C_2S$	$C_3A$	$C_4AF$
1	1300	0,18	3,220	0,70	1,98	1,12	10,26	58,43	4,79	22,13
2	1340	0,21	3,170	0,81	1,89	0,94	37,23	35,05	4,75	18,27
3	1380	0,30	3,170	0,92	1,91	0,95	59,55	14,39	4,58	16,96

gélatineuse contenant les hydroxydes d'aluminium, de fer et le gel de l'acide silicique.

Fig. 3 - Dérivatogrammes du ciment durcissant dans les conditions normales pendant 3, 7, 28, 180, 360, 720 jours (courbes 1-6)

De faibles inflexions sur les courbes d'ATD de toutes les compositions aux températures 380°-410°C caractérisent les transformations des produits gélatineux en cristallins, ainsi que la déshydratation de  $C_3AH_6$ .

L'effet endothermique aux températures 500-530°C correspond à la décomposition de l'hydroxyde de calcium, qui se forme lors de l'hydratation des minéraux du clinker. C'est dans ce même intervalle de températures qu'a lieu la déshydratation ultérieure des hydroaluminates ou hydroaluminoferrites mentionnés. Cependant l'intensité de ce pic reflète essentiellement la quantité d'hydroxyde de calcium dans la pierre de ciment.

L'effet endothermique aux températures 800-830°C correspond à la décomposition du carbonate de calcium dû à la carbonatation atmosphérique. Mais la dépendance de la grandeur de cet effet de la composition minéralogique du ciment et de la durée de durcissement rend possible de le rapporter à la présence de l'hydrosilicate de calcium.

A la température de 800°C c'est la déshydratation de l'hydrosulfoaluminate de calcium à basse teneur en sulfate qui a lieu. A 830 - 840°C a lieu le départ de l'eau de constitution des hydrosilicates du type de la tobermorite, de  $C_2SH_2$ , ainsi que de l'hydrosilicate  $C_2S \cdot Aq$ .

L'étude des résultats de l'analyse thermique différentielle ainsi que des diagrammes aux rayons X montre que le processus de durcissement des ciments en question ne diffère pas de façon tangible de celui des ciments portlands courants.

Les propriétés mécaniques des ciments ba-

TABEAU IV  
Essais physico-chimiques des éprouvettes normales

Composition	Consistance normale %	Prise		Résistance à la rupture par compression/ flexion, en $10^{-1}$ N/mm <sup>2</sup>							
		début	fin	3j	7j	28j	90j	180j	1an	2 ans	3 ans
1	24,5	2h55	4h05	50/18	91/20	208/44	276/61	579/67	578/74	616/77	650/89
2	23,82	2h45	5h00	186/33	305/58	411/60	437/68	555/68	562/70	638/79	669/90
3	23,17	1h00	6h00	206/50	306/55	512/67	560/68	630/71	635/73	685/86	730/92

salitiques (tableau IV) sont en bon accord avec les données de l'analyse physico-chimique. On constate la période d'induction et celle de l'accroissement progressif de la résistance mécanique. Il faut souligner, que ces ciments atteignent la résistance à la rupture par compression de  $5000 \text{ N/mm}^2$  à 28 jours. Ultérieurement la résistance croît toujours de façon régulière. A trois ans elle dépasse  $6500 \text{ N/mm}^2$  dans tous les cas.

Les ciments basaltiques sont caractérisés par une résistance élevée à la flexion. Cette propriété s'explique par le développement d'hydrates fibreux.

On peut citer encore quelques propriétés intéressantes de ces ciments; à savoir: faible dégagement de chaleur, faible retrait et expansion, haute stabilité lors des variations d'humidité.

La stabilité au gel est assez forte. Les éprouvettes ont subi 200 cycles de congélation et de dégel alternés sans destructions visibles et sans baisse de résistance supérieure à 25 %.

L'étude de l'action d'une solution corrosive contenant 5 %  $\text{Na}_2\text{SO}_4$ , 0,2 %  $\text{CaSO}_4$ , 1 %  $\text{MgSO}_4$  (eau de mer) sur ces ciments a montré leur haute résistance à la corrosion. Pratiquement le coefficient de stabilité dépasse 0,8 pour n'importe quelle durée de conservation ce qui permet de les recommander en qualité de ciments résistant aux sulfates.

Les essais standardisés démontrent que ces ciments peuvent être utilisés à titre de ciment pour puits de pétrole. Pour les puits "froids" ils conviennent par leur teneur élevée en silicates ce qui leur confère une activité hydraulique élevée sans accélérer la prise. Pour les puits "chauds" ils conviennent par suite de la teneur faible en aluminat tricalcique et élevée en aluminoferrite de calcium.

## CONCLUSIONS

Les ciments basaltiques peuvent être utilisés comme liants usuels et comme liants spéciaux résistant aux sulfates et pour puits de pétrole.

# Raw material effect on clinker quality

## *L'influence de matières premières sur la qualité du clinker*

B. WERYNSKI, Doctor of Engineering, Research Director, Institute for Building Industry Cementing Materials, Opole, Poland,

A. WERYNSKA, Master of Engineering, Institute for Building Industry Cementing Materials, Opole, Poland.

**RESUME :** La production de ciments a haute résistance se base sur différentes méthodes qui conduisent à la formation de clinker ayant une teneur élevée en silicates calciques, ceux-ci ayant leur structure cristalline propre. On connaît des moyens d'augmenter la résistance de ciments par l'introduction au mélange cru de petites quantités d'additifs étrangers.

Dans l'ouvrage présenté on a utilisé l'influence d'oxydes  $MgO$ ,  $Na_2O$ ,  $K_2O$  et  $SO_3$  se trouvant dans les matières brutes naturelles, telles que le "muschelkalk" d'origine triasique et une argile keuperique, sur l'activité hydraulique de clinker. A l'aide de diverses méthodes d'analyse, telles que radiocristallographie, thermogravimétrie et microscopie on a conduit des analyses structurales et a constaté, que les porteurs d'oxyde de magnésium et d'oxydes de métaux alcalins sont les chlorites, les micas et les kaolinites, qui se trouvent dans les argiles et - en petites quantités - dans le calcaire.

En mélangeant ces matières premières, on a obtenu des farines crues de compositions chimiques différentes. Les clinkers obtenus par la cuisson de ces crus différaient par leurs facteurs de saturation de 0,90 à 0,94 et par leurs modules siliciques - de 2,27 à 2,72. L'examen des résistances des pâtes de ciment préparées à partir de ces clinkers a prouvé, que le clinker ayant le module de saturation 0,93 et le module silicique 2,52, après avoir été broyé jusqu'à obtenir une surface spécifique Blaine de  $350 \text{ m}^2/\text{kg}$  environ, répondait aux exigences du ciment portland 550, après 28 jours de durcissement. L'augmentation de la surface spécifique de ce ciment à  $460 \text{ m}^2/\text{kg}$  environ, permettait l'obtention du ciment de résistance  $18,2 \text{ MN/m}^2$  après 1 jour et de  $74,0 \text{ MN/m}^2$  après 28 jours de durcissement. Un important accroissement de la résistance du clinker a été obtenu grâce à la haute teneur en silicates calciques ( $C_3S$  - 72 %,  $C_2S$  - 8,1 %) et à la modification de leur structure cristalline due à l'influence de l'oxyde de magnésium et des oxydes de métaux alcalins.  $MgO$ ,  $Na_2O$ ,  $K_2O$  et  $SO_3$  ont joué le rôle de minéralisateurs dans la cuisson du cru et de stabilisateurs des variétés polymorphes de silicates calciques, en créant avec ces silicates des solutions solides d'une activité hydraulique élevée.

**SUMMARY :** The manufacture of rapid-hardening cements is based on various methods leading to the creation of clinker of a high total contents of calcium silicates, those having an adequate crystal structure. There are ways of increasing the strength of cements by introduction of little amounts of foreign additives to the raw mix.

In the work presented the influence has been utilised of oxides  $MgO$ ,  $Na_2O$ ,  $K_2O$  and  $SO_3$  present in natural raw materials such as shelly limestone of Triassic origin and Keuperous clays, over the hydraulic activity of clinker. By means of various methods like x-ray diffractometry, thermogravimetry and optical microscopy a structural analysis of these raw materials has been made and it's been found out that the carriers of magnesium oxide and of alkali metals oxides are chlorites, micas and kaolinites occurring in clays and - in small quantities - in limestone.

Raw mixes of different chemical composition have been composed of these raw materials. The clinkers obtained by burning these raw mixes differed one from the other in their lime saturation factor - from 0,90 to 0,94 and in their silica ratio - from 2,27 to 2,72.

The examinations of the cement pastes made out of the clinkers showed that the clinker of a lime saturation factor of 0,93 and a silica ratio of 2,52, composed of natural raw materials, after being ground to a fineness of ca.  $350 \text{ m}^2/\text{kg}$  (Blaine), meets requirements for portland cement grade 550 after 28 days of hardening. Increasing the fineness of this cement to ca.  $460 \text{ m}^2/\text{kg}$  enables to obtain a cement of a strength of  $18,2 \text{ MN/m}^2$  after 1 day, and that of a strength of  $74,0 \text{ MN/m}^2$  after 28 days of hardening. A high increase in the strength of clinker has been obtained thanks to its high contents of calcium silicates ( $C_3S$  - 72 %,  $C_2S$  - 8,1 %) and thanks to the adequate modifications of the crystal structure of these minerals, resulting from the influence of both magnesium oxide and of oxides of alkali metals.

$MgO$ ,  $Na_2O$ ,  $K_2O$  and  $SO_3$  were playing the role of both mineralisers during the burning of raw mix and stabilisers of the polymorphic modifications of calcium silicates, forming with these silicates solid solutions of an increased hydraulic activity.

The development of science in cement chemistry and of research methods enabled to rich present knowledge concerning the relations occurring between physico-chemical properties of initial raw material and raw mix and the processes of clinker minerals forming.

It is known that the hydraulic activity of cements deciding about their strengths is influenced by many agents related to each other, which is a research problem in many countries.

The main components of portland clinker are following: tricalcium silicate  $C_3S$ , dicalcium silicate  $C_2S$ , tricalcium aluminate  $C_3A$ , and tetracalcium aluminoferrite  $C_4AF$ . Their form is a function of their internal structure which consequently depends on chemical composition, mineralogical composition, degree of fineness of raw mix, the conditions of clinker burning and cooling, and first of all the reactions performing as a result of diffusion in liquid phase.

Thus, to obtain clinker of high hydraulic activity raw mix should be characterized by homogeneity of chemical composition and high chemical activity during burning process.

The effect of raw material origin on clinker minerals forming kinetics should be regarded from the following view points:

- mineralogical form under which its main oxides ( $CaO$ ,  $SiO_2$ ,  $Al_2O_3$ ,  $Fe_2O_3$ ) appear in raw materials;
- mineral origin (natural from mineral deposits or artificial e.g. waste products);
- the effect of the degree of hydration of minerals on reaction kinetics;
- the role of isomorphous admixtures in reaction performance in solid phase.

The optimal set of raw materials for clinker production is formed by limestones containing fine-crystalline calcium carbonate and clays formed of hydrated silicates and aluminosilicates of a high specific surface.

Phase composition and petrographical structure and texture of minerals included in raw mix have a great effect on the process of formation of minerals in clinker.

$CaO$  appears in limestones as calcite, dolomite, rarely as aragonite, gypsum, phosphate, feldspar and also in the form of isomorphous admixtures as adsorbed cation  $Ca^{2+}$  in clay components (1).

$SiO_2$  appears in raw mix first of all as quartz, chalcedony, seldom as cristobalite and opal. Besides, silica is a component of different clay minerals, of kaolinite, montmorillonite, hydromica, chlorites groups and other similar minerals.  $Al_2O_3$  and iron oxides are in calcereous and clay raw materials as hydrargillites, diaspores, boehmites, hydrohematites, lepidocrocites etc.

Thus the reactivity of raw mix is influenced by dissociation process, dehydration process and destruction of crystal lattice of minerals, performing at higher temperatures.

The most reactive  $CaO$  is formed at higher temperatures from thermal dissociation of fine-crystalline calcite (aragonite) and dolomite.

Active silica can appear in clinkerization process at the temperatures 773 - 1373 K during dehydration process of clay components.

The grain size and specific surface of reagents

have a great effect on reaction time in solid phase.

Quartz and chalcedony grains in raw mix should have sizes not bigger than 30 microns, and for production of high-strength and fast-hardening cements - 15 microns (2).

The time of clinkerization process depends upon the size of  $CaO$  and its activity, which makes it diffuse in crystal lattice of  $SiO_2$  thus forming dicalcium silicate and then tricalcium.

According to Krawczenko (3) the time of diffusion of  $CaO$  in  $SiO_2$  lattice is 4 - 5 times shorter than diffusion of  $SiO_2$  in  $CaO$ .

The presence of different modifications of iron oxides in raw mix influences considerably its reactivity, which increases; especially important is the presence of  $FeO$ , which as active mineralizer accelerates the dissociation of  $CaCO_3$ .

The fineness of raw mix and its increased specific surface influence the amount of minerals in clinker and the amount of free  $CaO$ . The other factor influencing the reaction time in clinkerization process is the share of water separated during clay and some not clay minerals burning.

Depending upon the kind of minerals dehydration performs within a large range of temperatures: 473 K - 1273 K, i.e. the temperatures at which raw mix reactions perform first of all in solid phase.

The role of reaction mineralizers in solid phase is played also by isomorphous admixtures occurring in small amounts in natural raw materials. These mineralizers are following:  $MgO$ ,  $SO_3$ ,  $K_2O$ ,  $Na_2O$ ,  $P_2O_5$ ,  $TiO_2$ ,  $SrO$ ,  $BaO$ ,  $Cr_2O_3$  (4).

The positive effect of isomorphous components appears in the change of physico-chemical properties and in the increase of chemical activity of the liquid phase during clinkerization process as well as in the increase of hydraulic activity of clinker, resulting from stabilization of polymorphic modification of calcium silicates (5).

The presence of  $Al_2O_3$ ,  $Fe_2O_3$ ,  $MgO$  in raw mix decreases the temperature of dissociation of calcium carbonates, which starts already at 723 K. In the range of temperatures 973 - 1273 K, hydrated aluminosilicates disintegrate, forming unstable products, which react with  $CaO$  "in statu nascendi". The reactions between the components take place as a result of ion diffusion in solid solutions. The amount of liquid phase depends upon temperature and also upon the presence of mineralizers decreasing the eutectic point of solutions.

The effect of various agents on liquid phase properties has compound character and depends upon their chemical origin and concentration. The kinetics of reactions taking place in the liquid phase are influenced by the physical forces as: viscosity, surface tension and ions mobility in solution (6).

The effect of various chemical compounds on a liquid phase viscosity is shown in Figure 1 (according to Butt, Timashev, Osokin).

At the presence of  $Na_2O$  and  $K_2O$  the increase of liquid phase viscosity is observed. The addition of about 1.5 - 2.0 % of  $MgO$  decreases the liquid phase viscosity proportionally to its concentration.

Fig. 1. Isothermes (1723 K) of viscosity of the solution saturated at 1723 K in presence of:

- 1 -  $K_2O$ , 2 -  $Na_2O$ ,  
3 -  $MgO$ , 4 -  $K_2SO_4$ ,  
5 -  $Na_2SO_4$ , 6 -  $SO_3$

Figure 2 shows the effect of compounds on surface tension of liquid phase.

Fig. 2. Isothermes (1723 K) of surface tension of the solution composed of  $CaO$ ,  $SiO_2$ ,  $Al_2O_3$ ,  $Fe_2O_3$  in presence of:

- 1 -  $MgO$ , 2 -  $Na_2O$ ,  
3 -  $SO_3$ , 4 -  $K_2O$

At presence of  $MgO$ ,  $Na_2O$ ,  $K_2O$ , and  $SO_3$  the surface tension of liquid phase decreases.<sup>3</sup> In the liquid phase of clinker, the mobility of ions  $Na^+$  and  $K^+$  is overcoming considerably the displacement speed of silicoxide anions; thus their presence causes intensification of solution process of belite in liquid phase. The introduction of  $MgO$  into the alkalic solution of liquid phase enables to accelerate the reaction of disintegration of dicalcium silicate, 2 or 3 times. The greatest intensity of tricalcium silicate formation is observed at reactive grains of  $CaO$  interaction with liquid phase characterized by high surface tension and minimal viscosity. The presence of  $SO_3$  in liquid phase results in acceleration of contact layers corrosion and acceleration of ions diffusion into the crystal lattice of silicates.

The knowledge of dependence between both viscosity and surface tension of the liquid phase and the concentration oxide in this phase enables to modify certain physical and chemical parameters of liquid phase solution, and consequently the structure of minerals formed in it.

Solid solutions of basic clinker minerals including magnesium, potassium and other compounds are formed from polymineral liquid phase with isomorphous substances.

Woerman and others (7) proved that up to 2 % of  $MgO$  and ca. 1 %  $Al_2O_3$  are included in solid solution in tricalcium silicate. Alite with the admixtures  $Al^{3+}$  and  $Mg^{2+}$  is defined as a solid solution of  $54 CaO \cdot 16 SiO_2 \cdot Al_2O_3 \cdot MgO$ , where  $Al_2O_3$  and  $MgO$  are stabilizers. In the system  $CaO - MgO + Al_2O_3 - Fe_2O_3 - SiO_2$  the role of alien ions

essential for the stabilization of polymorphic modifications of tricalcium silicate is not so important when other stabilizing components e.g.  $Cr_2O_3$ ,  $SrO$ ,  $P_2O_5$ ,  $TiO_2$ ,  $BaO$  are introduced.

The research conducted by many authors and concerning accessorial components effect on hydraulic activity of clinker showed that there can be determined proper concentrations of these components causing the optimal activity increase effect e.g.  $P_2O_5$  - 0.2 - 0.3 %,  $Cr_2O_3$  - 0.5 %,  $SO_3$  - 0.5 %,  $TiO_2$  - 2 - 3 %,  $B_2O_3$  - 0.5 %,  $SrO$  - 2.4 %,  $BaO$  - 0.1 % (8, 9, 10).

Basing upon discussed literature the thesis can be put that applying natural calcareous raw materials and clays including in their composition hydrated magnesium silicate and micas and illits, it is possible to obtain clinkers of right phase composition, which ground with addition of gypsum can give high quality cements.

#### Results and discussion

The examination of effect of accessorial components included in raw material on cement quality was conducted basing on four clinkers. Shell limestone of trias origin and keuperous clays were used as raw materials for clinker production. The basic raw materials were chosen basing on geological documentation and wide examination of deposits, applying condensed prospection drill grid. To examine chemical composition of calcareous and clay deposits, x-ray fluorescence analysis was applied. Moreover, trace elements were determined by absorption spectrometry method. The chemical composition of raw materials was presented in Table I.

TABLE I

Chemical composition	Limestone %	Clay %
$LiO_2$	40,3	10,7
$SiO_2$	5,6	54,9
$Fe_2O_3$	0,7	6,0
$Al_2O_3$	2,0	14,0
$CaO$	50,2	7,5
$MgO$	0,6	3,4
$SO_3$	0,1	0,3
$Na_2O$	0,03	0,29
$K_2O$	0,024	2,90

Table II shows trace elements content in raw materials.

TABLE II

Chemical composition	Lime %	Clay %
$ZnO$	0,006	0,014
$CuO$	0,0017	0,0031
$V_2O_5$	0,005	0,036
$MnO_2$	0,027	0,226
$Cr_2O_3$	0,0039	0,0136
$PbO$	0,007	0,007
$NiO$	0,004	0,007

The mineral composition of raw materials was examined by thermogravimetry and x-ray radiography.

Figure 3 presents the diagrams of differential thermal analysis.

Fig.3.

DTA curves for  
clays

Three characteristic endothermic peaks can be seen on the diagram. At temperature 423K endothermic peak says about lattice water removal from clay minerals. At the temperature 853K we can observe dehydration of illit and kaolinite and also disintegration of crystal lattice of laminar minerals. At the temperature 823 - 973K there is a characteristic endothermic peak for chlorites. At that temperature the loss amounting 75 % of groups  $\text{OH}^-$  of brucite layer is observed. Endothermic peak at the temperature 1133K indicates the thermal disintegration of  $\text{CaCO}_3$  and dolomite and also endothermal reaction of lattice destruction of chlorites.(11).

Fig.4. Diffractogram for clays

Fig.5. Diffractogram for limestones

Figure 4 and 5 show diffractogram for clays and limestones. As a result of complex examination it was stated that shell limestone of trias origin is composed mainly of calcite more than 91 %, quartz and some small amounts of clay minerals as illit and chlorite.

The clays include first of all aluminosilicates i.e. chlorites ( $d = 14 \text{ \AA}$ ), micas, illits, muscovites, biotites and caolinites and among them dickit, nasrite, halloysite.

In clay and in limestone samples the presence of small quantities of  $\text{SiO}_2$  in form of quartz was observed, but most of silica is included in minerals of caolinite, mica and chlorites group.

In clay examination about 3 % of potassium oxides ( $\text{K}_2\text{O}$ ,  $\text{Na}_2\text{O}$ ) was observed.

The sinterability of limestones and clays was examined by hightemperature microscope and it was states that sintering temperature for both raw materials is at the same range 1425K - 1523K.

The raw mix was composed with dried limestones and clay, ground before to a great degree of fineness. At all samples the content of fraction < 5 microns was over 20 %, but fraction 5 - 30 microns between 41 - 55 % and fraction > 88 microns about 10 %. Four clinkers of different chemical and mineral composition were burned with the raw mix described above. It is shown in Table III.

TABLE III

#### CHEMICAL AND MINERAL COMPOSITION OF CEMENT CLINKERS

(See page I - 187)

All clinkers are characterized by SF amounting 0.90 - 0.94. Silica ratio (SR) for clinkers on level between 2.27 - 2.72. The value of alumina ratio (AR) for all samples is similar and is in the range of 2.0 - 2.34. The phase respectively composition of clinker was calculated basing on microscopic examinations. Microscopic examinations for clinkers I to IV are presented in Figures 6,7,8,9.

Fig. 9.  
Clinker IV  
(x800)

The microsection has been etched with the 1 % solution of  $\text{HNO}_3$  in alcohol.

Figure 6 presents clinker I of lime saturation factor  $\text{SF} = 0.90$ ,  $\text{SR} = 2.27$ ,  $\text{AR} = 2.0$ . It is alite-belite clinker of content:  $\text{C}_3\text{S} = 68.4\%$ ,  $\text{C}_2\text{S} = 10.5\%$ .

The conglomerations of alite crystal of irregular cross-section are visible. There are also alite grains of elongated cross-section with corroded edges and on their surface belite inclusion can be seen. Grains of irregular shapes can be observed in the structure of this clinker; it is due to progressive deposition of crystals at the presence of alumina and in the form of solid solutions and due to variation of liquid state composition during crystallization process.

Figure 7 shows clinker II of  $\text{SF} = 0.92$ ,  $\text{SR} = 2.54$ ,  $\text{AR} = 2.30$ . It is alite clinker,  $\text{C}_3\text{S} = 70.2\%$ ,  $\text{C}_2\text{S} = 8.3\%$

of fine-crystalline structure (the alite grain diameter = 30 microns). Most of them are alite crystals of hexagonal cross-section with edges corroded by liquid phase and visible enclaves and occlusions of  $\text{C}_2\text{S}$ .

Figure 8 shows clinker III of  $\text{SF} = 0.93$ ,  $\text{SR} = 2.49$ ,  $\text{AR} = 2.33$ . It is high alite clinker  $\text{C}_3\text{S} = 72.0\%$ . Alite crystals of hexagonal cross-section are distributed uniformly in aluminato-ferrite filling substance. This clinker is characterized by very clear alite crystals crystallization of axis ratio 1.4:1 and 5:1. In alite crystals there are observed quite often irregular and slot micropores and enclaves.

Microscopic picture (Figure 9) shows clinker IV of  $\text{SF} = 0.94$ . Alite crystals of irregular and polygonal cross-section of average diameter about 40 microns have on their edges and surfaces numerous inclusions, free grains of  $\text{CaO}$  are also seen.

X-ray examination of clinkers confirmed the presence of tricalcium silicate and in smaller amounts dicalcium silicate and tricalcium aluminate and also some tetracalcium aluminoferrite. As example, the diffractogram of clinker III was shown (Figure 10).

Fig. 10. Diffractogram for clinkers III

All clinkers were ground with the addition of the same quantity of gypsum (5 %) to four different specific surfaces amounting  $230 \text{ m}^2/\text{kg}$  -  $470 \text{ m}^2/\text{kg}$ . As a result it was obtained 16 cement samples which were examined concerning physical and strength properties. The results were compiled in Table IV.

Analyzing the results of cements obtained from trias limestones and keuperous clays, very considerable effect of these raw materials origin on strength properties of cements especially after 28 days can be observed.

Complex examination of mineral composition of limestone proved that it is composed with fine-crystalline calcite and similar clay minerals; it can be seen on x-ray and microscopic photographs and on thermograms. As it results from x-ray radiography and thermogravimetry, keuperous clays are composed with aluminosilicates i.e. chlorites, mica, kaolinites, quartz and quartz silica. Chlorites, as laminar silica, introduce magnesium compounds with clays to raw mix (3.4% of  $\text{MgO}$  was confirmed analytically) but mica and clay - potassium compounds ( $\text{K}_2\text{O} = 2.9\%$  and  $\text{Na}_2\text{O} = 0.29\%$ ).

The presence of minerals characterized by highly developed specific surface in raw mix causes the decrease of eutectic point and enables sintering of this mix.

\*/. MINERAL COMPOSITION DETERMINED BY OPTICAL MICROSCOPY

The examination of raw materials sinterability confirmed that the range of temperatures for limestone and clays softening is the same, thus active CaO will react with silicaluminates in state "in statu nascendi" when raw mix shows the highest chemical activity. From microstructure of formed clinker minerals it can be concluded about sintering conditions of raw mix at the presence of sintering process intensifiers i.e. magnesium, sodium, potassium compounds and other accessoric components. Complex examination of clinker mineral composition presented on x-ray photography confirms the presence of calcium orthosilicate i.e. alite and some belite and filling substance, composed mainly with tricalcium aluminate and mixture of aluminates and calcium ferrites appearing as tetracalcium aluminoferrite.

The microscopic examinations shown in Figures 6, 7, 8 and 9 enable to determine crystalline structure of minerals.

Clinkers of different lime saturation factor varying between 0.90 - 0.94 have different increase of strength in time, which is presented in Figure 11.

Fig.11. Influence of the lime saturation factor on mortar strengths after 28 days of hardening

At increasing SF the systematic increase of strength after 1 and 3 days of hardening is observed. The

highest strength i.e. 19.6 MN/m<sup>2</sup> after 1-day hardening is obtained for clinker IV of SF amounting 0.94. This clinker has the highest value of alumina phase C<sub>3</sub>A - 15.2 % and free CaO - 1.5 % and silica ratio 2.72. It is presumed that the increase of strength at the initial phase was positively influenced by free Ca included in clinker (1.5%), which after hydration became a center of crystal nuclei for hydrated silicates and calcium aluminates.

The minimal decrease of strength of this clinker after 7 and 28 days compared to other samples was probably caused by the content decrease of C<sub>3</sub>S and by a little different crystalline structure.

High lime saturation factor and increased silica ratio caused the formation of small, irregular alite crystals (12) which can be seen in Figure 9. The highest strengths after 7 days i.e. 48.5 MN/m<sup>2</sup> and after 28 days i.e. 74 MN/m<sup>2</sup> and at specific surface amounting 468 m<sup>2</sup>/kg are obtained by clinker III of lime saturation factor 0.93 and silica ratio 2.52. This clinker has the highest total content of oxides MgO, Na<sub>2</sub>O, K<sub>2</sub>O equaling 1.403 %. As Woerman and others (7) make known, the presence of these oxides in mineral synthesis process caused the crystallization of alite characterized by better symmetry and higher hydraulic activity.

Fig.12. Influence of the cement fineness on the strengths of cement pastes of a different mineralogical composition

Solution of MgO in alite and belite crystal lattice gives solid solutions of defected lattice and also fine-crystalline structure of this clinker (20-40 microns) resulted in higher hydraulic activity of this clinker and higher strengths.

Figure 12 shows cement specific surface effect on its strength, clinker III given as an example.

The clinker grinding to specific surface about 350 m<sup>2</sup>/kg let us obtain cement mark 550 of 28 days strength amounting 59.4 MN/m<sup>2</sup>. The increase of specific surface up to about 450 m<sup>2</sup>/kg gives cement of high strength parameters i.e. after 1 day - 18.2 MN/m<sup>2</sup>, after 3 days - 37.1 MN/m<sup>2</sup> and after 28 days - 74.0 MN/m<sup>2</sup>, which meets requirements for fast hardening and high strength cements.

Basing on quoted above examinations it can be said that there is a considerable effect of raw materials on the quality of clinker produced.

The clinkers of high strengths and high mark cements (after grinding with gypsum addition) i.e. 550 and higher (examined according to ISO) can be obtained with raw materials containing magnesium compounds in the form of chlorides and potassium oxides contained in mica and illites.

# Reactivity of belite stabilized by $\text{Ca}_5(\text{PO}_4)_3\text{OH}$

## *Réactivité de la bélite stabilisée avec $\text{Ca}_5(\text{PO}_4)_3\text{OH}$*

B. MATKOVIC, "Rudjer Boskovic" Institute, Zagreb,

V. CARIN, T. GACESA, R. HALLE, Research Department of Jucema, Zagreb, Yougoslavie.

RESUME : L'hydraulicité de la bélite activée avec de l'apatite a été étudiée sur des échantillons préparés à partir de produits chimiques purs et à partir d'un mélange de calcaire et sable quartzeux. La modification qui se formait dans le clinker ( $\beta$ -,  $\alpha$ - $\text{C}_2\text{S}$  ou leur mélange) dépendait de la quantité de stabilisant dans le cru. Les clinkers et leurs produits d'hydratation furent caractérisés par des analyses chimiques et thermiques, la diffraction des rayons X la microscopie optique et la microscopie électronique à balayage. Les essais de résistance prouvaient que la forme  $\alpha'$  seule ou combinée avec la forme  $\beta$  avait des résistances plus élevées que  $\beta\text{-C}_2\text{S}$ .

Pour évaluer l'effet stabilisant de l'apatite, les auteurs comparaient les résistances à la compression des clinkers de bélite activée avec  $\text{Ca}_5(\text{PO}_4)_3\text{OH}$  à celles des clinkers stabilisés avec  $\text{BaSO}_4$ . Les résultats obtenus indiquent qu'en présence d'apatite les résistances sont considérablement plus basses pendant le premier mois d'hydratation, les différences étant moins prononcées aux âges ultérieurs, sur tout pour la modification  $\alpha'$ .

SUMMARY: Hydraulic activity of belite doped by phosphate was investigated on samples prepared from pure chemicals and on those from limestone and quartz sand. Depending on the stabilizer level in the raw mix there was either  $\beta\text{-C}_2\text{S}$  or  $\alpha'$ -modification or a mixture of the two polymorphs found in clinker. Clinkers and their hydration products were examined by chemical and thermal analyses, X-ray diffraction, optical and scanning electron microscopy. Strength testings disclosed that  $\alpha'$ -form alone or in combination with  $\beta$ -polymorph had better strengths than  $\beta\text{-C}_2\text{S}$ .

To estimate the stabilizing effect of  $\text{Ca}_5(\text{PO}_4)_3\text{OH}$  the compressive strengths were compared with those on clinkers doped by  $\text{BaSO}_4$  where they were considerably higher during the first month of hydration, although the differences diminished at later ages, especially for the  $\alpha'$ -modification.

## 1. INTRODUCTION

Several tetrahedral groups (phosphates, borates, vanadates, sulphates) can substitute the silicate groups in  $C_2S$  solid solutions. It is well known (1,2,3,4,5) that phosphates are efficient for the formation of  $\beta$ -,  $\alpha'$ - and  $\alpha$ - $C_2S$ . When  $Ca_2P_2O_7$  is used as stabilizer the  $\beta$ -form has ample hydraulic properties,  $\alpha'$ -modification has some, but  $\alpha$ -polymorph has none (2). In  $C_2S$  solid solutions stabilized by  $B_2O_3$  (6) and  $V_2O_5$  (7) higher strength development was observed on  $\alpha'$ - $C_2S$  than on  $\beta$ - $C_2S$ . Notwithstanding the fact that numerous data are available on this subject it is hard to predict the effect of a certain minor element on the hydraulicity of belite clinkers prepared from different raw materials under different burning conditions. The present paper deals with the effects which different levels of apatite in the raw mix can have on the stabilization of dicalcium silicate phases and their hydraulic activity.

## II. EXPERIMENTAL DATA

### (1) Preparation of specimens

Chemicals used for the preparation of belites were analytical grade  $CaCO_3$  and  $SiO_2$  and pure grade  $Ca_5(PO_4)_3OH$ .

The initial mix was homogenized, calcined at  $1000^\circ C$ , pressed into pellets and sintered at  $1450^\circ C$  for 90 minutes, then reground, compacted and resintered under identical conditions. The product was air-quenched and ground to the specific surface of  $3600 \pm 100 \text{ cm}^2/\text{g}$  (Blaine).

TABLE I

Raw materials for belite clinkers (w.%)		
Components	Limestone	Quartz
$SiO_2$	0.10	97.20
$Al_2O_3$	-	0.97
$Fe_2O_3$	0.07	0.30
CaO	55.90	0.63
Ign. loss	43.88	0.43
MgO, $SO_3$ , $Na_2O$ and $K_2O$ not detected		

The raw materials used for belite clinkers are listed in Table I.

The components for belite clinkers were ground to the respective fineness (no residue on  $200 \mu\text{m}$  m. s.

sieve and less than 10% on  $90 \mu\text{m}$ ), homogenized, calcined at  $1000^\circ C$ , pressed into pellets and fired at  $1450^\circ C$  for 90 minutes, air-quenched and ground to the specific surface of  $3600 \pm 100 \text{ cm}^2/\text{g}$ .

Polished samples etched with 1%  $HNO_3$ -alcohol solution were studied by optical microscopy in reflected light, while SEM observations were made on fracture surfaces coated with a layer of gold.

The water/cement ratio for all cement pastes was 0.28. Samples were compacted in  $1 \times 1 \times 4 \text{ cm}$  moulds on vibrating table.

Mortar specimens were prepared according to the Yugoslav standard (based on RILEM-CEMBUREAU method and ISO Recommendation 679). The mix ratio was cement:graded sand 1:3 and the w/c ratio 0.5 constant. Mortars were mixed mechanically, then compacted in  $4 \times 4 \times 16 \text{ cm}$  moulds on vibrating table.

Paste and mortar specimens were stored 24 hours at  $20 \pm 2^\circ C$  and relative humidity of minimum 90%. Moulds were removed after 24 hours, and specimens stored in water at  $20 \pm 2^\circ C$ .

Samples for hydration study were ground, washed in acetone, dried in vacuum and conserved in desiccator above KOH.

### (2) Investigation methods

X-ray diffraction, wet chemical methods, optical and scanning electron microscopy and thermal analysis served to examine the prepared samples. X-ray diffraction, thermal analysis and microscopic examinations were used to determine the  $C_2S$  modifications and to study the process of hydration. The peak temperature of  $\alpha'_H \rightarrow \alpha$ - $C_2S$  conversion in doped samples was determined by differential thermal analysis and the morphology of specimens studied by scanning electron microscopy. Compressive strength testings on paste and mortar samples were repeated three times to obtain mean values.

## III. RESULTS AND DISCUSSION

In preliminary investigations belites were synthesized from pure chemicals with the stabilizer added at different levels. Their hydraulic activity was determined by testing strengths on cement pastes. Since very high levels of stabilizer are needed to stabilize  $\alpha$ - $C_2S$ , this modification has not been

included into the present work.

Raw mix compositions and phases detected in belites are listed in Table II.

\* XD = X-ray diffraction; OM = optical microscopy.

$\beta$ -C<sub>2</sub>S was the reaction product in sample 1, while samples with higher levels of P<sub>2</sub>O<sub>5</sub> had  $\beta$ - and  $\alpha'$ -modifications coexisting, with the content of  $\alpha'$ -polymorph increasing proportionally to the increase of the stabilizer level and attaining its maximum in sample 5 where  $\alpha'$ -modification started to form. Samples where  $\alpha'$ -form coexisted with  $\beta$ -modification or where it was the main reaction product had better strengths than those where  $\beta$ -C<sub>2</sub>S prevailed.

In literature (3,8,9) it is generally accepted that in C<sub>2</sub>S stabilized by phosphates the  $\alpha$ -modification is hydraulically inert while  $\alpha'$ -modification develops lower strengths than  $\beta$ -polymorph. These results, however, were obtained with a specific stabilizer and under specific experimental conditions (2).

Since our initial investigation of strength development in pastes revealed that  $\beta$ -C<sub>2</sub>S stabilized by phosphates was less reactive than  $\alpha'$ -C<sub>2</sub>S, belite clinkers were synthesized from raw materials listed in Table I and their strength development determined not only on pastes but also on mortars, this being more indicative for the quality of cement (3).

It was also of considerable interest to study the hydraulic activity of  $\alpha'$ - and  $\beta$ -C<sub>2</sub>S prepared from specific industrial raw materials doped by Ca<sub>5</sub>(PO<sub>4</sub>)<sub>3</sub>OH because natural raw materials contain some minor elements which can incorporate into the crystal lattice of C<sub>2</sub>S together with phosphates and thus modify its hydraulic activity.

The chemical composition and phases detected in belite clinkers prepared from limestone, quartz sand and different amounts of Ca<sub>5</sub>(PO<sub>4</sub>)<sub>3</sub>OH are presented in Table III.

TABLE III

Chemical compositions (w.%) and phases detected in belite clinkers				
	P 1	P 2	P 3	P 4

$\beta$ -C <sub>2</sub> S	micr. ++++	++++	+++	+
	X-ray ++++	++++	+++	+
$\alpha'$ -C <sub>2</sub> S	micr.	(+)	(+)	+++
	X-ray		(+)	+++

Limestone and quartz of high purity were hence selected to avoid elevated contents of tricalcium aluminate and ferrite phase. The prepared clinkers had only one crystalline phase, i.e. belite, no free CaO and less than 6% amorphous phase as determined by optical microscopy in reflected light which also revealed a few grains of alite in sample P 4. The fact that  $\alpha'$ -C<sub>2</sub>S develops strength more rapidly than  $\beta$ -C<sub>2</sub>S was again confirmed by compressive strengths measured on pastes of belite clinkers, although the obtained values were lower than in case of belites prepared from pure chemicals.

Fig. 1 - Compressive strengths on mortars of belite clinkers stabilized by phosphate

The strength of sample P 4 with predominantly  $\alpha'$ - $C_2S$  is obviously higher than that in other samples where  $\beta$ - $C_2S$  coexists with  $\alpha'$ -form or where it is the main reaction product like in sample P 1 which was doped with the smallest amount of stabilizer.

Fig.2 - Reflected light microscopic photographs of belites stabilized by phosphate:  
(A)  $\alpha$ - $C_2S$ ; (B)  $\alpha'$ - $C_2S$  and (C)  $\beta$ - $C_2S$

The polymorphic modifications of dicalcium silicate were determined by X-ray diffraction and optical microscopy. Fig.2 illustrates the features typical for particular  $C_2S$  polymorphs. The  $C_2S$  crystal grains without lamellae Fig.2 (A) are those of  $\alpha$ - $C_2S$ ; (B) shows  $\alpha'$ -grains recognizable by skeleton structure, while (C) illustrates the  $\beta$ -form; complete grain exhibits only polysynthetic lamellae formed by phase transition of  $\alpha'$ - $C_2S$  into  $\beta$ -form.

Differential thermal analysis showed that the stabilizer had completely passed into  $C_2S$  solid solution during synthesis. The method proceeds from the fact that the decrease in phase conversion temperature depends on the level of stabilizer dissolved in  $C_2S$ . Peak temperatures of the endothermic  $\alpha'_H \rightarrow \alpha$ - $C_2S$  phase transformation plotted as a function of  $P_2O_5$  percentage in the raw mix are presented in Fig.3.

Fig.3 - Effect of  $P_2O_5$  concentrations on the  $\alpha'_H \rightarrow \alpha$ - $C_2S$  transition temperature

Scanning electron microscopy studies were made on samples doped with phosphates or barium sulphate (10) for comparison. It is obvious (Fig.4) that the shape and size of grains depend more on the content than on the kind of stabilizer.  $\beta$ - $C_2S$  crystals vary in size between 2 and 10  $\mu m$ , Fig. 4 (A) and (B), those of  $\alpha'$ - $C_2S$  between 10 and 20  $\mu m$  (C) and (D).

Fig.4 - SEM characteristic morphologies of belites with 1.47%  $P_2O_5$  (A); 6.66%  $BaSO_4$  (B); 4.70%  $P_2O_5$  (C) and 12.71%  $BaSO_4$  (D) in the raw mix

The hydration process was studied by thermal and X-ray analyses which confirmed that strengths develop with the advancement of hydration.

Fig. 5 presents the water content in C-S-H gel determined in the temperature range from 100 to 350°C by TG and DTG.

Belites from pure chemicals (samples 1-6) have a higher content of C-S-H gel than belite clinkers (samples P1-P4). In both groups the content of gel increases with higher levels of stabilizer and is higher in samples with  $\alpha$ -form than in those with  $\beta$ - $C_2S$ . The gain of the gel formation is most expressed up to 28 days.

Fig.5 - Water content in hydrated samples as function of hydration time

To estimate the effect of  $Ca_5(PO_4)_3OH$  as stabilizer belite clinkers doped with  $BaSO_4$  (10) were sintered from the same raw materials, ground to the same specific surface and tested on mortars in the same way as belite clinkers stabilized by phosphates. For comparison with the present data the chemical composition and phases detected in  $BaSO_4$  doped belite clinkers are presented in Table IV and their compressive strengths in Fig.6 (10). In the first month of hydration belite clinkers stabilized by phosphate had a remarkably lower strength but after 180 days the differences were less obvious, especially for the  $\alpha$ -modification.

TABLE IV

Chemical composition (w.%) and phases detected in belite clinkers stabilized by BaSO <sub>4</sub>		B 1	B 2	B 3
SiO <sub>2</sub>		32.68	30.87	28.24
Al <sub>2</sub> O <sub>3</sub>		0.32	0.31	0.27
Fe <sub>2</sub> O <sub>3</sub>		0.10	0.09	0.09
CaO		61.04	57.62	55.58
BaO		4.39	8.47	12.02
SO <sub>3</sub>		1.21	2.35	3.44
$\beta$ -C <sub>2</sub> S	micr.	++++	+++	++
	X-ray	++++	++	++
$\alpha'$ -C <sub>2</sub> S	micr.		+	+
	X-ray		++	++
$\alpha$ -C <sub>2</sub> S	micr.			+

Fig. 6 - Compressive strength of mortars from belite clinkers stabilized by BaSO<sub>4</sub>

The results obtained for Ca<sub>5</sub>(PO<sub>4</sub>)<sub>3</sub>OH stabilized C<sub>2</sub>S are in agreement with the findings for belites stabilized by B<sub>2</sub>O<sub>3</sub> (6), V<sub>2</sub>O<sub>5</sub> (7), BaSO<sub>4</sub> (10) and Ba<sub>2</sub>SiO<sub>4</sub> (11) but opposed to the statement that the hydraulic activity of  $\alpha'$ -C<sub>2</sub>S stabilized by phosphates is lower than that of the respective  $\beta$ -C<sub>2</sub>S (2,3, 8,9).

## IV. CONCLUSIONS

The kind and level of the stabilizer together with the preparation conditions have a strong effect on the hydraulic activity of C<sub>2</sub>S solid solution. Like other phosphates (2,4,5) Ca<sub>5</sub>(PO<sub>4</sub>)<sub>3</sub>OH is a good stabilizing agent for  $\beta$ - or  $\alpha'$ -C<sub>2</sub>S modifications. Stabilized by this compound under described conditions  $\alpha'$ -modification or a mixture of  $\alpha'$ - and  $\beta$ -C<sub>2</sub>S develop higher strengths than  $\beta$ -C<sub>2</sub>S.

Acknowledgement. The investigation was supported by U.S. Department of Transportation and by the Selfmanaging Community for Scientific Research of Croatia. SEM examinations were made at the University of Illinois, Urbana, Ill. 61801, U.S.A.

RESUME : Ceci est le premier d'une série de trois (5,6) comptes rendus sur les effets des fondants et des minéralisateurs utilisés pour accroître l'efficacité du procédé de clinkérisation du ciment. On a étudié les effets de fondants minéralisateurs tels que fluosilicates et fluorures sur l'équilibre des phases dans le système CAFS ainsi que dans ses sous-systèmes C-A-F et C-A-S. Dans ces deux derniers sous-systèmes, les températures d'apparition de la phase liquide sont relativement abaissées, les surfaces des champs primaires de la solution solide  $\text{C}_{12}\text{A}_7$  sont plus étendues, les champs primaires de  $\text{C}_3\text{A}$  sont réduits de beaucoup et dans le système C-A-S une ligne d'Alkemade semble être formée entre la solution solide  $\text{C}_{12}\text{A}_7$  et  $\text{C}_3\text{S}$ , ce qui a pour conséquence de rendre  $\text{C}_3\text{S}$  stable dans des limites de composition plus vastes que celles du système C-A-S pur. Il en résulte aussi la formation de nouveaux points invariants. De plus, la réaction de formation du  $\text{C}_3\text{S}$  est accélérée; sa formation se produit à des températures inférieures à la limite de stabilité apparente indiquée dans le système C-S pur, et l'aire de son champ primaire est agrandie. On a étudié des portions du système CAFS avec un fluosilicate. La solution solide  $\text{C}_{12}\text{A}_7$  reste la phase dominante, même avec l'ajout de 5 à 20 % de  $\text{Fe}_2\text{O}_3$  au système C-A-S ( $\text{CaSiF}_6$ ). Certaines des limites de phase des systèmes CAF et CAS contenant du fluosilicate peuvent logiquement être extrapolées au système complexe CAFS + fluosilicate. Ceci a été observé expérimentalement. Les effets sur les relations entre les phases et les phénomènes cinétiques qui s'y rattachent apparaissent être favorables à la fabrication du clinker, ce qui a pour conséquence d'augmenter l'efficacité du four.

SUMMARY: This is the first of a three-part series (5,6) studying the effects of fluxes and mineralizers to increase efficiency of the cement clinkering processes. The effects of flux mineralizers, primarily fluosilicates and fluorides upon phase equilibria in the system  $\text{CaO-Al}_2\text{O}_3\text{-Fe}_2\text{O}_3\text{-SiO}_2$  (C-A-F-S) and its subsystems C-A-F and C-A-S have been investigated. In both the latter subsystems the temperatures for first liquid formation are lowered substantially, the primary phase field areas of  $\text{C}_{12}\text{A}_7$  solid solution are vastly expanded, the field areas of  $\text{C}_3\text{A}$  are much diminished, and in the C-A-S system an Alkemade line appears to be formed between  $\text{C}_{12}\text{A}_7$  solid solution and  $\text{C}_3\text{S}$ , resulting in the stable existence of  $\text{C}_3\text{S}$  over a broader composition range than in the pure C-A-S system. This also results in the formation of new invariant points. Furthermore, reaction to form  $\text{C}_3\text{S}$  is accelerated; its formation takes place at temperatures below the apparent lower stability limit in the pure C-S system; and its primary phase field area is increased in size. Portions of the C-A-F-S system with fluosilicate were studied. When  $\text{Fe}_2\text{O}_3$  was added to the C-A-S ( $\text{CaSiF}_6$ ) system in amounts from five to twenty percent,  $\text{C}_{12}\text{A}_7$  solid solution was still found to be the dominant phase. Some of the phase boundaries determined from the C-A-F and C-A-S systems with fluosilicate, logically can be extrapolated into the complex C-A-F-S system + fluosilicate and are experimentally observed. The effects upon phase relations and related kinetic phenomena appear to be favorable to the cement clinker manufacturing process; resulting in greater kiln efficiency.

## INTRODUCTION

The efficiency of cement clinker production can be increased by the addition of minor amounts of other components classified as fluxes and mineralizers (1-6). However, these additions are likely to affect the final equilibrium phase relationships of the end products formed in the basic cement system,  $\text{CaO-Al}_2\text{O}_3\text{-Fe}_2\text{O}_3\text{-SiO}_2$  (C-A-F-S).<sup>\*</sup> The primary goal of this study was to understand the equilibrium relationships in the above basic system with the addition of calcium fluosilicate, and their effect on the clinkering process.

Studies of the effects of fluxes and mineralizers on the kinetics of alite formation (5) and upon the burnability of raw mixes (6) are described in separate parallel papers.

The fluosilicates can be classified as both fluxes and mineralizers because of their abilities to both lower the melting temperatures and to accelerate the reaction kinetics.

The importance of systematic studies to determine the phase equilibrium relationships in the system C-A-F-S with added fluxes (especially fluogride fluxes) has been discussed previously (2-4). Relevant previous studies in these systems or subsystems have also been reported earlier (1-4). Most previous studies used  $\text{CaF}_2$  as the flux component, but little systematic work had been done to ascertain the effect of  $\text{CaF}_2$  on the ultimate equilibrium phase products starting from a wide range of compositions. The published studies involved various subsystems of the major C-A-S system or the subsolidus phase relationships with  $\text{CaF}_2$  as one of the components. Since the cement manufacturing process involves an essential liquid formation step, for efficient flux utilization an accurate knowledge of the phase equilibrium relationships of the actual system including its liquidus surface is highly desired.

Before proceeding to determine the effects of fluxes on the complex system C-A-F-S (7), first the effects upon the two ternary systems, C-A-F (3) and C-A-S (4) were studied. The first system was studied adding 5 wt %  $\text{CaSiF}_6 \cdot 2\text{H}_2\text{O}$  (1.85 wt %  $\text{CaF}_2$ ), whereas the latter system was studied adding 5 wt %  $\text{CaSiF}_6$  (2.2 wt %  $\text{CaF}_2$ ). [Five percent  $\text{CaSiF}_6$  represents about 1.1 wt % F in the original starting material--cements with ~1.5 wt % F have been prepared commercially (8,9).]

Once the equilibrium relationships were established in the C-A-S system then the equilibrium relationships were studied with incremental additions of  $\text{Fe}_2\text{O}_3$ . The results summarized here include the effect of fluoride additions to both C-A-F and C-A-S systems, together with some observations of the effects of adding up to 20 wt %  $\text{Fe}_2\text{O}_3$  in the C-A-S system with 5 wt %  $\text{CaSiF}_6$ . (Typical cements contain ~5 wt %  $\text{Fe}_2\text{O}_3$ .) The compositions chosen in the C-A-F-S system lie mainly close to the CaO apex of the C-A-F-S tetrahedron (7), and encompass the important invariant points, phase boundaries, and pseudo-Alkemade lines.\*\*

\*Abbreviations: C = CaO, A =  $\text{Al}_2\text{O}_3$ , F =  $\text{Fe}_2\text{O}_3$ , S =  $\text{SiO}_2$ .

\*\*Pseudo because the systems are quaternary or more complex, though usually containing minor amounts of the added component.

## EXPERIMENTAL

The starting mixtures were usually made in batches of 2-3 gm using reagent grade chemicals:  $\text{CaCO}_3$ , silicic acid,  $\text{Al}_2\text{O}_3$ ,  $\text{Fe}_2\text{O}_3$ , and  $\text{CaSiF}_6 \cdot 2\text{H}_2\text{O}$ . The  $\text{CaCO}_3$ ,  $\text{Al}_2\text{O}_3$  and  $\text{Fe}_2\text{O}_3$  were first dried before weighing, but the silicic acid and the  $\text{CaSiF}_6 \cdot 2\text{H}_2\text{O}$  were used as received with weight losses quantified. The mixtures were first moistened with acetone and then blended thoroughly by grinding in an agate mortar. These mixtures were air dried, transferred to a covered Pt-crucible and then fired in an electrically heated pot furnace in air atmosphere at a temperature of 925-950°C (a temperature well below initial liquid formation) for one hour, to decompose the carbonate and the silicic acid. At this temperature,  $\text{CaSiF}_6 \cdot 2\text{H}_2\text{O}$  decomposes losing most of its  $\text{SiF}_4$ , and for all practical purposes behaves as  $\text{CaF}_2$ . In order to simulate the fluxing action in an actual clinkering process, this way of preparing the mixtures was found to have practical bearing allowing thorough mixing and better fluxing action. The sintered cake after firing was cooled, crushed and ground thoroughly in an agate mortar to assure proper homogeneity of the starting mixtures for the equilibration runs.

All the equilibration runs were made in sealed Pt tubes by suspending them in a controlled temperature quench furnace. At the conclusion of the runs, the samples were quenched in carbon tetrachloride. It was found that, for most of the mixtures, the quenching done either by quickly withdrawing the samples and then quenching in the liquid or by the conventional quenching (wire burn-out method) gave identical results. The identifications of the phases were mostly made by x-ray powder diffraction, supplemented by optical microscopy. In some cases, the presence of the quench phase could not be prevented even by the conventional quenching techniques. It should also be mentioned that some of the compositions studied were hard to quench to form glass, basically because many are not chemically in the glass-forming range. Additionally, maximum convenient furnace temperature operation limits, in combination with the presence of non-quenchable liquids, plus slow subsolidus reaction, sometimes made it difficult to make correct inferences. Difficulty was encountered in positively identifying the  $\text{C}_2\text{S}$  and  $\text{C}_3\text{S}$  in instances when they were both present, with either one only in small amount.

The temperatures were measured by a Pt/Pt90-Rh10 thermocouple and read through a digital thermometer (Doric Series 400 A Digital Trendicator). The thermocouple/digital thermometer was calibrated against the boiling point of tap water (98°C), the melting point of gold (1063°C), and diopside (1392°C), respectively. The temperatures reported here are reliable to  $\pm 2^\circ\text{C}$  taking into consideration both the furnace temperature fluctuations (controller error) and the thermometer error.

## RESULTS

**C-A-F System Plus Fluoride:** The subsolidus phase relationships in the normal ternary system at 1145°C is shown in Figure 1 (10). Characteristic of this system is the formation of extensive ranges of solid solutions. The major one of interest is that which is collectively called calcium aluminoferrite solid solution ( $\text{C}_4\text{AF}_{ss}$ , or  $\text{F}_{ss}$ ). All calcium aluminates can incorporate iron ( $\text{Fe}^{3+}$  ions replacing  $\text{Al}^{3+}$  ions) in their crystal structures. This type of substitution gives rise to the formation of a ternary phase T,

Figure 1. Subsolidus Relations in the Ternary  $\text{CaO-Fe}_2\text{O}_3\text{-Al}_2\text{O}_3$  System (10).

Figure 2. Liquidus Relations in the Ternary  $\text{CaO-Fe}_2\text{O}_3\text{-Al}_2\text{O}_3$  System (10).

lying on the join of two imaginary compounds  $\text{CA}_3$  and  $\text{CF}_3$  between 12 and 28 wt %  $\text{Al}_2\text{O}_3$  in the C-A-F triangle. The polythermal projection of the liquidus surface of this system is shown in Figure 2 (10). This figure shows the relative sizes of the primary phase field areas of all compounds including that of the ternary T-phase.

The changes to this system, upon the addition of fluosilicate, are shown in Figure 3. The solid lines show the newly-formed phase boundaries and the dashed lines show the "pure" system, plus sequences showing the postulated sequence of change of boundaries with increasing fluoride content.

When compared with the original C-A-F system, the addition of fluosilicate (fluoride) flux depresses the invariant temperatures which now become piercing points through a plane in the quaternary system. Also, the phase boundary positions are shifted substantially. This causes an expansion of the  $\text{C}_{12}\text{A}_7$ ss field, as a result of which two new invariant points are established. At the 5 wt %  $\text{CaSiF}_6 \cdot 2\text{H}_2\text{O}$  level, the  $\text{C}_3\text{A}$  phase field completely disappears at lower temperatures (solidus to subsolidus temperatures).

Similarly, the expansion of the T-phase field area reduced the area of the CA and  $\text{CA}_2$  fields ultimately eliminating the CA-CF boundary curve present in the original system.

**C-A-S System Plus Fluoride:** A portion of the ternary C-A-S diagram is shown in Figure 4 (11). This portion

(a) Subsolidus Phase Relationships.

(b) Liquidus Phase Relationships (3).

Figure 3. Phase Diagram of the System  $\text{CaO-Al}_2\text{O}_3\text{-Fe}_2\text{O}_3$  Modified by Addition of 5 wt %  $\text{CaSiF}_6 \cdot 2\text{H}_2\text{O}$ .

of the diagram is of interest to the cement chemist since most of the portland cement compositions are approximated by compositions within the  $\text{C}_3\text{S-C}_2\text{S-C}_3\text{A}$  triangle. The lowest melting temperature (eutectic) for any compositional mixtures within the  $\text{C}_3\text{S-C}_2\text{S-C}_3\text{A}$  triangle is  $1455^\circ\text{C}$ . This diagram also shows the pertinent phase field areas of the major compounds of interest in cement chemistry, other invariant points and Alkemade lines also.

Figure 4. Phase Equilibria in the Ternary System  $\text{CaO-Al}_2\text{O}_3\text{-SiO}_2$  (11).

Figure 5. Apparent Phase Equilibria in the System  $\text{CaO-Al}_2\text{O}_3\text{-SiO}_2$  with Addition of 5 wt %  $\text{CaSiF}_6$  (4b).

When fluosilicate is added to this system, the experimental data combined with existing data on this system can be best represented by the liquidus diagram shown in Figure 5 (4b). This figure is actually a polythermal projection of 5 wt %  $\text{CaSiF}_6$  section through the tetrahedron of the pseudoquaternary system  $\text{CaO-Al}_2\text{O}_3\text{-SiO}_2\text{-CaSiF}_6$ .<sup>\*</sup> A comparison of Figures 4 and 5 shows the notable differences. The primary phase field areas of  $\text{C}_3\text{S}$ ,  $\text{C}_3\text{A}$  and  $\text{C}_{12}\text{A}_7\text{ss}$  are vastly changed. Two new pseudo-Alkemade lines are formed, one joining  $\text{C}_3\text{S}$  and  $\text{C}_{12}\text{A}_7\text{ss}$  and the other joining  $\text{C}_{12}\text{A}_7\text{ss}$  and gehlenite. This gives rise to the formation of two new invariant points. Also, the temperatures of the invariant points among 3-phase assemblages from the original ternary system are lowered when fluosilicate is added to the original C-A-S system.  $\text{C}_3\text{A}$  was not detected in any quenching runs below  $\sim 1400^\circ\text{C}$ .

**C-A-F-S System with Added Fluoride Flux:**  $\text{Fe}_2\text{O}_3$  was added in amounts of 5, 10, and 25 wt % to some selected compositions in the C-A-S system along with 5 wt %  $\text{CaSiF}_6$ . These compositions were chosen at appropriate positions within the compatibility triangles presented in Figure 5. The data obtained to date are insufficient to construct the full quaternary system (plus the fifth component, fluoride flux); thus, it was attempted to observe the effect of adding a constant wt %  $\text{Fe}_2\text{O}_3$  to the C-A-S (+ fluoride) system keeping the compositions studied in a range relevant to those providing information about potential cement phase compositions. Also, since portland cements commonly have in the vicinity of  $\leq 5$  wt % of  $\text{Fe}_2\text{O}_3$  in their chemical compositions the 5 wt % level was selected first. However, compositions using higher  $\text{Fe}_2\text{O}_3$  contents were studied as well in order to better identify the  $\text{Fe}_2\text{O}_3$ -containing phases.

The results of the quench runs of the compositions studied are listed in Table 1. A careful examination of this table will show that some of the observed phases were not exactly as would be expected. In most cases crystalline " $\text{C}_4\text{AF}$ " was not found, except at  $\sim 1209^\circ\text{C}$  (was not present at  $1307^\circ\text{C}$ ), and probably was quenched from the liquid phase, to form a glass, even

with compositions containing 10 wt %  $\text{Fe}_2\text{O}_3$ . However, in general, the addition of 5 wt %  $\text{Fe}_2\text{O}_3$  was found to lower the temperature of liquid formation significantly over those of C-A-S system. Though not the "cement" invariant point, the lowest melting temperature in the original C-A-F-S system is at  $1280^\circ\text{C}$  among  $\text{C}_2\text{S}$ ,  $\text{C}_3\text{A}$ ,  $\text{C}_{12}\text{A}_7$  and  $\text{C}_4\text{AF}$  phases (7). The invariant points involving  $\text{C}_3\text{S}$  are also lowered and, due to the addition of fluoride flux,  $\text{C}_3\text{S}$  can be formed at temperatures as low as  $1200^\circ\text{C}$ , while it was unstable below  $1250^\circ\text{C}$  in the original C-S diagram.

Some of the equilibria established in the fluoride-modified C-A-S and C-A-F systems may be projected, into the C-A-F-S system. Equilibrium sets of three solid phases in the "ternary" system when projected into the "quaternary" system add a fourth phase, liquid. Some of the same features were observed experimentally in the C-A-F-S system.  $\text{C}_{12}\text{A}_7\text{ss}$  is still dominant in the C-A-F-S system. Though phase compatibilities have been determined (12,13), the only previous detailed equilibrium phase relationship study published on this system is by Uchikawa and Matuzaki (8) in an attempt to understand the process of making jet cement. They studied the C-A-S system with 1 wt %  $\text{Fe}_2\text{O}_3$  at 2 wt % and 5 wt %  $\text{CaF}_2$  level only. Although some of the basic results of their studies agree with the present observations, there are some differences in the temperatures of comparable invariant points. Since the compositions studied were not identical (i.e., 1 vs. 5 wt %  $\text{Fe}_2\text{O}_3$ ) this is not surprising. The invariant temperatures in the present study with 5 wt %  $\text{CaSiF}_6$  (2.2 wt %  $\text{CaF}_2$ ) even in the C-A-S system are lower than the former workers' values for the C-A-S system with 1 wt %  $\text{Fe}_2\text{O}_3$  at the 5 wt %  $\text{CaF}_2$  level. They also observed (8) that fluorine was not lost from the system. The contrast suggests that fluosilicate is an even better flux than  $\text{CaF}_2$  itself. Since the first emphasis of the present study was to understand the phase behaviors, no detailed characterization of the extent or compositional ranges of the solid solutions formed among the phases has yet been carried out.

## DISCUSSION AND CONCLUSION

The studies on both C-A-F and C-A-S systems with the fluoride flux show some common features. Apart from lowering the liquidus temperatures, the most significant feature in both systems is the formation of the solid solution phase  $\text{C}_{12-x}\text{A}_7\text{CaF}_2$ , which greatly increases the primary phase field area of  $\text{C}_{12}\text{A}_7\text{ss}$ . As a result of this expansion, the  $\text{C}_3\text{A}$  primary phase field area is reduced. At the level of fluosilicate addition studied, no  $\text{C}_3\text{A}$  was detected below solidus temperatures. Also, the increased area of  $\text{C}_{12}\text{A}_7\text{ss}$  primary field causes the development of new invariant points in the lime-rich regions of both the C-A-F and C-A-S systems. The temperature of the "eutectic" or "peritectic" points are not necessarily the temperatures of first liquid formation, but are piercing points of the quaternary univariant curve proceeding toward an invariant point. At the temperature of the true invariant point the onset of fluxing action occurs through the formation of a very small amount of liquid. It is also noted in the C-A-S (+ flux) system (Figure 5) that the  $\text{C}_3\text{S}$  primary phase field area is enlarged considerably. This is in agreement with the published results for C- $\text{C}_2\text{S}$ - $\text{CaF}_2$  system (14). Similarly, the existence of new pseudo-Alkemade line joining  $\text{C}_3\text{S}$  and  $\text{C}_{12}\text{A}_7\text{ss}$  in Figure 5 means that  $\text{C}_3\text{S}$  can be formed from

<sup>\*</sup>Actually as discussed earlier, much  $\text{SiF}_4$  is lost.

compositions for which it was previously impossible in the original system. Furthermore, the temperature of the quaternary invariant point, 1338°C among  $C_3S$ ,  $C_2S$ ,  $C_3A$  and  $C_4AF+L$  phases (7), which is most relevant to portland cement chemistry is further lowered by the addition of 5 wt %  $CaSiF_6$ , at a level of 5 wt %  $Fe_2O_3$ . Liquid is formed at temperature of  $\sim 1300^\circ C$ . However, the compatible phases are apparently  $C_2S + C_3S + C_{12}A_7 + C_4AF + L$ . With increasing percent of  $Fe_2O_3$ , the amounts of liquids at these temperatures were further increased. Formation of  $C_4AF$  in the quench runs was clearly observed by x-ray diffraction at compositions with 20 wt %  $Fe_2O_3$ . In some quench runs, unidentified peaks were observed in the x-ray diffraction patterns. They have been listed as unknown in the table. These were observed with compositions generally low in  $SiO_2$  content and when  $C_3S$  was expected as an equilibrium phase. Continued efforts in progress will attempt to characterize such phase or phases in greater detail.

It is noted in conclusion that from the standpoint of phase equilibria, compositions apparently favorable for cements may lie near mixture #15 (Table I) at 5 wt % levels of  $Fe_2O_3$  and  $CaSiF_6$ . From such a composition liquid formation takes place at a much lower temperature than without flux, and reaction kinetics are accelerated. The latter factors are discussed in the partial papers by Christensen and Johansen (5), and by Klemm and Jawed (6).

#### ACKNOWLEDGEMENTS

The support for this research came from National Science Foundation Grant ENG7617217. The authors would like to thank J. Weigner for his assistance.

# Mineral formation and Reactive Capacity of Portland Cement Raw Mixtures

## *Influence de la composition du cru sur la clinkérisation et la réactivité du ciment*

P.V. ZOZULJA, Can.T.Sc. Leningrad Technological Institute, Leningrad, U.S.S.R.

E.A. RODIONOV, Engineer Department of Chemical Technology of Binding Materials.

RESUME : Les particularités du processus de cuisson ont été observées, en continu, par examen diffractométrique des différentes phases qui se forment et disparaissent, au cours d'un traitement thermique bien programmé. Cette méthode permet de déceler les différences, dans la clinkérisation, dues à la composition minéralogique du cru. On a pu ainsi classer les crus, en fonction de leur comportement au cours de la cuisson. On peut aussi en déduire l'efficacité de l'action des composants minéralisateurs et établir des règles sûres, quant à l'effet de variation de la composition du cru, sur sa réactivité.

SUMMARY: The peculiarities of diffractometric study of sintering processes technique are considered. The technique is based on the principle of continuous registering the changes of the analytical line of the phase which appears or disappears in heat treatment of the raw mixture sample according to the predetermined temperature condition. The suggested technique permits to discover the differences in the process of sintering raw mixture charges which are due to the mineralogy of the raw material, enables to classify the raw mixtures according to their behaviour in heating, allows to reveal and to estimate the effect of mineralizing components and is a safe foundation for the comparative estimation of the charge reactivity when its chemical and component composition is changed.

The change of the nature of raw mixture components influences considerably the progress of mineral forming processes both at the stage of hard-phase reactions [1,2] and at the final, liquid-phase stage of clinker formation.

To characterize differences in the behaviour of raw mixtures during burning, several terms almost equal in their meaning are used in the chemistry and technology of clinker: sinterability, burnability, reactive capacity. Lately, a number of investigations has been carried out the authors of which try to depart from purely descriptive terminology and to work out the methods of obtaining criterial estimations of raw mixture thermal properties on the physico-chemical basis. The methods suggested for solving this task may be conditionally divided into three groups:

Methods of estimating reactive capacity on the basis of the properties of the original condition of raw mixtures and their separate components (reactivity [3], dispersity [4] etc.) may be included into the first-group.

Methods based on the characteristics of the sintering process estimating the peculiarities of raw mixture thermal behaviour (according to the degree and the rate of free CaO assimilation by the thermogravimetric method [5], by the intensity of shrinkage deformations [6], by determining the heat of solution [7] and the changes of the heat content of the material in the course of burning, etc. are included into the second group.

Methods based on the calculated determination of the criteria regarding the role of the most important clinker formation parameters (viscosity, the melt amount, the ratio of minerals - silicates, dispersity, the role of admixture components, etc.) are included into the third group.

A great number of the methods suggested does not allow to reproduce and to compare the data obtained in different laboratories for estimating the reactive capacity. The direct measurement of the material heat content in the process of burning by means of high temperature differential microcalorimetry should be considered one of the prospective methods.

Nevertheless, the principal and most widely used method applied in most countries at present is the method of determining sinterability according to dynamics of changing the amount of free CaO. The combination of calculated and experimental approaches gives positive results [8], however the expenditures to the preliminary experimental study in this case are too great and the method itself does not exclude the possibility of mistakes as a result of the influence of unknown factors (for instance, the mineralogy of the raw material).

The task of stabilizing raw mixture composi-

tions by employing new kinds of raw materials in the sphere of production and the usage of commercial wastes, the reduction of heat expenses, intensification and stabilization of the burning schedule, working out of the systems of automation control and the control of automatized technological processes require further development of the methods of rapid and reliable estimation of raw mixture behaviour in the process of burning and the estimation of the changes in their reactive capacity.

For the purpose of obtaining continuous information about the progress of mineral formation in the course of burning raw cement mix and for the reduction of time-consuming character of experiments determining the changes in the reactive capacity of raw mixtures the apparatus was elaborated at the department of chemical technology of binding materials, at the Leningrad Lenin Soviet Technological Institute. Also, the possibilities were studied to apply the method of Kinetic X-Ray-Phase Analysis (KRA) for the purpose mentioned. The method is based on the principle of continuous recording analytical X-ray diffraction intensity of the phase, appearing or disappearing in heating the investigated sample according to the predetermined schedule.

The realization of this method has become possible with the appearance of diffractometers [9], lately this method has acquired wide application in studying the changes in the phase state as a result of various chemical and thermal processes taking place.

Let us consider the possibilities and the peculiarities of applying the KRA method for studying the progress of mineral formation and the estimation of reactive capacity of cement raw materials. One may obtain valuable information on sintering process by continuous recording the dependance  $I - I(t)$ , where  $I_{CaO}$  is the diffraction CaO free line intensity of the phase  $CaO/d/n - 2.405$  in pulses per sec. and  $t$  - varying sample temperature. Since the diffraction line intensity is influenced by many factors the effect of which is difficult to control (the variation of the size, shape and the number of particles taking place in the diffraction, the influence of admixtures upon the recrystallization rate, variations in the kinetics of the processes taking place in the surface or inside the sample, etc.) the curves in the first approximation give information of the purely qualitative character. If it is necessary, however, they may be supplemented with chemical determination of  $CaO_{free}$  in various points of the curve that gives opportunity to compare quantitatively the data for different kinds of raw mixtures. The application of the diffractometric method for the description of the curve  $CaO - I(t)$  allows to increase the informative character of these curves, gives the identical results, enables to consider the influence of the gas atmosphere (by changing the medium composition in heating the sample), decreases labour-

consuming character and reduces the time of the experiment and it also forms the basis for automatic calculation and for the treatment of the results.

The installation for the KRA includes diffractometer URS-50 IM with modified system of recording on the basis of scintillation detector, high temperature kiln which may reach temperatures up to  $1500^{\circ}\text{C}$  and has heaters made of platinum-rhodium alloy containing 30 per cent of rhodium, a program unit with an electronic temperature controller, limiters of goniometer angular rotation, XY type two-coordinate recording potentiometer and temperature control potentiometer with temperature transducer. Block diagram of the apparatus is shown in Fig.1.

Fig.1. Block Diagram of the installation for Kinetic X-ray Phase Analysis.

1 - Reversing switch, 2 - goniometer, 3 - blocks of signal amplification and conversion, 4 - recording potentiometer, 5 - temperature register, 6 - photoelectric relay, 7 - control potentiometer, 8 - constant voltage regulator, 9 - voltage regulator, 10 - platinum-rhodium heater, 11 - couples, 12 - Actuating Mechanism, 13 - Electronic controller, 14 - Program control point adjustment.

To obtain the KRA curves the powdery sample is pressed in the platinum-rhodium cuvette having the size  $8 \times 15$  mm, which is placed in the corundum holder of the high temperature kiln. In the course of heating according to the predetermined temperature schedule (usually rate of heating was 10 deg. per min.) recording is made of the shape of the analytical line of the chosen phase. It is made in the fixed range of angular reciprocal rotation of the counter (in this case diffraction intensity of  $\text{CaO}_{\text{free}}$  ( $d/n - 2.405$  is registered). The rate of goniometer angular rotation amounts to 1-2 deg. per min. Time constant of the counting system is 5 sec. Integral curve of  $I_{\text{CaO}_{\text{free}}} - f(t)$  is obtained by outlining the peaks of diffraction lines.

Over fifty samples of commercial raw mixtures from cement factories of the Soviet Union and raw mixture samples made in laboratory were investigated. Some typical examples

of the curves are given in Fig.2. The checking of the shape of KRA curves according to the method of titration of the samples heated according to the same schedule and sharply cooled in fixed points showed good agreement of the results.

It should be noted that in literature [6] the authors met rather detailed curves drawn according to the method of chemical titration of  $\text{CaO}_{\text{free}}$  which remind in their character the free ones obtained by the KRA method. The data obtained by the authors allow to explain the shape of the curves from the point of view of raw material mineralogy influence and of a special course of mineral forming processes depending upon the reaction capacity of raw mixtures that is the basis of their composition optimization. The KRA curves give a rather visual evidence of the raw mixture reaction capacity and allow to classify them depending upon the character of mineral formation with considerably less time to obtain the necessary information than in the traditional method of obtaining the sinterability information by measuring the  $\text{CaO}_{\text{free}}$  content according to the method of successively burned samples.

Fig.2. The Curves of Kinetic X-ray Phase Analysis (KRA) for Various  $\text{CaO}_{\text{free}}$  types of Raw Mixtures According to their Binding Kinetics. The explanation of the figures 1, 2, 3, 4, 5 are given in the text.

Thus, for instance, Curve 1 shown in Fig.2 is characteristic for the cases when there is an effective mineralizer in the raw mixture. The mineralizing effect manifests itself in the change of temperature when the peak of  $\text{CaO}_{\text{free}}$  first appears, in the increase of the curve incidence and in the appearance of sharp peak, showing that, on the one hand, the speed of evolving  $\text{CaO}_{\text{free}}$  phase leaves behind its assimilation process and recrystallization and, on the other hand, the shape of the curve indicates to the rapid recrystallization and binding  $\text{CaO}$  with the rise of temperature. Curve 2 indicates to the high rate of dissociation of the carbonate component of the raw mix (in this case it is chalk) and, at the same time, to the retarded course of the mineralizing processes (and recrystallization) that shows

the low reaction capacity of the raw mixture.

Curves 3 and 4 are typical for the raw mixtures with low reaction capacity of the carbonate component (marble, hard limestone). Such type of the curves is characterized by shifting the intensity maximum of  $\text{CaO}_{\text{free}}$  peak to the area of higher temperatures (up to  $900^{\circ}\text{C}$ ) and by the hampered binding of  $\text{CaO}$  into clinker minerals.

Curve 5 shows the mode of binding  $\text{CaO}$  for the case when raw mixture contains considerable quantities of admixture oxides, such as  $\text{R}_2\text{O}$ ,  $\text{SO}_3$ ,  $\text{MgO}$ . Comparatively gently sloping part of the curve in the zone of higher temperatures indicates to the mineralizing effect of admixture components at the stage of hard-phase reactions and to the retardation of clinker-formation in the region of higher temperatures.

Considerable advantage of the KRA method is its continuity that allows to reveal some peculiarities of mineral formation which could be hardly found out, were the method of separate sample titration used. There is a depression in the curves of  $\text{CaO}$  assimilation when the intermediate compound, spurrite is formed in the range of temperatures in which hard-phase reactions take place. The depression appears as a result of binding carbonate component into a complex silico-carbonate phase spurrite, stable in air up to  $940 - 950^{\circ}\text{C}$ . The dissociation of this compound results in rapid evolution of new portions of  $\text{CaO}_{\text{free}}$  at high temperatures. In general, the formation of spurrite phase in raw mixtures seems to produce negative effect on the conditions of preparing raw mixtures for burning since the dissociation of spurrite takes place with great absorption of heat (50 k.kal/mole) and shifts the zone of material preparation to the range of higher temperatures promoting quick recrystallization and passivation of  $\text{CaO}_{\text{free}}$ . As to the commercial raw mixture samples, the formation of spurrite was characteristic for the cases when the loam component was represented by illite loams. Further experiments made with artificial mixtures of various carbonate rocks and silica components differing in their activity and dispersity (quartz, silicic acid, silica gel) in combination with other methods of analysis (petrography, DTA, dilatometry, high temperature X-Ray phase analysis) allowed to make a conclusion that combination of two factors promotes the formation of spurrite: low reaction capacity of carbonate component and high activity of silica one. Fig.3 shows the action of mineralizer  $\text{Na}_2\text{SiF}_6$  when F content varies from 0 to 1 per cent.\* The curves are reduced to the same scale by chemical determination of  $\text{CaO}_{\text{free}}$  in five points of the curve. Such an approach makes possible to determine exactly the effective concentration of mineralizer

The results and the treatment of the experimental data for this part of the work were done by Dolbilova I.B.

Fig.3. The Effect of Concentration of Mineralizer upon the Change of  $\text{CaO}_{\text{free}}$  Binding Character.

1 - 0%, 2 - 0,25%, 3 - 0,5%, 4 - 1%  $\text{Na}_2\text{SiF}_6$ .

in the raw mixture. The changes in the KRA curves with the increase of mineralizing addition content are characteristic and typical ones and allow to make a qualitative estimation and classification of the raw mixture components in the first approximation, these components being used in practice as the intensifiers of the burning process (for example, various complex commercial wastes, rocks, etc.). Varying heating conditions one can obtain KRA curves in the same scale irrespective of the heating rate (recording in coordinates  $I_{\text{CaO}_{\text{free}}} - f(t)$  that gives opportunity to obtain  $\text{CaO}_{\text{free}}$  easily comparable data on the influence of thermal treatment conditions upon the course of mineral formation. Such a technique may be used for obtaining the optimum burning schedule.

Thus, the curves of the kinetic X-Ray phase analysis (KRA) are the basis for the classification of raw mixtures depending upon the mineralogy and with regard to their reactive capacity, they make possible to obtain important information on the progress of mineral formation, allow to determine the effective action of mineralizing additions and to take into consideration the influence of variations in raw mixture chemical composition upon sinterability.

# Microscopical estimation of burning condition and quality of clinker

## *Estimation microscopique de la résistance du ciment*

Y. ONO, Dr. Engineering, Senior Research Chemist, Central Research Laboratory of Onoda Cement, Japon.

RESUME : Le clinker pulvérisé ou le ciment est immergé dans l'huile et observé au microscope. Les dimensions et la biréfringence des cristaux d'alite, les dimensions et la couleur des cristaux de belite sont fonction des conditions de cuisson, du mode de chauffage, de la température maximale, de la durée du temps de chauffage et du mode de refroidissement. La résistance à la compression du ciment à l'âge de 28 jours peut être estimée d'après ces caractéristiques cristallines. La contribution de la température maximale et celle du mode de refroidissement sont les plus importantes.

L'erreur de l'estimation microscopique, écart quadratique moyen, est  $17 \text{ kg/cm}^2$  par JIS. En comparaison de l'erreur de la mesure actuelle de la résistance ( $10 \text{ kg/cm}^2$  environ ou plus) et de l'erreur de l'estimation du module hydraulique, de la chaux libre, de la surface spécifique Blaine et de la résistance à l'âge de 7 jours ( $27 \text{ kg/cm}^2$ ), la précision de l'estimation microscopique est raisonnable.

SUMMARY : The pulverized clinker or cement is immersed in an oil and observed by polarizing microscope. Crystal size of alite and birefringence of alite, crystal size of belite and color of belite, change corresponding with the change of burning condition, heating rate, maximum temperature, burning time and cooling rate, respectively. From the above terms, the compressive strength at 28-day can be estimated. The contribution of maximum temperature and cooling rate is the most important.

The estimation error, root of mean square variance, is  $17 \text{ kg/cm}^2$ , JIS. Comparing with the error of actual strength test, about  $10 \text{ kg/cm}^2$  or more, and the estimation error from HM, free lime, Blaine and 7-day strength,  $27 \text{ kg/cm}^2$ , the microscopical estimation error is reasonable.

## INTRODUCTION

Microscopical observation is the most handy method to check the quality of cement. Cement or clinker powder is immersed in an oil, and observed by a polarizing microscope. The observation time is 5 or 10 minutes. The popular checking terms are fineness of cement, freshness of cement, free lime content, admixtures and so on. Moreover, the microscopical characters of clinker minerals show the burning condition of clinker and the hydraulic activity.

The microscopical method has been successfully used on the quality control in Onoda Cement plants for more than 15 years. Recently, the method has been used in many plants in Japan, the USA and Canada.

## BURNING CONDITION AND QUALITY OF CLINKER

The burning conditions are simplified as Fig. 1, and shown with the four terms: burning rate, maximum temperature, burning time and cooling rate.

Fig. 1. Schematic temperature-time relation of clinker burning.

The relations between the burning conditions and the microscopical characters of clinker minerals are rather simple, and we have many experimental and theoretical knowledges.

The relations between the hydraulic activity and the microscopical characters are complicated. There are many factors, which are closely related with activity, but can not be detected by microscope. However, the principal parts of the factors can be derived from the burning conditions, which can be detected by microscope. And so, the 28 days strength can be predicted by microscopical observation.

The early strength, at 1, 3 and 7 days, is strongly influenced by the particle size distribution of cement, the contents of alkali and sulfates,  $C_3A$  solid solution and probably many other unknown factors. Therefore, the early strength can not be predicted by microscopical observation.

The strength of cement principally depends on the activity of clinker minerals and the contents, and the fineness of cement. Usually the chemical composition, the content of free lime and fineness of cement are controlled in a narrow region. The detection of the activity of the clinker minerals in the cement is the most important factor for the estimation of the cement strength.

The activity of alite and belite changes according to the change of the temperature modifications, the content of impurities and the crystallinity. The kind of the temperature modifications can be detected from the optics and the inversion textures. The contents of impurities and the crystallinity can be deduced from the estimated burning conditions.

In principle, a high temperature form is unstable at room temperature, and is more active than the low temperature forms. The high temperature form stabilized completely in a solid solution is inactive.

In order to obtain the high temperature forms of alite and belite at room temperature, alite and belite must contain a large amount of impurities at burning temperatures. The solubilities are large at high temperatures, and small at low temperatures. The time at low temperatures, pre-ignition zone, must be possibly short. Possibly large amount of alite and belite must crystallize or recrystallize at high temperatures. The rate of diffusion of impurities in alite and belite is small.

Table 1. The relation between the burning condition, hydraulic activity and microscopical characters of alite and belite.

Hydraulic activity:	Excellent(+)	Good(vv)	Average(v)	Poor(-)
<u>Burning rate</u>	Quick	.....	.....	Slow
Size of alite ( $\mu$ )	15-20	20-30	(25)30-40	40-60(120)
<u>Maximum temperature</u>	High	.....	.....	Low
Birefringence of alite	0.010-0.008	0.007-0.006	0.006-0.005	0.005-0.002
<u>Burning time</u>	Long	.....	.....	Short
Size of belite ( $\mu$ )	(20)25-40(60)	(15)20-25	(10)15-20	5-10
<u>Cooling rate</u>	Quick	.....	.....	Slow
Color of belite	Clear(C)	faint Yellow(fY)	Yellow(Y)	Amber(A)

High crystallinity of alite and belite at high temperatures and quick cooling are also favorable. In order to attain the high crystallinity, clinker must be burnt at high temperatures for an adequate time. The disorder due to thermal vibration and rotation seems to be the center of inversion. Quick cooling from the lower limits of the stable temperature region of the high temperature form is favorable. However, it is not so easy to attain the ideal cooling curve in actual kiln operation, slow cooling from maximum temperature to the lower limit temperature and quick cooling.

The favorable burning conditions are "quick burning", "high maximum temperature", "long burning time" and "quick cooling".

#### BURNING CONDITION AND MICROSCOPICAL CHARACTER

##### Size of Alite

The size of alite principally depends on the burning rate and the crystallization rate.

If clinker is burnt quickly by short flame, a small part of alite crystallizes at low temperatures, and large part of alite crystallizes at high temperatures. The first crystallization at low temperature occurs by direct contact of  $\text{CaO}$  and  $\text{C}_2\text{S}$ . The crystallization rate is quick, and the crystal size is small. The crystallization rate at high temperatures is also quick, and the crystal size is small.

If clinker is burnt slowly by long flame, large part of alite crystallizes at low temperatures. In this case,  $\text{CaO}$  and  $\text{C}_2\text{S}$  recrystallizes into large crystal, and the crystallization rate of alite becomes slow, except at the first crystallization stage, and the crystal size of alite is large.

The crystal growth of alite by recrystallization with cannibalism is slow and negligible.

The size of alite in poor burnt clinker is small. This fact does not show that the size of alite depends on the burning temperature and burning time. In this case, low temperature raw material is near the discharge end of kiln, and temperature jumps, for example, from  $1100^\circ\text{C}$  up to  $1450^\circ\text{C}$ , and the crystallization rate is quick. In the clinker of 1000 ton per day kiln, less than 15 micron alite shows danger of poor burning. In the clinker of 4000 ton per day kiln, less than 20 micron is danger.

##### Birefringence of Alite

The birefringence of alite principally depends on the burning temperatures and the kind of temperature modifications. The highest temperature form, R-form, has the highest birefringence, 0.007 to 0.010. The disordered M-I form, having remains of R-form, or M-III form after I. Maki<sup>5)</sup>, has the next high birefringence, 0.005-0.007. Ordered M-I form has moderate birefringence, 0.004-0.005. Low temperature form, T-II, has low birefringence, less than 0.004.

D. H. Campbell shows a list of birefringences of alite reported by many workers. He pointed out that alite birefringences determined by powder mount and thin section are different. In addition, birefringences given

for alite by several other workers show wide differences.

S. Chromy<sup>2)</sup> studied the birefringence of alite by high temperature microscope. He found that R-form has a low birefringence at high temperature, and high birefringence at low temperatures, in the stable temperature region of R-form. The birefringence of M-form is the same as R-form at low temperature, and the birefringence of T-form is very low.

The low birefringence of R-form at high temperatures may be due to the thermal vibration and rotation, and R-form with low birefringence can not be quenched to room temperature.

Alite crystallized at low temperature, near the lower limit of the stable region, which is  $1250^\circ\text{C}$  for pure  $\text{C}_2\text{S}$ , contains a small amount of impurities, and inverts into low temperature forms through the cooling process. Alite crystallized at high temperatures contains a large amount of impurities, and R-form or disordered M-form with high birefringence is cooled to room temperature. Practically, birefringence of alite changes continuously according to the burning temperatures.

The birefringence of alite crystals occurring in a clinker nodule is not the same each other. Small alite crystal occurring near the cluster of free lime has low birefringence. Large or middle size alite crystal near the cluster of belite has high birefringence. Isolated alite, which may be blown and burnt in the high temperature flame, has very high birefringence.

I. Maki<sup>5)</sup> found that alite in the clinker containing  $\text{MgO}$  higher than 1.5% is M-III form with high birefringence, and alite in the clinker less than 1.5%  $\text{MgO}$  is M-I form with low birefringence. In Japanese cements, the  $\text{MgO}$  content is usually controlled from 1.5 to 1.8%. If  $\text{MgO}$  content is less than 1.5%, serpentine or olivine is added to the raw mixture. Therefore, alite in Japanese cement seems usually M-III form. The author has not sufficient data on the clinkers, which contain  $\text{MgO}$  higher than 1.8% and lower than 1.5%. However, alite in high  $\text{MgO}$  clinker has high birefringence, about 0.001 higher than normal clinker shown in Table 1, and alite in low  $\text{MgO}$  clinker has low birefringence, about 0.001 lower than Table 1.

Alite is weak against mechanical grinding and chemical attack of moisture, and the birefringence strikingly decreases.

##### Size of Belite

At low temperatures,  $1100$ – $1200^\circ\text{C}$ , belite crystallizes in a minute crystal of alpha prime form, and the crystal growth by cannibalism is slow. At about  $1400^\circ\text{C}$ , alpha prime form changes into alpha form. Crystal growth of alpha form is quick. Therefore, the crystal size of belite corresponds with the time maintained above  $1400^\circ\text{C}$ .

The crystal growth of belite differs according to the temperatures and circumstances. Feldspar melt reacts with  $\text{CaO}$ , and coarse alpha belite crystallizes from the melt. This belite is rich in alkali and colorless. Minute belite occurs from iron rich slags. The crystal growth is slow.

### Color of Belite

At the highest temperature of clinker burning, belite is alpha form, except very poor burnt clinker. The solubility of  $Al_2O_3$ ,  $Fe_2O_3$ , and  $Na_2O$  in alpha form is about 2%, 2% and 3%, respectively. The change of solubility in the temperature range of clinker burning is small. The solubilities of the above elements in alpha prime form are nearly zero, less than 0.5%.

At the highest temperature, alpha belite is saturated with  $Al_2O_3$  and  $Fe_2O_3$ , and contains an equilibrium amount of alkalis. Through the cooling process, alpha form changes into alpha prime form, and next into disordered beta form. The impurities in solid solution are saturated in alpha prime form and exsolved in colloidal dispersion state in belite. The color of belite changes from colorless to faint yellow, yellow and amber, according to the slow down of cooling rate.

If clinker is cooled quickly, about 40% alpha phase remains between the fine lamellas of disordered beta form, and exsolution of impurities does not occur. The belite is colorless.

If clinker is slowly cooled in the temperature range of 1400°C to 1300°C, alpha to alpha prime inversion takes place on the surface of belite through the melt of interstitial materials. The lamellas of alpha prime elongate into the interstitial melt, and the surface of belite becomes rough. The depressed cavities are filled with iron bearing phases, and the grain of belite cluster in cement shows deep amber color. The color is not the color of belite itself.

### ESTIMATION OF 28 DAYS STRENGTH

The author and his staff<sup>9)</sup> studied hydraulic activity of clinker minerals and strength of cement for more than 20 years. In 1965, the author and Y. Soda reported the survey of cement in Japanese market, and showed the change of activity of alite and belite is more important than the change of chemical composition, free lime and fineness of cement for the estimation of 28 days strength. In 1975, K. T. Mau, Vice President of Cyprus Hawaiian Cement Corporation, promoted a private seminar in Hawaii, Microscope Analysis Work Seminar. After the seminar, the author prepared a table on the relation between 28 day strength and burning condition, for the request of K. T. Mau and the participants.

Table 3. Multi regressive equations for estimation of 7 days and 28 days strength, standard deviation and regressive coefficient

		R.C.	S.D.
1)	$7d = 83 + 52(HM) - 21(FL) + 0.009(BL)$		
2)	$7d = 167 + 1.2(AS) + 18.8(AB) - 10.3(BS) + 9.5(BC)$	0.29	23.6
3)	$7d = 96 + 61(HM) - 18(FL) - 0.012(BL) + 2.9(AS) + 19.9(AB) - 13.1(BS) + 8.4(BC)$	0.74	16.7
		0.77	16.5
4)	$28d = 228 + 51(HM) - 54(FL) + 0.028(BL)$		
5)	$28d = 133 - 8(HM) - 29(FL) + 0.017(BL) + 1.1(7d)$	0.42	37.8
6)	$28d = 253 + 6.4(AS) + 21.9(AB) + 4.0(BS) + 21.5(BC)$	0.77	26.8
7)	$28d = 67 + 109(HM) - 22(FL) - 0.005(BL) + 7.7(AS) + 22.3(AB) + 0.6(BS) + 20.7(BC)$	0.91	17.1
8)	$28d = 175 + 0.5(7d) + 5.8(AS) + 13.1(AB) + 8.9(BS) + 17.0(BC)$	0.93	16.1
9)	$28d = 31 + 86(HM) - 15(FL) - 0.000(BL) + 0.4(7d) + 6.6(AS) + 14.8(AB) + 5.5(BS) + 17.6(BC)$	0.93	15.4
		0.94	15.1

Recently, K. Ogawa and S. Hanehara, staff of the author, statistically analyzed the data of Japanese cement reported in 1965, and calculated linear multi regression equation, between 7 and 28 days actual mortar strength and several available, using IBM 370-135 computer. From the equation, they made a new table on the relation between the 28 days strength and burning conditions. The difference between the table prepared in 1975 and the new table is less than 20 kg/cm<sup>2</sup>, except very weak cement.

Table 2. Data of Japanese cement, reported in 1965

### Cement Samples:

46 ordinary cements in Japanese market, 1962 and 1963.

### Notation of Terms, Used for Calculation:

Hydraulic Modulus: HM, free lime %: FL, Blain's specific surface cm<sup>2</sup>/gr: BL, Size of alite: AS, Birefringence of alite: AB, Size of belite: BS, Color of belite: BC, 7 and 28 days strength kg/cm<sup>2</sup> in JIS: 7d and 28d,

The grade of AS, AB, BS and BC are written in points, after the notation of J. Prout<sup>6)</sup> as follows. Excellent: 4, Good: 3, Average: 2, Poor: 1.

### Terms of Cement Samples: Mean, Maximum, Minimum and Standard Deviation:

	HM	FL	BL	AS	AB	BS	BC	7d	28d
Mean	2.08	0.71	3244	2.19	2.39	3.12	2.50	206	386
Max.	2.21	2.0	3610	3.5	4	4	4	256	455
Min.	2.00	0.2	3010	1.5	1.5	2	0.5	165	298
S.D.	0.04	0.30	131	0.52	0.60	0.74	1.38	24	40

The standard deviation of equation 1 and 4 in Table 3, estimation of 7 and 28 days strength from HM, free lime and Blain, is 23.6 kg/cm<sup>2</sup> for 7 days strength, and 37.8 kg/cm<sup>2</sup> for 28 days strength. The standard deviations, estimation errors, are practically equal to the standard deviations of cement strength, strength distribution, shown in Table 2, 24 kg/cm<sup>2</sup> for 7 days and 40 kg/cm<sup>2</sup> for 28 days. Equation 1 and 4 have no meaning of estimation.

The regressive coefficients of equation 2 and 3, estimation of 7 days strength from microscopical data and adding HM, free lime and Blain, are 0.74 and 0.77. The regressive coefficients show that the correlation between 7 days strength and microscopical data is strong. However, the accuracy of estimation is unsatisfactory.

When 7 days strength is known, 28 days strength can be estimated from HM, free lime, Blain and 7 days strength, using equation 5. However, the estimation accuracy, 26.8 kg/cm<sup>2</sup>, is less than microscopical estimation, 17.1 kg/cm<sup>2</sup>, of equation 6. The accuracy of microscopical estimation can be improved adding HM, free lime, Blain and 7 days strength, up to 15.1 kg/cm<sup>2</sup> of equation 9. However the improvement from 17.1 kg/cm<sup>2</sup> to 15.1 kg/cm<sup>2</sup> is not so large.

K. T. Mau wrote me that the Study of the Uniformity of Cement Strength conducted by the joint PCA/NRMCA Technical Liaison Committee was held from 1976 to 1977, and 120 grab samples were tested. The standard deviation of the microscopical estimation of 28 days strength was 220 lb/in<sup>2</sup> in ASTM, which was 16.3 kg/cm<sup>2</sup> in JIS.

Fig. 2. Microscopical estimation of 28 days strength,<sub>2</sub> calculated from equation 6. SD = 17.1 kg/cm<sup>2</sup>.

Table 4. Effect of burning condition on 28 days strength, kg/cm<sup>2</sup> in JIS.  
+: excellent, vv: good, v: average, -: poor, refer to Table 1.

Max. Temp.		+				vv				v				-

Notes:

Underline: Japanese cement in 1962-1963, 500-700 t/d kilns.

Asterisk(\*): Japanese cements in 1975-1979, 3000-8000 t/d kilns.

Recent 10 years, rotary kilns in Japan have been changed from old type of 500-700 t/d to modern SP kiln with pre-calcination burner of 3000-8000 t/d. Environmental pollution with SO<sub>x</sub> and NO<sub>x</sub> are prohibited by law. Fuel oil is going to be changed to coal and others. Nowadays, the burning conditions are floating, looking for the best conditions. The flame changed from short to long, and the burning zone was deeper, 20-40 m from the discharge end.

The burning conditions are shown as follows in order, / burning rate, maximum temperature, burning time, cooling rate /, after the notation of Table 1. For example, the burning condition, / burning rate is average(v), maximum temperature is good(vv), burning time is excellent(+), cooling rate is good(vv)/, is shown as (v, vv, +, vv). The 28 days strength is 410 kg/cm<sup>2</sup>, after Table 4.

## DISCUSSION

The microscopical analysis of clinker, shown in this paper, was prepared for the purpose of kiln site daily test. The terms of microscopical observation and the relation between the schematic burning conditions and the 28 days strength are possibly simplified. This method has been used in the plants of Onoda Cement as the most reliable guidance for the control of kiln operation. However, this microscopical method is never complete.

J.Prout of St. Mary's Cement Company, Ontario,<sup>6)</sup> pointed out that very small alite is indicative of under burn, and optimum belite size range will depend on flame conditions. His comments are absolutely correct. Although, Table 1 shows that quick burning and small alite is better than slow burning and large alite, and long burning time and large belite is better than short burning time and small belite. Excessive quick burning and excessive long time burning result in failure. For example, the clinkers asterisked, shown in Table 4 as excellent burning rate, (+,+,vv,vv)=445, (+,+,v,vv)=440, (+,vv,vv,vv)=420, (+,vv,v,vv)=415; contain free lime 1.0-2.0 %, and the actual mortar strengths are lower than the tables. The clinkers were burnt by RSP kilns of 5200 t/d. The limit of alite size must be determined comparing with actual test. After the settlement of SP kiln operation, Table 1 and 4 will be rewritten.

E.Fundal of F.L.Smith, Copenhagen,<sup>7)</sup> precisely measured the size of alite and the birefringence of alite. The terms of microscopical observation have wide distributions, and the precise measurements are troublesome. Although, precise measurements are important on basic studies. The merit of microscopy is overall sensitive observation and not in precise measurement.

B.Osbaek of Copenhagen<sup>8)</sup> shows that the effect of alkali on the 28-day strength is around -10 MPa per 1 % soluble alkali expressed in  $K_2O$  equivalents, and the estimation error is 2.7 MPa, which is about 20 kg/cm<sup>2</sup> in JIS. The estimation error may be the smallest in estimation from chemical analysis. The author has several data showing close relation between alkali content and strength of cement. The combination of alkali and microscopy will be hopeful to increase the accuracy of strength estimation. However, SP clinker contains all alkali of raw materials without expulsion, and alkali content of clinker does not change by burning conditions.

CEREG, France.

### RESUME

Ce texte est une synthèse de nombreuses études de clinkers et ciments effectuées au CEREG par microscopie optique avec le support d'autres techniques d'analyses telles que la fluorescence et la diffraction des rayons X.

Le thème retenu est l'étude du domaine de stabilité de l'alite et des paramètres industriels qui peuvent le réduire.

La vitesse de refroidissement des clinkers, l'atmosphère réductrice dans les fours sont des paramètres qui ont été étudiés par différents chercheurs.

La présence de matières combustibles naturelles ou ajoutées avec ou sans fluor dans les crus de cimenteries, les fortes teneurs en anhydride sulfurique et les faibles teneurs en alcalins dans les clinkers peuvent avoir des effets identiques. Les anomalies constatées sont mises en relation avec les propriétés des clinkers et ciments dans chaque cas considéré.

Des conditions et des matériels de fabrication doivent être modifiés pour éviter les inconvénients mis en évidence.

### SUMMARY

This paper is a synthesis of several clinker and cement studies carried out at the CEREG by optical microscopy and other technical analysis such as X ray fluorescence and diffraction.

The subject chosen is the study of alite stability and industrial parameters which could reduce it.

Cooling time and reducing atmosphere in the kiln have been studied by many authors. The presence of burnable materials with or without fluorine in raw materials, heavy percentages of  $SO_3$  and low percentages of alkalis in clinkers have the same effects. The observed anomalies are related to clinker characteristics and cement performances in each case.

Conditions and manufacturing equipment should be modified to avoid the disadvantages described.

## INTRODUCTION

Dans le cadre des économies d'énergie, plusieurs usines de la SOCIÉTÉ des CEMENTS FRANÇAIS consomment des matières à bas pouvoirs calorifiques telles que résidus charbonneux, schistes houillers, cendres volantes, scories, déchets industriels divers inutilisables dans d'autres types de fours. L'introduction de ces matières combustibles dans les crus, l'utilisation de poussières ferrugineuses, de fluorine qui permettent des économies substantielles d'énergie noble, nous ont donné l'occasion de mettre en évidence des processus de rétrogradation de l'alite qui n'étaient pas apparus auparavant (1)(2)(3)(4). Le mécanisme d'oxydation des matières combustibles contenues dans les crus est différent dans chaque procédé de fabrication, ce qui a posé à notre Société, divers problèmes technologiques à résoudre pour éviter les anomalies de cuisson. Les différents processus de rétrogradation de l'alite rencontrés au cours de nos examens au microscope optique sont décrits dans cette étude.

## 1/ CUISSON PROLONGÉE, REFROIDISSEMENT LENT

Les examens de trois boules de clinkers qui ont longuement séjourné dans la zone de clinkérisation montrent les différences de caractéristiques suivantes par rapport au clinker normal (Photographies 1 à 10) : la porosité diminue fortement, les cristaux d'alite se soudent entre eux, les inclusions de divers minéraux dans les cristaux d'alite disparaissent, les aluminates n'existent plus en tant que phase interstitielle, mais en petites plages à l'intérieur des cristaux d'alite qui se sont anormalement développés par cannibalisme et phagocytose, les cristaux de bélite ont aussi de fortes dimensions. Au cœur des boules de clinker, les plages de C<sub>3</sub>A sont constellées d'exolutions de bélite secondaire et certains cristaux d'alite ont subi une rétrogradation partielle en chaux libre et bélite secondaires. Les taux d'alite et de bélite augmentent alors que la quantité de phase interstitielle diminue fortement. Le C<sub>3</sub>A cubique disparaît plus rapidement que le C<sub>3</sub>A tétragonal.

Les examens par diffraction X montrent que l'alite M<sub>1b</sub> s'est transformée en alite T<sub>3</sub> par exsudation d'éléments en solution solide (figure 10 bis). La bélite  $\alpha$  présente dans le clinker normal a disparu.

Fig.10 bis - Polymorphisme de l'alite par suite d'une cuisson prolongée.

Les modifications des propriétés physiques et mécaniques sont les suivantes : la broyabilité du clinker diminue de 10 à 20 %, les temps de prise des CPA augmentent d'une heure, leurs résistances en compression baissent de 50 % à 8 heures, 30 % à 24 heures, 20 % à 2 jours, 10 % à 28 jours. Les variations enregistrées sont dues aux faibles taux de C<sub>3</sub>A, à la croissance exagérée des cristaux de silicates concomitante avec leur épurée et la transformation allotropique de l'alite M<sub>1b</sub> en alite T<sub>3</sub>, moins réactive à court terme.

## 2/ ATMOSPHERES REDUCTRICES DANS LES FOURS

Les clinkers cuits en atmosphère localement réductrice ont une écorce grise sur une épaisseur variable et un noyau beige à roux. L'écorce est grise par oxydation dans la zone terminale du four et dans le refroidisseur. Dans le clinker beige à roux, l'alite est partiellement rétrogradée.

Quand le clinker a été refroidi très rapidement, le C<sub>3</sub>A et le C<sub>4</sub>AF sont enchevêtrés, il est alors possible de diagnostiquer une rétrogradation due à une atmosphère réductrice, sinon, le C<sub>3</sub>A et le C<sub>4</sub>AF coexistent en plages séparées, le C<sub>3</sub>A et l'alite présentent les mêmes caractéristiques qu'au cours d'un refroidissement lent, il est alors difficile de préciser la cause des rétrogradations observées. Les descriptions précédentes sur les différences de couleur entre zones internes et externes des grains de clinker sont beaucoup plus spécifiques d'une rétrogradation par atmosphère réductrice que par refroidissement lent ; d'autre part avec les refroidisseurs modernes, les anomalies de rétrogradation par refroidissement lent sont très rares, seuls les très gros morceaux de clinker peuvent en présenter. Les conséquences sur les propriétés des clinkers et ciments sont les suivantes : la densité du clinker augmente et sa broyabilité diminue. La teinte des ciments est plus claire : dans l'échelle des W.C.I.E., l'augmentation peut atteindre 2 à 3 points ; la maniabilité des ciments diminue : l'augmentation du pourcentage d'eau de gâchage peut être cause de fissuration : les baisses de résistances peuvent atteindre 10 % à 2 et 7 jours et 20 % à 28 jours : elles sont compensées par broyage plus poussé des ciments.

## 3/ MATIÈRES COMBUSTIBLES DANS LES CRUS DE CIMENTERIES

Les matières combustibles présentes dans les crus ont des actions différentes suivant le procédé de cuisson considéré.

3.1 - Fours à voie humide

Les produits charbonneux pulvérulents s'agglomèrent en petits amas qui se mélangent mal avec les autres constituants de la pâte. Après son introduction dans le four, deux cas extrêmes peuvent être envisagés. Dans le premier cas, la pâte est totalement sèche avant sa sortie des chaînes dont les derniers rangs servent de broyeur. Il en sort un produit pulvérulent dans lequel les matières combustibles brûlent avant la zone de clinkérisation et ne perturbent pas la formation des minéraux. Dans le second cas, qui est souhaitable sans combustible dans le cru, la pâte contient encore 6 à 7 % d'eau, les derniers rangs de chaînes granulent ce produit ; les granules brûlent avec défaut d'oxygène jusqu'à la sortie du four. Pendant la clinkérisation les surchauffes locales dues à la présence d'agglomérats de combustible donnent au clinker un aspect localement scorifié avec pour effet une augmentation ponctuelle de la porosité alvéolaire (photographies 11 et 12). Dans ces plages, l'alite du clinker est aciculaire et elle est plus ou moins rétrogradée. L'intensité des rétrogradations est inversement proportionnelle à la porosité des grains de clinker (photographies 13, 14 et 15). On note aussi la présence de périclase dans les clinkers qui contiennent

environ 1 % de magnésie (photographie 16). Les conséquences sont les suivantes : la broyabilité des clinkers diminue de 10 à 15 %, les baisses de résistances des ciments sont les mêmes que dans le cas précédent et peuvent aussi être compensées par des finesses un peu plus importantes, des gonflements retardés sont à craindre comme le montre la photographie 17. Quand des produits charbonneux pulvérulents ou des goudrons sont injectés par une tuyère latérale, les risques de formations d'anneaux sont fortement accentués et le clinker produit contient aussi de l'alite rétrogradée.

### 3.2 - Fours voies semi-sèche et semi-humide

Les matières combustibles séquestrées à l'intérieur des granules se comportent comme dans le deuxième cas précédent, sauf dans les fours longs, équipés de croisillons qui peuvent émettre les granules.

### 3.3 - Fours voie sèche intégrale

Le cru est introduit sous forme pulvérulente, les matières combustibles brûlent avant d'arriver dans la zone de clinkérisation du four, mais quand l'argile est remplacée par des cendres volantes on constate des anomalies sur les retours d'électrofiltre : les cendres volantes subissent des séparations sélectives dans les cyclones et les électrofiltres, ces ségrégations ont pour conséquence la formation d'agglomérats enrichis en carbone et sesquioxyde de fer ou en silice et alumine. Les charges électrostatiques de ces agglomérats leurs donnent une cohésion suffisante pour résister aux contraintes mécaniques jusqu'à leur retour dans le four où ils favorisent la formation de petites boules de clinker très dures enrichies en phase interstitielle, que l'on retrouve de ce fait dans les refus de broyeurs. Cette anomalie est supprimée par adjonction d'un sélecteur sur les retours d'électrofiltre.

### 4/ PRESENCE SIMULTANEE DE FLUOR ET DE MATIERES COMBUSTIBLES

L'usine concernée est équipée de deux fours voie semi-sèche de 1200 et 1700 T/jour. Dans le cadre des économies d'énergie, l'aptitude à la cuisson du cru a été améliorée par l'utilisation de 4 % de schiste houiller d'un pouvoir calorifique de 1500 Th/T et de 0,5 % de fluorine. Les gains de thermies dus à ces deux ajouts sont additifs et varient entre 100 et 120 Th/T de clinker produit, soit une économie annuelle de 10.000 tonnes de fuel pour les deux fours. L'inconvénient est que le milieu réducteur créé par le schiste entraîne, en présence de fluorine, un allongement des temps de prise, qui passent de 2 h en moyenne à 5 h.

#### Analyses chimiques

Les bilans effectués montrent que 95 à 97 % du fluor introduit avec le cru sort avec le clinker. L'influence fortement retardatrice des fluorures alcalins est connue : les retards peuvent facilement atteindre 4 h avec 0,5 % de NaF, mais par une méthode mise au point à cette occasion, nous avons montré que le fluor contenu dans ces ciments n'était pas sous forme de fluorures alcalins très rapidement solubles dans l'eau de gâchage.

#### Examens au microscope optique

Ces examens ont montré que les temps de prise étaient d'autant plus longs que les clinkers étaient plus réduits et les cristaux d'alite plus rétrogradés. Parallèlement, la quantité de périclase et de chaux libre secondaire augmente dans les mêmes conditions (photographies 18 à 24).

#### Analyses par diffraction des rayons X

Dans les clinkers réduits, les analyses montrent l'augmentation des taux de bélite et de  $C_3A$  au détriment de l'alite et de  $C_4AF$ , l'augmentation de la chaux libre et du périclase, la disparition du  $C_{11}A_7CaF_2$ .

#### Interprétation

Les résultats fournis par les trois méthodes amènent à conclure que le  $C_{11}A_7CaF_2$  n'est pas stable en atmosphère réductrice (5)(6). dans un milieu appauvri en oxygène, la tendance des ions  $F^-$  à remplacer les ions  $O^{2-}$  dans les minéraux des clinkers semble très fortement augmentée. Les ions  $F^-$  libérés au cours de l'hydratation des ciments semblent avoir la même action que les ions  $F^-$  des fluorures alcalins solubilisés pendant le gâchage.

### 5 - RAPPORTS MOLAIRES ALCALINS/ANHYDRIDE SULFURIQUE

Les teneurs respectives en alcalins et en anhydride sulfurique dans les clinkers ont des incidences sur leur porosité, fragilité, granulométrie et sur la morphologie de leurs silicates.

#### 5.1 - Influence sur la granularité et la fragilité

Les clinkers dont le rapport alcalins/ $SO_3$  est voisin ou supérieur à 1 se caractérisent par les porosités montrées sur les photographies 25 et 26 : la zone corticale des grains est compacte et solide. La granularité des clinkers dépend essentiellement de leur composition chimique et minéralogique, du système de préparation et de cuisson du cru, du temps de cuisson à des températures supérieures à 1300°C, de la température maximale de cuisson.

Les clinkers dont le rapport alcalins/ $SO_3$  est nettement inférieur à 1 se caractérisent par les porosités montrées sur les photographies 27 et 28 : la cohésion est beaucoup moins importante, la zone corticale est très fragile, les clinkers contiennent 30 à 50 % d'éléments inférieurs au mm (Photographies 29 et 30).

#### 5.2 - Influence sur la morphologie des silicates

Les cristaux d'alite et de bélite ont des dimensions d'autant plus importantes que le rapport alcalins/ $SO_3$  est plus faible et le taux de  $SO_3$  plus fort (Photographie 31 et 32). Nous constatons aussi la présence de deux sortes de cristaux d'alite : les uns à bordures nettes comme sur la photographie 31, les autres à bordures plus ou moins corrodées sur une épaisseur variable (photographies 33 à 35). Ce type de rétrogradation qui débute par la bordure des cristaux ne ressemble à aucun des cas cités auparavant. La raison de ces rétrogradations semble être fournie par les minéraux intermédiaires qui se forment pendant la fabrication de ces clinkers.

#### 5.3 - Interprétations

##### Influence sur la granulométrie.

Le rapport alcalins/ $SO_3$  a une incidence directe sur la formation de certains minéraux intermédiaires dans les fours. Quand il est voisin ou supérieur à 1, le principal composé sulfaté mis en évidence au-dessus de 1300°C est  $K_2SO_4$ , quand il est nettement inférieur à 1, les composés intermédiaires mis en évidence sont  $(CaO.Al_2O_3)_3.CaSO_4$  et  $CaSO_4$ .

Le sulfaté de potassium dont les points de fusion et d'ébullition sont respectivement 1069°C et 1689°C distille progressivement jusqu'à la sortie du four et même dans le refroidisseur où il se condense ensuite en surface et dans les pores des grains du clinker. Leur cohésion n'est pas perturbée par cette distillation lente et elle est même renforcée par la condensation. Au contraire, la décomposition rapide de  $(CaO.Al_2O_3)_3.CaSO_4$  et de  $CaSO_4$  au-dessus de 1300°C

perturbe fortement la structure interne et superficielle des grains de clinker. La fragilité de la zone corticale est accentuée par le recyclage et la réagglomération tardive de poussières en provenance du refroidisseur.

#### Influence sur la taille des cristaux de silicates.

Le pouvoir minéralisateur des sulfates calciques est fortement accentué dans les fours industriels car ils y provoquent des recyclages beaucoup plus importants que les sulfates alcalins.

#### Influence sur la rétrogradation de l'alite.

L'aluminate de calcium sulfaté se décompose tardivement dans les fours en donnant  $C_3A$  et  $SO_4^{2-}$  qui est alors disponible pour entrer en solution solide dans le réseau de l'alite qui devient rhomboédrique (7). La réaction suivante peut être envisagée :  $(CaO.Al_2O_3)_3.CaSO_4 + 5 CaO + O^{2-} \rightarrow 3(CaO.Al_2O_3) + SO_4^{2-}$ . Pour que cette réaction puisse se produire, il faut de fortes teneurs en chaux libre au voisinage de l'aluminate de calcium sulfaté. Si cette chaux libre est disponible, les cristaux d'alite ne sont pas rétrogradés (photographie 31). Si la chaux libre n'est pas disponible elle est apparemment prélevée sur l'alite (photographies 33 à 35) quand les temps de réaction sont suffisants.

Il est donc très important pour la production de ces types de clinkers que le cru soit très homogène, qu'il soit fortement saturé en chaux, que le temps de cuisson entre 1300°C et 1450-1500°C soit suffisamment long pour permettre la transformation complète de  $(CaO.Al_2O_3)_3.CaSO_4$  en  $C_3A$ . Si cette transformation n'est pas complète on risque de retrouver du  $(CaO.Al_2O_3)_3.CaSO_4$  dans le produit fini avec pour conséquences des temps de prise courts et des gonflements anormaux même avec peu de chaux libre dans le clinker (8).

#### CONCLUSIONS

Au cours de cette étude, nous avons tenté de montrer une des facettes de l'apport de la microscopie optique à la compréhension de quelques unes des très nombreuses mutations dans les fours de cimenteries qui transforment les minéraux naturels des crus en minéraux artificiels des clinkers.

Cette recherche était principalement basée sur le domaine de stabilité de l'alite et sur les paramètres industriels qui peuvent le réduire.

Les économies notables d'énergie réalisées en introduisant des matières combustibles dans les crus de cimenteries ont des incidences sur la stabilité de l'alite et sur les propriétés des clinkers et ciments. Nous avons montré différents processus de dégradation de l'alite influencés par les procédés de cuisson et par la présence d'éléments mineurs tels que fluor, soufre, alcalins. Le polymorphisme de l'alite a aussi été mis en cause à deux reprises.

Pour pallier les inconvénients cités, les ingénieurs des usines ont dû modifier des conditions et des matériels de fabrication.

#### REMERCIEMENTS

Les auteurs remercient MM. BERTIN et MAES pour les travaux effectués au CEREG en microscopie et en diffraction X.

# La célite dans les ciments portland obtenus par fusion

## *Celite phase in portland cements from molten products*

J. MOISSET, B. COTTIN, A. PETIT - Lafarge S.A.,  
A. ROUANET, Laboratoire des Ultra-Réfractaires, C.N.R.S., France.

RESUME : Un cru de ciment Portland est traité au four solaire à des températures supérieures à la température de solidification dans l'air ou sous atmosphère réductrice pendant des temps très courts (quelques secondes). La vitesse de refroidissement peut être modérée ( $10^2$  deg. sec<sup>-1</sup>) ou rapide ( $10^5$  deg. sec<sup>-1</sup>). L'examen par diffraction X des produits traités met en évidence la cristallinité de toutes les phases ainsi que la réduction partielle ou totale du fer intervenue dans la phase liquide et son incidence sur la nature des phases. On note en particulier une destruction de la phase aluminoferrite de calcium qui induit la libération d'une fraction de la chaux et la formation d'aluminate tricalcique.

SUMMARY : Raw materials of Portland cement composition have been melted by means of a solar furnace at  $T > T_{\text{solidification}}$  in air or reducing atmosphere for a short time (few seconds). The cooling rate may be medium ( $10^2$  deg. sec<sup>-1</sup>) or high ( $10^5$  deg. sec<sup>-1</sup>). X-ray diffraction analysis showed crystallized phases and on another hand the phenomenon of a partially or wholly reduction of iron involved at the liquid state. Characteristics of the molten products due to this reduction are : the disappearing of calcium aluminoferrite and, inductively, the formation of a quantity of lime and the growth of tricalcium aluminate.

## A. INTRODUCTION.

Dans les clinkers obtenus dans les conditions habituelles de fabrication industrielle par frittage (de cru de ciment Portland au four rotatif), on obtient principalement de l'alite et un peu de bélite. La phase interstitielle entre la bélite et l'alite contient de la chaux, de l'alumine et des oxydes de fer. Elle a été identifiée par plusieurs auteurs comme étant une solution solide  $C_4AF - C_6A_2F$  nommée célite. La composition exacte de cette phase interstitielle est controversée. Certains auteurs considèrent que  $C_6A_2F$  est lui-même une solution entre  $C_2F$  et un hypothétique  $C_2A$ . Mais le  $C_2A$  ne peut-il pas être considéré comme une solution solide de  $C_{12}A_7$  et de  $C_3A$  ? Le diagramme C - A -  $Fe_2O_3$  a été étudié par plusieurs auteurs et Newkirk et Thwaite ont établi le détail d'une portion du diagramme C - CA -  $C_2F$  avec les zones de solution solide représentées par des hachures.

System :  $CaO-CaO.Al_2O_3-2CaO.Fe_2O_3$

Dans cette étude nous avons essayé de connaître en première approche, le comportement du fer dans le clinker à partir d'une phase liquide supposée homogène obtenue par fusion totale d'un cru industriel de ciment Portland. Cette solution subit un refroidissement jusqu'à la température ordinaire pour donner un "clinker fondu" dans lequel le fer apparaîtra dans la phase interstitielle sous formes  $Fe^0, Fe^{++}, Fe^{+++}$ .

Il est important semble-t-il de prendre en considération les quatre paramètres fondamentaux qui influencent l'état du système au cours du traitement thermique :

- la concentration des constituants
- la température T du système au proche voisinage de l'équilibre thermodynamique,

- les pression et nature du gaz,
- le temps t intervenant au cours du refroidissement ( $\Delta T/\Delta t$  vitesse moyenne estimée du refroidissement).

Ces quatre paramètres peuvent conjointement jouer sur :

## a) les phénomènes physiques :

- ségrégation entre phases comprises entre les liquidus et solidus,
- cristallisation des phases,
- vaporisation sélective d'une ou plusieurs espèces.

## b) les phénomènes chimiques :

- réduction totale ou partielle du fer,
- réduction à l'état solide entre phases au cours du refroidissement.

## B. EXPERIMENTATION.

Le traitement des matériaux à partir de l'état liquide est effectué au foyer d'un four à concentration de rayonnement solaire équipé pour opérer dans l'air ou sous atmosphère réductrice. Un dispositif de trempe rapide de type splat cooling permet d'atteindre des vitesses de refroidissement élevées.

On a envisagé quatre cas de figures pour les traitements thermiques :

- (C<sub>1</sub>) et (C<sub>2</sub>) : traitement dans l'air avec refroidissement normal (par simple rayonnement du produit traité après occultation du rayonnement solaire) et hypertrempe,
- (C<sub>3</sub>) et (C<sub>4</sub>) : traitement sous atmosphère réductrice (Argon + Hydrogène) avec refroidissement normal et hypertrempe.

## 1) Fusion du cru dans l'air.

Nous avons utilisé des petits fours solaires de 1,5 à 2 kW dits à axe vertical. Ils sont essentiellement constitués par un grand miroir plan (héliostat) de 4,5 m sur 6,5 m qui renvoie le rayonnement solaire sous forme de faisceau parallèle sur un miroir parabolique, ce dernier concentrant le rayonnement reçu en son foyer (Fig. 1).

La tache focale obtenue mesure environ 1 cm<sup>2</sup> et la température peut atteindre jusqu'à 3000°C. Dès que l'on s'écarte du foyer, celle-ci diminue de façon notable. Si l'on s'élève (ou descend) dans le cône de lumière, la vitesse de refroidissement sera plus faible que si l'on s'écarte horizontalement du foyer.

Ces petits fours solaires présentent deux avantages :

- énergie chimiquement pure éliminant tout risque de contamination du matériau avec l'élément chauffant,
- énergie dirigée permettant de chauffer l'échantillon sur un support réfrigéré sans interaction chimique entre ce dernier et le produit traité.

La fusion classique consiste à placer le produit à traiter sur un support en cuivre réfrigéré et à l'amener au foyer à l'aide d'un chariot. La fusion est extrêmement rapide et le produit fondu se présente sous la forme d'un globule de 1 cm de diamètre environ. Le retrait de la pla-

tine (support) du foyer provoque un refroidissement de quelques centaines de degrés/sec.

Fig. 1 - Schéma de principe d'une installation à axe vertical.

On peut également obtenir des produits hypereutectés à l'aide d'un montage du type "marteau-enclume", par écrasement du globule fondu (Fig. 2).

Fig. 2 - Appareil d'hypereutectage associé à un four solaire à axe vertical.

Le marteau est une masse de cuivre légèrement convexe qui vient s'ajuster dans la platine réfrigérée ayant la forme d'un creuset. Dès que la fusion s'établit, on laisse tomber le marteau sur le globule et on obtient alors des feuillets très fins de l'ordre de quelques dizaines de microns. La vitesse de refroidissement est estimée à  $10^5$ °C/s.

## 2) Fusion du cru solaire sous atmosphère réductrice.

Ce montage permet de travailler sous atmosphère contrôlée et de refroidir le produit fondu soit naturellement par retrait du foyer, soit en l'hypereutectant par écrasement de l'échantillon entre deux surfaces métalliques amenées brutalement en contact.

Le schéma de l'appareillage est représenté Figure 3. La masse de produit ( $\sim 0,5$  g) préalablement fondue sous forme de globule, est portée à l'état liquide au foyer du four solaire. Le marteau couissant sur des roues de guidage est soumis à une force mécanique variable par un ressort. Il peut ainsi être maintenu en position tension par un électro-aimant ou libéré brusquement sur l'échantillon fondu avec une vitesse variable (10 m/s au maximum). L'énergie de l'ensemble marteau-enclume, après la trempe du produit est absorbée par un amortisseur hydraulique.

Le profil des pièces d'écrasement a été conçu de manière à ne tremper que la partie liquide du globule fondu. L'occultation du rayonnement solaire n'intervient que dans la phase finale du processus. On évite ainsi un refroidissement du matériau avant le début de la trempe. L'ensemble de l'appareil est disposé à l'intérieur d'une capacité étanche permettant d'introduire un gaz quelconque sous une pression inférieure ou égale à la pression atmosphérique. Il est

également possible d'établir un courant gazeux permanent. Le rayonnement solaire pénètre au travers d'une coupole hémisphérique transparente de faible absorption. Les échantillons obtenus par hypertrempe se présentent sous forme de feuillets d'épaisseur comprise entre 10 et 50  $\mu$  selon la nature du produit. La vitesse de trempe est estimée à environ  $10^4$ °C par seconde.

Fig. 3 - Dispositif d'hypertrempe en atmosphère contrôlée, associé à un four solaire : schéma de principe.

### C. RESULTATS.

1) Les différentes phases après traitements thermiques sont observées par diffraction X (on a utilisé la radiation  $\text{CuK}\alpha$ ).

Ainsi (Figures 4 et 5) :

- Dans le cas du clinker ( $\text{C}_1$ ) le pic du  $\text{C}_3\text{A}$  ( $2\theta = 33^\circ.4$ ) est faible. Il est même dans ce cas inférieur à celui que l'on obtient dans le clinker industriel fabriqué à partir du même cru. Celui de l'alumino-ferrite ( $2\theta : 33^\circ.7$ ) atteint une dimension arbitraire de 76. La chaux n'apparaît pas et les pics correspondants au  $\text{C}_3\text{S}$  et  $\text{C}_2\text{S}$  sont normaux.

- Dans le cas du clinker ( $\text{C}_2$ ), hypertrempe la phase  $\text{C}_3\text{A}$  s'est considérablement accrue et l'alumino-ferrite disparaît. La teneur en chaux libre n'est pas nulle bien que non évaluable par diffraction X. Un recuit de 24 h à  $900^\circ\text{C}$  redonne le spectre de diffraction X du produit  $\text{C}_1$ .

- Dans les cas de clinkers ( $\text{C}_3$ ) et ( $\text{C}_4$ ) traités sous atmosphère réductrice on ne note aucun changement sensible des phases  $\text{C}_2\text{S}$  et  $\text{C}_3\text{S}$ . La phase  $\text{C}_3\text{A}$  par contre évolue très nettement, l'alumino-ferrite a disparu et on note dans les deux cas l'existence de chaux résiduelle. De plus, l'étude de ces produits par microscopie optique permet de mettre en évidence la présence de fer métal-

lique. Enfin un recuit de 1 h à  $1300^\circ\text{C}$  dans l'air de ces clinkers obtenus sous atmosphère réductrice, ne modifie en aucune façon le spectre de diffraction X initial. Ceci est à rapprocher de la fusion de  $\text{C}_4\text{AF}$  pur sous hydrogène qui donne du  $\text{C}_3\text{A}$ , de la  $\text{CaO}$  libre et du fer métallique visible à l'oeil nu sous forme de billes.

Fig. 4 - Spectres de diffraction X des clinkers  $\text{C}_1$  et  $\text{C}_2$ .

2) D'un point de vue physique on notera que :

- les phénomènes de ségrégation de phases pouvant se produire entre liquidus et solidus au moment du refroidissement n'interviennent pas dans la solidification des phases du clinker compte tenu du caractère stoechiométrique des silicates et aluminates de calcium,

- dans le cas de clinkers refroidis par hypertrempe, le  $\text{C}_3\text{S}$  se présente sous forme de petits cristaux allongés,

- la vaporisation sélective des oxydes de fer dans le mélange liquide, bien qu'ayant été observée par ailleurs, n'intervient pas non plus dans nos essais compte tenu de la rapidité de traitement thermique à la fusion (durée moyenne du traitement de l'ordre de quelques secondes),

- la vitrification des phases

aluminate et aluminoferrite n'a pas été observée après solidification même très rapide du "clinker fondu". A noter que dans ce cas là le comportement du  $C_3A$  est totalement différent de celui observé par ailleurs sur du  $C_3A$  pur dont la tendance à se vitrifier est d'autant plus élevée que la vitesse de refroidissement est plus grande.

Fig. 5 - Spectres de diffraction X des clinkers  $C_3$  et  $C_4$ .

#### D. CONCLUSION.

Tous ces résultats amènent à penser que :

- dans l'air le  $Fe^{3+}$  subit une réduction partielle à la température du liquide [ $T_{liq} = T_{fusion} + (200 \sim 300^\circ C)$  avec  $T_{fusion} = 1935^\circ C$ ] et l'on note la destruction de la phase aluminoferrite. Le refroidissement rapide ( $\Delta T/\Delta t \sim 10^5 \text{ deg. sec}^{-1}$ ) freine alors la réoxydation du fer et bloque la reformation de l'aluminoferrite. Il s'en suit un enrichissement du  $C_3A$  par recombinaison partielle de la chaux libre avec l'alumine en excès.

Le refroidissement normal du liquide ( $\Delta T/\Delta t \sim 10^2 \text{ deg. sec}^{-1}$ ) permet d'amorcer le processus inverse de la réoxydation du fer tel qu'on l'observe après un recuit du fondu dans l'air à  $900 \sim 1100^\circ C$ .

Le processus de réoxydation pourrait se schématiser selon :

- lorsque l'on procède à une fusion sous atmosphère réductrice, le  $Fe^{3+}$  subit une réduction totale jusqu'à l'état de fer métallique. Il semblerait que dans les conditions d'expérimentation utilisées (recuit 1 h à l'air à  $1300^\circ C$ ), la réoxydation du fer ne soit pas suffisante pour redonner l'aluminoferrite.

# Polymorphisme de l'alite et du C<sub>3</sub>A. Statistiques

## *Alite and C<sub>3</sub>A polymorphism. Statistics*

P. GOURDIN, E. DEMOULIAN, F. HAWTHORN, C. VERNET - Société des Ciments Français - CEREG, France.

### RESUME :

A l'aide d'une population de 60 clinkers, issus de 24 crus clinkérisés dans 32 fours rotatifs différents, les auteurs ont dégagé les relations statistiques entre la minéralogie du cru (teneur en quartz, présence d'argile illite ou kaolinite), les procédés de fabrication (voie humide, voie sèche, type de four), la composition chimique du clinker d'une part et les formes allotropiques de l'alite (monoclinique, trigonale) et du C<sub>3</sub>A (cubique, tétragonale) d'autre part.

En complément a été dégagée l'incidence de ce polymorphisme de l'alite et du C<sub>3</sub>A sur les résistances à la compression moyenne des ciments portland correspondants, de granulométrie comparable.

Il ressort de ce travail que les éléments mineurs comme MgO, SO<sub>3</sub>, K<sub>2</sub>O et P<sub>2</sub>O<sub>5</sub> des clinkers industriels ont une influence importante sur les résistances à la compression des ciments portland correspondants. Il confirme la meilleure hydraulicité de l'alite trigonale et du C<sub>3</sub>A cubique dans les clinkers industriels.

### SUMMARY :

Sixty industrial clinker samples from twenty-four raw mixes, burned in thirty-two rotary kilns were analysed in order to find the statistical relations between raw mix mineralogy (quartz, illite or kaolinite clays), clinkering processes (wet or dry processes, kiln), chemical composition of the clinker, in one hand, and the allotropic forms of alite (monoclinic or trigonal alite) and C<sub>3</sub>A (cubic or tetragonal C<sub>3</sub>A) on the other hand.

In addition, the consequences on the mean compressive strengths of corresponding portland cement with similar granulometry, have been studied.

This paper shows that the minor elements, such as MgO, SO<sub>3</sub>, K<sub>2</sub>O and P<sub>2</sub>O<sub>5</sub> in industrial clinkers have an important influence on the alite and C<sub>3</sub>A polymorphism and then on the compressive strengths of the corresponding portland cements. The best hydraulicity of trigonal alite and cubic C<sub>3</sub>A, in the industrial clinkers, is confirmed.

## INTRODUCTION

En 1969 et 1970, nous avons établi des relations entre la composition minéralogique et granulométrique des ciments portland et leurs performances (1) et (2). Les progrès réalisés dans la connaissance du polymorphisme du C<sub>3</sub>S et du C<sub>3</sub>A ont posé la question de l'influence de la structure de l'alite et de l'aluminate sur les propriétés des ciments. Des recherches effectuées à l'aide de clinkers de laboratoire et rapportées par GUINIER et REGOURD, en 1968 (3), ont montré que toutes les formes cristallines du C<sub>3</sub>S présentent une réactivité comparable mais que les oxydes entrés en solution solide dans le réseau du C<sub>3</sub>S induisent des variations d'activité hydraulique et de résistance mécanique dans les alites de synthèse, variations dues surtout aux imperfections cristallines. On a précisé que, en général, les ions de diamètre inférieur au diamètre de Ca<sup>2+</sup> augmentent l'instabilité des alites, donc leur hydraulicité (4). En 1972, Mme. REGOURD a publié les résultats de trois analyses de clinkers industriels et étudié les propriétés des minéraux (5); en 1974, elle a publié les résultats de huit analyses (6) et, en 1978, étudié le polymorphisme du C<sub>3</sub>A dans douze clinkers industriels (7).

Dans le présent travail nous recherchons s'il y a des relations entre les matières premières, les conditions de fabrication, la composition chimique des clinkers d'une part et le polymorphisme des phases cristallines, alite et C<sub>3</sub>A d'autre part, sur un grand nombre d'échantillons, représentatifs de la production de la SOCIÉTÉ DES CEMENTS FRANÇAIS, en 1978. Nous verrons l'influence importante des éléments mineurs. En complément, nous avons analysé les conséquences de la structure de l'alite et du C<sub>3</sub>A sur les résistances à la compression des ciments portland correspondants.

## METHODE D'ETUDE

Nous avons constitué une population de 60 clinkers issus de 24 crues de cimenterie, clinkérisés dans 32 fours rotatifs différents, répartis en 21 usines. Ces échantillons de mélanges crus et de clinkers ont été analysés de la façon suivante.

1 - Polymorphisme de l'alite et du C<sub>3</sub>A

Nous avons déterminé avec certitude la présence des différentes formes cristallines de l'alite par examen de la raie 1,76 Å qui est double (620 et 040) dans le cas de l'alite monoclinique M<sub>I</sub>, dissymétrique dans le cas de l'alite M<sub>II</sub> et simple (220) dans le cas de l'alite trigonale ou rhomboédrique R. Les formes cristallines du C<sub>3</sub>A ont été déterminées par examen des raies 2,69 Å du C<sub>3</sub>A cubique et 2,69 Å - 2,71 Å du C<sub>3</sub>A tétragonal sur l'insoluble dans l'acide salicylique.

## 2 - Paramètres considérés

## Mélanges crus :

Nous avons dosé quantitativement le quartz à l'aide des raies 4,25 Å - 3,34 Å et 1,82 Å par rapport aux raies 3,14 Å et 1,92 Å du silicium pris comme étalon interne et par la méthode des ajouts dosés; nous avons ensuite déterminé la présence et les intensités relatives des raies 10 Å et 7 Å des argiles de type illite et kaolinite, ainsi que les raies des feldspaths et de l'hématite, sur l'insoluble dans l'acide nitrique, en pH contrôlé (donc après élimination des carbonates), avant et après traitement à 550°C et au glycol, traitement qui permet de faire disparaître ou déplacer les raies de certains minéraux phyllitiques opale etc...

## Procédés de fabrication :

Nous avons examiné les relations entre le polymorphisme de l'alite et du C<sub>3</sub>A et le mode de fabrication (voie humide, voie sèche), la nature du combustible et l'influence du four rotatif (par comparaison avec le four de laboratoire).

## Clinkers :

Nous avons considéré la composition chimique CaO libre Al<sub>2</sub>O<sub>3</sub>, Fe<sub>2</sub>O<sub>3</sub>, TiO<sub>2</sub>, MnO, MgO, excès SO<sub>3</sub> (après saturation de K<sub>2</sub>O en K<sub>2</sub>SO<sub>4</sub>), excès de K<sub>2</sub>O (après saturation de SO<sub>3</sub> en K<sub>2</sub>SO<sub>4</sub>), Na<sub>2</sub>O, P<sub>2</sub>O<sub>5</sub>, donc avec une attention particulière aux éléments mineurs.

## 3 - Dépendance statistique

Pour dégager les relations entre le polymorphisme de l'alite et du C<sub>3</sub>A et les différents paramètres industriels, nous avons dressé des tables de fréquences d'apparition des formes allotropiques (caractère A) en fonction de la minéralogie du cru, du procédé de fabrication, ou de la composition chimique (caractère B). Dans le cas de la composition chimique, nous avons distingué, pour chaque élément, deux sous-populations, l'une constituée de clinkers riches en cet élément, l'autre par des clinkers pauvres de cet élément. Nous avons calculé, pour chaque relation, à partir des tables, la valeur  $\chi^2$  du test de Pearson qui permet de dire si la dépendance entre les deux caractères étudiés est significative au seuil de 5 % (8).

## RESULTATS OBTENUS

## 1 - Répartition des formes allotropiques dans les 60 clinkers

Utilisant la nomenclature proposée par Mme. REGOURD (9) nous avons mis en évidence les formes suivantes dans les 60 clinkers industriels examinés :

ALITE	C <sub>3</sub> A			TOTAL
	Cubique	Les 2 formes	Tétragonal	
R	11	0	0	11 (18%)
M <sub>II</sub> <sup>b</sup>	11	9	1	21 (35%)
M <sub>I</sub> <sup>b</sup>	7	17	4	28 (47%)
T	0	0	0	0
Total	29 (48%)	26 (43 %)	5 (9 %)	60 (100%)

Nous avons observé 2 fois le C<sub>3</sub>A orthorhombique (raies 624 et 264) associé au C<sub>3</sub>A cubique, mais jamais l'alite triclinique (sauf la forme T<sub>III</sub> dans un clinker "pathologique" décrit dans une autre communication (10))

## 2 - Associations de formes allotropiques

Le tableau précédent fait apparaître des associations fréquentes dans ce lot de 60 clinkers industriels :

- alite R et C<sub>3</sub>A cubique ;
- alite M<sub>I</sub><sup>b</sup> et C<sub>3</sub>A tétragonal (avec ou sans cubique).

On n'a pas vu une seule fois l'association entre alite R et C<sub>3</sub>A tétragonal, comme s'il y avait une incompatibilité entre ces deux formes. Le test de Pearson donne  $\chi^2=21,4 > 9,5$  au seuil de 5 % ce qui veut dire que ces deux caractères (forme de l'alite et forme du C<sub>3</sub>A) sont dépendants.

FACTEURS DU POLYMORPHISME DE L'ALITE ET DU C<sub>3</sub>A

Nous donnons maintenant tous les tableaux de fréquence des formes allotropiques d'alite et de C<sub>3</sub>A, en fonction des paramètres définis plus haut, afin d'en dégager les relations les plus étroites.

## 1 - Minéralogie du cru

QUARTZ	ALITE		
	M <sub>I</sub> b	M <sub>II</sub> b	R
Quartz > 8 %	5 (38 %)	3 (24 %)	5 (38 %)
Quartz < 8 %	6 (50 %)	5 (42 %)	1 (8 %)
25 échantillons	11 (44 %)	8 (32 %)	6 (24 %)
	C <sub>3</sub> A		
	C	C+T	T
Quartz > 8 %	9 (69 %)	3 (23 %)	1 (8 %)
Quartz < 8 %	5 (42 %)	6 (50 %)	1 (8 %)
25 échantillons	14 (56 %)	9 (36 %)	2 (8 %)

ILLITE-KAOLINITE	ALITE		
	M <sub>I</sub> b	M <sub>II</sub> b	R
10 Å > 0,27	10 (71 %)	4 (29 %)	0 (0 %)
7 Å > 0,07	4 (36 %)	4 (36 %)	3 (28 %)
26 échantillons	11 (41 %)	10 (37 %)	6 (21 %)
	C <sub>3</sub> A		
	C	C+T	T
10 Å > 0,27	5 (36 %)	8 (57 %)	1 (7 %)
7 Å > 0,07	6 (55 %)	5 (45 %)	0 (0 %)
26 échantillons	16 (59 %)	9 (33 %)	2 (18 %)

(Nous n'avons pas fait figurer les sous-populations 10 Å < 0,27 et 7 Å < 0,07).

## 2 - Procédé de fabrication

PROCEDES de FABRICATION	ALITE		
	M <sub>I</sub> b	M <sub>II</sub> b	R
Voie humide	7 (39 %)	5 (38 %)	6 (33 %)
Voie semi-sèche	6 (26 %)	14 (61 %)	3 (13 %)
Voie sèche	15 (79 %)	2 (11 %)	2 (10 %)
60 clinkers	28 (47 %)	21 (35 %)	11 (18 %)
	C <sub>3</sub> A		
	C	C+T	T
Voie humide	6 (33 %)	9 (50 %)	3 (17 %)
Voie semi-sèche	15 (65 %)	8 (35 %)	0 (0 %)
Voie sèche	8 (42 %)	9 (47 %)	2 (11 %)
60 clinkers	29 (48 %)	26 (43 %)	5 (9 %)

COMBUSTIBLES	ALITE		
	M <sub>I</sub> b	M <sub>II</sub> b	R
Charbon	3 (42 %)	2 (29 %)	2 (27 %)
Fuel ordinaire	7 (33 %)	9 (43 %)	5 (24 %)
Fuel Ord. + BTS	4 (40 %)	5 (50 %)	1 (10 %)
Fuel Ord. + Gaz	11 (58 %)	5 (26 %)	3 (16 %)
Gaz	3 (100 %)	0 (0 %)	0 (0 %)
60 clinkers	28 (47 %)	21 (35 %)	11 (18 %)
	C <sub>3</sub> A		
	C	C+T	T
Charbon	6 (86 %)	1 (14 %)	0 (0 %)
Fuel ordinaire	10 (48 %)	10 (48 %)	1 (4 %)
Fuel + BTS	5 (50 %)	3 (30 %)	2 (20 %)
Fuel + Gaz	8 (42 %)	9 (47 %)	2 (11 %)
Gaz	0 (0 %)	3 (100 %)	0 (0 %)
60 clinkers	29 (48 %)	26 (43 %)	5 (9 %)

## Influence du four rotatif :

Pour faire ressortir l'influence du procédé de fabrication industrielle sur le polymorphisme de l'alite et du C<sub>3</sub>A, nous avons comparé les clinkers issus des mêmes 19 crus préparés dans un four de laboratoire d'une part et fabriqués à l'usine d'autre part. Voici le tableau de répartition :

CUISSON	ALITE		
	M <sub>I</sub> b	M <sub>II</sub> b	R
Au laboratoire	7	5	7
A l'usine	7	8	4
	C <sub>3</sub> A		
	C	C+T	T
Au laboratoire	10	9	0
A l'usine	6	12	1

En réalité, l'influence de la fabrication industrielle est plus compliquée que le montre le tableau précédent. Nous l'avons mise en relation avec les variations de SO<sub>3</sub> et de K<sub>2</sub>O qui sont, en moyenne :

19 échantillons	SO <sub>3</sub>	K <sub>2</sub> O	soit excès SO <sub>3</sub>
Clinkers laboratoire	0,66	0,18	0,51
Clinkers usine	0,84	0,81	0,15

Ces tableaux montrent que c'est l'influence des teneurs en SO<sub>3</sub> et K<sub>2</sub>O dans le traitement industriel qui conditionne la répartition des phases. Nous reviendrons sur ce point.

On peut ajouter que les 19 clinkers industriels ici examinés montrent une relation remarquable entre le rapport SO<sub>3</sub>/K<sub>2</sub>O (en poids) et le polymorphisme de l'alite.

## 3 - Composition chimique

	ALITE		
	M <sub>I</sub> b	M <sub>II</sub> b	R
CaO libre > 1,5	10 (37 %)	13 (48 %)	4 (15 %)
Al <sub>2</sub> O <sub>3</sub> > 5,21	14 (47 %)	11 (37 %)	5 (11 %)
Fe <sub>2</sub> O <sub>3</sub> > 2,7	14 (47 %)	11 (37 %)	5 (16 %)
TiO <sub>2</sub> > 0,21	13 (41 %)	15 (47 %)	4 (12 %)
MnO > 0,03	11 (42 %)	12 (46 %)	3 (12 %)
MgO > 1,45	16 (84 %)	3 (16 %)	0 (0 %)
P <sub>2</sub> O <sub>5</sub> > 0,12	15 (54 %)	12 (43 %)	1 (3 %)
Excès SO <sub>3</sub>	12 (32 %)	15 (39 %)	11 (29 %)
Excès K <sub>2</sub> O	14 (70 %)	6 (30 %)	0 (0 %)
60 clinkers	28 (47 %)	21 (35 %)	11 (18 %)

	C <sub>3</sub> A		
	C	C+T	T
CaO libre > 1,5	13 (48 %)	13 (48 %)	1 (4 %)
Al <sub>2</sub> O <sub>3</sub> > 5,21	13 (43 %)	16 (53 %)	1 (4 %)
Fe <sub>2</sub> O <sub>3</sub> > 2,7	14 (47 %)	12 (40 %)	4 (13 %)
TiO <sub>2</sub> > 0,21	16 (50 %)	15 (47 %)	1 (3 %)
MnO > 0,03	9 (35 %)	15 (58 %)	2 (7 %)
MgO > 1,45	6 (35 %)	11 (58 %)	2 (10 %)
P <sub>2</sub> O <sub>5</sub> > 0,12	9 (32 %)	16 (57 %)	3 (11 %)
Excès SO <sub>3</sub>	26 (68 %)	10 (26 %)	2 (6 %)
Excès K <sub>2</sub> O	3 (15 %)	14 (70 %)	3 (15 %)
60 clinkers	29 (48 %)	26 (43 %)	5 (9 %)

	ALITE		
	M <sub>I</sub> b	M <sub>II</sub> b	R
Na <sub>2</sub> O > 0,19	8 (73 %)	2 (18 %)	1 (9 %)
Na <sub>2</sub> O < 0,19	4 (33 %)	6 (50 %)	2 (17 %)
23 clinkers	12 (52 %)	8 (35 %)	3 (13 %)
	C <sub>3</sub> A		
	C	C+T	T
Na <sub>2</sub> O > 0,19	3 (27 %)	6 (55 %)	2 (18 %)
Na <sub>2</sub> O < 0,19	3 (25 %)	9 (75 %)	0 (0 %)
23 clinkers	6 (26 %)	15 (65 %)	2 (9 %)

Dans les deux premiers tableaux ci-dessus, nous n'avons pas fait figurer les sous-populations CaO libre < 1,5, Al<sub>2</sub>O<sub>3</sub> < 5,21 etc... pour simplifier les tableaux.

CONSEQUENCE DU POLYMORPHISME DE L'ALITE ET DU C<sub>3</sub>A SUR LES RESISTANCES A LA COMPRESSION

Quelles sont les formes cristallines de l'alite et du C<sub>3</sub>A qui donnent les meilleures résistances à la compression des ciments portland ? Pour répondre à cette question, nous avons calculé les fréquences d'apparition des différentes formes dans les 60 clinkers industriels correspondant aux ciments portland développant les meilleures résistances à la compression à 2, 7 et 28 jours (c'est-à-dire supérieures à la moyenne de tous les échantillons essayés en 1978). On obtient le tableau suivant :

RESISTANCES à la COMPRESSION	ALITE		
	M <sub>I</sub> b	M <sub>II</sub> b	R
R <sub>C</sub> 2j > 26 MPa	7 (28 %)	14 (56 %)	4 (16 %)
R <sub>C</sub> 7j > 43 MPa	6 (29 %)	9 (42 %)	6 (29 %)
R <sub>C</sub> 28j > 58 MPa	4 (21 %)	7 (37 %)	8 (42 %)
	20 (40 %)	21 (42 %)	9 (18 %)
	C <sub>3</sub> A		
	C	C+T	T
R <sub>C</sub> 2j > 26 MPa	13 (52 %)	11 (44 %)	1 (4 %)
R <sub>C</sub> 7j > 43 MPa	12 (57 %)	7 (33 %)	2 (10 %)
R <sub>C</sub> 28j > 58 MPa	13 (68 %)	4 (21 %)	2 (11 %)
	23 (46 %)	22 (44 %)	5 (10 %)

Le test du  $\chi^2$  montre que la dépendance entre polymorphisme et résistances à la compression est ici significative puisque le calcul donne  $\chi^2 = 18,7$  (la dépendance étant significative pour  $\chi = 9,5$  avec 4 degrés de liberté).

## DISCUSSION

Les observations tirées de cette étude s'appliquent évidemment à la population de 60 clinkers industriels représentatifs de la production de la SOCIÉTÉ des CEMENTS FRANÇAIS en 1978.

Les tableaux, ou tables de contingence, que nous avons donnés font apparaître que la dépendance statistique entre les deux caractères examinés (polymorphisme et chacun des paramètres considérés) est plus ou moins étroite. Le test de Pearson comparant les groupes de fréquences observés aux groupes de fréquences théoriques, permet de dire si la dépendance est significative ou ne l'est pas. Voici les résultats :

	ALITE		C <sub>3</sub> A	
	$\chi^2$	seuil 5 %	$\chi^2$	seuil 5 %
Assoc. allotr.	18,7	significatif	18,7	significatif
Procédés	17,7	"	6,5	non signif.

Illite	13,7	"	7,6	significatif
R <sub>c</sub> 28 j	13,0	"	7,1	non signif.
SO <sub>3</sub> /K <sub>2</sub> O	10,3	"	15,0	significatif
P <sub>2</sub> O <sub>5</sub>	7,7	"	5,4	non signif.
Combustibles	7,5	peu signif.	10,8	significatif
iO <sub>2</sub>	4,6	non signif.	2,6	non signif.
R <sub>c</sub> 2j	4,3	"	1,9	non signif.
CaO libre	3,7	"	1,5	non signif.
Na <sub>2</sub> O	3,6	"	2,8	non signif.
R <sub>c</sub> 7j	3,4	"	1,9	non signif.
Quartz	3,3	"	2,1	non signif.
MnO	3,0	"	3,9	non signif.
Kaolinite	0,3	"	2,2	non signif.
Al <sub>2</sub> O <sub>3</sub> -Fe <sub>2</sub> O <sub>3</sub>	0,1	"	3,5 - 2,0	non s.

Nous limitant aux caractères significatifs définis par le test de Pearson, nous rassemblons ici les fréquences d'apparition des principales formes allotropiques de l'alite et du C<sub>3</sub>A en fonction de ces caractères et dans l'ordre décroissant des fréquences, de façon à faire ressortir le degré de dépendance. Nous figurons aussi les résistances à la compression.

#### Fréquences d'apparition des formes allotropiques

ALITE M <sub>I</sub> b	C <sub>3</sub> A C+T	C <sub>3</sub> A T
Voie sèche	79%	Exc. K <sub>2</sub> O 70%
Illite	71%	Illite 57%
Exc. K <sub>2</sub> O	70%	P <sub>2</sub> O <sub>5</sub> 57%
P <sub>2</sub> O <sub>5</sub>	54%	V. humide 50%
60 clinkers	47%	V. sèche 47%
V. humide	39%	R <sub>c</sub> 2j 44%
Exc. SO <sub>3</sub>	32%	60 clinkers 43%
R <sub>c</sub> 7j	29%	V. s. sèche 35%
R <sub>c</sub> 2j	28%	R <sub>c</sub> 7j 33%
V. s. sèche	26%	Exc. SO <sub>3</sub> 26%
R <sub>c</sub> 28j	21%	R <sub>c</sub> 28j 21%
		V. s. sèche 0%

L'alite M<sub>I</sub>b est plus fréquente dans les clinkers provenant de crus riches en argiles de type illite, caractérisés par des teneurs en MgO et alcalis supérieures aux teneurs moyennes. Ces clinkers conduisent à des ciments portland dont les résistances à la compression sont inférieures à la moyenne, à granulométries comparables. Le C<sub>3</sub>A tétragonal, souvent associé au C<sub>3</sub>A cubique et à l'alite M<sub>I</sub>b, se voit fréquemment dans les clinkers riches en alcalins, Na<sub>2</sub>O surtout, et est très favorable aux résistances à long terme.

Les alcalis provenant de crus argileux (illite) ne sont pas entièrement saturés par le SO<sub>3</sub> des fumées provenant des combustibles et entrent en solution solide dans le réseau du C<sub>3</sub>S et du C<sub>3</sub>A, stabilisant, à la température ambiante, les formes M<sub>I</sub>b du C<sub>3</sub>S et té-

tragonal du C<sub>3</sub>A. Notre observation confirme les 3 analyses au M.E.B. de Mme. REGOURD (6) :

	ALITE			C <sub>3</sub> A		
	M <sub>I</sub> b	M <sub>II</sub> b	R	C	C+O	T
MgO	1,0	1,3	0,6	1,5	1,9	0,9
SO <sub>3</sub>		0,06	0,2	0,2	0,2	0,2
K <sub>2</sub> O	0,2	0,1	0,1	0,7	0,8	3,1
Na <sub>2</sub> O	0,2	0,2	0,02	0,4	2,4	0,9

D'après MAKI et CHROMY, les fortes teneurs en MgO stabilisent M<sub>I</sub>b et même R (11) mais KRISTMANN a constaté que les faibles teneurs en MgO correspondent à l'alite trigonale (12). Enfin, d'après BENSTED (4) la présence de K<sup>+</sup>, de diamètre supérieur à Ca<sup>2+</sup>, dans le réseau du C<sub>3</sub>S, réduit l'hydraulicité de l'alite, ce que confirment nos observations.

Pour les autres formes, on a de même :

ALITE M <sub>II</sub> b	ALITE R	C <sub>3</sub> A cubique
Voie s. sèche 61%	R <sub>c</sub> 28j 42%	R <sub>c</sub> 28j 68%
R <sub>c</sub> 2j 56%	V. humide 33%	Excès SO <sub>3</sub> 68%
P <sub>2</sub> O <sub>5</sub> 43%	R <sub>c</sub> 7j 29%	V. s. sèche 65%
R <sub>c</sub> 7j 42%	Excès SO <sub>3</sub> 29%	R <sub>c</sub> 7j 57%
Exc. SO <sub>3</sub> 39%	60 clink. 18%	R <sub>c</sub> 2j 52%
V. humide 38%	R <sub>c</sub> 2j 16%	60 clink. 48%
R <sub>c</sub> 28j 37%	V. s. sèche 13%	V. sèche 42%
60 clink. 35%	V. sèche 10%	MgO 35%
Exc. K <sub>2</sub> O 30%	P <sub>2</sub> O <sub>5</sub> 3%	V. humide 33%
MgO 16%	Excès K <sub>2</sub> O 0%	P <sub>2</sub> O <sub>5</sub> 32%
V. sèche 11%	MgO 0%	Excès K <sub>2</sub> O 15%

L'alite trigonale R et le C<sub>3</sub>A cubique sont fréquents dans les clinkers issus de crus "quartzeux", pauvres en MgO et alcalis et caractérisés par un excès de SO<sub>3</sub> par rapport à K<sub>2</sub>O, donnant des ciments portland à résistances à la compression à 7 et 28 jours supérieures à la moyenne. Ces observations faites sur 60 clinkers industriels infirment le fait, signalé par les auteurs (13), que la présence de SO<sub>4</sub><sup>2-</sup> en solution solide diminue l'hydraulicité de l'alite car nous ne voyons cette diminution qu'à 2 jours seulement. Nous confirmons aussi les conclusions de HARADA, OHTA et TAKAGI d'après lesquels la vitesse d'hydratation initiale croît dans l'ordre pour les formes monoclinique et rhomboédrique (14).

Nous avons dégagé une dépendance entre le procédé de fabrication et le polymorphisme : si l'alite M<sub>I</sub>b est plus fréquente dans les clinkers voie sèche, l'alite R dans les clinkers voie humide (il y a des exceptions), cette observation est probablement fortuite, sauf si les matières premières aptes à la voie sèche sont riches en MgO et alcalis.

#### REMERCIEMENTS

Les auteurs remercient M. Paul MAES de sa collaboration pour les nombreuses analyses de clinker qui sont à l'origine de ce travail.

## CONCLUSION

L'influence des procédés de fabrication sur le polymorphisme de l'alite et du C<sub>3</sub>A est ressentie au travers des éléments mineurs tels que MgO, P<sub>2</sub>O<sub>5</sub> et de la balance entre K<sub>2</sub>O venu de l'argile et SO<sub>3</sub> venu en partie du combustible ; cela ressort des tables de dépendance statistique que nous avons dressées et du test de Pearson que nous avons calculé, sur une population de 60 clinkers industriels, issus de 24 crus, dans 32 fours rotatifs.

Nous n'avons pas mis en évidence le rôle d'autres caractères comme teneurs en Al<sub>2</sub>O<sub>3</sub>, Fe<sub>2</sub>O<sub>3</sub>, TiO<sub>2</sub>, probablement parce que les teneurs en TiO<sub>2</sub> de nos clinkers industriels sont trop faibles pour reproduire les effets observés au laboratoire (15).

Nous avons montré, en complément, que l'alite monoclinique M<sub>1</sub>b et le C<sub>3</sub>A tétragonal des clinkers provenant de crus "argileux" sont moins hydrauliques que l'alite monoclinique M<sub>1</sub>1b et surtout que l'alite trigonale ou rhomboédrique et le C<sub>3</sub>A cubique provenant de crus clinkérisés avec des combustibles riches en soufre.

RESUME : On a étudié les processus physico-chimiques qui se produisent dans un four rotatif alimenté en parallèle par deux flux distincts de matières crues, de composition chimique, granulométrique et de phase différente. Le deuxième flux (complémentaire) introduisait directement, dans les zones préparatoires du four, deux types de matières appropriées :

- des matières participant activement aux réactions de clinkérisation, dès l'apparition du liquidus (bélite fondue) dans la masse,
- des matières (laitiers de hauts fourneaux, laitier électrophosphoreux, cendres volantes), qui entrent elles-mêmes en fusion avant l'apparition normale du liquidus.

L'action activante des matières de ce deuxième flux, dans la cuisson du cru, est susceptible d'accroître fortement (de 20 à 25 %) la capacité de production du four rotatif et de réduire la consommation de combustible, tout en conservant les propriétés chimiques, physiques et mécaniques du clinker obtenu, et parfois même, en les améliorant.

SUMMARY: The physical and chemical processes taking place in a furnace being fed by two parallel flows of raw materials with different chemical, phase and granulometric compositions have been investigated. Used as the second (additional) flow introduced directly to the preparatory zones of the furnace are technogenic materials of two types:

- the materials which take an active part in the clinker formation reactions after the basic mass of the clinker melt appears in the raw charge (belite slime);
- the materials (blast furnace and electrothermophosphorus slags, fly ashes) which form the melt before it appears in the bulk of the charge.

The intensifying effect of technogenic materials in the calcination process has enabled to increase drastically (by 20-25%) the capacity of clinker calcination rotary furnaces and decrease specific consumption of fuel for calcination within the same range with preservation, and, on some occasions even improving, the physico-chemical and physico-mechanical properties of the clinker obtained.

On a élaboré en U.R.S.S. un procédé d'intensification du processus de clinkérisation, permettant d'accroître sensiblement (de 15-30%) le rendement des fours rotatifs de clinkérisation et de diminuer (de 12-25%) la consommation spécifique de combustibles pour la cuisson.

Ce procédé consiste en alimentation parallèle du four par deux flux de matières brutes de composition chimique, de phase et granulométrique différente. Le premier flux (principal) - les mélanges crus de constituants classiques ordinaires qu'on prépare et introduit dans le four de façon traditionnelle. Le deuxième flux (complémentaire) - les matières technogènes (rejets industriels) ayant subi le traitement thermique préalable en vue de la formation des silicates faiblement basiques, des aluminosilicates, des aluminates, des aluminoferrites de calcium. De tels composés apparaissent également dans le clinker-portland aux premiers stades de cuisson. Comme il est connu, leur synthèse est précédée par des dépenses de chaleur importantes.

On a étudié et proposé pour l'utilisation dans les cimenteries les sous-produits des branches métallurgique, chimique et énergétique de l'économie nationale (boues de néphéline, cendres et mélanges laitier-cendres des centrales thermiques, laitiers de haut fourneau, laitiers électrothermophosphoriques, etc.).

Les matériaux du deuxième flux sont introduits dans les fours rotatifs directement par leurs zones préparatoires du côté froid.

L'alimentation complémentaire des fours en matières technogènes prévoit la substitution partielle par ces dernières des constituants carbonaté et aluminosilicique du flux principal. Ceci change notablement le rapport des constituants crus dans la composition du système de cuisson et par conséquent la cinétique de la clinkérisation et les propriétés des produits de la cuisson. Le degré et le caractère de l'influence des matières utilisées pour l'alimentation complémentaire des fours sur la synthèse du clinker de ciment se déterminent par leurs paramètres physico-chimiques et la quantité de ces matières introduite dans le four.

Dans cette communication on considère deux groupes de matières du deuxième flux:

- (I) matières qui entrent activement en réactions de clinkérisation après l'apparition dans la charge crue de la masse principale du clinker fondu. La boue de néphéline (de bélite) représente ce type de matière technogène;
- (II) matières qui forment le bain fondu avant son apparition dans la charge crue principale. Ce sont des laitiers de haut fourneau, laitiers électrothermophosphoriques, cendres.

L'interaction de la boue de néphéline, introduite complémentirement et représentée

principalement par le silicate bicalcique sous forme  $\beta$ , avec la charge crue à excès du composant carbonique, commence principalement à se produire lorsque le clinker fondu apparaît dans le système de cuisson. Comme il est connu (1), dans ces conditions la réaction de formation des alites est limitée par la vitesse de dissolution dans la phase liquide de l'oxyde de calcium et de la bélite et dépend de leur habitus. Il importe de noter que les grains de bélite de la boue de néphéline forment des agrégats et se transforment en cristallites au cours du traitement thermique successif (la vitesse d'élévation de la température dans le four étant de 600°C/heure). Indépendamment de la dispersité initiale de la boue de néphéline, au moment de formation intense des alites leur dimension est de 20  $\mu\text{m}$ , ce qui n'entrave pas le stade final de cuisson.

De plus, la présence dans le système de cuisson des centres de cristallisation formés ( $\beta$ -C<sub>2</sub>S) contribue à l'accélération de la synthèse des minéraux faiblement basiques dans la charge crue mélangée déjà au premier stade de cuisson. Ceci est confirmé par les données de l'analyse des phases aux rayons X à haute température (fig. 1a), fixant dans le mélange 2 avec 25% de la boue de néphéline l'assimilation plus intense de la silice que dans la charge sans additions 1 ( $d = 3,40 \text{ \AA}$ ) et l'accroissement des constantes de la vitesse d'assimilation de la chaux dans le mélange 2 dans l'intervalle de température de 900 à 1000°C.

La composition de la phase intermédiaire de la boue de néphéline, contenant jusqu'à 1-1,5% d'oxydes alcalins, est un facteur complémentaire qui contribue à l'accélération de la synthèse de l'alite. D'après les résultats des recherches (3), la présence dans le bain fondu des cations très mobiles Na<sup>+</sup> et K<sup>+</sup> intensifie notablement la réaction de dissolution de la bélite grâce à la formation dans les limites de la couche superficielle de C<sub>2</sub>S des eutectiques facilement fusibles. Cet effet de l'influence intensifiante des ions alcalins se manifeste même dans la charge à deux constituants 3 (matériau carbonaté - boue de néphéline) malgré sa teneur limitée en phase liquide (17%) en comparaison des charges à plusieurs constituants.

L'étude des particularités de la clinkérisation en présence des matières technogènes du deuxième groupe a montré que l'action intensifiante de ces additions est due à leur fusion autonome précoce (les bains fondus du laitier de haut fourneau, du laitier électrothermophosphorique et des cendres apparaissent aux températures de 1260-1280°C, 1180-1220°C, 1240°C respectivement) et à l'interaction des bains fondus de laitiers et de cendres avec les constituants de la charge crue. Les observations effectuées à l'aide du microscope optique ont permis de déterminer le mécanisme de pénétration des matières du deuxième groupe, qui se trouvent à l'état fondu liquide, à l'intérieur des volumes microscopiques de la charge crue, en fixant les zones

Fig.1. Influence de la boue de néphéline sur le processus de cuisson dans l'intervalle de température de 800 à 1200°C. 1, 2, 3 sont respectivement les parts de la boue de néphéline dans le mélange cru. 0%, 25%, 76% (à deux constituants).

suyantes (fig.2): A - le laitier ayant subi le traitement thermique; B - la zone d'interaction du laitier avec la charge principale; C - la charge crue; D - la zone occupée autrefois par le laitier. La présence de cette dernière contribuera à la diminution de la résistibilité au broyage des clinkers obtenus.

Notant le mécanisme général d'interaction des matières de ce groupe avec les constituants de la charge principale, remarquons que chacun d'entre eux apporte des traits spécifiques dans la cinétique de la clinkérisation.

Lorsqu'on utilise en qualité de flux complémentaire le laitier granulé de haut fourneau, son action intensifiante initiale sur la cuisson est notée dans l'intervalle de température de 800 à 1000°C, ce qui corres-

Fig.2 Interaction du laitier avec la charge.

pond à la dévitrification active du laitier et à l'interaction des produits de sa cristallisation avec  $\text{CaO}$  de la charge principale avec formation du silicate bicalcique. Il convient de noter que les cristaux de  $\text{C}_2\text{S}$ , formés à partir de la méililite (phase prédominante du laitier de haut fourneau), se caractérisent, d'après les données des recherches (2), par une structure cristalline plus fine que les cristaux de bélite formés à partir du quartz. Ceci influe de façon favorable sur la vitesse de dissolution de  $\text{C}_2\text{S}$  dans le bain fondu. Quant au silicate bicalcique formé à partir des minéraux de laitier, il joue le rôle de germe cristallin, contribuant à l'accélération de la synthèse de la bélite dans la masse totale du mélange à plusieurs constituants.

On observe l'action intensifiante principale du laitier sur le processus de cuisson dans le système mixte lors de l'apparition dans ce dernier de la phase liquide. La quantité totale de cette phase croît en présence de laitier, facilitant la formation de l'alite. L'accroissement des vitesses d'assimilation de la chaux aux températures correspondant à l'état fondu liquide du laitier, qui est notable en comparaison de la charge sans laitier, en témoigne (fig.3) et s'accorde avec les recherches antérieures (4).

Lors des expériences avec additions du laitier de haut fourneau dans les matières brutes à réactivité différente, on a établi que son action intensifiante se manifeste au plus haut degré lorsqu'on utilise les matières brutes avec le constituant aluminosiliceux de basse réactivité et au moindre degré, avec le constituant de haute réactivité. Quant au dosage optimal du laitier de haut fourneau introduit complémentairement dans le système de cuisson, les modifications des paramètres chimiques de la charge qui s'ensuivent ne doivent pas di-

Fig. 3. Réactivité des charges crues avec additions du laitier granulé de haut fourneau. Comme matière aluminosilicique de base on a utilisé: a - argile sableuse, 1, 2, 3, 4 - charges comportant respectivement 0%, 10%, 14%, 22% de laitier; b - marne, 1, 2, 3, 4 - charges contenant respectivement 0%, 10%, 16%, 24% de laitier.

minuer sa réactivité et compliquer la clinkérisation. C'est donc le module silicique de la charge sommaire qui en servira de critère.

La substitution partielle dans les charges crues des constituants carbonaté et aluminosilicique par du laitier électrothermophosphorique, contenant des éléments modifiants et minéralisants (F,P), exerce une influence spécifique, en comparaison du laitier de haut fourneau, sur le déroulement de la cuisson. D'après les données de l'analyse thermique différentielle (Fig. 4) on peut constater entre autres le déplacement de la décarbonisation vers la zone des basses températures, l'apparition sur son effet du pic endothermique double ainsi que de la phase liquide, qui s'exprime par une brusque augmentation de la conductibilité électrique du mélange en cuisson. L'effet double de décarbonisation caractérise un "faux équilibre", il est dû à la formation de l'eutectique de basse température contribuant à l'accélération de l'interaction de CaO avec la silice de la charge principale, les minéraux faiblement basiques du laitier électrothermophosphorique qui se caractérisent par une grande activité à l'étape donnée de la cuisson (cette étape coïncide avec la dévitrification du laitier). La diminution de la concentration de l'oxyde de calcium dans la sphère de réaction crée des conditions favorables à un nouvel accroissement de la décarbonisation (deuxième effet endothermique). Les processus s'accompagnant de l'absorption des ions  $Ca^{+2}$  - porteurs de courant principaux - dans le réseau des silicates de

Fig. 4. Thermogrammes des charges 1, 2 contenant respectivement 0% et 25% du laitier électrothermophosphorique calculés pour la matière calcinée: a) courbe différentielle; b) courbe de conductibilité électrique.

calcium, sont à l'origine de la diminution de la conductibilité électrique. Dans ce cas le maximum de la bélite formée dans le mélange avec le laitier apparaît à 100°C plus bas que dans le mélange sans additions. L'apparition des effets endothermiques à des températures correspondant au ramollissement (1180°C) et à la fusion (1220°C) du laitier électrothermophosphorique répond évidemment à la dissolution des phases halogénées initiales des silicates de calcium et de la bélite dans la phase liquide avec formation de l'alite. Dans ce cas les effets endothermiques dans le domaine des températures de 1275°C et 1325°C sont moins forts que dans la charge sans laitier, car dans les mélanges avec le laitier électrothermophosphorique la plus grande partie des matières a déjà passé dans la phase liquide avec formation d'une grande quantité d'alite. On a déterminé que dans les mélanges contenant 20% et plus de laitier, la quantité d'alite formée à 1200-1250°C était de 75 à 95% (relatifs) contre 65% dans le mélange sans laitier. L'accroissement des constantes relatives de la vitesse d'assimilation de la chaux dans les charges contenant du laitier jusqu'à 1300°C confirme tout ce qui a été dit précédemment.

L'introduction complémentaire dans le four rotatif des cendres qui se caractérisent

par la composition acide (contenant par exemple  $Al_2O_3$  - 20%,  $Fe_2O_3$  - 15%, y compris  $FeO$  - 7%) accélère notablement l'agglomération en phase liquide. Dans ce cas, la diminution, en présence des cendres, du module silicique dans les charges en cuisson (de 2,65 dans le mélange témoin jusqu'à 1,7 dans la charge contenant 24% de cendres) communique au bain fondu du clinker des propriétés facilitant la synthèse de l'alite. Toutefois, la quantité de cendres du type donné introduite dans le lit de fusion est limitée à 8-10% (pour la substance calcinée), car une diminution excessive du module silicique entraîne la diminution des minéraux-silicates de calcium dans le clinker, par suite de quoi on pourrait obtenir un ciment à propriétés peu satisfaisantes. On peut élargir les limites d'introduction des cendres dans la charge crue par sa purification avec une matière, par exemple le laitier électrothermophosphorique, capable d'introduire dans le système de cuisson une quantité complémentaire des silicates de calcium et de normaliser de cette façon la composition chimique du clinker obtenu.

Comme il découle des résultats cités, les matières technogènes, en vertu de leur genèse, ne participent que faiblement aux processus en phase solide exigeant une surface spécifique développée et entrent en interaction avec la charge crue principalement au stade des réactions avec participation de la phase liquide. Dans ce cas, le degré de broyage des matières du deuxième flux ne jouera pas le rôle décisif en clinkérisation, qui est le sien dans l'achèvement du processus de cuisson dans la charge crue principale. Lors de la vérification de cette hypothèse on a noté que la vitesse d'assimilation de la chaux diminue naturellement avec l'accroissement du grain du constituant complémentaire. On a déterminé la dimension limite du grain pour les matières technogènes du deuxième groupe, en particulier pour le laitier granulé de haut fourneau, égale à 5-7 mm. Au-dessus de cette dimension la vitesse d'assimilation de la chaux diminue de façon inadmissible.

En ce qui concerne les grains solides de la boue de néphéline, sa granulométrie initiale plus fine en comparaison des laitiers granulés et le degré de basicité plus élevé assurent l'achèvement du processus de cuisson lorsqu'on introduit dans la charge crue une quantité complémentaire de boue de néphéline non broyée. Les données des analyses au microscope électronique ont permis de représenter plus nettement l'interaction de ses grains avec l'oxyde de calcium de la charge crue principale en démontrant que la pénétration du clinker fondu le long des limites des blocs cristallins de la bélite conditionne sa dissolution rapide.

Les résultats des études théoriques susmentionnées concernant l'efficacité de l'utilisation des matériaux technogènes lors de la synthèse du clinker de ciment

trouvent leur confirmation et leur application dans les conditions industrielles aux usines utilisant des fours de dimensions différentes. Le tableau I donne les résultats des essais industriels des fours avec alimentation complémentaire en matières technogènes. Il faut noter que l'introduction séparée mais synchronisée dans le four de deux flux exige un mélange de basicité élevée dont la valeur serait fonction de la quantité du matériau technogène introduit dans le four.

Tableau I

Caractéristique du fonctionnement du four et qualité du clinker

Dénomination des caractéristiques	Dimension relative au régime de cuisson ordinaire	Alimentation complémentaire des fours de dimension, m			
		3,3x3,6/70m avec les concentrateurs de la boue	4/150 m	4,5 x 170m	
		en boue de néphéline	en laitier de haut fourneau	en laitier électrothermophosphorique	en laitier électrothermophosphorique et cendres (1:1)
Accroissement du rendement du four	%	22	25	20	15
Economie du combustible moyen	%	15	20	16	20
Température des gaz perdus	±°C	+20	+10	+15	+20
Basicité de la boue crue (facteur de saturation)	1,0	1,0	1,09	1,18	1,19
Teneur du clinker, en $C_3S$ , %	-	55	70	62	61
Variation d'activité du clinker	± kgf/cm <sup>2</sup>	+10	+150	+40	+35

Le fait de mélanger deux flux directement dans le four joue un rôle important dans la cuisson. Les recherches dans les conditions industrielles ont montré que dans le four de 70 mètres on obtient une homogénéisation satisfaisante des matériaux introduits séparément et assurant la fabrication du clinker de qualité.

Ainsi, en utilisant les matériaux technologiques pour l'alimentation complémentaire des fours, on augmente leur rendement et diminue les dépenses spécifiques de chaleur pour la cuisson du clinker.

# Effect of Raw Materials on Cement Process, and Properties

## *Influence des matières premières sur la fabrication du ciment et ses propriétés*

G.R. GOUDA, Ph.D. Manager, Cement Technology, Fuller Company, Bethlehem, Pennsylvania, U.S.A.

RESUME : Deux crus différents ont été choisis, correspondant aux extrêmes maximum et minimum de la fabrication du ciment. Le cru n° 1 est caractérisé par des matières premières :

- A - molles
- B - faciles à broyer,
- C - faciles à cuire,

Le cru n° 2 est caractérisé par des matières premières :

- A - dures,
- B - difficiles à broyer,
- C - difficiles à cuire.

Des expérimentations ont permis des comparaisons complètes, notamment sur la préparation des crus (concassage et broyage), le processus de cuisson, les propriétés du ciment, l'importance des matériels nécessaires et la consommation d'énergie. La microstructure des deux clinkers produits a été examinée au microscope électronique à balayage.

SUMMARY: Two different raw mixes were selected to represent the minimum and the maximum extremes of the cement manufacturing process. Raw Mix No. 1 is characterized by:

- A. Soft raw materials
- B. An easily ground mix
- C. An easily burned mix

While Raw Mix No. 2 is characterized by:

- A. Hard raw materials
- B. A hard grinding raw mix
- C. A hard burning mix

A complete comparison, including the raw materials preparation (crushing and grinding), burning process, clinker grinding, cement properties, equipment sizing, and energy and power consumption of these two mixes has been studied. A scanning electron microscope was used to characterize the microstructure of the clinker produced from both raw mixes.

## INTRODUCTION

The raw materials used in the cement industry are formed naturally and thus vary widely from one place to another (1). The economy of any cement plant is affected by the different properties of the raw materials, which are the key considerations and the principal factors in designing the cement plant (2). These raw materials have considerable effect on the manufacturing process, clinker structure, and the properties of the cement. Two raw mixes were selected which represent the minimum and the maximum extremes of the cement industry. Each mix is characterized by its raw material resources which are completely different from the other. Both mixes were produced by the dry process using a suspension preheater. Each plant, due to its dissimilarities in raw materials, behaves completely differently from the other, as verified by the following information.

## RAW MATERIALS

The raw material used for raw mix 1 is soft limestone with compressive strength of about 200 kg/cm<sup>2</sup>. X-ray diffraction shows that it contains mainly calcite. Argillaceous materials--clay which is mainly kaolinite--is used in preparing the raw mix, with about 56% SiO<sub>2</sub>. The raw material used for the second raw mix is hard limestone with a compressive strength of about 650 kg/cm<sup>2</sup>. No other raw materials are available in the vicinity of the second plant except shale, which consists primarily of quartz and calcite. Small amounts of illite and ankerite are also found in the shale. The limestones from both plants were studied by scanning electron microscopy (SEM). The grains of the limestone of the first plant are small and have pointed edges, Figure 1. The grains of the second limestone are larger and more or less flat, Figure 2. The second limestone appears denser than the first one.

Fig. 1 - The microstructure of the limestone of the first plant showing small grains

Fig. 2 - The microstructure of the limestone of the second plant showing large and flat grains

## CRUSHING AND GRINDING PROCESSES

Both processes are different in each plant, and each plant's equipment is adapted according to the raw materials' properties. A single hammermill is used in the first plant, while a specially designed impactor hammer is used in the second one. The wear in the crushing area of the second plant is much more than that of the first one, primarily because of the quartz in the raw materials.

The residence time in the grinding process of the first plant is about 1/3 that of the second plant, even though the grinding systems are essentially the same. The grinding medium has normal hardness in the first mill, while in the second mill the medium has high hardness. The grinding medium wear in the second plant is more than triple that of the first plant.

## RAW MIX PROPERTIES

Both raw mixes are chemically and physically different from each other. Mix 1 is considered the ideal mix for cement manufacture while mix 2 is abnormal. Free silica in mix 1 is 2.82 while that of mix 2 is 12.35. The silica modulus in mix 2 is more than double that in mix 1. A.M. is within the reasonable limits in mix 1, but in mix 2 is high. For these reasons, mix 2 is ground very finely (3.6% residue on 170 mesh) in contrast to mix 1, which is ground to a residue of 14.6% on 170 mesh.

The cements produced from both plants is sold as ordinary Portland cement, although the cement of the second plant complies too with the requirements of moderate sulfate resistance or moderate heat of hydration cement.

## BURNING PROCESS

Sintering and the behavior of each raw mix in the rotary kiln is completely different. The first mix performs well in the kiln and forms a good coating. No precaution was taken in the equipment sizing.

In the case of the second mix, kiln size is larger than normal; the sintering process is difficult, and does not form a coating on the kiln bricks. The flame shape is long, the kiln rotates slowly, and the kiln is usually dusty. The clinker is smaller than that of the first mix. Comparative consumption is quite different; about 795 kcal/kg clinker is required to sinter the first mix, while about 915 kcal/kg is required for the second mix. The sintering temperature for the second mix is about 220°C higher than for the first one. The liquid phase of the first clinker is 25.50%, while that of the second mix is 17.20%, as calculated by the Lea and Parker formula. The preheater gas volume in the first plant is about 1.5 NM<sup>3</sup>/kg clinker; in the second plant, it is about 1.7 NM<sup>3</sup>/kg.

Table 1 shows the properties of the raw materials, raw mix components, grinding process, mix analysis, burning process and the fuel consumption of each plant.

## CLINKER MICROSTRUCTURE

Scanning electron microscopy was used to study the microstructure of both clinkers. Clinker produced from the first raw mix is shown in Figures 3 to 5. In general, the structure is opened with a porosity of about 15%. Polygonal, well developed, compact prismatic alite crystals with a size of about 25  $\mu$ m were observed, Figures 3 and 4. Small amounts of belite crystals with sizes smaller than the alite can be seen in Figure 4. Formations of C<sub>3</sub>S from C<sub>2</sub>S and CaO (from the surroundings) are shown in the same figure. The interstitial phases (aluminates and ferrite) are shown clearly in Figure 5, as well as a fracture of a calcium silicate grain (occurred during sample preparation for SEM).

Fig. 3 - Microstructure of the first clinker showing well-developed alite crystals

Fig. 4 - Small belite crystals (★) and large alite crystals (⊙)

Fig. 5 - Clear interstitial phases (★) surrounding the calcium silicate grains (⊙).

The microstructure of the clinker produced from mix 2 is shown in Figures 6 to 8. It is dense in comparison to the other clinker; its  $C_3S$  crystals are small in comparison to the  $C_2S$  crystals which are abnormally large, Figure 6. This is because such a raw mix remains in the higher sintering temperature range too long, during which the  $C_2S$  becomes coarser (1); also, the L.S.F. is low, and there is insufficient  $CaO$  for  $C_3S$  formation. Belite shows coarseness and secondary crystallization, Figure 7, which is probably due to excessive heat and  $SiO_2$  (3). A complex inner-belite crystal is shown in Figure 8, which may be due to the inversion into  $\beta$ -form while  $\alpha$ -form remains. No clear interstitial phases were observed in this clinker.

Fig. 6 - Microstructure of the second clinker, which is characterized by abnormally large belite (⊙) and small alite (★) crystals

Fig. 8 - A complex inner-belite crystals of the second clinker

### CLINKER GRINDING

The clinker produced from the second mix fractures easily and is more brittle in the first compartment, but its residence time in the second compartment is much longer in comparison to the clinker produced from the first mix. The grinding medium in the cement mill of each plant is different. This is because clinker 2 contains a large amount of  $\text{SiO}_2$  and  $\text{C}_2\text{S}$ , and is ground to a fine product. The cement mill of the second mix requires more air and water for cooling the cement mill system. Because mix 2 represents the maximum extreme, its clinker is ground even more finely than the clinker produced from the first mix to attain an acceptable property. Specific surface of the cement, measured by Blaine apparatus, is about  $2850 \text{ cm}^2/\text{gm}$  for the second clinker. The clinker properties and grinding are shown in Table II.

## CEMENT PROPERTIES

The cement produced from the first plant is darker than that of the second one. Although the cement produced from the second plant is ground more finely, its strength is lower than that of the cement produced from the first plant. In the early ages (after one day) the strength of the second cement is less than that of the first cement by about 25%; this can be attributed to low  $C_3S$ . After twenty-eight days, the strength of both cement mixes is about the same.

The properties of the ground cement are shown in Table II.

## TOTAL POWER CONSUMPTION

The total power consumption of both plants is shown in Table III; the second plant uses about 52% more power than the first plant. The raw materials and cement finish grinding processes are responsible for most of the increase in power consumption.

TABLE III			
POWER CONSUMPTION

## CONCLUSIONS

The raw materials of any cement plant affect the manufacturing process, the burning process, the fuel consumption, and the economy of the plant. It is economical to work with raw materials which are easier to grind and which form an easy-burning raw mix than those which form a hard-burning raw mix (4). If a wide variety of raw materials are available in the vicinity of a cement plant, it is advisable to choose and work with the most economic material.

# Sur le mécanisme de la cristallogenèse dans les microzones des grains de clinker

## *Mechanism and kinetics of crystall formation in the microvolumes of clinker grains*

V.V. TIMACHEV, membre correspondant de l'Académie des Sciences de l'U.R.S.S.,  
professeur à l'Institut Chimico-Technique Mendéléev,  
A.P. OSSOKINE, candidat ès sciences techniques,  
E.N. POTAPOVA, ingénieur, Moscou, U.R.S.S.

**RESUME :** On a étudié le mécanisme et la cinétique des processus de dissolution de  $\text{CaO}$  et de  $\text{C}_2\text{S}$  dans l'excès de la matière fondue, et de cristallisation de  $\text{C}_2\text{S}$  et de  $\text{C}_3\text{S}$  respectivement dans les systèmes  $\text{C}_2\text{S}$  - matière fondue et  $\text{CaO}$  -  $\text{C}_2\text{S}$  - matière fondue.

Les réactions de dissolution des minéraux sont contrôlées par la diffusion et leur vitesse dépend de la structure de la phase solide et de la composition de la matière fondue. Dans le système  $\text{CaO}$  -  $\text{C}_2\text{S}$  - matière fondue, le processus de dissolution devient plus intense grâce à la cristallisation simultanée du silicate tricalcique.

Le volume des cristaux de  $\text{C}_3\text{S}$  qui se forment lors du frittage isotherme du clinker est proportionnel au volume des cristaux de bélite dissous et cette correspondance s'observe jusqu'à l'obtention de l'état équilibré.

Les phénomènes de liquation ayant lieu dans le bain fondu modifient le mécanisme et la cinétique de la dissolution des minéraux, ce qui provoque à son tour la modification du stade de limitation du processus de formation de l'alite dans le grain de clinker en fonction de l'hétérogénéité locale de sa composition.

**SUMMARY :** Mechanism and kinetics of solution processes of  $\text{CaO}$  and  $\text{C}_2\text{S}$  in melt excess and crystallization of  $\text{C}_2\text{S}$  and  $\text{C}_3\text{S}$  in the systems of  $\text{C}_2\text{S}$  - melt and  $\text{CaO}$  -  $\text{C}_2\text{S}$  - melt, respectively, have been studied.

Mineral solution reactions are controlled by diffusion while their rate depends on solid phase structure and melt composition. In the system  $\text{CaO}$  -  $\text{C}_2\text{S}$  - melt the solution process intensified due to simultaneous crystallization of tricalcium silicate.

The volume of  $\text{C}_3\text{S}$  crystals formed in isothermal clinker sintering is proportional to the volume of the bélite crystals dissolved and this conformity is observed up to the state of equilibrium.

Liquation phenomena in the melt changes the mechanism and kinetics of mineral solution. Therefore, limiting stage of alite formation process is changed in clinker grain depending on local heterogeneity of its composition.

En généralisant les résultats des travaux (1 à 5) et d'autres études, on peut représenter le processus de synthèse de  $C_2S$  comme un ensemble de transformations physico-chimiques successives et parallèles dont les principales sont les suivantes :

1) formation des matières fondues microscopiques non équilibrées ayant des propriétés acido-basiques différentes en fonction de la composition de la phase solide de contact ( $CaO$ ,  $SiO_2$ ,  $C_2S$ , etc.) ;

2) dissolution dans le bain fondu de composés intermédiaires, qui s'accompagne d'une variation de sa composition et de sa quantité ;

3) migration de la matière fondue dans les grains d'oxyde de calcium et de bélite ;

4) dissolution des zones de contact des macroparticules, leur dispersion en blocs séparés ;

5) dissolution par diffusion des microcristaux de  $CaO$  et de  $C_2S$  dispersés et formés par recristallisation ;

6) diffusion des ions  $Ca^{2+}$ ,  $O^{2-}$ ,  $SiO_4^{2-}$  depuis les faces des particules qui se dissolvent vers les zones de croissance des cristaux de  $C_2S$  ;

7) formation des centres de cristallisation dans les zones sursaturées ;

8) croissance des cristaux de  $C_2S$ . On croit que les étapes les plus lentes limitant la cinétique de la formation de l'alite sont les réactions de dissolution des particules de départ de  $CaO$  ou de  $C_2S$  (N.A. Toropov, P.V. Roumiantsev, N.F. Vassiliéva, R. Kondo, S. Tchoï, etc.) et la diffusion des ions vers les cristaux croissants de  $C_2S$  (P.P. Boudnikov, I.V. Kravtchenko, B.E. Youdovitch, V. Iohansen).

Pour élucider les régularités de la synthèse de  $C_2S$  et déterminer le stade de contrôle, on a étudié les processus de dissolution de  $CaO$  et de  $C_2S$  dans l'excès de matière fondue et lors de la cristallisation du silicate tricalcique dans les microzones du grain de clinker.

#### DISSOLUTION DE $CaO$ ET DE $C_2S$

Le processus de dissolution fut étudié dans les conditions de convection naturelle et forcée. Dans les conditions statiques, on procédait à la dissolution des éprouvettes obtenues par décarbonisation du marbre à des températures de 1100 à 1400 °C. Elles se composaient de cristaux arrondis de  $CaO$  de 5 à 10  $\mu m$  de dimension qui se sont agrégés aux points de contact. La porosité des agglomérés variait de 44,76 (1100 °C) à 27,33 % (1400 °C) ; la dimension des pores était de (0,4 à 1,0) d des cristaux.

Dans les conditions dynamiques, on dissolvait les agglomérés de  $C_2S$  et de  $CaO$  dont la porosité était inférieure à 5 % et qui furent obtenus par compression des poudres correspondantes ayant les particules de dimension jusqu'à 60  $\mu m$  à 200 MPa, suivie d'un frittage isotherme à 1800-2000 °C pen-

dant deux heures. La dimension des pores dans les éprouvettes variait dans les limites de 180 à 5000 Å en diminuant avec l'élévation de la température de cuisson. Après la cuisson, les éprouvettes de 10-20 mm de diamètre et de 3.10<sup>-2</sup> m de longueur furent mises en rotation dans le bain fondu à la vitesse de 10 à 20 s<sup>-1</sup>. Pour les mesures on a préparé une installation spéciale (6) dont la conception permettait de réaliser le processus dans les conditions oxydantes à 1500 °C l'intensité de rotation des éprouvettes étant élevée et leur écart par rapport à l'axe de rotation étant minimale.

L'utilisation du disque tournant en tant que surface de réaction permet de régler l'épaisseur de la couche hydrodynamique et par là même l'épaisseur de la couche frontalière de diffusion limitant la vitesse de la réaction se déroulant dans le domaine de diffusion. Dans ce cas le processus se décrit approximativement par l'équation

$$I = 0,61 \cdot K \cdot D^{2/3} \cdot \eta^{-1/6} \cdot W^{1/2} \cdot \Delta C, \quad (1)$$

où  $I$  est la vitesse de dissolution, m/s ;  $D$  le coefficient de diffusion, m<sup>2</sup>/s ;  $\eta$  la viscosité cinématique, m<sup>2</sup>/s ;  $W$  la vitesse de rotation angulaire, rad/s ;  $K$  le coefficient ;  $\Delta C$  le paramètre de concentration égale à

$$\Delta C = \frac{C_1 - C_\infty}{1 - \sqrt{C_1}} ;$$

$C_1$  la concentration de saturation, fractions volumétriques ;  $C_\infty$  la concentration dans le volume de la matière fondue, fractions volumétriques ;  $\sqrt{V}$  le volume partiel du corps dissous égale à  $\sqrt{V} = \rho_m / \rho_{mf}$  ;  $\rho_m$  la densité du minéral dissous, kg/m<sup>3</sup> ;  $\rho_{mf}$  la densité de la matière fondue, kg/m<sup>3</sup>.

Conformément à l'équation (1), le mécanisme du processus étant diffusif, sa vitesse est proportionnelle à  $W^{1/2}$ , ce qui s'observe pour des agglomérés compacts de  $CaO$  et de  $C_2S$  (fig. 1). Si l'intensité de rotation des éprouvettes de  $C_2S$  varie dans les limites de 10 à 20 s<sup>-1</sup>, la vitesse de dissolution ( $I$ ) croît dans la gamme (0,8 à 1,25) · 10<sup>-8</sup> m/s, et pour  $CaO$  elle était pratiquement d'un ordre de grandeur plus élevée (2-3) · 10<sup>-7</sup> m/s. Cette différence est due à une mobilité plus élevée des ions  $Ca^{2+}$  devant  $SiO_4^{4-}$  (2).

Les valeurs des coefficients de diffusion des ions les moins mobiles qui sont  $Ca^{2+}$  pour  $CaO$  et  $SiO_4^{4-}$  pour  $C_2S$ , calculées d'après l'équation (1), ne dépendent pas de l'intensité de convection du bain fondu et sont égales à :  $D_{Ca^{2+}} = 1,45 \cdot 10^{-9}$  m<sup>2</sup>/s ;  $D_{SiO_4^{4-}} = 1 \cdot 10^{-10}$  m<sup>2</sup>/s. Ces valeurs sont en accord satisfaisant avec les résultats de la détermination de  $D$  des ions correspondants par la méthode capillaire (2), ce qui témoigne également du caractère diffusif du processus.

Fig. 1 - Influence de l'intensité de rotation ( $W$ ) des agglomérés de  $\text{CaO}$  (1) et de  $\text{C}_2\text{S}$  (2) sur la cinétique de leur dissolution dans le bain fondu eutectique.

Lors de la dissolution de  $\text{CaO}$  dans les conditions de convection naturelle, au premier moment d'interaction la matière fondue migre intensément dans le volume du grain par son système capillaire à la vitesse de  $(1-2) \cdot 10^{-3}$  m/s. Les processus de dissolution moléculaires se déroulant dans le volume et sur la surface de l'éprouvette ainsi que l'action de coincage de minces films de la phase liquide conduisent à ce que les petits cristaux séparés de  $\text{CaO}$  se trouvent entourés par la matière fondue.

La vitesse du processus de dissolution dépend dans une grande mesure de la densité des particules et la profondeur de la corrosion est proportionnelle à  $\tau^{1/2}$  (fig.2).

Le caractère rectiligne de la fonction  $\Delta d - \tau^{1/2}$  témoigne du fait suivant. Bien que par suite de la migration de la matière fondue et de la dissolution des zones de contact ait lieu le processus de dispersion des particules polydispersées en petits cristaux séparés, la vitesse générale de dissolution se détermine, également dans les conditions statiques, surtout par le transfert de masse des particules dissoutes qui s'effectue de la surface extérieure de l'éprouvette dans le volume de la matière fondue. Ceci permet d'utiliser l'équation (2) pour calculer le coefficient de diffusion effectif des ions  $\text{Ca}^{2+}$  :

$$D_{\text{eff}} = 0,15 \cdot K \cdot \left( \frac{\nu_1}{\Delta \rho} \right)^{1/3} \cdot \left[ \frac{I}{\Delta C^*} \exp \left( - \frac{\delta^*}{R + \frac{\delta^*}{4}} \right) \right]^{4/3} \quad (2)$$

où  $D_{\text{eff}}$  est le coefficient de diffusion effectif,  $\text{m}^2/\text{s}$ ;

Fig. 2 - Influence de la densité des éprouvettes de  $\text{CaO}$  sur leur vitesse de dissolution (1 - densité 2060 ; 2 - 2350 ; 3 - 2500  $\text{kg}/\text{cm}^3$ )

$\nu_1$  la viscosité cinématique,  $\text{m}^2/\text{s}$  ;

$\Delta \rho = \frac{\rho_1 - \rho_\infty}{\rho_\infty}$  la différence fractionnaire de densité ;  $I = DR/d\tau$  la vitesse de dissolution,  $\text{m}/\text{s}$  ;  $R$  le rayon de l'éprouvette,  $\text{m}$  ;  $\delta^* = (C_1 - C_0)$  l'épaisseur effective de la couche de diffusion ;  $\frac{dC}{dy}$  le gradient de concentration sur la surface de séparation.

Avec l'augmentation de la densité des éprouvettes les valeurs de  $D_{\text{eff}}$  diminuaient (fig. 3) : ainsi pour  $\rho = 2060 \text{ kg}/\text{m}^3$  la valeur moyenne de  $D_{\text{eff}}$ , au cours des dix premières minutes de la dissolution, était de  $19,2 \cdot 10^{-7} \text{ m}^2/\text{s}$  et pour  $\rho = 2350 \text{ kg}/\text{m}^3$ , de  $11,2 \cdot 10^{-7} \text{ m}^2/\text{s}$ . Cette différence traduit le caractère compliqué du mécanisme de la dissolution des agglomérés de  $\text{CaO}$ , qui est dû de toute évidence au passage dans le bain fondu tant des ions séparés  $\text{Ca}^{2+}$  que des groupements polyioniques. Les dimensions de ces groupements (particules) dépendent de la structure des cristaux de la phase solide et d'après les données de (1) la grandeur des blocs peut être de  $1 \mu\text{m}$ .

#### RECRISTALLISATION DANS LE SYSTEME $\text{C}_2\text{S}$ - MATIERE FONDUE

Les processus de dissolution de  $\text{CaO}$  et de  $\text{C}_2\text{S}$  et de cristallisation de  $\text{C}_2\text{S}$  dans le grain de clinker dans lequel, à  $1450^\circ\text{C}$ , il se forme près de 30 à 40 % seulement

Fig. 3 - Variation des valeurs du coefficient de diffusion effectif de  $\text{Ca}^{2+}$  en fonction de la structure des éprouvettes de  $\text{CaO}$  en cours de dissolution et du temps de dissolution. Densité des éprouvettes de  $\text{CaO}$  ( $\text{kg/m}^3$ ) : 1 - 2060 ; 2 - 2350 ; 3 - 2500

de la matière fondue sont pratiquement simultanés, ce qui rend difficile leur étude. La cinétique de la recristallisation de  $\text{C}_2\text{S}$  fut étudiée dans le clinker béliétique contenant 30 % de matière fondue et 70 % de silicate dicalcique avec les particules de dimension de 60 à 90 et de 160 à 200  $\mu\text{m}$ . Les particules de  $\text{C}_2\text{S}$  étaient mélangées avec des charges préalablement refondues calculées pour l'obtention de la composition eutectique ( $\text{CaO}$  - 54,8 ;  $\text{SiO}_2$  - 6,0 ;  $\text{Al}_2\text{O}_3$  - 22,7 ;  $\text{Fe}_2\text{O}_3$  - 16,5 % en masse) ayant la température de fusion de 1338 °C (n° 1) et de la matière fondue qui se forme dans le clinker à 1450 °C ( $\text{CaO}$  - 57,0 ;  $\text{SiO}_2$  - 7,5 ;  $\text{Al}_2\text{O}_3$  - 22,6 ;  $\text{Fe}_2\text{O}_3$  - 12,9 % en masse) (bain fondu n° 2). À partir des mélanges obtenus on a formé sous pression de 200 MPa des tablettes de 10 mm de diamètre et de 0,7 g de poids. Les tablettes étaient soumises au frittage isotherme à 1450 °C dans un four vertical en platine-rhodium, suivi d'une trempe dans le milieu aqueux. Pour éprouvette étalon on a pris un aggloméré cuit pendant 1 mn. Sa structure cristalline traduisait tous les changements survenus dans la composition dispersée de  $\text{C}_2\text{S}$  et dus à la compression de la masse et à la désintégration thermique.

On déterminait la cinétique de la dissolution des grains d'après le changement d'aire des sections fixées sur les photos. On a déterminé trois grandeurs : concentration volumique des particules de  $\text{C}_2\text{S}$  en cours de dissolution (%); concentration volumique des cristaux de  $\text{C}_2\text{S}$  se dégageant de la matière fondue (%); concentration volumique de toute la phase solide (%).

Fig. 4 - Variation des concentrations volumiques de la phase solide (1, 2) dans le système "bain fondu saturé (30 %) -  $\text{C}_2\text{S}$  (70 %)" et de la vitesse de dissolution de  $\text{C}_2\text{S}$  dans les bains fondus eutectique (3) et saturé (4). 1 - particules de  $\text{C}_2\text{S}$  de départ ; 2 - cristaux dégagés du bain fondu par recristallisation

La vitesse de dissolution des particules de  $\text{C}_2\text{S}$  dans les bains fondus eutectique et saturé au cours des premières 5 à 7 minutes est sensiblement différente (fig. 4), ce qui s'explique par la non-saturation du bain fondu eutectique en calcium et en silice à la température de l'expérience de 1450 °C. Toutefois, après la saturation du bain fondu n° 1 les vitesses de dissolution des particules de  $\text{C}_2\text{S}$  restant dans les deux systèmes deviennent pratiquement identiques. Les variations ultérieures des concentrations volumiques des grains en cours de dissolution et des cristaux de  $\text{C}_2\text{S}$  se dégageant des bains fondus saturés sont interdépendantes (fig. 4).

La dispersion des grains de départ est le stade initial du processus de dissolution de  $\text{C}_2\text{S}$  dans le clinker fondu saturé. Ensuite, on assiste à la dissolution de petites particules et à la redéposition de la matière de la phase solide sur des monocristaux plus gros ou sur leurs agrégats avec formation d'une frange de  $\text{C}_2\text{S}$  secondaire cristallisé. Il est caractéristique qu'avec l'accroissement de l'épaisseur de ce film la vitesse de dissolution diminue, atteignant au bout de 10 mn 0,36 % de la phase sol./mn.

Après environ 10 à 15 mn, sous l'action de

la matière fondue qui migre continûment à travers le film vers la surface de la particule la liaison entre les restes du grain de départ et les cristaux nouvellement dégagés qui constituent le film enveloppant devient plus faible : il en résulte que les particules de ce dernier sont arrachées, par les courants de convection de la matière fondue, à la surface de la phase de départ et se déplacent dans l'espace intergranulaire.

La variation de concentration volumique des grains en cours de dissolution est décrite par l'équation exponentielle

$$U = e^{a-bt}, \quad (3)$$

où  $a = \ln U_0$ ,  $U_0$  est la teneur initiale du système en  $C_2S$ ,  $t$  le temps,  $b$  le facteur dépendant des dimensions des particules de départ : pour 160 à 200  $\mu$   $b = 0,0047$ , pour 60 à 90  $\mu$   $b = 0,003$ . Alors la vitesse de dissolution sera

$$I = be^{a-bt}, \quad (4)$$

où  $b = \frac{I_0}{U_0}$ ,  $I_0$  est la vitesse de dissolution au moment d'interaction initial. L'équation (4) peut s'écrire sous la forme

$$I = I_0 e^{-\frac{I_0}{U_0} t}. \quad (5)$$

Compte tenu du mécanisme diffusif du processus de dissolution de  $C_2S$  et en se servant de l'équation de Nernst on peut écrire

$$I_0 = D \frac{\Delta C}{\delta} \cdot S_0. \quad (6)$$

Les grandeurs  $D$ ,  $\Delta C$ ,  $\delta = f(\Delta C, D)$  ne varient pas dans le temps et on a

$$I_0 = K S_0. \quad (7)$$

En portant cette valeur dans l'équation (5) on obtient

$$I = K \cdot S_0 \cdot e^{-\frac{K S_0}{U_0} t}. \quad (8)$$

Il découle de l'expression (8) que la vitesse de dissolution des grains de  $C_2S$  dans le bain fondu est fonction de leur concentration de départ et de la surface d'interaction initiale. Il convient de noter que bien que le processus de dissolution se décrive de façon assez satisfaisante par l'équation (8), toutefois par suite de la dispersion périodique des particules de départ on observait à certains instants une accélération importante de la réaction, ce qui conditionne probablement le caractère périodique du processus de formation du clinker, établi également dans les travaux de I.V. Kravtchenko, M.T. Vlassova, B.E. Youdovitch, W. Kurdowski, etc.

#### FORMATION DE L'ALITE DANS LE SYSTEME $CaO - C_2S$ - MATIERE FONDUE

La méthodologie des études était la même que dans le cas précédent à cette différence près que le système comprenait encore

des grains denses de  $CaO$  de dimension moins de 60  $\mu$ m en quantité assurant, après l'achèvement des réactions, la formation de 50 % (en volume) de  $C_3S$ .

Dans le clinker contenant  $C_2S$  et  $CaO$  les processus de dissolution des grains des deux minéraux dans le bain fondu se déroulent à une vitesse plus élevée que dans le cas où une des phases fait défaut. En effet, selon les données de la figure 5 la vitesse de dissolution de  $C_2S$  dans le clinker avec le coefficient de saturation de 0,89 était de 7,02 % de la phase sol./mn, alors que dans le système " $C_2S$  - bain fondu saturé" la valeur absolue de la vitesse de dissolution de  $C_2S$  dans les mêmes conditions de température et de temps était 6 fois moindre et dans le système " $C_2S$  - bain fondu eutectique" 1,5 fois moindre. Par conséquent, l'élimination constante des ions  $Ca^{2+}$  et  $SiO_4^{4-}$  du bain fondu intensifie brusquement le processus de dissolution.

Durant les premières 5 mn, la vitesse de dégagement de  $C_2S$  était de 6,9 % de la phase sol./mn et correspondait pratiquement à la cinétique de la dissolution de  $C_2S$  (fig. 5).

Fig. 5 - Variation des vitesses de dissolution de  $C_2S$  (1) et de cristallisation de  $C_3S$  (2) en fonction du temps de frittage à 1450 °C du clinker avec  $KS = 0,89$

Et cette correspondance n'était pas perturbée par augmentation de la durée du traitement isotherme jusqu'à l'obtention de l'état équilibré. Ce fait témoigne d'une absorption pratiquement instantanée des ions passés dans la matière fondue par des cristaux croissants.

La plupart des cristaux de  $C_3S$  croissent sur la surface des particules de départ du bélite et de telle sorte que l'axe long soit dirigé perpendiculairement à la tangente à la surface de  $C_2S$  au point de for-

mation de  $C_2S$ .

Au fur et à mesure de la formation sur toute la surface du grain de départ du bélite du film monomoléculaire des germes quasi bidimensionnels de  $C_2S$ , l'éventualité de l'apparition de ces germes sur la surface du support diminue et le processus de cristallo-genèse se poursuit grâce à la croissance des germes de l'alite susmentionnés. La frange formée par des monocristaux n'a pas de structure cristalline parfaite. Sur la surface du support il y a également des défauts (par exemple, les microfissures). Il peut en résulter l'extension de la surface du support et la compression de la surface des nouvelles formations à leur point de contact, conduisant à la limite au détachement des particules de la frange à partir du support.

Les phénomènes de liquation ayant lieu dans le clinker fondu (2) peuvent modifier notablement la cinétique des processus de dissolution et de cristallisation. Dans les bains fondus salins qui se forment sur la base de Na, K, F, Cl, la vitesse de dissolution du bélite croît de 3 à 10 fois, atteignant 1 de  $CaO$ . Avec l'accroissement de basicité de la phase liquide en présence des ions Na, K, Ba, Sr  $^{1}CaO$  diminue de 2 à 4 fois pour la concentration des oxydes de 3 ou 4 %. Dans les bains fondus acides l'oxyde de calcium se dissout 1,5 à 2 fois plus intensément que dans le clinker fondu. La microliquation métastable due à la solubilité de  $SiO_2$ , de  $C_2S$ , de  $CaO$  et la mobilité des anions silicoxygénés et de  $Ca^{2+}$  différentes conduit à ce que dans les domaines plus acides (bélitiques) la cinétique de la formation de l'alite est contrôlée par la dissolution de  $C_2S$  et la diffusion des ions  $Ca^{2+}$ . Dans ce cas les cristaux d'alite croissent dans le sens des zones bélitiques en les supprimant. Dans les domaines avec une concentration élevée des ions  $Ca^{2+}$  et surtout  $Na^+$  et  $K^+$ , le bélite corrode intensément (2) et le processus de synthèse de  $C_2S$  se détermine par la vitesse de dissolution de l'oxyde de calcium. Ainsi, le stade de limitation du processus de formation de l'alite peut varier dans le grain de clinker en fonction de l'hétérogénéité locale de sa composition et de la nature des ions étrangers.

# Caractéristique de la matière adhérente causant des troubles de fonctionnement et leur élimination

## *Characterisation and Elimination of Adherent Layers Causing Operational Troubles*

M. KOVACS, Dr. Research Scientist, Veszprem University of Chemical Engineering, Dept. Silicate Chemistry, Veszprém - Hungary,

K. BENYEI, Dr., Dept. Leader, Beremend Cement Works, Beremend, Hungary.

RESUME : On a étudié les composés volatils qui circulent dans les fours à voie sèche, et spécialement la relation entre l'enrichissement des composés alcalins et la formation de croûtes adhérentes.

On a constaté que des masses adhérentes se produisaient dans les cyclones des échangeurs de chaleur des fours Humboldt; on a constaté aussi, au moyen des analyses de phases, que ces produits étaient identiques à ceux produits en laboratoire et que la fusion des composés alcalins (notamment des chlorures alcalins) jouait un rôle important, en facilitant la formation de la spurite et des matières adhérentes.

L'addition de phosphate de chaux compense cet effet nocif des chlorures, des carbonates et des sulfates alcalins; toutefois  $P_2O_5$  empêche à la formation de la spurite et celle de l'alite. La présence simultanée dans le clinker de composés alcalins et de  $P_2O_5$  réduit la résistance du ciment, même si  $P_2O_5$  ne dépasse pas la proportion de 0,8 %.

SUMMARY: The results of research on the effect of alkaline circulating compounds on adherent layer formation are presented in this paper.

The phase composition of adherent layers formed in cyclone heat exchangers of the Humboldt clinker burning system, and of similar laboratory samples was examined. The alkali content (in particular, alkali chloride) acts not only as a flux but at the same time also promotes spurrite formation.

Although this latter effect can be successfully retarded by the addition of phosphates their use is not recommended, as phosphates retard alite formation too, which in turn deteriorates cement quality. The strength of cement is decreased considerably in the joint presence of alkalies and  $P_2O_5$ , even if  $P_2O_5$  concentration is as low as 0,8%.

## INTRODUCTION

La circulation des alcalins et du soufre se manifestant lors du cuisson à sec du clinker cause beaucoup de problèmes. En étudiant le principe concernant la formation des anneaux de matière ou des masses adhérentes conduisant aux engorgements des systèmes préchauffeurs, beaucoup de travaux ont réussi à montrer le rôle de l'enrichissement des composants volatils [1,2,3,4,5,6].

L'étude de la masse adhérentes se formant aux cyclones du système KHD de production du clinker à Beremend (Hongrie) nous a conduit aux constatations pareilles. Cette publication contient les résultats de ces études ainsi que ceux de nos expériences de laboratoire ayant le but suivant:

- a/ étudier la formation de la composition de phase caractéristique de la masse adhérente à un pourcentage d'alcalin élevé.
- b/ empêcher la formation de cette composition de phase à l'aide des additifs de  $P_2O_5$ .

Fig. 1 - Détail de la prise de diffraction X de poudre de l'échantillon adhérent obtenu du cyclone IV.

### Etude de la masse adhérente formée au système préchauffeur Humboldt

Cette étude a nécessité des prélèvements systématiques des masses adhérentes se formant dans tous les cyclones et toutes les chambres d'admission à régime continu. Les essais chimiques ainsi que les essais de diffraction X, de thermique et de microscopie électronique nous a aidé à déterminer les compositions chimiques et de phase de ces échantillons.

Cette publication contient un exemple de ces essais, tout en présentant le diagramme de diffraction X de poudre (figure 1), les diagrammes DTA, TGA, DTGA (figure 2), ainsi que la prise de microscopie électronique de deux parties d'un échantillon obtenu de la masse adhérente du cyclone IV (figures 3, 4). Le pourcentage d'alcalins de cet échantillon déterminé lors de l'analyse chimique est de 16% de poids en  $K_2O$  équivalent.

Fig. 2 - Diagramme DTA, DTGA, TGA de l'échantillon adhérent obtenu du cyclone IV.

Fig.3 - Cristaux de KCl dans les échantillons adhérents obtenus du cyclone IV. Microscope électronique a balayage (grossissement: 300x)

Fig. 4 - Cristaux de spurrite et de calcite dans les échantillons adhérents obtenus du cyclon IV. Microscope électronique a balayage (grossissement: 5500x)

Le pourcentage élevé de potassium ( $K_2O > 10\%$  en poids) caractérise en général les échantillons obtenus de la masse adhérente du cyclone IV. Normalement ce potassium s'enrichit au cyclone IV en forme de chlorure (fig.1, 3).

(Il faut noter que le pourcentage de chlorure de la farine brute de Beremend n'atteint pas 0,015 % en poids, il est donc superflu d'y utiliser le by-pass.)

Les masses adhérentes du cyclone IV et des autres niveaux du système préchauffeur ne

contiennent pas de sulfates alcalins et de sulfates alcalins de calcium. Le soufre introduit au système s'enrichit essentiellement en forme d'anhydrite ( $CaSO_4$ ) dans la masse adhérente du cyclone II.

Le tableau I contient les compositions de phase caractérisant les masses adhérentes des cyclones et de la chambre d'admission en se basant sur les résultats des essais ci-dessus de 70 échantillons.

TABLEAU I

Composition de phase caractéristique de la matière adhérente se produisant aux étapes du système préchauffeur (% en poids)

Endroit du prélèvement	Calcite $CaCO_3$	Anhydrite $CaSO_4$	Spurrite $2C_2S \cdot CaCO_3$	Portlandite $Ca(OH)_2$	Chaux libre $CaO$	Phases déterminées qualitativement
Cyclone I.	72,5	2,4	-	-	traces	Quartz
Cyclone II.	16,6	50,0	traces	3,3	traces	Quartz
Cyclone III.	48,3	3,8	traces	10,8	4,5	Minéraux de clinker et quartz
Cyclone IV.	26,6	2,4	22,5	3,2	4,3	Minéraux de clinker et quartz
Entre le cyclone IV. et le four	10,5	-	6,2	12,8	15,0	Minéraux de clinker
Chambre d'admission	19,7	traces	17,1	22,0	7,2	Minéraux de clinker

### Expérience de laboratoire

Le problème principal de l'usine de Beremend consiste dans la masse adhérente à pourcentage élevé d'alcalins et de spurrite du cyclone IV. Outre l'effet de  $P_2O_5$  empêchant la formation de spurrite, une relation entre la formation du spurrite caractérisant la composition de phase de la matière adhérente et les composés alcalins a été étudiée lors des expériences de laboratoire.

Les matières utilisées au cours des expériences sont les suivantes: farine brute d'usine,  $K_2CO_3$ ,  $Na_2CO_3$ ,  $KCl$ ,  $NaCl$ ,  $K_2SO_4$ ,  $Na_2SO_4$  et  $Ca_3(PO_4)_2$ .

Le mode de préparation des échantillons est le suivant:

- a) On mélange un composé alcalin d'une quantité équivalente à 1,2 % en poids de  $K_2O$  et de la farine brute. Un échantillon correspond à un seul composé alcalin.
- b) On mélange un composé alcalin et une quantité de  $Ca_3(PO_4)_2$  correspondant à 0,8 ou à 1,6 % en poids de  $P_2O_5$  selon la méthode de a). (Le pourcentage de  $P_2O_5$  concerne le clinker.)

A partir des mélanges préparés selon les méthodes a) et b) et de la farine brute sans additifs nous avons aggloméré des pastilles que nous avons cuit pendant deux heures dans un four électrique à température de 750 °C, 840 °C, 970 °C et 1400 °C.

La détermination de la composition chimique et de phase des échantillons ainsi préparés s'est effectuée par les essais chimiques, thermiques et de diffraction X.

Les composants de la farine brute d'usine et sans additifs ne montre pas la formation du spurrite aux températures d'essais.

On peut constater la formation la plus élevée dans les échantillons contenant des composés alcalins et cuits à 840 °C (figure 5).

Fig. 5 - Teneur de spurrite en fonction de la température de cuisson.

Tous les composés utilisés dans nos essais aident la formation de spurrite, mais c'est d'une façon différente: la présence des chlorures donne la formation la plus intensive, l'effet des carbonates est moins accentué, les sulfates montrent une efficacité bien réduite (figure 5).

$Ca_3(PO_4)_2$  empêche la formation de spurrite. Cet effet inverse s'augmente avec la quantité de  $P_2O_5$  (figure 6).

Fig. 6 - Teneur de spurrite des échantillons cuits à 840 °C en fonction de  $P_2O_5$ .

Nous avons enfin compensé les compositions de phase des échantillons cuits à la température de 1450 °C. Malheureusement il faut constater que les échantillons contenant des composés alcalins et  $P_2O_5$  montrent une formation d'alyte bien réduite. Le pourcentage de 0,8% en poids de  $P_2O_5$  calculé sur clinker empêche déjà la formation d'alyte et les échantillons de  $P_2O_5$  contiennent outre le dérivé  $\beta$  du silicate dicalcique beaucoup de dérivés  $\alpha'$ .

Ces résultats contredisent nombreux données antérieures, par exemple que la présence de  $P_2O_5$  augmente la durée du durcissement en cas d'une matière première à pourcentage d'alcalin élevé, mais augmente aussi la résistance à la compression de 28 jours [7] que le  $C_3S$  et la solution solide de  $C_3S$  à pourcentage de  $P_2O_5$  réduit ne montre qu'une différence presque négligeable, en ce qui concerne l'hydraulicité [8] et enfin qu'un clinker dont le pourcentage de  $P_2O_5$  ne dépassant pas 1% en poids donne des ciments d'une résistance à la compression bien élevée et cet effet ne dépend pas de l'âge des échantillons [9].

Le résultat de notre analyse de phase montre un pourcentage d'alyte et de  $\beta$  silicate dicalcique moins élevé dans les échantillons de teneur de  $P_2O_5$  que dans ceux sans  $P_2O_5$ , ce qui est prouvé par des essais de résistance. La présence de  $P_2O_5$  dans les échantillons augmente la durée du durcissement et ces échantillons peuvent être caractérisés par une résistance moins élevée même de 28 jours que dans ceux sans  $P_2O_5$ .

#### CONCLUSION

L'additif de phosphate de calcium peut compenser l'effet des composés alcalins facilitant la formation de spurrite, mais la présence de  $P_2O_5$  empêche à la fois la formation de

spurrite et d'alyte même en cas d'un clinker ou le pourcentage de  $P_2O_5$  ne dépassant pas 0,8% en poids. Les additifs de  $P_2O_5$  empêchent donc la formation de spurrite, c'est-à-dire celle de la matière adhérente, mais c'est au détriment de la qualité du clinker.

# Influence du mode de broyage du clinker et des constituants secondaires sur la réactivité des ciments et sur la rhéologie

## *Clinker Grinding method and secondary components Their effect upon cement reactivity and rheology*

Y. LE JEAN, C.E.R.I.L.H., France.

### RESUME

Comparaison entre le broyeur à boulets et le broyeur à projection sous le double aspect de l'activation des produits et des caractéristiques rhéologiques des pâtes. On démontre que le broyeur à projection permet d'optimiser la courbe granulométrique pour obtenir des résistances très élevées à court terme. Cette augmentation s'accompagne toutefois d'une modification de la rhéologie des pâtes.

Le broyage sélectif des constituants secondaires du ciment, s'il est effectué suivant des règles prévues, permet d'augmenter le dosage de ses constituants sans pénaliser les résistances à court terme. Ces différences de comportement peuvent être expliquées par des paramètres physiques liés au mode de broyage.

### SUMMARY

Comparison between ball mill and jet-mill, from the double point of view of activation of the products and of the rheological characteristics of pastes. A clear indication is given that the jet-mill allows to obtain the best granulometric properties and, thus, very high strengths at early age. Nevertheless, this increase of strength comes with a change of the rheology of the pastes.

The selective grinding of secondary components of cement, when accomplished under the specified conditions, permits to increase the amount of its components without disadvantage for early age strengths. These differences of the behaviour can be explained by the physical parameters binded with the grinding method.

# 1. LE BROYAGE PAR PROJECTION

Le rendement du broyeur à boulets chute très rapidement dès que l'on essaie d'obtenir des finesses supérieures à 2500  $\text{cm}^2/\text{g}$  ; ceci est à attribuer à l'effet d'écran que les grains fins exercent au bénéfice des grains les plus gros et aussi au phénomène d'agglomération des fines particules. Si l'on veut éviter d'avoir des grains très gros dans la poudre, il faut consentir une quantité importante de grains fins qui, dans la plupart des applications, se révèlent inutiles.

Avec le broyage par projection sous vide une telle agglomération est impossible puisque le grain éclate sous sa propre énergie cinétique. Tous les grains ayant une même vitesse et n'étant pas freinés aérodynamiquement, les petits grains sont animés d'une énergie cinétique infiniment moins importante que les grains les plus gros et se trouvent moins sollicités à l'impact sur les cibles ; d'où sélectivité du broyage par projection sous vide et obtention de courbes granulaires resserrées des matériaux broyés.

Figure 1 - Broyeur à boulets (percussion)

Figure 2 - Broyeur à projection

Figure 3

La figure 3 illustre les différences de spectre granulométrique d'un sable de Fontainebleau broyé au broyeur à boulets et du même sable broyé au broyeur à projection sous vide. Ces deux poudres ont sensiblement la même surface spécifique mais le broyeur à projection a fourni que peu de grains supérieurs à 20 microns et aucun à 40 microns, ce qui constitue un avantage considérable sur le broyeur à boulets qui a produit 27 % de grains supérieurs à 40 microns.

Figure 4

La figure 4 illustre les différents spectres granulométriques d'un clinker de cimenterie broyé au broyeur à boulets et au broyeur à projection. L'avantage du broyeur à projection réside dans la facilité d'obtenir la finesse désirée. Le processus d'éclatement ne dépend que de la vitesse d'impact lorsque le grain ne comporte pas d'inhomogénéité. Le réglage du broyage s'effectue en ajustant la vitesse de rotation du rotor.

Les mesures granulométriques montrent que la surface spécifique en  $\text{cm}^2/\text{g}$  est devenue un paramètre insuffisant pour caractériser des poudres broyées par des procédés différents puisqu'à surface spécifique sensiblement égale on peut avoir des répartitions granulaires très différentes.

Tableau I

Matériaux	Dureté Vickers	Echelle de Mohs
Gypse	70	2
Calcite	110	3
Clinker	450 à 700	
Feldspath	720	6
Quartz	1280	7
Broyabilité $\text{cm}^2/\text{Joule}$		
Gypse	200	
Clinker	70	

Figure 5

Le tableau I et la figure 5 montrent l'influence de la broyabilité des différents composants du ciment. Le gypse est un élément tendre qui apporte les éléments fins et influence fortement la surface spécifique du mélange et le caractère rhéologique des pâtes, mortiers et bétons au cours de leur préparation et de leur mise en œuvre.

Le clinker étant de plus faible broyabilité, la sélectivité du broyage par projection donne une courbe granulaire particulièrement resserrée, proche de la courbe idéale recherchée pour tirer le meilleur parti du potentiel chimique du clinker.

## 2. INFLUENCE DE LA GRANULOMETRIE SUR LES RESISTANCES MECANQUES

Tous les essais se réfèrent à un seul gypse témoin et trois clinkers (G), (R) et (A), chacun d'eux étant broyé avec gypse et sans gypse pour délimiter l'influence de celui-ci, soit avec un broyeur à boulets (BB), soit avec un broyeur à projection (BP).

Tableau II et III  
Analyses chimiques des clinkers et CPA

## 2.1 Influence du gypsage

### a) Granulométrie (fig. 6)

Figure 6

Le clinker (G) et le gypse sont broyés séparément au broyeur à boulets. La surface spécifique du clinker est de 2950 cm<sup>2</sup>/g ; le gypse a été broyé à 5540 cm<sup>2</sup>/g et 10 000 cm<sup>2</sup>/g. Les ciments ont été gypsés à 5 % SO<sub>3</sub>.

A quantité égale de gypse, le ciment (A) donne de meilleures résistances que le ciment (B).

### b) Influence du pourcentage de gypse (fig. 7)

Figure 7

Clinker (C) et gypse sont broyés ensemble au broyeur à boulets. Les résistances mécaniques sont influencées par le pourcentage de gypse.

c) Influence du mode de broyage

Figure 8

Figure 9

Le résultat des essais montre que le ciment broyé au broyeur à projection permet, par l'optimisation du gypsage, d'obtenir un important gain des résistances mécaniques, et tout en améliorant d'autres caractéristiques telles que le gonflement et la fissuration.

La photo n° 10 prise au microscope optique montre que les gains de clinker restent polycristallins après un broyage au broyeur à boulets industriel. Par contre, le broyage fin par projection donne des grains monocristallins plus particulièrement par la libération de l'alite et du C<sub>3</sub>A, photo n° 11. Le procédé

de broyage par projection permet d'augmenter sensiblement le gypsage sans inconvénient.

Figure 10

Figure 11

## 2.2 Ajouts inertes

La structure monodimensionnelle du ciment obtenu par le broyage sélectif favorise l'incorporation de fillers inertes qui, au lieu de diluer le produit comme c'est le cas pour un ciment broyé au broyeur à boulets, jouent le rôle actif d'ajout de remplissage granulométrique.

La figure 12 montre qu'avec 30 % d'ajout inactif (FC) et 70 % de clinker gypsé, broyé au broyeur à projection, on obtient les performances d'un CPA 50. De la même manière, avec 40 % d'ajout inactif, on obtient les performances d'un CPA 40 et avec 50 %, celles d'un CPJ 35. Une étude récente du Laboratoire Central des Ponts et Chaussées, consacrée aux ciments de broyeurs à boulets, et les essais témoins effectués au CERILH montrent que les résistances mécaniques décroissent rapidement lorsque la teneur en ajout inerte croît, et qu'elles suivent approximativement la loi de FERET.

La figure 13 révèle qu'un même mélange [clinker (C) + gypse] broyé au broyeur à projection donne des résistances mécaniques ne suivant plus la loi de FERET. Les écarts, par rapport à cette loi, se traduisent par un gain important pouvant atteindre 50 % à 100 %.

A performances identiques, la teneur d'ajouts inertes est environ 30 % supérieure au taux d'ajout dans le cas où le clinker + gypse sont broyés au broyeur à projection (BP).

Figure 12

Figure 13

### 2.3 Ajouts actifs

Dans une moindre mesure que le clinker, les laitiers, les cendres volantes et les pouzzolanes sont des ajouts actifs connus et utilisés pour la fabrication de ciments normalisés. Leur action surtout pouzzolanique est sensible à moyen terme mais leur activité à court terme peut être augmentée par le broyeur à projection.

La figure 14 montre les résistances mécaniques obtenues avec le clinker (R), broyé avec ajout actif au broyeur à projection, pour un béton COPLA à 350 kg (granulat Béton Armé). Sur la même figure sont reportés deux ciments témoins de broyeur à boulets industriel [clinker (R)]. Bien que les ciments de broyeur à projection demandent un rapport E/C plus important, ceux-ci font apparaître leurs avantages en résistances mécaniques.

Figure 14

### 3. RHEOLOGIE ET RESISTANCES MECANQUES DES MORTIERS ET BETONS

Les mortiers et bétons confectionnés avec un ciment broyé au broyeur à projection sont caractérisés par une mauvaise rhéologie ne favorisant pas une bonne mise en place et un bon serrage dans les moules à éprouvettes. Néanmoins, les résistances mécaniques obtenues avec ou sans ajout sont très largement supérieures à celles obtenues avec un ciment de même composition broyé au broyeur à boulets. Tous les essais d'étalement sur mortier ont, pour référence, la Norme américaine FLOW-TEST C124-39.

#### 3.1 Influence de la granulométrie

a) L'influence de la granulométrie de chaque constituant du ciment est considérable sur la finalité des caractéristiques mécaniques d'un mortier et d'un béton. La cinétique d'hydratation est bouleversée par la séparation des phases du clinker dont la granulométrie se trouve resserrée (Photos 15 et 16). Les études de J.P. BERNARD, M. REGOURD et J.P. MERIC démontrent que les paramètres granulométriques ont une influence déterminante sur la cinétique d'hydratation des constituants du ciment.

Figure 15 (BB)

Figure 16

Figure 17

Un grain de 1 micron s'hydrate au cours du gâchage et ne contribue plus aux résistances du béton  
 " " de 2 microns est hydraté à 100% en 1 h 1/2  
 " " de 20 microns est hydraté à 69% en volume au bout de 7 jours  
 " " de 30 microns est hydraté à 52% en volume au bout de 7 jours  
 " " de 70 microns est hydraté à 70% en volume au bout de plusieurs mois et se comporte comme un granulats.

#### b) Influence de la granulométrie des agrégats et du ciment

Tous les mortiers témoins ont été confectionnés suivant la Norme AFNOR en vigueur NF P15-403, sans tenir compte de la granulométrie des ciments de broyeur à projection pauvres en éléments fins et en grains supérieurs à 20 microns, c'est-à-dire avec discontinuité granulométrique entre ciment et sable normalisé. L'optimum de remplissage granulométrique correspondant à une distribution privilégiée de particules d'ajouts inerts ou actifs, ou les deux à la fois, a été recherché à partir des formules de FULLER-BOLLOMEY et de JOISEL, pour obtenir une meilleure rhéologie des mortiers et, à rhéologie égale, réduire le rapport eau/ciment.

#### 3.2 Influence de la forme des grains de ciment et ajouts

##### a) Clinker

Les photos 17 et 18 montrent les différences importantes entre un grain de clinker (C), broyé au broyeur à boulets, et un grain de clinker broyé au broyeur à projection. Celui-ci donne des fragments à angles vifs et à surface lisse et les grains sont souvent monocristallins. Les différences d'aspect et de géométrie peuvent expliquer la mauvaise mobilité des grains au cours du gâchage et de la mise en place des mortiers et bétons dans les moules.

Figure 18

##### b) Ajouts

Les ciments aux cendres volantes ont généralement la propriété de donner des mortiers et bétons à bonne rhéologie. Cependant, une quantité importante d'essais montrent que les cendres volantes, composées essentiellement de micro-billes, pouvaient aussi bien améliorer que réduire la rhéologie des mélanges, (figure 19).

La granulométrie et la quantité de gypse ont une influence importante sur les résistances mécaniques des mortiers et bétons confectionnés, soit avec un clinker de broyeur à boulets, soit avec un clinker de broyeur à projection. Il y a lieu d'ajouter l'influence rhéologique du gypse en fonction de la composition potentielle du clinker, (figure 20). Pour mémoire, les CPA 50 de broyeur à boulets industriel donnent généralement des étalements compris entre 65 % et 75 % pour un rapport E/C = 0,5.

Figure 19

Figure 20

### c) Rapport Eau/Ciment

A caractéristiques rhéologiques égales, l'exigence en eau est plus élevée pour les ciments de broyeur à projection.

La figure 21 montre les écarts importants de E/C entre les ciments témoins CPA 50 et CPAL 40 de broyeur à boulet et les ciments de broyeur à projection avec ajouts. L'addition de cendres volantes et de filler calcaire montre l'effet bénéfique de ces ajouts et les possibilités de réduction du rapport Eau/Ciment. A rhéologie égale, le rapport Eau/Ciment est fonction :

- 1) du remplissage granulométrique (mouillage par insertion),
- 2) de la surface spécifique globale des particules (mouillage par adsorption),
- 3) de la nature minéralogique de chaque composant (mouillage par absorption) porosité ouverte,
- 4) de la forme géométrique de chaque composant (mobilité),
- 5) des charges électriques de surface (mobilité).

# Neutralisation des additions indésirables dans la matière première

## *Neutralisation of undesirable admixtures in raw materials*

I. LUGININA, docteur ès sciences techniques, Belgorod, U.R.S.S.

**RESUME :** La production du ciment, à partir de matières crues brutes, pose des problèmes de plus en plus aigus, du fait de l'épuisement des gisements de calcaires purs, et de l'emploi, de plus en plus fréquent, de déchets industriels pour la confection des crus. Ces problèmes peuvent être résolus par la neutralisation réciproque des additions.

La composition des composés intermédiaires qui se forment est connue, lorsque le cru contient des oxydes de magnésium, des alcalis ou du phosphore. On a trouvé des interactions chimiques permettant de neutraliser ces corps. Cet effet neutralisant s'accompagne d'ailleurs d'un abaissement de la température de décarbonatation et de la température de formation du liquidus.

L'addition de calcaires dolomitiques aux crus alcalins, accroît la résistance du ciment, et empêche la formation, pendant la cuisson, de silicates magnésio-alcalins. Ces derniers étant en contact avec les principaux silicates du clinker, ne se décomposent pas jusqu'à formation de périclase, comme dans le magnésium octaédrique.

**SUMMARY :** The cement production from nonconditional raw material is a very important problem in accordance with limiting of pure limestones and with the more wider use of industrial wastes in cement technology. This problem may be solved by mutual neutralisation of admixtures.

The composition of variable intermediate components is known. These compounds are formed when the raw material components include oxides of magnesium, of alkalies, of phosphorus. Chemical interactions, prosiding neutralisation of the given oxides are defined. The neutralised effect is accompaigned by decreasing of the temperature of decarbonisation and melting.

The addition of dolomit limestones into batches containing alkali, improve the strength of cement and leads to the formation of alkali-magnesium silicates by firing. The latter being in contact with the main climer silicate minerals do not decompose until selecting of periclase as magnesium is in the fourth octahedronal coordination.

La quantité de molécules de la matière se trouvant sur la surface s'élève considérablement à la mouture fine des corps cristallisés. Les couches superficielles et les phénomènes déterminent les propriétés de la matière dans l'état de poudre.

À la mouture fine de quelques matières prises ensemble commencent les réactions mécano-chimiques dont la valeur est proportionnelle à la grandeur de la surface des composants. On a découvert quelques sels doubles en étudiant des processus chimiques passant sous l'influence des catalyseurs dans le mélange des matières premières de ciment. Les sels doubles sont des composés complexes, c'est pourquoi les régularités de la formation des complexes doivent se répandre sur les composés apparaissant dans la matière première agglomérante dans des fours rotatoires. Dans ce travail on soutient sous le terme de "la formation des complexes" la capacité des sels de donner des sels doubles et des composés plus compliqués. Les réactions pareilles avec la formation des sels doubles entre le carbonate de calcium et les sels alcalins commencent à la température 300-400°C.

Un facteur déterminant la formation des complexes sous le chauffage des systèmes de sel est une présence du cation dans le mélange avec une grande action de polarisation en comparaison avec les autres. L'action polarisante du cation  $Mg^{2+}$  est presque 2 fois plus forte que de celui de calcium (3,3 pour  $Mg^{2+}$  et 1,8 pour  $Ca^{2+}$ ). En se basant sur les certaines régularités établies par les chimistes soviétiques et sur les travaux du groupe de technologues soviétiques commencés dans les années 30 par Jouravliev V.F. une supposition était faite que: premièrement- certains mélanges en état d'oxydes considérant indésirables peuvent entrer dans un constituant de nouveaux composés complexes; deuxièmement- de nouvelles formations peuvent avoir des propriétés visqueuses et leur apparition ne provoquera pas l'altération des propriétés du ciment. Enfin on peut supposer que de nouveaux composants amélioreront un pouvoir agglomérant du mélange de matière première.

La teneur limitée en additions (catalyseurs) et les températures relativement basses du commencement des interactions entre les constituants du mélange de matière première de ciment et l'addition ont prédéterminé la tendance d'assurer le contact des réactifs le plus étroit au moyen de leur mouture commune. Le réactif le plus probable est un carbonate de calcium, c'est pourquoi le contact le plus étroit est assuré à la mouture justement avec lui. Les essais pareils étaient avec l'addition des catalyseurs dans les mélanges de matières premières: fluorure de calcium, silicofluorure de sodium et phosphore de platre. On étudiait l'influence du contact initial du catalyseur à la mouture avec de différents composants des mélanges de matières premières. Avec cela la durée totale de mouture restait constante, il n'y a que le composant du mé-

lange de matière première qui était en contact avec le catalyseur aux premiers stades du broyage changeait.

On préparait les mélanges de différents constituants minéralogiques calculés pour l'obtention du ciment d'alite de celui durcissant vite, blanc et stable aux sulfates.

Il est établi que dans d'autres conditions de l'introduction du catalyseur les constituants minéralogiques clinkers, la concentration de nouvelles formations intermédiaires, le retrait et la solidité des granulés agglomérants, la quantité de clinker fondu changeait. Ayant examiné tous les mélanges on a établi une régularité commune: il convient d'assurer une mouture commune du catalyseur avec du calcaire pour l'obtention de la plus grande solidité du ciment préparé.

L'influence des conditions de la mouture du catalyseur avec de certains constituants du mélange de matière première est représentée partiellement. Un tableau 1 représente les résultats obtenus aux usines après l'application du procédé de mouture avec des résidus des pyrites qui était moins réussi et les résultats de la mouture optimale avec du calcaire. Il est à noter qu'il avait toute une série de changements dans le matériel agglomérant, mais pourtant en dépit de ces diversités toutes les compositions ont montré les plus grandes valeurs de solidité du ciment à la mouture des catalyseurs avec du calcaire. Le clinker du ciment blanc n'était pas une exception bien que le ciment de la plus grande blancheur fut obtenu à la mouture du kaolin avec le catalyseur.

L'élévation de l'activité de ciment à la mouture des fluorures avec du calcaire est expliquée par la formation de fluorure de silicium de calcium- $Ca_2Si_2O_7F_2$  (1). Le composé se fait pour toutes les variantes du mélange à condition qu'on ajoute le fluorure de calcium. Pourtant en faisant la mouture du catalyseur avec du calcaire on constate que sa teneur est maxima. La formation du carbonate de fluorure intermédiaire de la composition supposée ( $4CaCO_3 \cdot 7CaO \cdot CaF_2$ ) précède l'apparition du silicate de fluorure. Un carbonate de fluorure du calcium est fondu à la température 975°C avec la décomposition postérieure en dégageant un gaz carbonique. Si le mélange contient la silice, dans ce cas se forme un silicate de fluorure qui en se décomposant provoque l'apparition de l'alite et de la fusion à la température 1200°C.

L'élévation de l'activité de ciment obtenu du lit de fusion "catalyseur-calcaire" est expliquée par la teneur minimale des additions dans l'alite, par la microstructure optimale du clinker, par l'absence de l'aluminate tricalcique. Le composant facilement fusible du clinker de ces agglomérations est  $C_6A_2F$ . Il est à noter que la concentration max. de l'alite dans les clinkers étudiés ne garantissait pas la plus grande solidité du ciment après l'hydratation.

TABLEAU I

L'influence des conditions de la mouture du cataliseur avec les composants du mélange de matière première.

Clinker	Mouture commune du cataliseur	Composition minéralogique du clinker, %			Limite de solidité sous pres- sion - - - MPa à l'âge (jours)		Blancheur en comparai- son avec BaSO <sub>4</sub> , %
		Alite	Béalite	Substance intermédiaire			
					3	28	
D'alite	Résidus des pyrites et fluorure de cal- cium	70	6	24	37,1	53,1	On ne déter- minait pas
	Calcaire et fluo- rure	60	22	18	42,0	56,2	"-
Stable aux sul- fates	Résidus et fluo- rure	63	22	15	21,4	44,5	"-
	Calcaire et fluo- rure	60	24	16	26,0	47,4	
Vite dur- cissant	Résidus et fluo- rure	78	10	12	35,6	42,7	"-
	Calcaire et fluo- rure	65	20	15	38,9	51,0	
Blanc	Kaolin et fluo- rure	59	30	11	on ne dé-38,2 terminait		74,5
	Calcaire et fluo- rure	65	20	15	pas	41,2	69,0

Les conditions du contact initial du cataliseur exercent une influence fort importante à la composition et à la teneur en minéraux-flux aussi bien qu'à la teneur en alite.

La mise en application du procédé proposé aux usines de ciment a assuré l'élévation stable de l'activité de ciment à 5 ou 7% avec le décollage admissible du régime technologique du travail des fours; a amélioré la granulation du clinker; a éliminé la formation de la poussière de clinker.

En cherchant les procédés permettant neutraliser des additions indésirables dans le mélange de matière première de ciment, on a réussi à déterminer quelques nouveaux composants qui apparaissent à la clinkérisation. On peut diviser ces composés en deux groupes: 1- conservé dans le clinker prêt et changeant sa composition minéralogique et les propriétés du ciment:  $K_2MgSiO_4$ ,  $Na_2MgSiO_4$ ,  $K_2SO_4$ ; 2- composé se formant à la période précédente à la clinkérisation qui influencent à la formation de certains minéraux de clinker et élèvent la partie de leur solutions solides:  $K_2Ca(CO_3)_2$ ,  $Na_2Ca(CO_3)_2$ ,  $K_2Ca_2(SO_4)_3$ ,  $K_2Mg(CO_3)_2$ ,  $K_2Na(SO_4)_2$ ,  $Ca_7Mg_2P_6O_{24}$ ,  $Ca_{12}Si_4O_{19}F_2$ ,  $Ca_5Si_4CO_{11}$ ,  $Ca_5Si_2SO_{12}$ .

Les composés cités ci-dessus sont nommés intermédiaires. A notre avis il convient de les nommer variables. Le terme "intermédiaire" se rapporte aux minéraux-flux et au verre de clinker qui remplissent en effet des espaces entre des minéraux-silicates dans le clinker. De nouvelles formations citées ci-dessus sont stables dans l'intervalle limité des températures, retiennent des atomes et des ions des constituants volatils dans la solution solide; leur constituant change au chauffage et ils se décomposent facilement en sels et en oxydes.

En règle, toutes les nouvelles formations favorisent l'apparition des microfusions aux températures fort basses et accélèrent catalytiquement tout le procédé de l'agglomération. La commande consciente de ces interactions permet d'assurer la neutralisation complète des additions indésirables. Le dernier est réussi si les oxydes indésirables en réagissant donnent des composés stables. Donc, les interactions activent la clinkérisation, car la température de la formation de la fusion diminue et par conséquent le débit de chaleur pour le grillage sans provoquer le changement des indices qualitatifs du ciment. L'effet de neutralisation de la magnésie sur les lits de fusion alcalins est déjà connu. L'addition qui contient

le magnésium accélère une sublimation des oxydes alcalins (Figure 1).

Fig. 1 - Influence de l'oxyde de magnésium à la teneur en alcalin et en alite dans le clinker (CS=0,89).

1,2 - avec les sulfates de potassium et de sodium; 3,4 - avec les carbonates de potassium et de sodium.

Un phosphate de calcium et de magnésium ( $7CaO \cdot 2MgO \cdot 3P_2O_5$ ) apparaît à l'agglomération des mélanges de matière première de ciment à haute concentration des oxydes de magnésium et de phosphore. L'influence réciproque de la neutralisation des oxydes se voit bien en envisageant les données du tableau II.

Le premier groupe de composés formant des minéraux indépendants est moins nombreux mais ils diminuent aussi la température de l'agglomération. En prévoyant leur formation il est nécessaire de changer la composition du mélange de matière première, car une partie d'oxyde se dépense pour de nouveaux composants. De nouvelles formations influent sur les propriétés du ciment, par exemple, les silicates alcalino-magnésiques stimulent l'indurcissement des mâchefer et les oxydes de magnésium et de phosphore se trouvant en même temps dans le ciment élèvent une stabilité aux sulfates.

Les composés contenant le phosphore influent sur les lits de fusion de matière première de ciment alcalins. Voir les données du tableau III.

TABLEAU II						
Influence des oxydes de phosphore et de magnésium à la solidité						
CS; n=2,5; p=1,2	Teneur en additions, %		Oxyde de calcium disponible dans le clinker, %	Solidité des ciments sous pression, MPa à l'âge (jours)		
	$P_2O_5$	MgO		1	7	28
0,85	0	0	0	8,9	20,7	33,1
"	3	0	5,1	sont détruits		
"	3	4,5	0	4,1	14,9	26,9
0,90	0	0	0,2	9,9	23,3	33,4
"	3	0	7,2	sont détruits		
"	3	4,5	0,8	5,9	21,1	35,9
0,95	0	0	1,5	10,8	20,1	36,1
"	3	0	9,9	sont détruits		
"	3	4,5	3,5	4,3	16,1	25,3

TABLEAU III			
Influence des additions de sulfate de potassium et de concentrat d'apatite à la solidité			
Mélange de matière première CS=0,91; n=2,6; p=1,4 avec l'addition(%) en clinker	Solidité sous pression à l'âge (jours), MPa		
	3	7	28
Sans addition	14,8	19,4	30,2
Sulfate de potassium (5)	14,4	16,1	18,3
Pentoxyde de phosphore (0,5)	14,0	16,3	19,1
Sulfate de potassium (5) et pentoxyde de phosphore (0,5)	14,9	19,2	28,2

Ainsi l'influence négative de certains oxydes peut être compensée au moyen de leur neutralisation réciproque. Un schéma simplifié de la compensation est présenté au dessous:

La compensation de l'influence indésirable d'oxydes de magnésium est basée sur la réaction suivante:

Les réactions (1) vont jusqu'au commencement de la décarbonisation du magnésium carbonique. Si le sel alcalin ne se formera pas en silicate, il aura la possibilité de réagir avec le carbonate de calcium que provoquera une saturation postérieure des silicates de clinker par les oxydes alcalins. Donc l'addition du carbonate de magnésium dans les lits de fusion alcalins détourne la réaction suivante:

La réaction (1) freine aussi le dégagement du périclase à gros cristaux. Avec cela CaO est conservé pour la formation des minéraux silicates et assure l'obtention du clinker d'alite. On a été découvert avec cela des silicates alcalino-magnésiques  $K_2MgSiO_4$  et  $Na_2MgSiO_4$ . Il ya des renseignements que les silicates alcalino-magnésiques ne sont pas assez stables à haute température. C'est pourquoi on a fait les observations des changements des silicates alcalino-magnésiques en contact avec des minéraux de clinker dans un microscope chauffant. Il est établi au moyen de l'analyse de la composition de phase qu'en règle les silicates alcalino-magnésiques ne provoquent pas la formation du périclase dans le clinker. L'absence du périclase est expliquée par le changement du nombre de coordination du magnésium, qui peut diminuer dans les compositions alcalines jusqu'à 4 (au lieu de 6). Les tétraèdres  $MgO_4$  apparaissent au lieu des octaèdres  $MgO_6$ . L'étude des conditions de la formation des silicates alcalino-magnésiques montre que les derniers se forment facilement sur la base des silicates de magnésium naturels. Un grillage rapide est le plus favorable.

Une dépendance établie ne s'étend pas au mélange de l'aluminate tricalcique avec les silicates sodico-magnésiques dans lequel passe l'interaction suivant sous l'action de l'agglomération:

Une partie d'oxyde de magnésium se dégage en état du périclase et reste dans la composition du silicate de calcium magnésique. La porosité de la masse agglomérante s'élève à la sublimation de l'oxyde alcalin. La neutralisation réciproque des oxydes de magnésium et de phosphore est accompagnée par l'apparition d'un composé intermédiaire  $C_7M_2P_3$  qui se décompose à l'élévation de la température et en présence de l'oxyde de calcium suivant le schéma:

D'autres interactions sont aussi possibles, par exemple, avec la participation de la wollastonite. Pourtant le but essentiel du technologue est d'assurer une liaison inmanquable de l'oxyde de magnésium et de détourner la formation du périclase. En présence des alcalis et de phosphore l'oxyde de magnésium est fixé à la température 1200°C en silicates de calcium magnésique (diopside) et en autres qui se saturent de l'oxyde de calcium à l'élévation de la température et donnent une formule remplaçant le magnésium  $\alpha'_L - C_2S$  (2,3). Suivant les données de l'analyse du roentgen de phase des produits du grillage interrompu aux températures 1200 et 1250°C,  $\alpha'_L - C_2S$  dissout dans un bain fondu du clinker. Un silicate bicalcique peu soluble dans un bain fondu, stabilisé par le phosphore, apparaît dans les agglomérés ne contenant pas d'importantes additions de l'oxyde de magnésium. C'est pourquoi une quantité importante de l'oxyde de calcium est non assimilée et il n'y a pas d'alite dans l'aggloméré.

## CONCLUSIONS

En préparant des mélanges de matière première, il convient de prévoir les interactions possibles chimiques entre les additions indésirables et d'assurer leur neutralisation. Il y a le constituant des composés et les interactions chimiques allant à la période précédente à la clinkérisation qui assurent la neutralisation des additions alcalines, magnésiques et celles contenant le phosphore. On a proposé le terme des composants variables dans le mélange agglomérant de matière première à la différence des minéraux intermédiaires du clinker de ciment.

## Problems of the simultaneous and separate grinding at the production of blast furnace slag cement

### *Problèmes du broyage simultané ou séparé dans la production des ciments de laitier*

L. OPOCZKY, Head of Sci. Res. Group, Ph.D. Central Research and Design Institute for the Silicate Industry, Budapest, Hungary,

T.K. MRAKOVICS, Sci. Officer, Central Research and Design Institute for Silicate Industry, Budapest, Hungary.

RESUME : Le clinker et le laitier, lorsqu'ils sont broyés ensemble, exercent une influence mutuelle l'un sur l'autre. Cet effet peut aider ou retarder le broyage, selon la dureté et la tendance à la réagglomération des composants. On peut caractériser cet effet par un indice d'uniformité  $n$  et par l'écart type de la distribution granulométrique du produit broyé.

Ces facteurs permettent de choisir, lorsque l'on doit broyer un ciment de laitier en circuit ouvert, s'il y a lieu d'adopter le broyage séparé ou le broyage simultané. Si le broyage s'effectue en circuit fermé, le broyage simultané semble être le plus favorable à la qualité du ciment.

SUMMARY: The cement clinker and blast furnace slag ground together generally affect one another. This effect may aid but as well retard the grinding process depending on the hardness and tendency to aggregation of the components. This latter one can be characterized by the uniformity index  $n$  and the standard deviation, resp, of the particle size distribution of the ground product.

When grinding blast furnace slag cement in open circuit system the choosing between simultaneous and separate grinding is determined by the above factors. In a closed circuit system the simultaneous grinding seems to be more favourable in view of cement quality.

## INTRODUCTION

In the cement industry, both at raw meal- and cement grinding mixtures of two or more components are produced.

When making blended cements one can choose of two possibilities: the one is the post-mixing of the separately ground components, the other being the simultaneous grinding.

The choosing of the proper method is jointly determined by the energy consumption and the most favourable developing of the properties of the final product.

The literature of the problematics is very wide /1-5/, in this field Bombled /6/ has dealt with the special problems of the cement industry in details.

In our experiments the character of the simultaneous and separate grinding processes of cement clinker and blast furnace slag were studied in laboratory grinding equipments modelling the open and closed circuit grinding.

## MATERIALS AND METHODS

In order to present the results two kinds of industrial clinkers

$K_1$ :  $C_3S = 48,76\%$ ;  $C_2S = 26,24\%$ ;  $C_3A = 10,41\%$   
 $C_4AF = 7,14\%$  and

$K_2$ :  $C_3S = 45,04\%$ ;  $C_2S = 28,24\%$ ;  $C_3A = 11,42\%$   
 $C_4AF = 9,45\%$  /,

and 4 three kinds of granulated blast furnace slag  $H_1$ ,  $H_2$  and  $H_3$  were chosen. The materials were prepared by a hammer crusher to  $< 3,4$  mm grain size.

In our experiments we tried to modelize the open and closed circuit grinding processes. In the first case our experimental equipment was a 5000 cm<sup>3</sup>, 68 rpm iron-jacketed mill filled with 8 kg of 20 x 20 mm steel cyl-pebbles.

In the second case experiments were carried out in a Bond-type grindability testing mill /7/. To characterize the dispersity of the ground products the specific surface determined by permeability measurement  $/S_{Blaine}/$  and the granulometric composition  $/to 3\mu m/$  determined by sedimentation in alcohol were used. At the evaluation of the particle size distribution two constants of the Rosin-Rammler-Sperling-Bennett /RRSB/ distribution were applied: the particle size  $\bar{x}$  that belongs to the 36,8 % sieve residue and the uniformity index  $/n/$  of the ground product. This latter is proportional to the reciprocal of the standard deviation of the distribution if calculated by the logarithms of the particle size thus being calculable by mathematical-statistical method /8/. The value of  $\bar{x}$  can be read from the RRSB diagram.

The studying of the morphology of the grinding products and powder samples, resp., was made using an ISM-35 type scanning electronic microscope while the identification of the individual particles and components was carried out with the use of a LINK-290 type microprobe. The identification of alite and

belite was made on the base of the relation of the Si-Ca peaks while that of the interstitial phase and blast furnace slag particles was made on the base of the Al- and Fe as well as Mg and S peaks, respectively.

## DESCRIPTION OF THE EXPERIMENTAL RESULTS

The experimental materials were different in their grindability properties. Discussing the grindability properties we think of the grindability of the material /which is characterized by the surface produced per time unit:  $w = S/\tau$   $\text{mg}^{-1}\text{min}^{-1}$ / and of the tendency to interaction, aggregation of the particles of the material. It has been stated in former experiments that the uniformity index  $/n/$  of the ground product is a characteristic of the material's tendency to aggregation. Grinding products of small uniformity index i.e. of diffuse granulometric composition /e.g. limestone/ are generally more tending to aggregation than those ones of big uniformity index i.e. of more uniform granulometric composition /e.g. quartz//9/.

According to this characterization the clinker  $K_1$  in easier grindable and tending more to aggregation  $/w = 44.10^{-4} \text{mg}^{-1}\text{min}^{-1}; n = 1,35; \bar{x} = 34 \mu m/$ . Among the three blast furnace slags the most difficultly grindable and less tending to aggregation was that marked  $H_2$   $/w = 22.10^{-4} \text{mg}^{-1}\text{min}^{-1}; n = 1,26; \bar{x} = 33 \mu m/$ . The slag  $H_3$  is medium grindable and has a medium tendency to aggregation  $/w = 27.10^{-4} \text{mg}^{-1}\text{min}^{-1}; n = 0,95; \bar{x} = 32 \mu m/$ .  $H_1$  is between the above two in this respect  $/w = 27.10^{-4} \text{mg}^{-1}\text{min}^{-1}; n = 1,18; \bar{x} = 28 \mu m/$ . The values of  $n$  and  $\bar{x}$  belong to a grinding time of 75 minutes.

The different grindability properties of the experimental materials are related to the differences in the chemical-mineralogical composition as well as in the macro- and microstructure influenced by the production technology but this problematics will not be dealt with here.

The simultaneous and separate grinding experiments were carried out with three kinds of binary mixtures as follows:

- Mixture  $K_1-H_1$  - Mixture of an easily grindable  $/K_1/$  component tending to aggregation and a more difficultly grindable one  $/H_1/$  less tending to aggregation
- Mixture  $K_1-H_2$  - Mixture of an easily  $/K_1/$  and a medium grindable  $/H_2/$  material. Both components are tending to aggregation
- Mixture  $K_2-H_3$  - Both components are difficultly grindable and not tending to aggregation

Within these three and four, resp., mixing ratios were investigated.

## GRINDING EXPERIMENTS IN OPEN CIRCUIT SYSTEM

Fig.1. shows the change of the grindability  $/w/$  of the experimental mixtures as well as that of the uniformity index  $/n/$  at grinding in open circuit system. Dotted line

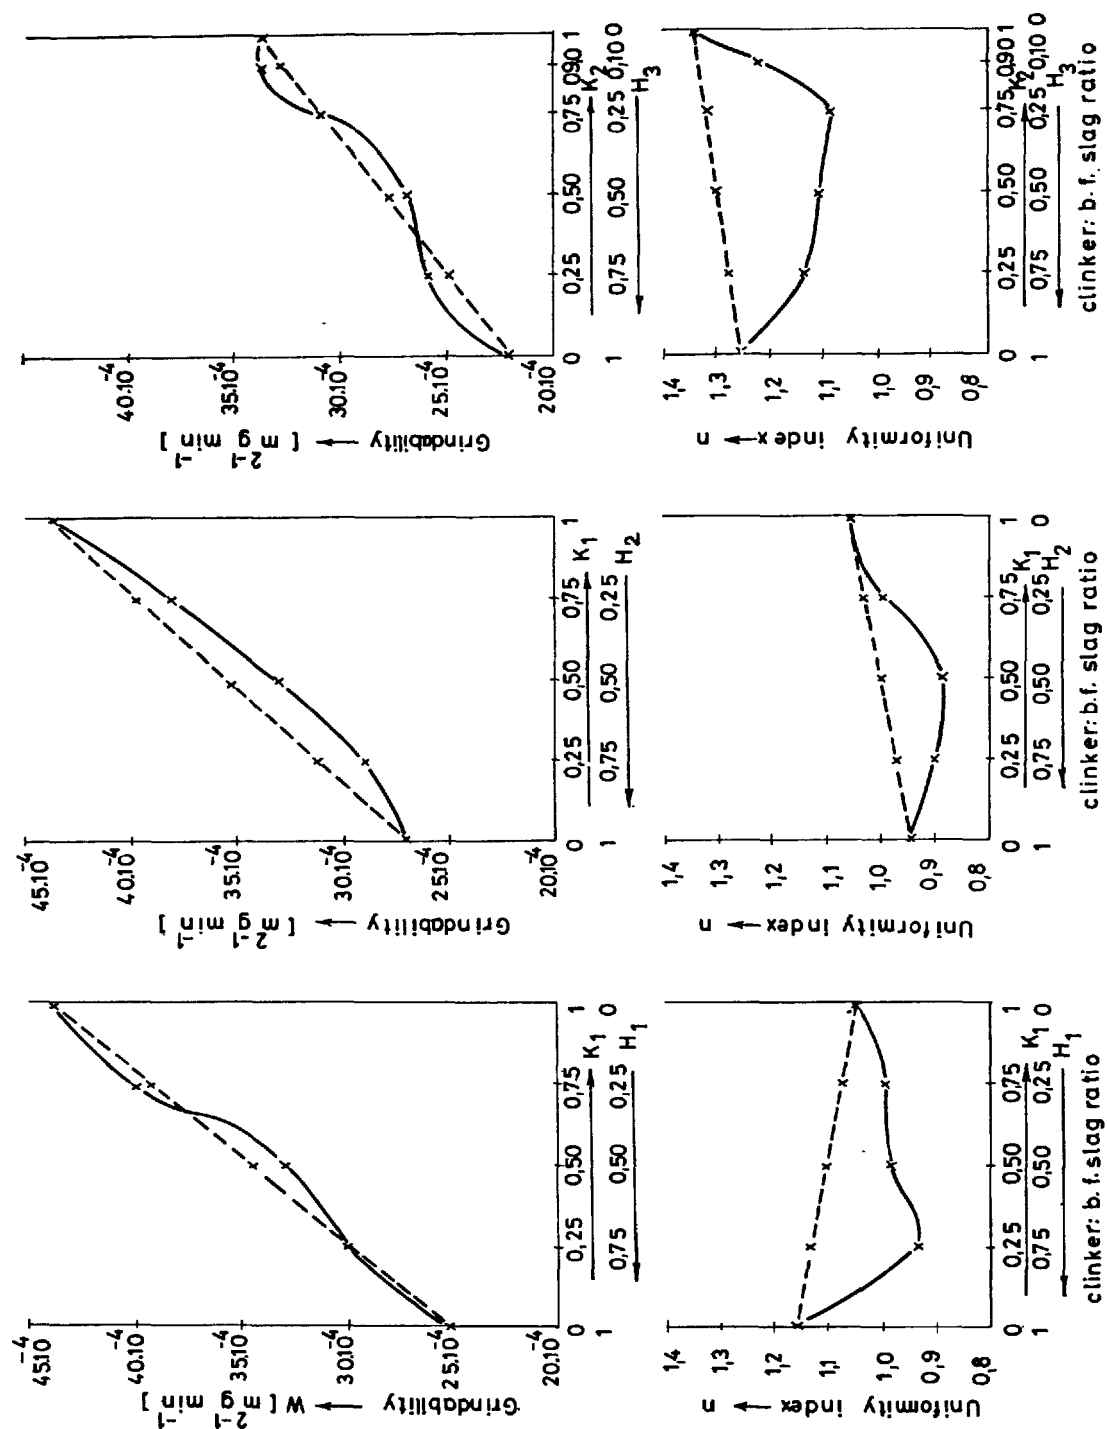

Fig.1. - Simultaneous and separate grinding in open circuit grinding equipment  
 ----- separate grinding  
 ————— simultaneous grinding

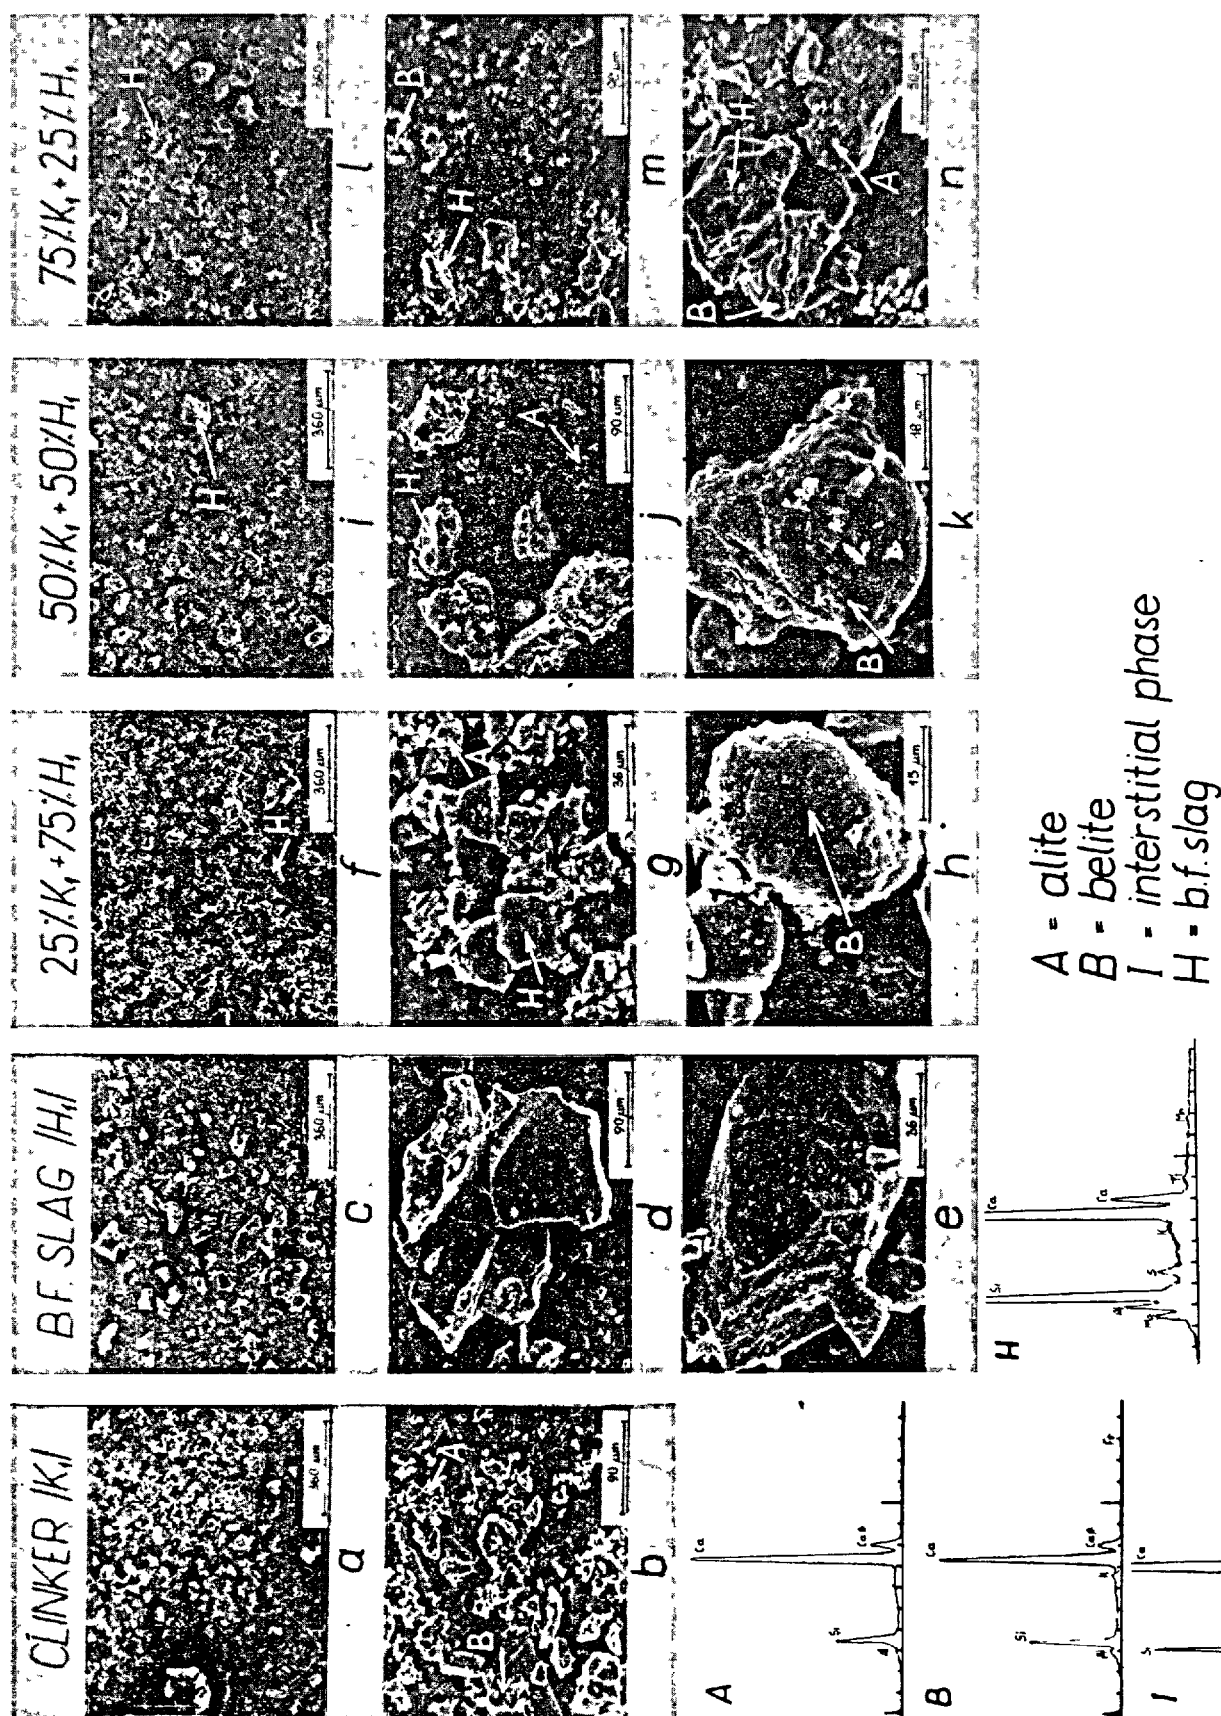

Fig. 2. - Study of the ground products by scanning electronic microscope and microprobe

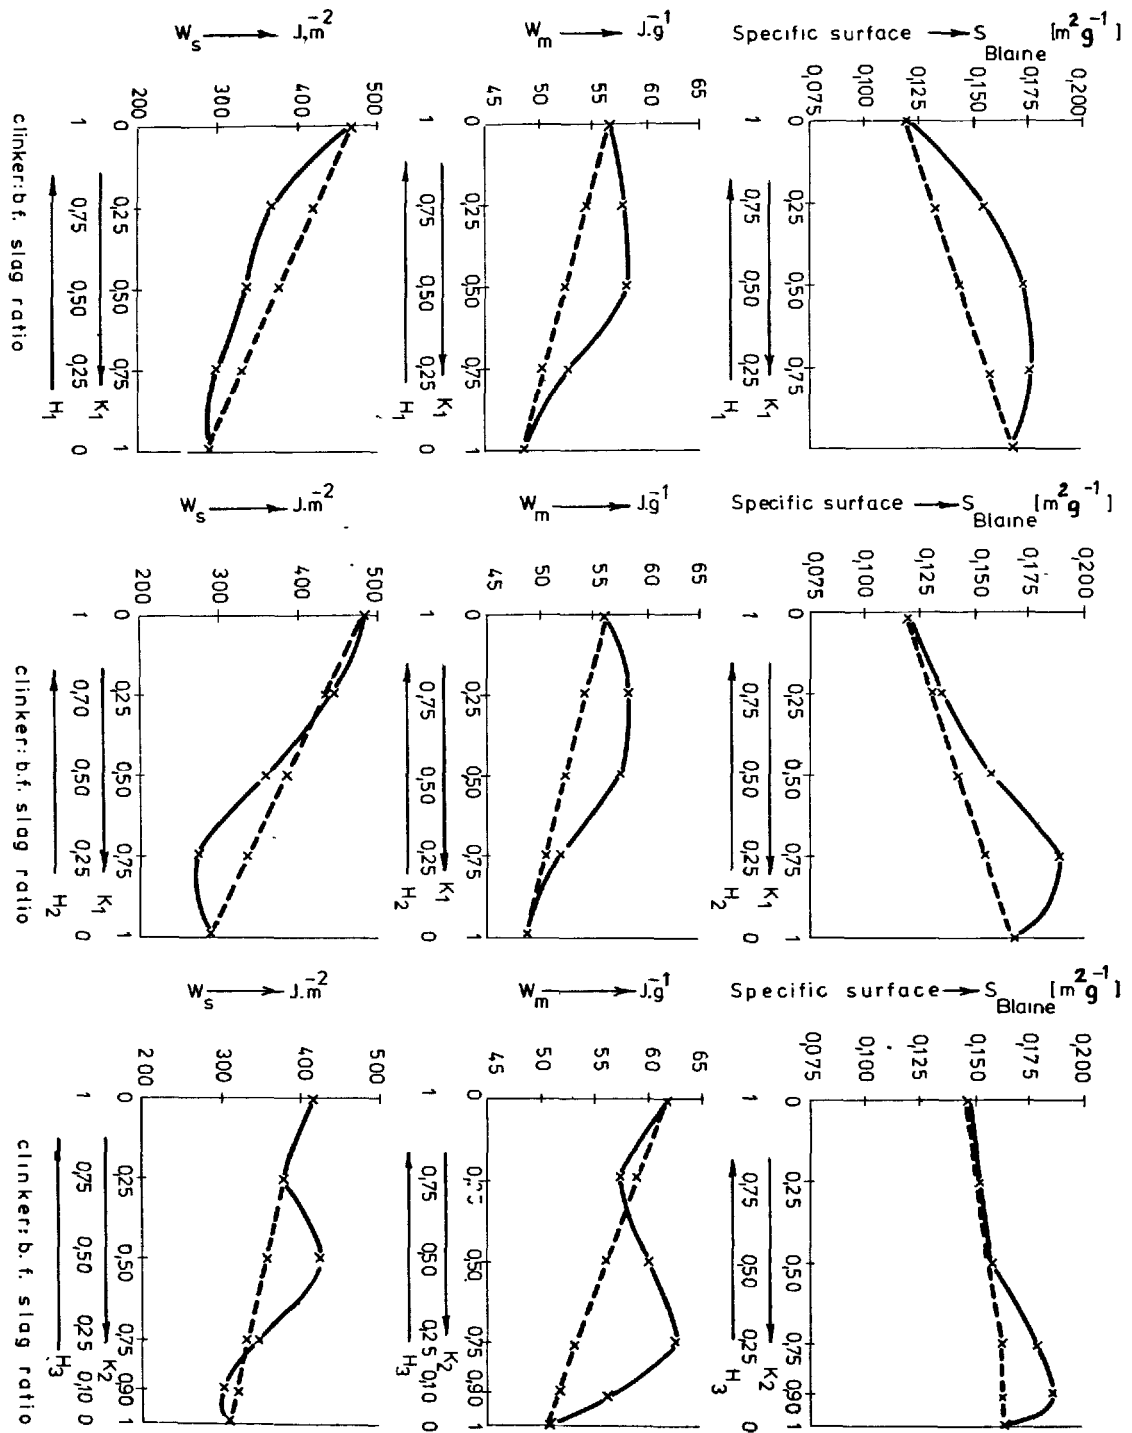

Fig.3. - Simultaneous and separate grinding in a closed circuit grinding equipment  
 - - - separate grinding  
 — simultaneous grinding

shows the separate while the continuous one the simultaneous grinding.

It may be stated that in general the standard deviation of the distribution according to particle size is always higher /the value of  $n$  is smaller/ at simultaneously ground mixtures than at the separately ground ones. This shows that the clinker and blast furnace slag are influencing the grindability of one another at simultaneous grinding.

At the separate grinding of the mixture  $K_1-H_1$  the value of  $n$  decreases with the increase of the clinker quota. At simultaneous grinding  $n$  comes to a minimum at 25 % clinker content then increases with the increasing clinker quota. Regarding grindability, according to Bond's method, in the range  $25\% < K_1 < 75\%$  the simultaneous grinding gives a less favourable work index than separate grinding. Since grindability is characterized by the surface formed during time unit and since the formation of surface is first of all due to the smaller size clinker particles, the increase of  $n$  accompanied by the increase of the work index suggests that at the simultaneous grinding of the 50 %  $K_1$  - 50 %  $H_1$  mixture the clinker is ground somewhat coarser, the slag somewhat finer than at separate grinding. In the other mixing ranges simultaneous and separate grinding are practically the same the former one being slightly more favourable. At the separate grinding of the mixture  $K_1-H_2$   $n$  increases with the increase of the clinker quota. At simultaneous grinding however, the value of  $n$  begins to increase only then if the clinker quota exceeds 50%. The change of  $n$  shows that in this mixture probably an interaction of particles takes place during simultaneous grinding since otherwise upon increasing clinker quota the value of  $n$  ought to have increased, too. Regarding the grindability and work index, resp., separate grinding is more favourable at this mixture.

At the separate grinding of mixture  $K_2-H_2$   $n$  increases with increasing clinker quota. At simultaneous grinding, in the range  $25\% \leq K_2 \leq 75\%$   $n$  remains practically unchanged; then increases if the clinker quota exceeds 75%. In the change of the  $n$ -value this mixture shows the biggest difference between simultaneous and separate grinding.

On the base of grindability and work index both at smaller / < 25% / and bigger / > 75% / clinker quota simultaneous grinding is more favourable while in the medium range the separate one is better. The change of the energy index and the  $n$ -value of the grinding products suggests that in case of  $25\% < H_2 < 75\%$  slag content the clinker is coarser and the slag is some finer ground than at separate grinding.

Supplementary informations were received about the change of simultaneous grinding by the investigation carried out with scanning electronic microscope and microprobe made on ground products and powder samples. Fig. 2. shows some exposures and spectra, resp., made on samples of the mixture  $K_1-H_1$

produced by millings for 75 minutes.

In Fig. 2, a and b show clinker / $K_1$ / grinding products while c, d, e show those ones of slag / $H_1$ /.

The granulometric composition of the clinker / $K_1$ / grinding product is diffuse, besides the larger size grains there are a lot of smaller ones, too. The size of alite /A/ particles identified by microprobe is generally 5-6  $\mu m$  and that of belite /B/ ones is 15-20  $\mu m$ . In the clinker grinding product the sticking of the smaller particles to the bigger ones or to one another /i.e. aggregation/ can be observed.

The blast furnace slag / $H_1$ / has a more uniform granulometric composition but it is in the coarser range of fineness. The main mass of particles is of 30-80  $\mu m$  size but a lot of 150-200  $\mu m$  ones can also be found. The particles are angular having "craters" in some places.

In Fig. 2, f, g and h show the mixture 25% $K_1$  - 75% $H_1$ . The size of slag particles changes from 20 to 120  $\mu m$  that is the slag particles are some finer here than at separate grinding. The characteristic size of belite /B/ particles is 30  $\mu m$  and that of alite /A/ ones is 10 - 15  $\mu m$ . The granulometric composition of the grinding product is diffuse, besides the larger and smaller slag particles a lot of fine and medium size clinker particles can be found. The sticking of the finer clinker particles on the coarser slag ones can also be observed.

In Fig. 2, exposures i, j and k show the 50% $K_1$  - 50% $H_1$  mixture. Average size of slag /H/ particles is 70-80  $\mu m$  while that of belite /B/ and alite /A/ ones amounts to 15 - 40  $\mu m$  and 10 - 15  $\mu m$ , respectively. This means that compared with the former mixture and separate grinding here the slag particles are finer and the clinker ones are a bit coarser. The granulometric composition is more uniform but it is in a coarser range of fineness. The interaction of particles is not considerable.

In Fig. 2, exposures l, m, n show the mixture 75% $K_1$  - 25% $H_1$ . The size of slag particles /H/ is 60-100  $\mu m$  while that of belite /B/ and alite /A/ ones amounts to 10 - 15  $\mu m$  and 3 - 5  $\mu m$ , respectively. In this case both the slag and the clinker were more finely ground than at separate grinding. The ratio of clinker particles determining the specific surface is big and the fine clinker particles are adhered not to one another but rather to the surface of slag grains. In this case blast furnace slag prevents the aggregation of clinker particles.

#### GRINDING EXPERIMENTS CARRIED OUT IN CLOSED CIRCUIT SYSTEM

Fig. 3 shows the experimental results of closed circuit grinding. The dotted line refers to the separate and the continuous one to simultaneous grinding. Since in this case the grinding takes place in a relatively coarse range / $S_p = 0,12 - 0,19 \text{ } \mu g^{-1}$ / the interaction of particles, i.e. aggregation is

of no importance. The specific surface  $S_B$  always increases with the increasing of clinker quota at separate grinding.

At the simultaneous grinding of mixture  $K_1-H_1$  the surface is always bigger than at separate grinding i.e. the clinker is always ground finer in this case.

At the mixture  $K_1-H_2$  in case of small clinker quota /up to cca 25%  $K_1$ / practically there is no difference between the two ways of grinding. Upon increasing the clinker quota the surface of the simultaneously ground product increases, reaching a maximum at 75%.

At the simultaneous grinding of mixture  $K_1-H_3$  the curve  $S_B$  has a similar shape. Upon increasing the clinker quota the surface is increasing also in this case reaching a maximum at 90% clinker quota.

The specific energy consumption  $w_m$  referred to mass unit is decreasing with the increase of clinker quota at separate grinding. At simultaneous grinding, the values of the energy index are generally less favourable. At mixtures  $K_1-H_1$  and  $K_1-H_2$  the  $w_m$  curves have similar shape. The energy consumption increases up to about 50 % clinker content then decreases with the further increase of the clinker quota.

At mixture  $K_2-H_3$  the simultaneous grinding is some more favourable up to 25 % clinker quota but with the further increasing of the clinker content the energy consumption increases rapidly.

The energy consumption  $w_s$  referred to unit surface changes in a different way since according to this characteristic the simultaneous grinding is more favourable. The  $w_s$  curve of mixture  $K_1-H_1$  is almost the mirror image of the  $w_m$  curve and a similar case can be found at mixture  $K_1-H_2$ . At mixture  $K_2-H_3$  the change of the curve  $w_s$  depends on the mixing ratio of the two components. At simultaneous grinding in case of low and high slag content the value of  $w_s$  is more favourable than in case of medium slag content.

## CONCLUSIONS

Different production technologies often need the preparation of mixture of ground products of various materials. The natural raw materials but also the artificial products/e.g. cement clinker/ may be composed of more minerals and behave as mixtures during grinding.

At simultaneous grinding the interaction of the components cannot be neglected in most cases. This interaction depends on the hardness /hard-hard, hard-soft, soft-soft/ of the partners forming the binary system as well as on their tending to aggregation which latter one can be characterized by the uniformity index  $n$  and the standard deviation of the particle size distribution, resp., of the ground product.

To characterize the interaction of the simultaneously ground components we have differentiated the so called "direct" and "indirect" effects. The direct effect means the super-

ficial adhesion of particles of the ground components and the aggregation, resp., which can aid the grinding process /in case if only one partner is tending to aggregation/ but mostly being harmful. Furthermore, the direct effect means the "abrading" effect of the one, generally harder, component affecting the other one. The "indirect" effect means an effect resulting from the excess of the one component thus being positive or negative depending on the mixing ratio. Cement clinker and blast furnace slag can principally be considered a hard-hard system but within this the slag is more or less harder. Their tending to aggregation is also different.

If both the clinker and slag are tending to aggregation, then in open circuit grinding aggregation - negatively influencing the process - may occur /e.g.: mixture  $K_1-H_2$ / . In this case the separate grinding is more convenient.

If only the clinker is tending to aggregation then providing certain mixing ratios simultaneous grinding is more favourable since the slag prevents the adhesion of the clinker particles to one another thus promoting the size reduction of the clinker particles/e.g. mixture  $K_1-H_1$ , at 25 % slag content/. If neither the clinker nor the slag is tending to aggregation and if the slag is very hard, then in case of certain mixing ratios simultaneous grinding is more favourable which can be explained by the "abrading" effect of the slag and thus the more effective size reduction of the clinker being present in excess /mixture  $K_2-H_3$ /.

At the simultaneous grinding of clinker and blast furnace slag in a closed circuit system - where the interaction of particles can not prevail - the clinker particles are generally more finely ground than at separate grinding and this is probably due to the "abrading" effect of the slag. In spite of the larger energy consumption the simultaneous grinding in closed circuit system seems to be better from the point of view of the quality of blast furnace slag Portland cement.

RESUME : Les auteurs du présent exposé traitent des données concernant l'effet du milieu gazeux, des catalyseurs ainsi que de la structure de divers carbonates de calcium (calcaires, craies) sur les paramètres cinétiques de leur dissociation.

On a étudié le mécanisme et la cinétique des réactions à l'état solide dans les mélanges de  $\text{CaCO}_3$  avec divers silicoaluminates : kaolinite, montmorillonite, gehlénite, pseudowollastonite, ainsi que dans les mélanges de  $\text{CaCO}_3$  avec l'argile, les laitiers mélilitique et pseudowollastonique ou avec leurs combinaisons.

On a établi une corrélation entre les énergies d'activation lors de la formation de bélite dans les réactions à l'état solide et les énergies d'activation lors de la formation d'alite ou de ses modifications dans des mélanges minéraux.

SUMMARY : Data on the influence of the composition of gas medium, catalysts and structure of different calcium carbonates (limestone, chalk) on the kinetic parameters of their dissociation are presented.

The results of investigations of the mechanism and kinetics of solid-phase reactions in the  $\text{CaCO}_3$  mixtures with different aluminosilicate minerals (kaolinite, montmorillonite, gehlenite, pseudowollastonite) as well in the  $\text{CaCO}_3$  mixtures with clays, melilite and pseudowollastonite slags and their combinations are discussed.

Interrelation between the activation energy of belite formation in solid-phase reactions and activation energy of formation of alite and its modifications in the mineral composition mixture has been found out.

Les recherches sur la réaction de dissociation de  $\text{CaCO}_3$  (à des fins purement analytiques), de calcite faisant partie de divers carbonates naturels (craies, calcaires) et de mélanges crus à base de ces carbonates ont montré, grâce à la méthode dite analyse thermique différentielle - thermogravimétrie différentielle (ATD-TGD) et à la spectroscopie infrarouge, que ce processus peut être exprimé par les équations cinétiques comme suit:

$$\sqrt[3]{1 - \alpha} = 1 - kt \quad (1)$$

ou bien

$$\sqrt[3]{1 - \alpha} = 1 - knt \quad (2)$$

où  $t$  - temps de décomposition de  $\text{CaCO}_3$ ,  $\alpha$  - degré de dissociation,  $k$  - constante de la vitesse.

Lorsqu'il s'agit des matières polydispersées, la constante de la vitesse dans l'équation (1) comprend également l'effet de la granulométrie, de la température et de la pression partielle de  $\text{CO}_2$ . Au cas où les expérimentations s'effectuent dans la couche mince de la substance réagissante, ce qui assure une évacuation rapide de  $\text{CO}_2$ , la cinétique de la réaction s'exprime par l'équation (2). Ici, on le sait, la constante de la vitesse est calculée compte tenu de la nature du constituant de carbonate (structure de la calcite, propriétés de minéraux accompagnateurs).

Grâce à la méthode de la spectroscopie IR, on a réussi à définir les constantes de la vitesse de dissociation de toute une série de calcaires et de craies provenant de différents gisements en territoire de l'URSS. Ces données ont permis de calculer les valeurs empiriques d'énergies d'activation de la dissociation ( $E_a$ ). La valeur  $E_a$  des calcaires étudiés varie entre 85 et 250 kJ/moles en fonction de la composition chimique et minérale ou des propriétés physico-mécaniques des carbonates.

On a constaté qu'à mesure que la fréquence des oscillations valentielles du groupe  $\text{CO}_3$  augmente dans les spectres IR de divers calcaires et craies, la valeur empirique d'énergie d'activation de la dissociation du carbonate de calcium et la valeur de microdureté de ces cristaux s'accroissent.

La basse de la valeur  $E_a$  de la dissociation des calcaires qui contiennent plus de six pour cent d'impuretés argileuses et de silices amorphes (en comparaison de  $E_a - \text{CaCO}_3$  - à des fins purement analytiques - qui est de 173 kJ/moles) s'explique par l'action catalytique des impuretés.

Lors du réchauffement, ces impuretés forment des surfaces actives de séparation avec calcite. Celles-ci accélèrent l'évacuation de  $\text{CO}_2$  de la zone de la réaction. Ainsi, l'activité chimique de la calcite au moment de la dissociation se détermine, dans une mesure égale, par la solidité des liaisons chimiques du réseau cristallin et par l'action catalytique des phases d'impuretés.

La comparaison des vitesses de dissociation de  $\text{CaCO}_3$  dans les mélanges crus aux modules et à la granulométrie égaux a montré que, dans le cas où les dépenses énergétiques sont aussi égales, l'addition pendant le broyage de 0,5 pour cent de la masse du nitrate de calcium  $\text{Ca}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$  fait notablement accélérer la réaction. Par ailleurs, les courbes cinétiques sont pratiquement exemptes de zones de "saturation". L'addition de la même quantité de  $\text{CaF}_2$  à un mélange pendant le broyage accélère le processus au stade initial et le ralentit sensiblement au stade final. L'usage en même proportion du phosphate d'aluminium en tant qu'additif rend la vitesse de dissociation de  $\text{CaCO}_3$  plus lente. Quant aux résultats concernant les recherches sur l'effet des sels sur la cinétique de la dissociation, ceux-ci ont été obtenus dans des conditions isothermiques et non isothermiques.

On sait que la pression partielle de  $\text{CO}_2$ , plus la composition du milieu gazeux dans la zone de la réaction de dissociation de  $\text{CaCO}_3$ , exercent un effet sensible sur la cinétique du processus (1).

Le tableau I présente les résultats des recherches sur la cinétique de dissociation de  $\text{CaCO}_3$  dans un même mélange cru - ce n'était que le milieu gazeux qui variait (méthode gravimétrique) - où  $\Delta T$  - intervalle des températures de décomposition rapide,  $\Delta \alpha$  - intervalle  $\alpha$  de décomposition rapide de  $\text{CaCO}_3$ ,  $k$  - constante de la vitesse de la réaction.

A en juger d'après les données du tableau I, au début, la zone de décomposition rapide dans le milieu  $\text{N}_2$  se manifeste dans les mêmes conditions que dans l'air ordinaire. Dans le milieu  $\text{N}_2 + \text{CO}_2$ , cette zone apparaît à une température plus haute, et dans le milieu  $\text{CO}_2$ , à des températures encore beaucoup plus considérables.

Milieu gazeux	$k, \text{min}^{-1}$	$\Delta T, ^\circ\text{C}$	$\Delta \alpha$
Air	0,1060	860-930	0,6
$\text{N}_2$	0,0809	860-960	0,5
90 p.c. de $\text{N}_2$ plus 10 p.c. de $\text{CO}_2$	0,1234	880-950	0,5
$\text{CO}_2$	0,1399	950-1050	0,3

Dans le flux d'azote, la zone de décomposition rapide de ce calcaire se déplace vers le domaine des températures plus basses.

On a étudié l'effet de la vitesse d'évacuation de  $\text{CO}_2$  depuis la zone de réaction sur la cinétique de décomposition de  $\text{CaCO}_3$  (des mesures de  $\text{CO}_2$  ainsi dégagée ont été faites par la méthode de la spectroscopie IR). Ces études ont montré que la valeur  $E_a$  de dissociation répond à l'équation (2):

$$E_a = E_{a_2} \pm \lambda + mQ \frac{P_0}{P_0 - P^m}$$

où  $E_a$  - énergie d'activation de la réaction inverse;  $\lambda$  - chaleur d'adsorption de  $\text{CO}_2$ ;  $Q$  - effet thermique de la réaction;  $P_0$  - pression équilibrée de  $\text{CO}_2$ ;  $p_m$  - pression effective de  $\text{CO}_2$ ;  $m$  - constante.

Le déroulement de la synthèse des produits de clinkérisation est fonction de l'état physique et des propriétés chimiques des constituants de base et détermine les dépenses énergétiques nécessaires pour la formation des minéraux de clinker (3).

La cinétique des réactions à l'état solide a été étudiée sur des mélanges  $\text{CaCO}_3$  (à des fins d'analyse uniquement) avec kaolin (gisement de Prossianaya), gehlenite synthétique et  $\alpha$  - pseudowollastonite (poudre polycristalline), pris dans des proportions différentes; les réactions se déroulaient dans les conditions de réchauffement rapide à des températures de 900 à 1.200°C. Les résultats de ces recherches sont présentés dans le tableau II. L'évaluation des valeurs de la densité optique des bandes d'absorption de  $\text{CaCO}_3$ ,  $\beta$  -  $\text{C}_2\text{S}$ ,  $\text{CS}$ ,  $\text{C}_2\text{AS}$  et  $\text{C}_3\text{A}$  a permis d'obtenir des courbes cinétiques de variation des concentrations molaires de ces composés dans les produits de cuisson.

Pour décrire mathématiquement la cinétique des réactions de synthèse, on a fait recours à des équations pseudo-topocinétiques généralisées:

$$kt = - \frac{1}{d \cdot m} \cdot \frac{1 - (1 - d)^{1-m}}{1 - m} \quad (3)$$

$$kt = - \frac{1}{d^{1-m}} \cdot \ln \frac{1 - d}{1 + d} \quad (4)$$

où  $m$  - facteur d'hétérogénéité. La variation  $m$  de 0 à 1 correspond au passage de la réaction depuis le domaine de diffusion vers le domaine cinétique.

Le tableau II montre la relation entre la composition de phases des produits de cuisson et le rapport des constituants de base.

On y voit également le rapport entre les paramètres cinétiques de la réaction de dissociation de  $\text{CaCO}_3$ , d'une part, et les paramètres cinétiques de la synthèse de  $\text{C}_2\text{AS}$ ,  $\text{C}_3\text{A}$  et  $\beta$  -  $\text{C}_2\text{S}$ , d'autre part.

Les calculs thermodynamiques ont montré que les réactions  $\text{CaCO}_3$  - kaolin, gehlenite et pseudowollastonite sont réalisables à des températures plus basses par rapport à la température de dissociation de  $\text{CaCO}_3$  (900°C). La baisse de  $E_a$  de dissociation de  $\text{CaCO}_3$ , dans des mélanges constitués de divers aluminosilicates, s'explique par une réaction triphasée avec carbonate qui aboutit à la formation du bélite, des aluminates et de  $\text{CaO}$ , exerçant une action catalytique sur le processus de dissociation. La réalisation de ces réactions est facilitée grâce aux transformations, de phase et chimique, des silicates d'alumine, à savoir le passage

du kaolin en métakaolinite, la stabilisation du réseau cristallin  $\alpha$  -  $\text{CS}$  et  $\text{C}_2\text{AS}$ .

Les données obtenus pendant les expérimentations témoignent que la formation du la bélite dans les mélanges chaux - argile peut être réalisée par différentes voies.

Les mélanges ayant un rapport stoechiométrique de  $\text{CaCO}_3$  à kaolin (soit 3,5 à 1), forment de la gehlenite et de  $\alpha$  -  $\text{CS}$ , dont l'interaction avec  $\text{CaCO}_3$  et  $\text{CaO}$  fournit la bélite et  $\text{C}_3\text{A}$ . Le surplus de  $\text{CaCO}_3$  (rapport 9 à 1) contribue à la formation de  $\beta$  -  $\text{C}_2\text{S}$  et  $\text{C}_3\text{A}$  à partir, semble-t-il, de métakaolinite et  $\text{CaO}$ ;  $\text{CS}$  ou  $\text{C}_2\text{AS}$  ne sont pas observés lors de l'usage de ces constituants. La formation de la gehlenite s'opère dans le domaine chimique ( $m = 0,98$ ).  $\text{C}_3\text{A}$  se crée à base de gehlenite et de  $\text{CaCO}_3$ , avec une plus basse  $E_a$  et des rapports plus faibles de constituants de base; le mécanisme de la réaction est chimique ( $m = 0,98$ ).

Pendant le réchauffement du mélange de  $\text{CaCO}_3$  et de kaolinite, se produisent des signaux de la résonance électronique paramagnétique avec  $g = 2,00$ , dont le pic d'intensité coïncide de façon satisfaisante avec le domaine des vitesses maximales des réactions de synthèse  $\beta$  -  $\text{C}_2\text{S}$  et  $\text{C}_3\text{A}$ .

Les résultats obtenus permettent d'expliquer la différence de réactivité des mélanges de base constitués par divers minéraux. La baisse de l'énergie d'activation de la dissociation des carbonates est fonction des possibilités de réaliser les réactions à l'état solide de  $\text{CaCO}_3$  avec aluminosilicates avant la dissociation proprement dite. On a étudié la corrélation des paramètres cinétiques de la formation de bélite en phase solide et d'alite dans les mélanges  $\text{CaCO}_3$ , d'une part, et diverses combinaisons de minéraux argileux et de laitiers constitués par méllilites et pseudowollastonites;

En se basant sur les données expérimentales obtenues, on peut conclure que la valeur énergétique d'activation de la formation du bélite en phase solide constitue un critère lors du choix des conditions optimales pour la fabrication du clinker.

Ainsi, l'énergie d'activation ( $E_a$ ) de la formation du bélite en phase solide étant supérieure à 180 kJ/moles ( $\text{CaCO}_3$  avec kaolin et montmorillonite), la formation d'alite est caractérisée par la valeur  $E_a$  allant de 150 à 170 kJ/moles et contrôlée totalement par la diffusion  $\text{Ca}^{2+}$  en bélite.

Au cas où la valeur  $E_a$  de la formation du bélite en phase solide est faible, c'est-à-dire au-dessous de 150 kJ/moles ( $\text{CaCO}_3$  avec laitiers de méllilite et de pseudowollastonite), juste avant la formation du clinker fondu on voit apparaître des cristaux du

Tableau II								
Constituants	Rapport des constituants (en poids)	Paramètres cinétiques des réactions						
		Dissociation de $\text{CaCO}_3$	Synthèse en phase solide					
			$\text{C}_2\text{AS}$		$\beta\text{-C}_2\text{S}$		$\text{C}_3\text{A}$	
		$E_a$	m	$E_a$	m	$E_a$	m	$E_a$
$\text{CaCO}_3$ + kaolin	3,5:1	143,8	0,98	83,8	-	-	-	-
	6:1	149,7	-	-	0,02	257,7	0,02	599,4
	9:1	174,1	néant		0,02	178,3	0,02	362,4
$\text{CaCO}_3$ + $\text{C}_2\text{AS}$	1,5:1	127,1	-	-	0,98	105,0	0,98	148,4
	4:1	113,8	-	-	0,02	153,4	0,02	416,8
$\text{CaCO}_3$ + $\alpha\text{-CS}$	1:1	97,6	néant		0,02	226,3	néant	
	3:1	111,9	néant		0,02	99,3	néant	

bélite résistante à la résorption. Dans ce cas, la valeur  $E_a$  de la formation d'alite constitue 200 à 400 kJ/mole, et c'est alors que le processus ne se limite pas que par la diffusion de  $\text{Ca}^{2+}$  en bélite, mais aussi par la vitesse de dissolution de la bélite.

Ainsi donc, la constitution minérale d'alumosilicate et la nature de carbonate définissent la cinétique de la formation et de la transformation des cristaux d'alite.

A partir des mélanges de  $\text{CaCO}_3$  avec kaolin, montmorillonite et leurs combinaisons, se forme une alite en modification essentiellement rhomboédrique. A partir des mélanges de  $\text{CaCO}_3$  avec hydro-mica et laitier de pseudowollastonite on obtient, dans les mêmes conditions une alite en modification monoclinique; avec laitiers de méllilite on obtient une alite en modification triclinique.

### RESUME

Le clinker est un matériau fragile auquel peuvent être appliqués les concepts de la mécanique de la rupture. Des mesures d'énergie spécifique de rupture  $\gamma_F$  ont été effectuées sur des prismes de clinker compactés et recuits à 1450 °C, par la méthode de l'éprouvette entaillée soumise en flexion simple à déformation imposée. Un indice de fragilité caractérisant l'aptitude à la déformation et à la fracture des différents minéraux du clinker a été mesuré par une méthode d'indentation utilisant le microduromètre VICKERS. La plus grande fragilité de  $C_3S$ , qui concentre les contraintes, explique le comportement du clinker au choc thermique. Deux types de fissuration dépendant de l'intensité du choc thermique ont été mis en évidence : fissuration macroscopique des granules et fissuration microscopique de  $C_3S$ . Des tests réalisés en laboratoire ont permis de relier la broyabilité du clinker au taux de fissuration de  $C_3S$ .

### SUMMARY

Clinker is a brittle material to which concepts of fracture mechanics can be applied. Measurements of fracture surface energy  $\gamma_F$  have been made on clinker prisms compacted and reburnt at 1450 °C, by the method of notched bending specimen in imposed deflection conditions. A brittleness index characterizing the aptitude to deformation and to fracture of the different clinker minerals has been measured by an indentation method using VICKERS micro-indenter. The greater brittleness of  $C_3S$  which concentrates the stresses, explains the comportment of the clinker to thermal shock. Two types of cracks depending on thermal shock intensity have been observed : macroscopic cracking of the granules and microscopic cracking of  $C_3S$ . Laboratory tests have permitted us to relate grindability of clinker to the rate of  $C_3S$  cracking.

## 1. INTRODUCTION

Le broyage du clinker entraîne une consommation d'énergie moyenne de  $38 \text{ kWh.t}^{-1}$  (1). Le coût énergétique élevé de cette opération justifie les recherches destinées à améliorer son rendement : mise au point de matériel nouveau (1, 2), étude du comportement du matériau à la fragmentation en relation avec sa composition minéralogique (3, 4), sa texture, son traitement thermique (5). Nous nous proposons, ici, d'appliquer à la fragmentation du clinker les critères relatifs à la propagation des fissures et à la rupture des matériaux, critères déjà largement utilisés par l'Industrie Céramique, notamment dans les problèmes de choc thermique dont nous verrons l'influence sur la fissuration et la broyabilité du clinker.

## 2. PROBLEMES GENERAUX DE LA FRAGMENTATION DU CLINKER

Le clinker est un matériau fragile auquel peuvent être appliqués les concepts de la mécanique linéaire de la rupture dus à GRIFFITH (6). La théorie de GRIFFITH, complétée depuis par de nombreux travaux, admet la préexistence de microfissures dont la progression stable (contrôlée) ou instable (non contrôlée), dans des conditions données de sollicitations, est déterminée par deux paramètres intrinsèques au matériau (7) : l'énergie spécifique de rupture  $\gamma_F$ , et la taille relative(a) des microfissures préexistantes. Les premières mesures de  $\gamma_F$  effectuées sur des éprouvettes entaillées, soumises en flexion simple à déformation imposée (8), indiquent des valeurs de l'ordre de  $12 \text{ à } 22 \text{ J.m}^{-2}$  pour des clinkers compactés sous forme de prismes  $80 \times 32 \times 7 \text{ mm}$ , recuits 2 heures à  $1450^\circ\text{C}$ , de masse volumique apparente  $\sim 3 \text{ g.cm}^{-3}$ , et de module de YOUNG  $E = 10^5 \text{ MPa}$ . Ces résultats sont vraisemblablement un peu plus élevés que ceux que l'on obtiendrait sur les granules de clinkers industriels généralement moins denses. Le tableau I regroupe quelques valeurs comparatives de  $\gamma_F$  pour divers matériaux. Il montre que l'énergie spécifique de rupture du clinker est assez élevée, mais que celle des monocristaux est beaucoup plus faible que celle des matériaux polycristallins correspondants. Dans ces derniers, une partie de l'énergie servant à la propagation des fissures est diffusée au niveau des discontinuités telles que les joints de grains, les pores, les inclusions ; la conséquence fréquente est l'arrêt de la fissure à la limite du cristal dans lequel elle avait été

amorcée. C'est ce qui est observé dans le clinker où les microfissures dans  $\text{C}_3\text{S}$  sont souvent arrêtées au niveau de la phase interstitielle.

Les relations entre  $\gamma_F$  et la composition minéralogique, les dimensions des cristaux, la porosité n'ont pas encore été établies pour le clinker.  $\gamma_F$ , énergie superficielle, constitue une mesure de la résistance à la fracture des solides. Pour le clinker, une valeur moyenne de  $\gamma_F$  de  $17 \text{ J.m}^{-2}$  signifie qu'une finesse de  $3500 \text{ cm}^2.\text{g}^{-1}$  exige théoriquement une énergie égale à  $1,65 \text{ kWh.t}^{-1}$  au lieu de  $38 \text{ kWh.t}^{-1}$ , valeur habituelle. Les concepts de la mécanique de la rupture appliqués au broyage par HUET (7) peuvent fournir une explication à cet écart important : dans les broyeur à boulets usuels, les conditions sont proches de la déformation imposée où il y a progression instable pour les faibles tailles relatives de microfissures et progression stable pour les tailles relatives élevées. Au début du broyage du clinker, la taille des fissures, du même ordre que celle des cristaux de  $\text{C}_3\text{S}$ , est petite devant celle des grains : la progression des fissures est instable avec rupture complète des grains ; l'énergie dépensée n'est pas très supérieure à l'énergie théorique. Par contre, aux stades plus avancés du broyage, la taille des microfissures devient grande relativement à celle des grains : on se trouve dans le cas de la rupture contrôlée où la progression des fissures ne peut être obtenue que par la répétition du choc. Une part importante de l'énergie est ainsi perdue et dissipée par les frottements entre grains et les déformations plastiques notables pour les petits grains (11). La complexité du phénomène s'accroît si l'on considère qu'au début du broyage la rupture est commandée par l'énergie spécifique de rupture de l'agrégat polycristallin mais qu'en fin de broyage la rupture dépend davantage de  $\gamma_0$  des cristaux proprement dits.

Le comportement du clinker à la rupture dépend également des propriétés de ses minéraux constitutifs,  $\text{C}_3\text{S}$ ,  $\text{C}_2\text{S}$ ,  $\text{C}_3\text{A}$ ,  $\text{C}_4\text{AF}$ . Ces minéraux, qui ont des structures essentiellement ioniques, ont tous un comportement fragile. La fragilité, que l'on peut définir schématiquement comme le rapport entre l'aptitude à la déformation et l'aptitude à la fracture, n'est pas la même pour tous ces composés. Un indice de fragilité a pu être déterminé par une méthode d'indentation utilisant la pyramide du microduremètre VICKERS (12). Le principe consiste à mesurer d'une part les dimensions de l'empreinte et d'autre part la longueur des microfissures qui apparaissent dans le prolongement de l'empreinte lorsque la charge dépasse une certaine valeur critique. La mesure des diagonales de l'empreinte permet de calculer la microdureté  $H$  qui représente l'aptitude à la déformation du cristal. L'évaluation de la longueur des microfissures conduit au calcul de la "ténacité"  $K_{IC}$  [identique au facteur intensité de contrainte, utilisé en mécanique de la rupture (7)], qui représente l'aptitude à la fracture du cristal. Le rapport  $H/K_{IC}$  donne un indice de fragilité. Les valeurs moyennes approchées, trouvées pour les minéraux du clinker ainsi que quelques valeurs tirées de la littérature sont portées dans le tableau II.

$\text{C}_3\text{S}$  est le minéral le plus fragile. Sa fragilité est en relation avec l'existence d'une direction de clivage privilégiée, qui entraîne une fissuration facile des cristaux (fig. 1).  $\text{C}_2\text{S}$  est beaucoup plus déformable que  $\text{C}_3\text{S}$  et l'essai d'indentation avec les charges utilisées (20 g ou 50 g) ne donne pas toujours des fissures visibles (fig. 2). L'aluminate tricalcique et l'aluminoferrite sont les composés les plus durs, c'est-à-dire les moins déformables. Dans les conditions

de nos essais et pour les clinkers testés, contenant respectivement 15 % de  $C_3A$  cubique et 13 % de  $C_4AF$ , la phase  $C_3A$  (fig. 3) apparaît plus fragile que la phase  $C_4AF$ , plus déformable, qui fissure très peu sous les charges utilisées.

Les propriétés globales du clinker, matériau polycristallin, ainsi que celles de ses minéraux constitutifs, expliquent son comportement à la fragmentation qui a lieu suivant un processus à la fois de libération fissurale et de libération minérale : les fissures progressent respectivement à travers les cristaux, en particulier les cristaux de  $C_3S$  pré-fissurés, et le long des limites de phases (fig. 4). Les fissures de  $C_3S$  sont le plus souvent bloquées ou détournées au niveau de la phase interstitielle, généralement peu fissurée, (fig. 5). Les cristaux ou amas de  $C_2S$  sont contournés par les fissures jusqu'à un stade avancé de la fragmentation. Ces cristaux, de forme arrondie, relativement déformables et ayant une certaine "mobilité" (13) par rapport à la phase interstitielle (fig. 6) donnent lieu à une libération minérale type : des individus cristallins sont fréquemment retrouvés intacts en fin de broyage.

### 3. FISSURATION ET RUPTURE PAR CHOC THERMIQUE

Le choc thermique provoque des contraintes susceptibles d'entraîner la fissuration et la rupture des granules de clinker. Les contraintes sont dues au gradient de température, à l'anisotropie des contractions, aux transformations polymorphiques, aux différences de coefficient de dilatation entre phases. Le refroidissement plus ou moins brutal induit, dans le matériau, une énergie thermo-élastique qui se dissipe sous forme d'énergie spécifique de rupture  $\gamma_F$ .

Si l'énergie thermo-élastique dissipée par le champ de contrainte autour d'une microfissure préexistante est supérieure à  $\gamma_F$ , la fissure progresse et peut entraîner la rupture. Le caractère stable ou instable de la progression est déterminé par la taille de la fissure.

Pour les matériaux céramiques, HASSELMAN (14) a montré, à partir d'un modèle idéal représentant les conditions les plus favorables à la rupture, que le domaine d'instabilité était limité par deux valeurs critiques de la taille des fissures : la différence de

température critique provoquant la propagation en fonction de la taille des fissures passe par un minimum. L'application à un clinker donne la courbe de la figure 7. A partir des hypothèses suivantes applicables aux conditions industrielles :

- $\Delta T \approx 800 - 900^\circ\text{C}$ ,
- 1 fissure par cristal de  $\text{C}_3\text{S}$ , soit  $N \approx 10^7$  fissures par  $\text{cm}^3$ ,
- longueur des fissures  $\approx 30$  à  $50\ \mu\text{m}$ ,

on voit que les courbes obtenues sont proches des courbes de stabilité au-delà desquelles la différence de température  $\Delta T$  n'est plus suffisante pour amorcer la propagation des fissures. Donc à moins de répéter le choc thermique, la rupture des granules aura peu de chance de se produire. C'est ce qui est généralement observé : les granules sont plus ou moins microfissurés mais non rompus. Pour les petites fissures amorcées dans le domaine d'instabilité, le taux d'énergie élastique dissipée est supérieur à l'énergie spécifique de rupture. Lorsque ces fissures atteignent les longueurs correspondant aux courbes en traits pleins, elles possèdent encore de l'énergie cinétique et progressent jusqu'à une taille limite donnée par les courbes en pointillés, calculées d'après (14). La figure 7 montre, qu'il y aurait probablement intérêt à avoir des clinkers à petits cristaux : l'énergie spécifique de rupture serait plus faible et les microfissures plus petites, se trouveraient dans la zone de progression instable.

Fig. 7 : Différence critique de température  $\Delta T_c$  amorçant la propagation des fissures en fonction de la taille des microfissures (courbes en traits pleins). En pointillés, limites de propagation des petites fissures instables [calculées d'après (14)].

#### 4. RELATION ENTRE L'INTENSITE DU CHOC THERMIQUE, LA FISSURATION ET LA BROYABILITE DU CLINKER.

Des granules de clinker de 1 cm de diamètre ont été fabriqués à partir de deux crus industriels, par cuisson au four électrique à  $1450^\circ\text{C}$ , pendant 2 heures. La composition minéralogique moyenne des clinkers, référencés A et B, analysés par diffraction des rayons X, est donnée dans le tableau III.

Tableau III : Composition minéralogique moyenne des clinkers testés (refroidissement lent).

	$\text{C}_3\text{S}$	$\text{C}_2\text{S}$	$\text{C}_3\text{A}$	$\text{C}_4\text{AF}$
Clinker A	62 %	17 %	15,5 %	5,5 %
Clinker B	65 %	18 %	3,0 %	13,0 %

Les clinkers ont subi les refroidissements suivants :

- refroidissement lent ( $300^\circ\text{C.h}^{-1}$ ),
- trempe dans l'eau à  $20^\circ\text{C}$  à partir de  $1450^\circ\text{C}$ ,
- trempe dans l'eau à  $20^\circ\text{C}$  à partir de  $1250^\circ\text{C}$ .

L'état de fissuration en fonction de l'intensité du choc thermique a été observé au microscope optique sur section polie, attaquée à l'aide d'une solution de borax à 2 % dans l'eau. Deux types de fissuration ont été observés (15) : d'une part une fissuration macroscopique avec des fissures larges, radiales, traversant le granule et provoquant parfois sa rupture ; d'autre part, une fissuration microscopique qui se développe essentiellement dans les cristaux de  $\text{C}_3\text{S}$  et beaucoup plus rarement dans la phase interstitielle. La fissuration macroscopique est d'autant plus importante que le choc thermique est intense. Mais paradoxalement, la fissuration microscopique est d'autant plus faible. Ainsi dans les clinkers trempés à  $1450^\circ\text{C}$ , la fissuration macroscopique est maximale, mais la fissuration microscopique y est minimale (fig. 8 et 9) ; les granules du clinker A, riche en  $\text{C}_3\text{A}$ , étaient fréquemment rompus en plusieurs fragments tandis que les granules du clinker B, riche en  $\text{C}_4\text{AF}$ , avaient mieux résisté au choc thermique vraisemblablement en raison du comportement moins fragile de la phase ferritique.

La trempe à l'eau à partir de  $1250^\circ\text{C}$  provoque une fissuration macroscopique faible, les granules sont entiers. Par contre, ce mode de refroidissement entraîne la fissuration microscopique la plus forte (fig. 10).

Le refroidissement lent ne provoque pas de fissuration macroscopique et la fissuration microscopique est intermédiaire.

Ce comportement du clinker au choc thermique est en relation avec les propriétés particulières de  $\text{C}_3\text{S}$ , notamment avec son indice de fragilité relativement élevé. Les fissures qui s'y produisent sont dues aux différences entre son coefficient de dilatation et celui de la phase interstitielle, et à l'anisotropie de ses contractions. Le tableau IV donne les coefficients de dilatation thermique de  $\text{C}_3\text{A}$  et  $\text{C}_3\text{S}$ , déduits des données cristallographiques (16,17).

Tableau IV : Coefficients de dilatation thermique mesurés de  $\text{C}_3\text{S}$  et de  $\text{C}_3\text{A}$  ( $10^{-6}.\text{C}^{-1}$ ).

$\text{C}_3\text{S}$ Triclinique 20-980 °C	$\text{C}_3\text{S}$ Trigonal 1050-1100 °C	$\text{C}_3\text{A}$ Cubique 20-1000 °C	$\text{C}_3\text{A}$ Orthorh. 500-1000 °C
$\alpha_a$ 10,2			
$\alpha_b$ 7,0	$\alpha_b$ 8,7	$\alpha$ 8	$\alpha_{ab}$ 9,7
$\alpha_c$ 13,9	$\alpha_c$ 49		$\alpha_c$ 13,2

Fig. 8 : Clinker A - Trempe à 1450 °C. Fissuration macroscopique forte.

Fig. 9 : Clinker A - Trempe à 1450 °C. Fissuration microscopique faible.

Fig. 10 : Clinker A - Trempe à 1250 °C. Fissuration microscopique forte.

Quand la trempe intervient à 1450 °C, la phase interstitielle se solidifie sous forme d'un verre. Les variations de volume et les différences de coefficient de dilatation entre le verre et  $C_3S$  sont plus faibles. Il en est de même pour les contraintes subies par le silicate qui se fissure moins. En outre, une partie de l'énergie élastique, qui dépend entre autre du module de YOUNG  $E$  (plus faible aux températures élevées), se dissipe en raison du comportement viscoplastique du matériau avant sa solidification complète. Par ailleurs, la présence d'un verre vraisemblablement plus fragile, associée à une énergie thermo-élastique néanmoins élevée, entraîne la propagation instable très rapide des fissures, jusqu'à la rupture des granules. L'excès d'énergie est dissipé sous forme d'énergie cinétique et d'énergie acoustique. L'énergie théorique consommée par la rupture des granules et la fissuration des cristaux dans les conditions de l'essai, est alors de l'ordre de 1 Joule, l'énergie théorique disponible étant d'environ 3 à 4 Joule.

Lorsque la trempe a lieu vers 1250 °C, température à laquelle la phase interstitielle est déjà cristallisée, les contraintes subies par  $C_3S$  sont maximales. L'énergie thermo-élastique disponible n'est plus suffisante pour provoquer la rupture complète des granules. L'énergie théorique consommée par la fissuration des cristaux de  $C_3S$  est du même ordre de grandeur que l'énergie thermo-élastique disponible. Les cristaux de  $C_3S$ , très fragiles, constituent des points d'amorçage de fissures privilégiés qui absorbent une grande partie de l'énergie. Les possibilités de fissuration de la phase interstitielle et la rupture des grains de clinkers sont ainsi limitées.  $C_3S$  joue le rôle de concentrateur de contraintes ; sa microfissuration empêche la propagation lointaine des fissures, l'énergie thermo-élastique étant diffusée dans toute la masse du granule.

Les tests de broyabilité, effectués à l'aide d'un microbroyeur à résonance DANGOUMAU sur les deux clinkers A et B et pour les trois modes de refroidissement, indiquent que les clinkers les plus microfissurés sont les plus broyables. Les résultats sont illustrés par la figure 11 qui montre l'évolution de la surface spécifique Blaine en fonction du temps de broyage. Dans tous les cas, les clinkers trempés à partir de 1250 °C possèdent la meilleure broyabilité. L'effet est le plus marqué sur le clinker A riche en  $C_3A$ , minéral relativement plus fragile et plus sensible au choc thermique que  $C_4AF$  abondant dans le clinker B. Les différences de broyabilité entre les clinkers trempés à partir de 1450 °C et les clinkers refroidis lentement sont peu importantes.

Fig. 11 : Finesse Blaine des clinkers A et B, en fonction du temps de broyage.

Ces essais montrent qu'il doit exister pour chaque clinker une température optimale de trempe, qui entraîne une microfissuration maximale de la phase  $C_3S$  avec augmentation corrélative de la broyabilité. Cette température est voisine de la température de solidification de la phase liquide. Les chocs thermiques à très haute température ne semblent pas apporter d'amélioration notable de la broyabilité dans les conditions de nos essais.

## 5. CONCLUSIONS

Le comportement du clinker à la rupture est déterminé par deux paramètres intrinsèques au matériau :

- l'énergie spécifique de rupture  $\gamma_F$  (environ 12 à 22 J.m<sup>-2</sup>),
- la taille des microfissures préexistantes, du même ordre de grandeur que celle des cristaux de C<sub>3</sub>S.

La connaissance de ces paramètres et leur utilisation dans le cadre de la mécanique de la rupture peuvent fournir une explication au mauvais rendement du broyeur à boulets aux stades avancés du broyage.

Le comportement du clinker à la rupture dépend aussi des propriétés particulières de ses minéraux constitutifs. Leurs  $\gamma_F$  sont dix à vingt fois plus faibles que celles de l'agrégat polycristallin. Leurs indices de fragilité mesurés sont : 4,7 pour C<sub>3</sub>S ; 2,9 pour C<sub>3</sub>A et environ 2 pour C<sub>2</sub>S et C<sub>4</sub>AF.

La grande fragilité de C<sub>3</sub>S explique le comportement du clinker au choc thermique. La trempe à 1450 °C, lorsque le clinker est pâteux, induit une microfissuration faible de C<sub>3</sub>S. Elle provoque l'apparition de fissures macroscopiques et la rupture des granules. La trempe à 1250 °C donne une microfissuration importante de C<sub>3</sub>S, qui concentre une grande partie des contraintes empêchant la rupture des granules. Cela se traduit par une augmentation de la broyabilité alors que la trempe à 1450 °C n'apporte pas d'amélioration sensible.

Les essais et résultats rapportés ici ne sont qu'une première tentative d'interprétation, à l'aide de la mécanique de la rupture, du comportement du clinker à la fragmentation. Ils devront être largement complétés et précisés par la suite.

**Remerciements :** Nous adressons nos plus vifs remerciements au Prof. C. HUET et à M. VALAKOON qui nous ont permis de réaliser les premières mesures d'énergie spécifique de rupture du clinker.

Nous remercions également Catherine PEYRE et Françoise MOINE pour leur participation à ce travail.

# The effect of $\text{Al}_2\text{O}_3$ , $\text{BaO}$ and $\text{B}_2\text{O}_3$ admixtures on $\text{C}_3\text{S}$ structure

## *L'effet des additions $\text{Al}_2\text{O}_3$ , $\text{BaO}$ et $\text{B}_2\text{O}_3$ sur la structure du $\text{C}_3\text{S}$*

W. KURDOWSKI, Research Center of the Industry of Binding Materials, Krakow,  
M. HANDKE, G. SIEMINSKA, School of Mining and Metallurgy, Institute of Materials Science,  
Krakow, Poland.

RESUME : On a étudié, à l'aide des rayons X, transformée de Fourier et IR, des échantillons de silicate tricalcique avec une petite addition de  $\text{Al}_2\text{O}_3$ ,  $\text{BaO}$  et  $\text{B}_2\text{O}_3$ .

Les études ont été exécutées sur les échantillons avec l'addition d'un seul oxyde, ainsi qu'avec la combinaison de deux oxydes :  $\text{Al}_2\text{O}_3 + \text{BaO}$  et  $\text{Al}_2\text{O}_3 + \text{B}_2\text{O}_3$ , dans des proportions variées.

On a trouvé que dans la solution solide  $\text{C}_3\text{S}-\text{Al}_2\text{O}_3$  ce n'est que l'aluminium en coordination tétraédrale qui peut stabiliser la forme  $\text{T}_{\text{II}}$  et que l'introduction du cation Ba dans la solution solide provoque une transformation des octaèdres  $[\text{AlO}_6]$  en tétraèdres  $[\text{AlO}_4]$ .

Le cation Ba remplace dans le réseau  $\text{C}_3\text{S}$  seulement le cation Ca qui n'est pas coordonné par les tétraèdres  $[\text{SiO}_4]$ . De très petites quantités de l'addition de  $\text{B}_2\text{O}_3$  décomposent  $\text{C}_3\text{S}$  en  $\beta-\text{C}_2\text{S}$  et  $\text{CaO}$ , et en solution solide  $\text{C}_3\text{S}-\text{Al}_2\text{O}_3$ .

SUMMARY : The tricalcium silicate samples with small admixtures of  $\text{Al}_2\text{O}_3$ ,  $\text{BaO}$  and  $\text{B}_2\text{O}_3$  were investigated by X-ray diffractometry and Fourier Transform IR spectroscopy.

The studies were performed on samples with single oxide admixture and also with double :  $\text{Al}_2\text{O}_3+\text{BaO}$  and  $\text{Al}_2\text{O}_3+\text{B}_2\text{O}_3$  in different ratio. It was found that in  $\text{C}_3\text{S}-\text{Al}_2\text{O}_3$  solid solution only tetrahedral coordinated aluminum can stabilize  $\text{T}_{\text{II}}$  form, and when Ba cations are introduced into solid solution,  $[\text{AlO}_6]$  octaehdra are transformed into  $[\text{AlO}_4]$  tetrahedra.

The Ba cation replaces only the Ca cation noncoordinated by  $[\text{SiO}_4]$  tetrahedra in  $\text{C}_3\text{S}$  lattice. Very small quantity of  $\text{B}_2\text{O}_3$  admixture decomposes  $\text{C}_3\text{S}$  into  $\beta-\text{C}_2\text{S}$  and  $\text{CaO}$  as well as  $\text{C}_3\text{S}-\text{Al}_2\text{O}_3$  solid solution.

## INTRODUCTION

The production technology of rapid hardening high strength cements requires some modifications in the classical methods of clinker production. One of the directions in which changes should go, consists in using admixed metal oxides introduced into charge during clinker production. The effect of these admixtures has been studied by many authors [1,2,3,4]. They have confirmed the real effect of the admixtures on different properties, for example on clinker hydraulic activity. Presence of the admixtures in the clinker changes structure and texture i.e. defects of clinker phase crystals, modification of crystal habit and size, stabilization of defined polymorphs of di- and tri-calcium silicate, appearance of new phases including admixtures. The action mechanism of admixtures, and especially the correlation between the character of the component and clinker properties, have not been satisfactorily investigated as yet.

The barium oxide is one of the additions advantageously modifying clinker properties, as has been shown by Kurdowski [5]. The purpose of our work was to investigate the effect of the BaO and  $B_2O_3$  admixtures on the  $C_3S$  structure as well as on the  $C_3S-Al_2O_3$  solid solutions. The Portland clinker is a species of very complicated mineral composition. In order to simplify the studies, we have investigated only one but, in our opinion, the most important one of clinker components, which is  $C_3S$ .

The infrared absorption spectroscopy has been used as a main method. This method, as opposed to diffraction method, allows to infer about short range order. X-ray diffraction was used as the phase identification method and as the confirmation of some conclusions resulting from the infrared absorption spectra.

## EXPERIMENTAL

Two sample series were prepared. The first was pure  $C_3S$  with admixed 0,037 - 2,5 mole % BaO and 0,034 - 0,625 mole %  $B_2O_3$ . The second was  $C_3S$  including 0,25, 1 and 5 weight %  $Al_2O_3$  to which different quantities of BaO or  $B_2O_3$  were introduced. The samples of the first series have been prepared as follows: to the stoichiometric mixture of the  $CaCO_3$  and  $SiO_2$  the corresponding quantity of the water solution of  $Ba(NO_3)_2$  or  $H_3BO_3$  has been added. These water suspensions were dried at  $100^\circ C$  and then in the platinum crucible were decalcinated at  $1000^\circ C$  and next heated several times at  $1550^\circ C$ . The samples of second series have been prepared similarly. The additions of the BaO and  $B_2O_3$  were introduced to previously prepared  $C_3S-Al_2O_3$  solid solution. Syntheses were controlled using X-ray patterns and infrared spectra of the synthesized samples.

Infrared absorption spectra were obtained through application of Fourier Transform Spectrometer FTS-14 Digilab. The application of optimum measurement parameters and double precision of the spectra calculations from the interferograms resulted in a very high signal to noise ratio in measurements. This allows to interpret the very small changes of the spectra.

## RESULTS AND DISCUSSION

Figure 1 and 2 show the medium and far infrared spectra of the  $C_3S$  including Ba /fig.1/ and B /fig.2/ admixtures. The admixture concentration is given in mole percentage; 1 mole corresponds to the 0,04 mole of BaO or 0,02 mole of  $B_2O_3$  for 1 mole of  $3CaO \cdot SiO_2$ .

One can notice in these spectra that the increase of the admixture concentration causes the change of the intensity and half-bandwidth of some bands. At first the intensity of the  $815\text{ cm}^{-1}$  band which is characteristic for symmetric stretch vibration of

Fig. 1. FIR and MIR spectra of the  $C_3S$  samples with BaO admixtures

Fig. 2. FIR and MIR spectra of the  $C_3S$  samples with  $B_2O_3$  admixtures

the Si - O bond in  $C_3S$  is changed. This intensity changes from 2,45 to 1,15 /relative units/ for the samples with  $B_2O_3$  admixture and 2,9 to 1,2 with BaO. In the case of  $B_2O_3$  series simultaneous increase of the  $847\text{ cm}^{-1}$  band intensity is observed. This band is very intense in the  $\beta$ - $C_2S$  and  $\alpha'$ - $C_2S$  spectra. Intensity of this band increase from 62 to 79 /relative units/. For the BaO series intensity of this band is the same within the limits of error.

The different role of both BaO and  $B_2O_3$  admixtures is illustrated on the figure 3 which shows the dependence of the

Fig. 3. The correlation between  $815\text{ cm}^{-1}$  band intensities and admixture concentrations

$815\text{ cm}^{-1}$  band intensity on the concentration of barium and boron admixtures in the  $C_3S$ . For boron these changes are rectilinear and for barium hyperbolic.

As the  $815\text{ cm}^{-1}$  band is characteristic only for  $C_3S$ , therefore from figure 3 the conclusion can be drawn that barium ions are introduced partially in the  $C_3S$  structure and any presence of the boron ions decomposes this structure on  $C_2S$  / $847\text{ cm}^{-1}$  band/ and CaO. This conclusion is confirmed by the X-ray patterns and agrees with the findings of other authors. The comparison of the half-bandwidths in the medium infrared, therefore the bands resulting from  $[SiO_4]$  tetrahedra vibrations /6/, allows to confirm that it changes only in the case of  $B_2O_3$  admixture. This fact shows that barium ions introduced in the  $C_3S$  lattice do not disturb essentially the crystal structure and the position of the  $[SiO_4]$  tetrahedra.

The analysis of the far infrared spectra, and therefore the range characteris-

ties for the lattice vibrations indicates that the increase of the Ba ions concentration in the  $C_3S$ , does not cause the change of the band intensities but the width of the bands below  $300\text{ cm}^{-1}$  changes. According to the assignment of these bands [6] the change of their shape indicates that barium ions substitute the calcium ions. As the substitution of barium ions does not change the  $[SiO_4]$  band width we can conclude that the barium cations substitute mainly these calcium cations which are not coordinated with the  $[SiO_4]$  tetrahedra oxygens.

The far infrared spectra of the samples with  $B_2O_3$  confirm completely the previous conclusion that the presence of the  $B_2O_3$  decomposes the  $C_3S$  structure. At the higher concentrations of the  $B_2O_3$ , the spectrum is only a superposition of the  $C_3S$  and  $\alpha'$ - $C_2S$  spectra what results from the computer subtraction of the spectra. This conclusion is in accordance with Miroea [7].

The problem of the  $Al_2O_3$  dissolution in the  $C_3S$  structure and the influence of this admixture on the structure and properties of the  $C_3S$  is very important from the cement chemistry point of view because  $Al_2O_3$  is always present in allite phase in the Portland cement clinker. This was studied by many authors and for example Bigare et al. [8] has confirmed that in the  $C_3S$  structure up to 1,2 weight %  $Al_2O_3$  is dissolved, and at the concentration above 0,4 weight % this admixture stabilizes  $T_{II}$  form of  $C_3S$ . Further concentration increase of  $Al_2O_3$  decreases the  $C_3S$  polymorphic transition temperatures what was shown by Hahn, Rysel and Woereman [9]. Butt, Timashev and Kaushanskij [10] have confirmed that up to 0,3 weight % of  $Al_2O_3$ , aluminum cations substitute only the calcium ions and they have the coordination number of 6; at the higher concentration, aluminum cations with the coordination number of 4 substitute silicon cations. The introduction of aluminum ions causes defects of the  $C_3S$  lattice and, in consequence, the increase of its hydraulic activation.

Fig.4. FIR and MIR spectra of the  $C_3S$  samples with  $Al_2O_3$  admixtures : 1.-0,25 ; 2.- 0,5 ; 3.- 1 and 4.- 5 mole % of  $Al_2O_3$

On the figure 4 the medium and far infrared spectra of the  $C_3S - Al_2O_3$  solid solutions are shown. It is easy to see that up to 1 mole % /0,45 weight %/ no great changes in the spectra appear. Exceeding this value results in a sharp change of the spectra connected with the stabilization of the  $T_{II}$  form. By comparing the spectra of the  $T_{II}$  form stabilized by another addition / $MgO$ ,  $ZnO$ /, it is possible to notice that both the mechanism of the  $Al_2O_3$  stabilizing action differs, and the structure of this form is slightly different, the stabilizing properties being shown by the aluminum ions with tetrahedral coordination.

The purpose of the next step of our investigations was to learn how the double admixtures  $Al_2O_3 + BaO$  and  $Al_2O_3 + B_2O_3$  act upon the structure of  $C_3S$ . Figure 5a,b,c and 6a,b,c show the medium and far infrared spectra of the samples containing different quantities of the  $Al_2O_3$  and  $BaO$ . In the series with 0,25 mole % of the  $Al_2O_3$  no great changes of the spectra accompanying the increase of  $BaO$  concentration, are observed /compare fig.5a and 6a/. The only observed change is the broadening of bands indicating the increase of the defecting of the  $C_3S$  crystal lattice. In the spectra of the

Fig.5. MIR spectra of  $C_3S-Al_2O_3$  solid solutions with BaO admixtures. A-0,25 mole%  $Al_2O_3$  + : 1 - 0,5 weight %, 2 - 1 weight %, 3 - 4 weight % of BaO. B - 1 mole %  $Al_2O_3$  + : 1 - 0,5 w.%, 2 - 1 w.%, 3 - 4 w.% of BaO. C - 5 mole %  $Al_2O_3$  + : 1 - 0,5 w.%, 2 - 1 w.%, 3 - 4 w.% of BaO.

Fig.6. FIR spectra of  $C_3S-Al_2O_3$  solid solutions with BaO admixtures. The concentrations as on figure 5.

next series /compare fig.5b and 6b/ with the increase of the BaO concentration we can observe important changes and for example in the case of the 4 weight % BaO the spectra are identical with the ones of the  $T_{II}$  form, in spite of the fact that the quantity of the single  $Al_2O_3$  and BaO in the sample was insufficient for stabilization

of this form. In this case cooperation of both admixtures is observed. The mechanism of this cooperation can be explained by dislodging the aluminum ions by the barium ions from the calcium sublattice to the  $[SiO_4]$  tetrahedra one. Due to this the quantity of the tetrahedral aluminum ions in the crystal increases up to the level suffi-

cient to the stabilization of the  $T_{II}$  form, because only the aluminum in the tetrahedral coordination has got stabilizing properties. In the case of 5 mole %  $Al_2O_3$  series, barium ions have been introduced to the  $C_3S$  lattice of the  $T_{II}$  form, not of  $T_I$  form /compare fig.5c and 6c/. In the spectra of these samples the disappearance of some bands is observed with the increase of BaO concentration, which means the increase of crystal symmetry of these solid solutions. By comparing the sample spectra of the 5 mole %  $Al_2O_3$  and 2,5 mole % BaO with the spectra of different polymorphs of  $C_3S$  it can be concluded that we have got now the spectrum of  $M_I$  form, which cannot be obtained by the stabilization of  $Al_2O_3$  admixture only. The cooperation of both  $Al_2O_3$  and BaO stabilizing admixtures here appeared. These conclusions have been confirmed by the X-ray patterns.

The same investigations were carried out on the effect of  $B_2O_3$  admixture / the same mole percentage as BaO / on the  $C_3S - Al_2O_3$  solid solutions. These investigations have shown that  $B_2O_3$  does not dissolve in the  $C_3S - Al_2O_3$  solid solutions, nor does it dissolve in the lattice of the pure  $C_3S$ , and similarly decomposes  $C_3S$ .

# Formation of syngenite during cement grinding

## *Formation de la syngénite au cours de broyage du ciment*

W. KURDOWSKI, Professor, Research Centre of the Industry of Binding Materials,  
Z. WELISZEK, Engineer, Research Centre of the Industry of Binding Materials, Pologne.

**RESUME :** On a observé la grande instabilité de la qualité du ciment obtenu dans un broyeur finisseur fonctionnant en circuit ouvert. Les variations des propriétés du ciment se manifestaient surtout par manque d'augmentation des résistances pour un accroissement de la surface spécifique de 3000 à 4500 cm<sup>2</sup>/g, ou même plus.

On a trouvé que cette instabilité résultait de la formation de syngénite au cours de la fragmentation du ciment dans le broyeur finisseur. La phase de syngénite se forme assez facilement dans le processus de broyage des clinkers riches en K<sub>2</sub>SO<sub>4</sub>, à la température de 80° - 160°C, en présence de la vapeur d'eau injectée dans le broyeur.

Les recherches effectuées donnent des conclusions permettant d'éviter la formation gênante de la syngénite.

**SUMMARY :** Well - marked instability of the quality of a cement obtained in the finish mill, operating in open circuit, has been observed. The variations of cement properties find expression chiefly in the lack of the increase in strengths with the growth of the specific surface of the cement from 3000 to 4500 cm<sup>2</sup>/g or even more.

It has been found, that this instability results from the formation of the syngenite during cement grinding in the finish mill. The syngenite phase forms rather easily in the grinding process of clinker with high K<sub>2</sub>SO<sub>4</sub> content, at the temperature of 80° - 160°C, in the presence of water vapour, originating from water injection into the mill.

Carried out investigations give the conclusions allowing to avoid the harmful formation of syngenite.

## INTRODUCTION

As is well known, in the modern, dry method of cement production a clinker with higher alkali content is obtained. In European raw mixes the content of potassium surpasses about three times the sodium content. The potassium content, mainly in the form of  $K_2SO_4$ , exceeds for the most part 1%, reaching sometimes 1.5%.

The manufacturing of cement from the clinker with such an amount of this component causes a number of problems. Through the strengths after 1 day of hardening increase, nevertheless the strengths after 28-days are lowered /1/. Furthermore the cement obtained from such a clinker is susceptible of syngenite formation during the storage of the cement in the silos, as was noticed by Nielsen /2/.

High early strengths of manufactured cements require rather high dispersion of the product. The installation Minipebs, designed by F.L. Smidth /Fig. 1/, makes a modern solution of the problem of cement grinding to high fineness.

Fig. 1 - Grinding system with the Minipebs mill. 1 - Unidan mill, 2 - Minipebs mill

This high capacity installation is equipped with a primary mill Unidan, which gives a cement having Blaine specific surface 3000-3200  $cm^2/g$  and with a finish grinding mill Minipebs, allowing to grind the cement to a specific surface as high as 6000  $cm^2/g$ .

With all unquestionable advantages of this grinding system, in the case of grinding the clinker with high  $K_2SO_4$  content large variations in the properties of obtained cement have been stated. The strength of mortars do not appear to increase or even is reduced with the growth of the specific surface of cement. This phenomenon is not observed when the cement is ground in a laboratory mill.

The results of examination of cements obtained from the same clinker in an industrial mill and a laboratory mill, are given in Table I. It should be noted, that the granulometric compositions of these two cements, one from the Minipebs mill and other from the laboratory mill, were similar /Table II/.

TABLE I		
Mill	Blaine specific surface, $cm^2/g$	Compressive strengths after 1 day, $N/mm^2$
Unidan	3400	13.5
Minipebs	4700	13.8
Laboratory	4700	20.2

TABLE II		
Particle size $\mu m$	Percentage by weight in the cement from mill	
	Minipebs	Laboratory
above 200	0.04	0.6
200 - 30	14.46	21.4
30 - 20	15.0	16.2
20 - 5	46.9	43.0
below 5	23.6	18.8

The examination of these cements has been carried out with DTA /Fig. 2/.

Fig. 2 - DTA curves. a/ cement from Minipebs mill, b/ laboratory cement, c/ cement with anhydrite

It has been found, that in a cement from Minipebs mill the calcium sulphate disappears with simultaneous appearance of the syngenite, which is characterized by an endothermic effect at the temperature 250° - 260°C, connected with removing of water molecule. In the case of the cement ground in a laboratory mill this effect is not observed.

This fact stimulated us to carry out adequate investigations tending towards better knowledge of this problem.

## LABORATORY INVESTIGATIONS

In conditions modelling the cement mill atmosphere the studies were carried out to determine the field of formation of the syngenite in a cement with increased  $K_2O$  content.

For these studies a cement ground in laboratory mill to a specific surface of about  $4500 \text{ cm}^2/\text{g}$ , from a clinker with chemical and phase composition and modular characteristics given in Table III.

TABLE III			
Chemical composition		Phase composition <sup>1/</sup>	
Content of the component in weight-percent			
Ign. loss	0.56	Free CaO	0.7
SiO <sub>2</sub>	22.44	C <sub>3</sub> S	58
Al <sub>2</sub> O <sub>3</sub>	4.96	C <sub>2</sub> S	10
Fe <sub>2</sub> O <sub>3</sub>	2.90	C <sub>3</sub> A	8
CaO	64.77	C <sub>4</sub> AF	9

K <sub>2</sub> O	1.23	Na <sub>2</sub> SO <sub>4</sub>	0.3
Na <sub>2</sub> O	0.15	K <sub>2</sub> SO <sub>4</sub>	1.2
Lime saturation factor		0.86	
Silica ratio		2.85	
A : F ratio		1.71	
<sup>1/</sup> Potential phase composition calculated with Newkirk formulas with the content of silicates modified by MgO /3/			

Also a further cement was prepared, which contained - instead of calcium sulphate dihydrate - the hemihydrate. SO<sub>3</sub> content in both cements was the same, 3.3%.

These cements were next exposed to the action of the air, the temperature of which varied in the range of 80° to 160°C and with water vapour content of 100 to 1200 g/Nm<sup>3</sup>. The presence of the syngenite was determined by DTA.

In this way the field of existence of the syngenite in given temperature range and humidity, reflecting the atmosphere which occurs in cement mill, was determined. This field is presented in Fig. 2.

It has been stated, that the syngenite exists in whole studied temperature range ; at the same time it has been found that the syngenite forms more easily in a cement containing calcium sulphate hemihydrate. Obviously the formation of the syngenite requires at least partial dehydration of the gypsum. Therefore at the temperature below 70° - 75°C the formation of this compound is not observed, even in the case of

very high humidity of the air.

Fig. 3 - Syngenite formation in cement depending on the temperature and water vapour content in the air. 1 - cement with calcium sulphate dihydrate, 2 - cement with calcium sulphate hemihydrate

With the increase of the temperature in the mill larger and larger amounts of gypsum are dehydrated. At the temperature of the order of 120° - 160°C, despite of appreciable dehydration of the gypsum, at low humidity of the vent air, the syngenite will not form, because of too lower water vapour pressure. This is why at higher temperatures a larger content of water vapour in the air is necessary for originating this compound.

Similar conditions will occur in the mill during hot clinker grinding, as in this case an injection of considerable amounts of water for cement cooling is required.

On the ground of a heat balance of the mill system the diagrams for both mills are drawn. /Fig. 3/ of the function

$$t_c = f/m, t_n/$$

where:

$t_c$  - the temperature of material leaving the mill,

$m$  - the amount of injected water,

$t_n$  - the temperature of feed material.

In the diagram prepared in such a way the field of existence of the syngenite has been plotted. In practice, the range of operation of the mill in dependence of given factors without deterioration of the quality of the product, makes a region between maximum permissible temperature of the cement leaving the mill, viz. 110°C, the range of the syngenite occurrence and dew-point, below which the water vapour will condense. In this last case, apart from syngenite, aluminate hydrates can be formed.

The temperature 110°C should be accepted as highest permissible temperature of the cement, as its surpassing will cause a false set of the cement during subsequent

storage. According to Nielsen /2/, as low temperature as 90°C influences negatively the properties of the cement during its storage.

Fig. 4 - Operating conditions of grinding system with Minipebs mill

#### CONCLUSIONS

It is evident from presented diagram, that for a temperature of cement leaving the Minipebs mill ranging from 90° to 100°C it is necessary to maintain the temperature of the feed 50° - 70°C. As during conveying the cement from the Unidan mill to the Minipebs mill it is hardly to expect the lowering of its temperature, that's just the temperature which should have the cement leaving the mill Unidan. In practice it can be obtained, when the temperature of clinker do not surpass 60°C.

In the case, when the clinker leaving the kiln is cooled in planetary coolers and there is no possibility to cool the clinker to such a temperature, it is necessary to install a cement cooler between the mills. Then the temperature of the clinker can be as high as 100°C.

The second solution of this problem consists in the intensification of ventilation of the Minipebs mill. For example a doubling of the amount of ventilation air increases the permissible temperature of the material entering the Minipebs mill to 90°C; this allows then to introduce to the Unidan mill a clinker 70° - 80°C /Fig. 5/.

Fig. 5 - Operating conditions of Minipebs mill with doubled amount of vent air

Another preventive measure consists in replacing of part of gypsum addition with the natural anhydrite. In this case the conditions for syngenite formation are missing. This was confirmed by DTA examination of the cement with addition of anhydrite /curve "c" in Fig. 2/, obtained in conditions, for which in the case of cement added with gypsum the syngenite forms easily.

## Processing characterization on the industrial scale cement production

### *Prévision de la qualité d'un ciment, en production industrielle*

S. TAKAGI, Doctor, Sc in Eng. Senior research chemist, Central research laboratory of  
Sumitomo Cement Co., Ltd.,

A. KAWASHIMA, Research chemist. Central research laboratory of Sumitomo Cement Co., Ltd.

RESUME : Le but de l'étude entreprise était de confirmer les bases de la prévision des qualités d'un ciment en précisant les relations entre d'une part les propriétés physiques et mécaniques du ciment, dans des conditions diverses, et d'autre part la composition du clinker et les conditions de cuisson de ce clinker. Il est bien connu que l'action des composants du clinker dépend du processus de la clinkérisation, principalement du gradient de température du four et de la vitesse d'échauffement des matières premières. A ce point de vue, une première étude des modifications intervenues dans la phase d'équilibre et dans la structure du clinker, a été faite.

Selon ces vues, il a été établi que l'on pouvait prévoir à l'avance, les propriétés physiques et mécaniques d'un ciment, en se basant notamment sur le processus de la clinkérisation et sur l'histoire thermique du matériau.

SUMMARY : The object of this experiment is to confirm the root of characterization by clarifying the correlation between the physical behaviour and burning condition of clinker from characterization of principal compounds in clinker at various cases of conditions.

It is well known that, the stational logic of principal compounds in clinker was depending upon clinkering process of rawmixes, mainly heating rate and temperature gradient in kiln. From this point of view, opening discussion of this character shift for the phase equilibrium and structural phenomenon in clinker was able to be developed under those results.

According to this consideration, the physical properties of cement in the future were able to be estimated by judging characterized phenomenon of clinker owing to operating condition in burning and the thermal history in clinkering rawmixes.

In this report the relation between the good quality of products depending upon operating conditions of kiln and shifting grade of character of principal compounds in clinker was discussed.

### Introduction.

In the cement industry, the most important property of portland cement is the mechanical behaviour that has been frequently controlled by chemical composition, volume weight, uncombined CaO content of clinker and others.

But it is certain that these indications are not related to the character of clinker such as composition and structure in a broad sense.

In this study, the strength behaviour of cement was discussed about existence of character shift from the state of principal compounds of clinker depending upon manufacturing conditions.

Consequently the improvement of the clinker burning and the estimation of quality of cement was possible on the basis of those described character data.

The results will contribute to the establishment of economical product of cement industry.

### Analysis of character.

The term "material characterization" means to make widely clear the composition, structure, and other described data of material in the system analysis.

Since the existence of a particular material is described as its character, its property will be shown by the characters.

In such consideration, the character of materials will show the property in past to future corresponding to the dimensions through the time and other factors.

Therefore, if it is possible to analyse the character of material, several properties of material will be estimated by means of character analysis.

In cement industry, according to characterization of clinker from this point of view, the production of controlled quality of clinker was possible to perform by consideration of the range setting with burning techniques.

From the fact that the character setting of clinker is closely correlated to different conditions in burning, the following three steps were considered in this approach.

First step was consideration of burning rate of clinkering process as maximum temperature, temperature gradient and temperature distribution in kiln.

The indicative character of clinker mainly consists of characteristic structure of each phase, degree of growth of crystallite phase such as habit, size and irregularity of silicate crystal with structural stoichiometry due to conditions of nucleation, reaction kinetics and solid solubility limits without burnability of used raw mixes.

The second step was consideration of cooling rate of clinker for outlet from maximum temperature zone of kiln.

In this case, it was found that the character shifting of principal compounds in clinker was closely connected with cooling history in kiln, phase transition phenomena by shifting of phase equilibrium, exsolution by solid solubility limit and others.

Third step was consideration of effect of rapid quenching for AQC outlet from kiln

outlet.

The character shifting was expressed by comparison of change of character among each step.

The good processing of cement making was possible to control according to the described character by characterization of clinker in clinkering process depending upon various kiln operating conditions, such as rotating velocity and scale of kiln, type and setting position of burner, quantity of fuel, temperature and pressure of oil, primary air condition and secondary air temperature, draft of kiln, O<sub>2</sub> content of kiln inlet, kiln bedding of raw mixes, operating conditions of AQC and others.

Figure-I shows the relation between the macro characters of principal compounds in clinker and those effective parameters.

Figure-I Characteristic character shifting under various making conditions of clinker.

The relationship between characters and properties in the principal compounds of clinker.

In unique properties of material, the source of property is divided into two media present derived from described character comprised of the statistical mean and the deviation from statistical mean in the composition and structure of materials (1).

Even if cement should be consisted of same components of the principal compounds, the compressive resistance may be ranged about 280 to 430 Kg/cm<sup>2</sup> at four weeks.

Recently the chemistry of cement has been advanced through the characterization of clinker (2)(3)(4)(5)(6) and its hydration products. (7)(8)(9).

In the relation of clinker character to property, П.Р. ЧУМАКОВ et al reported that if the habit of alite phase involved in clinker is more distinct, higher strength may be expected (10).

Furthermore, H.M.Sylla et al (11) showed that the higher strength was possible for the clinker quenched below temperature at 1200°C. Each report made very important suggestion of the character of clinker to property of cement.

Figure-2 shows that the strength property related to the macro character of principal compounds of clinker obtained from several points of view on the characterization.

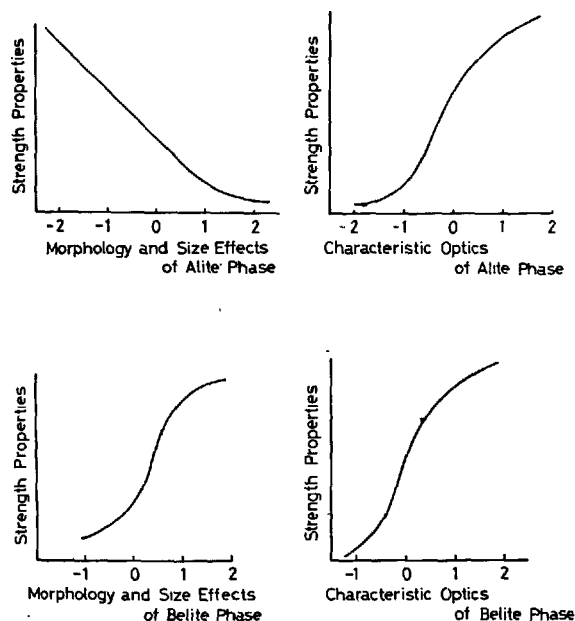

Figure-2 Correlation between the strength behaviour and character shifting of principal compound in clinker.

In the expression of the characters, they are divisible into two media about the type of description such as "value" and "pattern" in the composition and structure of clinker with which are difficult to deal.

For the latter, recognition by pattern was essential because of difficulty to express it by using the numerical value as shown in figure-2.

That is, by applying a graphical solution, the relationship of the distribution of each factors to the average value is able to be made clear.

The relation between the summation of described character and the strength properties of four weeks on the cement produced by conventional type of kiln and NSP is shown in the corresponding part of sigmoidal curve of figure-3.

Figure-3 Correlation between the compressive strength of four weeks and its summation of character in clinker.

From these results, economical efficiency will be able to be higher when the best condition for clinker making in which the resulting clinker has a constant level of character is established.

#### Conclusion

In this work, the relationship between characters and properties of cement under the processing of burning were shown. It was made up that the burning of clinkers with a high grade constant is possible to perform by controlling a number of operating conditions depending upon such characters of the clinker as composition, structure and other characters appeared in clinkering process.

It may be sure that, the burning technique on a base of such analysis by characterization contributes to the establishment of the operating condition.

RESUME : La chimie de l'hydratation du ciment portland à haute résistance aux sulfates et du ciment portland blanc, a été examinée jusqu'à deux heures d'âge à l'aide de plusieurs techniques instrumentales. Les comparaisons avec la chimie du ciment portland ordinaire ont été effectuées. Les différences qui sont observées sont discutées.

SUMMARY :The hydration chemistry of sulphate-resisting and white Portland cements up to two hours has been examined with the aid of a variety of instrumental techniques. Comparisons have been made with the chemistry of ordinary portland cement. Differences occurring are discussed.

## INTRODUCTION

Less is known about the hydration behaviour of sulphate-resisting Portland cement (SRPC) and white Portland cement (OPC) than that of ordinary Portland cement (OPC). In comparison with the latter SRPC contains very small quantities of  $C_3A$  (less than 3% generally) and WPC has very little iron-containing material (ferrite phase normally less than 1.5%). Such changes as have taken place in major constituents of these cements might well be expected to have distinctive effects upon early hydration behaviour.

SRPC clinker is made by burning calcareous and argillaceous raw material with iron oxide, and sometimes sand as well to give a satisfactory silica ratio. WPC clinker is produced from calcareous material and china clay (low in iron); because of the lack of sufficient iron containing material, which normally acts as a flux during burning, combination of the raw materials is more difficult. Higher burning temperatures than usual ( $\sim 1550-1600^\circ C$ ) are often necessary to achieve clinkering. As a result, WPC clinker frequently has a very low alkali content, caused by alkali loss through volatilisation, and higher free lime values than comparable OPC clinkers. Both SRPC and WPC clinkers are ground with gypsum to produce the finished cements. The general properties of these cements have been extensively described. (1,2,3).

In the present study, a number of production SRPC's, WPC's and OPC's have been hydrated for up to two hours and compared.

## EXPERIMENTAL

The SRPC's, WPC's and OPC's were each hydrated at a water:cement ratio of 0.5 (10g cement: 5 ml water) at ambient temperature in a glove box under nitrogen for reasons previously discussed (4,5). Samples of each cement were respectively hydrated for 5, 10, 15, 30, 60, 90 and 120 minutes. At the end of the allotted hydration period each sample was dried by quickly washing with AnalaR acetone thrice under suction, followed by storage in a vacuum desiccator over silica gel.

These hydrated cement samples together with specimens of the anhydrous cements were studied by differential thermal analysis (DTA) and infrared spectroscopy (IR). DTA was carried out by employment of simple conventional equipment that had chromel-alumel thermocouples attached to a Kent potentiometric recorder (6). Heating rates of  $20^\circ C$  per minute were utilised. Since ettringite was the most reliable hydration compound to quantify, it was determined quantitatively (6). IR was performed on a Unicam SP1200 infra-red spectrophotometer over the wavenumber range  $4000-400cm^{-1}$  using potassium bromide disc and Nujol mull media. Extensive band overlap precluded quantitative determination of major hydration components like ettringite. Some of these hydrated specimens were also examined by scanning electron microscopy (SEM) on a Cambridge Stereoscan instrument. The SRPC's were subjected to quantitative X-ray diffraction (QXRD) on a Philips instrument, primarily to elucidate the nature of the ferrite phase.

In addition, hydration of one of each of the SRPC's, WPC's and OPC's was investigated by conduction calorimetry (7). Samples were mixed externally with water at water:cement ratio 0.4 (15g cement in 6ml water) and the heat liberated during hydration was measured up to 45 hours.

Water consistency and setting time determinations of the cements were carried out by the British Standards method (8) and surface area measurements by the Rigidon modification of the Lea Nurse procedure.

## RESULTS

The DTA and IR data showed that less ettringite was formed at up to two hours hydration for the SRPC's and WPC's than for the OPC's examined. SEM revealed insufficient structure in the micrographs to make any definite conclusions. The quantitative DTA data is given in Table 1 and typical differential thermograms at two hours hydration are illustrated in Figure 1. Physical and chemical data for all twelve cements examined is depicted in Tables 2 and 3. The QXRD results for the SRPC's are shown in Table 4. Some useful solubility data has been quoted in Table 5. The results of the conduction calorimetric examination are illustrated for three cements (one of each type investigated) in Figure 2 and the data tabulated in Table 6.

## DISCUSSION

## a) SRPC's

The observation that the SRPC's reacted to form significant quantities of ettringite when their  $C_3A$  contents were very low, indicated that substantial quantities of ettringite were being formed from the ferrite phase by its reaction with lime and calcium sulphate. It was not known precisely how much of the ferrite phase had reacted at up to two hours, since XRD, whilst being able to identify the presence of ettringite, is not per se sufficiently reliable to determine accurately small changes in the quantities of the anhydrous clinker phases present at these early hydration times. Also, iron (III) substituted ettringite gives similar DTA, IR and XRD data to pure ettringite with which it readily undergoes solid solution. It is thus not possible at present to quantify independently ettringite arising from  $C_3A$  and ettringite formed from the ferrite phase. Further evidence for the involvement of the ferrite phase in early hydration is afforded by the greater quantities of ettringite formed by cements A and B in comparison with C and D together with changes in the hydralime contents. The former have higher free lime contents than the latter, which presumably gave a greater propensity for the ferrite phase to react. Cement A has a higher specific surface area and water soluble  $K_2O + Na_2O$  content than cements B, C and D, which might account for A giving the highest levels of ettringite of these SRPC's, even more than B.

A comparison of the hydration behaviour of cements B and C clearly points to the involvement of the ferrite phase in early cement hydration. These two cements (from the same Works) differ appreciably in free lime content, but have fairly similar values for  $SO_3$ , total and water soluble alkalis,  $C_3A$  and specific surface area. Significantly more ettringite was produced at all times from five minutes to two hours for cement B (free lime 1.9%) than for cement C (free lime 0.8%).

From the solubility data (Table 5) it might be thought that a higher free lime content should favour less ettringite being formed, because a high lime solubility coincides with low alkali and sulphate ion solubilities and vice versa. The presence of sulphate ions in solution should favour ettringite formation by being able to readily approach the surfaces of the aluminate material. However, for the ferrite phase to react to form ettringite, there must be adequate quantities of lime available, since, what might be considered as an iron (III) substituted  $C_3A$  system needs to react with lime to produce a  $C_3A$  aq hydrated system such as ettringite, when sulphate ions are present in the hydrating medium.

QXRD for these SRPC's (Table 4) gave higher  $C_3A$  values than the Bogue calculation method did.<sup>3</sup> Even allowing for the approximations contained in the latter, one reason for this is shown by evaluation of the %  $C_2F$  values from the ferrite present. In these cements the ferrite phase is not simply  $C_4AF$  but lies within the range  $C_4AF - C_6AF_2$ . Thus there is a lower aluminate content in the ferrite phase than if its composition were to have been  $C_4AF$ , and hence the true  $C_3A$  value is higher than that calculated by the simply Bogue approach.

#### b) WPC's

Consider now the WPC's E, F, G and H. These contain very little iron, hence the ferrite phase is negligible (0.8 - 1.4% for these cements according to the simple Bogue calculation in Table 4). All have low alkali (especially water soluble alkali) contents and relatively high free lime values as mentioned earlier.

Despite the fact that cements E and F had higher  $SO_3$  contents (2.6, 2.8% respectively) than the SRPC's (2.1 - 2.3%), this did not lead to more ettringite being formed. The low alkali levels of the WPC's meant that the solubility of lime increased whilst that of sulphate decreased (Table 5). Thus, less sulphate ions were available for reacting with  $C_3A$  and there was insufficient ferrite phase present to react with the lime and afford at least some degree of compensation for the effect of the lower sulphate ion solubility. Although the specific surface areas of these cements were very high, particularly for G and H, in no instance did the level of ettringite formation approach, let alone exceed, that for the OPC's I, J, K and L. This could only be attributed to the aforementioned effect of the lower water soluble alkali contents.

#### c) OPC's

For the OPC's I, J, K and L the effect of marked changes in  $C_3A$  and  $SO_3$  content were noticeable, but changes in free lime appeared to be less influential for ettringite formation than with the SRPC's and WPC's. Most ettringite was formed by cement I, which had highish  $SO_3$  and  $K_2O$  levels and a high  $C_3A$  content. Least ettringite was produced by cement L, which had a moderate  $C_3A$  content and low  $SO_3$ , water soluble ( $K_2O + Na_2O$ ) and free lime. Cement K formed slightly more ettringite than L at all ages examined; the  $SO_3$  and free lime were significantly higher, but the

water soluble ( $K_2O + Na_2O$ ) and  $C_3A$  were more comparable. Cement J produced even more ettringite than K, but the only significantly different factor noted was the higher  $Na_2O$  content.

The greater levels of ettringite formed from the OPC's on the one hand compared with the SRPC's and WPC's on the other appear to be due principally to the combined effects of higher  $C_3A$  and/or alkali (particularly water soluble)<sup>3</sup> contents. The higher the quantities of water soluble alkali are, the lower the solubility of lime and the higher the solubility of sulphate ions is. Thus more sulphate is readily available to react with  $C_3A$  and in consequence more ettringite is formed.

As previously observed (5,10) no direct correlation was apparent between degree of ettringite formed at these early hydration times and setting behaviour. This applied not only to the OPC's but to the SRPC's and WPC's as well.

#### CONDUCTION CALORIMETRY

All three cements types (SRPC, WPC, OPC) revealed an initial rapid heat evaluation. Such heat evolution has been generally attributed to arise from heat of wetting and free lime hydration, but recent work (11) had indicated that there is not in general a significant overall hydration of free lime immediately upon mixing Portland cements of different types with water. The major contribution to this peak appears to be hemihydrate to gypsum, hydration, the hemihydrate arising from gypsum decomposition during grinding of clinker with gypsum, although heat of wetting must also be a factor here.

The supplementary peaks, where present, (e.g. for the WPC E) are indicative of delayed reaction ensuing significantly after initial mixing has taken place. They are likely to be due to either extended heat of solution effects, or significant hydration of interstitial material ( $C_3A$ /ferrite) after initial mixing, or both.

The second major heat peak, which arises outside the early hydration period, but is included here for completeness, appears to be due largely to alite hydration (7, 11) and the points corresponding to the setting times can be observed near the base of the initial slope of this heat peak. For cement C a slight split was apparent in the second heat peak, which might well be due to the formation of significant quantities of C-S-H of a slightly different type, such as a higher polymer, at this stage of hydration.

No third major heat peaks were observed here, because the  $C_3A$  contents of the three cements were not high enough (not ~12% or more) to be independently observed under the experimental conditions employed.

Conduction calorimetry has thus been shown to be of use in assisting hydration studies of these three cement types.

#### CONCLUSION

Examination of the early hydration behaviour of a

number of commercial SRPC's and WPC's in relation to OPC's showed that less ettringite was formed at all stages with the SRPC's and WPC's investigated. This was related to the alkali levels, especially the water soluble alkalis,  $C_3A$ , ferrite and free lime quantities. Specific surface area per se did not appear to have a great influence upon ettringite formation with these SRPC's and WPC's.

#### ACKNOWLEDGEMENT

I wish to thank Dr. S.P. Varma for providing the QXRD data, Mr. M.J. Coole for the conduction calorimetric measurements and Mr. C. Zaris for experimental assistance.

# A study on the evaporation products of the liquid phase of a cement paste

## *Etude du produit de l'évaporation de la phase liquide d'une pâte de ciment*

P. KITTL, Researcher, Department of Materials (IDIEM), Chile.

A. GOLDSCHMIDT, Researcher, Microanalyse Laboratory, Geology Department, University of Santiago, Chile.

C.T.A. SUCHICITAL, Assistant Professor, Department of Materials Engineering, Federal University of São Carlos, S.P. Brazil.

RESUME : Les phases liquides de deux pâtes; l'une du ciment Portland commercial (CPC) et l'autre du  $C_3S$  ont été obtenues par pressage. La cristallisation de la phase liquide a été obtenue par séchage lent et étudiée par Microscopie Optique, Microscopie Electronique à Balayage et Microsonde Electronique. CH,  $CSH_2$ , KH, NH et des petites quantités de  $C_4ASH_{12}$ ,  $C_4ASH_{12}$  et  $C_6AS_3H_3$  ont été trouvés dans la phase solide résiduelle cristallisée provenant du ciment (CPC); de la même façon, du CH et du S ont été trouvés lorsque la phase solide résiduelle cristallisée provenait du  $C_3S$ . Nous supposons que  $C_3S$  se dissout, et que S par action pouzzolanique se transforme en CHS qui précipite avec le CH résiduel. Ainsi, le mécanisme d'hydratation du  $C_3S$  semble être principalement une dissolution-précipitation; il se produit dans l'hydratation du ciment CPC un mécanisme topochemique dont il résulte que la phase hydratée se développe directement à partir du clinker.

SUMMARY : The liquid phase of two pastes, one of a commercial Portland cement (CPC) and the other of  $C_3S$ , was extracted by pressing. Crystallization of the liquid phase was produced by slow-drying, and it was studied by Optical Microscopy, Scanning Electron Microscopy and Microprobe. CH,  $CSH_2$ , KH, NH and small quantities of  $C_4ASH_{12}$ ,  $C_4ASH_{12}$  and  $C_6AS_3H_3$  were found in the remaining crystallized solid phase arising from CPC, the presence of CHS was not detected; similarly, CH and S were found when the remaining crystallized solid was originated from  $C_3S$ . It is believed that  $C_3S$  becomes dissolved, and S, through a pozzolanic action transform in to CHS, which precipitates with the remaining CH. Thus the hydration mechanism in  $C_3S$  seems to be mainly a dissolution-precipitation, and in CPC it is the topochemical mechanism, which means that the hydrated phase grows directly from the clinker.

## INTRODUCTION

The contradictions among the two main theories for the hydration mechanism of a clinker - the Le Chatelier theory<sup>(1)</sup> defended mainly by Williamson<sup>(2)</sup> and by Dron et al<sup>(3)</sup>, and the Topochemical theory defend mainly by Kapranov<sup>(4,5)</sup> motivated the present study on the composition of the evaporation products of the liquid phase of a cement paste.

The hydration mechanism proposed by Le Chatelier implies a constant dissolution and precipitation, of the hydration products from a supersaturated solution. The Williamson idea is that this fact is due to an increase in temperature, since the hydration is an exothermic reaction. This mechanism requires that all the mass involved in the process of hydration, must dissolve and latter to precipitate. But, as it has been observed<sup>(2)</sup>, the hydration products are formed around the clinker particles, and this hydrated layer would immediately inhibit that hydration proceeds. Then, it becomes necessary to consider an incoming flux of water to the clinker-hydrated material interface, and an out-going flux from the dissolved clinker to the surrounding media (Fig. 1,1). The growth process would then take place in the water-hydrated material interface.

The topochemical mechanism sustains that hydration of the clinker particles is due to the penetration of the water molecules into the solid structure, through the already mentioned hydrated layer, and a dissolution of the soluble parts, leaving a silica structure. After reacting with CH this struc-

ture transforms into tobermorite (CHS), see figure 1,2. Even though the C, H and S proportions in tobermorite of the hydrated cement are variable, here it will be considered as CHS. The topochemical mechanism is then characterized by a chemical reaction leaving a silicate structure which then forms the insoluble, or very little soluble structure of the hydrated cement; this is also the phase which has the highest mechanical resistance.

The present work is a study on the solid phases obtained by evaporation of the liquid phase of cement pastes extracted by pressure, and the identification to the different associations present in such solid phases. The objective is to increase the learning understanding existing at present on the hydration mechanism of clinker.

## MATERIALS AND METHODS

The chemical analysis of the commercial Portland cement used is given in Table listed below.

TABLE			
Chemical Analysis of the Comercial Portland Cement			
Compound	%	Compound	%
CaO	63.27	K <sub>2</sub> O	1.01
SiO <sub>2</sub>	19.26	TiO <sub>2</sub>	0.65
Al <sub>2</sub> O <sub>3</sub>	5.55	Na <sub>2</sub> O	0.61
Fe <sub>2</sub> O <sub>3</sub>	2.88	MnO <sub>2</sub>	0.17
SO <sub>3</sub>	2.86	P <sub>2</sub> O <sub>3</sub>	0.10
MgO	1.97		

This cement was mixed with water, in ratio w/c=0.5, for 3 minutes and left to age 7 minutes and 24 hours. The liquid phase was extracted by pressing the mixture in a steel mold, collected, filtered and stored. For all these operations a plastic equipment was used.

As a comparison material practically pure C<sub>3</sub>S was used, employing the same preparation procedure as in CPC to obtain the liquid phase.

The samples were prepared by depositing an amount of the stored liquid in a scanning electron microscope sample holder, which was covered with platinum or with plastic. Such samples were then placed in a tightly closed desiccator to be dried. The evaporation residues, thus obtained

Fig.1. Mechanism of clinker hydration: (1) Le Chatelier model, (2) Topochemical model.

were then covered with a deposited layer of gold or graphite.

All the sample features were then analysed in a optical microscope (OM), scanning electron microscope (SEM) and with an electron microprobe (EM) following the usual techniques in each case.

Fig. 2. OM of the solid phase obtained by evaporation of the liquid phase of a CPC paste. The general background and the crystalline agglomerates can be observed.

Fig. 3. EM of the solid phase obtained by evaporation of the liquid phase of a CPC paste. The presence of Si can be noticed.

Fig. 4. EM of the solid phase obtained by evaporation of the liquid phase of a CPC paste. The presence of Al, in the same region as in Fig. 3, is distinguished.

Fig. 5. EM of the solid phase obtained by evaporation of the liquid phase of a CPC paste. If can be seen the presence of Ca in the same region as Fig. 3 and 4.

## RESULTS

In gneral, the samples from the CPC liquid phase, observed under the OM presented uniform background with some crystalline agglomerates (Fig.2) having in general, a needle or globular like appearance. Analysis the samples under the EM, the background shows an uniform and abundant distribution of

Fig. 6. SEM of the solid phase obtained by evaporation of the liquid phase of a CPC paste. Needle like agglomerates, probably of  $C_6AS_3H_{31}$  or  $C_4ASH_{12}$  can be noticed.

Fig. 8. An  $S(SiO_2)$  particle in a  $C(CaO)$  background. EM Electron Absorption.

Fig. 7. OM of the solid phase obtained by evaporation of the liquid phase of a  $C_3S$  paste. There it is shown large C deposits and a cracked media of Ca-Si.

K, Na, Ca and S, corresponding to  $KH$ ,  $NH$ ,  $CH$  and  $\overline{SCH}_{0.5}$  which are soluble, being K the most abundant one. These observations are in agreement with results already reported<sup>(5)</sup>. On the other hand, the agglomerates shows the associations Ca-S, Ca-Si-Al, Ca-Al (Fig. 3, 4, 5), some of them with superposition of K and Na, the Ca-Si association was nowhere seen. The crystalline formations were identified,

Fig. 9. EM of the solid phase obtained by evaporation of the liquid phase of a  $C_3S$  paste. The presence of Ca appears in the same region as in Fig. 8.

as reported before<sup>(5)</sup>, being gypsum ( $\overline{SCH}_2$ ) with some K and Na on them. Other precipitates containing S and Ca were found. Zones of needle like formation which presented the associations Ca-Al-S and Ca-Al-Si, which correspond probably to  $C_4ASH_{12}$ ,  $C_4ASH_{12}$  or  $C_6AS_3H_{31}$  (Fig. 6) also appeared.

For the samples obtained by evaporation of the liquid phase from  $C_3S$ , it was observed a cracked background and agglomerates of crystalline formations

Fig. 10. EM of the solid phase obtained by evaporation of the liquid phase of a  $C_3S$  paste. It can be seen the presence of Si in the same region as in Figs. 8 and 9.

(Fig. 7). An Em analysis revealed a background made up mostly of Si and C, and large agglomerate of C. In this background the Si appears in the form of particles, as can be seen by Electron Absorption Analysis (Fig. 8). In figures 9 and 10 can be seen that Si and Ca are not combined.

#### DISCUSSION

The basic hypothesis of this work is that if precipitation takes place during the hydration process of clinker, it will be reproduced during the slow evaporation of the liquid phase.

Regarding to the evaporation products arising from the liquid phase of the CPC paste, it is important to notice that the presence of the Ca-Si association which must correspond to tobermorite, was not detected. The lack of this CHS formations in the evaporation products indicates that the hydration process of CPC is the topochemical one, which means that the hydrated phase grows directly from the clinker.

Correspondingly, the evaporation products arising from the liquid phase of pure  $C_3S$  show the presence of isolated S and C. If the theory of Tadros et al.<sup>(6)</sup> is right, this fact indicates that an ulterior formation of SCH through the action of C on S will occur. Thus  $C_3S$  hydration involves dissolution precipitation and a puzzolanization process.

Latter on, the SCH inhibits dissolution and the topochemical process is then followed<sup>(6)</sup>. This mechanism has been confirmed through the morphology of the hydrated  $C_3S$ <sup>(7)</sup>, and it is quite probable that the hydration of  $C_2S$ <sup>(8)</sup> will be governed by the same above mechanism.

# On physicochemical foundations of hydration and setting of binding systems

## *Bases physico-chimiques de l'hydratation et de la prise des liants hydrauliques*

I.P. VYRODOV, Professor of Physics, Dr. of Chemistry, Head of Physics Department of the Krasnodar Polytechnical Institute.

RESUME : La formation topochemique de particules très dispersées, thermodynamiquement instables, et provoquant une sursaturation dans les pâtes de ciment, est l'idée principale de la théorie développée par l'auteur. Le processus, thermodynamiquement stable, de formation de nouveaux cristaux hydratés, s'effectue à la fois par une "distillation" à partir des phases homogènes anhydres, et par la coalescence de nouveaux composés, moins stables thermodynamiquement, qui se produisent à la surface des constituants en cours d'hydratation.

L'effet de destruction de ces croûtes de coalescence, qui retarde le processus topochemique, se manifeste statistiquement avec force dans la période initiale de la prise.

On estime que la formation de liaisons interparticulaires est commandée par le mécanisme de cristallisation de nouveaux composés et par l'action de forces auto-cohésives. On propose alors une méthode universelle d'évaluation de l'activité hydraulique d'un clinker, basée sur une loi exponentielle simple de l'hydratation des liants hydrauliques.

On a constaté une bonne corrélation entre l'activité hydraulique ainsi mesurée et la classification réglementaire des ciments.

SUMMARY : There has been developed a theory the main point thereof relates to a topochemical formation of high dispersive thermodynamically unstable particles causing oversaturation of cement mortars. Thermodynamically stable process of recrystallization of new formations is accomplished both by "distillation" through the homogenous phase and by coalescence of thermodynamically less stable new formations which occur on the surface of hydration.

Cooperative destruction effect of coalescent crusts which retard the topochemical process statistically occurs with strength drop at an early stage of the binding system hardening.

It is estimated that the formation of interparticle contacts is defined by the recrystallization mechanism of new formations and by action of autohesive-cohesive forces.

There has been offered a universal method of hydraulic activity evaluation, which is based on a common exponential law of binding systems hydration process. Correlation between the cement mark (grade) and its hydraulic activity has been determined.

The topochemical theory has mainly been discussed in detail by the author in his works / 1-8 /. According to the diagram primary hydration products formed as a result of said topochemical reactions are being dissociated due to their thermodynamic instability.

Upon reaching the saturation level of mortar relative to greater particles, the so-called critical particles (nuclei), the latter become also thermodynamically unstable. Process of further particle dissociation goes on and results in oversaturation towards more and more growing particles. It proceeds until thermodynamically stable nuclei are originated in the mortar by fluctuation. The nuclei growth promotes oversaturation relaxation and size increasing of critical nuclei. During the first stage of distillation there takes place degradation of particles with a poor crystal structure, while during the second

stage when the particles are distilled through the homogenous phase of the mortar, they are recrystallized with a proper atomic structure.

Evolution of oversaturated states has been complicated with processes of crust formation and of continuous fluctuating particle origination during the whole period of these oversaturated states. As to the intersecting processes of dissociation and coalescence of contacting particles they are taking place on the surface of reactions on the initial period of hydration. Coalescent formation of crust stimulates a quick saturation relaxation and establishment of the inductive period. Taking into account all peculiarities mentioned above the whole process before the absolute oversaturation relaxation is described by using a system of equations for the distribution function  $f(R, t)$  as well as oversaturation  $\Delta = C - C_{\infty} = \Delta C + \alpha/R / I/$ :

$$\frac{\partial f}{\partial t} + \text{div}_R (fR) = \phi = \left(\frac{\partial f}{\partial t}\right)_{\text{topochem.}} + \left(\frac{\partial f}{\partial t}\right)_{\text{fluct.}} \quad (1)$$

$$R = \frac{D}{Rd_k} \left( \Delta - \frac{\alpha}{R} \right), \quad (2)$$

where

$D$  - ion diffusivity in the mortar,

$\alpha_k$  - density of particles being crystallized,  $\alpha = \frac{G}{KT} V C_{\infty}$ ,

$G$  - specific interphase energy

$V$  - atomic volume

$k$  - Boltzman constant

$T$  - absolute temperature

Function  $f(R, t)$  is a fundamental property of the binding system evolution. According to its asymptotical behaviour it is possible to build up a theory concerning the binding system strength at the end of its hardening. It is possible to establish a strength drop moment  $t^*$  with the help of  $f(R, t)$ , although in practice specialists take interest in strength drop in connection with the technological conditions. This problem has already been solved with allowance for the size distribution function for the initial assumed particles of the binding system /6/. It is of importance to increase dispersity of the solid component as well as hydraulic activity of the binding system to stimulate

a strength (drop) when tycotropnoreversible macroproperties are being developed, i.e. during that period which is considered to be not dangerous for building up the strength. Oversaturation (t) is known to be of no less importance. Its behaviour has been thoroughly studied both theoretically /2,8/ and experimentally /9/. Formation of the coalescent crust which retards or sometimes (while breaking blockade) accelerates formation of oversaturated states / 8,10 / results in exhibiting periodical properties with a period depending upon crust porosity, hydraulic activity, ultimate watersaturation value of the topochemical surface as well as phenomenological coefficients / 6 /, see also / 3 /, vol.II, book 2, p.108.

While analyzing influence of f (R, t) upon strength formation / 6, II / one can

prove the exponential law of strength increment / 6 /:

$$\Delta R(t) = R_M - R(t) = R_M \exp(-Kt^n), \quad (3)$$

where

$R_M$  - mark value of strength

K - conversion constant, and as a rule  $n=1$ . Introducing the actual water-cement ratio  $X = W/C$  / 11,13 / into this formula one can get the general formula of strength:

$$R = \eta_1^* X (\alpha + X) (\eta_2 + X)^{-2} (1 - \exp(-Kt)), \quad (4)$$

where value of parameters  $\alpha$ ,  $\eta$  are revealed in the works / 12-14 /.

The semiphenomenological consideration of other strength characteristics such as porosity introduced into the formulae like /4/ provides the proper coincidence both experimental and theoretical data / 2,15,16 /.

As yet no structure of pores and anisodesmicity of the particles shape has been considered by us. It is possible to build up a quantitative theory for such systems by way of introducing the divergent item into / 3 / which takes into account the particle growth along the fibres as well as an extra equation like / 2 / to show direction of the particle growth.

Cohesive and autohesive-cohesive links of the fibres to be inosculated develop strength not only by direct inoscultation but also by-side reactions namely by reinforcement of the residual solid mass of the cement stone. While these two functions of fibres are being atrophyed, the stone strength characteristics are transferred to the continuum wherein a relict function of crack fibre extinguishing is realized with a number of cracks decreased; the latter are developed in the continuum of the cement mortar and are come out along direction of the fibre localization / 11 / either by conveying energy of cracks to the place of fibre accumulation, or by formation (and coalescence) of cavities in this region. Brittle destruction common to the continuum is thus transformed into viscous at the expence of the static distribution of fibre accumulations.

Let us concern one more molecular-kinetic aspect of the theory - physicochemical foundations of the concrete thermal processing. It has already been noted in our work / 17 / that the most intensive energy transformation of autohesion of quartz fibres occurs in the temperature range of 20-40°C, its saturation point is at 90°C. This value

is valid for all or nearly all interparticle interactions in the cement stone and concrete. Therefore thermal conditions of concrete processing should provide the permissible quantity of the mass that failed to react. This quantity by the moment when the maximum temperature of concrete is achieved can result in allowable decrease of strength by partial destruction of formed contacts being highly saturated due to autohesion energy  $W_a = W [T(t), t]$ .

As far as the experimental data are approximated by exponential functions  $W_t(T) \sim T^n$ ,  $W_m(t) \sim t^n$  one can find a link between optimum time of concrete thermal treatment  $t_0$  at upper  $T = T_M$  and physicochemical parameters-factors of concrete strength / 17 / by way of converting energy variation of autohesion into zero:  $\delta W_a = 0$ . The given results

are in accordance with those presented by M. Venua / 18 / at VI Congress, they refer to dependence of concrete compression strength upon steaming temperature.

Experimental data on hydration processes and setting of binding systems show that the quantity of reacting component mass  $m(t)$  and hydration rate are linked by ratio:

$$1 - \beta(t) = \frac{m(t)}{m_0} = \exp(-kt^n) \quad (5)$$

Conversion constant in ratios /3-5/ reflects the system activity, it can therefore be chosen as a base upon standardization (unification) of a notion concerning hydraulic activity  $\gamma$ . For this purpose time of relaxation  $\tau$  is introduced. After this period  $m(\tau) = e^{-1}$ . Hence,  $\beta(\tau) = 1 - e^{-1} = 0.632$  and  $K = \tau^{-n}$ . Thus we approach the definition of hydraulic activity  $\gamma = K$  according to the formula:

$$\gamma = K = \tau^{-n} \quad (6)$$

Thus taking time  $\tau$  which characterizes hydration rate of the system  $\beta = 0.632$ , one can find the numerical value of hydraulic activity  $\gamma$ . This value can also be estimated either by kinetic data forming direct relationships in  $\ln \frac{m}{m_0}(\Delta t)$  from  $\Delta t$  or by using  $R(\tau) = 0.632 R_M$ . Hence, the cement grade being determined by value  $R_M$  is directly linked with its hydraulic activity ( $\gamma = \tau^{-1}$ ). If

$$\frac{\Delta R}{R_M} = e^{-K_R t} = e^{-K_m t} = 1 - \beta(t) \quad (7)$$

it is easy to get  $R(\tau) = (1 - e^{-K_R/K_m}) R_M$ . It points to the correlation of the given values. Correlation between values of  $K_R$  and  $K_m$  is indicated by the fact that the binding system belongs to one of three groups / 5 /. These groups and the definition of the binding system / 5,8 / reflect the fundamental properties of heterogenous systems which involve required and sufficient conditions for exhibiting adhesive properties of the system. All this taken into account will reveal perspectives of the general systematics and prediction of the binding systems.

## Some applications of infrared spectroscopy in the fields of cement and concrete

### *Quelques applications de la spectroscopie infrarouge dans les domaines du ciment et du béton*

Surendra Nath GHOSH, Ph. D. Cement Research Institute of India.

RESUME : L'étude passe en revue des travaux que l'auteur et ses collègues ont faits dans le domaine des applications de la spectroscopie infrarouge (IR) au ciment et au béton. La technique IR a été employée avec succès pour identifier et caractériser des roches, des minéraux et des produits qui s'y rapportent. On y traite des méthodes de détermination de la magnésie dans les calcaires et du quartz  $\alpha$  dans les briques siliceuses cuites. A l'aide de l'IR, l'on peut évaluer qualitativement l'aptitude d'un cru à la fabrication de ciment Portland. Le spectre IR d'un cru étant caractéristique, le mode d'emploi éventuel de l'IR pour déterminer la proportion relative des silicates est indiqué. En employant cette technique, le processus de l'hydratation du ciment "Porsal" a été étudié. Des applications aux domaines des bétons de polymères à la corrosion du béton, à l'appréciation des granulats et à la carbonatation et à l'hydratation du ciment sont relatées. En outre, sont indiquées les possibilités d'application de l'IR à l'analyse des gaz du four et à l'étude des problèmes concernant les spectres d'états solides.

SUMMARY : The paper reviews the work done by the author and his colleagues in the field of applications of IR spectroscopy in cement and concrete. The IR technique has been used successfully in the identification and characterization of rocks, minerals and products which are related. Methods for estimation of dolomite in limestone and  $\alpha$ -quartz in fired silica bricks have been discussed. The burning of an OPC raw meal can be evaluated qualitatively by IR. The IR spectrum of an OPC is characteristic and the possible use of ascertaining the relative proportion of silicate phases has been given. The hydration behavior of "Porsal" cement has been studied by this technique. Applications to the areas of polymer-concrete, concrete-corrosion, aggregate-evaluation, carbonation and hydration of cement, etc. have been referred. Finally, the problems in dealing with solid state spectra have been touched besides indicating the possible application of IR in the analysis of kiln gas.

## INTRODUCTION

This paper reviews the work done by the author and his colleagues in the field of applications of Infra-red spectroscopy (IR) in cement and concrete since 1973. The IR technique is a powerful one and is being used in different fields for quite some time. There has been considerable interest for applying this technique by cement chemists during the last several years. The technique, though being versatile, has its limitations but there is ample evidence to apply this technique singularly or in conjunction with other techniques. In our attempts we have tried to explore the possibilities in areas, such as (i) characterization of rocks, minerals, products, etc., and estimation of these materials; (ii) formation characteristics of ordinary Portland cement (OPC) from raw meal; (iii) identification of OPC phases, OPC and other cements and their hydration-characteristics; and (iv) polymerization process in polymer-mortar, concrete - deterioration, and water-proofing compounds, etc.

Both absorption and attenuated total reflection (ATR) spectral studies were conducted in solid and liquid phases and details of experimental procedures can be obtained from references listed at the end.

## SPECTRAL INVESTIGATIONS

The results of our spectral investigations are described in short giving the advantages and limitations of the method and suggestions for further improvements where applicable. The spectral regions are limited to 1600-400  $\text{cm}^{-1}$  and the hydroxyl - stretching region.

## ROCKS, MINERALS AND PRODUCTS

IR studies on 49 rocks, minerals and products were conducted (1) with a view to finding simple laboratory methods for rapid identification, estimation and correlation with reactivity, etc., of these materials. The spectra of calcite, aragonite, magnesite and dolomite are presented in Fig.1. Each spectrum of these rocks has characteristic IR bands in the 700  $\text{cm}^{-1}$  region, i.e. 711 (Calcite), 727 (dolomite), 748 (magnesite) and 700 and 1083  $\text{cm}^{-1}$  (aragonite). These bands are very sharp in most rock samples studied and it is possible to estimate the relative percentages of these materials from the spectrum of a composite rock sample. Quantitative estimation of dolomite in limestone was developed (2) by simply correlating the intensity of the 727  $\text{cm}^{-1}$  band of dolomite to its concentration (Absolute method) or by the intensity ratio of 727  $\text{cm}^{-1}$  and 711  $\text{cm}^{-1}$  bands in dolomitic limestone rocks to the concentration of dolomite (Relative method). Some of the early results are shown in Table I. Correlation diagrams (straight lines) were obtained using standard mixes with known percentage of dolomite in calcite.

Fig. 1 - Spectra of rocks used in the manufacture of cement.

It was observed that for certain dolomitic limestones the relative method was found to give better results than the absolute method. This method is quite rapid and reliable. Qualitative information about the nature of limestone rocks associated with silica, jasper, phosphate, etc., can be quickly obtained from their IR spectra. The spectrum of a coral limestone sample shows very little silica

while that of a limestone sample containing high percentage of jasper indicates intense lines in the  $1000\text{ cm}^{-1}$  and in the  $800\text{ cm}^{-1}$  regions.

TABLE I

Sample Nos.	Chemically determined		Dolomite percentage recalculated from MgO %	Dolomite Content	
	CaO	MgO		IR %	DTG %
RS 727	41.10	10.17	46.53	42.5	41.4
BMLS 8	34.63	5.0	22.88	20.5	17.4
RM 353	49.65	3.43	15.78	14.8	15.8

The spectra of orthoclase, feldspar, silica and jasper are distinctive though the spectra of the first two and last two are nearly equivalent. Crystallinity or degree of disorder in certain local clay samples was studied in conjunction with the pure minerals, kaolin, etc. The spectra of these local clay samples were poorly resolved and the bands are generally broad. It is not difficult to distinguish kyanite, tourmaline, topaz and talc from one another. The important micas can be differentiated rapidly from their spectra. Though the spectrum of crysolite asbestos can be accounted for partly by tremolite. The spectral investigations were also undertaken to analyse apatite rocks (3). The spectrum of a complex apatite rock containing calcite, dolomite and silica is shown in Fig.2

The spectra of industrial products, such as sillmanite brick, high alumina brick and red clay bricks are rather not distinctive while the spectra of by-products, such as slags are characteristic (1). The conversion of crystalline blast furnace slag to glassy slag appears to be difficult to be determined from the IR spectrum because of overlapping spectra. The spectrum of a ferro-chrome slag is made up of mostly  $\gamma\text{-C}_2\text{S}$  while the crystalline blast-furnace slag contains melilite.

The problem of estimating quartz in fired-silica bricks was referred to us for quality control purposes. It was observed during the course of the investigation that the tridymite line overlaps with the strongest x-ray line for quartz at  $3.34\text{ \AA}$  (4). The IR spectrum of fired silica bricks consisting of quartz, tridymite, cristobalite, etc., was found to be useful in the low-frequency region because the  $690\text{ cm}^{-1}$  quartz peak is quite sharp and not overlapped. However, the detection limit of quartz is normally 4-5% by this method (Fig.3). Attempts were made to correlate the impact strength of aggregates by studying the mineral assemblages of rocks with IR techniques (5). Though no direct correlation can possibly be made out of this, it was observed that rocks, such as calcite, quartzite, granite, etc., were higher quality aggregates when impurities, such as silica in glassy state existing in calcite rocks

or the material had some part in glassy state.

Fig.2 - Spectrum of a complex apatite rock sample.

#### SPECTRA OF OPC AND OTHER CEMENTS

The absorption and ATR spectra of OPC and its phases have been reported (6,7). The OPC phases have distinctive spectra but the spectrum of OPC is the resultant of these phases and is predominantly of the silicate phases which contribute about 80% of OPC. In our studies on synthetic cements with varying proportions of the silicate phases, the  $900\text{ cm}^{-1}$  region strongband (Si-O stretch) was found to alter in shape and splittings (8). An attempt was made to correlate this spectral behaviour with qualitative estimation of the silicate phases as brought out in an institutional manual (9). In general, it was seen that with the increase in belite content, the splitting in the  $845\text{ cm}^{-1}$  region band was pronounced and a possible criterion for a first-hand quality control of cement has been indicated (9) as shown in Fig.4. The controversy over the coordination number of Al in  $\text{C}_3\text{A}$  has been mentioned (6) but it appears that no definite information on it can be obtained.

Fig.3 - Estimation of  $\alpha$  - quartz by IR.

The ATR spectra of certain standard cements are quite interesting since the systematic appearance of bands (TABLE-II) with changes in intensity, etc., can be made use of for further study in the estimation of the quality of a particular cement.

The author feels that there is a potential scope for using these data in a computer towards quality control of cement.

The transformations of OPC raw meal in a vertical shaft kiln plant were studied by IR as well as XRD. The IR spectral data were published (10). The spectra registered transformations, such as the decomposition of clay (shifting of 1000  $\text{cm}^{-1}$  band, etc.) the formation of  $\beta$  - C2S with some undecomposed calcite and the gradual formation of alite up to the sintering temperature which can be seen in Fig.5. The information thus obtained are admittedly qualitative but pictorial.

Fig. 4 - Spectra of cements with variable composition.

S : Strong,      Sh: Shoulder,      W : Weak

Fig.5 - Spectra of a cement raw mix at different stages of heating up to the sintering temperature.

Studies made on ring-samples showed that the IR spectra did indicate the presence of carbonate (calcite) and sulphate complexes along with  $C_2S$  but no definite compound compositions could be found (10). The IR spectra appear to be quite powerful in identifying slight hydration ( $3600\text{ cm}^{-1}$  region band) and carbonation ( $1400\text{ cm}^{-1}$  band) in standard cement samples exposed once to atmosphere.

During the investigation of a new cement "Porsal" (11), the IR spectral runs of the anhydrous and hydrated cement were taken. The anhydrous cement spectrum truly represents the broad composition of the cement, for example, the high percentage  $\beta$ - $C_2S$  phase and aluminate phases (sharp lines) as shown in Fig.6. The spectrum of 1-day hydrated cement is washed off of the aluminate phases. The broadening of IR bands (silicate) in the spectra of 7-day and 28-day samples is noticeable.

The conversion of monomer methyl methacrylate to polymer methyl methacrylate in mortar-matrix was studied by IR but quantitative conversion was not studied. The spectrum of the in-situ polymerised polymer is similar to that obtained normally (8).

The IR technique was found to rapidly decipher the decomposition products of concrete exposed to sewage environment (12). The spectra of the samples taken from the inner surface indicated high amounts of calcite and sulphate besides silica. The technique was also applied in deciphering a water-proofing compound (8). The spectrum of the water-proofing compound indicated the presence of calcite, sodium stearate and calcium hydroxide ( $3650\text{ cm}^{-1}$  band).

The selection rules for solid state spectra are different from those for gas or liquid spectra. Factor group analysis of  $C_3S$  showed that 29 bands should be expected in its spectrum but actually we observed about 8 bands in the region upto  $400\text{ cm}^{-1}$ . The space group for  $C_3S$  is  $C_{3v}^5$  ( $R\bar{3}m$ ) with 9 molecules per unit cell. The total number of internal modes is  $15A_1 + 2A_2 + 14E$ , where  $A_1$  and  $E$  modes are IR active. In the case of  $\beta$ - $C_2S$  of

space group  $C2h^5 (P_{21}/n)$  with 4 molecules per unit cell, the expected IR active internal modes are  $12 A_u + 12 B_u$  and we observed about 7 bands (6). The reason is poor resolution, overlapping, etc.

Fig.6 - Spectra of Porsal Cement.

The appearance of an extra band and shifting of bands were observed in the spectrum of a gypsum sample heated to 600°C. The mineral gypsum shows at 669 and 605  $cm^{-1}$  while the heated sample shows three bands in this region at 675, 618 and 599  $cm^{-1}$  in their spectra as shown in Fig.7. This is due to the lifting of degeneracy of the bending mode ( $SO_4$ ) and this may happen due to substitution resulting in lowering of site-symmetry of a molecule in a crystal lattice.

The presence of impurities, polymorphic forms, glassy phase, etc, may alter drastically the spectrum of a substance in solid state and accordingly precaution may be taken against these when analysing a spectrum of a substance in solid state. There are cases of changes due to reactions taking place while pelleting (KBr) of a solid sample. We observed (6) the appearance of 565  $cm^{-1}$  band in the spectrum of  $\beta$ - $C_2S$  in KBr-pellet while this band is absent in the paraffin-mull of  $\beta$ - $C_2S$ .  $\gamma$ - $C_2S$  has this band both in KBr or paraffin-mull spectrum.

Fig.7 - Spectra of a gypsum sample.

The IR technique is quite powerful in the analysis of gas. The author feels that this technique may be of some value with very little of further development in the analysis of kiln gases.

Table III gives the detection limits of some gases (courtesy - Perkin Elmer Co, USA).

TABLE III		
Gas	Detection Limit (PPM)	$cm^{-1}$ range
CO	12.5	2250-2050
CO <sub>2</sub>	0.7	2500-2200
SO <sub>2</sub>	1.0	1250-1000

#### CONCLUSION

The applications of IR techniques in the fields of cement and concrete are to some extent qualitative; however much useful information can be obtained quite rapidly. The technique's value can be improved further by attaching a computer to the spectrometer. The ATR method appears to be promising in the study of surface-hydration, curing-process, etc.

# Hydration of $C_4AF$ + gypsum : study of various factors

## *L'hydratation du $C_4AF$ + gypse : étude de divers facteurs*

V.S. RAMACHANDRAN (Senior Research Officer) and J.J. BEAUDOIN (Associate Research Officer)  
Division of Building Research, National Research Council of Canada, Ottawa, Ontario  
K1A 0R6 Canada.

RESUME: Les auteurs hydratent de l'aluminoferrite tétracalcique ( $C_4AF$ ) contenant du gypse dans des proportions de 0, 5, 10, 20 et 30% à 25 ou 80°C soit sous forme de disques (précompactés à des pressions de 140 et de 690 MPa), soit sous forme de poudre pour des rapports eau/ciment de 0.5 et de 1.0. Ils identifient et quantifient les produits d'hydratation pour des périodes variant de quelques minutes à sept jours au moyen de la méthode thermique différentielle. La séquence de formation des hydrates, c'est-à-dire l'hydrate hexagonal, l'hydrate cubique, l'ettringite, l'hydrate à basse teneur en sulfoaluminates et la solution solide, de même que leurs interconversions dépendent principalement de la température, de la teneur en gypse et du rapport initial eau/solide. Les auteurs montrent que l'ettringite n'est pas nécessairement un précurseur de la formation d'un hydrate à basse teneur en sulfoaluminates lorsque l'hydratation se fait à un très faible rapport eau/solide et à 80°C.

SUMMARY: Tetracalcium aluminoferrite ( $C_4AF$ ) mixed with gypsum in amounts of 0, 5, 10, 20 and 30% was hydrated at 25 or 80°C either as discs (pre-compacted at pressures of 140 and 690 MPa) or in powder form at water/cement ratios of 0.5 and 1.0. Hydration products formed at periods ranging from a few minutes to seven days were identified and estimated by the Differential Thermal Technique. The sequence of formation of hydrates - viz, hexagonal hydrate, cubic hydrate, ettringite, low sulfoaluminate and solid solution - and their interconversions were primarily dependent on gypsum content, temperature and initial water/solid ratio. The study indicated that ettringite need not necessarily be a precursor of the formation of low sulfoaluminate hydrate when hydration is carried out at a very low w/s ratio and 80°C.

## INTRODUCTION

The ferrite phase comprising 8 to 12% of an average portland cement has received very little attention with respect to its hydration and physico-mechanical characteristics. This may be ascribed partly to the assumption that the ferrite and C<sub>3</sub>A phases in cement behave in a similar manner. There is evidence, however, that in the presence of gypsum significant differences exist in the hydration behaviour of C<sub>3</sub>A and C<sub>4</sub>AF, and there is no unanimous opinion on the sequence of hydration and types of hydration products formed under different conditions.

In an earlier investigation (1) of the effect of temperature on the physico-mechanical characteristics of hydrating C<sub>4</sub>AF at very low w/c ratios, several new observations were made. This work has been extended to a sequential examination of the hydration products formed in the system C<sub>4</sub>AF-CaSO<sub>4</sub>·2H<sub>2</sub>O-H<sub>2</sub>O (using varying w/s ratios) hydrated for different periods at 25 or 80°C.

## EXPERIMENTAL

Tetracalcium aluminoferrite (C<sub>4</sub>AF) used in this investigation had the following chemical analysis: Al<sub>2</sub>O<sub>3</sub> = 20.43%, Fe<sub>2</sub>O<sub>3</sub> = 32.65%, CaO = 45.82% and free CaO < 0.5% and loss on ignition 0.37%; the surface area was 3300-3400 cm<sup>2</sup>g<sup>-1</sup> (Blaine).

Eight groups of starting materials, the temperature of hydration, and the periods at which the thermograms were obtained are described in Table I.

The samples were analysed semi-quantitatively by the DSC (Differential Scanning Calorimetric) technique using the DuPont 900 thermal analysis system. Details of these measurements have been described (1). X-ray powder photographs were obtained with a Philips Camera using a CuK $\alpha$  source; length changes were measured by a modified Tuckerman gauge extensometer (2); and rate of heat development during hydration was determined by a conduction calorimeter (1).

## RESULTS AND DISCUSSION

Different types of hydration products are formed in the C<sub>4</sub>AF-CaSO<sub>4</sub>·2H<sub>2</sub>O-H<sub>2</sub>O system, depending on initial proportions of materials, temperature and time of hydration. The compounds that may be present at a

particular time of hydration may consist of unreacted C<sub>4</sub>AF, CaSO<sub>4</sub>·2H<sub>2</sub>O and H<sub>2</sub>O and the hydrated products C<sub>4</sub>(A,F)H<sub>13</sub> (hexagonal phase), C<sub>3</sub>(A,F)H<sub>6</sub> (cubic phase), C<sub>3</sub>(A,F)3CS·H<sub>32</sub> (ettringite), C<sub>3</sub>(A,F)CS·H<sub>12</sub> (low sulphoaluminate) and a solid solution of the low sulphoaluminate with C<sub>4</sub>(A,F)H<sub>13</sub>. In this paper, the solid solution is also referred to as low sulphoaluminate. In each mole of the hydrated product containing x mole of Fe and y mole of A,  $x + y = 1$ .

Tetracalcium aluminoferrite (C<sub>4</sub>AF) does not show any thermal effect in the temperature range studied. Gypsum indicates two endothermal effects with peaks in the range 150 to 200°C, representing the stepwise removal of water. At low concentrations of gypsum the two peaks may merge in a single endothermal peak at about 150 to 160°C. Free water is indicated by an endothermal effect at about 100°C. The hexagonal phase exhibits an endothermal peak at about 160 to 175°C, the cubic form at about 300 to 325°C. Ettringite is identified by an endothermic peak at about 110 to 125°C and the low sulphoaluminate phase by an endothermal effect at about 200 to 210°C. Another of lower intensity is exhibited at about 300°C. The solid solution of low sulphoaluminate with C<sub>4</sub>(A,F)H<sub>13</sub> has thermal effects similar to those of low sulphoaluminate. Small variations in the characteristic peak temperatures may occur, but because products of hydration are examined sequentially at different intervals these variations do not pose any problems for identification.

Thermal curves of C<sub>4</sub>AF-gypsum mixtures formed at 140 MPa and hydrated for different lengths of time at 25°C are shown in Figure 1. Figure 1A represents the thermograms of C<sub>4</sub>AF hydrated for different periods. The first endothermal effect occurring at about 100°C is due to desorbed water, the second at 170 to 180°C represents the dehydration of the hexagonal phase, and that at about 300 to 320°C is caused by the partial dehydration of the cubic phase. At 1 h both hexagonal and cubic phases are present. As hydration progresses, increased amounts of the cubic phase are formed by the conversion of the hexagonal phase, which is also formed continuously. Even at 7 days there is no complete conversion of the hexagonal to the cubic phase.

TABLE I - Materials Examined by the Differential Thermal Technique

Series	Sample	Compacting Pressure (MPa)	w/s Ratio	Temperature (°C)	Time* of Hydration
I	C <sub>4</sub> AF + 0,5,10,20 or 30% gypsum	140	-	25	1,3,5,7 h; 1,3,7 d
II	C <sub>4</sub> AF + 0,5,10,20 or 30% gypsum	140	-	80	15 m; 1,3,7 h; 1,2,7 d
III	C <sub>4</sub> AF + 5,10,20 or 30% gypsum	690	-	25	4 h, 16 h; 2 d, 7 d
IV	C <sub>4</sub> AF + 5,10,20 or 30% gypsum	690	-	80	4 h, 16 h; 2 d, 7 d
V	C <sub>4</sub> AF + 5,10,20 or 30% gypsum	-	0.5	25	2 d
VI	C <sub>4</sub> AF + 5,10,20 or 30% gypsum	-	0.5	80	2 d
VII	C <sub>4</sub> AF + 5,10,20 or 30% gypsum	-	1.0	25	2 d
VIII	C <sub>4</sub> AF + 5,10,20 or 30% gypsum	-	1.0	80	2 d

\* (m = min, h = hr, d = day)

Fig. 1 - Differential thermal behaviour of  $C_4AF$  + gypsum (140 MPa) hydrated to different periods at  $25^\circ C$

Formation of the hexagonal phase and its conversion to the cubic phase proceeds much faster in the  $C_3A-H_2O$  system than in the  $C_4AF-H_2O$  system (3). Whereas  $C_3A$  forms hexagonal plates within a few minutes of contact with  $H_2O$ , the  $C_4AF$  phase hydrated to the same extent may not develop a well-defined morphology (4). It appears that a higher surface area product enveloping the unhydrated  $C_4AF$  grains impedes the diffusion of water molecules more efficiently than the crystalline product formed on the  $C_3A$  grains.

Addition of 5% gypsum alters the hydration behaviour of  $C_4AF$  (Figure 1B). In the first hour of hydration gypsum (peaks in the range  $150$  to  $170^\circ C$ ), the hexagonal phase (peak at about  $180^\circ C$ ), and ettringite (peak at about  $105$  to  $110^\circ C$ ) are present. As hydration progresses the intensity of the peak due to ettringite decreases. Low sulphaaluminate formed from the conversion of ettringite can be identified by a peak at about  $200^\circ C$ . At 7 days the major phases present in the system are the low sulphaaluminate and the hexagonal form. The absence of an intense endothermal peak at  $300^\circ C$  suggests that at 5% gypsum the conversion of the hexagonal to the cubic phase is retarded.

Similar observations were reported on the inter-conversion reactions in the  $C_3A-H_2O$ -gypsum system (5). It was suggested that sorption of even small amounts of  $SO_4^{--}$  are capable of retarding the conversion of hexagonal to cubic phase. As the amount of gypsum in the mixture is increased from 5 to 30%, larger amounts of ettringite are formed within minutes of contact with water (Figure 1 (C to E)). The commencement of conversion of ettringite to low sulphaaluminate is delayed as the concentration of gypsum is increased in

the mixture. Almost complete inhibition of the formation of the hexagonal phase also occurs. In most samples both ettringite and monosulphate co-exist at periods of hydration from a few hours to several days.

The relative amounts of unreacted gypsum and high and low sulphaaluminate contained in samples at different times at  $25^\circ C$  are shown in Figure 2. Calculations suggest that within 1 h relatively more gypsum has reacted to form ettringite in mixtures containing larger amounts of gypsum (Figure 2B). Conduction calorimetric data also indicate that in the first 30 min larger amounts of heat are developed in mixtures containing greater amounts of gypsum. Although almost all gypsum has reacted at 7 h in samples containing 5 to 20% gypsum, substantial amounts are still present in the mixture prepared with 30% gypsum (Figure 2A). All samples show a general decrease in the amount of ettringite after 3 to 7 h of hydration and an increase in the amount of the low sulphaaluminate phase. It is generally believed that ettringite begins to convert to low sulphaaluminate after all gypsum has been consumed. In mixtures containing low amounts of gypsum this may be valid; but at 30% gypsum, although there is a decrease in the amount of ettringite and an increase in the amount of low sulphaaluminate, there is still a substantial amount of unreacted gypsum at 7 h. It appears that after this length of time the reaction between ettringite and  $C_4AF$  to form low sulphaaluminate progresses at a faster rate than the reaction between  $C_4AF$  and gypsum to form ettringite. A higher rate of decrease in the amount of ettringite in the sample containing 30% gypsum after 7 h indicates that the

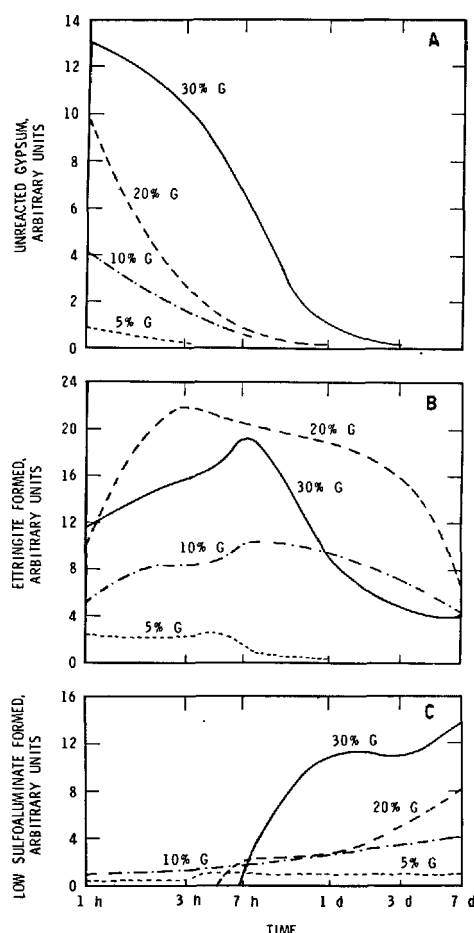

Fig. 2 - Relative amounts of various phases present in the  $C_4AF-CaSO_4 \cdot 2H_2O$  (140 MPa) system hydrated at  $25^\circ C$  for different periods. (G: per cent gypsum with respect to  $C_4AF$ )

$C_4AF$  surface becomes more easily accessible for the formation of ettringite and its conversion to monosulphates after this period (Figure 2B). Length change measurements reveal that the mixture containing 30% gypsum shows as high an expansion as 10.8% at 7 h, compared to only 2.9% for that containing 20% gypsum. A higher expansion may result in a higher porosity and better availability of the  $C_4AF$  surface for reactions.

Differential thermal characteristics of  $C_4AF$ -gypsum mixtures containing 0, 5, 10, 20 and 30% gypsum (pressed at 140 MPa) and hydrated at  $80^\circ C$  to different periods are shown in Figure 3. The  $C_4AF$  sample forms a large amount of the cubic phase within 15 min (Figure 3A). Hydration occurs at a faster rate at  $80^\circ C$  than at  $25^\circ C$ , as evidenced by an almost complete absence of the hexagonal phase after about one day. At  $80^\circ C$  there is a possibility of direct conversion of the  $C_4AF$  to the cubic form without the formation of a metastable phase (6). At an addition of 5% gypsum, low sulfoaluminate is formed even at

15 min (Figure 3B). A concurrent formation of the cubic phase is also evident, increasing as hydration progresses. At a dosage of 5% gypsum, the formation of the cubic form is retarded more efficiently at 25 than at  $80^\circ C$  (Figure 1B). As the percentage of gypsum is increased from 5 to 30%, lower amounts of cubic phase are formed owing to the preferential reaction of  $C_4AF$  with gypsum to form sulfoaluminate. The rate of consumption of gypsum and formation of low sulfoaluminate are shown in Figure 4. The low sulfoaluminate form evident at 15 min increases as hydration progresses (Figure 4B); the ettringite phase, if present at all, is formed in small amounts. It is generally suggested that the initial product of hydration of  $C_3A$  or  $C_4AF$  in the presence of gypsum is ettringite. The non-existence of ettringite in  $C_4AF$ -gypsum mixtures formed at 140 MPa and hydrated at  $80^\circ C$  suggests that in a low porosity system, in which the particles of gypsum and  $C_4AF$  are in intimate contact with each other, the mobility of ions is restricted, and at this temperature a direct formation of low sulfoaluminate may be favoured. The other possibility is that ettringite formed initially converts to low sulfoaluminate at an extremely fast rate. Further work is in progress to resolve the question of the mechanism involved in the direct formation of low sulfoaluminate in low porosity systems.

Figure 5 compares the thermal characteristics of hydrated products prepared from  $C_4AF$ -gypsum mixtures (pressed at 690 MPa) containing 5, 10, 20 and 30% gypsum and hydrated to different periods at  $25^\circ C$ . Generally, gypsum is consumed at a slower rate in this mixture and the rate of ettringite formation and its conversion to low sulfoaluminate is retarded to a greater extent than in one formed at 140 MPa (Figure 1B to E). At a pressure of 690 MPa the particles in the sample are in much more intimate contact with each other and the effective porosity is much lower than in that prepared at 140 MPa.

The mobility of ions is restricted in samples made at a higher pressure, facilitating the formation of products at the original sites of the starting materials. Hydration and interconversions may be impeded, therefore, in samples formed at 690 MPa.

The thermograms of  $C_4AF$ -gypsum mixtures formed at 690 MPa and hydrated at  $80^\circ C$  for different periods are shown in Figure 6. There is evidence of simultaneous formation of both ettringite and low sulfoaluminate as a consequence of high temperature and low porosity.

Figure 7 represents the thermal curves of  $C_4AF-CaSO_4 \cdot 2H_2O$  mixtures hydrated at  $w/s = 0.5$  or  $1.0$  for two days at 25 or  $80^\circ C$ . Most samples hydrated for two days at  $25^\circ C$  contain mainly low sulfoaluminate. The interconversions seem to occur at a faster rate at higher  $w/s$  ratios. At  $80^\circ C$  and low gypsum content,  $C_4AF$  hydrates to form the cubic form. The conversion of ettringite to monosulphate also occurs at a faster rate. A combination of higher  $w/s$  ratio and higher temperature is conducive to faster hydration and interconversions.

Most samples were also subjected to XRD studies. In many, especially at earlier times of hydration, though thermal peaks indicated the formation of various products of hydration, XRD did not. Either the amounts of hydration products were low or they were not well crystallized for identification purposes by XRD technique.

## CONCLUSIONS

1. The sequence of reactions and interconversions in the  $C_4AF$ - $CaSO_4 \cdot 2H_2O$ - $H_2O$  system at low w/s ratios and high temperatures is different from those occurring at normal w/s ratios.
2. In this low porosity system there is evidence at the original sites of the reactants of formation of cubic hydrate, low sulphoaluminate and ettringite.
3. At very low w/s ratios and higher temperatures low sulphoaluminate need not result from the conversion reaction involving ettringite.
4. Contrary to general belief, conversion of ettringite to low sulphoaluminate can occur even in the presence of gypsum.
5. The Differential Thermal Technique is more sensitive than XRD for identifying and estimating various hydration products in the  $C_4AF$ - $CaSO_4 \cdot 2H_2O$ - $H_2O$  system.

# Study of the Structure and Crystallization properties of Tricalcium Silicate ( $C_3S$ ) and dicalcium Silicate $\beta$ ( $\beta - C_2S$ ) Hydrate, and the new Calcium Silicate Hydrate (C-S-H (III) C-S-H (I<sup>1</sup>) and C-S-H (II<sup>2</sup>))

*Etude de la structure et de la cristallographie du Silicate tricalcique ( $C_3S$ ), du silicate bicalcique  $\beta$  ( $\beta - C_2S$ ) et des silicates calciques hydratés : C-S-H (III), C-S-H (I<sup>1</sup>) et C-S-H (II<sup>2</sup>)*

F. HANNAWAYYA, Dr. of Chemical Technology, Department of Inorganic Chemistry The Royal Institute of Technology (Kunglia Tekniska Högskolan, KTH) S-100 44 Stockholm, Sweden.

RESUME: L'hydratation d'un mélange de  $C_3S$  et de  $\beta - C_2S$ , dans un bocal maintenu à la température ambiante, produit un même type de silicate hydraté (C-S-H) et diverses quantités de chaux hydratée. Les propriétés de  $Ca(OH)_2$ , la phase aqueuse, la composition, le mécanisme de la réaction avec l'eau et la structure des cristaux formés ont été examinés en détail.

Dès l'origine Hannawayya a donné le nom de C-S-H(I<sup>1</sup>), de C-S-H(II<sup>2</sup>) et de C-S-H(III) aux divers silicates de calcium hydratés, qui sont formés par l'hydratation des mélanges de  $\beta - C_2S$  et de  $C_3S$ , selon les proportions respectives de ces deux constituants. Les limites supérieures et inférieures du rapport moléculaire  $CaO/SiO_2$  sont 1,56 et 1,88 pour la production du C-S-H(II) et 2,25 et 2,90 pour la production du C-S-H(III).

La présente recherche concernant le C-S-H a été effectuée lorsque l'équilibre de l'action des divers constituants a été atteint. Le rapport C/S dans la phase anhydre était choisi, de façon à atteindre les divers équilibres déterminés par la théorie. Les produits hydratés formés constituent une série de combinaisons de compositions variées. Leurs structures cristallines ont été examinées au microscope électronique à transparence et à l'appareil de diffraction X.

SUMMARY : The concentration of  $C_3S$  and  $\beta - C_2S$  by bottle hydration at room temperature produced a similar type of calcium silicate hydrate (C-S-H) and different amount of calcium hydroxide. The properties of  $Ca(OH)_2$ , the aqueous phase, the composition, the mechanism of the reaction with water, and the structure of the crystalline compounds formed in C-S-H system are discussed in details.

Hannawayya originally gave the name C-S-H(I<sup>1</sup>), C-S-H(II<sup>2</sup>) and C-S-H(III) to the calcium silicate hydrate which is produced by bottle hydration of  $\beta - C_2S$  and  $C_3S$  hydrate respectively. The lower and upper limits of  $CaO/SiO_2$  mole ratio of C-S-H(II<sup>2</sup>) are 1.56 and 1.88 respectively, and of C-S-H(III) are 2.25 and 2.90 respectively.

The present research deals with the system  $CaO-SiO_2-H_2O$  (C-S-H), in which equilibrium is reached through interaction between the components. The ratio of  $CaO/SiO_2$  was determined in the solid phases under condition of hypothetical equilibrium in solution, in which the  $CaO$  concentration was varied. The products formed are a series of compounds, whose composition varies. Their crystal structure are illustrated by scanning electron microscopy and X-ray diffraction.

## INTRODUCTION AND GENERAL DISCUSSION

A study of the hydration of individual phases ( $C_3S$  and  $\beta-C_2S$ ) is essential for a basic understanding of the hydration of portland cement and has important bearing on the phenomenon of setting, development of strength, durability, etc.

This investigation was based on the determination of calcium silicate hydrates ( $C-S-H(I^1)$ ,  $C-S-H(II^2)$ ) and ( $C-S-H(III)$ ) and calcium hydroxide formed by bottle hydration of  $C_3S$  and  $\beta-C_2S$  respectively. Bottle hydration of  $C_3S$  and  $\beta-C_2S$  have the potential to form metastable products ( $C-S-H$  system) which transform slowly. Final equilibrium is approached by the interaction of the components and takes several months. Bottle hydration is a method in which the anhydrous phase is mixed with an excess of water (usually more than 10 times its own weight) and placed in a rotating wheel. The progress of the present investigation shows for the first time metastable equilibrium curves of  $C_3S$  (HANNAWAYYA, fig.5) and its calcium silicate hydrate(III) ( $C-S-H(III)$ ) and of  $\beta-C_2S$  (HANNAWAYYA, fig.5) and its two calcium silicate hydrate ( $C-S-H(I^1)$  and  $C-S-H(II^2)$ ). The product  $C-S-H(II^2)$  was studied extensively, its X-ray and electron diffraction data are presented elsewhere [1].

Gibbs Phase Rule is applied in this research to determine whether true metastable equilibrium in the reaction between the components could occur in a certain period of time during bottle hydration of  $C_3S$  and  $\beta-C_2S$ . The use of the phase rule is basic for an understanding of the reaction which gives rise to silicates or portland cement clinker and for knowledge of the chemical nature of the product.

HANNAWAYYA [2] investigated  $C_3S$  in an excess amount of water (bottle hydration). LEDUE [3] showed that dicalcium silicate was the essential hydraulic material of portland cement. The hardening of the cement was explained as being due entirely to the hydration of the  $2CaO \cdot SiO_2$ , the fine needles of the  $CaO \cdot SiO_2 \cdot aq.$  becoming interlaced and penetrating the gel of the same composition. The products formed at room temperature in the system  $CaO \cdot SiO_2 \cdot H_2O$  has been studied by KALOUSEK [4] using the method of differential thermal analysis. Various mixture of calcium hydroxide and silica gel were prepared and aged for 28 days. The products led KALOUSEK to postulate a continuous series of compounds having the end composition of  $C_3S_2H_4$  and  $C_4S_3H_4$ . Some investigators [5-7] have studied the structure and morphology of  $C-S-H$  (calcium-silicate-hydrate) and have presented evidence for the semi-crystalline fibrous forms of the hydration products. Others [8-10] have discussed the fibrous particles which appear as bundles and aggregates, and (sometimes) as sheets having an interlacing structure oriented in 3 directions at an angle of about  $60^\circ$ . The author emphasizes that the hydration of calcium silicates is an important reaction. Moreover, the  $\beta-C_2S$  compound is vital in several fields of silicate science, especially, different kinds of cement, refractories, and slag.

Many authors have estimated or measured C/S mole ratio of  $C-S-H$  which is produced from  $C_3S$  hydrate. DIAMOND [11] reported a ratio between  $1.9 \pm 0.2$  by Spot EDXA determination. GRUTZECK and ROY [12] used Electron Probe Microanalysis (EPMA), for direct measurement on a single  $C_3S$  paste hydrated for 24 weeks. They obtained an average value of  $1.7 \pm 0.1$ . LOCHER [13] found ratio between 1.5 and 1.75 by thermogravimetry. KANTRO et al [14] reported ratio between 1.4 and 2.0 TAYLOR  $C_2SH(II)$  [8] first reported ratio close to 2.0 and later he estimated it to be 1.75. LEA [15] reported ratio of completely-hydrated-silicate, about 1.4-1.6.

Hydrated  $C_3S$  and  $\beta-C_2S$  should yield a fixed maximum of C/S mole ratio. The author took evidence from the hydration of  $C_3S$  and  $\beta-C_2S$  to deduce 2 formulae which fix the values of C/S mole ratio thus providing the missing link. The author suggests that the upper limit of the  $CaO/SiO_2$  ratio of  $C-S-H(III)$  should be 2.90. This value never reaches 3.0 (see equation 1) and the upper limit of  $CaO/SiO_2$  ratio of  $C-S-H(II^2)$  should be 1.88. This value never reaches 2.0 (see equation 2).

## MATERIALS AND METHODS

The initial material used in this investigation, tricalcium silicate ( $C_3S$ , is composed as follows: 75.6844 wt.%  $CaO$ , 26.3156 wt.%  $SiO_2$ , and beta-dicalcium silicate ( $\beta-C_2S$ ), is composed as follows: 66.2440 wt.%  $CaO$ , 33.6575 wt.%  $SiO_2$ , and 1.0985 wt.%  $Al_2O_3$ . The shaking apparatus shown in figure 1 was employed. By shaking different amounts of tricalcium silicate or beta-dicalcium silicate with a fixed amount of distilled water, a change in concentration occurs on reaction. The amounts of  $C_3S$  are calculated from equation 1 and those of  $\beta-C_2S$  calculated from equation 2.

$$\frac{(3 - C/S)W_0}{228} = \frac{[CaO]}{1000} \quad \text{----- (1)}$$

$$\frac{(2 - C/S)W_0}{172} = \frac{[CaO]}{1000} \quad \text{----- (2)}$$

where  $W_0$  (g/litre) is the starting weight of  $C_3S$  or  $\beta-C_2S$ , C/S refers to the  $CaO/SiO_2$  ratio, and  $[CaO]$  to the millimole concentration in the solution.

Fig.1. Shaking apparatus.

Samples of different concentration, e.g. 0.3, 0.5, 2.0, 3.0, 4.5, 8.0, 9.72, 15.50, 31.92, 40.47 and 82.88 gm of  $C_3S$ , and/or e.g. 0.5, 1.5, 2.25, 7.88 and 35.0 gm of  $\beta-C_2S$  in 1000 ml. of distilled water, were shaken at room temperature in the shaking apparatus. The use of glass bottles was found to be undesirable whenever prolonged treatment with aqueous solutions was required due to the effect of the high alkalinity (above PH 11) of aqueous phase (see tables 1 and 2). Shaking took place for varying lengths of time, and once a week the concentration of  $CaO$  in the solution was estimated by titration to determine when the reaction had almost ceased (fig. 2 of  $C_3S$ : curve I, 0.3 gm; curve II, 0.5 gm; curve III, 2.0 gm; curve IV, 3.0 gm; curve V, 4.5 gm; curve VI, 8.0 gm; curve VII, 9.72 gm; curve VIII, 15.50 gm; curve IX, 31.92 gm; curve X, 40.47 gm; curve XII, 82.88 gm. and/or fig. 3 of  $\beta-C_2S$ : curve I, 0.5 gm; curve II, 1.0 gm; curve III, 1.5 gm; curve IV, 2.25 gm; curve V, 7.88 gm; curve VI, 35.0 gm).

Fig. 2. Variation of the  $Ca(OH)_2$  content of bottle hydrated  $C_3S$  with time of shaking.

Fig. 3. Variation of the  $Ca(OH)_2$  content of bottle hydrated  $\beta-C_2S$  with time of shaking.

The contents of the bottle were then filtered and the precipitate dried. Using e.g. eqns 1 and 2, an arbitrary weight of  $C_3S$  and  $\beta-C_2S$ , respectively, was chosen and added to the bottle which were then inserted into the rotating shaking apparatus (fig. 1). The shaking period was varied as described above, until the reaction had almost ceased.

Immediately after filtration, as shown in fig. 4, the PH of the clear filtrate was measured by means of a high-alkali glass electrode. The calcium concentration of the filtrate was determined by titration, 50 ml. being titrated with HCL using phenolphthalein as indicator. One ml. of HCL is equivalent to 0.03705 gm. of  $Ca(OH)_2$ . The precipitate on the glass filter was placed in a vacuum desiccator for one hour. The precipitate was then brushed into a weighed crucible and dried under vacuum at  $105^\circ C$  to constant weight. After drying, the precipitate was quantitatively analysed by X-ray diffraction 16 to determine the uncombined calcium oxide as calcium hydroxide. The results of the calculation are given in tables 1 and 2. Scanning electron microscopy was used for the morphological study.

## RESULTS AND DISCUSSION

The reactions that cause setting and hardening of Portland cement are collectively described as hydration reactions, i.e. the combination of ions in aqueous solution with one or more molecules of water by the formation of coordinate links.  $\beta$ -dicalcium silicate ( $\beta$ - $C_2S$ ) is the essential hydraulic material of Portland cement together with  $C_3S$ . This is due to the reactivities of anhydrous silicates ( $\beta$ - $C_2S$  and  $C_3S$ ) towards water at ordinary temperature and the characteristic of their hydration products. The hydration products of  $\beta$ - $C_2S$  and  $C_3S$  are calcium hydroxide (CH) and calcium silicate-hydrate (C-S-H), which grow into a space lattice, filling the spaces between the grains so that the entire product forms one single mass.

The mechanism of bottle hydration of  $\beta$ - $C_2S$  hydrate and scanning electron microscopy and X-ray diffraction of  $\beta$ - $C_2S$  paste hydration after 1 day up to 36 days is described in detail by [16].

## (i) PHASE EQUILIBRIUM THROUGH INTERACTION OF COMPONENTS

The present investigation concerns system  $CaO-SiO_2-H_2O$  (from bottle hydration of  $\beta$ - $C_2S$  and  $C_3S$ ) in which equilibrium was approached through interaction of the components. The progress of the reaction has ordinarily been observed by determining the  $CaO/SiO_2$  ratio in the solid phase under conditions of hypothetical equilibrium in a solution in which the  $CaO$  concentration was varied.

The solution of this problem is complicated and interesting. The differences between the investigations are indicated in various details of the curves and their interpretation. Most of the differences are probably due to a failure to obtain equilibrium between the solution and the colloidal hydrate; other investigators ascribed these differences to variations in the size of the colloidal particles resulting from the different conditions in the test procedure.

This paper presents the typical curves for  $C_3S$  and  $\beta$ - $C_2S$  (HANNAWAYYA, fig.5) showing the  $CaO/SiO_2$  molar ratio in the solid phase plotted against the  $CaO$  concentration of the solution at assumed equilibrium. The investigation concludes that the value of the  $CaO/SiO_2$  ratio depends somewhat on the state of hydration and also on drying at sufficient temperature.

HANNAWAYYA called the hydrate from  $\beta$ - $C_2S$  with a  $CaO/SiO_2$  mole ratio which varied from 0.20 to 0.62, calcium-silicate-hydrate (I<sup>1</sup>) or C-S-H(I<sup>1</sup>). When the  $CaO/SiO_2$  ratio was increased at lime saturation and varied from 1.56 to 1.88, HANNAWAYYA called it calcium-silicate-hydrate(II<sup>2</sup>) or C-S-H(II<sup>2</sup>).

HANNAWAYYA also called the hydrate from  $C_3S$  with a  $CaO/SiO_2$  ratio which varied from 2.25 to 2.90, calcium-silicate-hydrate(III) or C-S-H(III) this occurs at lime saturation. The quantity of water in the structure associated with C-S-H(III) and C-S-H(II<sup>2</sup>) seemed to be larger than that with C-S-H(I<sup>1</sup>). The  $H_2O/SiO_2$  ratio depending on the degree to which

Fig. 5. Equilibrium curve showing the relation between the  $CaO/SiO_2$  mole ratio and the concentration of  $CaO$  in solution at room temperature.

it was dried and substantially independent of  $CaO/SiO_2$  ratio. Fig.5 shows that the result of the experiments differed depending on the shaking time, due to different concentrations of  $C_3S$  or  $\beta$ - $C_2S$ /litre. TAYLOR's curve [17] is included for comparison. Many explanations e.g. (18, 19, 20, etc.) concern the slope of the curve rises gradually to a  $CaO$  concentration.

The author explains that the change from a gradual to a nearly vertical rise in the curve occurs because  $Ca(OH)_2$  begins to precipitate at lime saturation, causing a rapid rise when the saturation point is passed. It seems that it is difficult to decide upon a fixed value for  $CaO$  concentration but in practice, a close approximation can be obtained. It appears that the gradual rise of the slope of the curve, represented by a  $CaO/SiO_2$  ratio from 0.45 to 0.62 of  $\beta$ - $C_2S$  and 1.209 to 1.49 of  $C_3S$ , occurs in places where the concentration of  $Ca(OH)_2$  (or CH) increases in the solution. The molecules of  $Ca(OH)_2$  would be attached to the surface of the hydrosilicate by adsorption up to the lime saturation point, and  $(CH)_{n+1}CSH$  would be produced by adsorption, and this is reversible according to the following equation:

Here, Gibbs phase rule is valid because it is a true equilibrium. The author suggests that the upper limit of the  $CaO/SiO_2$  ratio of  $\beta$ - $C_2S$  should be 1.88 for C-S-H(II<sup>2</sup>), and of  $C_3S$  should be 2.90 for C-S-H(III). These values never reached 2.0 in  $\beta$ - $C_2S$  nor 3.0 in  $C_3S$ .

## (ii) SCANNING ELECTRON MICROSCOPY

(a) Morphology of C-S-H(I<sup>1</sup>) and C-S-H(II<sup>2</sup>) were clearly discussed in 16.

## (b) Morphology of C-S-H(III)

The morphology, shown by scanning electron microscopy, of C-S-H(III) of  $\text{CaO/SiO}_2$  mole ratio varying between 2.25 to 2.90 is described by the author as mass crystals of high solidity, and a net of crystals development folded into the shape of a cigar. Under microscopy this crystal is transparent like glass. See Figures 6 and 7, magnified 5000 times. Figure 8 presents the morphology of the C-S-H(II<sup>2</sup>) from  $\beta\text{-C}_3\text{S}$  included for comparison with the cigar shape of C-S-H(III) from  $\text{C}_3\text{S}$ .

Fig.6. C-S-H(III), The shape of cigar.

Fig.7. C-S-H(III), shows the crystal like glass.

## (iii) X-RAY DIFFRACTION DIAGRAMS

(a) X-ray diffraction diagrams of C-S-H(I<sup>1</sup>) and C-S-H(II<sup>2</sup>). Their diagrams were clearly discussed in [16].

(b) X-ray diffraction diagram of C-S-H(III). The X-ray diagram of samples in which the  $\text{CaO/SiO}_2$  ratio were 2.50, 2.75, 2.80, and 2.90 contained a strong CH pattern together with a weak pattern of unreacted  $\text{C}_3\text{S}$ , and

Fig.8. C-S-H(II<sup>2</sup>). (X400). Its crystal has also the shape of cigar.

a pattern of C-S-H(III) at 3.038 Å (v. very strong), 1.929 Å (very strong), 2.455, 5.471 Å (strong), 9.654 Å (weak). (see fig. 9).

## CONCLUSIONS

The present paper reviews present-day knowledge of the bottle hydration reaction of  $\text{C}_3\text{S}$  and  $\beta\text{-C}_3\text{S}$  compounds, generally considered to be chiefly responsible for the hydraulic properties of Portland cement.

## ACKNOWLEDGEMENTS

The author is deeply grateful to Professor INGMAR GRENTHE who is the head of the Institute of Inorganic Chemistry, the Royal Institute of Technology (Kungliga Tekniska Högskolan, KTH) who made this research possible by putting his department facilities at the author's disposal. Thanks are also due to members of the Institute of Inorganic Chemistry for their help in various directions.

# The effects of several heavy metal oxides on the hydration and the microstructure of hardened mortar of $C_3S$

## *Effets de quelques oxydes de métaux lourds sur l'hydratation du $C_3S$ et sur la structure fine des corps durcis*

C. TASHIRO, Asst. Professor, Yamaguchi University, Faculty of Engineering, Ube, Japan.

RESUME : Les effets de quelques oxydes ou hydroxydes de métaux lourds sur l'hydratation du  $C_3S$  sont déjà bien connus.  $Cr_2O_3$ ,  $Fe_2O_3$ ,  $NiO$ ,  $Cu(OH)_2$ ,  $ZnO$ , ou  $PbO$  ont été employés comme additifs au  $C_3S$  afin d'étudier l'effet produit sur l'hydratation de ce dernier, et le comportement des corps durcis, la structure fine, la résistance à la compression, le taux d'hydratation et la quantité de chaleur dégagée au premier stade d'hydratation.

$Cr_2O_3$ ,  $Fe_2O_3$ ,  $NiO$ ,  $Cu(OH)_2$ ,  $ZnO$  et  $PbO$  produisent des effets sur le degré d'hydratation du  $C_3S$ , les caractères des hydrates, la structure fine, ainsi que la résistance à la compression.  $Cu(OH)_2$ ,  $ZnO$ , et  $PbO$  retardent le premier stade d'hydratation et y exercent des effets particulièrement remarquables.

SUMMARY: The effects of heavy metal oxides or hydroxides on the hydration of  $C_3S$  have not been clarified. In the present study,  $Cr_2O_3$ ,  $Fe_2O_3$ ,  $NiO$ ,  $Cu(OH)_2$ ,  $ZnO$  or  $PbO$  was added as an additive, and the effects of such compounds on the hydration of  $C_3S$  were examined on the hardened hydrates and their microstructure, compressive strength, degree of hydration reaction and heat liberation in early hydration.

$Cr_2O_3$ ,  $Fe_2O_3$ ,  $NiO$ ,  $Cu(OH)_2$ ,  $ZnO$  and  $PbO$  affect the degree of hydration of  $C_3S$ , properties of hydrates and microstructure and compressive strength of hardened mortars.  $Cu(OH)_2$ ,  $ZnO$  and  $PbO$  retard the early hydration of  $C_3S$ , produce particularly pronounced effects.

## INTRODUCTION

A study was conducted on the hydration of  $C_3S$  and the effects of addition of  $Cr_2O_3$ ,  $Fe_2O_3$ ,  $NiO$ ,  $Cu(OH)_2$ ,  $ZnO$  or  $PbO$  on the fine structure of the hardened  $C_3S$  mortar as part of a series of studies on the effects of heavy metal oxides on the hydration of cement, characterization of hydrated and properties of hardened hydrates (1-3).

The hydration of  $C_3S$  was investigated by measuring the heat of early hydration, ignition loss and compressive strength while the fine structure was examined by observation under a scanning electron microscope and determinations of powder x-ray analysis and pore size distribution.

## EXPERIMENTAL

The experimental  $C_3S$  was synthesized from reagents at  $1,500^\circ C$  and was found to have a specific surface area (Blaine method) of  $2,700 + 200 \text{ cm}^2/\text{g}$ . The mortar was prepared by mixing  $C_3S$  and Toyoura standard sand at a ratio of 1 : 2 with Water/ $C_3S$  = 0.65. The additive such as  $Cr_2O_3$ ,  $Fe_2O_3$ ,  $NiO$ ,  $Cu(OH)_2$ ,  $ZnO$  and  $PbO$  is a reagent grade material and is added to 5 mol% of the total inclusive of such additive.

Removal of the mortar from the mold is undertaken one day after mixing in principle and curing was carried out in moist air. The test specimen has a dimension of  $1 \times 1 \times 4 \text{ cm}$ . The compressive strength reported here is the average of two specimens. The ignition loss was computed from the loss in weight produced by heating the specimen at  $1,000^\circ C$  for one hour.

## EXPERIMENTAL RESULTS AND DISCUSSION

Compressive strength

The compressive strength is shown in Fig.1. Development of strength in the early period is strongly hindered by  $Cu(OH)_2$ ,  $ZnO$  and  $PbO$ . In particular, the hindering effect of  $Cu(OH)_2$  is very pronounced not only in the early period but also at an age of 28 days. On the other hand,  $Cr_2O_3$ ,  $Fe_2O_3$  and  $NiO$  exert no significant influence or slightly promote development of the strength at an age of 3 days.

Ignition loss

The ignition loss of the mortar is presented in Fig.2. It seems that  $Cu(OH)_2$ ,  $ZnO$  and  $PbO$  yield smaller ignition losses. In particular,  $Cu(OH)_2$  reduces the ignition loss to about 1/4 of the value obtainable without addition of  $Cu(OH)_2$  at an age of 28 days. On the other hand,  $Cr_2O_3$ ,  $Fe_2O_3$  and  $NiO$  exert a small influence.

Heat liberation in early period

The results of differential calorimetric analysis between  $C_3S$  without and with heavy metal oxides are shown in Fig.3. The acceleration of heat liberation shows the acceleration of hydration reaction, heat of adsorption or heat of formation of an complex and all, which occurred by additives.

ratio of heat liberation shows the acceleration of hydration reaction, heat of adsorption or heat of formation of an complex and all, which occurred by additives.

Fig.2 - Ignition loss of  $C_3S$  mortars without and with heavy metal oxides or hydroxide.

Fig.3 - Differential calorimetric analysis of  $C_3S$  without and with heavy metal oxides or hydroxide.

### Powder x-ray analysis

The powder x-ray diffraction patterns are shown in Fig.4. As is apparent from figures,  $\text{Ca(OH)}_2$  in hydrate in  $\text{C}_3\text{S}$  adding  $\text{Cu(OH)}_2$  is negligible. And that in  $\text{C}_3\text{S}$  adding  $\text{ZnO}$  or  $\text{PbO}$  is a slight amount.

Fig.4 - X-ray powder diffraction patterns of  $\text{C}_3\text{S}$  mortars with addition of 5mol% heavy metal oxides.

### Observation under scanning electron Microscope

The scanning electron micrographs are shown in Fig.5 and 6. At an age of 3 days,  $\text{Cu(OH)}_2$ ,  $\text{ZnO}$  and  $\text{PbO}$  distinctly produce a retarding effect on the hydration. At an age of 28 days, there are observed retardation of the hydration by  $\text{Cu(OH)}_2$  and some effects of  $\text{ZnO}$  and  $\text{PbO}$  on formation of hydrates. Powder x-ray diffractometry indicated that the hydrates are tobermorite in gel and slaked lime. On the other hand,  $\text{Cr}_2\text{O}_3$ ,  $\text{Fe}_2\text{O}_3$  and  $\text{NiO}$  did not produce any significant effect.

### Pore size distribution

The pore size distribution of a 28-day old specimen is shown in Fig. 7. The additives produced changes in pore size distribution and  $\text{Cu(OH)}_2$  increases the total pore volume and  $\text{ZnO}$  in particular increased the number of pores greater than 27,000 Å.

### Hydration and Microstructure

As is apparent from above figures, the additives can be divided into three groups with respect to their characteristic effects on the relation among compressive strength, ignition loss, heat liberation, X-ray analysis and observation under scanning electron microscope: (a) no additive,  $\text{Cr}_2\text{O}_3$ ,  $\text{Fe}_2\text{O}_3$  and  $\text{NiO}$ ; (b)  $\text{ZnO}$  and  $\text{PbO}$ ; and (c)  $\text{Cu(OH)}_2$ . The group of  $\text{ZnO}$  and  $\text{PbO}$  yields a smaller ignition loss but develops a roughly equal strength compared with the group of no additive,  $\text{Cr}_2\text{O}_3$ ,  $\text{Fe}_2\text{O}_3$  and  $\text{NiO}$  at 28-day specimen.

On the other hand, the presence of a correlation between hydration and pore size distribution is not clearly demonstrated. It is generally stated that reduction of the total pore volume and shift of pore size distribution towards smaller pore are connected with an increase in hydration or strength (4). However, as is apparent from Fig.1 and 7, considerable differences exist in pore size distribution and pore volume for a given strength. This suggests that the additives affect the hydrates not only in structure but also in compositions.

The mechanism of this hindering effect on the strength or retardation of hydration is not clear, but it is thought that surface of  $\text{C}_3\text{S}$  grain is coated by metal ion or complex; invasion of water to inner parts is hindered. The coating action may be correlated to ionic potential of metal ions. Namely, ionic potential of  $\text{Ca}^{2+}$  is 0.50,  $\text{Cr}^{3+}$ : 0.23,  $\text{Fe}^{3+}$ : 0.21,  $\text{Ni}^{2+}$ : 0.34, and  $\text{Zn}^{2+}$ : 0.37,  $\text{Cu}^{2+}$ : 0.36,  $\text{Pb}^{2+}$ : 0.62, consequently, metal ions of ionic potential similar to  $\text{Ca}^{2+}$  give the hindering effect.

When added  $\text{Cu(OH)}_2$ , concentration of  $\text{CaO}$  in bottle hydration is larger than that of no addition in early hydration. It shows the acceleration of hydration as illustrated by Fig 3. And  $\text{Cu}^{2+}$  is no detectable amount

## CONCLUSION

$\text{Cr}_2\text{O}_3$ ,  $\text{Fe}_2\text{O}_3$ ,  $\text{NiO}$ ,  $\text{Cu}(\text{OH})_2$ ,  $\text{ZnO}$  and  $\text{PbO}$  affect the degree of hydration of  $\text{C}_3\text{S}$ , properties of the hydrates and the compressive strength and fine structure of the hardened hydrates and  $\text{Cu}(\text{OH})_2$ ,  $\text{ZnO}$  and  $\text{PbO}$  produce particularly pronounced effects.

The mechanism of this effects is not clear, but it seems due to similarity of ionic potential.

The author wishes to thank K. Okuni for help of experiment.

# A thermoanalytical method for the determination of the amount of calcium hydroxide in systems containing hydrated Portland cement

## *Une méthode de l'analyse thermique pour la détermination quantitative de l'hydroxyde de calcium dans des systèmes contenant du ciment portland hydraté*

F.G. BUTTLER, Dr., and S.R. MORGAN, Chemistry Department, Teesside Polytechnic, Middlesbrough, England.

RESUME : On décrit une méthode d'analyse pour la détermination quantitative de l'hydroxyde de calcium dans des systèmes contenant du ciment portland hydraté. Cette méthode utilise du dioxyde de carbone gazeux pour convertir l'hydroxyde de calcium en carbonate; celui-ci est décomposé ensuite à une température élevée. La quantité résultante de carbonate de calcium est proportionnelle à l'hydroxyde de calcium présent dans les échantillons, à condition que ceux-ci soient chauffés à 200°C avant d'être exposés au dioxyde de carbone gazeux. De cette façon on empêche la carbonatation des silicates et des aluminates hydratés de calcium. Il est possible d'employer cette méthode pour des échantillons de mortiers récemment prélevés, sans autre traitement avant l'analyse thermique. On donne une comparaison de cette méthode avec d'autres, actuellement utilisées pour la détermination de l'hydroxyde de calcium dans les ciments hydratés.

ABSTRACT: A method of analysis is described for the determination of the amount of calcium hydroxide present in systems containing hydrated Portland cement. The method involves the conversion of  $\text{Ca(OH)}_2$  to  $\text{CaCO}_3$  using gaseous  $\text{CO}_2$ , followed by the high temperature decomposition of the  $\text{CaCO}_3$  formed. The amount of  $\text{CaCO}_3$  formed is proportional to the amount of  $\text{Ca(OH)}_2$  present in the samples provided that the samples are heated to 200°C before exposure to gaseous  $\text{CO}_2$ . In this way the carbonation of hydrated calcium silicates and aluminates is prevented. The method can be used on freshly drilled samples of mortars without any pre-treatment before thermal analysis. A comparison of the method with others available for estimating  $\text{Ca(OH)}_2$  in hydrated cements is given.

## INTRODUCTION

A number of methods involving the estimation of the amount of  $\text{Ca(OH)}_2$  present have been used to study the reactions occurring between water and the compounds present in Portland cement. These methods include quantitative X-ray diffraction, thermal analysis and the extraction of the calcium hydroxide with solvents (1). Another method for studying these systems is that of trimethylsilylation. With this technique, information is obtained with respect to the silicates produced during hydration (2).

The methods used to estimate the amount of calcium hydroxide present tend to give widely differing results. Quantitative X-ray powder diffraction only measures the amount of crystalline material present, and amorphous  $\text{Ca(OH)}_2$ , will not be detected. Solvent extraction suffers from the disadvantage that the amount of  $\text{Ca(OH)}_2$  removed is dependent on the time of extraction, and, in addition, calcium ions may also be removed from other compounds present. Thermogravimetry is usually carried out by monitoring the loss of water from the hydrated compounds with respect to temperature and time. The interpretation of results can be difficult due to the overlap of the step corresponding to the loss of water from calcium hydroxide with the steps due to loss of water from other hydrated compounds present. This is particularly true when the technique is applied to set Portland cements. Similar problems arise with differential thermal analysis and the measurement of areas of overlapping peaks. A comparison of results using these techniques on a sample of set Portland cement has already been made (3).

## THEORY

The analytical method is based on the fact that, as it dehydroxylates, calcium hydroxide reacts rapidly with gaseous carbon dioxide to form calcium carbonate, and provided there is sufficient time of exposure of the calcium hydroxide to the carbon dioxide, the reaction can be used quantitatively. The amount of calcium hydroxide originally present can then be determined by using the high temperature decomposition of the calcium carbonate formed. Provided the bulk of the water present in the samples is removed at low temperatures and before they are exposed to carbon dioxide, it is thought that there is little or no carbonation of other compounds arising from the hydration of Portland cement. This procedure overcomes the problem associated with the concurrent loss of water from hydrated calcium silicates and aluminates and from the calcium hydroxide, since all the water has been removed at lower temperatures than that observed for the decomposition of calcium carbonate.

## EXPERIMENTAL

Because the calcium hydroxide generally contained some calcium carbonate most experiments started with calcium oxide prepared by ignition of 'Analar' calcium carbonate. Suitable portions of the calcium oxide and finely divided quartz were weighed into the crucibles to be used for the thermal analysis and the calcium oxide converted into calcium hydroxide by adding slightly more than the required amount of carbon dioxide free distilled water immediately before analysis.

A series of mortars were prepared as 5.0 cm cubes and stored at 20°C. These mortars ranged from 1:3 mixtures of Portland cement:British standard sand with a water:cement ratio of 0.45 to similar mixtures in which up to 60% of the cement was replaced by fly ash, the water content of the mortars remaining the same. The samples for analysis were prepared by drilling, and were analysed without any further treatment.

The TG experiments were carried out using Stanton Automatic thermo-recording balances, models HT5 and TRI. The samples were contained in conical fused alumina crucibles and the weight changes determined with dynamic atmospheres of nitrogen and mixtures of nitrogen and carbon dioxide with flow rates of 100 cm<sup>3</sup>/min over the samples. Various heating rates and sample and crucible sizes were used (see Table I).

## RESULTS

Fig. 1 shows the results obtained when a laboratory sample of  $\text{Ca(OH)}_2$  containing 10.2%  $\text{CaCO}_3$  was heated in atmospheres of nitrogen and in a mixture of 80% nitrogen and 20% carbon dioxide. After the initial loss of free water, the loss between 350 and 550°C in nitrogen corresponded to the loss of water from the  $\text{Ca(OH)}_2$  and the final loss to the decomposition of the  $\text{CaCO}_3$  present in the sample. In the nitrogen/carbon dioxide atmosphere there was little carbonation below 300°C but the reaction became rapid as the water was lost from the  $\text{Ca(OH)}_2$ . The final step in an atmosphere of nitrogen and carbon dioxide was due to the decomposition of the  $\text{CaCO}_3$  formed from the  $\text{Ca(OH)}_2$  and to the  $\text{CaCO}_3$  originally present. The higher temperature of decomposition was a consequence of the presence of carbon dioxide in the gas stream. Calculation from these results showed that 93% of the  $\text{Ca(OH)}_2$  had been converted into  $\text{CaCO}_3$ .

The results obtained from the carbonation of the  $\text{Ca(OH)}_2$  produced from CaO are shown in Table I. These were obtained by heating the samples in nitrogen with a flow rate of 100 cm<sup>3</sup>/min, and then holding the temperature at 200°C until the evolution of water was negligible. The temperature of the samples was then raised again at the recorded heating rates but the atmosphere was changed to 80% nitrogen and 20% carbon dioxide. At about 700°C, after the carbonation reactions were complete, the purging gas was changed again to nitrogen in order to allow the  $\text{CaCO}_3$  formed to decompose easily. Changes in the poise of the balances due to changes in the purging gas were found to be very small. The shapes of the TG curves obtained were very similar to that shown in Fig. 1 except that they had an additional loss due to the free water present.

Finely divided quartz of about  $75\mu$  diameter was used as diluent for the  $\text{CaO}$ , and therefore of the  $\text{Ca(OH)}_2$ , in order to represent the drilled aggregate from mortar and concretes.

The results show that, using a variety of heating rates, sample and crucible sizes, and differing concentrations of  $\text{Ca(OH)}_2$  in the samples, over 90% of the  $\text{Ca(OH)}_2$  present was converted into  $\text{CaCO}_3$ . A heating rate of  $3^\circ\text{C}/\text{min}$  was selected in order that the exposure time of the  $\text{Ca(OH)}_2$  to carbon dioxide should be as long as possible within a normal working day.

The results obtained using the Portland cement:sand mortars are shown in Fig.2. The samples were prepared by drilling holes to the centre of the cubes and were analysed immediately without any further treatment. The thermo-analytical conditions were the same as those described above. Fly ash was used as a replacement for some of the Portland cement in the mortars since it was known that over short periods of time at  $20^\circ\text{C}$  there was no noticeable reaction between the calcium hydroxide formed on hydration of the cement with this particular fly ash (4). There was an additional advantage in that the particle size distribution of the fly ash was similar to that of the cement which it was replacing.

All of the results shown in Fig.2 were obtained on 11 day old mortars and have been corrected for the loss on ignition arising from the fly ash. They show that the amount of  $\text{Ca(OH)}_2$  found was directly proportional to the Portland cement content of the mortars, and that the carbonation method is suitable for monitoring such systems.

#### DISCUSSIONS AND CONCLUSIONS

Although the results using pure  $\text{Ca(OH)}_2$  have not shown 100% carbonation, no attempt has been made to multiply the amount of  $\text{Ca(OH)}_2$  found in hydrated Portland cements by an appropriate factor. It is felt that the particle size distribution and surface area of the  $\text{Ca(OH)}_2$  present in hydrated cements is likely to be different, and probably much smaller, than that produced in the experiments starting with  $\text{CaO}$ . It is therefore probable that the percentage carbonation of the  $\text{Ca(OH)}_2$  in hydrated cements will be greater. However, even if this should be proved to be not so, the method offers a way of estimating more than 90% of the  $\text{Ca(OH)}_2$  present, and, moreover, one in which a mass change is involved and one where no pre-treatment of the samples is necessary. The method should be compared with the others that are available, with their inherent difficulties, as described in the introduction. Estimation, by the ethylene glycol extraction method, of the amount of  $\text{Ca(OH)}_2$  present in the mortar samples always gave variable results which were much higher than those obtained by this carbonation method as soon as the extraction time exceeded one hour.

It should be noted that this method relies on the unreactivity of hydrated calcium silicates and aluminates to gaseous carbon dioxide under the experimental conditions used. It was found during the development of the method that the results with freshly drilled pastes and mortars were not as reliable if the carbon dioxide were added before

most of the water was removed. The results using the technique described imply that the amount of reaction of the hydrated calcium silicates and aluminates is very small. Further work on this aspect is in progress. However, whatever is the outcome of these experiments, the carbonation method gives a ready way of following the changes that occur in systems containing hydrated Portland cement over periods of time and temperature (4).

# Hydration and strength of $\alpha$ -, $\alpha'$ - and $\beta$ - dicalcium silicates stabilized with Na-Al, K-Al, Na-Fe and K-Fe

## *Hydratation et résistance de $\alpha$ -, $\alpha'$ - et $\beta$ - dicalcium silicates stabilisés par Na-Al, K-Al, Na-Fe et K-Fe*

Kazutaka SUZUKI, Dr. Professor, Department of Inorganic Materials, Nagoya Institute of Technology, Suketoshi Ito, Sumio Shibata and Namitsugu Fugii, Japan.

RESUME : L'étude a porté sur l'hydratation et la résistance à la compression des diverses formes cristallines du  $C_2S$ , stabilisées à l'aide de Na et Al (Na-Al), K et Al (K-Al), Na et Fe (Na-Fe) et K et Fe (K-Fe).

Dans les séries comportant la substitution Na-Fe et K-Fe, les phases  $\alpha$  et  $\beta$  cristallisent séparément, mais la phase  $\alpha'$  est accompagnée de la phase  $\alpha$ . Dans les séries comportant la substitution Na-Al et K-Al, seules les phases  $\alpha'$  et  $\beta$  se sont formées.

Généralement lors de l'hydratation de ces phases polymorphiques, de petites quantités de  $Ca(OH)_2$  se forment en même temps que des feuillets de silicate monocalcique hydraté (C-S-H). Dans les phases comportant la substitution alcali-Al, il se forme beaucoup moins de  $Ca(OH)_2$  et de C-S-H.

La résistance des mortiers préparés avec les phases comportant la substitution K-Fe est supérieure à celle comportant la substitution Na-Fe. La phase  $\alpha$  stabilisée avec K-Fe a une résistance notablement plus grande que celle des phases  $\alpha'$  et  $\beta$  et qui s'approche de celle des ciments portland.

Dans les séries comportant la substitution alcali-Al, on n'a pas obtenu de résistances très élevées. On a mesuré les variations en fonction du degré d'hydratation, de la résistance à la compression de la phase  $\alpha$  cuite à 1360, 1440 et 1520°C. Les points sont pratiquement alignés sur une même droite, ce qui montre que ces phases ont le même processus d'hydratation. Cependant, les points correspondant à la phase  $\alpha$  avec substitution K-Fe, et cuits à 1360 et 1440°C, et ceux correspondant à la substitution Na-Fe cuite à 1360°C sont situés hors de cette ligne. Ceci montre que l'hydratation de ces produits suit un processus différent.

Lors du frittage à 1360 ou 1440°C, le matériau interstitiel qui se forme autour des cristaux de  $C_2S$  est instable. Les ions  $Ca^{2+}$  et les ions alcalins, de cette phase, se dissolvent rapidement dans l'eau et donnent une haute résistance dès le début de l'hydratation.

SUMMARY : The hydration of dicalcium silicate polymorphs stabilized with Na and Al (Na-Al), K and Al (K-Al), Na and Fe (Na-Fe), K and Fe (K-Fe), and their compressive strength were investigated. In the Na-Fe, K-Fe substituted series, the  $\alpha$  and  $\beta$  phases were crystallized as a single phase but  $\alpha'$ -phase accompanied  $\alpha$ -phase. In the Na-Al, K-Al substituted series, only  $\alpha'$  and  $\beta$ -phase were formed. Generally in the hydration of these polymorphs, small amounts of  $Ca(OH)_2$  were formed, together with foil like calcium silicate hydrate (C-S-H). In the alkali-Al substituted modifications, far less of  $Ca(OH)_2$  and C-S-H were formed.

The strengths of mortars prepared with the K-Fe substituted phases surpassed those of the corresponding Na-Fe substituted phases. The  $\alpha$ -phase stabilized with K-Fe exhibited compressive strength markedly higher than those of  $\alpha'$  and  $\beta$ -phases and approached those of portland cement mortars. In the alkali-Al substituted series the effective compressive strength was not expected.

Compressive strengths versus hydration ratios were plotted in a figure for the  $\alpha$ -phase burned at 1360, 1440 and 1520 °C. Almost the all of the plotted points formed a straight line and this showed that these phases had the same hydraulic process. But the plots of K-Fe substituted  $\alpha$ -phase burned at 1360 and 1440 °C and of Na-Fe substituted  $\alpha$ -phase burned at 1360 °C stood off this line. This shows that these phases hydrate with different process. In the sintering process at 1360 °C or 1440 °C, the interstitial material was formed in unstable around the  $C_2S$  crystal.  $Ca^{2+}$  or alkali ion dissolved in water quickly from this phase and gave high strength in the early hydration time.

## INTRODUCTION

Dicalcium silicate ( $C_2S$ ) hydrates via the same mechanism as  $Ca_3SiO_5$ . However, it is thought that the higher temperature polymorphs exhibit greater hydraulicity than the lower temperature polymorphs because their free energies are larger. The influence of polymorphs on hydraulic activity and strength has been discussed in several papers. Boikova et al. (1) investigated the effect of  $P_2O_5$ ;  $\alpha'$ - $C_2S$  containing 14%  $3CaO \cdot P_2O_5$  was found to have greater hydraulicity than  $\beta$ - $C_2S$ . Gutt and Osborn (2), who studied the strength of  $\alpha'$ - and  $\beta$ - $C_2S$  stabilized with  $K_2O$ , found that the strength of  $\alpha'$ - $C_2S$  containing 3.6%  $K_2O$  surpassed that of  $\beta$ - $C_2S$  containing 2.1%  $K_2O$ . Bikbau (3) investigated the hydraulicity and strength of  $\alpha$ -,  $\alpha'$ - and  $\beta$ - $C_2S$  in which Ba was substituted for Ca; the  $\alpha$ -phase exhibited the greatest compressive strength. Jelenic et al. (4) reported that the degree of hydration and compressive strength of  $B_2O_3$ -substituted  $\alpha$ - $C_2S$  were greater than those of  $\beta$ - $C_2S$  when alit was contained. In these studies however, the additional stabilizer was limited to only one component. The authors studied the hydration and compressive strength of cements composed of  $\alpha$ -,  $\alpha'$ - and  $\beta$ - $C_2S$  stabilized with Na and Fe (Na-Fe), K and Fe (K-Fe), Na-Al (Na-Al), K and Al (K-Al).

## EXPERIMENTAL PROCEDURE

Assuming that Na or K is substituted for Ca, and Fe or Al for Si, the crystal chemical substitution of each atom was carried out, and the ratio of Ca + Na or K : Si + Fe or Al was always fixed to 2:1. The mixtures were prepared from crushed quartz (99.9%),  $CaCO_3$  (99.9%) and the additives ( $Na_2CO_3$ ,  $K_2CO_3$ ,  $Al_2O_3$  and  $Fe_2O_3$ ), and pressed into small cylinders (20mm diameter  $\times$  20mm height), burned at 1360, 1440 and 1520°C for 30 min. in a SiC furnace and quenched in air. The clinkers were crushed and powdered to a fineness and other compounds were examined by X-ray diffraction.

One part was used to make pastes having a water cement ratio of 0.36, another was mixed with silica sand to make 1:2 mortars, kneaded with water and shaped into rectangles 2x2x8 cm in size. The quantity of added water to mortars necessary to have identical flow was decided by an improved way that followed the standard method using Vicat Tester. In this way the water cement ratio was fixed between 0.62 and 0.65. The compressive strengths were measured at suitable intervals of curing. Each ten pieces of mortar were tested and averaged their data. Simultaneously the hydration products of pastes and their microstructural characteristics were also examined by X-ray diffraction and scanning electron microscopy. The dispersion of additives into interstitial material or  $C_2S$  crystals was examined by X-ray micro analysis. To investigate the hydration process of the  $C_2S$  polymorphs, the mixtures of each phase with 10% of quartz were blended, and moulded into 2x2x8 cm with water cement ratio of 0.36. These test pieces were cured for one day at 90% relative humidity and thereafter in water at 20°C. The quantitative X-ray diffraction was tested at the ages of 7, 14 and 28 days. The degree of hydration was determined by applying

$$\frac{I_t / I_{qt}}{I_0 / I_{q0}} = 1 - \alpha_t$$

$I_0, I_t$  Intensity of analytical diffraction of  $C_2S$  in the original and after hydration time  $t$ . The diffraction

400, 130 and 110 lines were used for  $\alpha$ -,  $\alpha'$ - and  $\beta$ -phase respectively.  $I_{q0}, I_{qt}$  Intensity of 101 diffraction of quartz in the original and after hydration time  $t$ .  $\alpha_t$  Degree of hydration of  $C_2S$  at hydration time  $t$ .

## RESULTS

**Synthesized Products** The ranges where each polymorph is stable are shown in Fig. 1. In the Na-Fe, K-Fe substituted series, the  $\alpha$ -phase was easily crystallized as a single phase in an extensive substituted amount of Na or K and Fe by quenching from above 1360°C. The  $\alpha'$ -phase was formed at above 1440°C, always accompanied by  $\alpha$ -phase. The  $\beta$ -phase was formed in smaller substitution range at above 1440°C, and in the composition in which Na or K was substituted above 0.13 mole,  $K_2O \cdot 23CaO \cdot 12SiO_2$  or  $Na_2O \cdot 3CaO \cdot 2SiO_2$  was crystallized, in the composition in which only Fe was substituted,  $\gamma$ -phase was formed and after that  $CaFeO_4$  was formed with Fe increasing. In Na-Al and K-Al substitution, the  $\alpha$ -phase did not form in any burning temperature, but  $\alpha'$ - and  $\beta$ -phase were crystallized at above 1440°C, accompanied by a small quantity of  $3CaO \cdot Al_2O_3$ . In Na-Al series,  $Na_2O \cdot 8CaO \cdot 3Al_2O_3$  was formed in the composition where larger Na was contained.

The samples for the experiment were adopted from these ranges as shown in Table 1.

Fig. 1 - Substituted range of Na or K and Fe or Al to stabilize  $\alpha$ -,  $\alpha'$ - and  $\beta$ -phase. Symbol was used as follows:  $N_2C_3S_2$ :  $Na_2O \cdot 3CaO \cdot 2SiO_2$ ,  $K_2C_{23}S_{12}$ :  $K_2O \cdot 23CaO \cdot 12SiO_2$ ,  $N_2C_8A_3$ :  $Na_2O \cdot 8CaO \cdot 3Al_2O_3$ , CF:  $CaFeO_4$ , and  $C_3A$ :  $3CaO \cdot Al_2O_3$ .

Table 1 - Compositions of mixtures

Sample designation	Composition	Phases formed	Heating temperature(°C)

		$\beta$	1440

**Hydration Products** Characteristically, early hydration of portland cement results in crystallization of fairly large amount of  $\text{Ca}(\text{OH})_2$ , together with a small amount of calcium silicate hydrate (C-S-H). In the hydration of  $\text{C}_2\text{S}$ , however, only small amount of  $\text{Ca}(\text{OH})_2$  was formed. The hydration ratio was shown in Fig. 2.

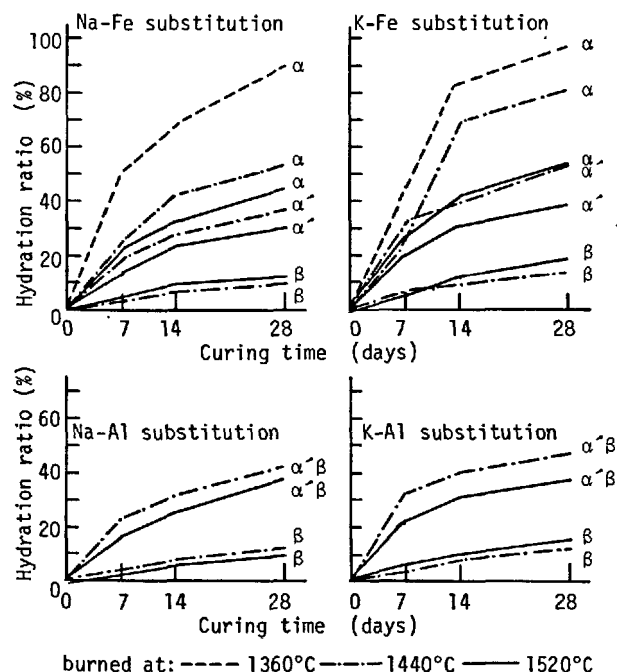

Fig. 2 - Change in hydration ratio of the polymorphs by their burning temperature.

In the Na-Fe and K-Fe substitution, the hydration ratio of  $\alpha$ -phase was greatly changed by burning temperature, and the lower the burning temperature was, the more rapidly the hydration proceeded forming much  $\text{Ca}(\text{OH})_2$  and foil like C-S-H. The hydration ratios of Na-Al and K-Al substituted series, were generally low and far less amount of C-S-H was formed.

**Compressive Strength** The 1 : 2 mortars were prepared in accordance with the Japanese Industrial Standard, and their compressive strengths were tested. The results were shown in Fig. 3.

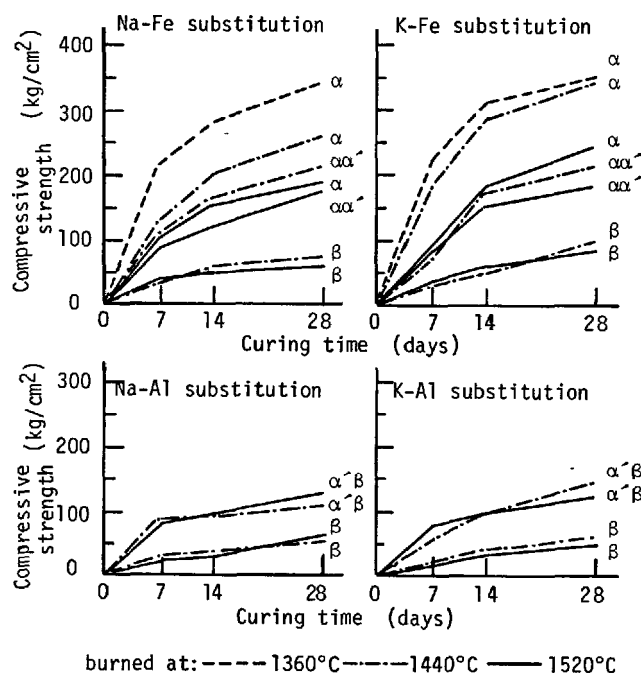

Fig. 3 - Changes in compressive strength of each phase with curing time.

The  $\alpha$ -phase exhibited compressive strength markedly higher than those of  $\alpha'$  and  $\beta$ -phase. Also, the strength of it stabilized with K and Fe surpassed that of the corresponding Na-Fe substituted phase. The effects of burning temperature on the strength were clearly characterized as the better development of strength in the lower temperature burning. But the Na-Fe substituted phase burned at 1440 and 1520 °C showed especially slow hardening corresponding to the low strength development. In the Al substituted series, effective compressive strengths were not expected, as will be discussed later.

Compressive strengths versus hydration ratios were plotted for Na-Fe and K-Fe substituted  $\alpha$ -phases as shown in Fig. 4. Two lines were formed with different inclinations. The  $\alpha$ -phases burned at lower temperature exhibited a rapid development of early strength within 7 days, while the other  $\alpha$ -phases showed a slow hardening and low strength in this period. Their different hydration ratios will probably be caused by their phase structure as will be discussed later.

Fig. 4 - Compressive strengths versus hydration ratio for  $\alpha$ -phases.

#### DISCUSSION

As was shown in Fig. 1, the  $\alpha$ -phases were crystallized when about the same molecules of alkali and Fe were substituted for Ca and Si respectively. We could not get  $\alpha'$  as a single phase, it accompanied  $\alpha$  when comparatively much of alkali was substituted. It is supposed that this phase has a continuous solubility with  $K_2O \cdot 23CaO \cdot 12SiO_2$  or  $Na_2O \cdot 3CaO \cdot 2SiO_2$ , but we need more investigation hereafter. The  $\beta$ -phase crystallized at the range where far less quantity of alkali or Fe was contained and also where only alkali was substituted to Ca ( $\sim 0.13$  mole). When only Fe or Al was substituted for Si in low quantity,  $\beta$  and  $\gamma$ -phase were formed. But in high quantity of Fe,  $\alpha$ -phase and  $CaFeO_4$  were produced, and in high quantity of Al,  $\beta$ -phase and  $3CaO \cdot Al_2O_3$  were produced. The components that composed  $C_2S$  crystal were quantitatively analyzed with the technique of X-ray micro analysis. Consequently each component was uniformly distributed in Na-Fe and K-Fe substituted series. Table III shows the results on the samples burned at 1360 °C.

Table III. - Compositions of each phase calculated from the analyzed data by X-ray micro analysis. The oxygen was added assuming  $(Ca, Na \text{ or } K)O/(Si, Fe)O_2 = 2$ .

Phase produced	Composition
$\alpha$	$Ca_{1.80}Na_{0.18}Si_{0.82}Fe_{0.17}O_4$
$\alpha, \alpha'$	$Ca_{1.81}Na_{0.21}Si_{0.89}Fe_{0.12}O_4$
$\beta$	$Ca_{1.87}Na_{0.11}Si_{0.95}Fe_{0.06}O_4$
$\alpha$	$Ca_{1.80}K_{0.19}Si_{0.87}Fe_{0.18}O_4$
$\alpha, \alpha'$	$Ca_{1.79}K_{0.22}Si_{0.88}Fe_{0.11}O_4$
$\beta$	$Ca_{1.88}K_{0.12}Si_{0.94}Fe_{0.08}O_4$

Comparatively great decreases of alkali and Fe were observed in  $\alpha$  or  $\alpha'$ -phase. Some of them moved into the liquid that was formed around  $C_2S$  crystal as an inter-

stitial phase and other alkalis vaporized in the burning process. On the vaporization of alkalis, we will investigate hereafter in relation to the manufacturing procedure.

In the Na-Al and K-Al substituted series, none of the  $\alpha$ -phase was formed and  $\alpha'$ -phase was always accompanied by  $\beta$ . The distributions of alkalis and Al in  $\alpha'$  and  $\beta$ -crystal were not constant and we could not determine the composition.

Lattice lengths of  $\alpha$ - $C_2S$  were measured by X-ray diffraction as shown in Fig. 5. In the Na-Fe substitution a and c axis increased as Na and Fe were substituted, but in the K-Fe substitution only a axis increased by substituting K for Ca. The c axes of Na-Fe substituted  $\alpha$  were larger than those of K-Fe substituted, not corresponding to the ion size of Na and K. This must be studied hereafter from the point of crystal chemical investigation.

Fig. 5 - Change in lattice lengths of  $\alpha$ -phases with the substitution range. Samples were burned at 1360°C.

Any change in the lattice lengths was not observed when the burning temperature was changed. This fact means that the substituted quantity of additives will not change by burning temperature, then the lattice strains of them are the same. The lattice strain was investigated from the line broadening as shown in Fig. 6. Four reflection of 102, 110, 201 and 202 were used for the calculation, and the change of  $\beta \cdot \cos \theta / \lambda \times 10^{-3}$  with  $\sin \theta / \lambda$  was plotted for  $\alpha$ -phases burned at 1360, 1440 and 1520°C. The lattice strains of K-Fe- $\alpha$  are slightly larger, however, no great changes of their strains by burning were observed.

Fig. 6 - Lattice strain profile of Na-Fe and K-Fe substituted  $\alpha$ -crystal.  $\epsilon$ : lattice strain,  $\theta$ : reflection

angle,  $\lambda$ : wave length,  $\beta$ : breadth of diffraction profile.

From these investigation, it is clear that the hydration and the strength were greatly affected by the hydraulicity or solubility of interstitial phase. When K-Fe and Na-Fe substituted  $\alpha$ -phase were crystallized at low temperature (for the former, at 1360 and 1440 °C, and for the latter, at 1360 °C), the liquid phase coagulated around these crystals in unstable and the dissolution of Ca, SiO<sub>2</sub> and other components into water takes place immediately after contacting with water as shown in Table IV. The analysis of Ca and SiO<sub>2</sub> dissolved in water was proceeded as follows. The dispersed solution was obtained by stirring 2g of C<sub>2</sub>S with 10 ml of water. After continuing the stirring for 5 and 20 minutes, the filtered solution was analyzed. Ca ion concentrations were determined by titrating with ethylene diamine tetraacetic acid (EDTA). Soluble SiO<sub>2</sub> was estimated colorimetrically, using reduced silico-molybdic acid.

Table IV - Ca and SiO<sub>2</sub> dissolved in water from  $\alpha$ -C<sub>2</sub>S pastes

Sample designation	Burning temperature(°C)	Dispersed time (min)	Ca mmole/g	SiO <sub>2</sub> mmole/g $\times 10^{-1}$	Ca/SiO <sub>2</sub>
K-Fe - $\alpha$	1360	5	5.86	0.67	88
		20	2.61	1.00	26
	1440	5	3.46	0.78	44
		20	1.45	1.33	11
	1520	5	2.71	1.67	16
		20	0.80	1.34	6.0
Na-Fe - $\alpha$	1360	5	1.40	1.34	10
		20	0.95	1.34	7.0
	1440	5	1.05	1.67	6.3
		20	0.80	1.64	4.8
	1520	5	1.05	2.45	4.3
		20	0.70	2.22	3.2

The hydration of  $\alpha$  crystal and the hardening were accelerated by their dissolution and affects the high development of strength. This is also clearly understood from Fig. 4.

The hydration products were observed by electron microscopy. In the all of this series the foil like crystal was observed, and its quantity corresponds approximately to their compressive strengths.

#### CONCLUSION

In the Na-Fe and K-Fe substitution, the  $\alpha$ -phase could be stabilized easily, but in the Na-Al and K-Al substitution, only  $\alpha'$  and  $\beta$  phases were crystallized. The  $\alpha$ -phase exhibited high compressive strength and hydraulicity, and the strength of K-Fe substituted  $\alpha$ -phase surpassed others as shown in Fig. 3 and the effects of their burning temperature were characterized as the better development of strength and hydraulicity in the lower temperature burning.

RESUME : Par un ensemble de méthodes d'analyse physico-chimique, y compris la détermination de la composition de la phase liquide, sont étudiées : les caractéristiques de l'hydratation du ciment, la composition et la cinétique de cristallisation des formations nouvelles, les transformations de phase de l'eau et le durcissement à des températures au-dessous de zéro. On peut noter une influence favorable sur les propriétés du ciment durci, d'une cure préalable à des températures au-dessus de zéro, avant la congélation.

L'introduction d'adjuvants-électrolytes représentant la combinaison de deux ou trois sels, est un procédé efficace de l'intensification du durcissement des ciments sous les températures au-dessous de zéro. Non seulement ils réduisent la quantité de glace, mais par le changement de la composition, du pH et de la force ionique de la phase liquide, ils accélèrent l'hydratation des composants siliceux du clinker. Ils assurent aussi une cristallisation intensive de l'ettringite dans les états initiaux et protègent contre le développement des processus destructifs pendant le durcissement ultérieur.

SUMMARY: Peculiarities of cement hydration, composition and kinetics of crystallization in new formations, phase water transformation and hardening under below zero temperature have been studied by complex of methods for physicochemical analysis, including investigations of liquid phase composition. Favourable effects of cement stone precuring under above zero temperature before freezing on its properties have been noted.

Effective method of cement hardening intensification under below zero temperatures is the introduction of electrolyte admixtures, representing combination of two or three salts. They do not only decrease the quantity of ice but accelerate hydration of silicate component of clinker, changing composition, pH and ionic force of liquid phase as well as they ensure intensive crystallization of ettringite on early stages that prevents development of destructive processes in further hardening.

Les problèmes concernant le durcissement du béton soumis à des températures au-dessous de zéro, sont très actuels et significatifs pour la construction durant toute l'année /1,2/. Nous avons étudié l'hydratation cinétique du ciment et les transformations de l'eau en phases, de même que le durcissement du ciment et du béton avec ou sans les différents anti-gel, pour les basses températures. Ces recherches avaient pour but d'étudier le changement cinétique dans la composition de la phase liquide et la capacité de silicate tricalcique à se hydrater - tout cela est par la méthode analytique aux rayons X, de même que la teneur en eau d'hydratation et en éttringite - par les méthodes chimiques.

Le décroissement de la température provoque une réduction de la capacité d'hydratation du ciment. L'hydratation et le durcissement du ciment à des températures au-dessous de zéro sont les fonctions directes de sa teneur en eau non-congelée. A des basses températures au-dessous de zéro et proches à 0°C, l'hydratation du ciment est ralentie. A l'âge de 28 jours, lorsque la température reste au même niveau (-20°C), les 28% de silicate tricalcique se trouvent déjà hydratés. L'abaissement ultérieur de la température jusqu'à -50°C provoque un brusque décroissement du degré d'hydratation de C<sub>3</sub>A (et cette valeur n'est égale qu'à 7,6%). Pour les températures entre -10°C et -20°C toute la quantité de silicate tricalcique reste pratiquement non-hydratée (Tableau I).

TABLEAU I			
Hydratation du ciment portland à des températures au-dessous de zéro			
Durée d'exposition à +20°C avant la congélation (conditions normales)	t°C	Degré d'hydratation de C <sub>3</sub> A, en %	Teneur en eau d'hydratation, %
0	-2	26	4,05
0	-5	7,6	1,48
0	-10	2	1,63
0	-20	2	0,64
3	-20	3	0,60
6	-20	7	0,99
12	-20	21,5	3,35
24	-20	30	4,63
72	-20	42	6,49

Remarque: Eprouviettes exposées au gel jusqu'à 28 jours d'âge et essayées immédiatement avant le dégel.

L'exposition préalable de la pierre de ciment à des températures au-dessus de zéro étant favorable pour l'hydratation subéquente, toutefois celle-ci ne permet pas

d'intensifier essentiellement ce processus.

Une amélioration qualitative peut y être obtenue par addition des anti-gel dans le béton, dont le rôle pour l'abaissement de la température de congélation d'eau dans les pores est bien connu. A titre de ces anti-gel, comme le chlorure et le nitrate de calcium, le nitrite de sodium et autres adjuvants, sont de plus en plus répandus les compositions qui comprennent un certain nombre de sels à savoir: le nitrite-nitrate de calcium (NNK, ici et ailleurs - abréviation russe), le nitrite-nitrate-chlorure de calcium (NNKhK) et d'autres. Le chlorure, le nitrate et le nitrite de calcium, aussi bien que les adjuvants complexes, fabriqués sur leur base (NNK et NNKhK), sont les adjuvants à l'effet polyvalent, dont l'action consiste non seulement à abaisser la température de congélation de la phase liquide dans les pores, mais à favoriser l'accélération d'hydratation du ciment, influençant sur les composants du clinker, tels comme les silicates, les aluminates et les aluminoferrites. Avec ces derniers, ils forment les compositions de type de sels doubles /3-5/. Leur influence sur la composante de silicate, se manifestant en sa plus parfaite solubilité, en accélération de vitesse d'hydratation, en transformation de la morphologie et du degré de polymérisation d'hydrosilicates /6-7/, est conditionnée, en premier lieu, par le changement de valeur de pH et de force ionique dans la phase liquide. La présence des sels modifie la composition de la phase liquide et la valeur de saturation superflue par rapport à des phases initiales d'hydratation, ce qui même, réciproquement, a un changement de la cinétique de formation de leurs cristaux et d'éttringite tout d'abord.

L'addition du NNKhK en quantité de 3% du poids du ciment à +20°C provoque un abaissement de pH et une augmentation, pour un ordre de valeurs, de la force ionique dans la phase liquide, par rapport au système sans ledit adjuvant. On observe l'hydratation accrue du ciment, ce qui peut être confirmé par le caractère même des courbes cinétiques C<sub>Ca</sub>2+ (τ) et C<sub>R</sub> + (τ) - fig. I.

La montée brusque de la courbe cinétique C<sub>R</sub> + (τ) témoigne que la dissolution des grains de clinker passe plus activement, de même que le décroissement rapide de la courbe C<sub>Ca</sub>2+ (τ), ainsi que l'absence de points d'extrémum sur la courbe caractérisant le ciment portland, témoignent la formation intense des cristaux dans les phases contenant le calcium /3/. Les courbes analogues, caractérisant la pâte avec addition du NNKhK, durcie à -50°C, sont moins inclinées.

Cette allure de courbes cinétiques, tout aussi comme les renseignements sur la cinétique de contenance d'eau liée, dont la teneur augmente continuellement avec le temps, allant jusqu'à 9% dans 12 heures, témoigne que l'hydratation passe suffisamment vite à des températures au-dessous de zéro.

Fig. I - Modification en composition de la phase liquide pendant l'hydratation du ciment à +20°C et à -5°C.

1, 2 et 3 - sans adjuvant, à 20°C;

4, 5, 6, 7, 8 et 9 - avec adjuvant de NNKhK à 20°C;

10, 11, 12, 13, 14 et 15 - avec adjuvant de NNKhK à -5°C.

L'addition du NNKhK influe sur la formation cinétique des cristaux doubles à des températures au-dessus aussi bien qu'au-dessous de zéro. La présence de chlorures, des nitrates et de nitrites de calcium intensifie la formation d'ettringite ( $C_6AS_3H_{32}$ ) au moment initial. Dans 10 min après le gachage à +20°C, à peu près de 75% de gypse se trouvent liés en  $C_6AS_3H_{32}$ . La formation des cristaux d'ettringite se termine prati-

quement vers 2 h, lorsqu'il reçoit 83% de gypse, en même temps que la formation de 6,85% de  $C_6AS_3H_{32}$  a eu lieu. Pour la même période, on peut voir que la courbe cinétique  $CSO_4^{2-}$  (7) présente une allure de chute correspondant à la disparition du gypse de la phase solide. Comme on a déjà mentionné ci-dessus, le caractère brusque de la courbe  $CCa^{2+}$  (7) dépend de la formation abondante des cristaux d'ettringite. Dans la suite, la teneur en  $C_6AS_3H_{32}$  ne s'augmente point mais présente même une tendance à se diminuer (4% dans 24 h et 2,78% dans 7 jours). Pendant l'hydratation du ciment portland exempt du NNKhK la teneur d'ettringite croît continuellement et dans 2,6 et 24 h correspond à 3,6; 5,5 et 8,5%.

La formation d'ettringite dans la pâte avec addition de  $CaCl_2$ ,  $Ca(NO_2)_2$  et de NNKhK, dont le durcissement a lieu à la température de -5°C, touche à sa fin pendant les premiers heures après le gachage. La teneur en ettringite dans ce cas pratiquement ne change pas avec le temps, ce qui assure le non-développement des processus destructifs pour le compte de la cristallisation d'ettringite secondaire. L'addition de nitrite de sodium n'accélère pas l'hydratation et n'intensifie pas la formation d'ettringite au période initial (Tableau II).

TABLEAU II

Quantité d'ettringite pendant l'hydratation du ciment avec adjuvants:  $CaCl_2$  - 5%,  $Ca(NO_2)_2$  - 5%, NNKhK - 3%,  $NaNO_2$  - 5% à  $T = -50^\circ C$

Temps, h	Pourcentage d'ettringite correspondant à l'adjuvant de			
	$CaCl_2$	$Ca(NO_2)_2$	NNKhK	$NaNO_2$
I	4,1	6,0	6,2	2,4
2	3,8	6,2	6,2	2,4
4	3,8	6,3	5,8	3,3
6	3,8	6,0	5,8	3,1
8	3,1	5,9	5,9	4,0
12	3,1	6,3	6,0	4,0
16	3,0	6,3	5,7	4,2
24	3,5	6,4	5,3	4,4

Les chlorures, les nitrates et les nitrites de calcium non seulement n'accélèrent la formation des cristaux d'ettringite, mais aussi participent eux-mêmes dans la formation des sels doubles, qui sont les éléments de base pour la formation de la structure lors de durcissement, ce qui est confirmé par la concentration décroissante des ions correspondants dans la phase liquide, ainsi que par leur présence dans la phase solide. Le plus fort décroissement de cette concentration conforme à une phase liquide de chlorures, tandis que le décroissement moins prononcé correspond aux nitrates et finalement - aux nitrites, lorsque celui devient presque nul. Dans 24 h, en tenant compte de la température, de 40 à 60% de chlorures peuvent passer en phase solide. L'éloigne-

ment de telle grande quantité d'ions de calcium et de chlorures hors de cette phase ne se trouvant point undamnifié par son enrichissement, pendant l'hydratation, à l'égard des ions de métaux alcalins et d'hydroxyl, la température de congélation de la phase liquide montre une hausse; toutefois celle-ci ne mème pas à des conséquences graves et néfastes, parce que, dans le béton frais, additionné de tels produits, il existe déjà vers le moment donne la pierre de ciment, caractérisée par une structure capillaire, suffisamment compacte et fine, ce qui favorise le décroissement de la température de congélation de la phase liquide.

Cette température, dans le cas d'addition de nitrite de sodium, reste pratiquement sur le même niveau, la concentration de celui-ci restant inchangable. L'éloignement des nitrites hors de la phase liquide, lorsqu'ils sont liés aux sels doubles, sera compensé par leur concentration toujours croissante, tout cela pour le compte de la volume décroissante de la phase liquide pendant l'hydratation. Ainsi, l'effet favorable du  $\text{NaNO}_2$ , utilisé comme adjuvant dans le ciment et dans le béton durcissants, est-il conditionné généralement par un abaissement de la température de congélation de la phase liquide, assurant l'effet d'hydratation au gel d'un côté et les des destructions moins prononcées de la structure de l'autre, celles-ci étant conditionnées par la transformation d'une partie de l'eau en glace. Quant à la formation de la structure avec les sels doubles sur base du  $\text{NaNO}_2$ , leur rôle reste secondaire.

Les études des transformations à phases de l'eau pendant la congélation du béton, réalisées par la méthode analytique de calorimétrie, ont démontré que l'utilisation des anti-gel favorise la réduction considérable en quantité et en qualité de la glace dans le béton et participe aussi à une modification de la vitesse de congélation. Comme les courbes 1 et 4 le montre (fig. 2), les bétons et la pâte de ciment exempts d'adjuvant NNKhK et soumis à l'action de gelée immédiatement après la confection, se caractérisent par la congélation pratiquement complète de la liquide dans les pores, lorsque la température est au-dessous de  $-4^\circ\text{C}$ .

La teneur en glace dans les éprouvettes de béton avec addition de 3% de NNKhK du poids de ciment, soumis à l'action de gelée immédiatement après la confection (courbe 2), est égale à 72%. L'exposition préalable du béton à des températures au-dessus de zéro provoque une diminution supplémentaire de la quantité de glace. Ainsi, après 24 h de l'exposition avant la congélation des éprouvettes (courbe 3), la teneur en glace n'était-elle égale qu'à 27%.

L'addition du NNKhK est capable à influencer essentiellement sur la modification cinétique de teneur en glace dans le béton. Si pendant l'exposition au gel de la pâte de ciment on du béton exempts d'adjuvants,

Fig. 2 - Quantité de glace dans le béton après 28 jours de congélation à  $T = -5^\circ\text{C}$ .

1 - béton sans adjuvant; 2 - béton avec 3% du NNKhK; 3 - idem, congelé dans 24 h; 4 - pâte normale, sans adjuvant, congélation immédiate.

la teneur en glace ordinairement est augmentée, l'addition du NNKhK fait une sensible réduction de glace avec le temps. De même, la teneur en glace dans le béton sans adjuvants, soumis à température de  $-20^\circ\text{C}$  était égale à 87% dans 24 h et à 98% à l'âge de 28 jours. Les résultats de l'ingénieur N. DOMACHEVSKY montrent, qu'avec addition du NNKhK l'augmentation considérable de teneur en glace ne peut avoir lieu que durant les premiers jours de durcissement au gel, après quoi la vitesse de ce phénomène se trouve sensiblement réduite et dans 28 jours cette teneur diminue de 22% (fig. 3, courbe 3).

On peut voir la chose à la température de  $-5^\circ\text{C}$ , mais dans ce cas la diminution de la teneur en glace y était égale à 12%. Ces renseignements témoignent que l'hydratation du ciment avec adjuvant passe d'une manière intense, de même que les phénomènes destructifs, causés par la transformation de l'eau à phases, sont moins prononcés, ce qui assure, en somme, le durcissement plus intense du béton par temps froid.

Les recherches présentées ici et ayant pour but d'étudier le problème de durcissement du béton avec ou sans adjuvants anti-gel soumis à des températures au-dessous de zéro, ont confirmé les résultats obtenus. Ces études ont été effectuées avec le béton de classe "300", congelé immédiatement après la confection ou dans 24 h de conservation normale, jusqu'à 90 jours de mise en froid dans une chambre souterraine, en contact avec le sol toujours congelé à température de  $-3^\circ\text{C}$ .

Fig. 3 - Influence du NNKhK sur la quantité de glace dans le béton

1+4 - béton congelé immédiatement après la confection; 5 - dans 24 h de conservation normale.  
1 - béton sans adjuvant,  $T = -2^{\circ}\text{C}$ ; 2 - idem, à  $T = -5^{\circ}\text{C}$ ; 3 - 3% de NNKhK,  $T = -2^{\circ}\text{C}$ ; 4 - 3% de NNKhK,  $T = -5^{\circ}\text{C}$ ; 5 - 3% de NNKhK,  $T = -2^{\circ}\text{C}$ ; 6 - 3% de NNKhK,  $T = -5^{\circ}\text{C}$ .

La conservation pendant 24 h suivant la caractéristique de température correspond à des conditions réelles de congélation du béton dans les ouvrages, p.ex. dans les fondations sur pilotis. La fig. 4 donne un exemple de courbes qui montrent une augmentation de la résistance du béton avec addition de 3% de  $\text{NaNO}_2$  + 0,2% de sulfolevure (SDB, abréviation russe). Comme on peut voir, le béton sans adjuvants, mis directement sur terre congelée, vers 90 jours n'a augmenté sa résistance que de 20% par rapport à celle de 28 jours. Après le durcissement normal de 24 heures la résistance du béton de même âge était égale à 56%. L'addition de susdit sel en quantité de 3% du poids de ciment fait augmenter la résistance du béton, car, pour la même période, ce dernier est capable d'obtenir la valeur (classe) de résistance de 28 jours on environ (dans le cas de son exposition au gel immédiatement après la confection). La susdite méthode du bétonnage en hiver a été utilisée en particulier pour le coulage des fondations de la cheminée en béton armé, de 180 m d'hauteur, à Norylsk, au lieu du bétonnage par chauffage électrique, utilisé auparavant, plus coûteux et compliqué.

Pour faire une estimation de l'efficacité d'utilisation de différents produits anti-gels enfluent sur le durcissement du béton au gel jusqu'à  $-10^{\circ}\text{C}$ , on a entrepris les essais spéciaux. Ces expériences se rapportent à des bétons ayant la classe de résistance "400". Les dosages des additions étaient: 3% - à  $T = 0 + -2^{\circ}\text{C}$ ; 5% - à  $T =$

Fig. 4 - Augmentation de la résistance du béton à  $T = -3^{\circ}\text{C}$ .

1 - sans adjuvants chimiques, béton congelé immédiatement; 2 - sans adjuvants chimiques, béton congelé dans 24 h de conservation normale; 3 - avec addition de 3% de  $\text{NaNO}_2$  + 0,2% de SDB, congélation immédiate; 4 - idem, congélation dans 24 h de conservation normale.

$-5^{\circ}\text{C}$  et 7,5% - à  $T = -10^{\circ}\text{C}$ . On n'utilisait que le nitrite de sodium, le nitrate de sodium, le nitrite de sodium en pourcentages égaux avec le chlorure de calcium et le NNKhK en proportion égale entre les composants. L'analyse de résultats obtenus (tableau III) montre que lorsqu'on ajoute les produits chimiques dans le béton, il est possible d'obtenir la résistance demandée du béton au gel dans 90 jours, qui sera égale à 75+100% de la résistance à 90 jours de conservation dans les conditions normales, on 60+84% de la même valeur de résistance dans 28 jours.

Ces essais ont confirmé l'efficacité d'utilisation des adjuvants complexes, ayant, dans leur composition, l'accélérateur de durcissement ( $\text{CaCl}_2$ ), surtout à l'âge jeune.

En Union Soviétique, plus de 25 ans, on utilise avec efficacité et sur une large échelle les différents anti-gel pour le bétonnage par temps froid des structures massives de bâtiments et des ouvrages. Pour

élargir l'efficacité d'utilisation de la capacité d'hydratation et des propriétés structurelles du ciment, enflant sur la formation de la structure optimale du béton, ce derniers temps, on a commencé à pratiquer l'utilisation des anti-gel avec les produits à action superficielle. Donc, dans les standarts, il est admix d'utiliser ces adjuvants à des températures de dehors jusqu'à  $-25^{\circ}\text{C}$ .

Pour les conditions climatiques plus dures, aussi, que pour l'approchement des délais de décoffrage et de mise en charge des structures achevées, cette méthode est utilisée en combinaison avec celle du thermos on avec le traitement thermique. Pour compléter les standarts officiels, les manuels de recommandations et les instructions ont été créés et publiés /8/.

TABLEAU III

Influence des anti-gel sur le durcissement du béton à des températures au-dessous de zéro

Adjuvant	Age du béton	Résistance, du béton en % de $R_{28}$ à température, $^{\circ}\text{C}$			
		+20	0+-2	-5	-10
Sans adjuvant	7	-	12	-	-
	28	100	45	5	1,5
	90	-	57	10	6
$\text{NaNO}_2$	7	-	23	20	17

	90	-	89	88	91
$\text{NaNO}_2$ + $\text{CaCl}_2$	7	-	42	47	41
	28	II2	84	83	84
	90	-	98	97	102
NNKhK	7	-	45	32	27
	28	127	70	75	70
	90	-	81	85	75

## CONCLUSIONS

L'hydratation du ciment et le durcissement du béton à des températures au-dessous de zéro, sont considérablement retardés à moins qu'ils n'en se stoppent pas totalement. Pour intensifier ces processus il est utile d'y ajouter les différents anti-gel, qui engendrent le décroissement de la température de congélation de la phase liquide, accélèrent l'hydratation du ciment, modifient en quantité et en qualité, la vitesse de formation de glace dans le béton, ce qui provoque finalement le durcissement accéléré du ciment et du béton. Le procédé le plus efficace consiste à utiliser les adjuvants complexes. L'addition de tels produits anti-gels et le traitement plus prolongé du béton avant sa congélation assurent la pos-

sibilité du bétonnage à des températures au-dessous de zéro.

# The effects of $\text{Cu}(\text{OH})_2$ on the hydration of $\text{C}_3\text{A}$

## *Action du $\text{Cu}(\text{OH})_2$ sur l'hydratation du $\text{C}_3\text{A}$*

C. TASHIRO, Asst. Professor, Yamaguchi University, Faculty of Engineering, Ube, Japan,  
J. OBA, Master of Engineering.

RESUME : Plusieurs études ont déjà été faites, par divers chercheurs, sur l'action d'additifs sur l'hydratation du  $\text{C}_3\text{A}$ . Mais le cas des oxydes ou des hydroxydes de métaux lourds a été peu exploré. Dans la présente étude,  $\text{Cu}(\text{OH})_2$  est ajouté à  $\text{C}_3\text{A}$ , et on a observé, pendant la période d'hydratation, la concentration en  $\text{CaO}$  et  $\text{Al}_2\text{O}_3$  de la phase liquide, la quantité de chaleur dégagée et la nature des hydrates.

$\text{Cu}(\text{OH})_2$  retarde, à ses débuts, l'hydratation du  $\text{C}_3\text{A}$ , abaisse la concentration de  $\text{CaO}$ , augmente celle d' $\text{Al}_2\text{O}_3$  et empêche la formation de cristaux de  $\text{C}_3\text{AH}_6$ , dans la phase liquide. Dans le même temps, les cristaux hexagonaux d'aluminate de calcium se forment progressivement. La vitesse d'hydratation obéit à la loi suivante :

$$(1 - \sqrt[3]{1 - \alpha})^n = kt.$$

SUMMARY : The effects of additives on the hydration of  $\text{C}_3\text{A}$  have been investigated by a number of researchers. However, the very little knowledge has been gained on how heavy metal oxides or hydroxides affect the hydration of  $\text{C}_3\text{A}$ . Therefore, in the present study,  $\text{Cu}(\text{OH})_2$  was added to  $\text{C}_3\text{A}$ , and  $\text{CaO}$  or  $\text{Al}_2\text{O}_3$  concentration of liquid phase under hydration, heat liberation in early hydration reaction,  $^{2,3}$  characterization of hydration products and rate of hydration were examined.

$\text{Cu}(\text{OH})_2$  retards the early hydration, tends to decrease the solubility of  $\text{CaO}$  and increases the solubility of  $\text{Al}_2\text{O}_3$  in liquid phases under hydration, and so hinders the formation of  $\text{C}_3\text{AH}_6$ . In the meantime, hexagonal calcium aluminate hydrates grow with the passage of curing time, and rate of hydration in second stage follows  $(1 - \sqrt[3]{1 - \alpha})^n = kt$ .

## INTRODUCTION

The effects of gypsum on the hydration of  $C_3A$  have been investigated by a large number of researchers(1-3). However, the effects of heavy metal oxides have not been published to data. The studies present an fundamental data of hydration of Portland cement clinker. On the other hand, the studies are under way in recent years on disposal of industrial wastes containing heavy metals through solidification of such wastes by cement(4-6).

For these reasons, heavy metal oxides are added to  $C_3A$  and the effects on the hydration were examined(7). It has become apparent that  $Cu(OH)_2$  and  $ZnO$  strongly retard the early hydration of  $C_3A$ .

Therefore, in the present study, in order to clarify the mechanism of the retardation,  $Cu(OH)_2$  was added to  $C_3A$  and effects on the bottle hydration of  $C_3A$  were examined on  $Cu^{2+}$ ,  $CaO$  and  $Al_2O_3$  concentration in liquid phase and on the characterization of hydrates.

## EXPERIMENTAL

$CaCO_3$  and  $Al_2O_3$  were mixed to a composition of  $C_3A$  and the mixture was calcined twice, each time at  $1350^\circ C$  for 5 hours. The calcined material was then ground to a Blaine value of about  $3500 \text{ cm}^2/\text{g}$ .  $Cu(OH)_2$  is commercially available as reagent.

$Cu(OH)_2$  was added as  $0.8C_3A + 0.2Cu(OH)_2$  mol. The hydration was carried out in water with 20water/ $C_3A$ , at  $20^\circ C$  for 3 days under vibrating condition with 120 time/min.

The hydrates were filtered off, washed with acetone, and dried in vacuum. The solution separated from the bottle hydration was analysed by EDTA titration or spectrophotometer with  $CaO$ ,  $Al_2O_3$  and  $Cu^{2+}$ .

The hydrates were observed and identified by a polarization microscope, powder x-ray diffractometry, differential thermal analysis, and a scanning electronic microscope.

The hydration rate was calculated from  $C_3A$  in hydrates which was heating at  $650^\circ C$  for 3 hours. And the quantities of  $C_3A$  were measured by X-ray scanning techniques with  $\alpha-Al_2O_3$  as an internal standard.

## EXPERIMENTAL RESULTS AND DISCUSSION

## Hydrates

Without  $Cu(OH)_2$ : The powder x-ray diffraction, differential thermal analysis and scanning electron micrographs of hydrates obtained from hydration reaction are shown in Fig. 1, 2 and 3 respectively. As is apparent from the X-ray differential analysis, after 10 minutes from water mixing,  $C_3AH_6$  forms in a considerable amounts and hexagonal hydrates is slight amount. But the scanning micrographs indicated that platy and needle like crystals grow and characteristic crystal of  $C_3AH_6$  is not observed. This is believed to

be due to the very small grain and high crystallization of  $C_3AH_6$ . With the passage of hydration time, new formation of hexagonal hydrates increase as the amount of unhydrated  $C_3A$  decrease, and after one day, hexagonal hydrates decompose and transfer to  $C_4AH_{13}$ . Then, the hexagonal hydrates are chiefly  $C_4AH_{13}$ .

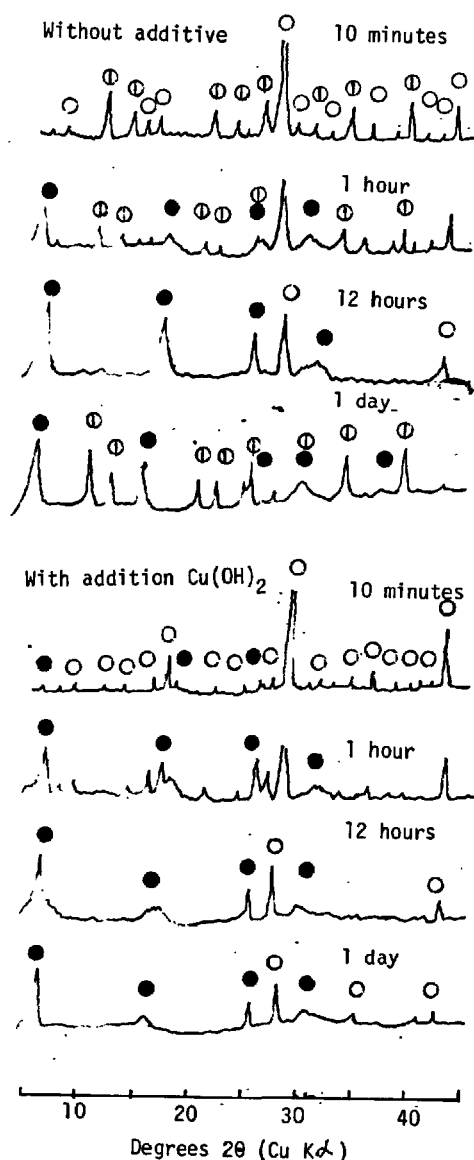

Fig.1-X-ray powder diffraction patterns of  $C_3A$  hydrated without and with addition  $Cu(OH)_2$ .

○  $C_3S$   
 ⊙  $C_3AH_6$   
 ● Hexagonal hydrates ( $C_4AH_{13}$ )

Fig.2 - DTA curves of  $C_3A$  hydrates without and with addition  $Cu(OH)_2$ .

With addition  $Cu(OH)_2$ : After 10 minutes from water mixing,  $C_3AH_6$  hardly appears and fine platy crystal grows on the  $C_3A$ . With the passage of hydration time, hexagonal hydrates grows. After 3 days, it indicated that the hydrates formed are mostly hexagonal phases. From one day, Formation of  $C_2AH_8$  is observed.

The ratio of quantity between  $C_3AH_6$  and hexagonal hydrates is shown by ratio of an end-thermic peak area of differential thermal analysis at about 330 vs 120 and 220°C as shown in Fig.2 and 4. Its illustration explains well the formation of hydrates.

Fig.4 - Relation between DTA peak area of  $C_3AH_6$  and hexagonal phases.

#### $CaO$ and $Al_2O_3$ concentration in liquid phase

The concentration of  $CaO$  and  $Al_2O_3$  in liquid of bottle hydration without and with addition  $Cu(OH)_2$  is shown in Fig. 5.

After 30 seconds from water mixing,  $CaO$  concentration becomes 551 ppm without additive, and 497 ppm with addition  $Cu(OH)_2$ . At about 1.5 hours,  $CaO$  concentration temporarily increases because of the  $C_4AH_13$  transfer to  $C_3AH_6$ . Namely, excess  $CaO$  component solves in liquid.

On the other hand,  $Al_2O_3$  concentration is 272 ppm without additive, and 325 ppm with addition  $Cu(OH)_2$ .  $Al_2O_3$  concentration is gradually decreases until one hour from water mixing, and subsequent concentration is kept at about 100 ppm.

$CaO/Al_2O_3$  mol ratio in liquid phase without and with addition  $Cu(OH)_2$  is 7 to 8, which is higher than that of  $C_3A$ . This data similar to report of Kondo(8), but the relation between concentration and hydration time differs because of difference of water/ $C_3A$  and finess of  $C_3A$ .  $CaO/Al_2O_3$  mol ratio with addition  $Cu(OH)_2$  is lower than that of case of no addition. On the contrary,  $CaO/Al_2O_3$  ratio of hydrates certainly higher. Namely,  $C_4AH_8$  trend to be formed than  $C_3AH_6$ .

Fig.3 - Scanning electron micrographs of  $C_3A$  hydrated without and with addition  $Cu(OH)_2$ . 5  $\mu$ m

A : Without additive after 10 minutes.  
 B : Without additive after 2 hours.  
 C : Without additive after 6 hours.  
 D : Without additive after 3 days.  
 E : With addition  $Cu(OH)_2$  after 10 minutes.  
 F : With addition  $Cu(OH)_2$  after 2 hours.  
 G : With addition  $Cu(OH)_2$  after 6 hours.  
 H : With addition  $Cu(OH)_2$  after 3 days.

### $\text{Cu}^{2+}$ concentration in liquid phase

$\text{Cu}^{2+}$  concentration is shown in Fig. 5. After 30 seconds from water mixing,  $\text{Cu}^{2+}$  is 1.75 ppm, and after 10 minutes, becomes 3 ppm, and decreases to 0.8 ppm at 1 hour. This shows that,  $\text{Cu}^{2+}$  is soluble with increase of pH, after 10 minutes, reached to maximum 10 ppm, for this period,  $\text{Cu}^{2+}$  is adsorbed on the  $\text{C}_3\text{A}$  or hydrates and subsequently, adsorption of  $\text{Cu}^{2+}$  is accelerated with increasing hydration.  $\text{C}_3\text{A}$  adsorbed by  $\text{Cu}^{2+}$  is apt to be developed the hexagonal hydrates. Because of addition  $\text{Cu}(\text{OH})_2$ , solubility of  $\text{CaO}$  from  $\text{C}_3\text{A}$  decreases and that of  $\text{Al}_2\text{O}_3$  increases, and calcium aluminate containing saturated  $\text{CaO}$  is formed as hexagonal hydrates. Then,  $\text{Cu}$  represents as  $[\text{Cu}(\text{OH})_4]^{2-}$  (9) or  $\text{Ca}_2[\text{Cu}(\text{OH})_4]$  in solution.

Fig. 5 - The concentrations of  $\text{CaO}$ ,  $\text{Al}_2\text{O}_3$  and  $\text{Cu}$  in liquid phase.

### Rate of hydration

The rates of hydration of  $\text{C}_3\text{A}$  without and with addition  $\text{Cu}(\text{OH})_2$  are shown in Fig. 6. As is apparent from this illustration, hydration of  $\text{C}_3\text{A}$  is divided into two stages. In the case of  $\text{C}_3\text{A}$  without additive, first stage is an early stage for 10 minutes from water mixing. When  $\text{Cu}(\text{OH})_2$  added, this first stage hydration is retarded and the stage is prolonged up to 1 hour.

The second stages of hydration without and with additive satisfy the hydration formula (8)

$$(1 - \sqrt[3]{1 - \alpha})^n = kt$$

where  $\alpha$  is hydration rate,  $t$  hydration time and  $n, k$  constant. The rate of hydration in second stage is slower than the first stage. In the case of no additive,  $k = 1.05 \times 10^{-2}$ ,  $n = 3.82$  and with addition  $\text{Cu}(\text{OH})_2$ ,  $k = 3.9 \times 10^{-3}$ ,  $n = 3.72$ . The order of the hydration reaction is really stage known as diffusion rate-determining stage. And first stage during the first 10 minutes is concordant with the results of Buikova (10).

The retardation of hydration in early stage is measured by differential calorimetric analysis as shown in Fig. 7. The difference in heat of hydration is about - 21.8 kcal/mol.

Fig. 6 - Rate of hydration of  $\text{C}_3\text{A}$  without and with addition  $\text{Cu}(\text{OH})_2$ .

Fig. 7 - Differential calorimetric curve on the initial hydration of  $\text{C}_3\text{A}$  with addition  $\text{Cu}(\text{OH})_2$ .

### Effects of addition $\text{Cu}(\text{OH})_2$

As the above descriptions, in the early stage of hydration,  $\text{Cu}(\text{OH})_2$  is solved and adsorpted by  $\text{C}_3\text{A}$  or hydrates, and consequently, hydration is retarded, concentration of  $\text{CaO}$  in liquid phase decreases and  $\text{Al}_2\text{O}_3$  increases and hexagonal hydrate is formed.

The mechanism of retardation of hydration is no clear but it seems that surface of  $\text{C}_3\text{A}$  or hydrates is coated by  $\text{Cu}^{2+}$  and invasion of water to inner parts is prevented, and this effect is responsible for similarity of ionic potential and crystal structure F.C.C. between  $\text{Ca}^{2+}$  and  $\text{Cu}^{2+}$ .

### CONCLUSION

To examine the effects of  $\text{Cu}(\text{OH})_2$  on the hydration of  $\text{C}_3\text{A}$ , experiments on bottle hydration were carried out and the effects on the hydrates, their microstructure, concentration of  $\text{CaO}$ ,  $\text{Al}_2\text{O}_3$  or  $\text{Cu}^{2+}$ , and rate of hydration were studied.

The results are as follow.

$\text{Cu}(\text{OH})_2$  strongly retards the early hydration of  $\text{C}_3\text{A}$ , and hinders the formation of  $\text{C}_3\text{AH}_6$ . In the meantime, hexagonal hydrates grow with the passage of hydration time. And  $\text{Cu}(\text{OH})_2$  affects the  $\text{CaO}$  and  $\text{Al}_2\text{O}_3$  concentration of liquid phase.  $\text{CaO}/\text{Al}_2\text{O}_3$  mol ratio in liquid phase is lower than that of case of no addition.

The hydration of  $\text{C}_3\text{A}$  is distinguished between first stage and second stage. Without additive, the first stage is an early stage for 10 minutes, and with addition, this is prolonged up to 1 hour. The both second stages of hydration without and with  $\text{Cu}(\text{OH})_2$  addition satisfy the hydration formula  $(1 - \sqrt{1 - \alpha})^n = kt$ .

It seems that the mechanism of retardation of hydration is owing to coating or adsorption on the  $\text{C}_3\text{A}$  with  $\text{Cu}^{2+}$ . This action is responsible for similarity of ionic potential and crystal structure between  $\text{Ca}^{2+}$  and  $\text{Cu}^{2+}$ .

# The composition of CSH phase(s) in hydrated $C_3S$ paste

## *Composition des phases HSC dans la pâte hydratée de $C_3S$*

D.L. RAYMENT and A.J. MAJUMDAR, Building Research Establishment, Garston, Grande-Bretagne.

RESUME : La microsonde électronique Microscan 9 a été utilisée pour déterminer les compositions des phases d'hydrate de silicate de calcium (HSC) dans les pâtes de silicate tricalcique hydrate (rapport eau/solide 0,6) à l'âge d'un mois et d'un an. Les analyses faites sur divers éléments de microstructure considérés comme étant des phases de HSC, à des voltages électroniques accélérés de 6 à 25 kV montrent que les coefficients C/S mesurés sont influencés par le voltage du faisceau électronique utilisé, dépendant vraisemblablement du volume des régions particulières analysées. Par exemple, les grains qui offrent des caractéristiques morphologiques semblables donnent des valeurs C/S de  $1.44 \pm 0.08$  et  $1.62 \pm 0.06$  à des voltages de faisceau de 6 et de 15 kV respectivement. Au contraire, les grains non-hydrates de  $C_3S$  qui sont présents dans les échantillons de pâte donnent  $3.09 \pm 0.09$  et  $3.06 \pm 0.04$ , car les coefficients C/S à ces voltages et les échantillons de tobermorite naturelle provenant de plusieurs sources ne montrent pas d'effet important des variations de voltage dans leurs analyses.

L'étendue des variations observées dans les coefficients C/S des divers éléments de microstructure de la pâte avec le voltage du faisceau sera discutée. Ces variations ne sont pas considérées comme étant dues à la détérioration du faisceau.

SUMMARY: The electronprobe microanalyser Microscan 9 has been used to determine the compositions of the calcium silicate hydrate phase(s) in hydrated tricalcium silicate pastes (water/solid ratio 0.6) at the age of one month and one year. Analyses carried out on various microstructural elements considered to be CSH phase(s) at electron accelerating voltages in the range 6-25 KV show that the measured C/S ratios are influenced by the beam voltage used, presumably depending on the volume of individual regions analysed. For instance, particles displaying similar morphological features gave C/S values of  $1.44 \pm 0.08$  and  $1.62 \pm 0.06$  at 6 and 15 KV beam voltages respectively. By contrast, unhydrated  $C_3S$  grains present in the paste samples gave  $3.02 \pm 0.09$  and  $3.06 \pm 0.04$  as the C/S ratios at these two voltages and natural tobermorite samples from several sources did not show any significant effect of voltage variations on their analyses.

The extent of the variations observed in the C/S ratios of the various microstructural elements in the paste with beam voltage will be discussed. These variations are not considered to be due to beam damage.

## INTRODUCTION

The importance of calcium silicate hydrate (CSH) phases as the principal cementing agent in concrete is well recognised. These phases are very poorly crystalline and occur as aggregates of very small particles often intermixed with other products of cement hydration. The application of electron microscopy, particularly the scanning electron microscope (SEM), in recent years has been very useful in the characterisation of the CSH phases, enabling Diamond(1) to classify them into several microstructure-types.

The composition(s) of the CSH phase(s) in hydrated cements are, however, more difficult to determine. Using the SEM in conjunction with an energy-dispersive X-ray microanalysis (EDAX) system, a comprehensive study of the elemental composition of the gel phase in hydrated Portland cement was made in this laboratory a few years ago(2). It was pointed out that the task of isolating the CSH phase(s) free of other hydration products within the volume of X-ray excitation in an SEM is a formidable one and only a statistical assessment of the results was possible. Recognising these difficulties Dent Glasser et al(3) have recently attempted X-ray microanalysis of dispersed CSH particles produced by the hydration of tricalcium silicate (C<sub>3</sub>S) using a transmission electron microscope (TEM). For isolating the CSH phase(s), this method of analysis is undoubtedly superior but as the authors have remarked hydrate phases that are strongly attached to the unhydrated grains can sometimes escape dislodgement and, therefore, are not analysed. Moreover, there is at present a prevalent view that in hydrated C<sub>3</sub>S the composition of the CSH phase(s) varies with its distance from the unhydrated core and indeed such variations form an important part of the interesting speculations(3-5) that are currently being made about the mechanisms of cement hydration. In an electron-optical study of a dispersed cement paste sample, information on the progressive nature of the microstructure development in CSH is likely to be, at least, partially lost and from this point of view X-ray microanalyses carried out with an SEM or an electron probe microanalyser (EPMA) have merits of their own.

Some aspects of the microanalysis of CSH phase(s) in hydrated C<sub>3</sub>S by EPMA, particularly the effect of electron beam voltage on the analysis are described in this paper.

## EXPERIMENTAL

Two samples of C<sub>3</sub>S paste were examined in this study. One was a 30-day material prepared using a water/solid ratio of 0.6 and previously described by Stucke and Majumdar(6) and the other represented the same sample hydrated for a further period of 11 months. For the second sample, which was hydrated for a total period of one year hydration had been temporarily arrested at one month to obtain the specimens for the earlier study(6). From the point of view of assessing the effect of electron accelerating voltage on the C/S ratio of CSH, this interruption in the hydration processes is considered not very important. Two specimens of naturally occurring tobermorite from two different localities were also analysed.

The specimens examined by EPMA were polished sections of samples impregnated in resin, the final polishing having been done with 0.25  $\mu$ m diamond paste. The mineral wollastonite was used as the standard for Ca and Si. After polishing the C<sub>3</sub>S paste specimens were lightly etched by immersing them in ethanol containing 1% HNO<sub>3</sub> for 3 seconds. These and the standard specimen were vacuum coated with ~30 nm of carbon in the same operation. SEM examinations were carried out on freshly fractured surfaces which were sputter coated with 20 nm of gold.

The instrument used in the analysis was a Microscan 9, a computer controlled EPMA having a take-off angle of 75° manufactured by the Cambridge Instrument Company. The SEM used was a 'Stereoscan IIA' from the same Company. Initially, the EPMA analysis of the 30-day sample was carried out at 15 KV to obtain comparisons with the previous SEM/EDAX results(6). The analysis was then repeated at 10 KV when it was observed that there were systematic differences between the results obtained at the two voltages. This was confirmed by analyses carried out on the one year old sample and it was felt that an experimental assessment of the voltage effect on CSH phase analysis was warranted. Analyses were, therefore, carried out at different voltages in the range 6-25 KV.

It is well known that materials such as CSH are likely to suffer from beam damage during analysis in an EPMA. To reduce this effect a probe current of 1 nA was used throughout. At the lower accelerating voltages the count rates were consequently low (for example, ~24 c/sec for CaK $\alpha$  and SiK $\alpha$  on wollastonite at 6 KV) and the counting times were increased at the lower accelerating voltages to reduce the statistical error. The analysis times on the standard and unknowns were kept the same at each accelerating voltage to ensure that the level of carbon contamination (due to cracking of pump oil) on the specimens were similar.

The primary standard wollastonite was analysed each day prior to the analysis of the hydrated C<sub>3</sub>S samples. The Ca and SiK $\alpha$  count rates were measured from 6 or more positions on the standard, 20  $\mu$ m apart, and an average taken. A new set of positions were chosen each time the standard was analysed and only those sets of analyses that gave coefficients of variation less than 2.0% were accepted. During the first measurements on the standard a peak searching routine was performed by the spectrometers. At low count rates this took 3-4 minutes and during this period the electron probe remained focussed on the specimen. This sometimes led to inconsistent results which were rejected. During subsequent analyses this problem did not arise as the probe was blanked off from the specimen at all times except when emergent X-rays were counted. For all analyses the background count rates were measured at a distance of 100 from the centroid of the peak on the side of the increasing Bragg angle.

With the hydrated C<sub>3</sub>S samples, the regions to be analysed were selected on the basis of morphological features seen in their back-scattered electron images. In the initial work at 10 and 15 KV analyses were carried out on one spot only once and between 5 and 20 positions were analysed. Where unhydrated C<sub>3</sub>S grains were present, they served as internal

standards. The stability of the instrument could be judged by performing analysis on them periodically. As a further check, analysis of the woolastonite standard was carried out from time to time.

In the study concerned with the effect of beam voltage on the C/S ratios of CSH phase(s) measurements were first made at an accelerating voltage of 6 KV. The voltage was then increased to a predetermined level and the appropriate analysis carried out. The voltage was then reduced to 6 KV and the C/S ratio re-determined. If there was no significant difference between this figure and the previous one, both measured at 6 KV, the voltage was increased to the next higher value. This procedure was repeated until the highest selected voltage (ie 25 KV) was reached. When the analysis from successive 6 KV measurements showed a significant difference, the spot position was moved  $\sim 2 \mu\text{m}$  along the centre line of the region analysed. For each selected voltage at least seven spot analyses were obtained and the average taken.

#### RESULTS AND DISCUSSION

##### (a) Microstructure of C<sub>3</sub>S pastes

The microstructure of one month old C<sub>3</sub>S paste has been described previously in some detail(6). Figure 1 is a low-magnification SEM photograph showing fibrous CSH (Type I after Diamond(1)) and large Ca(OH)<sub>2</sub> crystals. Figure 2 is a corresponding EPMA photograph taken on the polished sample. In this micrograph the fibrous detail is missing and it is thought that vacuum impregnation of the sample with resin employed in the preparation of polished specimens is responsible for the covering up of this detail.

Fig 1 SEM photo showing fibrous CSH in one month old C<sub>3</sub>S paste

Higher magnification SEM and EPMA photographs of the C<sub>3</sub>S/CSH interface are shown in Figures 3 and 4. The rim surrounding the unhydrated C<sub>3</sub>S core, described in the earlier paper(6) as 'inner product' represent Type IV CSH in Diamond's(1) classification. The dark region in the EPMA photographs (Figures 2 and 4) is a mixture of the embedding resin and CSH, probably of the Type I variety. Between this and the inner product layer there is seen (Figure 4) a dense but granular structure.

Fig 2 Backscattered EPMA photo corresponding to Fig 1

Fig 3 C<sub>3</sub>S/CSH interface, SEM photo of one month old C<sub>3</sub>S paste

Fig 4 C<sub>3</sub>S/CSH interface, EPMA photo corresponding to Fig 3.

Low magnification SEM and EPMA micrographs of the one year old C<sub>3</sub>S paste are shown in Figures 5 and 6. It can be seen that in comparison with the 30-day sample the hydration rim is wider here and the proportion of hydrated material greater. In this Type IV CSH rim that surrounds the C<sub>3</sub>S core, a discontinuity was often seen. Analysis of C/S ratios of hydrate regions on either side of the

Fig 5 SEM photo of one year old C<sub>3</sub>S pasteFig 6 EPMA photo of one year old C<sub>3</sub>S paste

discontinuity gave virtually the same results ( $1.7 \pm 0.15$  for 6 measurements and  $1.63 \pm 0.05$  for 11 measurements, all at 15 KV). It can only be assumed that this discontinuity was caused by the arrest in the hydration process in the sample at one month as mentioned in a previous section. In other respects the microstructure of the one year sample was essentially the same as that of the one month old sample and the CSH exhibited Type I and IV morphologies. In some EPMA photographs the fibrous Type I CSH was clearly discernible forming the outermost hydration layer.

#### (b) C/S ratios in CSH phase(s)

The C/S ratios of unhydrated C<sub>3</sub>S grains, Type IV CSH and Type I CSH obtained by microanalysis at 10 and 15 KV are listed in Table I. It is clearly seen that for immature C<sub>3</sub>S, the effect of increasing the beam voltage was to increase the C/S ratios of both CSH IV and CSH I phases in a significant way. This trend was also observed for CSH phase(s) present in the one year old sample albeit to a lower extent. No such trend was found in the analyses performed on hydrated C<sub>3</sub>S cores. The other noteworthy observation was that the Type I CSH in the pastes showed a much wider scatter in the Ca and Si count rates from spot to spot although the scatter in the C/S ratios was significantly lower than that observed for Type IV CSH in the 30-day old sample.

TABLE I ANALYSIS OF PASTE HYDRATED C<sub>3</sub>S

SAMPLE	ACCELERATING VOLTAGE (KV)	C/S	NO. OF ANALYSIS	95% CONFIDENCE INTERVAL
A. One month old water/solid = 0,6				
C <sub>3</sub> S	10	3.02	13	$\pm 0.07$
	15	3.05	6	$\pm 0.09$
CSH Type IV	10	1.60	5	$\pm 0.16$
	15	1.82	9	$\pm 0.22$
CSH Type I	10	1.52	6	$\pm 0.05$
	15	1.74	5	$\pm 0.05$
B. One year old water/solid = 0,6				
C <sub>3</sub> S	10	3.04	7	$\pm 0.03$
	15	3.00	6	$\pm 0.06$
CSH Type IV	10	1.60	20	$\pm 0.07$
	15	1.66	17	$\pm 0.05$
CSH Type I	10	1.60	6	$\pm 0.10$
	15	1.65	11	$\pm 0.12$

#### (c) Effect of beam voltage on C/S ratios of CSH

The variations in the C/S ratios of the Type IV CSH phase with beam voltage observed with both one month and one year old C<sub>3</sub>S pastes are shown in Figure 7. The variations shown for each voltage represent at least six different spot analyses. The hydrate rims analysed rarely exceeded 1.5 μm for the one month sample but they were approximately 5 μm wide in the one year old sample. It is seen that the voltage effect is more pronounced for the one month old sample where the CSH phase consists of smaller and thinner particles. It is also evident from Figure 7 that unhydrated C<sub>3</sub>S grains do not show this voltage effect and neither does the tobermorite sample from Portree which has a dense, featureless microstructure (Figure 8). The other tobermorite specimen, from Zacatecas in Mexico has a platy microstructure intermixed with FeS<sub>2</sub> (Figure 9) and a slight dependence of its C/S ratio on the beam voltage has been recorded.

In order to explain the observed voltage effect on CSH phase analysis it is necessary to consider the effective ranges of the electron in the hydrate as this would be the limiting distance up to which the electrons are still capable of exciting characteristic X-radiation. Many workers have studied this problem, both theoretically and experimentally and a summary is given in the review by Beaman and Isasi(7). Calculations based on some of the relationships tabulated in reference 7 show that for a material of composition C<sub>3</sub>S<sub>2</sub>H<sub>3</sub>(8) having a density of 2.7 the electron penetration for calcium X-ray generation increases from ~0.3 μm at 6 KV to ~5-6 μm at 25 KV. For lateral spread of electrons the radius

Fig 7 Variation of C/S ratio with accelerating voltage.

Fig 8 Tobermorite from Fortree, EPMA photo

of the probe diameter, typically 0.14 and 0.08  $\mu\text{m}$  at 6 and 25 KV respectively for the instrument used, has to be added to these values. Of all the studies cited by Beaman and Isasi(7), the work of Andersen(9) who measured the penetration and spread of the volume of X-ray excitation with a Si/SiO<sub>2</sub> combination is perhaps the most relevant to the present study. The values of electron penetration and spread for C<sub>3</sub>S and C<sub>3</sub>S<sub>2</sub>H<sub>3</sub> calculated from the expressions given by Andersen are shown schematically in Figure 10 for different electron accelerating

Fig 9 Tobermorite from Mexico, EPMA photo

voltages.

Calculation of the quantitative X-ray resolution as defined by Reed(10) were also made without the correction due to Duncumb. The results obtained gave values that were higher than Andersen's spread values by up to 18% in the range 6-25 KV. The estimates illustrated in Figure 10 leave no doubt that high electron accelerating potentials have a very pronounced effect on the size of X-ray excitation volume in CSH and allied materials. In the present

Fig 10 Effective electron penetration and spread for  $C_3S$  and  $C_3S_2H_3$

work polished specimens of  $C_3S$  pastes have been subjected to microanalysis by the EPMA. In these specimens the location of the cutting plane through any hydrated  $C_3S$  particle is difficult to establish without definite knowledge of the size and shape of the particles concerned. As the electron ranges increase appreciably with accelerating potential, at high KV's say, 15-25 KV, the analysis of the CSH phase is likely to include a contribution from the underlying material which could either be unhydrated  $C_3S$  or  $Ca(OH)_2$  or both. In each case the estimated C/S ratio will increase, and the effect will be more pronounced in the thinner and smaller hydrate particles analysed. Results shown in Figure 7 supports this view. That the lowest scatter in the observed C/S ratios of the hydrates correspond to analyses carried out at the lowest beam voltage is also in agreement with the above argument. Judged from this point of view, the most accurate estimate of CSH phase(s) in hydrated  $C_3S$  samples from EPMA is likely to be obtained if the analysis is carried out at the lowest possible beam voltage that is compatible with a reasonable count rate. Present work would indicate that Type IV CSH in  $C_3S$  pastes has a C/S ratio of  $1.44 \pm 0.08$ .

Because the fibrous, Type I hydrate appeared only as a mixture with the resin the amount of hydrate in any analysis volume was variable. This is reflected in the high variation in the Ca and Si weight percent results and the low variation in the C/S ratios. The analyses of this hydrate also showed a reduction in the C/S ratio with decreasing accelerating voltage.

This reduction was most significant for the thirty day old sample where the proportion of unhydrated  $C_3S$  would be greatest. The volume analysed by the probe is expected to be similar in both the Type IV and the Type I/resin materials.

The CaO and  $SiO_2$  analyses obtained at 6 KV for the Type IV hydrate was used to calculate the formula of the hydrate. It was assumed that remainder of the hydrate was chemically combined water. The molar proportions obtained were  $3 \pm 0.3$ ,  $2.07 \pm 0.16$ ,  $3.6 \pm 0.62$  for CaO,  $SiO_2$  and  $H_2O$  respectively for the one year sample and  $3 \pm 0.3$ ,  $2.1 \pm 0.17$  and  $3.0 \pm 1.0$  for the thirty day sample.

These observations need to be confirmed by other workers but they strongly suggest that the stoichiometry of the different types of CSH phase(s) in mature  $C_3S$  pastes may not be far removed from the ideal formulae  $3CaO \cdot 2SiO_2 \cdot 3H_2O$  put forward by Brunauer et al many years ago(8).

#### (d) Beam Damage

In some instances beam damage has been observed on CSH particles on prolonged electron bombardment. Typical examples are shown in Figure 11. While studying the effect of beam voltage on Type IV CSH phase analysis it has been observed that as a consequence of increasing the voltage from 6 KV to 25 KV in stages as described, the final spot analysis at 6 KV (ie after 9 analyses altogether on the spot requiring a total analysis time of 7-8 minutes) can show a depletion in the calcium content of up to ~35%. The silicon content remains relatively unaffected. The instability of calcium bearing minerals due to electron bombardment has been reported in the literature(11). In the analysis of small and thin CSH particles particular attention needs to be paid to this aspect.

Fig 11 Electron beam damage in CSH

#### CONCLUSIONS

- 1 The C/S ratios of Type IV and Type I CSH phase(s) present in immature  $C_3S$  pastes as determined by EPMA were found to be  $1.82 \pm 0.22$  and  $1.74 \pm 0.05$  respectively at 15 KV. Previous SEM/EDAX analyses on the same sample gave  $1.9 \pm 0.1$  and  $1.6 \pm 0.1$  at the same voltage. The agreement between the two sets of results is considered to be good.
- 2 The C/S ratios of Type IV and Type I CSH phase(s) present in one year old  $C_3S$  pastes as determined

- by EPMA were  $1.66 \pm 0.05$  and  $1.65 \pm 0.12$  at 15 KV. A similar study by Grutzeck and Roy(12) on the hydration rim around C<sub>3</sub>S in a 24-week old paste gave a C/S ratio of  $1.7 \pm 0.1$ , also at 15 KV.
- 3 The C/S ratios of CSH phase(s) obtained by EPMA were dependent on the beam voltage used. At the lowest beam voltage used (ie 6 KV) where the analysis is least affected by the penetration and lateral spread of the electron beam, the C/S ratio obtained for Type IV CSH was found to be  $1.44 \pm 0.08$ .
  - 4 The present work suggest that the stoichiometry of CSH phase(s) in mature C<sub>3</sub>S pastes is not far removed from the ideal formula  $3\text{CaO} \cdot 2\text{SiO}_2 \cdot 3\text{H}_2\text{O}$ . It is not impossible that CSH phases exhibit different morphologies but their equilibrium compositions are very similar.

# Caractéristiques thermochimiques du ciment et accélération de durcissement du béton

## *Thermochemical characteristics of cement and acceleration of concrete setting*

I.B. ZACEDATELEV, professeur, chef de laboratoire, VNIPI Teploproekte, Moscou, U.R.S.S.

**RESUME :** Les recherches calorimétriques d'hydratation du ciment permettent non seulement d'obtenir des informations complètes sur la cinétique du processus en fonction de la composition minéralogique et granulométrique du ciment, mais aussi d'évaluer, sans perturbation du cours naturel du processus, l'influence spécifique des effets thermiques, chimiques et mécaniques.

Le présent rapport a pour objet l'étude de l'ensemble des facteurs cinétiques, thermodynamiques et énergétiques sur l'hydratation du ciment dans des conditions de durcissement accéléré par un traitement thermique.

Des recherches expérimentales effectuées à l'aide d'un dispositif calorimétrique automatisé ont permis, non seulement de déterminer l'influence de la température sur la vitesse d'hydratation, mais aussi de mettre en évidence l'influence de cette température en fonction du degré d'achèvement du processus d'hydratation. Elles ont montré ainsi l'action différente de la température à quatre étapes distinctes du processus d'hydratation, dans des conditions isothermes.

On a observé que l'augmentation, avec la température, du dégagement de chaleur de l'hydratation du ciment était inévitable, à chaque étape du processus d'hydratation, surtout quand le degré d'hydratation était compris entre 0 et 0,8. Ceci met en opposition les caractéristiques cinétiques et thermodynamiques de l'hydratation.

Les résultats ont montré qu'une dérogation au principe thermodynamique de Le Chatelier n'avait pas d'influence nocive sur l'hydratation. Donc l'indépendance, vis à vis de la chaleur dégagée par l'hydratation, d'une action thermique extérieure, tant en durée qu'en intensité, est bien fondée. On en a déduit une méthode d'optimisation du traitement thermique des structures en béton, pour obtenir un durcissement accéléré et utiliser au mieux la chaleur d'hydratation.

**SUMMARY:** Calorimetric investigation of cement hydration gives full information about kinetics of process not only depending on mineralogical and grain composition of cement but allows without breaking natural course of process to estimate specific influence on it of thermal, chemical and mechanical kinds of action.

The present paper accented combined consideration of kinetic, thermodynamical and power factors of cement hydration process at accelerated hardening of concrete at application of thermal action.

Experimental investigation of kinetic characteristics of process (carried out on automated calorimetric device) allowed to determine not only dependence of damped influence of temperature factor (with increase of temperature level) on hydration rate but also revealed influence of temperature factor in relation to degree of completeness of hydration process. Also non-equivalence of temperature function at four different stages of hydration process at isothermal temperature regimes is showed.

Inevitability of intensification of heat liberation of cement at application of thermal action at any stage of completeness of hydration process, especially in limits up 0 to 0.8, is revealed. It causes contradiction between kinetic and thermodynamical characteristics of process.

Results of accomplished physicochemical investigation do not reveal negative influence of infringement of thermodynamical principle of Le Chatelier. Thus freedom of choice of time of application and intensity of outer thermal influence on hardening system "cement-Water" is substantiated without dependence of action of inner source of heat. Considered ways of optimization of thermal regimes of accelerated setting of cement predetermine more full usage of cement hydration heat in kinetics of heating of products and structures.

L'étude des caractéristiques thermochimiques du ciment à l'aide des dispositifs calorimétriques automatisés à large gamme de conditions limites (1) a permis d'obtenir de nouvelles données sur l'influence des paramètres du régime sur les processus d'hydratation. Pour évaluer l'influence de la température sur la cinétique d'hydratation, il est nécessaire d'adopter une méthode plus stricte de détermination de la fonction de température du processus  $f_t$ . L'analyse des données expérimentales obtenues sur base du principe des dégagements calorifiques égaux démontre la nécessité de leur comparaison non pas à choix arbitraire des états équivalents des systèmes durcissants à températures différentes, mais aux états précisément fixés, définis par le degré d'hydratation  $L$ :

$$L = \frac{Q_3^x}{Q_3}$$

où:  $Q_3^x$  - représente le dégagement calorifique au moment  $x$ ,  $Q_3$  - représente le dégagement calorifique total.

En vue de simplifier l'expérience, la valeur de  $Q$  peut être limitée par la valeur totale du dégagement calorifique à l'âge de 28 jours  $Q_3^{28}$ , car à cet âge le degré d'hydratation d'un système (pâte de ciment, mortier de ciment ou béton) à des températures différentes tend à une même valeur (2). On a trouvé expérimentalement les rapports de vitesse  $V$  et durée  $\tau$  pour les températures de 313, 333 et 353°K relatifs à la température normale de durcissement (293°K) pour chaque valeur relative du degré d'hydratation  $L$ , déterminée aux intervalles de 10%:

$$\frac{V_t}{V_{20}} = \frac{\tau_{20}}{\tau_t}$$

Ce qu'il y a de particulier, c'est que, en comparant l'intensité du dégagement calorifique ( $dQ_3/d\tau$ ) de telle manière, les valeurs maximales se concentrent dans une même zone à toutes les températures de conservation isotherme (fig.1). Ce fait démontre la justesse de tel approche à la détermination de la fonction de température d'hydratation et confirme, du point de vue de thermochimie du ciment, l'identité du mécanisme d'hydratation à différentes températures.

Telle méthode d'évaluation de l'influence de température sur l'hydratation et le dégagement calorifique du ciment a permis de déceler certaines particularités de leur apparition à différentes étapes du processus. On a remarqué que, tout d'abord, à l'étape d'hydratation  $L = 0 + 0,3$ , l'influence de la température sur l'intensification du dégagement calorifique des ciments de tous types était maximale. Ce fait est contribué par la rupture des métastables gaines-protectrices entourant les grains de ciment, ainsi que par l'activation du transfert par diffusion et par convection des

Fig. 1. Intensité de dégagement calorifique en fonction de température aux différentes durées et aux différents degrés d'hydratation du ciment: — au temps absolu; - - - au degré d'hydratation ( $L$ ) relatif

produits d'hydratation dans le système durcissant. Ayant atteint les valeurs maximales, la fonction de température diminue aux étapes plus avancées à cause d'accroissement de la densité des gaines qui protègent les grains du liant.

Pourtant, on a remarqué que, aux valeurs  $L = 0,45 + 0,5$ , pour un certain nombre de ciments, la température intensifie derechef le processus d'hydratation. A notre avis, ce fait est dû à la teneur élevée du ciment initial en fractions grosses (40-60  $\mu$ ).

Après l'étape d'hydratation active de ces fractions on a observé derechef la diminution des valeurs de la fonction de température du processus. Donc, pour évaluer les processus cinétiques d'hydratation et de dégagement calorifique sous l'influence de température dans des conditions isothermes de durcissement, il faut prendre en considération la composition granulométrique du liant.

En examinant l'influence des caractéristiques thermochimiques du ciment sur durcissement accéléré du béton, il faut faire attention tout d'abord aux régimes thermiques de ces processus. La plupart des problèmes concernant l'utilisation pratique des données de la cinétique d'hydratation et de dégagement calorifique des ciments doivent être résolus pour les régimes thermiques non-stationnaires. Le durcissement accéléré du béton est en général effectué dans des conditions de programme thermique compliqué,

y compris l'irrégulier chauffage et refroidissement.

Jusqu'à présent, de nombreux travaux se rapportant à l'hydratation du ciment ne concernaient essentiellement que l'influence de la température dans des conditions isothermes; aussi la plupart des recommandations d'utilisation des propriétés physico-chimiques du ciment avait-elles été données à base de régularités du régime isotherme d'hydratation du ciment et ne représentaient pas toute la complexité des processus réels. Donc, il est nécessaire d'effectuer expérimentalement des recherches de la cinétique de dégagement calorifique dans des conditions de température non-stationnaires. Les recherches de l'influence des températures variables sur l'intensité de dégagement calorifique du ciment sont effectuées d'après une méthode spéciale. Cette méthode consiste à agir sur le mortier de ciment dans le vase du calorimètre différentiel automatisé à température 293°K aux étapes différentes d'hydratation par une impulsion thermique, la valeur de cette impulsion étant choisie de telle sorte que la température du matériel à étudier soit élevée à vitesse de 5, 10 et 15°C/h. Les régularités obtenues de variation de vitesse de dégagement calorifique en fonction de la durée de conservation préalable ont montré que l'action thermique sur le ciment durcissant conduit inévitablement à l'intensification du dégagement calorifique, pratiquement indépendamment du degré d'hydratation (fig. 2). Il est à noter que l'intensité maximale de dégagement calorifique est atteinte au moment final d'élévation de température, et que la valeur absolue de dégagement calorifique dépend de la durée de l'action thermique.

On a constaté l'abaissement monotone de l'intensité du dégagement calorifique en fonction du degré d'achèvement du processus d'hydratation dans les limites  $L = 0,1-0,8$ . Cependant, même si le maximum de dégagement calorifique est atteint au cours de conservation préalable ( $t = 293^\circ\text{K}$ ,  $\tau = 15\text{h}$ ,  $L = 0,2-0,28$ ), le chauffage extérieur du système durcissant à vitesse  $15^\circ\text{C/h}$  provoque une intensité de dégagement calorifique 2,5 fois plus grande que celle de la période maximale.

Les résultats obtenus ont montré l'inévitabilité d'intensification des réactions exothermiques d'hydratation du ciment sous l'action thermique à n'importe quelle étape de durcissement actif du béton. Donc, au cours de durcissement accéléré du béton, il est impossible d'assurer le principe thermodynamique de Le Chatelier qui consiste à la séparation des périodes d'action des sources thermiques intérieures et extérieures en vue d'obtenir des conditions de maximale plénitude des réactions chimiques. Quelles sont les conséquences de telle contradiction insoluble entre les conditions thermodynamiques de réalisation de la maximale plénitude du processus d'hydratation et les conditions cinétiques de développement de la vitesse maximale de ce processus? Pour répondre à

Fig. 2. Intensité de dégagement calorifique aux différentes étapes de traitement thermique ( $t' = 15^\circ\text{C/h}$ ): a) valeurs réelles de "rejaillissement" de l'intensité; b) le schéma recommandé de point de vue thermodynamique d'application de traitement thermique.

cette question on a exécuté des recherches physico-chimiques<sup>\*</sup> de l'influence de différentes formes de conjugaison des caractéristiques cinétiques et thermodynamiques du processus d'hydratation sur les propriétés finales de la pierre de ciment.

On a examiné la cinétique d'hydratation et de formation de structure de la pierre de ciment à quatre régimes thermiques (fig. 3), ensuite le durcissement se poursuivait dans des conditions d'humidité normale pendant une durée de 28 jours. Dans les deux premiers régimes, on a simulé les conditions favorables (régime 1) et défavorable (régime 2) relativement à l'observation du principe de Le Chatelier à la période initiale d'hy-

\* Les collaborateurs suivants ont pris part à ces recherches: D.D. Cotelnicoff, S.A. Chifrine, E.E. Coulago, V.P. Poddoubenko

Fig. 3. Régimes thermiques de différentes conjugaisons des caractéristiques cinétiques et thermodynamiques d'hydratation du ciment.

dratation, dans les régimes 3 et 4 - la même chose au moment de dégagement calorifique propre maximal. La détermination de l'eau de constitution et de la chaleur d'hydratation du ciment, l'analyse quantitative et qualitative aux rayons X, les recherches à l'aide du microscope électronique, ainsi que la détermination de résistance à la compression ont démontré qu'il n'y avait pas de différence considérable entre les caractéristiques des systèmes durcissant dans des conditions favorables (refroidissement) et défavorables (chauffage).

Il y avait un devancement d'hydratation aux régimes 1 et 3, ce qui démontre l'influence prédominante des caractéristiques cinétiques. Ces régimes se caractérisent aussi par une plus grande valeur de résistance finale des échantillons à l'âge de 28 jours. En même temps, l'étude de la structure poreuse aux rayons des pores de 0,05 à 25  $\mu$  a montré son identité pour les échantillons qui avaient durci selon les régimes 2 et 4 et ceux qui avaient durci dans des conditions d'humidité normale. Les échantillons qui avaient durci selon les régimes 1 et 3 contenaient plus de pores à rayons 0,6-8  $\mu$  en comparaison aux ceux qui avaient durci dans des conditions d'humidité normale.

Ainsi, les données obtenues permettent de conclure que la combinaison de l'action thermique extérieure (à l'intensité de 15°C/h) avec le dégagement thermique intérieur n'influence d'aucune manière la cinétique et le degré d'hydratation, cette dernière étant un processus physico-chimique irréversible.

Donc, il est possible de choisir une durée d'application et d'intensité de l'action thermique extérieure au béton dans un intervalle plus large. La liberté de choix du temps de début de traitement thermique et de l'intensité d'apport calorifique au béton est d'une grande importance énergétique. En effet, la consommation d'énergie extérieure pour chauffage des articles et structures en béton doit être envisagée en totalité avec les caractéristiques thermo-chimiques des ciments, ainsi qu'avec la possibilité de maximale utilisation de dégagement calorifique intérieur dans le béton durcissant.

Au cours d'accélération de durcissement du béton sous l'action thermique - à l'usine ainsi qu'à la construction de structures monolithes - l'étape d'élévation de température du béton est critique au point de vue de détermination de puissance de la source énergétique extérieure. Donc, la participation de la source calorifique intérieure en rapport avec le potentiel thermo-chimique du ciment doit être assurée tout d'abord à cette étape de traitement thermique du béton. Il apparaît que la plus raisonnable solution de ce problème consiste à l'utilisation des régimes étendus ("doux") de traitement thermique, quand la vitesse d'élévation de température du béton peut être comparée au degré d'intensification de chaleur d'hydratation du ciment.

La participation de la source calorifique intérieure au chauffage du béton dépend non-linéairement de l'intensité du traitement thermique extérieur. Si on diminue la vitesse d'élévation de température, l'influence de l'effet thermo-chimique d'hydratation du ciment sur le chauffage du béton accroît sensiblement (fig. 4).

Outre l'intensité de traitement thermique extérieur, la participation du dégagement calorifique intérieur au chauffage du béton est influencée par la durée de ce traitement. En diminuant la période de conservation préalable on peut observer une tendance d'accroissement de participation du dégagement calorifique au chauffage du béton, aux régimes "doux" d'élévation de température (3-5°C/h) qui suivent. Dans des conditions de traitement thermique plus intense, la durée de conservation préalable du béton influence moins la participation du dégagement calorifique au chauffage du béton. Il est à noter que, outre l'économie d'énergie thermique de 40 à 60%, les régimes "doux" de traitement thermique du béton permettent de réduire les processus physiques de destruction dans le béton. Les caractéristiques physico-mécaniques et structurales finales du béton chauffé dans des régimes "doux" sont identiques à celles du béton durci dans des conditions d'humidité normale.

Fig. 4. Degré de participation de la chaleur d'hydratation du ciment ( $Q_3$ ) à la consommation totale d'énergie thermique ( $P$ ) pour chauffage du béton à la durée de conservation préalable: 1-0h; 2-2h; 3-6h; 4-10h; 5-24h

#### CONCLUSIONS

Pour évaluer les processus cinétiques d'hydratation et de dégagement calorifique du ciment, il faut déterminer l'influence du facteur de température aux degrés équivalents d'achèvement des processus d'hydratation ( $L$ ) dans des conditions isothermes à températures différentes.

On a mis en évidence l'inévitabilité d'intensification de dégagement calorifique au traitement thermique à quelque étape d'hydratation du ciment ( $L = 0 + 0,8$ ), ce qui provoque une contradiction entre les caractéristiques thermodynamiques et cinétiques du processus.

Il est démontré par les résultats des recherches physico-chimiques que la dérogação du principe thermodynamique de Le Chatelier n'a pas d'effet nocif sur la cinétique et le degré d'hydratation du ciment.

L'optimisation de la durée et de l'intensité de l'action thermique extérieure permet de recommander des régimes économes de durcissement accéléré du béton diminuant la consommation d'énergie de 40 à 60%.

RESUME : Est étudié le comportement des minéraux principaux du ciment portland durci tels que : hydrosilicate, hydroaluminate et oxyde du calcium hydraté sous différents régimes de traitement thermique à la vapeur ou à sec. Est établi le rapport direct entre la stabilité thermique des formations nouvelles et les propriétés de déformabilité et de résistance du ciment durci.

Est déterminée l'influence de l'adjuvant hydraulico-actif provenant d'un agrégat poreux finement moulu (kéramsite) sur les propriétés du ciment durci. Cet adjuvant exerce une action plastifiante qui dépend de sa composition en grains et en minéraux. Sont mises en évidence les formations dans les zones de contact, et l'évolution de la microstructure du ciment étudié, qui améliore sa compacité et son durcissement.

SUMMARY: Behaviour under different regimes of moist steam curing and dry heating for main minerals of portland cement hardened paste - hydrosilicate, hydroaluminate, hydrate calcium oxide has been studied. A direct dependence between thermal stability of new formations and deformative and strength properties of hardened cement paste has been given.

There has been determined the influence of hydraulically active admixture from fine-ground porous aggregate-ceramsite on properties of hardened cement paste. The admixture produces a plasticizing action, which depends on its grain and substance fineness. Regularities of forming of contact zone and microstructure of steam-cured hardened cement paste, resulting in its compaction and strengthening, has been revealed.

Les caractéristiques techniques du ciment durci et du béton sont dans une mesure considérable conditionnées par la stabilité de leurs composantes minérales et de leurs structures. Pendant le durcissement du ciment la composition de la phase liquide change et cela entraîne les changements, de phase dans certaines nouvelles formations d'hydrates. D'autre part, dans les conditions d'exploitation du béton (par exemple, sous le chauffage) les changements des minéraux du ciment durci et la reconstruction de la microstructure ont lieu aussi.

Dans la pierre de ciment portland sans adjuvants un hydroaluminat de calcium à haute basicité,  $C_4AH_{13}$ , se cristallise. L'examen radiographique a montré que dans les conditions de haute saturation de la phase liquide par les ions de calcium (dans le ciment d'alite-aluminate) une transformation d'  $\alpha$  -  $C_4AH_{13}$  dans  $\beta$  - forme a lieu. Cela n'exerce pas de grande influence sur la résistance du ciment durci /5/.

Pendant un long durcissement dans les conditions normales ou sous le traitement thermique la transformation de  $C_4AH_{13}$  hexagonal dans  $C_3AH_6$  cubique a lieu et cela abaisse la résistance du ciment durci. Si la température dépasse  $150^\circ C$  l'hydroaluminat cubique de calcium se décompose en  $C_4A_3H_3$  et  $Ca(OH)_2$ . Sous l'élévation ultérieure de la température on peut observer la déshydratation de  $Ca(OH)_2$  ( $t^\circ = 450 - 520^\circ C$ ) et la décomposition postérieure de  $C_4A_3H_3$  ( $t^\circ = 620^\circ C$ ) /3-5/.

Dans la pierre de ciment portland additionnée de gypse et sous la température normale hydrosulfoaluminat de calcium  $C_3A \cdot 3CaSO_4 \cdot H_{31}$  est la nouvelle formation essentielle contenant l'aluminate (ettringite) dont la stabilité est déterminée par la composition minérale du ciment de base (Fig.1). Dans les ciments d'alite-aluminate

Fig. 1 - Les cristaux d'ettringite  $C_3A \cdot 3CaSO_4 \cdot H_{31}$  sous la température normale. Une réplique platino-carbonique,  $\times 10000$

et d'alumoferrite c'est l'ettringite qui est une nouvelle formation stable. Il paraît que ses cristaux aciculaires "renforcent" le ciment durci et le font par cela plus consolidé. Dans le ciment de bélite-aluminate après la fixation complète du

gypse a lieu la transformation d'ettringite dans monosulfoaluminat de calcium,  $C_3A \cdot CaSO_4 \cdot H_{12}$ . L'augmentation de la résistance des éprouvettes dans cette période est ralentie /4/.

Le traitement par le chauffage dans la vapeur contribue aussi à la transformation partielle d'ettringite dans monosulfoaluminat de calcium. Au cours de chauffage à sec sous la température  $100^\circ C$  l'ettringite perd  $20H_2O$  et commence à se décomposer en dégageant le gypse bi-hydraté et le gypse semi-hydraté. A la Fig.2 sont présentées les clichés radiographiques d'ettringite chauffé gamme des températures étant  $20-800^\circ C$ . Est montré que sous la  $t^\circ = 100^\circ C$  les lignes principales d'ettringite ( $d = 9,8; 5,7; 3,86; 3,48; 2,57; 2,2 \text{ \AA}$ ) diminuent brusquement; une ligne à partir de  $d = 7,6 \text{ \AA}$  appartenante au gypse.

Sous le chauffage jusqu'à la température  $200^\circ C$   $6H_2O$  reste dans l'ettringite; un dérèglement dans la structure cristalline du minéral a lieu; le changement de ses propriétés optiques et les résultats de l'analyse radiographique le témoignent. On peut observer la disparition des lignes principales d'ettringite.

Fig. 2 - Les radiographies d'ettringite chauffé des températures 20, 100, 200, 400, 600,  $800^\circ C$

Le chauffage jusqu'à la température  $400^\circ$  et  $600^\circ C$  amène à la décomposition d'ettringite en  $CaO$ ,  $C_{12}A_7$  et  $CaSO_4$ . Une ligne faible d'anhydrite a partir de  $d = 3,49 \text{ \AA}$  paraît sous la  $t^\circ = 400^\circ C$ . Sous la température  $600^\circ C$  on peut voir les lignes  $CaO$  ( $d =$

2,41 Å),  $C_{12}A_7$  ( $d = 4,9$  Å) et  $CaSO_4$  ( $d = 3,49$ ; 2,87; 2,32; 2,2 Å) à la Fig.2. Après le chauffage sous la température 800°C une décomposition complète a lieu /5/. A la place de lui (d'ettringite) sur les clichés radiographiques (Fig.2) sont marquées des lignes nettes des produits de décomposition cités plus haut. Fig.2 les clichés radiographiques d'ettringite sous les températures telles que: 20, 100, 200, 400, 600, 800°C.

La composition de hydrosilicate de calcium dans le ciment hydraté varie de  $C_2SH_2$  au  $CSH(B)$  /3-5/. Au cours de durcissement du ciment durci dans les conditions normales la composition de hydrosilicates de calcium pratiquement ne change pas mais ses cristaux s'agrandissent un peu (Fig.3). Au cours de traitement autoclave, surtout si on y additionne de silice, la composition de hydrosilicate change vers  $CSH(B)$ . Avec cela on peut observer sa cristallisation nette qui amène à l'augmentation de la résistance des éprouvettes (Fig.4). Un traitement autoclave de longue durée contribue à la formation dans le ciment durci de gros cristaux de tobermorite  $C_4S_5H_5$  (Fig.5).

Fig. 3 - Les cristaux de hydrosilicate de calcium  $C_2SH_2$  sous la température normale. Une réplique platino-carbonique, x 10000

Fig. 4 - Les cristaux de hydrosilicate de calcium  $CSH(B)$  après le traitement autoclave. Une réplique platino-carbonique, x 10000

Fig. 5 - Les cristaux de tobermorite  $C_4S_5H_5$  après le traitement autoclave de longue durée. Une réplique platino-carbonique, x 10000

Sous le chauffage du ciment durci dans le milieu sec à l'air une déshydratation progressive des nouvelles formations hydrosiliciques a lieu. On peut en juger d'après la réduction de la quantité de l'eau hydratée, d'après l'accroissement de la masse spécifique des éprouvettes ainsi que d'après la diminution de grandeur des lignes  $CSH(B)$  sur les clichés radiographiques. La déshydratation du ciment durci est accompagnée par la diminution de volume de la phase solide, par l'augmentation de la porosité, par l'affaiblissement de la résistance (par rapport aux éprouvettes de durcissement normal).

L'hydrate d'oxyde de calcium  $Ca(OH)_2$  (portlandite) se forme pendant l'hydratation de  $C_3S$  et se dégage dans le ciment durci, en général, en état d'agglomérations microgranulées. Dans les zones inétanches et sur les parois des pores se forment les cristaux plus gros de portlandite. Sous le chauffage au-dessus de température 500°C la déshydratation de  $Ca(OH)_2$  a lieu, avec cela les grains de  $CaO$  se forment dans le ciment durci. Dans les conditions de durcissement sec à l'air dans le ciment durci a lieu une facile carbonatation de portlandite qui se transforme dans la calcite. La calcite est une composante stable du ciment durci et contribue au compactage et à la consolidation de ce dernier. L'aragonite et le vaterite sont les variétés de la calcite. La décomposition thermique de la calcite a lieu sous la température 780-820°C /4,5/.

Les résultats des études complexes ont témoigné un rapport direct entre la stabilité thermique des nouvelles formations et les propriétés techniques du ciment durci.

Les changements importants du composé de phase et de microstructure du ciment de portland durci se produisent en présence des particules des agrégats poreux hydrauliquement actifs et à dispersion fine (pulvérulentes). Par la réalisation des essais spéciaux on a déterminé l'influence de ces particules sur les caractéristiques

rhéologiques et sur les caractéristiques de résistance du ciment durci.

En qualité d'agrégat poreux de base on a utilisé le kéramsite dont le grain a une structure zonaire (zone extérieure et zone intérieure) et dont la composition chimico-minéralogique, la structure et les propriétés physiques pour chaque zone sont inégales. Il est présenté par la phase de verre (~70%) d'une composition alumosiliceuse. Quartz est le minéral principal, de la phase cristalline (~20%), les minéraux de second ordre sont tels que: feldspath, spinelle, hematite et d'autres - 10% au total.

On a effectué les études du ciment durci et des mortiers de ciment - sable avec du sable quartzéux et additionnés de particules pulvérulentes des zones extérieure (P.e.) et intérieure (P.i.) du granule de kéramsite en quantité de 5-20%; ses particules remplacent la partie de masse du ciment. Le nombre maximum des particules répondait au teneur en ces particules dans le béton de kéramsite réel. La surface spécifique,  $S_{sp}$ , de particules soit correspondait à celle du ciment de base,  $S_{sp} = 3000 \text{ cm}^2/\text{g}$ , soit en était considérablement supérieure,  $S_{sp} = 7000 \text{ cm}^2/\text{g}$ . Le ciment de portland alitique a été à faible teneur en aluminates. On a étuvé les éprouvettes sous la température  $85^\circ\text{C}$  avec la régime 3+6+3, après cela avant la réalisation des essais (pendant 28 jours et plus) on les a conservé dans la chambre du durcissement normal. On a réalisé la comparaison avec des compositions sans particules (composition-témoin) avec  $\mathcal{E}\text{au}/\text{Liant} = \text{const.}$  et  $\mathcal{E}\text{au}/\text{Liant} \neq \text{const.}$

Indépendamment de la composition minéralogique et de la composition en grains des particules pulvérulentes, à  $\mathcal{E}\text{au}/\text{Liant} = \text{const.}$ , a eu lieu l'épaississement de la pâte de ciment; ce processus devient de plus en plus intensif à mesure de l'augmentation de leur nombre et de leur dispersité. Plasticité de mélanges des mortiers se change en fonction de la dispersité et de la composition minéralogique des particules. La résistance du ciment durci et du mortier composé de ciment et de sable (avec  $\mathcal{E}\text{au}/\text{Liant} = \text{const.}$  et avec  $\mathcal{E}\text{au}/\text{Liant} \neq \text{const.}$ ) à l'âge de 1; 28 et 360 jours change d'une façon identique en fonction de la quantité et du type des particules. A la Fig.6 sont représentés les diagrammes du changement relatif de la résistance des mortiers composés de ciment et de sables. Sont présentés les résultats des essais pour les mélanges des mortiers à consistance uniforme à l'âge de 28 jours.

La présence des particules de la zone extérieure du granule de kéramsite en quantité jusqu'aux 10% et avec  $S_{sp} = 2700 \text{ cm}^2/\text{g}$  et jusqu'aux 20% avec  $S_{sp} = 7000 \text{ cm}^2/\text{g}$  n'abaisse pas la résistance. Le plus grand dépassement de la résistance de 10% dans le premier cas et de 20% - dans le deuxième cas est caractéristique pour les compositions contenant 3-5% et 10% des particules.

Fig. 6 - Le changement de la résistance relatives  $R_p/R_t$  des mortiers selon la quantité des particules (en %) avec  $S_{sp} = 2700$  et  $7000 \text{ cm}^2/\text{g}$   
 $R_{p.e.}$  - la résistance des mortiers avec des particules de la zone extérieure de kéramsite,  $R_{p.i.}$  - la résistance des mortiers avec des particules de la zone intérieure de kéramsite,  $R_t$  - la résistance des mortiers sans particules (composition témoin)  
 — compositions avec  $\mathcal{E}\text{au}/\text{Liant} = \text{const.}$ ;  
 ---- compositions à consistances égales ( $\mathcal{E}\text{au}/\text{Liant} \neq \text{const.}$ ).

L'introduction des particules extraites de la zone intérieure du granule de kéramsite avec  $S_{sp} = 2700 \text{ cm}^2/\text{g}$  abaisse la résistance à mesure de l'augmentation de leur nombre; avec  $S_{sp} = 7000 \text{ cm}^2/\text{g}$  on peut constater l'augmentation de la résistance de 20% accompagné par l'accroissement de la masse volumétrique proportionnellement à la teneur en adjuvant; dans le même temps dans d'autres cas la masse volumétrique diminue un peu /2/.

On a déterminé que les particules de la zone extérieure du granule de kéramsite se distinguent de celles des particules de la zone intérieure du granule par leur composition chimico-minéralogique, par une plus grande activité hydraulique, par des plus petites masses spécifique et volumétrique. Elles ont une structure imbriquée, stratifiée et aux pores fins (aux pores  $< 1 \text{ mkm}$ ). Les particules de la zone intérieure du granule ont une surface régulière et vitreuse, les pores y sont rarement situés et ont le diamètre de  $\sim 10 \text{ mkm}$  (Fig.7). C'est pourquoi à mesure de diminution de grains la porosité des particules de la zone extérieure du

granule presque ne change pas; et la structure des particules de la zone intérieure du granule change brusquement jusqu'à devenir compacte-dans les particules <15 mkm.

Fig. 7 - Les particules d'écorce (a,b) et celles de noyau (c) du kéramsite, SEM.

Par la méthode de radio-phase et par la méthode microscopique on a déterminé, que 5-10% des particules de la zone extérieure du granule intensifient l'hydratation du ciment (jusqu'aux 10%), et avec cela cette intensification est plus grande pour la surface spécifique 7000 cm<sup>2</sup>/g que pour la Ssp. = 2700 cm<sup>2</sup>/g. Les particules de la zone intérieure du granule ralentissent quelque peu l'hydratation à mesure de l'accroissement de leur nombre et de leur dispersion. Le ciment durci avec les particules de kéramsite indépendamment de leur type se distingue de ciment de base par la diminution de quantité de portlandite et par une accroissement considérable de la teneur en hydrosilicates de calcium à faible basicité, CSH(I) (partiellement Al - substitués) qui y sont la phase principale de gélification.

Dans le ciment durci à la limite avec les particules de kéramsite il y a des couches

consolidées de 20-30 mkm de largeur (avec des particules de la zone extérieure du granule) et de 10-15 mkm de largeur (avec des particules de la zone intérieure du granule) qui se distinguent par la couleur dans un microscope polarisant (exceptionnellement en lumière réfléchie) /2/. Ces couches se caractérisent par une microdureté élevée qui abaisse à la mesure de leur éloignement de contact et dont la valeur approche à celle de microdureté du ciment durci en volume /1,2/. La microdureté et le volume des couches entourant des particules de la zone extérieure du granule sont plus grands que ceux entourant les particules de la zone intérieure du granule. Par un complexe des méthodes physico-chimiques on a déterminé que c'est une couche intermédiaire entre la partie centrale de particule de l'agrégat et le ciment durci non-changé qui contient des nouvelles formations ainsi que les moindres (<1-2 mkm) incorporations de l'agrégats. Donc, autour les moindres particules de kéramsite qui ont une grande microdureté se forme un microvolume du ciment durci (avec un durcissement 5 fois plus grand) dont le diamètre dépasse de 7-10 fois les dimensions de la particule. Avec une teneur considérable en telles particules ces couches se rapprochent et s'entre-croisent et forment un nouveau type du ciment durci compacté d'une résistance élevée.

#### CONCLUSIONS

Le traitement par le chauffage dans la vapeur du ciment durci contribue à l'élévation du degré d'hydratation des minéraux de clinker et à une cristallisation plus nette de nouvelles formations des hydrates. Le chauffage à sec sous la température 100°C ne provoque pas de changements sensibles dans la composition minérale de phase et de dérèglements dans la structure; les propriétés du ciment durci sont maintenues. Sous 200°C une déshydratation partielle et un dérèglement de la structure cristalline ont lieu; cela amène à l'augmentation des déformations de retrait et à l'affaiblissement de la résistance du ciment durci. Une postérieure conservation humide des éprouvettes chauffées contribue à la reconstitution de la microstructure du ciment durci à la diminution des déformations et à l'augmentation de la résistance. Le chauffage sous la température 100°C et au-dessus provoque une décomposition thermique des compositions des dérèglements irréversibles de la microstructure du ciment durci et des pertes de ses propriétés.

Dans le ciment durci contenant les particules pulvérisantes de kéramsite une élévation du degré d'hydratation (jusqu'aux 15%) et une diminution de la teneur en portlandite ont lieu. Sous l'effet de l'interaction chimique de particules avec la solution de Ca(OH)<sub>2</sub> du ciment durci dans le dernier augmente la teneur en hydrosilicates à basse basicité et se forme la structure aux

pores fins. Outre cela, dans la zone de contact se forment des couches chimiquement changées du ciment durci qui sont d'une microdureté élevée. Les résultats obtenus, contrôlés pendant la production des bétons réels nous permettent de considérer les particules de kéramsite (de la zone extérieure du granule  $< 60$  mkm, de la zone intérieure du granule  $< 20$  mkm) comme des composantes pour la formation de gel et les considérer comme une partie du ciment.

# On ettringite and modification of slag cement

## *Sur l'ettringite et l'amélioration des ciments de laitier*

Zonghan LOU, Associate Professor, Xianyu Xu, Lecturer, and Ren Han, Lecturer, Chekiang University, Chine Populaire.

RESUME : En examinant la formation, la morphologie, la transformation, la stabilité et l'expansibilité de l'ettringite ( $3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot 3\text{CaSO}_4 \cdot 31\text{H}_2\text{O}$ ) dans les ciments formés de gypse et de laitier et dans les ciments de laitier, et en étudiant le mécanisme de l'activation du laitier granulé, les auteurs ont abouti aux règles qui permettraient de fabriquer un ciment sans retrait, ou légèrement expansif, en mélangeant du clinker de ciment portland, du gypse et du laitier. Ce nouveau ciment aurait plus de clinker et moins de gypse que les ciments "laitier-gypse" et moins de clinker et plus de gypse que les ciments de hauts-fourneaux, de façon à mieux utiliser les propriétés de l'ettringite.

Quand l'hydratation de ce nouveau ciment atteint un certain stade, les phases cristallines de  $\text{Ca}(\text{OH})_2$  et de  $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$  disparaissent, laissant C-S-H (B) et l'ettringite comme produits principaux de l'hydratation. Au début de l'hydratation, lorsque la phase aqueuse est saturée en chaux, l'ettringite forme sur les grains d'aluminate des sortes de hérissons. Lorsque l'hydratation progresse,  $\text{CaO}$  s'épuise graduellement, et l'ettringite s'étend à toute la solution en grains distincts. Ce ciment a une résistance élevée, surtout à la traction. Il augmente légèrement de volume lors de la prise; il est stable ensuite. Il présente une bonne résistance aux sulfates et une faible chaleur d'hydratation. Et ce qui est encore plus important, il produit moins de poussière que le ciment "laitier-gypse".

SUMMARY: From the comparison made on formation, morphology, transformation, stability and expansibility of Ettringite ( $3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot 3\text{CaSO}_4 \cdot 31\text{H}_2\text{O}$ ) in gypsum slag cement and portland blast-furnace slag cement, the authors have brought forward, in connection with the discussion on the mechanism of the activation of granulated blastfurnace slag, a proportioning principle of preparing a non-shrinking or slightly expansive cement from portland cement clinker, slag and gypsum. The new cement is designed to have a larger clinker content and a smaller gypsum content as compared with the usual gypsum slag cement, and at the same time a smaller clinker content and a larger gypsum content as compared with the portland blastfurnace slag cement, so as to bring out all the positive factors of the Ettringite. As the reactions of hydration of this new cement reach a certain stage, the crystalline phases of  $\text{Ca}(\text{OH})_2$  and  $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$  will disappear, leaving CSH(B) and the Ettringite as its main products. During the early stage of hydration, when the hydrating solution is saturated with  $\text{CaO}$ , the Ettringite builds up on the aluminate particles in hedgehoglike form. As hydration proceeds, however, the  $\text{CaO}$  gradually depletes, and the Ettringite is formed in the entire solution in discrete particles. The cement proves to have high strength, especially high tensile strength. It expands slightly on hardening, but it is volume-stable otherwise. It has good sulfate resistance and comparatively low heat of hydration. Most important of all, it does not cause dusting trouble like the gypsum slag cement.

## INTRODUCTION

It becomes more and more clear that ettringite ( $3\text{CaO}\cdot\text{Al}_2\text{O}_3\cdot3\text{CaSO}_4\cdot31\text{H}_2\text{O}$  -- E-salt for short) plays an important role in the hydration and hardening of different kinds of cement. Along with the progress of researches in this field, it is obvious that ettringite has not brought the positive effects into full play in the hydration and hardening of the principal varieties of slag cement, i.e., slag Portland cement (SPC) and gypsum slag cement (GSC). Taking account of the relation of chemical interaction and restriction between common Portland cement clinker (K), granulated blastfurnace slag (S) and anhydrous gypsum (G), our studies were to find out certain appropriate proportions between them, in order that certain reasonable physico-chemical conditions can be created to enable the quantity, growing rate, morphology, transformation, stability and expansion of the newly formed ettringite, to develop in the direction we expected, offering the principal theoretical basis for the preparation of a special kind of slightly expansive slag cement. Our studies were just an attempt to bring forth both the advantage of ettringite and the benefit of slag into full play.

ON THE FORMATION OF  
ETTRINGITE AND ITS EFFECTS AND  
LIMITATION IN SLAG CEMENTS

The formation, the development and the transformation of ettringite play an important role in the hydration and hardening of these two kinds of slag cement, i.e., SPC and GSC. In earlier days the authors (1)(2) and other researchers (3) had noticed the difference in appearance of ettringite in these slag cements in SPC ettringite was observed, Under polarized microscope as crystals distributing in an aggregate manner backed up with a solid phase, whereas in GSC, ettringite was observed as needle crystals distributing individually. Both of these different crystals were found through X-ray examination and DTA to be the same constitution -- ettringite. On the other hand, the crystalline phase of  $\text{Ca}(\text{OH})_2$  appeared obviously in set cement of SPC, but not in GSC, and the concentration of  $\text{Ca}(\text{OH})_2$  in the liquid phase rapidly approached a very low value. It is due to the fact that the admixture of clinker to SPC generally consists of 50-60%, but to GSC only of 3-5%. So the morphology of ettringite in these two kinds of cement must be the direct result caused by different alkaline conditions hydration and hardening of cement. In order to testify this concept, experiments were carried out as follows: blend synthesized pure mineral of  $3\text{CaO}\cdot\text{Al}_2\text{O}_3\cdot(\text{C}_3\text{A})$  and dihydrous gypsum according to the chemical compositions of ettringite, put this blend in  $\text{Ca}(\text{OH})_2$  solutions containing 0.15, 0.30, 0.50, 0.80 and 1.10g/l CaO respectively; sealing them on microscopy slides; and observe them microscopically. The results

were shown as below.

0.15g/l 0.30g/l 0.50g/l 0.80g/l 1.10g/l

Figure 1. The relations between the morphology of ettringite and the concentration of CaO.

The same result was obtained with pure minerals  $12\text{CaO}\cdot7\text{Al}_2\text{O}_3\cdot(\text{C}_{12}\text{A}_7)$  and  $\text{CaO}\cdot\text{Al}_2\text{O}_3$  (CA). The morphology of ettringite in these experiments agreed with those of these slag cements.

The morphology of ettringite is a reflection of the behaviour and the kinetics in the formation of ettringite. It is obvious that from the phase diagrams of systems of  $\text{CaO}-\text{Al}_2\text{O}_3-\text{H}_2\text{O}$  and  $\text{CaO}-\text{CaSO}_4-\text{H}_2\text{O}$  (6), the solubilities of gypsum, especially those of calcium aluminates, are seriously inhibited in solutions saturated or nearly saturated with CaO. Nevertheless, CaO and gypsum are comparatively soluble materials, so the liquid phase of set cement always contains more  $\text{Ca}^{++}$  and  $\text{SO}_4^{--}$  but less  $\text{AlO}_2^-$ . Inevitably, the ions  $\text{Ca}^{++}$ ,  $\text{SO}_4^{--}$  and  $\text{AlO}_2^-$  form precipitates of ettringite crystals almost at once. As a result,  $\text{AlO}_2^-$  is released from aluminates in solid phase and a concentration gradient is established around the solid particles. Consequently, ettringite grows step by step as crystals distributing in aggregate manner backed up with solid particles containing aluminates. Whereas, when the concentration of CaO in solution is low, the solubility of gypsum and aluminates becomes much larger, thereupon, ettringite forms in solution as needle crystals distributing individually in a random way. Therefore, these two different configurations of ettringite are closely related to their formation processes. Substantially it is a subject of kinetics.

The intrinsic impedance of the formation of ettringite is its expansion. Theoretical calculation shows that during the formation of ettringite the expansion of the total volume of solid phases increased more than doubled. Ettringite crystals were distributing in aggregate manner backed up with solid particles; they might grow in certain directions and bring crystal-growing pressure to bear upon the circumferential matrices. As a result, the volume expansion of crystalline phase together with the crystal growing pressure makes possible the bulk expansion of set cement. Ettringite in SPC is just such a case we consider. It is necessary to control accurately the gypsum content in cement blend, so as to restrict

the quantity of ettringite formed. The formation of ettringite would end essentially when the cement paste is still in its plastic state in order to avoid the disintegration due to the expansion of ettringite.

On the other hand the needle shaped ettringite crystals were distributing singularly, they might grow freely on both ends. This growth bring forth low or even no crystal growing pressure, and few effects in the bulk change of set cement. In this case, the force making possible the bulk expansion of set cement mainly depends on the volume expansion of crystalline phase. Ettringite in GSC just belongs to this type. Even though ettringite forms in large amounts, the volume change on setting still remains contractive, the contraction being small with the interior structure becoming more compact.

Fig.2 Ettringite formation in slag cements.

It is clear from the above expositions that different clinker contents in cement bring about different alkaline conditions of hydration, that ettringite forms in different configurations, and that different forces were made possible in the bulk expansion of set cement. In fact it is a problem related to the chemical interaction and restriction between K, S and G.

Another important problem, we should pay attention to, is the long-term stability of ettringite in these two slag cements.  $3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{CaSO}_4 \cdot 12\text{H}_2\text{O}$  (abbreviated as L-salt) was found in set cement of SPC by X-ray examination. When  $\text{CaO} \cdot \text{Al}_2\text{O}_3$  is introduced into SPC, L-salt becomes more pronounced. This L-salt must be transformed from ettringite.

We have verified further these experiments, that in the case of high  $\text{CaO}$  concentration and low  $\text{CaSO}_4$  concentration, e.g.,  $\text{CaSO}_4/\text{Al}_2\text{O}_3 \leq 1$ , ettringite could transform into L-salt. Just because of this, ettringite is not stable in SPC from a long-term viewpoint(5).

But GSC is not the case. After the hydration and hardening of GSC, gypsum is in excess and solubility of  $\text{CaO}$  approaches a very low value. Therefore, ettringite would exist stably forever in GSC. This was confirmed by the experimental results of the long-cured set cement of GSC.

The following experiments were carried out with synthesized E-salt and L-salt.

E-salt +  $\text{CaSO}_4$  — E-salt

L-salt +  $\text{CaSO}_4$  — E-salt

This confirms that ettringite exists stably in GSC(5).

But ettringite can not stand the action of carbon dioxide in atmosphere. We put synthesized pure ettringite in moist  $\text{CO}_2$  for seven days and found that it was completely decomposed into aragonite  $\text{CaCO}_3$  and dihydrous gypsum as shown by X-ray examination.

This is because of the neutralization of  $\text{Ca}^{++} + \text{CO}_2 = \text{CaCO}_3 \downarrow$ , which depresses the  $\text{CaO}$  concentration in the liquid phase, causing the decomposition of ettringite by disturbing its concentration in equilibrium. GSC is a cement of low alkalinity and it produces insufficient CSH(B) to shield ettringite against the action of  $\text{CO}_2$ . As a result, ettringite in GSC might be destroyed or decomposed by  $\text{CO}_2$  in atmosphere, and it is known as "dusting", the formation of a spongy layer on the surface of set cement.

The instability of ettringite in GSC and SPC under different conditions is also a substantial problem relating to the chemical interaction and restriction between K, S and G. The physico-chemical conditions of the hydration and hardening of these two slag cements have inhibited the positive effect of ettringite.

#### ETTRINGITE AND THE MODIFICATION OF SLAG CEMENT

According to our study on ettringite in both gypsum slag cement and slag Portland cement, and for the purpose in developing all the positive factors of the ettringite, we revised the ratio between clinker, slag and gypsum to certain appropriate components to bring about a new kind of slightly expansive slag cement. Portland cement clinker produced by general cement plants and granulated blastfurnace slag produced by steel mills are adaptable; As with gypsum, anhydrous or calcined gypsum meet the needs. Thus, the new cement is designed to have greater clinker and less gypsum portion as comparing with the usual gypsum slag cement, on the other hand to have less clinker and greater gypsum portion as comparing with slag portland cement.

This new kind of slightly expansive cement is a mixture of clinker, slag and gypsum. After concocting with water, it gets into the colloided state, in which clinker hydrates rapidly, separating out  $\text{Ca}(\text{OH})_2$  that will dissolve in water together with gypsum, while the powder of slag is soaking into the solutions. Hence a series of physical, chemical and physico-chemical changes occur among the clinker, slag and gypsum, resulting in the set cement becomes as hard as natural stone. This kind of cement has both the main characteristics of main characteristics of slight expansion and lower heat of hydration.

After hydration of this cement, a large quantity of ettringite exists which may be found through XRD and TDA:

Fig.3 XRD and TDA of slightly expansive slag cement

It proves that the presence of ettringite in slightly expansive slag cement is an obvious fact.

The formation of ettringite absorbs quite a quantity of CaO. From XRD and DTA it is clear that the crystalline phase of  $\text{Ca}(\text{OH})_2$  does not appear in the set cement. It will be entirely different if we remove gypsum from this cement blend, so that ettringite will certainly not come into existence and the crystalline phase of  $\text{Ca}(\text{OH})_2$  will be obviously found in XRD and DTA curves, shown as follows.

Fig.4 XRD and DTA of slightly expansive slag cement (with gypsum removed)

These experiments suggest that the formation of ettringite is a process which continuously absorbs CaO and lowers the basicity. This can be shown from the change (decrease) of CaO content in aqueous solution during hydration.

Fig.5 The decreasing of CaO content during hardening of slightly expansive slag cement.

Therefore, at the beginning of the hydration of cement, with CaO nearly saturated in the hydrating solution, ettringite forms crystals in aggregate manner, backed up with a solid phase, and then with the decreasing of CaO content in hydrating solution, it forms needle-like crystals distributing individually. Both of them form successively but exist simultaneously. As stated above, the ettringite crystals are distributing in aggregate manner, the volume expansion of crystalline phase combined with crystal growing pressure makes possible the bulk expansion of set cement. Whereas the ettringite crystals are distributing individually, so they bring about seldom or never crystal growing pressure, and have less effect on bulk expansion of set cement which is mainly caused by volume expansion of crystalline phase. Therefore, this cement differs both from GSC and from SPC in having appropriate expansion. Our experiments which will be stated later would prove that the formation of ettringite is completed within 7 days. Other experiments confirm that the expansion of set cement reaches the limit within 7 days, moreover the expansion of this cement is much more stable than others.

Fig.6 Ettringite formation in slightly expansive slag cement.

While the ettringite is produced in large amount, hydrated calcium silicate is formed massively too. According to 140°C heat-absorbing valley and the 920°C heat-diffusing peak on TDA curve, and through analysis in combination with the phase equilibrium in system  $\text{CaO-SiO}_2\text{-H}_2\text{O}$ , it is obvious that in this case hydrated calcium silicate formed must be  $(0.8-1.5)\text{CaO}\cdot\text{SiO}_2\cdot(0.5-2.5)\text{H}_2\text{O}$ , i.e. CSH(B), but must not be  $(1.7-2.0)\text{CaO}\cdot\text{SiO}_2\cdot(2-4)\text{H}_2\text{O}$ , i.e.  $\text{C}_2\text{SH}_2$ . CSH(B) plays more important role in the strength and other properties of this cement.

Granulated blastfurnace slag accounts for a great part. In connection with the mechanism of the activation of this slag, we would know, clinker in these cement components offers CaO for activation of slag and at the same time the minerals in it hydrate and harden independently, among them  $\text{C}_3\text{A}$  and

$C_4AF$  combine with gypsum and form a crystalline phase of ettringite. Thus the clinker acts both as the independent cementing component and as the alkaline activator. On the other hand, gypsum acts as sulphate activator. Both of them activate the slag. Slag is the unstable glass in the system  $CaO-Al_2O_3-SiO_2$ . The alkaline stimulation brings about the formation of CSH(B) and partial disintegration of granulated slag glass, thus furnishes the prerequisite to the sulphate stimulation. Meanwhile the sulphate stimulation brings about the formation of ettringite which upsets certain established equilibrium and promotes the alkaline stimulation. Therefore, the development of the strength of set cement is based on the cementation of clinker and the multiply repeated promotion between these two stimulations. This cement has high strength.

In hydration of different slag cements, the alkaline stimulation plays an important role in SPC which consists of much more clinker and less gypsum, whereas the sulphate stimulation develops fully in GSC with less clinker and excessive gypsum. Both are considered as the basic weak points which are unreasonable for the under-development of the reactions of slag. We keep the proper ratio between clinker and gypsum used in this slightly expansive slag cement, thus both the alkaline and sulphate stimulations would develop more fully and the slag would react more effectively. As mentioned above, we know, in slightly expansive slag cement, one of the principal hydrated products is CSH(B) in which the ratio between  $CaO$  and  $SiO_2$  approaches to 1, and the unacted slag in large quantity remained. Thereby, the concentrations of both  $CaO$  and  $CaSO_4$  tend to decrease to low values, finally approaching equilibrium concentrations of both hydrated products, ettringite and CSH(B), as the limit. This state of the slightly expansive slag cement ensures the long time stable existence of ettringite, and prevents the latter from transforming into L-salt. It also has the ability of resistance to sulphate corrosion, though this cement contains a large quantity of unacted slag which offers the active  $Al_2O_3$ , but without the necessary condition of basicity, therefore can not react with  $SO_4^{2-}$  in water to form ettringite. Besides, even if some ettringite forms, it will be the crystals distributing individually, and is unlikely to disintegrate the set cement due to its expansion.

The constancy of volume and soundness is another problem we should pay greater attention too. Compared with SPC, this cement contains excessive gypsum, and compared with GSC, it contains much more clinker. From the traditional viewpoint about cement compositions, both cases are impermissible. Thus an important problem is put before us, in order to answer this problem related with the long-time safety of construction, which has been deeply concerned, the following experiments were carried out in two aspects.

1) Pure ettringite ( $3CaO \cdot Al_2O_3 \cdot 3CaSO_4 \cdot 31H_2O$ )

and pure L-salt ( $3CaO \cdot Al_2O_3 \cdot CaSO_4 \cdot 12H_2O$ ) were synthesized and their solubilities in aqueous solution in equilibrium with crystals were determined respectively. The solubility products calculated are  $1.1 \times 10^{-40}$  for ettringite and  $1.7 \times 10^{-28}$  for L-salt in which the former being much less than the latter(5). At the beginning of the hydration of cement, the concentration of  $CaSO_4$  in liquid phase is enough, but that of  $Al_2O_3$  is comparatively too low. This condition absolutely benefits the formation of ettringite and not of L-salt. Large amount of X-ray diffraction patterns of set cement for ages of 1, 2, 3, 7, 14, 28, 90, 360 days and 4 years show that ettringite persists in large quantity but L-salt only appears once in trace after long time. Therefore, it is confirmed both theoretically and practically that in no case can L-salt form in large amount at the beginning of the hydration and then changes into ettringite which causes expansive disintegration(6).

2) It was verified that the formation of ettringite finished within 7 days by comparing the relative intensities on the X-ray diffraction patterns of set cement of the expansive slag cement, prepared with dihydrous gypsum for ages of 3 and 7 days, and of set cement powder for age of 60 days with addition of 0.5% and 1% dihydrous gypsum. (In fact this expansive slag cement is prepared with anhydrous or calcinated gypsum. But it is difficult to resolve  $CaSO_4$  from ettringite and the main mineral  $C_2AS$  in slag, for their main relative intensities on X-ray diffraction patterns are duplicate and covered each other.) The remaining amount of unreacting gypsum in set cement can be detected. It was confirmed that the left-over gypsum was very few after 3 days and only trace after 7 days, as compared with that obtained with the specimen with addition of 0.5% and 1% dihydrous gypsum.

Fig.7 The X-ray examination of set cement specimens

Meanwhile, according to the X-ray examination on cement specimens prepared with calcinated gypsum at ages of 3, 7, 28, 60 and 90 days, the main spectra of ettringite, i.e.,

$d=9.73\text{\AA}(100)$ ,  $5.61\text{\AA}(80)$ ,  $3.88\text{\AA}(50)$ ,  $2.77\text{\AA}(40)$  principally reached maximum within 7 days. This also meant that the formation of ettringite approximately finished within 7 days. Since gypsum will disappear and the formation of ettringite will finish within a short time, so the constancy of volume would be good and there will be no danger of to get disintegration caused by further formation of ettringite.

Another powerful evidence of the constancy of volume and soundness is the fact that we built a small dam, 32m long and 15m height with this slightly expansive slag cement in 1975, and until now no cracks, chaps or local swellings are found in it any where and its surface is still compact and smooth.

#### SOME CONCLUSIONS

1) On the basis of our studies on ettringite in both slag cements, SPC and GSC, the proportioning ratio between K, S and G can be revised to suit a reasonable physico-chemical condition of hydration and hardening of cement, thus bringing about a new slightly expansive slag cement which is characterized by fully developing the advantage of ettringite. This slightly expansive slag cement can be prepared from granulated blastfurnace slag, common portland cement clinker and anhydrous gypsum with simple common cement production process, though it may conserve slightly more power to get better pulverization. This cement is characterized by slight expansion and low heat of hydration. The strength developed by this cement using plastic mortar (Chinese National Standards GB177-77) is as follows for example: compressive strength ( $\text{kg}/\text{cm}^2$ ): 3days-131; 7days-320; 28days-437; bending strength ( $\text{kg}/\text{cm}^2$ ): 3days-30.2, 7days-76.5, 28days-88.7. ratio of linear expansion when neat cement tested 0.2%, heat of hydration less than 40 Kcal/kg within 7days. So this cement is applicable to the mass concrete building of water conservancy that it would bring about some basic changes in the construction of the mass concrete building(11). 2) On the other hand, this slightly expansive slag cement might be a basic reform of GSC. Through this reform, the main defects of GSC, such as poor constancy of quality, poor resistance to weathering in storage of cement and dusting on setting, etc, would be all overcome. Therefore it is reasonable to produce this slightly expansive cement instead of GSC, and any GSC plant can be easily transferred to produce this slightly expansive cement without changing its raw materials and technological processes but only modifying the K-S-G ratio in proportioning of cement, though the GSC might sometimes have a higher strength.

The long-period production and application of slag cements have accumulated a wealth of practical knowledge on ettringite. Our study is an attempt to make fully effective use of ettringite in cement industry. The development of this slightly expansive slag cement is the natural result of the deepening of the comprehension of ettringite.

# Solubility product and stability of ettringite

## *La stabilité de l'ettringite et le "produit de solubilité"*

Feipeng ZHANG, Lecturer, Zhifa ZHOU, Lecturer, and Zonghan LOU, Associate Professor, Chekiang University, Chine Populaire.

RESUME : La formation, le développement et la transformation de l'ettringite jouent un rôle capital dans l'hydratation, le durcissement et le processus de corrosion des divers ciments, notamment les ciments de laitier et les ciments expansifs. Du fait que l'ettringite est un membre de la série des composés complexes du type  $3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot m\text{Ca}(\text{X et/ou Y}) \cdot n\text{H}_2\text{O}$ , les auteurs envisagèrent la possibilité de prévoir la formation et la stabilité de l'ettringite, en même temps que sa transformation entre les membres de la série. Des expériences ont été faites en tenant compte de ces composés complexes apparentés.

Les résultats obtenus, et indiqués ci-dessous, confirment les vues des auteurs :

Le concept de "produit de solubilité" peut aussi éclairer d'une manière satisfaisante le mécanisme de l'hydratation, du durcissement et de la corrosion des ciments divers, compte tenu de l'ettringite.

SUMMARY: The formation, development and transformation of Ettringite play a decisive role in the hydration, hardening and corrosion processes of various cements, especially the slag cement and the expansive cement. In view of the fact that Ettringite is a member of the series of complex compounds of the type  $3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot m\text{Ca}(\text{X and/or Y}) \cdot n\text{H}_2\text{O}$ , the authors envisaged the possibility of predicting the formation and stability of Ettringite as well as the mutual transformation among the members of the series. Experiments, therefore, have been carried out with respect to some of the related complex compounds. The results as illustrated below prove to support the authors' views.

The conception with reference to the solubility product may also satisfactorily explain the mechanism of hydration, hardening and corrosion processes of various cements related to Ettringite.

## INTRODUCTION

The formation, the development and the transformation of ettringite play an important role in the hydration, hardening and corrosion processes of different kinds of cement on their strength development, constancy of volume and soundness, sulphate-resisting ability and so forth. Ettringite is one of the main hydration products in gypsum slag cement and also the expansive element in expansive cement. But ettringite is just one of the compounds in a series of complex compounds of the type  $3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot m\text{Ca}$  (X and/or  $\text{Y}_2$ )  $\cdot n\text{H}_2\text{O}$ , with  $\text{X} = \text{SO}_4^{2-}$ ,  $\text{CO}_3^{2-}$ , and  $\text{Y} = \text{Cl}^-$ ,  $\text{Br}^-$ ,  $\text{I}^-$ ,  $\text{OH}^-$ ,  $\text{NO}_3^-$  or  $\text{BrO}_3^-$ : that is to say, there are quite a number of related complex compounds.

Different kinds of cement differ in compositions and display their respective hydration and hardening behaviours. The change of the concentration of  $\text{Ca}^{++}$ ,  $\text{AlO}_2^-$  and  $\text{SO}_4^{2-}$  ions in liquid phase of set cement behaves in complex ways. Cements are also used with addition of blastfurnace slag, pozzolanas blending and different additives, such as  $\text{CaSO}_4$ ,  $\text{CaCl}_2$ ,  $\text{NaCl}$ ,  $\text{CaCO}_3$ , etc, which being in  $\text{Ca}^{++}$ ,  $\text{Na}^+$ ,  $\text{SO}_4^{2-}$ ,  $\text{Cl}^-$ ,  $\text{CO}_3^{2-}$  or other ions. Set cement in concrete construction might be acted by different active ions over a long period of time. When used in sea or salt lake, the concrete will be acted upon by different ions, such as  $\text{Cl}^-$ ,  $\text{SO}_4^{2-}$  etc; whereas in spring water it might be acted upon by  $\text{HCO}_3^-$  ion: for underground construction in saline alkali soil area, it will be corroded by  $\text{Cl}^-$ ,  $\text{SO}_4^{2-}$ ,  $\text{CO}_3^{2-}$ , etc; and even in air, it will be also acted upon by  $\text{CO}_2$  and water vapor and so on. So the stability of ettringite in every possible case must be thoroughly examined.

There are many academic papers on the comprehensive study, discussion and comments on  $3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot m\text{Ca}$  (X and/or  $\text{Y}_2$ )  $\cdot n\text{H}_2\text{O}$  (1)(2)(3)(4)(5)(6)(7)(8). In this paper, it is our purpose to try to explain the stability of ettringite by applying "the rule of solubility product", though it is only an attempt.

## EXPERIMENTS

The hydration products of cement consist of gelatinous portion and crystalline portion. Ettringite and related complex compounds are of crystalline phases which are rarely soluble electrolytes and are under the rule of solubility product.

We have synthesized the following complex compounds which are of practical importance.

For determination of the concentration in equilibrium with crystals in aqueous solution, complex compounds were synthesized, with chemically pure reagents checked by chemical analysis as raw materials: E-salt with  $\text{Ca}(\text{OH})_2$  and  $\text{Al}_2(\text{SO}_4)_3 \cdot 18\text{H}_2\text{O}$ , Cl-salt with  $\text{Ca}(\text{OH})_2$  and  $\text{AlCl}_3 \cdot 6\text{H}_2\text{O}$ , L-salt with  $\text{Ca}(\text{OH})_2$ ,  $\text{Al}_2(\text{SO}_4)_3 \cdot 18\text{H}_2\text{O}$  and  $\text{CaO} \cdot \text{Al}_2\text{O}_3$ , and C-salt with  $\text{Ca}(\text{OH})_2$ ,  $\text{CaO} \cdot \text{Al}_2\text{O}_3$  and  $\text{CaCO}_3$ . Syntheses were carried out between solutions, except  $\text{CaO} \cdot \text{Al}_2\text{O}_3$  and  $\text{CaCO}_3$ , which should be pulverized, then added into the solutions to react with other reagents. In solutions the concentration of the starting materials were usually limited below 0.05N. The concentration of some ions were increased to make the precipitation complete (usually applying nearly saturated  $\text{Ca}(\text{OH})_2$  solution,) and distilled water reboiled to be free of  $\text{CO}_2$ . In order to get rid of the effect of  $\text{CO}_2$ , all the synthesizing operations, such as filtration, should be done as fast as possible and the products must be kept in desiccators with decarbonating agent "alkali-lime".

After the X-ray examinations about their purity, in which C-salt was not quite pure, containing some  $\text{CaCO}_3$ , their solubilities in mg/l in aqueous solution at  $25^\circ\text{C}$  were determined respectively by volumetric analysis as

follows:

The Concentrations in equilibrium  
(mg/l) table I.

Compound	E-salt	L-salt	Cl-salt	C-salt
Duration of Equilibrium	3 days	4 days	3 days	11 days
CaO	68.5	168.0	180.0	78.6
CaSO <sub>4</sub>	177.5	44.8	CaCl <sub>2</sub> 73.6	CaCO <sub>3</sub> 70.2
Al <sub>2</sub> O <sub>3</sub>	36.4	93.8	61.2	65.3

According to the above-mentioned value of concentrations in equilibrium with their crystalline phases, we converted them into concentrations in mg-mole per liter and molar ratios composition as follows:

The concentrations in my mole per liter and molar ratios of composition

table II.

Compound	E-salt		L-salt		Cl-salt		C-salt	
Soln	mg-mole	molar	mg-mole	molar	mg-mole	molar	mg-mole	molar
Comp	per liter	ratio	per liter	ratio	per liter	ratio	per liter	ratio
CaO	1.223	3.422	2.977	3.233	3.206	5.321	1.403	2.21
CaSO <sub>4</sub>	1.303	3.650	0.330	0.36	CaCl <sub>2</sub> 0.664	1.11	CaCO <sub>3</sub> 0.702	1.11
Al <sub>2</sub> O <sub>3</sub>	0.358	1	0.920	1	0.601	1	0.634	1

The constants of solubility product were calculated in accordance with the following dissociation reactions of these complex compounds.

$$K_{s.p}^E = (\text{Ca}^{++})^6 \cdot (\text{AlO}_3^-)^2 \cdot (\text{SO}_4^{--})^3 \cdot (\text{OH}^-)^4$$

$$K_{s.p}^L = (\text{Ca}^{++})^4 \cdot (\text{AlO}_2^-)^2 \cdot (\text{SO}_4^{--})^1 \cdot (\text{OH}^-)^4$$

$$K_{s.p}^{\text{Cl}} = (\text{Ca}^{++})^4 \cdot (\text{AlO}_2^-)^2 \cdot (\text{Cl}^-)^2 \cdot (\text{OH}^-)^4$$

$$K_{s.p}^C = (\text{Ca}^{++})^4 \cdot (\text{AlO}_2^-)^2 \cdot (\text{CO}_3^{--})^1 \cdot (\text{OH}^-)^4$$

The solubility products were calculated from the dissociation reactions, giving E-salt as an example:

$$\text{We take, } (\text{Ca}^{++}) = (\text{CaO}) + (\text{CaSO}_4)$$

$$(\text{OH}^-) = 2 \times (\text{CaO})$$

$$(\text{AlO}_2^-) = 2 \times (\text{Al}_2\text{O}_3)$$

$$(\text{SO}_4^{--}) = (\text{CaSO}_4)$$

then,

$$K_{s.p}^E = (1.223 \times 10^{-3} + 1.303 \times 10^{-3})^6 \cdot (2 \times 0.3575 \times 10^{-3})^2 \cdot (1.303 \times 10^{-3})^3 \cdot (2 \times 1.223 \times 10^{-3})^4 = 1.1 \times 10^{-40}$$

The rest may be inferred by analogy. Thereby, the following values of solubility product were obtained.

Compound	E-salt	L-salt	Cl-salt	C-salt
SP	$1.1 \times 10^{-40}$	$1.7 \times 10^{-28}$	$1.0 \times 10^{-30}$	$1.4 \times 10^{-30}$

Furthermore, the solubility product values of Cl-salt and C-salt are quite close, the experiment was carried out to confirm the sequence: The mixture of 1gm Cl-salt +  $\frac{1}{2}$ gm Ca(OH)<sub>2</sub> + 1gm CaCO<sub>3</sub>, which had been cured in moist state for 3 years, was examined, still as Cl-salt and CaCO<sub>3</sub> in stable state. Thereby, it is confirmed that the solubility product of Cl-salt is smaller than that of C-salt.

Generally speaking, these solubility data are adaptable though our determinations were not quite precise. According to these determinations the sequence of the solubility product values, which we expected, is as follow:

$$\text{E-salt} < \text{Cl-salt} < \text{C-salt} < \text{L-salt}$$

From the above sequence of solubility product values, according to the rule of solubility product, the conclusion is: The general tendency of equilibrium between these complex compounds is that E-salt is the first to form and the most stable to exist over a long period of time.

We have also performed some experiments dealing with the transformations among the complex compounds, such as:

(1gm E-salt in 1 liter water with 1gm NaCl added.)

E-salt +  $\text{CaCO}_3 \rightarrow \text{C-salt}$  (but aragonite  $\text{CaCO}_3 + \text{E-salt}$ )

(in one liter water 1.71gm  $\text{Al}_2(\text{SO}_4)_3 \cdot 18\text{H}_2\text{O}$ , 2.50gm  $\text{Ca}(\text{OH})_2$  and 0.25gm  $\text{CaCO}_3$  added)

Specimens blended with water, and cured in moist state for 3 years, were examined under X-ray, the results are as follows:

5gm E-salt +  $\text{H}_2\text{O} \rightarrow \text{E-salt}$  (no change)

5gm E-salt + 1gm  $\text{CaCO}_3 \rightarrow \text{E-salt}$  (no change)

5gm E-salt + 1gm  $\text{CaCO}_3 + 1\text{gm Ca}(\text{OH})_2 \rightarrow \text{E-salt}$  (no change)

1gm Cl-salt + 1gm  $\text{CaSO}_4 + \frac{1}{2}\text{gm Ca}(\text{OH})_2 \rightarrow \text{Cl-salt}$  (changed)

In addition, further results are as follows:

L-salt +  $\text{CaCl}_2 \rightarrow \text{E-salt} + \text{Cl-salt}$

L-salt +  $\text{CaCO}_3 \rightarrow \text{E-salt} + \text{C-salt}$

These experimental results mentioned above are all ruled by the sequence of solubility product values.

But in special case the E-salt would sometimes transform into L-salt, such as:

E-salt +  $\text{CaO} \cdot \text{Al}_2\text{O}_3 \rightarrow \text{L-salt}$

(1gm E-salt in 800ml  $\text{H}_2\text{O}$ , 0.4gm  $\text{CaO} \cdot \text{Al}_2\text{O}_3$  and 0.3gm  $\text{CaO}$  added)

It is not ruled by the sequence of solubility product values.

#### DISCUSSION AND CONCLUSION

1. The gypsum slag cement and some expansive cement were designed to have more gypsum which would partially remain in the hardening cement pastes, thus:

E-salt +  $\text{CaSO}_4 \rightarrow \text{E-salt}$ ,

L-salt +  $\text{CaSO}_4 \rightarrow \text{E-salt}$ ,

According to the rule of solubility product, because of excessive gypsum, Ettringite would not be able to transform into L-salt and would exist stably for a long period of time.

Besides, The slightly expansive slag cement which we studied<sup>(10)</sup> would keep that the concentrations of both  $\text{CaO}$  and  $\text{CaSO}_4$  in hydrating solution tend to decrease to low values, finally approaching equilibrium concentrations of the hydrated products, ettringite and  $\text{CSH(B)}$ , as the limit. The state of this cement insures the long time stable

existence of ettringite too.

Fig. XRD of two set cement specimens of the slightly expansive slag cement for age of 4 years.

2. Our experiment showed that equal mole mixture of  $\text{C}_3\text{A}$  and  $\text{CaCO}_3$ , or  $\text{C}_4\text{AH}_x$  and  $\text{CaCO}_3$ , or  $2\text{Ca}(\text{OH})_2 + \text{CaO} \cdot \text{Al}_2\text{O}_3 + \text{CaCO}_3$  form C-salt easily in the presence of water. In the aqueous solution the equilibrium concentration of  $\text{CaCO}_3$  is less than that of C-salt. On the contrary, the solubility product of  $\text{CaCO}_3$   $8.7 \times 10^{-9}$  is greater than that of C-salt  $1.4 \times 10^{-30}$ , in active  $\text{Al}_2\text{O}_3$ -containing solution saturated with  $\text{Ca}(\text{OH})_2$ ,  $\text{CaCO}_3$  will be converted into C-salt. It is an inevitable outcome. To certain cement, such as portland slag cement, when blended with insufficient gypsum, it is feasible to add some  $\text{CaCO}_3$  powder (pulverized limestone) to decrease the concentrations of active  $\text{Al}_2\text{O}_3$  and  $\text{CaO}$  in liquid phase in set cement in order to prevent the transformation of E-salt to L-salt, and the C-salt is contained in set cement, thus the long-time stable existence of E-salt is insured.

3. It has been several decades since  $\text{CaCl}_2$  was used as an accelerator. It was confirmed that after the addition of  $\text{CaCl}_2$  to cement paste, Cl-salt will form immediately with soluble  $\text{Al}_2\text{O}_3$  and  $\text{CaO}$  in paste.

We believe the very fact that is the substantial essence of the mechanism of the acceleration of hydration was due to the addition of  $\text{CaCl}_2$ . In comparison with  $\text{CaCl}_2$ ,  $\text{CaSO}_4$  is much less soluble in water. The solubility of  $\text{CaSO}_4$  is only about 2 gm/l at room temperature and is further restricted by the concentration of  $\text{Ca}(\text{OH})_2$  obviously as shown in  $\text{CaO}-\text{CaSO}_4-\text{H}_2\text{O}$  phase diagram<sup>(9)</sup>.

Whereas  $\text{CaCl}_2$  has chemical affinity for water, its solubility is 745 gm per liter(7), usually the water -- cement ratio is 0.5, when we add only 1% of  $\text{CaCl}_2$  to the cement, the concentration of  $\text{CaCl}_2$  in liquid phase of set cement will be 20gm/l. Therefore at the beginning of the hydration of cement paste containing certain amount of active  $\text{Al}_2\text{O}_3$  and  $\text{CaO}$ , Cl-salt should form immediately and rapidly. The solubility product of Cl-salt  $1.1 \times 10^{-30}$ , is greater than that of E-salt  $1.1 \times 10^{-40}$ , thus greatly accelerating the transformation of Cl-salt to E-salt. This is the very reason why we are able to explain the mechanism of accelerating the formation of E-salt by  $\text{CaCl}_2$  as confirmed earlier by Nemat Tenoutasse(4). In our experiments, X-ray and other examinations, Cl-salt appeared obviously, Synthesized Cl-salt looks like fibres which possess tensile force somewhat like the asbestos fibres in the prefabricated asbestos-cement articles. Cl-salt distinctly strengthens the set cement as rib lath in concrete. It is clear that the long time stable existence of E-salt is insured due to the, Cl-salt contained in the set cement.

4. When excessive active  $\text{Al}_2\text{O}_3$  and  $\text{CaO}$  exist, E-salt can transform into L-salt, which by itself is usually unstable. This fact is difficult to be explained with the rule of solubility product. Therefore, we once inclined to agree with the hypothesis about the existence of solid solution between  $\text{C}_3\text{A} \cdot 3\text{CaSO}_4 \cdot 32\text{H}_2\text{O}$  and  $\text{C}_3\text{A} \cdot \text{Ca}(\text{OH})_2 \cdot n\text{H}_2\text{O}$ ; but the latest studies denied this possibility because they are different in crystal structure. Some people suspected, though generally recognized, the existence of solid solution between  $\text{C}_3\text{A} \cdot \text{CaSO}_4 \cdot 12\text{H}_2\text{O}$  and  $\text{C}_3\text{A} \cdot \text{Ca}(\text{OH})_2 \cdot n\text{H}_2\text{O}$  (2).

It is hard to synthesize pure L-salt, whereas pure E-salt is rather easy to prepare. Once we kept a large amount of synthesized pure L-salt in a sealed ground glass stoppered bottle; after several months (moisture 3-5%), L-salt all transformed into

E-salt and  $\text{C}_4\text{AHx}$ , as examined by X-ray. L-salt is a metastable compound; its formation and stable existence require high basicity ( $\text{CaO}$ ) and low concentration of  $\text{CaSO}_4$ , maintaining the molar ratio  $\text{CaSO}_4/\text{Al}_2\text{O}_3 \leq 1$ . In portland cement and Portland slag cement, L-salt may be transformed from E-salt which is formed at the beginning of hydration;(8) Deducing from the system of  $\text{CaO}-\text{Al}_2\text{O}_3-\text{CaSO}_4-\text{H}_2\text{O}$ , we can reach the same conclusions(10). The above mentioned transformation requires us to continue this study more thoroughly.

With the increase of varieties of cement, the extensive adaption of different admixture and additives, and the increasing development of the steam cured silicate materials of fly ash and slag. The type of complex compounds  $\text{C}_3\text{A} \cdot m\text{Ca}(\text{X and/or Y})_2 \cdot n\text{H}_2\text{O}$  would play an even more important role.

Many research workers made thorough and extensive studies on these complex compounds, and acquired a vast amount of knowledge and experimental data in this field. But it is an urgent need to sum up all these accomplishments so as to raise the general theoretical level. Our present research is just one of the attempts along this line

## Effect of $\text{Ca}(\text{OH})_2$ on alkali-silica reaction

### *Effet de $\text{Ca}(\text{OH})_2$ sur l'alcali-réaction*

Associate Professor Tang MING-SHU and Lecturer Han SU-FEN, Department of Silicate Engineering, Nanjing Institute of Chemical Technology, Chine Populaire.

RESUME : L'action sur l'opale de solutions de pH différents a été étudiée. Les résultats montrent que la quantité de  $\text{SiO}_2$  dissous croît rapidement quand les solutions ont des pH supérieurs à 12 à 12.5. Des recherches comparatives des réactions alcalis-silice dans le ciment portland, le ciment alumineux, le ciment métallurgique sursulfaté et le ciment sulfaté de boue rouge ont été faites.

Les réactions alcalis-silice dans le ciment portland sont les plus importantes, quoique leur teneur en alcalis soit à peu près la même que celle des autres ciments. Ceci peut être expliqué par le fait que la concentration en ions  $\text{OH}^-$  du liquide interstitiel de la pâte du ciment portland est forte, et en même temps le pH est toujours supérieur à 12.5, alors même que la teneur en alcalis n'est pas grande.

Ce n'est pas le cas pour les autres ciments. Le mécanisme de l'inhibition de la réaction alcalis-silice par des matériaux pouzzolaniques peut être expliqué rationnellement, en prenant l'action de  $\text{Ca}(\text{OH})_2$  en considération, et vérifié expérimentalement. La suggestion est faite que la réaction alcalis-silice causée par des alcalis, qui viennent des sources autres que du ciment, peut être empêchée en utilisant du ciment contenant peu ou pas de  $\text{Ca}(\text{OH})_2$ .

Summary: The action on opal by solutions of different pH values has been investigated. Results show that the amount of  $\text{SiO}_2$  dissolved increases rapidly when the solutions have pH values greater than 12-12.5. Comparative studies of the alkali-silica reaction in portland, aluminous, supersulphated and red mud-sulphated cements respectively were then carried out. Alkali-silica reaction in the portland cement is the most noted though the alkali content is about the same as in the other cements. This might be explained by the fact that the  $\text{OH}^-$  ions concentration of pore solutions in portland cement paste is rather high, as the pH value is always greater than 12.5 even though the alkali content is low. It is not the case with other cements. The mechanism of inhibiting alkali-silica reaction by the pozzolanic materials may be reasonably explained by taking the effect of  $\text{Ca}(\text{OH})_2$  into consideration and has been verified experimentally. Suggestion is made that the alkali-silica reaction caused by alkali came from sources other than cement can be prevented by using cements containing little or no  $\text{Ca}(\text{OH})_2$ .

## I. Introduction

Stanton<sup>(1)</sup> discovered in 1940 the destructive action on concrete of the alkali-silica reaction. Since then, extensive investigations have been made in many countries and several comprehensive review papers have been reported<sup>(2,3,4,5)</sup>. Certain reactive aggregates, such as flint, rhyolite and andesite, have been found in the dam structures built in China. In addition, many cement factories in China are still producing a large amount of cement with high alkali content. Consequently, field observations and laboratory experiments to disclose the intrinsic nature of the alkali-silica reaction are urgently needed.

The role of  $\text{Ca}(\text{OH})_2$  in alkali-silica reaction has been studied by many authors. Powers<sup>(6)</sup> concluded that the diffusion rates of alkali versus calcium ions would be an important factor. The alkali-silica complex formed would cause expansion, but the lime-alkali-silica complex formed would not do so. This is known as competitive reaction theory<sup>(7)</sup>.

Hansen<sup>(8)</sup> suggested that the migration of  $\text{Ca}^{2+}$  ions into opal would also induce expansion, because the volume occupied by calcium silicate thus formed would be larger than that of the opal itself. Moskvina<sup>(4)</sup> reported that both alkali and  $\text{Ca}(\text{OH})_2$  would take part in reaction, but at the same time the latter would regenerate the alkali ions to make the reaction going further. In addition, the semipermeable membrane which develops osmotic pressure would be formed by the reaction of  $\text{Ca}(\text{OH})_2$  with reactive aggregate.

Experimental work done previously by the present author<sup>(9)</sup> confirmed that the  $\text{Ca}(\text{OH})_2$  would increase the expansion caused by alkali-silica reaction. The objective of the present work is to investigate the effect of  $\text{Ca}(\text{OH})_2$  on alkali-silica reaction by considering as the most influential factor the relation of  $\text{Ca}(\text{OH})_2$  to the  $\text{CH}^-$  ions concentrations of pore solutions in the cement pastes.

## II. Experimental results and discussion.

### 1. Effect of solutions with different pH values on opal.

The great importance of  $\text{CH}^-$  ions concentrations to alkali-silica reaction was well recognized by many investigators. In order to illustrate quantitatively the action of various pH solutions on opal, buffer solutions with different pH values were prepared by mixing 0.1 mol glycocoll and NaCl solution with 0.1 mol NaOH solution, according to the predetermined volume ratios. Buffer solution was used to make the  $\text{CH}^-$  ions concentration drop comparatively small during the reaction.

Experiments were carried out by putting 2 grams of opal (0.25 - 0.75 mm) in each plastic container with 70 ml. of buffer solution, then sealing them to prevent carbonization. After keeping it at room temperature ( $\sim 22^\circ\text{C}$ ) for 24 days, the dissolved silica was determined by photoelectric colorimeter. The aim of these experiments was to examine the corrosion on opal by solutions which have different  $\text{CH}^-$  ions concentrations but the same  $\text{R}^+$  ions concentrations. Experimental results are shown in Fig.1. It can be clearly seen that only a

Fig. 1. Silica dissolved in different pH buffer solutions

little silica is dissolved when the pH value of the solution is less than 12.0 - 12.5, but beyond these values, the amount of silica dissolved increases rapidly. These results can be utilized to explain the different behavior of alkali-silica reactions in various types of cement.

## 2. Alkali-silica reactions in different types of cement.

Mortar bars containing 6% (by weight of sand) of opal (0.15 - 0.30 mm) were made of different cements. Expansion after ageing was determined by measuring the length changes. The results are given in Table I. It shows that the expansion of portland cement is much greater than the others when their alkali contents are almost the same. This is supposed to be due to the difference of  $\text{OH}^-$

Table I Expansion of mortar bars containing opal

No.	Type of cement	Mix of cement	Alkali content expressed as equiv. $\text{Na}_2\text{O}$ (%)	Age	Expansion (%)	Condition of mortar bars
1	Portland		1.22	2 years	1.275	Cracked
2	Aluminous		1.17	3 years	0.054*	Good
3	Supersulphated	blast-furnace slag:gyssum:clinker=81:15:4	1.61	2 years	0.112*	Good
			2.61	2 years	0.160*	Good
			3.01	2 years	0.~89	Cracked
4	Red mud-sulphated	red mud:clinker:gyssum:blast-furnace slag=40:10:15:30	1.27	4 months	0	Good
			1.77	4 months	0.001	Good

① The original alkali contents of No.1,2,3,4 are 0.52%, 0.17%, 0.31% and 1.27% respectively (calculated as equiv.  $\text{Na}_2\text{O}$ ), the alkali make-up is added when mixed;

② Red mud is the waste slag from alumina factory, containing 75%  $\text{CaO}$ . Its alkali content is calculated as equiv.  $\text{Na}_2\text{O}$  to be 2.61%;

③ \* means the expansion value is same as that with no opal

ions concentrations in the pore solutions. To verify this, the ions concentrations were determined by using the method proposed by Schwiete<sup>(10)</sup> but modified by the present author. Cement paste with  $\text{W/C} = 0.65$  was prepared. After keeping the sample at room temperature ( $\sim 25^\circ\text{C}$ ) for 18 days, the liquid was expelled out of the cement paste by a pressure of  $45 \text{ N/mm}^2$  instead of centrifugation. The  $\text{OH}^-$  ions concentrations of pore solutions thus obtained were then determined. The results are shown in Table II.

Table II  
Ions concentrations of pore solutions in cement pastes

Type of cement	Alkali content expressed as equiv. $\text{Na}_2\text{O}$ (%)		Ions concentrations (mM/l)	
	original	total*	$\text{R}^+(\text{Na}^+ + \text{K}^+)$	$\text{OH}^-$
Portland	0.43	1.2	359.3	434.7
Aluminous	0.08	1.2	414.3	pH=12.97 (detd. by pH-meter)
Supersulphated	0.60	1.79	445.7	31.3

\*The alkalis other than original are added when mixed.

Comparison of the results shows clearly that the  $\text{OH}^-$  ions concentration of portland cement is much greater than that of super-

sulphated cement, but the difference of  $\text{R}^+$  ions concentrations is small. As mentioned above, the opal would be attacked more seriously as the concentrations of  $\text{OH}^-$  ions are much higher. This is also confirmed by microscopic observations. Nearly all of the opal in portland cement paste ( $\text{Na}_2\text{O} = 1.72\%$ ) was attacked and cracks were distributed over the whole surface, while the opal in the supersulphated cement ( $\text{Na}_2\text{O} = 1.61\%$ ) maintained its original contour (Fig. 2).

With respect to aluminous cement, though the  $\text{OH}^-$  ions concentration is lower than that of portland cement, but it is much higher

Fig. 2. Opal in cement pastes of (a) portland cement and (b) supersulphated cement, aged for the same period of 75 days.

than that of supersulphated cement. Consequently the opal is still attacked seriously. The  $\text{OH}^-$  ions concentrations of red mud-sulphated cement paste however determined with a  $\text{W/C}$  value higher than 0.65, is the smallest one among all the cements tested. Obviously, the opal in the paste of this cement would be reacted upon only slightly.

The higher  $\text{OH}^-$  ions concentration of pore solutions in portland cement paste is related to the presence of solid  $\text{Ca}(\text{OH})_2$  in the paste. According to Maiquori,<sup>(11)</sup> the total  $\text{OH}^-$  ions concentration of  $\text{Ca}(\text{OH})_2 + \text{NaOH}$  solution is always higher than that of  $\text{NaOH}$  present alone (Fig. 3).

It must be pointed out that the  $\text{Ca}(\text{OH})_2$  present may keep the pH of pore solutions greater than 12.5 even if the alkali content is very low. As mentioned above, opal is reacted upon severely under such pH value conditions. Therefore, the alkali-silica

Fig. 3. The total alkalinity of NaOH and  $(\text{NaOH} + \text{Ca}(\text{OH})_2)$  solutions

reaction may go on in portland cement though the alkali content is low, or even though a great part of alkali has been used up. Thus, D.O. Woolf<sup>(12)</sup> did report the expansion produced by the small amount of reactive aggregate in a low alkali cement.

It is very interesting that Diamond<sup>(5)</sup> interpreted the alkali-silica reaction by emphasizing the effect of the ions concentrations in the pore solutions. The present work suggests that the different behavior of alkali-silica reaction in different types of cement as above described are just due to their different concentrations of  $\text{OH}^-$  ions in pore solutions.

### 3. Mechanism of inhibiting alkali-silica reaction by additives.

Additives such as pozzolana and slag were proved by many investigators to be very effective to inhibit the alkali-silica reactions. The mechanism, however, as both Lea<sup>(13)</sup> and Malquori<sup>(11)</sup> stated, is yet to be elucidated.

Three questions might be put forward for discussion: (a) In order to reduce expansion, why should a large quantity of additives be always needed, as the alkali content of the cement amounts to approximately 1% only? (b) Why do certain additives cause expansion when a little amount of them is used? (c)

Certain high alkali pozzolanas, in reacting with  $\text{Ca}(\text{OH})_2$ , may release most part of the alkali contained, can these pozzolanas be used to inhibit the alkali-silica reaction? Presumably, these questions can be answered by taking the effect of  $\text{Ca}(\text{OH})_2$  into consideration.

The pozzolana in pozzolanic cement reacts not only with alkali but also with  $\text{Ca}(\text{OH})_2$ , both of them are released by portland cement clinkers during the process of hydration. The large amount of  $\text{Ca}(\text{OH})_2$  present in the hydrated cement may regenerate the alkali absorbed by pozzolanic materials. Furthermore, the alkali contained in pozzolanas can also be released by ion exchange with  $\text{Ca}(\text{OH})_2$ . Therefore, to inhibit an alkali-silica reaction, it is necessary to add a large amount of pozzolanic materials until there is enough to reduce the  $\text{Ca}(\text{OH})_2$  to such an extent that it will release or regenerate only a little alkali. It needs not, however, to take away all the  $\text{Ca}(\text{OH})_2$  because the last remaining  $\text{Ca}(\text{OH})_2$  would be embedded in the hydrated parts. In practice, the alkali-silica reaction can be inhibited only when the pozzolanic materials added amount to more than 25 - 30%. If a small amount (~10%) of high alkali pozzolanic materials such as fly ash or pozzolana is added, the  $\text{R}^+$  and  $\text{OH}^-$  ions concentrations of pore solutions would increase instead of the reverse. Thus the alkali-silica reaction will be accelerated. The high alkali pozzolanas, however, might have an inhibiting effect, if the amount added is sufficiently high. This has been proved in the laboratory and with field constructions. For example, in Italy,<sup>(11)</sup> pozzolanic cements made from high alkali pozzolanas were mixed with reactive aggregates, but no trouble was found thenceforth.

Two experiments were done with a portland cement ( $\text{Na}_2\text{O} = 1.2\%$ ) to which 25% of fly ash and 45% of calcined clay were used respectively. The alkali-silica reaction in both samples was found to be inhibited. For the purpose of illustrating the role of  $\text{Ca}(\text{OH})_2$ , extra 10% of low temperature calcined lime

was added in both samples. Expansion of mortar bar increased evidently with time (Fig. 4).

Fig. 4. Expansion of mortar bars made from pozzolanic cement with opal added.

It was thus proved that additives must absorb enough  $\text{Ca(OH)}_2$  in order to inhibit the alkali-silica reaction. In general, the inhibiting ability of blastfurnace slag is inferior to pozzolana, because the  $\text{Ca(OH)}_2$  absorbed by blastfurnace slag is less than by pozzolana.

It is highly likely that the mechanism of inhibition by pozzolanic materials would be not only to reduce the alkali-silica reaction but also related to the structure of the cement paste. Further work of investigation is to be planned.

4. Prevention of alkali-silica reaction caused by alkali from sources other than cement.

Bredsdorff<sup>(2)</sup> had call attention to the fact "that in cases where alkalies may be contained in the mixing water, in the aggregate or in the surroundings of concrete, special precautions, besides the use of low alkali cement, are called for." According to the discussion mentioned above, it would be expected that supersulphated cement may not cause severe alkali-silica reaction even if the surrounding water contains alkali salts. On this account, mortar bars containing opal were kept in alkali salt solutions and their length changes

were measured. The results are shown in Table III.

Table III  
Expansion of mortas bars kept in solutions of alkali salts

Type of cement	Alkali content expressed by equiv. $\text{Na}_2\text{O}$ (%)	Opal, % replacement of sand by weight	Solutions	Period of ageing (months)			
				1	4	9	13
Portland	0.52	0	5% $\text{Na}_2\text{SO}_4$	0.036	0.035	0.043	0.109
	0.52	6	5% $\text{Na}_2\text{SO}_4$	0.032	0.067	0.68	1.41
Supersulphated	0.61	0	5% $\text{Na}_2\text{SO}_4$	0.045	0.040	0.055	0.057
	0.61	6	5% $\text{Na}_2\text{SO}_4$	0.058	0.059	0.058	0.065
	0.61	0	5% $\text{NaOH}$	0.069	0.068	—	0.074
	0.61	6	5% $\text{NaOH}$	0.061	0.060	0.076	0.088
	1.31	0	5% $\text{Na}_2\text{SO}_4$	0.129	0.121	0.123	0.127
	1.31	6	5% $\text{Na}_2\text{SO}_4$	0.128	0.125	0.128	0.132

Results showed that the mortar bars made from low alkali portland cement and being kept in 5%  $\text{Na}_2\text{SO}_4$  solution expanded 1.41% and cracked after 13 months. But those made from supersulphated cement and being kept either in 5%  $\text{Na}_2\text{SO}_4$  solution or in 5%  $\text{NaOH}$  solution expanded only slightly. In particular, these expansions were almost the same as those of the mortar bars, which, with no opal in them, had been kept under the same conditions. Hence, it can be expected that by using such cements as supersulphated or portland cement, with the sufficient amount of pozzolana or slag being added, the alkali-silica reaction caused by the alkali from sources other than cement could be prevented, since hydration of these cements will produce little or no  $\text{Ca(OH)}_2$ .

Discussions so far are concerning mainly the effect of  $\text{OH}^-$  ions on alkali-silica reaction. Mention may be made on the migration of  $\text{Ca}^{2+}$  ions. By using EDAX technique, it is discovered that the  $\text{Ca}^{2+}$  is concentrated on the surface of the larger opal particles (1 cm) (Fig. 5a, the shadows show the elements on surface and the points show the elements in center). But it is verified by repeated tests that with the smaller opal particles (0.25 - 0.75 mm), a large amount of  $\text{Ca}^{2+}$  ions is concentrated in the center of opal (Fig. 5b). It seems that the  $\text{Ca}^{2+}$  ions also take part in and promote the alkali-silica reaction.

Fig. 5. EDAX of opal in cement pastes  
(a) Opal size,  $\sim 1$  cm;  
(b) Opal size, 0.25 - 0.75 mm.

### III. Conclusion.

1. Alkali-silica reaction is actually a base-acid neutralization reaction. Hence, when the concentrations of  $R^+$  ions is fixed, the more concentrated the  $OH^-$  ions solution is, the more vigorous is the reaction.

2. The differences of expansion caused by alkali-silica reaction in different types of cement are mainly due to the difference of  $OH^-$  ions concentrations in the pore solutions of cement pastes.

3. The alkali-silica reaction may be effectively inhibited, if a sufficient amount of pozzolanic materials is added to the cement. A large part of  $Ca(OH)_2$  would be vanished in reaction and the last remained  $Ca(OH)_2$  could be embedded by the hydrated products.

4. The alkali-silica reaction caused by alkali from sources other than cement can be prevented by the use of supersulphated cement or cement with additive such as pozzolana or blastfurnace slag.

# Effect of glucose on the hydration of portland cement

## *Action du glucose sur l'hydratation du ciment portland*

N.B. SINGH and P.N. OJHA, Department of Chemistry, Gorakhpur University, Gorakhpur (U.P.), India.

RESUME : L'action du glucose, à diverses concentrations, sur l'hydratation du ciment Portland a été étudiée en utilisant la calorimétrie, l'analyse thermique différentielle et la diffraction X. On a mesuré la quantité de chaux libérée par l'hydratation du ciment, et la résistance à la compression de ciments additionnés ou non de glucose. Le potentiel Zéta de ces ciments, additionnés ou non de glucose, a été déterminé par électrophorèse. Ce potentiel Zéta du ciment anhydre ou hydraté pendant 24 heures, ou encore hydraté pendant 24 heures en présence de  $2,0 \times 10^{-2} M$  de glucose a été trouvé égal respectivement à + 14,6 mv, -8,4 mv et + 4,5mv. Les résultats montrent qu'en présence de glucose, la vitesse de réaction entre le  $C_3A$  et le gypse est augmentée, et dépend de la concentration en glucose; ainsi, une concentration plus grande en glucose provoque une vitesse de réaction plus élevée. L'effet global du glucose est de retarder l'hydratation. Ces résultats ont été exprimés en fonction du potentiel Zéta.

SUMMARY: Effect of different concentration of glucose on the hydration of portland cement have been studied. Calorimetric, DTA and X-ray diffraction techniques were used for the hydration studies. Percent free lime of the hydrated cement and the compressive strength of the hardened cement in the presence and absence of glucose were determined. Zeta potential of the cement hydrated in the presence and absence of glucose have also been calculated by determining the electrophoretic velocity. The zeta potential values of unhydrated cement, hydrated for 24 h and hydrated for 24 h in the presence of  $2.0 \times 10^{-2} M$  glucose were found to be + 14.6 mv, -8.4 mv and + 4.5 mv respectively. Results indicate that in the presence of glucose, the rate of reaction between  $C_3A$  and gypsum is increased and this depends on the concentration of glucose i.e. greater is the concentration, faster is the rate of reaction. The overall effect of glucose is the retardation of hydration. The results have been explained in terms of zeta potential value.

## INTRODUCTION

Effect of admixtures, both accelerators and retarders, on the hydration of cements have been studied extensively. The saccharide compounds (or sugars as they are commonly called) are one of the effective retarders and have been studied by various research workers<sup>1-7</sup>. Suzuki and Nishid<sup>1</sup> studied the retarding effect of saccharides on the hydration of cements and they explained their results in terms of adsorption theory. Breuer<sup>2</sup> also explained the retarding action of sugars in terms of adsorption theory. During the action of polysaccharides on the hydration of cement pastes, Young<sup>1</sup> found that in the presence of alkalis, the degradation of saccharides take place and the degraded products are more effective retarders. Milestone<sup>3</sup> also supports the Young's observation and he found that the sugar acids of glucose are at least ten times more effective in retarding the hydration of  $C_3A$  than glucose. Previte<sup>9</sup> found that the retarding power of saccharides are related to the molecular size and conformation. Mariampol'skii et al.<sup>10</sup> studied the retarding action of saccharic, aldonic and uronic acids and their salts on the hydration of cements and explained their results in terms of chelation between organic compounds and the  $Ca^{2+}$  ions. Singh<sup>11</sup> on the other hand believes that the gluconates retard the hydration of portland cement by poisoning certain growing nuclei.

Recently Singh<sup>12,13</sup> studied the effect of glucose on the hydration of portland cement and found that it accelerates the reaction between tricalcium aluminate and gypsum.

The survey of the literature shows that although the effects of organic additives such as sugars on the hydration of cements have been studied extensively, there are still significant disagreements regarding the mechanism of their action.

The purpose of this article is to study the mechanism of the action of glucose on the hydration of portland cements. The results have been interpreted in terms of zeta potential ( ).

## EXPERIMENTAL

**Material:** Portland cement (ACC) was used for the hydration studies. Glucose (G. Merck) was used as an admixture.

**Method:** Heat of hydration were determined by a microcalorimeter. The details of the method are described elsewhere<sup>14</sup>. The experiments were performed at 30°C at  $W/c = 0.5$ .

Hydration of the cement ( $W/c = 0.5$ ) in the presence and absence of glucose was stopped at various intervals of time by absolute ethyl alcohol.  $0.5 \times 10^{-2}M$ ,

$1.0 \times 10^{-2}M$ ,  $1.5 \times 10^{-2}M$  and  $2 \times 10^{-2}M$  glucose solutions were used for the study.

Measurement of electrophoretic velocity

For the measurement of electrophoretic velocity, a similar method as adopted by Kastogi et al.<sup>15</sup> was used. The apparatus used is shown in Fig. 1. The cement particles were homogenized mechanically and dispersed in isopropyl alcohol. The experimental cell was fixed in a vertical

Fig. 1. Apparatus for measurement of electrophoretic velocity.

position and the suspension was introduced into the experimental cell through J till half of the tube was filled. The stopcock, S, was now closed and pure isopropyl alcohol was gently filled in the remainder of the tube, XY, so that distinctly sharp boundary B was formed. The internal diameter of XY was 0.33 cm. A potential difference was applied through coiled platinum electrodes, P<sub>1</sub> and P<sub>2</sub>, 12.7 cm. apart with an electronically operated power supply in such a way that movement of the boundary occurred in the downward direction. The position of the boundary at various time intervals was noted and the rate of movement of boundary or the electrophoretic velocity was thus determined. Corrections were made for the downward movement due to the action of gravitational forces. From the electrophoretic velocity, potential was calculated. The experiments were performed at 35°C and for anhydrous cement, and cement hydrated for 24 h in the presence and absence of  $2.0 \times 10^{-2}M$  glucose solution.

X-ray diffraction patterns of the hydrated samples were taken with a x-ray diffractograph using  $CuK_{\alpha}$  radiations. The following x-ray lines are used for the analysis.

Phase	$d(\text{\AA}^{\circ})$
$C_3S$	2,776, 3.02
$C_3A$	2.70

$\text{Ca(OH)}_2$	4.90
$\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$	7.56
$\text{C}_3\text{A} \cdot 3\text{CaSO}_4 \cdot 31\text{H}_2\text{O}$	9.70

DTA of the hydrated samples were made with a manual differential thermal analyser. Calibration curve by using different concentration of gypsum in alumina were also made.

Free lime content was determined by the extraction method<sup>16</sup>. The samples were extracted for one hour with a mixture of iso-propyl alcohol and acetoacetic ester at boiling temperature, after which the suspensions were cooled down and filtered. The extracted lime were determined by titrating against 0.1N HCl.

Compressive strength of the samples in the form of 4"x4"x16" bricks were measured at different intervals of time in the presence and absence of glucose.

## RESULTS

### Heat of hydration

The heat of hydration of cement in the presence and absence of glucose with different hydration times are given in Fig. 2. From the figure it is clear that as soon as the cement comes in contact to water rapid heat evolution takes place and after which the reaction slows down.

Fig. 2. Effect of glucose on the heat evolution of cement.

This early heat liberation may be due to cement wetting, dissolution of alkalies, hydration of hemihydrate, free lime and  $\text{C}_3\text{A}$ . The hydration reaction is very slow during the induction period which

continues approximately upto 5 hrs. After the induction period is over the reaction accelerates with time, and reaches a maximum value at around 10 hrs. and after which deceleration of the reaction starts and ultimately it becomes very slow. During this period mainly the hydration of  $\text{C}_3\text{S}$  phase takes place. In the presence of different concentration of glucose ( $1.0 \times 10^{-2} \text{ M}$ ,  $1.5 \times 10^{-2} \text{ M}$  and  $2.0 \times 10^{-2} \text{ M}$ ) the rate of heat evolution is decreased and the time for maximum heat evolution is increased. The overall effect is that by increasing the concentration of glucose the hydration of cement is decreased.

### X-ray Studies

The variation of concentration of  $\text{C}_3\text{S}$ ,  $\text{C}_3\text{A}$  and gypsum in the solid samples hydrated at different intervals of times, as represented in terms of x-ray intensities, are shown in Fig. 3. From the figure it appears that in the absence of glucose, the concentration of  $\text{C}_3\text{S}$  phase is constant upto approximately 10 hrs and after which it starts decreasing.

Fig. 3. Variation in x-ray intensity for the different phases of cement during hydration.

In calorimetric curve, also a maximum comes at about 10 h of hydration. After this time the x-ray intensity starts decreasing and reaches to 50% at 24 hr. This shows that only nearly 50% of  $\text{C}_3\text{S}$  is hydrated at 24 h. On the otherhand in the presence of  $2.0 \times 10^{-2} \text{ M}$  glucose solution, the x-ray intensity remains constant upto nearly 18 h and then starts decreasing and reaches to 90 at 24 h. Here also a maximum appears at around 18 h. A decrease of only 10 in the x-ray intensity simply indicates that in the presence of glucose the hydration of  $\text{C}_3\text{S}$  phase is practically negligible.

In the absence of glucose, the x-ray intensities of the C<sub>3</sub>A phase are constant upto nearly 10 h and then start decreasing whereas in the presence of  $2.0 \times 10^{-2}$  M glucose, there is not much variation in the x-ray intensity of the C<sub>3</sub>A phase (Fig. 3). In other words the concentration of C<sub>3</sub>A is roughly constant during the time of experiment in the presence of glucose.

As indicated by the x-ray intensity, in the absence of glucose, the gypsum is consumed between 18 and 24 hr. Whereas in the presence of  $2.0 \times 10^{-2}$  M glucose solution, it is consumed in between 4-8 hr. (Fig. 3). This is supported by DTA experiment also. The consumption of gypsum is as a result of the reaction between C<sub>3</sub>A and gypsum with the formation of ettringite. This reaction is accelerated in the presence of glucose and hence gypsum is consumed quickly. Since only a small amount of C<sub>3</sub>A is involved in the reaction, its concentration is not effected much.

In the absence of glucose, the presence of calcium hydroxide is indicated only after 4 h whereas in the presence of  $2.0 \times 10^{-2}$  M glucose, it does not come even upto 24 h.

### ξ Potential

The electrophoretic velocity is given from double layer theory as

$$(V_e)_{g=0} = D \xi E / f \pi \eta \quad \dots (1)$$

where,  $\eta$  = viscosity of the medium,  $D$  = its dielectric constant,  $\xi$  = zeta potential of the interface,  $g$  is the gravitational field per unit mass and  $f$  is between 4 and 6. According to regorous theory of Debye and Hiickel, it is 6, when the electrophoretic drag due to double layer is also considered<sup>17</sup>. In equation (1);  $E = \Delta\phi / \ell$ , where  $\Delta\phi$  is the potential difference and  $\ell$  is the distance between the two electrodes. Thus, on substituting the value of  $E$  in equation (1).

$$V_e = D \xi \phi / \ell f \pi \eta \quad \dots (2)$$

A plot of  $V_e$  against  $\Delta\phi$  (Fig. 4) would give a straight line. The slope of the curve will be equal to  $D$

$$\text{Thus, } \xi = \frac{\ell f \pi \eta}{D} \text{ slope} \quad \dots (3)$$

The zeta potential for pure cement, and cement hydrated for 24 h in the presence and absence of  $2.0 \times 10^{-2}$  M glucose solution were calculated by using eq.(3)

Fig. 4. Variation of electrophoretic velocity with the applied voltage

and are given in table I. From the table it is clear that the zeta potential is positive and maximum for unhydrated cement whereas it is decreased considerably for other samples. In the cement hydrated in the absence of glucose, the zeta potential even becomes negative.

Table I

Zeta Potential ( $\xi$ )  
Temperature = 35°C

Sample	Zeta Potential (mV)
Cement	+ 14.6
Cement hydrated for 24 h	- 8.4
Cement hydrated for 24 h in $2.0 \times 10^{-2}$ M glucose	+ 4.5

### Free lime content

The variation of percent free lime with hydration time is shown in Fig. 5. In the absence of glucose, the percent free lime is roughly constant upto 5 hr (~1%) and after which increases rapidly and then becomes slow after 18 h. In the calorimetric experiment also, the induction

period is upto 5 h and hence the free lime determination shows that the hydration is very slow upto 5 h and it increases only after the induction period is over. In the presence of glucose, the percent free lime is very low ( $< 1\%$ ) and is nearly constant during the course of experiment. This simply shows that in the presence of glucose the hydration is decreased considerably.

Fig. 5. Variation of free lime content with the hydration time.

#### Compressive Strength

The variation of compressive strength with hydration time in the presence of different concentration of glucose solution is given in Fig. 6. From the figure it is

Fig. 6. Effect of glucose on the compressive strength of cement.

clear that in the presence of glucose the strength is lower at early stages of hydration but becomes nearly equal to that hydrated in the absence of glucose

at latter stages of hydration. The decrease of compressive strength and the time of equalization of the two strengths (in the presence and absence of glucose) increases with the increase in glucose concentration.

#### DISCUSSION

Results indicate that in the presence of glucose, the overall hydration of the cement is retarded and the gypsum is consumed quickly. A positive value of zeta potential indicates that the overall charge on the cement grains are positive. The development of charge on the cement grains may be due to the non-stoichiometry present in the constituent compounds of the cement. The cement grains with a positive surface when comes in contact to water, a dipole, dipolar interaction starts. As a result of this dipole-dipole interaction, the reaction proceeds and various hydrates are formed, at the surface of the cement grains. These hydrates may take some time for reorientation of charges, which causes the induction period of the hydration reaction. Once the reorientation of the charges is over, the reaction will accelerate with time and hydrates thus formed are probably rich in OH<sup>-</sup> groups and because of this the overall charge on the hydrated cement grains become negative and accordingly the zeta potential. On the other hand the zeta potential of the cement hydrated in the presence of glucose is decreased. This decrease in zeta potential can be explained as: As soon as cement grains come in contact to glucose solution, glucose molecules are adsorbed on the cement grains. Since the glucose molecules are neutral and bulky, they act as a screen. As a result of this the magnitude of the effective charge on the cement grains are decreased. Because of the lower effective charge, the dipole-dipole interaction between water and glucose adsorbed cement grains are decreased and the overall magnitude of charge on the hydrated cement in presence of glucose is decreased. This causes a retardation of hydration and a decrease in the zeta potential of the hydrated sample in the presence of glucose. The decrease in zeta potential can be explained with the help of following equation

$$\xi = \frac{4\pi\epsilon d}{D} \quad \dots(4)$$

where  $d$  is the double layer thickness,  $\epsilon$  is the charge density and  $D$  is the dielectric constant of the medium. Thus keeping  $D$  as constant,  $\xi$  will depend mainly on  $\epsilon$ .

However it is difficult to explain the accelerating action of glucose on the reaction of gypsum with C<sub>3</sub>A on the basis of zeta potential unless a separate experiment with C<sub>3</sub>A alone is performed.

The decrease in free lime and strength in the presence of glucose is mainly due to lower degree of hydration.

#### CONCLUSION

From our results the following conclusions can be made.

1. Calorimetric experiments indicate that the hydration of cement is retarded in the presence of glucose. By increasing the concentration of glucose, the induction period and the time for maximum heat evolution is increased whereas the total amount of heat evolved is decreased.
2. X-ray diffraction and differential thermal studies indicate that in the presence of glucose, the reaction between C<sub>3</sub>A and gypsum is accelerated. This is indicated by early consumption of gypsum in the presence of glucose.
3. The zeta potential of unhydrated cement was found to be +14.6 mv, whereas the zeta potential of the cement hydrated in the presence of absence of  $2.0 \times 10^{-2}$  M glucose for 24 h were found to be -8.4 mv and +4.5 mv respectively.
4. The positive value of zeta potential of the unhydrated cement indicates a positive charge on the cement and this may be due to the nonstoichiometric compounds present in the cement. The hydration reaction is considered as a dipolar interaction between positively charged cement grains and water dipoles.
5. The negative value of the zeta potential indicates a negative charge on the hydrated cement which may be due to more OH<sup>-</sup> groups on the surface of the hydrated cement. A decrease in zeta potential in the presence of glucose is explained as a result of adsorption.
6. The compressive strength of the cement in the presence of glucose is decreased in the early days of hydration whereas after longer time it becomes nearly equal.
7. In the presence of glucose, the percent free lime is less than one and remains constant upto 24 h, whereas in the absence of glucose it is nearly one upto 5 h and after than it increases rapidly.

#### ACKNOWLEDGMENTS

The authors are thankful to Dr. P. Rastogi, Dr. I. Das and Mr. V.N. Srivastava for giving help during the course of experiment.

# Conditions of the Hydroxyl Ellestadite Formation in Mixtures containing Calcium Sulphate

## *Les conditions de la formation de l'hydroxyle-ellestadite dans les mélanges comprenant du sulphate de calcium*

Z. SAUMAN, Professor, Research Institute of Building Materials, Brno,  
F. VAVRIN, Professor, Technical University, Brno, CSSR, Tchécoslovaquie.

RESUME : Au cours du traitement hydrothermique des mélanges de sable quartzueux et de chaux avec addition de plâtre, l'hydroxyle-ellestadite se forme  $Ca_{10}(SiO_4)_3(SO_4)_3(OH)_2$ . Dans le cas d'une teneur très accentuée, celui-ci cause la détérioration des caractéristiques mécaniques et physiques des produits autoclavés. Dans les mélanges de CaO et de quartz à granulométries différentes, et avec plâtre, on a constaté qu'au cours du processus hydrothermique, la quantité de la phase susmentionnée formée est maximum pour une dimension des particules de quartz comprise entre 60 et 90  $\mu m$ .

Avec du quartz de granulométrie inférieure à 10  $\mu m$ , l'hydroxyle-ellestadite se forme au commencement de la réaction et se décompose immédiatement en phase tobermoritique et en sulphate de calcium. L'augmentation de la grandeur des particules de quartz prolonge cette décomposition dans le temps. Dès le remplacement partiel de la chaux par le  $C_3S$  ou par le ciment, ce composant se forme, mais seulement pour des teneurs en plâtre plus élevées (> 10 %).

SUMMARY : During the hydrothermal processing of mixtures of quartz sand with lime and a gypsum rock admixture is formed hydroxyl ellestadite  $Ca_{10}(SiO_4)_3(SO_4)_3(OH)_2$  which in a more pronounced quantity causes the deterioration of the physical and mechanical properties of autoclaved products. It was found in mixtures of CaO with quartz of a different granulometry and gypsum rock that in the course of the hydrothermal process is formed the maximum quantity of the above phase when employing quartz with particle size within 60 to 90  $\mu m$ .

When quartz of granulometry under 10  $\mu m$  is employed, hydroxyl ellestadite is formed at the beginning of the reaction, but it is immediately decomposed into tobermoritic phase and calcium sulphate. With growing quartz particle sizes, the decomposition period of the latter is prolonged. Already through the partial replacement of lime by  $C_3S$  or cement there occurs the formation of this component only at higher gypsum rock content (> 10%).

## INTRODUCTION

Studies of  $\text{SO}_4^{2-}$  ions influence onto the  $\text{CaO-SiO}_2\text{-H}_2\text{O}$  system under hydrothermal conditions have shown that the transformation of CSH gel into 11 Å tobermorite is accelerated by the relatively low additions of  $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$  (1-3).

As soon as, however the content of the added  $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$  in the starting mixture above 3-4% is increased, the formation of hydroxyl ellestadite/ $\text{Ca}_{10}(\text{SiO}_4)_3(\text{SO}_4)_3(\text{OH})_2$  could be noted. At the same time it was found that increasing sulphate additions lead to a proportional increase in the contents of the formed hydroxyl ellestadite (further only : HXEL).

With regard to the fact that the experimental part of this work was aimed at the formation of HXEL under production technology conditions of autoclaved building materials on the basis of quartz sand, lime and cement, also their physical and mechanical properties were studied.

It was proved that an increasing content of sulphate ions in the above system causes the reduction of strengths after the hydrothermal processing of the investigated mixtures, proportionally to the quantity of the formed HXEL. This fact follows from the actual particles morphology of the above phase (4).

The formation of HXEL and the effect of gypsum rock in mixtures of cement and quartz sand, respectively, onto the actual mechanism of the reactions, were studied also by Takemoto and Kato (5) and Djabarov and Slatanov (6).

## EXPERIMENTAL

Starting raw material components and method of their preparation.

For the experimental work there was employed  $\alpha$ -quartz (low) having following chemical composition (%) :

Moisture content - 0,09; ignition loss - 0,11;  $\text{SiO}_2$  - 99,75;  $\text{Al}_2\text{O}_3$  - traces;  $\text{Fe}_2\text{O}_3$  - 0,06;  $\text{TiO}_2$  - 0,01;  $\text{CaO}$  - traces;  $\text{MgO}$  - traces;  $\text{K}_2\text{O}$  - traces;  $\text{Na}_2\text{O}$  - traces.

$\text{CaO}$  was obtained by igniting  $\text{CaCO}_3$  (Merck, anal. grade) at  $1050^\circ\text{C}$ , 4 h.

As the sulphate component  $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$  (anal. grade) was employed. Quartz, employing laboratory air classifier and suitable sieves was separated into following fractions ( $\mu\text{m}$ ) : < 5, 5-10, 20-30, 30-40, 40-60, 60-90, 90-100, 100-150, 150-200, 200-300, 300-400, 400-500 and 500-600.

Furthermore there was employed portland cement clinker with following phase composition (%) :  $\text{C}_3\text{S}$  - 69,1;  $\beta\text{-C}_2\text{S}$  - 13,2;  $\text{C}_4\text{A}$  - 6,2;  $\text{C}_6\text{AF}_3$  - 6,9, from which also cement was obtained by grinding with 4%  $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$  to the fineness of  $3200 \text{ cm}^2/\text{g}$  (Blaine)?

## RESULTS AND THEIR DISCUSSION

Formation and stability of HXEL in relation to quartz granulometry and length of the hydrothermal process.

Quartz fraction mixtures were homogenized with  $\text{CaO}$  in a mass ratio of 80:20 simultaneously with 10%  $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$  (converted to a lime-quartz mixture) and processed in the form of a paste or suspension (solid phase :  $\text{H}_2\text{O}$  = 1 : 10) hydrothermally in small pressure vessels at  $193^\circ\text{C}$ , isothermal holding period 5 h. From the prepared X-ray diagrams there was employed the height of the 2,83 Å diffraction line (corresponding to HXEL) for plotting the graphical relationship between the relative quantity of the above phase and the quartz granulometry.

It follows from Fig.1 that a larger HXEL quantity is formed in the paste, whereas in mixtures with fine quartz fractions (<40  $\mu\text{m}$ ) this component could not be positively identified. In both series the highest HXEL quantity was determined in samples that contained quartz with the granulometry of 60-90  $\mu\text{m}$ .

Fig. 1 - Formation of HXEL in relation to the quartz granulometry.

I. Suspensions		II. Pastes	
No.	$\mu\text{m}$	No.	$\mu\text{m}$
1	30 - 40	6	200 - 300
2	60 - 90	7	300 - 400
3	90 - 100	8	400 - 500
4	100 - 150	9	500 - 600
5	150 - 200		

Fig. 2 shows the morphology of the HXEL crystals prepared synthetically and finally Fig. 3 represents the microstructure of the No. 2 mixture.

HXEL crystals are characterized by a columnar shape which predetermines the low binding properties of this component.

Fig. 4 indicates the existence of HXEL in relation to the isothermal holding period (0, 1, 2, 3, 4 and 5 h) and the quartz granulometry.

Fig. 2 - SEM of synthetically prepared HXEL

Fig. 3 - SEM of sample No. 2 suspension.

Even though in mixtures with the finest quartz fractions (< 5 and 5-10  $\mu\text{m}$ ) HXEL is formed at the beginning of the reaction, it is subsequently decomposed into tobermorite and calcium sulphate.

In the following mixtures the HXEL quantity is markedly higher at the beginning of the reaction and its decomposition is shifted towards the longer periods of time. When employing the 40-60  $\mu\text{m}$  granulometry, then only after a 4 hour period it was possible to prove a very slight decrease in HXEL contents. It was also found that HXEL formed in a mixture with quartz of 60-90  $\mu\text{m}$  granulometry does not decompose even within 5-10 hours (193°C).

Definition of temperature and  $3\text{CaO} \cdot \text{SiO}_2$  influence onto the HXEL formation.

With regard to the employment of cement as one of the starting raw material components in the production of autoclaved building materials, it appeared expedient to give precision to the above mentioned influence onto the formation of HXEL, in two different types of mixture processing: steam curing at 100°C (9 h) and autoclaving at two temperatures: 175°C and 193°C (5 h).

Fig. 4 - Formation and existence of HXEL in relation to the quartz granulometry and the reaction period (193°C).

The composition of the investigated mixtures is shown in Table I.

TABLE I

Mix. design.	Quartz (60-90 $\mu\text{m}$ ) (%)	$3\text{CaO} \cdot \text{SiO}_2$ (%)	$\text{CaO}$ (%)	$\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ (%)
1	80,0	20,0	-	-
2	80,0	20,0	-	10,0
3	80,0	19,0	1,0	10,0
4	80,0	15,0	5,0	10,0
5	80,0	10,0	10,0	10,0
6	80,0	5,0	15,0	10,0
7	80,0	-	20,-	10,0

As can clearly be seen from the characteristic angular region of the X-ray diagrams (Fig. 5), the lowest HXEL quantity was formed at 100°C. The last two mixtures, processed at 175°C, exhibit a somewhat larger proportion of this component; at the same time in sample "7" it is no longer possible to identify the presence of 11 Å tobermorite, since the major newly formed phase is HXEL.

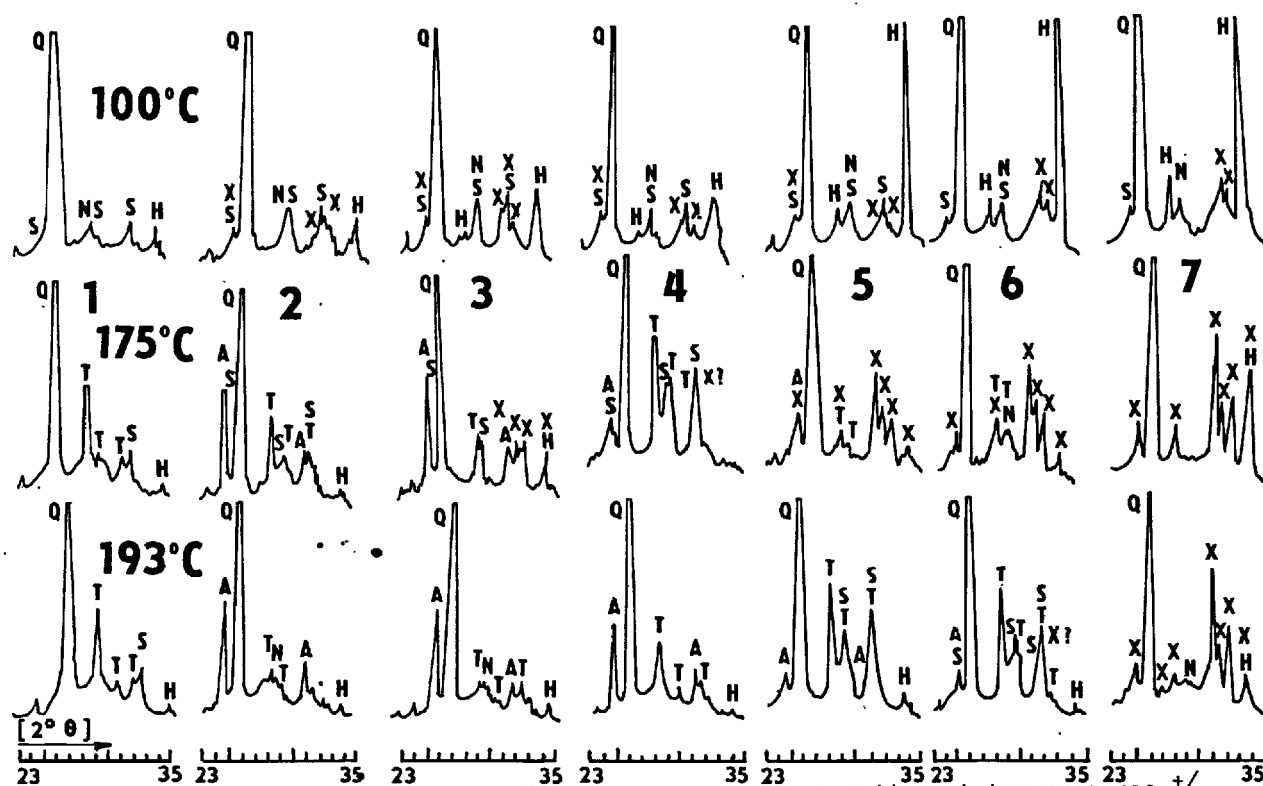

Fig. 5 - X-ray diffraction diagrams of pastes processed at different temperatures. +/ 35

As long as the temperature of 193°C was used, there was formed a pronounced HXEL quantity only in mixture "7", in mixture "6" its presence appears to be controversial.

Influence of a graded sulphate addition onto the formation of HXEL.

It was proved by orientated experiments that the bottom limiting contents of clinker (cement) in the investigated quartz-CaO mixtures which suppress the formation of HXEL, correspond to the value of 7-10%. In order to clarify the influence of  $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$  onto the formation of HXEL there were selected mixtures containing 80% quartz, 12,5% CaO, 7,5% portland cement clinker and a graded gypsum rock fraction (0-20%).

In mixtures in the form of paste processed at 193°C/5 h with a growing addition of  $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ , the quantity of anhydrite increases. Starting with 15% gypsum rock there occurs a pronounced decrease of the anhydrite and 11 Å-tobermorite in connection with the formation of HXEL (Fig. 6).

+/ Used symbols :

A -  $\text{CaSO}_4(\text{III})$ ; H -  $\text{Ca}(\text{OH})_2$ ; N -  $\text{CSH}_n$ ;  
Q - quartz; S -  $\text{CaSO}_4 \cdot 1/2\text{H}_2\text{O}$ ; T - 11 Å-tobermorite; X - hydroxyl ellestadite.

Fig. 6 - Formation of main phases related to gypsum rock additive (quartz 60-90 μm, 193°C/5 h).

#### CONCLUSIONS

The highest quantity of hydroxyl ellestadite in quartz mixtures of varying granulometry with CaO and gypsum rock subjected to hydrothermal processing was noted, when using particles of 60-90 μm in size. Even though in the case of very fine quartz (<10 μm), HXEL is formed at the beginning of the reaction, it is immediately decomposed with the formation of 11 Å-tobermorite and calcium sulphate.

With quartz particles growing in size, the stability period of HXEL is prolonged. If the lime is fully or partly replaced by cement, the above mentioned phase is formed only after a considerable addition of gypsum rock.

# A Kinetic Study of Alite Hydration

## *Etude cinétique de l'hydratation de l'alite*

A. BEZJAK, Faculty of Pharmacy and Biochemistry, University of Zagreb,

I. JELENIC, V. MLAKAR and A. PANOVIC, Association of Yugoslav Cement Producers, Yugoslavia.

**RESUME :** Les auteurs ont étudié la cinétique de l'hydratation de l'alite dans le système pur minéral-eau, dans le mélange alite- $C_3A$ -plâtre et dans les pâtes du ciment portland, en appliquant un procédé qui tient compte des effets des interactions des processus, déterminants pour la vitesse de la réaction. Les échantillons étaient hydratés à un rapport eau-solide de 0.5 à 20°C et en présence ou absence des sulfates alcalins. Les degrés d'hydratation de l'alite à des âges allant de 4h. à 2 mois furent déterminés par la diffraction des rayons X. L'équation d'Avrami-Erofeev et les équations de la cinétique linéaire ou quadratique servaient à calculer les paramètres. Pour une distribution des tailles des particules donnée, on calculait les degrés d'hydratation en supposant des contributions différentes de chaque processus déterminant la vitesse de réaction. La comparaison des degrés d'hydratation calculés et observés a fourni une relation linéaire entre le temps d'hydratation  $t$  ( $\alpha$ -observé) et le temps réduit  $\tau$  ( $\alpha$ -calculé/ $\alpha$ -observé) et a donné le paramètre nécessaire pour calculer les constantes de la vitesse de réaction. Les degrés d'hydratation calculés correspondant aux degrés d'hydratation observés, montrent la contribution des mécanismes à chaque étape d'hydratation de l'alite. Les valeurs des constantes de vitesse de germination et de croissance des produits d'hydratation sont de l'ordre de  $11.0 \cdot 10^{-2}$  à  $2.2 \cdot 10^{-2} \text{ h}^{-1}$  et celles de l'interaction à l'interface à  $6.7 \cdot 10^{-2}$  à  $25 \cdot 10^{-2} \mu\text{m h}^{-1}$ . Le processus de la diffusion contrôlée montre l'existence de deux ou trois étapes, avec des constantes de vitesse nettement plus grandes pour la première étape que pour la deuxième ou la troisième, surtout pour les systèmes qui contiennent des sulfates alcalins. Les très grandes vitesses observées pour la première étape de diffusion sont essentiellement responsables de l'effet accélérateur des sulfates alcalins.

**SUMMARY :** The kinetics of alite hydration in pure mineral-water system, in the alite- $C_3A$ -gypsum mixture and in Portland cement pastes with high and with low  $C_3A$  content was studied by applying a procedure that takes into account the effects of simultaneous action of different rate-determining processes. Specimens were hydrated at 0.5 water-to-solid ratio at 20°C, in presence and in absence of alkali sulphates. The degrees of alite hydration at various ages ranging from 4 hours to 2 months were determined by quantitative X-ray diffraction. Avrami and Erofeev's expression and linear and quadratic rate equations were used to calculate the parameters required. The degrees of hydration for a given particle size distribution were calculated presuming different contributions of particular rate-determining processes. The comparison of the observed and the calculated degrees of hydration providing linear relationship between hydration time  $t$  ( $\alpha$ -observed) and relative time  $\tau$  ( $\alpha$ -calculated =  $\alpha$ -observed) yields the parameter required for the calculation of actual rate constants. Computed contributions to the calculated degrees of hydration, corresponding to the observed ones, show the distribution of the rate-determining mechanisms at particular stages of alite hydration. The obtained values of the rate constants for nucleation and growth of hydration products range between  $11.0 \cdot 10^{-2}$  and  $2.2 \cdot 10^{-2} \text{ h}^{-1}$ , and those for phase-boundary interaction between  $6.7 \cdot 10^{-2}$  and  $25 \cdot 10^{-2} \mu\text{m h}^{-1}$ . The diffusion-controlled process proved to be two- or three-stage in nature, with the rate constants for the first stage being considerably higher than for the second or the third one. This applies especially to the systems containing alkali sulphates, and the extraordinarily high rate constants of the first-stage diffusion are most responsible for the observed acceleratory effect of the readily soluble alkalies.

## INTRODUCTION

The hydration kinetics of C<sub>3</sub>S has been extensively studied on pure mineral-water systems (1-8). Numerous data obtained by several investigators indicate that the rate of hydration process during the acceleratory stage is controlled either by nucleation and growth of hydration products or by phase-boundary interaction. The C-S-H phases that form at this stage influence the course of the subsequent, diffusion-controlled reaction.

In a complex cement-water system the rate of alite hydration depends on a number of parameters, and so does the development of C-S-H binding material. It seems that the course of this development can be decisive for the final properties of Portland cement pastes, since there is evidence that the rate of hardening per se influences the ultimate strength of mortars, with the cause of the rate change from one sample to another being secondary (9). In an attempt to explain the observed correlation between the rate of hardening and the final strength as exactly as possible, the kinetics of alite hydration in Portland cement pastes should be considered first. When seeking to evaluate the most reliable rate constants for the hydration process in such a complex polysize system, the effects of simultaneous action of different rate-determining mechanisms should be taken into account. By applying a procedure which includes this item (10) we investigated the influence of alkali sulphates on the kinetics of alite hydration in various Portland cement pastes, and in some simpler systems as well.

## MATHEMATICAL SOLUTIONS FOR THE EVALUATION OF KINETIC PARAMETERS

As already mentioned in the introductory part, different rate-determining processes follow after one another in the course of alite hydration, which implies that within a given polysize system they can act simultaneously. The fractions hydrated according to different laws at the same time are decided by both the rate constants and the particle size distribution. In accordance with the present state of knowledge on the hydration kinetics of alite, it can be assumed that the process of nucleation and growth, followed by eventual impingement of growth products, is the slowest step at early ages. In the subsequent period it is either the phase-boundary interaction or the diffusion process that becomes the slowest step, the latter being definitely the rate-determining one at high degrees of hydration. The described course of the hydration process can be represented for a single particle *i* by the following series of basic equations:

$$G_1(\alpha_i) = k_1 t \quad (1)$$

$$G_2(\alpha_i) - G_2(\alpha_{1i}) = k_2(t - t_{1i})/R_i \quad (2)$$

$$G_3(\alpha_i) - G_3(\alpha_{2i}) = k_3(t - t_{2i})/R_i^2 \quad (3)$$

where  $\alpha_i$  degree of hydration of particle *i* at time *t*

$t_{1i}$  time when  $G_2$  process has become the rate-determining one

$\alpha_{1i}$  degree of hydration of particle *i* at time  $t_{1i}$

$t_{2i}$  time when  $G_3$  process has become the rate-determining one

$\alpha_{2i}$  degree of hydration of particle *i* at time  $t_{2i}$

$k_1, k_2, k_3$  rate constants

$R_i$  original radius of particle *i*

$G_1(\alpha)$ ,  $G_2(\alpha)$  and  $G_3(\alpha)$  functions denote the process of nucleation and growth of hydration products, of phase-boundary interaction and of diffusion respectively. Their explicit forms are usually the following:

$$G_1(\alpha) = [-\ln(1-\alpha)]^{1/n} \quad (4)$$

$$G_2(\alpha) = 1 - (1-\alpha)^{1/3} \quad (5)$$

$$G_3(\alpha) = [1 - (1-\alpha)^{1/3}]^2 \quad (6)$$

When one rate-determining process substitutes the other, their rates ( $d\alpha/dt$ ) have to be equal. For different  $R_i$  values the exchange of the rate-determining processes will take place at different  $\alpha_{1i}$  and  $\alpha_{2i}$ , since the apparent rate constants for both the phase-boundary interaction and the diffusion process depend upon  $R_i$ . If the hydration of a particle with the original radius  $R_L$  has become controlled by the phase-boundary interaction at time  $t_0$  (i.e. when the maximum rate of nucleation and growth has been achieved), and if the hydration of a particle with radius  $R_D$  has become diffusion-controlled at the same time, then Eqs. 1, 2 and 3, combined with Eqs. 4, 5 and 6, can be transformed into:

$$[-\ln(1-\alpha_i)]^{1/n} = A \tau \quad (7)$$

$$[1 - (1-\alpha_i)^{1/3}] - [1 - (1-\alpha_{1i})^{1/3}] = B(\tau - \tau_{1i})R_L/R_i \quad (8)$$

$$[1 - (1-\alpha_i)^{1/3}]^2 - [1 - (1-\alpha_{2i})^{1/3}]^2 = C(\tau - \tau_{2i})R_D^2/R_i^2 \quad (9)$$

where  $A = \left(\frac{n-1}{n}\right)^{1/n}$

$$B = \frac{n}{3} \left(\frac{n-1}{n}\right) \exp\left(-\frac{n-1}{3n}\right)$$

$$C = 2B \left[1 - \exp\left(-\frac{n-1}{3n}\right)\right]$$

and  $\tau = t/t_0$  (10)

If  $\alpha_{1i}$ ,  $\alpha_{2i}$  and  $\tau_{1i}$ ,  $\tau_{2i}$  values have been determined by using the conditions of equal rates at the exchange points of the rate-determining mechanisms, the expressions 7, 8 and 9 can be applied to compute the  $\alpha_i$ - $\tau$  relationship for a given set of  $R_L$ ,  $R_D$  and *n* values. The total calculated degree of hydration  $\bar{\alpha}_{calc.}$  for the relative time  $\tau$  is then

$$\bar{\alpha}_{calc.}(\tau) = \sum_i \alpha_i w_i \quad (11)$$

where  $\bar{\alpha}$  total degree of hydration

$w_i$  weight fraction of particles with original radius  $R_i$

Calculations have to be made for different sets of  $R_L$ ,  $R_D$  and  $n$  values. When the set has been correctly assumed, a linear relationship is obtained between  $t(\alpha\text{-observed})$  and  $\tau(\alpha\text{-calculated} = \alpha\text{-observed})$ . In other words, a plot of  $t$ -s for experimentally determined  $\alpha$ -values versus  $\tau$ -s belonging to adequate  $\alpha$ -values, calculated according to Eq. 11, gives a straight line provided that  $R_L$ ,  $R_D$  and  $n$  have been assumed correctly. It is obvious from relation 10 that the slope of this line corresponds to  $t_0$ -value. By using graphically determined  $t_0$  the most reliable values of actual rate constants are obtained, since

$$k_1 = A/t_0 \quad (12)$$

$$k_2 = R_L B/t_0 \quad (13)$$

$$k_3 = R_D^2 C/t_0 \quad (14)$$

If the actual rate constants change after a certain period of hydration, the  $t_0$  slope will change as well. For the time interval in which the linear relationship is not preserved, calculations should be repeated with new sets of tentative  $R_L$ ,  $R_D$  and  $n$  values, until linear relationship with a new  $t_0$  slope has been achieved.

#### EXPERIMENTAL PROCEDURE

Two industrial clinkers, C-1 and C-2, similar in alite content but different in aluminate content, were used for the kinetic study of alite hydration in Portland cement pastes. Their phase compositions as determined by X-ray diffraction and calculated after chemical analysis, are shown in Table I, and their alkali and sulphate contents are presented in Table II.

Phase	C-1		C-2	
	XD	Calc.	XD	Calc.
C <sub>3</sub> S	65	63.4	65	58.2
C <sub>2</sub> S	12	16.0	12	19.9
C <sub>3</sub> A	3	6.0	9	9.8
F.f.	7	11.1	4	8.6

The clinkers were ground in a laboratory ball mill, and the particle size distribution of the obtained samples was determined by the Coulter-Counter method (Table III). In order to obtain cements with higher contents of readily soluble alkalies, C-1 and C-2 samples were blended with 1 and 2%  $K_3NS_4$  ( $3K_2SO_4 \cdot Na_2SO_4$ ) respectively, giving two additional samples marked C-1' and C-2'. For the sake of comparison of the kinetic parameters of alite hydration in cement pastes with the kinetic parameters of alite hydration in somewhat simpler systems, a sample of pure alite (A) and a mixture (M) containing 90% alite and 10% C<sub>3</sub>A were also prepared. Monoclinic alite stabilized by  $MgO$  and  $Al_2O_3$ , and cubic C<sub>3</sub>A were synthesized from

analytical grade chemicals at 1450°C. After double refining satisfactory products were obtained, as confirmed by X-ray diffraction analysis. The pure phases were ball-milled and thereafter gently homogenized in order to obtain mixture M. Simple systems containing alkali sulphates, i.e. A' and M' mixtures were prepared by adding 2%  $K_3NS_4$  to each A and M sample. The particle size distribution of pure alite A, which was used for the preparation of all the mixtures, is also given in table III.

Prior to hydration 5% analytical grade gypsum was admixed to each C-1, C-1', M and M' sample, and 5% to each C-2 and C-2' sample. All samples were paste-hydrated at 0.5 water-to-solid ratio, cast into cylinders 15 mm in diameter and cured for 24 hours at 100% rh. After 24 hours they were unmolded and stored separately in tightly closed polyethylene vessels containing saturated  $Ca(OH)_2$  solution. Casting and curing was done at 20°C. After various ages ranging from 4 hours to 2 months the specimens were ground, washed with acetone, dried in vacuum and examined by X-ray diffraction. For quantitative analysis the samples were further ground and simultaneously homogenized with 10% quartz which was taken as an internal standard. To determine the degree of alite hydration the intensity of the 620°400 reflection group of alite and the intensity of the 10.1 reflection of quartz were used. The scan rate was 1/4°/min, and the ratio of alite to quartz peak areas of the mean from five samples served for calculating the degree of hydration.

## RESULTS AND DISCUSSION

The data on the observed degrees of alite hydration at different ages are given in Table IV and linear relationships between  $t(\alpha\text{-observed})$  and  $\tau(\alpha\text{-calculated} = \alpha\text{-observed})$  in Fig. 1. The relationships are calculated for the 240-hour interval and shown for the 80-hour interval. The  $R_L$  and  $R_D$  values used to compute the corresponding  $\alpha_{\text{calc.}} = \tau$  interdependence are quoted in the respective diagrams. All the represented  $t\text{-}\tau$  relationships are obtained with  $n = 3$ .

As seen from Fig. 1 a unique slope  $t_0$  was obtained in not one case, which proves that the hydration rate constants of particular rate-determining processes change after a certain period of time, even for the pure alite specimen. An inspection of the composed  $\alpha_i$  contributions (Eqs. 7, 8, 9) to  $\alpha$ -values reveals that different rate-determining mechanisms act simultaneously indeed, especially during the first  $t_0$  interval, and sometimes also during the second one. The distribution of rate-determining processes for alite hydration in various samples are illustrated in Fig. 2 where the diagrams show the percentages of particles reacting according to Eq. 7, 8 and 9 respectively, at various degrees of alite hydration. Intervals with different  $t_0$ -values are separated by vertical lines.

The rate constants were calculated according to Eqs. 12, 13 and 14 using  $t_0$ -s given in Fig. 1. The obtained values are listed in Table V for each sample and each  $t_0$ -interval. The consecutive intervals are marked I, II and III respectively. To facilitate the discussion on the obtained  $k$ -values two rows are added at the bottom of Table V. They contain the time of transition from one

Fig. 1 -  $t\text{-}\tau$  relationships

$t_0$ -interval to the other, with the belonging degrees of hydration given in parentheses. As quoted in Table V, the obtained value of the rate constant for nucleation and growth process in pure alite paste amounts to  $11.0 \cdot 10^{-2} \text{h}^{-1}$  this being consistent with the value obtained by Tenoutasse and De Donder (4) who followed the kinetics of alite

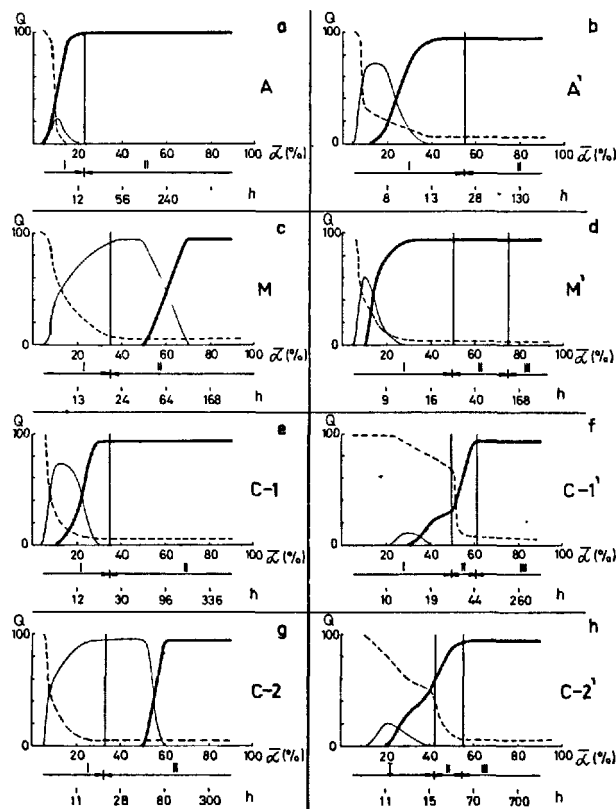

Fig. 2 - Percentages of particles ( $Q$ ) that react according to Eq. 7 (dotted line), Eq. 8 (thin line) and Eq. 9 (full line) at various  $\alpha$ .

TABLE V  
Rate Constants for Alite Hydration in Simple Systems and in Cement Pastes

Interval		Value of Rate Constant for Alite Hydration in Sample:							
		A	A'	M	M'	C-1	C-1'	C-2	C-2'
I	$k_1 (\text{h}^{-1})$	0.110	0.067	0.044	0.073	0.048	0.022	0.087	0.052
	$k_2 (\mu\text{m h}^{-1})$	0.067	0.092	0.080	0.110	0.074	0.190	0.110	0.250

hydration by using monosize specimens. However, in our sample the nucleation and growth process is the major rate-determining mechanism only at very low degrees of hydration (Fig. 2a). It is already in the first  $t_0$ -interval that the rate of hydration is diffusion-controlled for a high percentage of particles. The transfer from the process controlled by nucleation and growth to the process controlled by diffusion includes a short period in which the phase-boundary interaction is the rate-determining mechanism. The phase-boundary interaction is detectable as the slowest step of reaction for a small fraction of particles between 6 and 9 hours. After the degree of hydration has reached 20%, the second period will start during which all particles react according to Eq. 9, with the  $k_3$ -value diminished (Table V). It is interesting to note that the observed change in the rate constant for the diffusion-controlled reaction occurs at the same degree of hydration at which significant structural changes in C-S-H were ascertained (11).

When pure alite hydrates in the presence of alkali sulphates (sample A'), the rate-determining processes that act simultaneously are distributed in a different way (Fig. 2b). In that case the phase-boundary interaction is the rate-determining mechanism for a considerably higher percentage of particles and for a considerably longer period of time, the main reason therefor being the larger rate constant of the diffusion process which takes place during the first  $t_0$ -interval.

The high value of the diffusion-rate constant can be explained by the higher permeability of the hydration coating formed in the presence of alkali sulphates and by the  $\text{Ca}^{2+}$ -concentration gradient existing between the alite grain boundary and the bulk of the liquid phase. After approximately 24 hours, once the degree of hydration has reached about 55%, the second period starts in which the rate of hydration is governed by the diffusion process only, with its rate constant significantly diminished in comparison with the previous one (Table V).

In sample M containing 10%  $\text{C}_3\text{A}$  and 5% gypsum the hydration process of alite is accelerated as well, though only after 12 hours (Table IV). The first-stage diffusion across the layer of hydration product is also in this case very fast, and it is not the rate-determining process until ~50% hydration has been reached (Fig. 2c). At the time of transition from the first to the following  $t_0$ -interval the majority of particles hydrate according to linear kinetics (Eq. 8), but the rate constant of the rate-determining phase-boundary interaction is much smaller in the second  $t_0$ -interval (Table V). It amounts to  $1.6 \cdot 10^{-2} \mu\text{m h}^{-1}$ , and a similar value for the linear rate constant is given in reference 2. The cause of the decrease of  $k_2$ -value for sample M is evident from the diagram showing the courses of both alite and  $\text{C}_3\text{A}$  hydration in sample M (Fig. 3a). As indicated in the diagram the onset of the second  $t_0$ -interval characterized by the low  $k_2$  coincides with the renewed  $\text{C}_3\text{A}$  hydration, which means that it starts when the sulphate ions have been depleted from the liquid phase. Such a slow phase-boundary interaction was not detected as the rate-determining mechanism for alite hydration in sample M' containing besides gypsum also alkali sulphates, which is due to the fact that the renewed  $\text{C}_3\text{A}$  hydration in sample M' is shifted to later ages (Fig. 3b) when the rate constant of the diffusion-controlled alite hydration is already much lower than during the first  $t_0$ -interval. The onset of the second  $t_0$ -interval for sample M' does not coincide with any significant change in the course of  $\text{C}_3\text{A}$  hydration. However, it occurs at the same degree of alite hydration as observed in sample A' (Table V), indicating that the changes of the diffusion-rate constants are in both cases very likely associated with the incorporation of  $\text{SO}_3$  in C-S-H.

The kinetic parameters obtained for alite hydration in Portland cement pastes are less reliable than those obtained in simple systems, because individual cement particles are not always monophase grains. Nevertheless, they exhibit the diverse features of the kinetic behaviour of alite in cements with and without alkali sulphates. The observations gained on cement pastes are in general agreement with the observations on simple systems. The rate constants calculated

Fig. 3 - Courses of alite and  $C_3A$  hydration and standardized intensities of 10.1 reflection of ettringite for samples M (a),  $M'$  (b), C-2 (c) and C-2' (d)

from  $t_0$ -values (Fig. 1) show that the rate of phase-boundary interaction is considerably enhanced by the addition of alkali sulphates, which is even more pronounced than in the case of simple systems. That is the reason why the hydration of alite in cements containing alkali sulphates is controlled by the nucleation and growth mechanism for the majority of particles in the first  $t_0$ -interval (Figs. 2f and h), the more so as the rate constants for the diffusion process in this interval are very high. The very slow phase-boundary interaction observed for alite hydration in sample M is also detectable during the second  $t_0$ -interval in the C-2 paste containing high  $C_3A$  and low alkalies. The course of  $C_3A$  hydration in sample C-2 (Fig. 3c) allows the same explanation for the decreased  $k_2$ -value as has been offered for alite hydration in sample M. Similarly to the simple system containing alkali sulphates, a slow phase-boundary interaction was not detected as the rate-determining step of alite hydration in sample C-2', because sulphates are still present in the liquid phase during the  $t_0$  (I) and  $t_0$  (II) intervals in which the diffusion process is fast. The presence of sulphates in the liquid phase is confirmed by the continuous ettringite formation in the two  $t_0$ -intervals (Fig. 3d). For the alite hydration in sample C-2' the differences between  $k_3$ -constants are found to be the greatest, but to fully elucidate the factors influencing these differences further work is needed.

The described approach to the kinetic study of alite hydration can be improved by introducing some modified expressions for the  $G_1(\alpha)$ ,  $G_2(\alpha)$  and  $G_3(\alpha)$  functions into the calculation procedure. Structural investigations of C-S-H for particular  $t_0$ -intervals, accompanied by monitoring the changes in the liquid phase at the transition points between two adjacent intervals, will certainly also contribute to better understanding of the kinetic behaviour of alite in the course of the hydration process.

## CONCLUSIONS

The determination of reaction-rate constants by taking into consideration the effects of simultaneous action of different rate-determining mechanisms provides better insight into the kinetic behaviour of alite during its hydration process in various cement pastes.

The diffusion-controlled reaction is shown to be two- or three-stage in nature. The very high rate constants of the first-stage diffusion are predominantly responsible for the acceleratory effect observed in the systems containing alkali sulphates.

# Formation de la structure des ciments avec fausse prise

## *Structure formation of cements with false setting*

Z.B. ENTINE, candidat ès sciences techniques, L.S. KLIQUEVA, ingénieur,

Ou. I. PAPIACHVILI, candidat ès sciences techniques, NIITzement, Moscou, U.R.S.S.

RESUME : En opérant sur des modèles de ciment, on a révélé le rôle particulier des formes de gypse dans le phénomène de la fausse prise, sans toutefois épuiser toutes les particularités des systèmes ciment-eau pour lesquels on ne doit pas oublier l'importance des propriétés du clinker, et tout particulièrement de sa teneur en alcalis. Les ciments à prise normale et fausse, au moment du développement de la fausse prise, se caractérisent par une bonne corrélation entre la teneur de la phase liquide en  $SO_3$  et en alcalis, de même qu'entre la conductibilité électrique dans la phase liquide et sa teneur en alcalis, la conductibilité électrique et la teneur en  $SO_3$ . La différence en composition de la phase liquide des ciments à prise normale et fausse se manifeste au moment qui précède le développement de la fausse prise, quand dans la phase liquide des ciments à fausse prise se dégage un précipité de gypse dihydraté et d'ettringite. Avec le passage de la prise normale à la fausse, la composition ionique de la phase liquide se caractérise par une élévation de la teneur en ions  $Ca^{2+}$  et  $SO_4^{2-}$ , du fait de la dissolubilité élevée du semi-hydrate devant le dihydrate, et par la diminution du déficit en anions, de la valeur du pH et de la conductibilité électrique de la phase liquide.

Les résultats de l'étude ont permis de formuler, en la soutenant par des expériences, une théorie concernant le mécanisme de la fausse prise.

SUMMARY: Investigations of model cements have revealed a specific part played by gypsum forms in the false setting phenomenon which, however, does not exhaust all the peculiarities of the cement-water systems wherein properties of clinker, especially alkali content, are also very essential. The moment of origination of false setting for normal and false setting cements is characterised by good correlation between the content of  $SO_3$  and alkalis in the liquid phase, as well as the electrical conductivity of the liquid phase and the content of alkalis, the electrical conductivity and the content of  $SO_3$ . The differences in the composition of the liquid phase of the normal and false setting cements occur only at the moment preceding origination of the false setting, when a deposit comprising dihydrate gypsum and ettringite precipitates from the liquid phase of the false setting cements. The ion composition of the liquid phase at the transfer from normal setting to false one is characterised by increased content of  $Ca^{2+}$  and  $SO_4^{2-}$  ions owing to increased solubility of hemihydrate as compared with bihydrate; decrease of anion deficit, hence the pH value and electrical conductivity of the liquid phase.

The investigation results have been used as grounds for putting forward and supporting experimentally a hypothesis of the false setting mechanism.

La variation anormale des propriétés rhéologiques de la pâte de ciment aux stades initiaux de durcissement connue sous la dénomination de fausse prise vu sa nature temporaire ne constitue pas un défaut insurmontable du ciment mais elle influe négativement sur l'utilisation efficace du ciment dans le béton. Les causes de la fausse prise sont assez variées: déshydratation du gypse au cours de la mouture du ciment, déshydratation du gypse suivie d'hydratation superficielle du ciment au cours de l'aération dans les silos, présence dans le ciment des sulfates et carbonates alcalins, introduction de certains agents tensio-actifs (1, 2, 3, 4), etc. D'où la variété d'hypothèses proposées pour expliquer le mécanisme de la fausse prise reliant ce phénomène soit à la cristallisation du gypse (2, 3, 4), soit à l'influence d'hydroxydes alcalins sur la précipitation topochimique de l'ettringite (5), soit à la formation de pellicule d'hydrocarbo-aluminate de calcium sur les particules  $C_3A$  et abaissement du pouvoir réacteur de l'ion  $SO_4^{2-}$  dans la solution (6), soit à la cristallisation de composés alcalins complexes du type de syngénite (7), soit à l'apparition de charge de signe opposé sur les différentes phases du clinker (8).

Malgré la diversité des causes de la fausse prise dans tous les cas on est en présence d'une manifestation externe identique ce qui permet, lors de l'étude de la fausse prise de rechercher un mécanisme unique de fausse prise qui décrirait de façon satisfaisante ce phénomène malgré la variété des causes l'ayant provoqué. À son tour cela permet de choisir en qualité de modèle une "variante gypseuse" de fausse prise qui peut être facilement reproduite, se construit par des procédés élémentaires et facilite l'étude de divers modes de prise sur des matériaux notablement identiques.

Les modèles de ciment destinés à l'étude de la fausse prise étaient préparés à partir des clinkers industriels dont la constitution minéralogique théorique est donnée au tableau I pour les variantes suivantes:

- 1.- ciment ordinaire moulu en laboratoire (ciment normal);
- 2.- idem après chauffage à la température de  $150^\circ C$  durant 3 h;
- 3.- ciment moulu en laboratoire avec gypse préalablement déshydraté jusqu'à obtenir une modification hémihydratée;
- 4.- ciment moulu en laboratoire fabriqué du clinker rechauffé préalablement à  $150^\circ C$  durant 3 h et broyé en grenaille;
- 5.- ciment moulu en laboratoire avec chauffage préalable du gypse et du clinker en grenaille à la température de  $150^\circ C$  durant 3 h.

Les particularités de la formation de la structure des modèles de ciment ont été suivies en fonction des variations de la résistance plastique ( $P, mm$ ) et de la conductibilité électrique ( $\chi, \text{ohm}^{-1} \cdot \text{cm}^{-1}$ ) du

système en voie de durcissement (respectivement du mortier de ciment-sable et de la pâte de ciment).

Dénomination	Constitution, %				
	$C_2S$	$C_3S$	$C_3A$	$C_4AF$	$R_2O$
De Briansk	60	17	4	15	0,36
De Nîkolaev	44	27	10	13	0,85

Le processus de formation de la structure au cas de gâchage du ciment par l'eau est décrit par diverses courbes de résistance plastique et des courbes corrélatives de la conductibilité électrique (fig.1).

Fig.1 Variation de la résistance plastique (a) et de la conductibilité électrique (b) en fonction du mode de prise.

D'après la forme des courbes de formation de la structure on est en mesure de distinguer deux types de fausse prise du ciment: le 1-er type se caractérise par une perte totale de la plasticité et le II-ème par une perte partielle de la plasticité à la fin du processus de malaxage. L'étude d'un grand nombre de ciments de fabrication industrielle et au laboratoire a montré qu'à chaque ciment correspond l'une des paires de courbes de formation de la structure mentionnées. Des études plus poussées de modèles de ciment ont établi qu'entre les deux modes de fausse prise il n'y a pas de frontière insurmontable - il est possible d'obtenir pour un même ciment l'un et l'autre mode de prise suivant le degré de déshydratation du gypse laquelle à son tour est fonction du régime de traitement thermique du ciment.

Le rôle des deux composants du ciment, le clinker et le gypse, dans le phénomène de fausse prise est illustré par les courbes de résistance plastique de la figure 2 établies pour des variantes diverses du modèle de ciment donné.

Fig.2 Variation de la résistance plastique pour les différentes variantes du modèle de ciment fabriqué à partir du clinker de Briansk (a) et de Nikolaev (b)

(Variantes de modèle: 1—●—, 2—×—, 3—△—, 4—○—, 5—▲—)

L'analyse des particularités et des formes de manifestation de la fausse prise sur les modèles de ciment établit le rôle important des formes déshydratées du gypse dans le phénomène de fausse prise: dans tous les cas la déshydratation du gypse entraîne la fausse prise du ciment et cela indépendamment du fait que le gypse s'est déshydraté durant le chauffage du ciment ou a subi une déshydratation préalable. Le traitement thermique du clinker seul n'entraîne pas de fausse prise si en même temps le gypse n'a pas été déshydraté.

Toutefois les variations observées dans la nature du processus de formation de la structure des ciments à gypse déshydraté ne peuvent être expliquées par l'acquisition par le gypse d'une structure propre du fait d'une réhydratation du semi-hydrate lors du gâchage du ciment par l'eau. Ce phénomène est confirmé par les différences dans le degré de manifestation de la fausse prise dans des ciments fabriqués avec des clinkers divers, mais possédant une teneur identique en gypse de même que par la confrontation de courbes de formation de la structure de ciments ayant des courbes semblables pour le mélange moulu (normal et rechauffé à 150°C) de sable quartzéux et de gypse (fig.3).

Fig.3 Variation de la résistance plastique (a) et de la conductivité électrique (b) au cours du gâchage du mélange moulu de sable quartzéux et de gypse.

Pour éclaircir le mécanisme des processus exerçant une influence sur la variation du mode de prise on a étudié la composition des phases liquide et solide de la pâte de ciment aux stades initiaux de l'hydratation. La phase liquide était prélevée 2 et 10 minutes après le gâchage du ciment (E/C 0,25) sous pression de 150 MPa.

Pour la phase liquide prélevée 10 minutes après le gâchage des ciments présentant une prise normale et fausse on observait une corrélation étroite entre la teneur en oxydes alcalins et en d'autres composants de même qu'avec sa conductivité électrique. Les coefficients de corrélation correspondants sont indiqués au tableau II, tandis que la figure 4 offre un exemple de dépendance entre la teneur en  $SO_3$  et  $R_2O$  dans la phase liquide, de même qu'entre la conductivité électrique de la phase liquide et la teneur en alcalis.

On n'a pas décelé de différences notables dans la composition ionique de la phase liquide des ciments à prise normale et fausse au moment du développement de la fausse prise (c'est-à-dire, 10 minutes après le gâchage). Dans tous les cas la composition ionique de la phase liquide présente un déficit d'anions, c'est-à-dire, l'insuffisance d'anions déterminés par rapport à la somme de cations existants ( $\Sigma C - \Sigma A$ ). Le déficit stable d'anions dans la phase liquide est conditionnée par la fixation par ions du calcium de l'anion  $HCO_3$  introduit dans la phase liquide avec les carbonates alcalins du clinker. Le déficit d'anions est quelque peu inférieur au cas de ciments à fausse prise et, partant, plus faible est la quantité

d'ions  $\text{OH}^-$  compensant ce déficit ce qui se traduit par un abaissement de la valeur du pH et de la conductibilité électrique de la phase liquide des ciments à fausse prise.

Tableau II					
Temps écoulé depuis le gâchage	Rapports de corrélation				
	$\text{SO}_3 - \text{R}_2\text{O}$	$\text{CaO} - \text{R}_2\text{O}$	$\chi - \text{R}_2\text{O}$	$\chi - \text{SO}_3$	$\chi - \text{CaO}$
2 min	0,848	-0,138 <sup>x</sup>	0,992	0,886	manque
10 min	0,978	-0,826	0,932	0,976	-0,648
<sup>x</sup> au-dessous du niveau de signification					

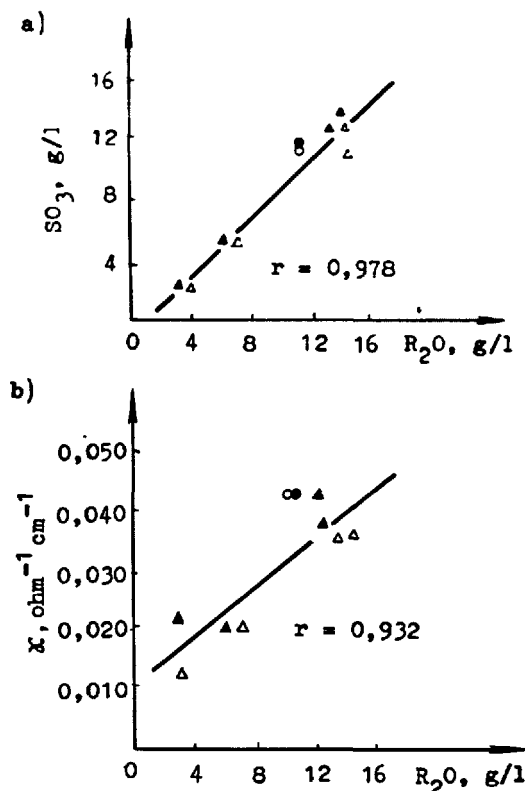

Fig.4. Rapports entre  $\text{SO}_3$  et  $\text{R}_2\text{O}$ ,  $\chi$  et  $\text{R}_2\text{O}$  dans la phase liquide prélevée 10 minutes après le gâchage du ciment moulu en laboratoire à prise normale (▲) et fausse (Δ) et du ciment industriel à prise fausse après un malaxage initial (○) et répété (●).

Les rapports propres à la composition et à la conductibilité électrique de la phase liquide prélevée 10 minutes après le gâchage sont communs aux ciments de fabrication industrielle et en laboratoire indépendamment de leur composition chimique et minéralogique. La figure 4 indique les points obtenus expérimentalement de la composition et

de la conductibilité électrique de la phase liquide du ciment industriel à fausse prise, lesdits points se superposant sur la ligne de régression calculée pour les ciments moulus en laboratoire ce qui confirme la nature commune des résultats obtenus.

La phase liquide des ciments à fausse prise 2 minutes après le gâchage (c'est-à-dire au stade précédant le développement de la fausse prise) se caractérise par un si haut degré de sur saturation, qu'une fois prélevée elle donne lieu à une sédimentation qui se compose, selon les analyses aux rayons X et chimique, de gypse dihydraté et d'ettringite. 2 minutes après le gâchage dans la composition ionique de la phase liquide passant de la prise normale à la fausse, on observe un accroissement caractéristique d'ions  $\text{Ca}^{2+}$  et  $\text{SO}_4^{2-}$  du fait de l'élévation de la dissolubilité des semi-hydrates devant les dihydrates: il y a également un abaissement du déficit d'anions, de la valeur du pH et de la conductibilité électrique de la phase liquide (fig.5).

Fig.5. Variation de la composition de la phase liquide 2 minutes après le gâchage au cours du passage de la prise normale à la fausse.

Cependant, comme il découle du tableau II, il se maintient dans ce cas également un rapport assez étroit entre la teneur dans la phase liquide en ions alcalins et en ions de sulfates. Cela signifie que la teneur en ion  $\text{SO}_4^{2-}$  dans la phase liquide est conditionnée non seulement par la présence du semi-

hydrate et sa dissolubilité élevée mais également par la force ionique de la phase liquide régie essentiellement par la teneur en alcalis. La force ionique de la phase liquide exerce à son tour une action sensible sur la vitesse de formation et de croissance des germes d'hydrates cristallins.

On peut donc, sur la base des résultats de l'étude de la composition et des propriétés de la phase liquide, formuler l'hypothèse sur le mécanisme de la fausse prise. La fausse prise du ciment est en rapport avec la formation de la structure primaire gypse-ettringite dont la condition nécessaire de formation est la sursaturation de la phase liquide en ion  $\text{SO}_4^{2-}$ . L'intensité de formation de la structure primaire gypse-ettringite, autrement dit le degré de manifestation de la fausse prise, est conditionnée par la force ionique de la phase liquide.

Fig. 6. Variation du mode de prise en fonction de la variation de la force ionique de la phase liquide (1 - gâchage par l'eau; 2, 3, 4 - gâchage par la solution  $\text{Na}_2\text{SO}_4$  à concentration 10, 20 et 30 g/l de  $\text{Na}_2\text{O}$ ).

Au cas de sursaturation de la phase liquide en ion  $\text{SO}_4^{2-}$  et de force ionique réduite de la phase liquide, c'est-à-dire au cas de ciments à faible teneur en alcalis, il est le plus probable qu'il se formera une quantité limitée de germes d'hydrates cristallins qui se développent de façon intense. Le développement d'une structure gypse-ettringite rigide conditionne la perte totale par le système de la plasticité une fois le malaxage achevé, c'est-à-dire la fausse prise du type I.

L'élévation de la force ionique de la phase liquide avec l'accroissement de la teneur en alcalis et la sursaturation de la phase liquide en ion  $\text{SO}_4^{2-}$  entraînera la formation d'une quantité beaucoup plus grande de germes d'hydrates cristallins dont la croissance est par contre moins rapide, ce qui influence sur le mode de prise dont le type est intermédiaire entre la prise normale et la prise nettement fausse, c'est-à-dire on est en

- a) Désagrégation des parcelles initiales du ciment

- b) Formation autour des grains initiaux de cristaux aciculaires des produits d'hydratation

- c) Stade initial de formation de produits d'hydratation à la forme allongée

- d) Enchevêtrement des cristaux en forme de tiges

Fig. 7. Microphotographies électroniques (10 000 x) du ciment à prise normale (a, b) et fausse (c, d) après 5 minutes d'hydratation.

présence de la fausse prise du type II.

Cette hypothèse a été soumise à l'expérience par variation contrôlée du mode de prise avec introduction proportionnelle d'ions alcalins et d'ions de sulfates (fig.6). Comme le montre la figure 6, avec l'élévation de la force ionique de la phase liquide, on observe un passage régulier de la courbe caractéristique de la fausse prise du type I aux courbes caractéristiques de la fausse prise du type II.

Cette hypothèse sur le mécanisme de la fausse prise est également confirmée par les microphotographies électroniques du ciment hydraté à base du clinker à faible teneur en alcalis ( $0,49 R_2O$ ) de l'usine "Bolchevik".

Pour un ciment à prise normale après 5 minutes d'hydratation, on observe une désagrégation de parcelles initiales avec formation autour d'elles de cristaux aciculaires produits par l'hydratation (fig.7 a,b). Par contre, au cas de la fausse prise, on observe une formation intense de la structure gypse-ettringite, ainsi qu'un ralentissement de l'hydratation du clinker, par suite du blocage de la surface des grains du clinker avec des constituants nouveaux (fig.7 c, d). La formation de la structure gypse-ettringite s'accompagne de la fixation d'une grande quantité d'eau aussi bien chimiquement que par adsorption à la suite du développement de la surface des constituants nouveaux et conditionne la perte temporaire de plasticité du système en voie de durcissement.

Au cas où il est possible de détruire la structure gypse-ettringite par un nouveau malaxage, les propriétés rhéologiques de la pâte de ciment se rétablissent complètement, phénomène observé généralement dans la pratique lorsqu'on utilise les ciments à fausse prise. Toutefois le développement et la consolidation de la structure gypse-ettringite peuvent être si poussés que le malaxage répété est incapable d'arrêter l'épaississement précoce et, dans ce cas, la fausse prise peut devenir une prise rapide.

### RESUME

La spectrométrie de photoélectrons XPS est une méthode sensible et reproductible pour l'étude de l'hydratation initiale de  $C_3S$ . Elle révèle des transformations à la surface des grains du silicate dès les premiers instants de leur contact avec l'eau dans des pâtes de rapport eau/ $C_3S$  = 0,5. Ces modifications ont été mises en évidence par un changement dans l'environnement des atomes de Si et une variation du rapport Ca/Si. La surface de  $C_3S$  est, entre cinq secondes et une minute, un site d'échanges continuels entre le solide et la solution. Ce stade correspond à la précipitation d'un hydrate primaire de rapport C/S  $\ll$  3. Au-delà de la première minute se forme un hydrate secondaire de rapport C/S  $\approx$  2 qui subsiste jusqu'à la fin de la période dormante.

Le fluorure de sodium dissous dans l'eau de gâchage jouerait son rôle de retardateur en supprimant la formation de l'hydrate primaire. L'épaisseur du premier hydrate formé, de rapport C/S  $\approx$  2, atteindrait 60 Å à 3 minutes.

### SUMMARY

X-ray Photoelectron Spectrometry is a sensitive and reproducible method for the study of the early hydration of  $C_3S$ . XPS reveals surface transformations of silicate grains from the first few seconds of their contact with water in pastes (water/ $C_3S$  = 0,5). These modifications have been evidenced by a change of the environment of Si atoms and a variation of the Ca/Si ratio. The  $C_3S$  surface, between five seconds and one minute, is a site of continuous exchange between the solid and the solution. This stage corresponds to the precipitation of a primary hydrate with a ratio C/S  $\ll$  3. After one minute, a secondary hydrate with a ratio C/S  $\approx$  2 is formed and it subsists up to the end of the dormant period.

Calcium fluoride dissolved in mixing water would play its retarder effect in leaving out the formation of the primary hydrate. The thickness of the first hydrate formed with a ratio C/S  $\approx$  2 would attain 60 Å at 3 minutes.

## 1. INTRODUCTION

The initial hydration of  $C_3S$  has not yet been completely clarified because of the complexity of the physico-chemical changes occurring during the dormant period at the surface of grains. SKALNY *et al* (1) have recalled the results of numerous studies of  $C_3S$  hydration and their interpretation related to the theory of a protective layer or a delayed nucleation.

In previous works (2, 3), we have shown the importance of the first five minutes from the contact between  $C_3S$  and  $H_2O$ . In this paper, we develop the results of our studies by XPS on the evolution of the surface  $C_3S$  crystals under normal conditions of hydration and with dissolved NaF as admixture.

## 2. X-RAY PHOTOELECTRON SPECTROMETRY XPS

X-ray Photoelectron Spectrometry XPS, also called ESCA (Electron Spectroscopy for Chemical Analysis) is a technique for measuring the kinetics energy of electrons photoejected from a solid surface using soft X-rays. The kinetic energy  $E_K$  of the photoelectrons can be related to the binding energy  $E_B$  which these electrons had originally in the solid (4).

XPS is a rather new technique in the cement field. In the study of silicate materials, this method has been used for determining the surface composition of materials from the intensity of the peaks of different chemical elements (5, 6 et 7).

For a conducting sample, the relation between the kinetic energy of photoelectrons and the binding energy is :

$$E_K = h\nu - E_B - \Phi_S$$

$h\nu$  : energy of impinging photons,

$\Phi_S$  : work function of the material of the spectrometer.

In the case of an insulator sample, the same relation must be corrected by a factor due to the surface charging effects of the sample. Nevertheless,

it is possible to determine the binding energy of the electrons by means of an external standard. Using the carbon  $C_{1s}$  peak of the contamination layer and assuming that the charging shift is the same for the sample and for the contamination layer, the expression of the binding energy becomes :

$$E_B = E_K(C_{1s}) + E_B(C_{1s}) - E_K$$

In our experiments the value of  $E_B(C_{1s})$  is assumed equal to 285.0 eV.

### 2.1 Characteristics of the X-ray photoelectron spectrometry

[a] The depth of investigation : This depth into the oxides and silicates varies from 50 to 100 Å. It has been chosen to 3  $\lambda$  ( $\lambda$  is the mean free path of the ejected electrons). It corresponds to 95 % of the analyzed electrons. The other 5 % come from deeper zones (8). It is sufficient to provide data in volume while still allowing surface analysis.

[b] The qualitative aspect : It is possible to determine chemical elements on the surface of solid samples. For most of the elements (hydrogen excepted), a minimum atomic concentration is required to detect, it is generally about 1 %. The variation of the binding energy (chemical shift) is significant of a change in the atomic surrounding.

[c] The quantitative aspect : In fact, it is a quantitative method providing it can be standardized on fresh fracture surfaces of homogeneous materials of known composition.

[d] The fiability of the measures : Measurements of the intensity of peaks are easily reproduced and are usually of a quality superior to  $\pm 10$  %, providing that a ratio of concentrations in a homogeneous material is determined.

[e] The facility of sampling : The samples do not require any particular preparation. Cleavage surfaces, grains, powders and fibers may be analyzed in the same way.

Fig. 1 : XPS spectrum of  $C_3S$ .

## 2.2 The apparatus

The apparatus utilized was an AEI ES 200 Photoelectron Spectrometer fitted with a magnesium anode ( $MgK\alpha = 1253.6$  eV) under an irradiation power of 240W. The XPS peaks studied were :  $Ca_{2p}$   $3/2$  ( $E_B = 346.9$  eV),  $Si_{2p}$  ( $E_B = 101.2$  eV),  $O_{1s}$  ( $E_B = 530.9$  eV) and  $C_{1s}$  ( $E_B = 285.0$  eV). The samples were fixed on adhesive conducting tape. The analyzed area was about  $25\text{ mm}^2$ .

A typical spectrum of  $C_3S$  is shown in the figure 1. The XPS peaks correspond to the inner shell electrons of calcium, oxygen and silicon of the sample. The carbon  $C_{1s}$  peak is due to the contamination by oil vapor from the diffusion pumps.

## 2.3 The calibration curve

In order to determine the Ca/Si ratios in hydrated silicates, a standard curve was drawn (2). The ratio of the area of the XPS peaks ( $Ca_{2p}/Si_{2p}$ ) was compared to the atomic ratios Ca/Si in materials of a well determined composition : synthetic glasses ( $Na_2O - CaO - MgO - SiO_2$  system) kindly furnished by SAINT-GOBAIN Industries, natural wollastonite  $Ca_3SiO_5$ , dicalcium silicate  $Ca_2SiO_4$  and tricalcium silicate  $Ca_3SiO_5$ . The variation of the XPS results determined on several samples of the same anhydrous  $Ca_3SiO_5$  preparation is less than 5 %.

## 3. $C_3S$ HYDRATION

### 3.1 Material

The tricalcium silicate was synthesized at  $1600^\circ C$  by solid state reaction of a mixture of amorphous silica and reagent grade/calcium carbonate in a closed platinum crucible. The product of this synthesis was air quenched and analyzed by X-ray diffraction, atomic absorption and electron probe microanalysis.

After grinding to a specific surface of  $3000\text{ cm}^2\text{g}^{-1}$ , a series of pastes was prepared with distilled water (water/solid = 0.5). At selected intervals, between 5 seconds and 4 hours, the hydration was stopped by the addition of acetone.

### 3.2 Results

The results of the photoelectron spectrometry are presented in the form of a kinetic curve (fig. 2) and a table giving the position of the XPS peaks  $Ca_{2p}$   $3/2$ ,  $Si_{2p}$ ,  $O_{1s}$  (Table I).

The variation of the  $Ca_{2p}/Si_{2p}$  ratio (fig. 2) from approximately 5 seconds to 5 minutes proves the importance of the perturbations on the surface of the grains. These results show that the value of the  $Ca_{2p}/Si_{2p}$  ratio is always lower in hydrated samples than in  $C_3S$ , but the binding energy and the shape of the  $Si_{2p}$  peak show that the surface of the hydrated particles begins to differ significantly from that of the anhydrous  $C_3S$  within a very short period. In particular, it is noticed that the differences of the binding energies  $Ca_{2p}$   $3/2 - O_{1s}$  tend toward the constant while those relative to  $Ca_{2p}$   $3/2 - Si_{2p}$  and  $Si_{2p} - O_{1s}$  vary significantly between the anhydrous sample and the hydrated samples. These last results demonstrate a variation in the binding energy of the  $Si_{2p}$  electrons from 5 seconds on.

### 3.3 Interpretation

The XPS data relating to  $C_3S$  can be interpreted in the framework of a model suggested by the XPS studies of the glass/water solutions interactions (9). With this model, it would be possible to explain the form of the XPS kinetic curve of  $Ca_3SiO_5$  hydration, the evolution of the dissolution of calcium and silicate ions, the existence of a dormant period and the setting of the paste.

Fig. 2 : Kinetic curve of hydration of  $C_3S$

Table I : Difference between the binding energies of the XPS peaks,  $Ca_{2p}$   $3/2$ ,  $Si_{2p}$ ,  $O_{1s}$  and width at mid-height of the  $Si_{2p}$  peak.

Time	$\delta (Ca_{2p} \ 3/2 - Si_{2p})$ eV $\pm$ 0.2	$\delta (Si_{2p} - O_{1s})$ eV $\pm$ 0.2	$\delta (Ca_{2p} \ 3/2 - O_{1s})$ eV $\pm$ 0.2	Width at mid-height of the $Si_{2p}$ peak eV $\pm$ 0.1
0	245.7	429.7	184.1	2.5
5, 10, 15, 30 sec 1, 3, 5, 15 min 1, 2 hours	245.1	429.3	184.2	2.8
4 hours	245.1	429.1	184.0	2.4

[1] At the beginning of the  $C_3S-H_2O$  reaction and after protonation of silicate and oxygen ions, a congruent dissolution of  $Ca_3SiO_5$  is assumed (10,11). We emphasize in this regard, that in an open medium with a high rate of percolation, the interaction can limit itself to this first stage because of the lack of accumulation of the dissolution products.

[2] The second stage detectable in the first few seconds (5 seconds on the curve fig. 2) corresponds to the formation of a Primary Hydrate with a ratio  $C/S \ll 3$  on the grains of the anhydrous silicate. The cloud of points show that the surface, between 5 seconds and 1 minute, is a site of continuous exchange and not in a state of equilibrium.

The quantitative interpretation of the XPS data has been carried out in a previous paper (5). The computed thickness of the Primary Hydrate is 8 Å. It should be noted that this thickness is comparable to the thickness of the layer of  $C_3S$  dissolved after one minute in the experiments of FUJI and KONDO (10). This value is 7 Å for a  $w/s = 0.7$  and a specific surface of  $3800 \text{ cm}^2 \cdot \text{g}^{-1}$ .

[3] The third stage manifests itself by an increase of the  $I_{Ca}/I_{Si}$  ratio in which the maximum is attained at the end of one minute of hydration. This situation can be explained by the formation of a Secondary Hydrate having a  $Ca/Si$  ratio higher than that of the Primary Hydrate but lower than the observed maximum value of 2.7 because the latter includes a contribution of the underlying  $C_3S$ . This reaction is compatible with a dual origin of  $Ca^{2+}$ : the solution (process a) and the inner part of the grain (process b). These latter ions are a part of the ions released by the solid during the advancement of the interface hydrate- $C_3S$ .

In this regard, the values of the intermediate  $Ca/Si$ , between 2 and 2.7 (fig. 2), would confirm the hypothesis of the chemisorption of  $Ca^{2+}$  ions on a surface enriched in silicon, hypothesis deduced from the measures of the  $\zeta$  potential, giving a positive charge to the  $Ca_3SiO_5$  particles in the first minutes of hydration (12). That the values of the  $Ca/Si$  ratios are superior to 2 is explained by the contribution to the XPS signal of the subjacent anhydrous  $C_3S$ , the amount of the Secondary Hydrate still being very low.

Finally, the proposed model assumes that a layer of the Secondary Hydrate with  $C/S \approx 2$  grows on a substratum of  $C_3S$ . This assumption is strongly suggested by the value  $C/S \approx 2$  obtained when this layer is thicker than 60 Å at  $t > 15$  minutes.

Subsequently, the  $Ca/Si$  ratio indicated on the kinetic curve slowly decreases and tends asymptotically towards a value close to 2 in about 15 minutes. At this moment, the thickness of the layer of the Secondary Hydrate has sufficiently increased (via the process b also) so that the contribution of the  $C_3S$  to the XPS signal is negligible. This thickness is equal to 3 times the mean free path of the  $Ca_{2p}$  and  $Si_{2p}$  electrons, that is to say approximately 60 Å.

The formation of the Secondary Hydrate could also be partly explained by the precipitation from solution. This mechanism explains why silica concentrations in solutions drop drastically after some minutes of hydration (10, 11). In our model, this process cannot be distinguished from the process a and probably occurs simultaneously. The Secondary Hydrate develops and persists through the dormant period up to the supersaturation of the solution.

In slowing down the transfers between the solution and the reactional interface, we could consider that the Secondary Hydrate plays the role of a barrier which accounts for the low activity of the induction period revealed by the calorimetric curves. However the rate of  $C_3S$  hydration and the nucleation of hydrates are governed by the concentration of  $Ca^{2+}$  and  $OH^-$  in the solution. This was shown by BARRET *et al* (13), YOUNG *et al* (14): either removal of  $Ca^{2+}$  and  $OH^-$  from the solution reactivated the hydration of  $C_3S$  or, on the contrary, a supersaturated solution used as mixing water strongly delayed the dissolution of  $C_3S$  crystals.

[4] After four hours, important reorganizations take place in the interior of the Secondary Hydrate as evidenced by the change in the shape of the  $Si_{2p}$  peak. Apparently, this modification indicated the end of the dormant period.

The end of the dormant period manifests itself by the brutal nucleation of  $Ca(OH)_2$  and the Tertiary Hydrate (C-H-S Type I) with dimeric silicate ions ( $Si_2O_7$ )<sup>6-</sup>.

One hypothesis to explain this new stage is that of the existence of a not very permeable, superficial barrier that slows down the exchanges between the solution and the solid. In this case, the end of the dormant period corresponds to a brutal increasing in the porosity of that barrier, by the formation of cracks, for example at the grain boundaries or at dislocations emergency. In this hypothesis the reorganizations observed in the Secondary Hydrate are the cause of the brutal increase in its porosity. This schema shows that the  $C_3S$ , protected till that moment, can be placed in contact with a very alkaline solution susceptible of leading to a large congruent dissolution. The silica, thusly liberated, precipitates at the same time in the form of the Tertiary Hydrate.

### 3.4 The role of aging

In order to test the effect of aging on the kinetics of hydration, we placed about 500 mg of  $C_3S$  in a chamber at 20 °C, with uncontrolled conditions of humidity and atmospheric  $CO_2$ .

After five and eight days, several samples were analyzed by XPS. The aging was characterized by an increase in the  $Ca_{2p}/Si_{2p}$  ratio and an enhancement of the  $C_{1s}$  peak related to the carbon of  $CO_3^{2-}$  ions. Slight modifications were observed on the  $Si_{2p}$  peak. A kinetic curve of the hydration of a carbonated sample has been drawn on fig. 3. Qualitatively, the shape of this curve is the same as for uncarbonated  $C_3S$ . Nevertheless because of the presence of the calcium carbonate, it is not possible to relate the XPS ratio to the atomic ratio  $Ca/Si$ .

After heating this last sample at 1500 °C during one hour, the aspect of the hydration curve (fig. 4) is a little different, probably by a modification occurred on the surface of the grains during the heating. This curve retains the same tendency as that of the carbonated sample (fig. 3) but remains different from that of the fresh sample (fig. 2) with higher  $Ca/Si$  ratios and delayed formation of the Secondary Hydrate.

Carbonation has a retarder effect on  $C_3S$  hydration and the composition of hydrates has not been determined.

Fig. 3 : Kinetic curve of hydration of a carbonated  $C_3S$  sample.

Fig. 4 : Kinetic hydration curve of the carbonated  $C_3S$  sample after heating at 1500 °C.

#### 4. THE ROLE OF NaF ADMIXTURE

##### 4.1 Sample preparation

The pastes were prepared in the same manner as above with a solution containing 1 % NaF.

The XPS peaks studied were  $Ca_{2p}$ ,  $Si_{2p}$ ,  $O_{1s}$ ,  $C_{1s}$ ,  $Na_{2s}$  ( $E_B = 63.0$  eV) and  $F_{1s}$  ( $E_B = 683.6$  eV).

##### 4.2 Results

The results are reported in the form of a kinetic curve (fig. 5) and a table (Table II) giving the position of the XPS peaks.

The variations of the binding energy and the shape of the  $Si_{2p}$  peak are the same as for  $C_3S$  hydration in pure water.

The kinetic curve decreases regularly up to 3 minutes and the value of the Ca/Si ratio is close to 2 all over the dormant period. The third stage observed in the system  $C_3S-H_2O$  which manifests itself by an increase in the Ca/Si ratio does not exist in the system  $C_3S-H_2O+1\%$  NaF.

Fig. 5 : Kinetic curve of hydration of  $C_3S$  with 1 % NaF admixture.

Table II

Hydration of  $C_3S + 1\%$  NaF : Evolution of the binding energies of the XPS peaks  $Ca_{2p}^{3/2}$  and  $Si_{2p}$ , and width at mid-height of the  $Si_{2p}$  peak.

Time of hydration	$\delta Ca_{2p}^{3/2} - Si_{2p}$ eV $\pm 0.2$	width of the $Si_{2p}$ peak at mid-height eV $\pm 0.2$
0	245.6	2.4
10, 30 seconds 1, 3, 5, 15 minutes 4 hours	244.9	2.8

#### 4.3 Discussion

The interpretation of the kinetic XPS curve is not univocal. A possible interpretation could be a lack of precipitation of the Primary metastable Hydrate and the direct formation of the Secondary Hydrate. This formation combined perhaps with  $CaF_2$  precipitation would explain the important drop in the calcium concentration in the solution noticed by YOUNG *et al* (14) in comparison with hydration in pure water. The value of the ratio  $Ca_{2p}/Si_{2p}$  at the plateau strongly suggests that the thickness of the layer of the hydrate is higher than the depth of investigation of the method i.e. superior to 60 Å at about 3 minutes.

In this interpretation, the difference between the length of the dormant period for hydration in pure water and in NaF solutions could be related to a "memory effect" in the texture of the hydrate. Such effects would determine the behaviour of the hydrated layer around anhydrous  $C_3S$  grains over long periods : reactivity with Na and/or F and recrystallisation.

The same interpretation could be available for 4 °C experiments of MENETRIER *et al* (15). Low temperatures are well known to delay the setting of the cement pastes.

## 5. CONCLUSION

The XPS method seems well adapted to the study of the early interactions between  $C_3S$  and water. It could allow, with the utilisation of other techniques (SEM, STEM, chemical analysis of solutions) the understanding of the mechanisms which occur during the hydration of  $C_3S$ . However, due to the carbonation, it underlines the difficulty in obtaining a good sample for the quantitative surface analysis.

Our data suggest the existence of at least two intermediate hydrates during the dormant period. For hydration with dissolved NaF admixture, the formation of the Primary Hydrate would not take place and the formation of the Secondary Hydrate would be predominant.

# Condensation properties of dispersed products of portland cement hydration and rehydration

## *Propriétés agglomérantes des composants dispersés du ciment, après leur hydratation ou leur réhydratation*

V.D. GLUKHOVSKY, Prof. Dr. Technical Sciences,

P.V. KRIVENKO, Cand. Technical Sciences,

R.F. RUNOVA, Cand. Technical Sciences, Institute of Civil Engineering, Kiev, U.R.S.S.

**RESUME :** On a étudié les propriétés agglomérantes du ciment portland et du  $\beta$   $C_2S$  hydratés puis broyés et comprimés, en fonction de leur degré de réhydratation et de leur composition. On a montré que, bien que cette dernière ait une influence sur la résistance finale obtenue, elle ne détermine pas les propriétés agglomérantes du produit. Ces propriétés sont déterminées par l'état physique du produit hydraté et broyé. L'hydratation du ciment à des températures comprises entre 400 et 1000° entraîne la formation de produits amorphes ou de cristaux instables, qui ont un effet déterminant sur la capacité de réagglomération.

Il a été trouvé que ces propriétés agglomérantes ne dépendent pas de l'eau combinée ou adsorbée; et, e dépendent pas seulement des produits d'hydratation. Ces propriétés ont été observées dans des ciments ou du  $\beta C_2S$  complètement hydratés.

On a montré que cette réagglomération dégageait de l'énergie et que les propriétés agglomérantes étaient fonction de l'énergie dégagée. La transformation de l'énergie interne en énergie thermique accompagne la solidification du matériau et se produit dès que la compression met les particules en contact.

**SUMMARY :** The dependence of condensation properties of dispersed products of hydration and rehydration of Portland cement clinker and  $\beta C_2S$  on the degree of their rehydration and substance composition has been observed. It is shown that, although the latter has an influence on the relative strength of the stone being synthesized, it does not determine the condensation capacity of the binder. This capacity is determined by the physical state of the dispersed substance. The rehydration of hydrates within the temperature range of from 400 to 1000°C is accompanied by formation of amorphous and unstable crystalline structure phases, this determining their capacity for both the contact and hydration hardening.

It has been found that the condensation capacity of dispersed substances under examination does not depend on the presence in the system of chemically combined and physically bound gravitation water, it being displayed not only by the hydration products. These properties are also found in the products of complete rehydration, as well as in ground Portland cement clinker and  $\beta C_2S$ .

The estimation of these phases is given from the point of view of availability in them of excessive free energy. It is shown that this energy determines the capacity for condensation. The transformation of such energy into thermal energy, its release accompanying the synthesis of the stone from dispersions at the moment of contact forming between the particles has been recorded.

**INTRODUCTION:** The capacity of mineral systems to reveal binding properties is linked with the nature of their interaction with water. The possibility of revealing hydration binding properties is assumed only for the substances of slow and limited solubility (1). It led to the discovery of binding properties in the compounds of alkaline-earth metals (2) and to the development of their hardening theories the basis of which underlie the regularities of transition of anhydrous dispersed substances into aqueous formations.

The discovery of contact hardening (3) and the ability to such hardening of anhydrous binding substances and dispersed products of their hydration, partial or complete rehydration (4) permits a further step in generalizing the regularities of this process and an inference that neither physically nor chemically combined water is the determining factor in the condensation of dispersed systems into a water-resistant stone. According to these generalizations, the capacity of mineral systems to reveal the binding properties is determined by their energy potential, this being a function of the physical state of the substance by which they are represented.

The synthesis of a water-resistant stone can be realized at the moment of contact forming between both the aqueous and anhydrous dispersed mineral particles in the event of them being in a mutable (amorphous or unstable) crystalline state. The process of contact as well as of hydration condensation is accompanied by intensive release of thermal energy. The release of the latter continues even after the petrification of the dispersed system due to a gradual transition of the binder particle substance into a stable state, the particles comprising the concrete stone. This permits to draw a conclusion that the condensation properties of the products of hydration and rehydration of Portland cement and its separate minerals are manifested as the effect of structure ordering in these substances (5).

Using the principles of this effect, a series of experiments was conducted on the investigation of condensation properties of the dispersed products hydration, partial or incomplete rehydration of Portland cement and  $\beta$ -C<sub>2</sub>S aimed at the extension of the ideas about the causes of Portland cement condensation into stone-like formations.

**EXPERIMENTAL METHODS:** Portland cement clinker and  $\beta$ -C<sub>2</sub>S crushed to a specific surface of 3500 cm<sup>2</sup>/g, the products of their hydration as well as of partial and complete rehydration have been employed as the investigation objects. The hydrates were obtained by wet grinding process at B/T=5 with subsequent autoclaving at constant stirring at P<sub>gauge</sub> = 0.8 MPa of suspensions of initial substances, as well as of mixtures of  $\beta$ -C<sub>2</sub>S with additions of CaO and SiO<sub>2</sub> in quantities ensuring the synthesis

of high-base and low-base calcium hydrosilicates, respectively. The autoclaving was conducted up to the full hydration of anhydrous minerals. Following that they were dried at a temperature of 100±5°C up to a powdery state. The synthesized products were rehydrated at 400, 600, 800 and 1000°C by heat treatment followed by rapid cooling.

To determine the properties of dispersions under investigation at contact hardening, sample cylinders were made of them under pressure at specific load of 400 and 200 kgf/cm<sup>2</sup> applied for 1 min. The samples were pressed without water addition. They were tested immediately after pressing, as well as after 14, 28 and 120 days of storage in water and under dry-air conditions. The samples were placed into water immediately after pressing.

To determine their capacity to hydration hardening, the powders were mixed with water to the consistency of a normal-density paste from which sample cubes were prepared.

Structural changes in the substances were studied by X-ray diffractometric, electron-microscopic, infra-red spectroscopic, and differential-thermal analyses. The presence of excessive free energy in the systems under investigation was estimated by the results of thermobarographic analysis the essence of which underlies the recording of thermal effects springing up during condensation of dispersed substances in the process of their pressing.

**KNOWN CONDENSATION PROPERTIES OF HYDRATE SUBSTANCES:** In our paper (1) has been shown that, in contrast to natural hydrates of stable crystalline structure, the dispersed hydration products of Portland cement and its component minerals, while being in the metastable state, reveal for a long time the capacity of forming stone-like bodies at the moment of particles approach without the supply of thermal energy, these bodies retaining their shape and strength in water; they manifest also the ability of forming in them water-resistant structural bonds capable of restoration after mechanical dispersion due to iterative approach of particles or bonds strengthened due to distance reduction between them; the condensation of such dispersions into a water-resistant stone is the result of the reciprocal attraction forces inherent in the hydrate particles of unstable structure and is manifested as the effect of their structure ordering since these forces decrease in the process of substance transformation from the amorphous into the unstable crystalline state and disappear as their crystalline structure becomes stabilized; the condensation capacity of the hydrated dispersions is the function of the state of their structure only, whereas the strength of the cement stone is at the same time the function of their substance composition as well; the hydrate dispersions represented by unstable-structure substances should be regarded as independent hydraulic

binding substances of contact hardening.

Condensation capacity of dispersed products of rehydration is characterized by the fact that the powdery products of partial or complete rehydration of hydrates obtained by autoclaving dispersed Portland cement,  $\beta$ -C<sub>2</sub>S and its mixes with CaO and SiO<sub>2</sub>, like the hydrates proper, reveal the capa-

city for contact hardening during a long period of time since they are condensed into stone-like formations acquiring strength and water-resistance at the moment of contact appearance between the particles of these dispersions (Table I).

Table I  
Strength of samples immediately after dry pressing  
at a pressure of 400 kgf/cm<sup>2</sup> and in-water storage

Hydrate designation	Hydrated substance composition	Compression strength, kgf/cm <sup>2</sup> , of autoclaved dispersion samples rehydrated at temperature, °C, after pressing (following 14 days of in-water storage)				
		100	400	600	800	1000
A	2.5CaO·SiO <sub>2</sub> ·nH <sub>2</sub> O	110	115	120	125	120
		152	167	380	350	290
B	2CaO·SiO <sub>2</sub> ·nH <sub>2</sub> O	105	110	100	100	120
		137	160	320	240	250
C	CaO·SiO <sub>2</sub> ·nH <sub>2</sub> O	72	75	90	57	40
		112	90	190	80	75
K	Hydrated Portland cement clinker	95	105	115	120	120
		125	170	300	310	350

The obtained data permit an assertion that the condensation capacity is revealed independent of the presence of gravitation, chemically and physically combined water in the system.

This conclusion can be made from the fact that the samples moulded without water from dry powders of substances analysed gain strength with the passage of time when stored under dry-air conditions and do not decompose in water immediately after pressing and acquire strength in hot water. Ground Portland cement clinker and  $\beta$ -C<sub>2</sub>S also reveal the ability for contact hardening.

In contrast to the hydrates, the rehydration products like the Portland cement clinker and  $\beta$ -C<sub>2</sub>S, when mixed with water, manifest the capacity for hydration hardening revealed to a greater extent with the increase of the degree of substance rehydration.

Estimating the condensation capacity of the investigated substances by the strength of samples immediately after their pressure-moulding and prolonged dry-air and in-water storage (Table II), it can be noted that it depends on the chemical composition of the dispersed substances and their rehydration temperature.

Table II  
Strength changes in samples dry-pressed  
at a pressure of 400 kgf/cm<sup>2</sup>

Hydrate designation	Compression strength, kgf/cm <sup>2</sup> , of samples press-moulded from autoclaved dispersions rehydrated at temperature, °C, stored in open air/water, days									
	100		400		600		800		1000

	165	260	210	270	410	490	245	310	280	350
C	115	145	120	160	172	204	70	86	60	70
	217	270	180	205	230	280	90	105	95	115
K	175	240	180	200	300	320	370	400	300	350
	157	182	206	250	350	380	400	450	360	400

The strength increases with the increase of their basicity, independent of petrification conditions, hydration or contact hardening, higher strength is characteristic of samples obtained from hydration and rehydration products formed on the basis of the mix of  $\beta$ -C<sub>2</sub>S and calcium oxide ( $2.5\text{CaO} \cdot \text{SiO}_2 \cdot n\text{H}_2\text{O}$ ); it increases correspondingly in hydration products of  $\beta$ -C<sub>2</sub>S ( $2\text{CaO} \cdot \text{SiO}_2 \cdot n\text{H}_2\text{O}$ ) and its mix with SiO<sub>2</sub> ( $\text{CaO} \cdot \text{SiO}_2 \cdot n\text{H}_2\text{O}$ ). Similar dependence has been revealed in the studies of substances having similar composition and synthesized by autoclaving from chemically pure oxides.

It should be noted that the samples moulded from damp powders also retain their strength in water right after the pressure-moulding. In this case introduction of water into the system somewhat reduces the initial strength of the stone body synthesized from dispersed hydrates and enhances the strength of samples made of partially or fully rehydrated dispersed substances.

The increase of the moulding pressure in all instances results in the rise of the initial stone strength. So, at the moulding pressure of 2000 kgf/cm its strength immediately after pressure-moulding reaches 500-600 kgf/cm<sup>2</sup>. However, the degree of the moulding pressure effect decreases with the rise of the basicity and the degree of dispersed substance rehydration. But here a positive effect on the strength of a stone body synthesized from dry powders increases with its impregnation with water right after the moulding.

The physical state of the hydrates varied in the course of their rehydration. The study of the changes in the physical state of dispersed substances obtained in the systems under consideration, with their partial and complete rehydration, was aimed at the determination of its effect on the condensation capacity.

The initial hydrates were represented by gel-like and submicrocrystalline calcium hydrosilicates whose clear identification is hampered by their structure irregularity. Calcium oxide added to  $\beta$ -C<sub>2</sub>S during the synthesis of hydrate A had considerably reacted with it at autoclaving which enabled the obtaining of a hydrate of utmost basicity. This is signified by the presence of relicts with  $d=2.28$ ;  $2.49$ ;  $2.74$ ;  $3.03\text{\AA}$  on the X-ray photograph and of endoeffects on the DTA line at 180, 380 and 480°C characteristic of C<sub>2</sub>SH(B). The addition of silica to  $\beta$ -C<sub>2</sub>S in the synthesis of hydrate B promoted the drop of basicity in the hydrosilicates being formed; phase (A) is identified on the X-ray photograph by lines with  $d=2.71$ ;  $2.76$ ;  $3.01$ ;  $3.04\text{\AA}$ , and on the thermograph - by the exoeffect of wollastonite crystallization at 820°C.

The presence of unstable-structure hydrate phases in the products obtained by autoclaving  $\beta$ -C<sub>2</sub>S and mixes on its basis is also confirmed by the way of water removal during thermographic examinations; it oc-

curs at temperatures up to 850°C with the highest intensity within the temperature ranges of from 100-300 and 500-700°C; a highly intensive exoeffect of amorphous hydrosilicates crystallization has been recorded within the temperature range of 300-500°C.

The initial rehydration stage of the hydrates being examined is accompanied at 400°C by the removal of zeolitic and adsorption water, this having no effect on the strength characteristics of samples from dispersed products of rehydration. The rehydration at 600°C results in the development of substance amorphism. At this temperature the structures of high-basicity calcium hydroxides are subject to a greater degree of destruction, this being reflected by the weakening of lines of the corresponding hydrates on the X-ray photographs. This process is even more intensified at 800°C, when parallel to it commences the crystallization of anhydrous calcium silicates it being signified by rudimentary relicts on X-ray photographs with  $d=2.18$ ;  $2.70$ ;  $2.80\text{\AA}$  pertaining to wollastonite. The presence in rehydration products at this temperature of residual hydrosilicates is signified by low-intensity endoeffects at 200 and 780°C as well as by the presence of valent oscillations in the OH-group within the band range of  $3600\text{ cm}^{-1}$  on the spectrogram; the presence of silica gel is indicated by the absorption band  $960-1000\text{ cm}^{-1}$  and the presence of anhydrous crystalline substances is confirmed by the endoeffect at 780°C connected with their recrystallization and being the most intensive for the hydrate  $2.5\text{CaO} \cdot \text{SiO}_2 \cdot n\text{H}_2\text{O}$ . The identity of the rehydration process at 600°C and 800°C is signified by close strength characteristics of samples right after their pressure moulding, the samples having been obtained from rehydration products at these temperatures. However, their strength rises in the course of time under dry-air and water conditions to a greater extent in samples of more amorphous dispersions (600°C), this being due to the process of substance structure ordering. The rehydration at 1000°C is accompanied by the crystallization of unstable anhydrous silicate phases.

These formations rehydrated within the temperature range of from 600-1000°C display a tendency both to the contact and the hydration hardening.

The rehydration processes of Portland cement clinker products are more complex on account of the polymineral substance composition, although the changes in the physical state of the substance occur in the same succession, i.e. through the crystallization of hydrates, their amorphization up to the formation of unstable anhydrous crystalline phases.

The above investigations show that the dispersed hydrosilicates and their rehydration products, while in the metastable state, reveal the capacity of condensing into wa-

ter-resistant bodies at the moment of contact forming between them irrespective of their substance composition. As can be seen

from the data of Table III, this capacity is not connected with the presence of chemically combined water in the substance.

Table III  
Content of chemically combined water in hydrates  
and their rehydration products

Rehydration temperature, °C	Specific surface, cm <sup>2</sup> /g			Loss of ignition, %		
	Designation of hydrates					
	A	B	C	A	B	C
100	7400	6500	6400	23.00	21.60	16.70
400	7100	5900	6350	15.30	12.20	8.20
600	8000	6100	6000	10.81	9.67	5.23
800	8100	6800	7100	2.63	4.40	0.32
1000	4000	3560	5600	0	0	0

The ability thus established is explained by that all the investigated substances, while in the unstable state, have surplus free energy which becomes apparent during the condensation of these substances in the form of reciprocal attraction forces directed at the structure ordering, i.e. at the displacement of microparticles in a macrosystem aimed at its compaction and further order establishment. This energy has to be transformed into thermal energy and be emitted as a thermal flux when the particles approach.

Such thermal energy liberation has been recorded by Yu.A. Shepljakov by differential thermobarographic analysis which enables the recording of the thermal effect at the moment the pressure-moulding load acts upon the standard and examined dispersions. When standard and examined dispersed substances of stable crystalline structure are pressure-moulded, no energy is liberated throughout the entire interval of the moulding pressure increase. Due to this the differential thermobarogram appears as a straight line. In the studies of ground clinker and  $\beta$ -C<sub>2</sub>S, their hydration products, as well as products of their partial and complete rehydration, i.e. substances of unstable structure, the thermobarograms have recorded exothermic effects. This can be explained by the transformation of kinetic energy, spent on structure ordering, into thermal energy and confirms the above assumptions.

The reciprocal attraction forces of unstable structure macroparticles, like gravitational ones, are incapable of saturation. They allow attraction of a considerable number of other particles due to which they cannot be explained by chemical bonds which, as is generally known, can be saturated. These forces surpass considerably the gravitational ones, but have an insignificant radius of action and because of that can be referred to as electromagnetic surfaces forces.

## CONCLUSIONS

Ground cement clinker and  $\beta$ -C<sub>2</sub>S, as well as the dispersed products of their hydration, partial and complete rehydration are capable of instant condensation into water-resistant stone during their pressure moulding both in dry and wet state. In this connection all of them can be regarded as hydraulic binders of contact hardening.

The formation processes of constructional and technological properties of the concrete stone on the basis of such binders and hydration hardening binders are accompanied by liberation of thermal energy. Their resulting quality and direction depend on the kinetics of the internal energy changes in the stone, which can be determined as a sum total of rest energies of particles it has been condensed from; the kinetic energies of these particles moving in a certain manner in a resting body and of potential energies of fields accomplishing the interaction between the particles, or potential energies of attraction forces between them.

The control of the rate at which the internal energy of the stone is changing opens possibilities of controlling the process of its structure and properties formation. So, in the pressure-moulding of Portland cement and  $\beta$ -C<sub>2</sub>S powders, as well as of completely rehydrated products of their hydration, both dry and wet, water-resistant stone is condensed which has an initial strength. However, this strength and its growth in the course of time depend on the presence of water in the system.

This follows from the fact that the initial strength of the stone obtained from dry powders often proves to be lower than the strength of a stone pressure-moulded from the mixes of these powder with water. The higher is the basicity of the powders, the greater is the water effect. It is explained by that the internal energy of bodies condensed from dry powders represented by substances capable of chemical hydration by

water proves to be higher and its decrease is slower than in bodies condensed from mixes of these powders and water. The process of internal energy changes in such anhydrous systems can be speeded up by impregnating the anhydrous stone with water. In the latter case the rate of the stone strength growth and the strength itself considerably exceed these parameters in a stone obtained from wet powders. When powders of aqueous mineral systems are used, such as the hydration products of the aforementioned anhydrous formations and their partial rehydration, the structure stabilization, strength growth in the course of time and the decrease of the internal energy of a concrete stone synthesized from dry powders runs faster than in a stone made of the mixes of these powders with water.

This permits an assertion that water, while being not a determining factor in the condensation of binding systems into a water-resistant concrete stone, in a number of cases can serve as one of the control factors in the rate of changing its constructional and technological properties. It must be noted that the degree of water effect is determined not only by the mere fact of its presence in the system but depends on the time of its introduction - before or after the moulding of the stone.

The binders and concretes of the contact hardening make it possible to extend the nomenclature of hydraulic binders and to diversify their production technique; to obtain structures fully water-resistant and having their design strength immediately after their pressure-moulding; to bring the production technology of the concrete structures as close as possible to the metal-working technology and to develop principally new highly productive technological methods not used in this field hitherto.

Although some of the above possibilities seem at first sight quite hypothetical, they signify that we have reached the stage when the prospects for the development of the artificial stone production on the basis of the principles of the structure ordering effect are far beyond those limits which are considered conceivable. Generalized form they reveal one of the tendencies in the world's development of the building materials production.

# The Influence of the Content and Distribution of Alkalies on the Hydration Properties of Portland Cement

## *Influence du contenu et de la répartition des alcalis sur les propriétés d'hydratation du ciment Portland*

B. OSBAECK, F.L. Smidth & Co. A/S Vigerslev Alle 77,  
E.S. JONS, DK-2500 Valby, Copenhagen, Denmark.

**RESUME :** Les alcalis contenus dans le clinker de ciment Portland se trouvent, en partie, sous la forme de sulfates solubles, et en partie sous la forme de composants des minéraux de clinker. L'effet des alcalis sur l'évolution des résistances du ciment peut être attribué à des modifications de la composition de la phase liquide causées par les sulfates alcalins, ou à des modifications des propriétés hydrauliques des minéraux de clinker causées par les alcalis dans leurs réseaux cristallins.

Pour pouvoir évaluer l'importance de la répartition des alcalis, il a été cuit en laboratoire une série de clinkers qui ne se différencient les uns des autres que par leur teneur en alcalis et la répartition de ceux-ci. A partir de ces clinkers, on a produit des ciments d'une teneur en gypse variable.

Les propriétés de résistance des ciments ont été étudiées en mesurant les résistances du mortier à la compression. Pour des ciments choisis, le degré d'hydratation du  $C_3S$ ,  $C_3A$  et  $C_4AF$  a été mesuré à différents intervalles.

L'effet général obtenu par le déplacement des alcalis des minéraux de clinker dans les phases de sulfates par augmentation du contenu de  $SO_3$  dans les clinkers a été une augmentation des résistances initiales et une diminution des résistances ultérieures. Des teneurs élevées de gypse dans les ciments semblent amoindrir ces effets.

Sur la base des mesures du degré d'hydratation sont discutées les causes possibles des effets observés sur les résistances.

**SUMMARY:** The alkalies in Portland cement clinker are found partly as soluble sulphates and partly as constituents of the clinker minerals. The effects of alkalies on the strength development properties of hydrating cement can be attributed to changes in the composition of the liquid phase mainly caused by the alkali sulphates, or to changes in the hydraulic properties of the clinker minerals caused by the presence of alkalies in their lattice structure.

In order to evaluate the importance of the distribution of the alkalies, a series of laboratory-burned clinker, differing only in content and distribution of alkalies, have been prepared, and have been ground to cement fineness at various gypsum addition levels.

The strength-producing properties of these cements have been investigated by measuring their mortar compressive strength. Selected cements were subjected to determinations of degree of hydration of  $C_3S$ ,  $C_3A$ , and  $C_4AF$  at various ages.

Transferring alkalies from the clinker minerals to sulphate phases, achieved by increasing the  $SO_3$ -content in the clinker, generally resulted in an increase in early strength and a decrease in late strengths. High gypsum contents in the cements tended to weaken the effects.

Based on results of the degree of hydration measurements, possible causes of the observed effects on strength are discussed.

## INTRODUCTION

Industrially manufactured Portland cement clinker normally contain 0-2% of alkalis. Despite these low levels, however, alkalis have been shown to have a strong influence on many of the properties of Portland cement (1). Furthermore, recent investigations have indicated that the variations in strength-producing properties of industrially manufactured Portland cement clinker may be due largely to variations in their alkali content (2,3).

The alkalis in Portland cement clinker are present partly as easily soluble sulphates and partly as constituents of the clinker minerals (4). The investigations mentioned above have indicated that it is the soluble alkalis that affect strength. Moreover, additions of alkali salts to a cement have been shown to affect its strength development in fundamentally the same way (2,5-7). On the other hand, several authors have demonstrated that incorporation of alkalis into the structure of the clinker minerals may change their hydraulic properties (8-10); thus changes in strength properties of clinker due to such effects should also be considered.

In order to evaluate the importance of the distribution of alkalis, a series of laboratory-burned clinker, differing only in content and distribution of alkalis, have been prepared, and their strength-producing properties have been investigated in cements containing varying amounts of gypsum.

## EXPERIMENTAL

**Clinker:** A raw mixture was prepared from naturally occurring materials of low alkali- and  $\text{SO}_3$ -content. The desired alkali- and  $\text{SO}_3$ -contents were obtained by adjusting this raw mixture with additions of  $\text{K}_2\text{SO}_4$ ,  $\text{K}_2\text{CO}_3$ ,  $\text{Na}_2\text{SO}_4$ ,  $\text{Na}_2\text{CO}_3$ , and  $\text{CaSO}_4$  sufficient to allow for volatilization during the burn.

A clinker burning was carried out according to the following procedure: 300 g of the raw mix, ground to  $<90\mu$ , is packed loosely in a platinum crucible and calcined at  $950^\circ\text{C}$ . Then the crucible is covered and placed in an electric furnace at  $1450^\circ\text{C}$ . After 40 minutes the furnace is switched off. When the temperature has decreased to  $1300^\circ\text{C}$ , (in about 30 minutes) the crucible is removed from the furnace and permitted to cool further in laboratory surroundings.

Each clinker was composed of 3-5 batches of clinker prepared as described above; the composition was checked by full chemical analyses, including determinations of soluble alkalis (ASTM C-114).

**Cement:** Cements of varying  $\text{SO}_3$ -content were prepared by grinding the clinker with different amounts of a 1:1-mixture of gypsum and hemihydrate. After each cement had been ground for 15 minutes in a ball mill, its  $\text{SO}_3$ -content, specific surface (Blaine) and grain size distribution (LASER-granulometry) were checked.

**Mortar:** The strength development of the cements prepared was tested using a "small prism" method similar to the ISO-RILEM-method: From a mortar mix of 3 parts of standard sand, 1 part of cement, and 0.5 parts of water, 4 small prisms ( $2 \times 2 \times 15 \text{ cm}$ ) are cast. Since each prism is cut into 3 pieces ( $2 \times 2 \times 5 \text{ cm}$ ), each casting yields 12 pieces for compressive strength testing. In the present investigation, the following number of specimens were broken at each age: 1 day (2) - 3 days (3) - 7 days (2) - 28 days (3), and 90 days (2). The strength results obtained using this method are about 25% higher than those obtained by the ISO-RILEM-method. The bulk density of the prisms was measured after 1 day of hardening.

**Paste:** The degree of hydration of the clinker minerals after 1, 3, and 28 days of paste-hardening ( $w/c = 0.44$ ) was measured in selected cements by means of X-ray diffraction with 10%  $\text{CaF}_2$  as internal standard. The  $\text{C}_3\text{S}$ -content was established from the peaks at  $30.1^\circ$  and  $51.7^\circ 2\theta$  ( $\text{Cu} - \text{K}\alpha$ ). The contents of  $\text{C}_3\text{A}$  and  $\text{C}_4\text{AF}$  were measured after extraction of the silicate-phases with a solution of salicylic acid in methanol. A reliable measurement on  $\text{C}_2\text{S}$  could not be achieved.

Prior to their use for determination of the degree of hydration, the paste samples, in the form of small,  $1 \text{ cm}^3$  cylinders, were tested for compressive strength. The results were in good agreement with the results from the mortar specimens, but the reproducibility lower.

## RESULTS

The chemical compositions of the clinker are given in table I, which also includes the calculated potential mineralogical compositions. The alkali contents and distributions are characterized by the following terms: The total alkali content, expressed as %K<sub>2</sub>O-equivalent ( $\bar{K}_{tot} = K_2O + 1,52 \times Na_2O$ ), the molar ratio of sulphur to alkali ( $MSO_3 = SO_3 / (0,85 \times \bar{K}_{tot})$ ), and the content of soluble ( $\bar{K}_s$ ) and insoluble ( $\bar{K}_g$ ) alkalies, also expressed as %K<sub>2</sub>O-equivalent. As can be seen from the table, three levels of total alkali contents are represented (0,8, 1,6 and 2,4%  $\bar{K}_{tot}$ ). For the two highest levels, three different distributions of alkalies are obtained, corresponding to three different  $MSO_3$ -values.

Data describing the cements, as well as their performance in mortar, are collected in table II. The grain size distributions of the cements were well described by a Rosin-Rammler-expression; thus they are characterized by just two parameters: the steepness (n) and the 20μ-residue (R<sub>20μ</sub>). As expected, the directly measured Blaine-values of the cements were strongly dependent on the content of gypsum. A specific contribution of about 10 m<sup>2</sup>/kg per 1% of gypsum was evaluated by means of regression analysis on the available data.

This value was used to calculate the equivalent Blaine values for cements containing 4% gypsum (B(4%)). These corrected Blaine values are assumed to give a better description of fineness variations for the clinker part of the cements.

The mortars are characterized by their 1-day bulk density and compressive strengths as measured. Differences in these strength results can be attributed to differences in clinker composition (content of alkalies and SO<sub>3</sub>), content of gypsum, fineness and mortar density. In order to isolate the effects of clinker composition and gypsum content, the strengths were corrected for the influence of fineness and mortar density.

To eliminate the influence of fineness, equivalent strengths of cements with B(4%) = 300 m<sup>2</sup>/kg were calculated using the following empirical values of the effect of an increase of fineness of 10 m<sup>2</sup>/kg: + 0,9 MPa for σ<sub>3</sub>, σ<sub>7</sub> and σ<sub>28</sub> and + 0,45 MPa for σ<sub>1</sub> and σ<sub>90</sub>.

The calculated bulk density of a mortar free from air is 2300 kg/m<sup>3</sup>. Consequently the prepared mortars all contain more or less air (cf. table II). An attempt to eliminate this effect on strength consists of calculating all strength values back to the same mortar density (γ<sub>0</sub> = 2300 kg/m<sup>3</sup>) using the following formula:

$$\frac{\sigma_o - \sigma}{\sigma_o} = 5 \times \left( \frac{\gamma_o - \gamma}{\gamma_o} \right)$$

This is infact the commonly used rule saying that introduction of 1% air causes a 5% reduction in strength.

Fig.1 shows the 1-, 3- and 28-day strengths, corrected for differences in cement fineness and mortar density (σ"), plotted as a function of the total SO<sub>3</sub>-content at various levels of  $\bar{K}_{tot}$  and  $MSO_3$ . The results show a marked effect of the total SO<sub>3</sub>-content on early strength. Increasing clinker  $MSO_3$  results in higher 1-day strengths for total-SO<sub>3</sub>-contents up to about 4%. All cements of higher SO<sub>3</sub>-content seem to yield equal 1-day strengths.

For cements with 4% gypsum (framed points in fig. 1) a clear positive effect of increasing  $MSO_3$  is found. However, the effect could be interpreted as a combined effect of increasing the total SO<sub>3</sub>-content in the cement and increasing the fraction of soluble alkalies. After 3 days of hardening the initial advantage of a high  $MSO_3$  has disappeared, and later on a negative effect becomes dominant. It is clear from fig. 1 that increasing  $\bar{K}_{tot}$  or  $MSO_3$  at constant  $\bar{K}_{tot}$  brings about a decrease in 28 days strength. Apparently, this negative effect is diminished when the total SO<sub>3</sub>-content in the cement is increased up to the optimum level regarding 28-days strengths.

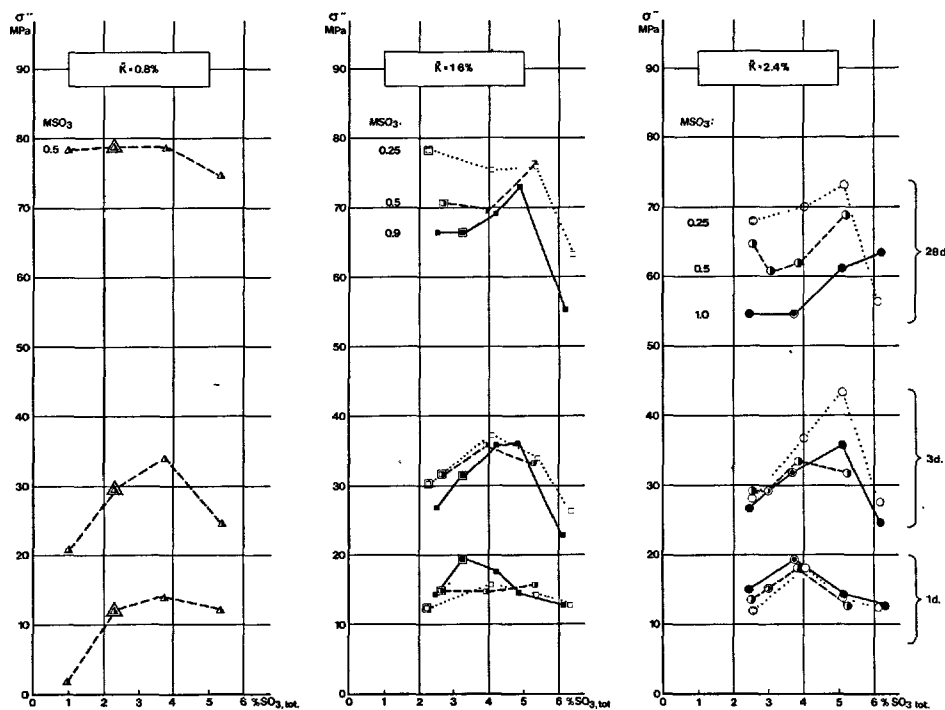

Figure 1:  
Mortar compressive strength (corrected to same clinker fineness and mortar density) versus total  $\text{SO}_3$ -content of cement. Shown for three different total-alkali levels ( $\bar{K}$ ) and three different clinker  $\text{SO}_3$ -to-alkali mole ratios ( $\text{MSO}_3$ ).

## DISCUSSION

A previous statistical investigation on strength properties of plant-produced clinker showed that the content of soluble alkalis was the parameter correlating most strongly to strength (2). That it is the soluble part of the alkalis which are most important for strength properties has been verified in the present work.

Fig. 2 shows the close connection between 28-day strength and content of soluble alkalis in clinker. The previously found quantitative effect of  $\sim 10$  MPa per 1% increase in  $\bar{K}_s$  is verified here recalling that 10 MPa in ISO-RILEM-strength corresponds to 12,5 MPa in the method used here.

The previous findings were based on cements containing 4% gypsum. The present investigation indicates that the negative effect can be somewhat counteracted by adding more gypsum, but in these cases the  $\text{SO}_3$ -contents of the cement will exceed the limits of 3-4%  $\text{SO}_3$  presently specified in cement standards. The side effects of such high  $\text{SO}_3$ -contents could be expansion problems and, as indicated here, reduced early strengths (fig. 1). Too much gypsum may be detrimental to strength development even up to 28-days (fig. 1 and 2).

Strength results in fig. 1 and 2 are corrected for differences in cement fineness and mortar density. It could be argued whether the latter correction is relevant, as there seems to be a correlation between mortar densities obtained and content of soluble alkalis (Table II). It is assumed that the presence of soluble alkalis causes entrainment of air in mortar during mixing by promoting premature structure formation in the paste (precipitation of gypsum, syngenite or ettringite). Such an indirect effect of alkalis will introduce a general reduction of strength at all ages, but most pronounced at late ages.

As this air-entraining effect presumably is strongly dependent on the mix proportions and mixing procedure, we have chosen in this presentation to evaluate the effects of alkalis on strength after applying corrections for density differences.

Apart from a potential density effect, alkalis may affect strength development in the following ways:

- By changing the rate of hydration of one or more of the clinker minerals
- or
- by changing the strength producing quality of the products of hydration.

Figure 2: 28-days compressive strength of mortar versus content of soluble alkalis in clinker.

In the present study the degree of hydration of  $C_3S$ ,  $C_3A$  and  $C_4AF$  after 1, 3 and 28 days has been measured in cements containing 4% gypsum. These measurements indicate an accelerating effect of soluble alkalis on hydration of all three phases (table III), which is in good agreement with their effect on 1-day strength.

It could be debated whether this accelerating effect is achieved because of more alkali in the liquid phase or because of less alkali in the clinker minerals. However, the close resemblance between the hydration and strength behavior of clinker K-5 ( $\bar{K}_S = 0,76$ ,  $\bar{K}_{-S} = 0,81$ ) and clinker K-7 ( $\bar{K}_S = 0,80$ ,  $\bar{K}_{-S} = 1,52$ ) supports the belief that alkalis influence the hydration and strength development primarily by changing the composition of the liquid phase.

The marked negative effect of soluble alkalis on the 28-days strength does not seem to be clearly linked to a corresponding effect on the degree of hydration of the clinker minerals, even though the data might give some suggestions in that direction. More data are needed to clarify such effects, and, furthermore, knowledge of the behaviour of belite in this respect is necessary to get a complete picture.

Ce- ment	TABLE III Degree of hydration								
	$C_3S$			$C_3A$			$C_4AF$		
	1d	3d	28d	1d	3d	28d	1d	3d	28d
C-2.2	0.26	0.57	0.84	0.18	0.43	0.76	0.04	0.18	0.50
C-4.1	0.37	0.54	0.75	0.18	0.40	0.70	0.00	0.14	0.41
C-5.1	0.39	0.53	0.75	0.18	0.39	0.66	0.02	0.20	0.47
C-6.2	0.44	0.63	—	0.12	0.41	—	0.00	0.20	—
C-7.1	0.33	0.60	0.73	0.14	0.49	0.66	0.02	0.25	0.43
C-8.2	0.39	0.62	0.70	0.25	0.57	0.65	0.04	0.26	0.37
C-9.2	0.56	0.69	0.74	0.27	0.56	0.62	0.11	0.32	0.43

However, the fact that soluble alkalis enhance strength only for the first three days' hydration, and inhibit its development thereafter, could be interpreted as indicating that the quality of the hydration products may be an important factor in the strength decline.

The favourable influence of high gypsum-contents on late strengths of cements rich in soluble alkalis is in good agreement with earlier findings (12-14). This effect could be due to the fact that more gypsum is necessary to counteract the faster removal of gypsum from the system caused by the alkalis. Thus the presence of gypsum to control the composition of the liquid phase is believed to be favorable for the hydration of  $C_3S$ . However, too much gypsum will be detrimental to strength development even after 28 days. This could be due to a prolonged retardation of the  $C_3A$ - and  $C_4AF$ -phases and thus a reduced contribution from these phases to the total hydrate formation.

A more profound understanding of the influence of alkalis on the strength development properties of cement must, in our opinion, be based on an understanding of the changes induced by alkalis to the complex interactions between  $C_3S$ ,  $C_3A$  and gypsum. It is our hope that the present, primarily empirical investigation may serve as a source of inspiration to the investigation of such considerations.

## CONCLUSIONS

The influence on cement strength of the content of alkalis in clinker is dependent on the content of  $SO_3$  in clinker as well as the content of gypsum in the cement.

Increased  $SO_3$  levels in clinker of the same alkali content imply that a greater fraction of the alkalis will be in a easily soluble form. The effect of this transfer of alkalis will generally be an increase of early strength and a decrease in late strengths.

However, the effects are modified by the content of gypsum in the cements. Thus the effect on early strength seems to be absent when gypsum content is higher than the optimum content. By analogy high gypsum contents tends to diminish the negative effect of alkalis on late strengths.

While the positive effect of soluble alkalies on early strength seem to be associated with a faster hydration of the clinker minerals ( $C_3S$ ,  $C_3A$ ,  $C_4AF$ ) it is less clear whether the strength decline at later ages is due to diminutions in degree of hydration or to adverse effects on the quality of the hydrates.

An additional negative effect due to air entrainment with increasing amounts of soluble alkalies was found.

# On the reactions leading to calcium silicate hydrate, calcium hydroxide and ettringite during the hydration of cement

## *A propos des réactions produisant le silicate de calcium hydraté, l'hydroxyde de calcium et l'ettringite pendant l'hydratation du ciment*

H.M. JENNINGS, Lecturer, and P.L. PRATT, Professor in the Department of Metallurgy and Materials Science, Imperial College of Science and Technology, London, SW7, England.

**RESUME :** La première partie de cette communication examine certains aspects phénoménologiques de l'hydratation du ciment de Portland (PC), ainsi que de son constituant pur : le silicate tricalcique ( $C_3S$ ). Les deux systèmes comportent une phase initiale, d'une durée d'à peu près quatre heures, pendant laquelle il y a très peu de réaction. Pendant cette période, il paraît se produire dans le ciment Portland une sorte de membrane qui crée la prise initiale du ciment. Au contraire, le  $C_3S$  paraît seulement former une couche légère d'hydrate qui se délite lentement. Pendant toute cette période, les ions de calcium et aussi l'hydroxyde se dissolvent. A la fin, l'hydroxyde de calcium est précipité d'une solution sursaturée et une réaction rapide s'amorce, produisant un gel de C-S-H. Avec le PC, des aiguilles d'ettringite sont produites après la phase initiale.

Les produits courants qui se forment dans le PC peuvent être distingués, soit par leur composition, soit par leur morphologie. Par contre, si la composition de la phase aqueuse varie, la composition des produits qui se forment peut changer dans une gamme beaucoup plus large. Les produits peuvent alors comporter une plus grande variation que celle que l'on rencontre normalement. Ce fait, et d'autres résultats qui indiquent que la formation de l'hydrate de calcium et de l'ettringite résulte d'un mécanisme de réaction en solution, conduisent à penser que le C-S-H est produit par une réaction "quasi solide".

Une théorie du mécanisme des réactions mettant en jeu  $C_3S$ , ou  $C_3S + C_3A$  et le gypse est esquissée. Dans tous les cas une enveloppe inhibitive se forme autour des grains pendant la période initiale.

Avec le  $C_3S$  pur, cette membrane est fragile et se délite rapidement; une nouvelle enveloppe se forme immédiatement dès que la solution aqueuse augmente de pH. Avec le ciment Portland, cette enveloppe est plus robuste. Pendant la période initiale, l'eau pénètre dans les grains, et dès que la réaction s'amorce, un gel de C-S-H se forme, dont l'inhibition diminue avec le développement de la réaction, ce qui termine la phase initiale. La couche pauvre en calcium réagit rapidement, ensuite une réaction, modérée par la diffusion de l'eau vers le centre des grains, se poursuit dans les couches non encore hydratées. Dans le ciment Portland, des aiguilles d'ettringite se forment alors, probablement par osmose.

**SUMMARY :** The first part of this paper explores some phenomenological features of both the hydration of portland cement (PC) and the pure constituent of tri-calcium silicate ( $C_3S$ ). Both systems exhibit an induction period lasting about four hours where very little reaction takes place. During the induction period the PC system appears to form a membrane which is responsible for the initial "set" of cement.  $C_3S$ , on the other hand, appears to have only a delicate hydrate layer which slowly exfoliates. Throughout this period both calcium and hydroxide ions enter solution. At the end, calcium hydroxide precipitates from a supersaturated solution and rapid reaction takes place forming a C-S-H gel. In PC ettringite needles form during the post induction period.

The usual products which form in PC can be separated both compositionally and morphologically. In a system where compositions of the aqueous phase are altered however, the composition of products formed can be varied throughout a much wider range. The products, therefore, can tolerate greater variation than is normally seen. This, coupled with other results indicating that both calcium hydroxide and ettringite form by essentially through solution reaction mechanisms suggests that C-S-H forms by a reaction taking place in the "quasi solid" state.

An overall mechanism for the reaction of  $C_3S$ , and of  $C_3S$  with  $C_3A$  and gypsum, is outlined. Both cases form an inhibitive envelope around the particles during the initial stages. For pure  $C_3S$ , the delicate membrane exfoliates and a new one immediately forms as the unreacted surface is exposed to high pH aqueous phase. For PC the envelope is much more robust. Throughout the induction period water is imbibed into the "solid" and when finally a reaction takes place a C-S-H gel product forms which no longer inhibits further reaction, thus ending the induction period. The calcium-depleted layer quickly reacts followed by diffusion-controlled reaction of the unaffected core. In PC ettringite needles then form, possibly by an osmotic mechanism.

## INTRODUCTION

Of the several early products formed during the hydration of Portland cement (PC), by far the most important are calcium silicate hydrate (C-S-H), calcium hydroxide (CH) and ettringite ( $C_3A \cdot 3CSH_2$ ), and related phases referred to as Aft. In addition to detailed study of many aspects, both chemical and physical, of the overall reaction, each constituent has been studied in detail by first simplifying the system to the pure reactants. This paper combines some results of a microscopic investigation of the hydration of both PC and the pure constituent  $C_3S$ , with some other experimental observations obtained both in our laboratory and reported in the literature. The purpose is to attempt to produce a self consistent model for the mechanisms of important hydration reactions.

## REACTIONS OCCURRING IN PORTLAND CEMENT

The products which form by the end of the first few days of reaction at W/C ratios of 0.5 are chemically and physically very distinct. Although the exact compositions are not critical to this paper the following suggests average impurities typically (1) found in the principle phases in PC. For C-S-H impurities in ratios Si:Al, Si:Fe and Si:S of 11, 43 and 15 respectively occur. Aft has roughly the composition of ettringite but may contain Si and may have some sulphate replaced by hydroxide. CH is usually quite pure but may contain small amounts of silicate. Figure 1 is an electron micrograph of a five day old specimen which has been kept moist (2) during observation; a number of phases are shown growing into an open pore. Although the morphology changes somewhat during drying (2), analytical microscopy has established that the square-ended bundles of needles compositionally are consistent with ettringite;

it should be noted that all needle-like morphologies observed in PC contain various amounts of the appropriate elements of Aft. The thin transparent membranes around and between the needles are almost certainly C-S-H because when dried and placed in an analytical microscope Ca and Si can be detected almost exclusively. Underneath this detached surface layer of C-S-H and making up the major fraction of C-S-H in hydrated PC, is a finer, less structured product. Here, significant quantities of impurities may be present, as reported by Lachowski et al (1). Small crystals of CH form throughout the surface products, as seen near the base of the needles, and with the passage of time they can often grow forming large well-faceted crystals.

Ettringite formed in PC is crystalline while C-S-H is amorphous, and although both are non-stoichiometric materials they can be separated compositionally. It is interesting to note that the highest substitution of impurities seems to occur in fine grain completely hydrated specimens (3). Under contrived conditions (4), however, the compositional distinction between Aft phases and C-S-H can become blurred. For example, in fibres, Figure 2, grown by the "dilution technique" (4) and containing various amounts of Al, S and K, the Si count can vary from 0-80% of the total depending on the details of the dilution; the other elements can exhibit great variation as well.  $Ca(OH)_2$  on the other hand, exhibits almost no compositional variation. In spite of the great compositional variation that can be tolerated in products in the PC system the fact that relatively pure C-S-H and Aft form simultaneously, particularly in the early stages and in intimate proximity with one another demands that they have separate formation reactions in the hydrating PC system.

Fig. 1 - H.V.E.M. and wet cell micrograph of 5 day old, W/C = .5, specimen. Square-ended needles contain Al, S and Ca whereas thin foils contain Ca and Si exclusively.

Fig. 2 - SEM of fibres, containing variable amounts of Al, S, K, Si and Ca grown by dilution technique.

In describing the various reactions which take place, it is important to define the location of the reaction site. When a grain of cement is placed in water certain elements dissolve and water may start entering the boundaries of the grain. As water continues to enter the grain a layer near the surface may lose some of its solid properties, becoming a quasi-solid. Thus, this paper will refer to solution reactions, quasi-solid reactions and reactions that take place on the surface between the two. There is, of course, an unreacted core where no reaction has yet taken place.

Although in PC there is a tendency for the smaller particles to be rich in Al phases most particles are polymineralic. Thus, on average, any one particle contains the elements required for all products.

#### Formation of Calcium Hydroxide:

CH appears to form from solution by a process of precipitation. The concentration of calcium ions is known to become supersaturated with respect to calcium hydroxide very soon after mixing with water and towards the end (or at the end) of the induction period nucleation takes place throughout the solution. In spite of the fact that many elements and ions are in solution it seems that bonding requirements and a rather inflexible structure hinder the incorporation of foreign atoms into CH. It is interesting to note (5) that the precipitation of CH in the presence of excess silicon ions is retarded and this could be related to structural intolerance of impurities.

#### Formation of Ettringite and related Aft:

There is evidence to suggest (6,7) that ettringite also forms via a solution mechanism. Although there may be a tendency for crystalline square-ended ettringite needles to form preferentially on  $C_3A$  grains the evidence is that, like Portlandite, Aft phases also precipitate throughout the solution on the surface of the particles. For example, some experiments (4) show evidence for a membrane covering the particles of PC, but only when they exist in an aqueous solution containing the relevant elements for at least a matter of 15 minutes. If placed in large quantities of distilled water a distinct membrane never forms, suggesting that at least some of the constituents must dissolve reaching a certain concentration before they can precipitate. When the membrane has formed, hollow needles can be grown by adjusting

concentrations so as to encourage an osmotic mechanism as in Figure 2. Since similar needles, are found in ordinary PC systems growing into pores, Figure 3, we suggest that some of the ingredients are pumped down the centre of the needle to the end where reaction takes place causing further growth. Although data on the solubility of Al is scarce it may be that only very small quantities of Al are in solution, particularly in the presence of sulphates, and this may account for the slow reaction of  $C_3A$  in the early stages of hydration. In fact the formation of a membrane may involve the transportation of all ingredients except Al through solution, while Al is transported to the reaction site through the solid where it either reacts or dissolves and reacts and precipitates. At some time after the membrane forms, needles start to grow.

Fig. 3 - H.V.E.M. and wet cell micrograph of 6 day old P.C., W/C = 5. Fluid in needle shot out just before photo was taken.

Here, Al rich material may be transported down the centre of the needles whereupon it reacts with other elements that are in solution. More generalized dissolution-precipitation throughout the solution may account for a variety of morphologies, but we feel that the Aft forms via a solution mechanism and the composition of the product is related to the composition of the aqueous solution. The lack of Si in solution is the main reason why only small amounts of Si are present in Aft.

#### Formation of C-S-H:

Measurable quantities of silicates are found in solution only during the first few minutes (8,9) after mixing cement with water. We believe that as the pH rises the silicates precipitate out of solution forming the thin transparent membrane around all the particles present. In the PC system the dissolution of Al is suppressed in the early stages by the presence of sulphates. Thus if the product forms on  $C_3S$  substrate, the composition of this membrane appears to be largely C-S-H. If the product forms on  $C_3A$  it may contain Aft phases. After this early rapid reaction, Aft slowly forms underneath the exfoliating thin transparent C-S-H membrane.

Unlike many silicates found in nature, the C-S-H formed after the induction period is best described as an amorphous gel of colloidal dimensions and variable stoichiometry. Thus, we have considered three points regarding the formation of C-S-H in PC after the induction period: (1) it forms in a system in which there are essentially no silicates in solution, (2) it forms by a reaction which must be physically separated from other reactions taking place in PC and (3) it forms in circumstances which restrict its ability to order. Taken together a quasi-solid state reaction is suggested.

THE REACTION OF PURE  $C_3S$ 

Hydrating pure  $C_3S$  exhibits an induction period, lasting about four hours, similar to that observed in PC. In the case of pure  $C_3S$  however, the "dilution technique", used previously (4) on PC systems, was unable to establish the existence of any well defined membrane.

Nevertheless, during the first few hours, we have observed C-S-H products "peeling" away from the surface, figure 4, an observation similar to that reported by Ménétrier et al (10). Our observations were made while the grains were kept moist. If the specimens are dried in air, the thin membranes formed during the induction period can become detached, figure 5, forming a morphology sometimes referred to as "cigar" shaped. Analysis shows them to have a very high calcium content with C/S = 2.5 - 3.5

Fig. 4 - H.V.E.M. and wet cell micrograph of 3 hr hydration of  $C_3S$ , W/C = .5.

Fig. 5 - TEMSCAN of  $C_3S$  hydrated for  $\frac{1}{2}$  hr, W/C = .5. Thin foils are readily peeling away from surface,

At the end of the induction period a reaction occurs rapidly, forming a colloidal gelatinous layer around the particle as seen in figure 6. It should be noted that the needle morphology is absent (so long as the specimen is kept moist) and the quasi-solid region, where the C-S-H product is now forming, is in contact with the particles, where water enters the solid. As this reaction continues the bonding becomes stronger and the process of separating the particles, during preparation of thin specimens (1), can pull the

gelatinous layer into the drawn out root-like morphology seen in figure 7. Thus, the often seen C-S-H needles are artefacts formed either by rolling up thin membranes or by drawing out the gelatinous product, but they are not a naturally occurring morphology.

Fig. 6 - H.V.E.M. wet cell of  $C_3S$  hydrated for 6 hrs. W/C = .5.

Fig. 7 - TEMSCAN micrograph of 4 day  $C_3S$  W/C = .5 showing gelatinous layer being pulled away from surface.

A MECHANISTIC MODEL FOR THE REACTION OF  $C_3S$  WITH AND WITHOUT  $C_3A$  AND GYPSUM.

This section will outline some of the important features of our proposed reaction mechanism for PC when mixed with water. As already discussed we believe the overall reaction to be the sum of separate mechanisms which, although possibly interconnected when taken together, can lead to distinct and well-defined separate products. Figure 8 is a schematic representation of (a) pure  $C_3S$  hydration, and (b)  $C_3S$  and  $C_3A$  hydrating together.

## Initial Reaction:

When either  $C_3S$  or PC is placed in water both calcium and, to a lesser extent, silica (9,11) dissolve during the first seconds. The pH quickly rises to about 12.5, (8,12) and in both cases the silica

Fig. 8 - Simplified schematic of reaction sequence of pure C<sub>3</sub>S and C<sub>3</sub>S + C<sub>3</sub>A + gypsum.

concentration in solution quickly drops (9,11) to an almost unmeasurable level. Now Birchall, Howard and Bailey (8) have pointed out that, in the cement system, SiO is almost insoluble in the pH range of 11.0-13.5. We think, therefore, that as the pH reaches a value of about 11 a layer of hydrate with high C/S ratio precipitates from solution. For C<sub>3</sub>S this dissolution and consequent reduction in surface calcium, followed almost immediately by precipitation of high C/S product, accounts for the fall and subsequent rise in the C/S ratio as observed on the surface by ESCA techniques (10). For PC, the initial layer of hydrate may contain small amounts of elements such as S, and possibly Al if it forms on C<sub>3</sub>A.

#### Induction Period:

During the induction period calcium (and in the case of PC, S, K and possibly to a lesser extent Al) continue to dissolve and water is imbibed into the silica-enriched zone as discussed by Dent-Glasser (13). For C<sub>3</sub>S the boundary between liquid and solid undergoes continual change and at first the thin delicate precipitated membrane peels off, exposing the underlying area to water of high pH which causes an immediate reaction forming another layer of C-S-H. In the case of PC, the initial C-S-H is slowly replaced by a membrane probably with composition approaching Aft which can form only as Al becomes available, and whose composition may change with time. Here (as opposed to pure C<sub>3</sub>S) the continued formation of the membrane, a through-solution process which does not depend on soluble silicates, accounts for the agglomeration or "set" of PC during the early stages by enveloping and tying the particles together. Both the rheology of the mix as well as the long term course of the reaction can thus be profoundly affected by such things as the introduction of sulphates (discouraging the

dissolution of Al), or artificial buffering of the pH. In both cases water continues to be imbibed slowly into an ever-thickening layer rich in silicate-species, and the membrane should be considered more enveloping and possibly inhibiting, than protective.

#### End of Induction Period:

In spite of the fact that all the ingredients necessary to form C-S-H are present in the "quasi-solid", the reaction does not proceed rapidly during the induction period, possibly because of the small amount of H<sub>2</sub>O and/or because the local "pH" is not high enough.<sup>2</sup> This situation is gradually overcome with the passage of time and the continued imbibing of water into the "quasi-solid". When finally the conditions become favourable for the formation of C-S-H, the induction period comes to an end and a quasi-solid state reaction takes place. Unlike the surface reaction which continually (and slowly) heals the rupturing membrane, this reaction forms a colloidal gel which is much less effective at slowing the transportation of water to the interior. At first the reaction is rapid as water flows into the volume already depleted in calcium but very quickly it becomes diffusion-controlled. As the reaction proceeds inwards fresh reaction product pushes the early product into the volume of original void space. This diffusion-controlled interior product is formed under much more constrained conditions and is therefore denser, as has been observed (14), than the product formed at the end of the induction period. There is, however, no real distinction between "inner" and "outer" product, the distinction is really between early and late product.

The end of the induction period is also signalled by the precipitation of CH. In the case of PC the wholesale destruction of the membrane, which may be considered as an envelope (behaving as an inhibiting membrane) may be encouraged by CH precipitation.

In either case the calcium-depleted layer reacts rapidly to form C-S-H without the necessity of expelling calcium. The later product, however, requires the removal of calcium before C-S-H can form. The thickness of the calcium-depleted zone before the end of the induction period can be affected by many variables that determine the amount of calcium taken into solution; this thickness can control the morphology and density of the early product as well as the distribution and morphology of the CH formed throughout.

During this renewed reaction ettringite needles, and needles whose composition resembles Aft, form in PC, possibly by local osmotic mechanisms where the now depleted calcium in solution (caused by CH formation) causes water to pump into the inside of a membrane still surrounding the particles. Micrographs showing a bulging membrane have already been reported (15).

In several respects this overall mechanism is a combination of both delayed nucleation and protective membrane theories. The nucleation of C-S-H is delayed by the membrane which in the case of  $C_2S$  is very thin and is continually rupturing and re-healing. When, however, the gel finally starts to form under the membrane it forms a product which is no longer protective and a renewed reaction starts. Because the early product remains this model is different from the proposal that an early protective product slowly transforms into a non-protective product.

#### CONCLUSIONS

1. The reactions forming C-S-H and ettringite and Aft are separate in the PC system. C-S-H forms by a quasi-solid state reaction and ettringite and Aft form from solution.
2. In the pure  $C_2S$  system C-S-H forms from solution only during the first few minutes of reaction. This forms a thin inhibitive membrane (slowing the transportation of water) which is repaired by a surface reaction. When a reaction takes place in the quasi-solid state the product is gelatinous and no longer has inhibitive properties.
3. Portlandite forms from solution but its structure tolerates less impurities than other phases present.

# Propriétés électrocinétiques à la surface des minéraux du ciment Portland

## *Electrokinetic surface properties of Portland cement minerals*

A. ZELWER, Ing. C.N.A.M. - C.E.R.I.L.H., Paris, France.

### RESUME

Nous limitons les propriétés des surfaces solides apportées par les ciments en cours d'hydratation aux premières heures en excluant le début de la prise, les résultats étant destinés à améliorer l'action des adjuvants en relation avec le comportement rhéologique des bétons frais.

Le potentiel ZETA (PZ) ne rend compte des charges électriques et des énergies d'interaction coulombiennes entre particules que pour des surfaces solides en équilibre ioniques stables et au repos. Toute perturbation mécanique (agitation, malaxage) entraîne un réarrangement ionique conduisant à un PZ complètement différent, non mesurable.

Les suspensions et les pâtes de ciment sont des systèmes "dynamiques" : l'apparition, la transformation de nouvelles phases solides hydratées et l'évolution ionique de la phase liquide maintiennent hors d'équilibre une interface composite car cinq phases minérales, au moins, contribuent à l'hétérogénéité de la surface des grains :  $C_3S$ ,  $C_2S$ ,  $C_3A$ ,  $C_4AF$  et le gypse. Pour un tel système le concept de PZ n'a pas de signification et doit être remplacé par celui de "PZ dynamique" (PZD).

La simulation d'un système "dynamique" à partir d'une suspension stable (QUARTZ-EAU) montre que les variations relatives de PZD en fonction du temps sont mesurables à condition de les relier au pH et à la force ionique de la solution en réalisant un traitement automatique instantané du mouvement électrophorétique (calculateur et anémométrie laser doppler - ALD).

En pâte concentrée on ne peut pas atteindre directement les objectifs fixés : la forte sursaturation d'un volume limité de phase liquide interstitielle masque un PZD "global" ne tenant pas compte des hétérogénéités de surface.

En suspension diluée, une analyse statistique très fine des mouvements électrophorétiques rend beaucoup mieux compte des hétérogénéités de surface.

Les suspensions de  $C_3S$  et de ciment portland ont un PZD négatif (celui du  $C_3S$  est le plus faible). Le  $C_3A$  paraît avoir un PZD très fortement positif.

D'autres essais sont encore nécessaires pour confirmer ces résultats et les étendre à tous les minéraux purs du ciment.

### SUMMARY

We limit our study of the properties of the solid surfaces developed by the cements during their hydration to the first hours, excluding the beginning of the set, the results are intended to put in practice a better knowledge of the action of the admixture in relationship with the rheological behaviour of fresh concrete.

The ZETA Potential (ZP) expresses the electrical charges and the Coulombian interaction energies between particles only for solid surfaces in a stable ionic equilibrium and in a motionless state. Every mechanical perturbation (agitation, mixing) causes an ionic rearrangement leading to a completely different immeasurable ZP.

Cement suspension and pastes are "dynamic" systems : the apparition, the transformation of new hydrated solid phases and the ionic evolution of the liquid phase, keep out of equilibrium a composite interface, since at least five mineral phases contribute to the heterogeneity of the surface of the grains :  $C_3S$ ,  $C_2S$ ,  $C_3A$ ,  $C_4AF$  and gypsum. For such a system, the concept of ZP is meaningless and must be replaced by that of "dynamic ZP" (DZP).

The simulation of a "dynamic" system from a stable suspension (QUARTZ-WATER) shows that the relative variations of DZP in function of the time are measurable provided that they are related to the pH and to the ionic force of the solution by realizing an instantaneous automatic treatment of the electrophoretic movement (calculator and doppler laser anemometry - DLA).

In a concentrated paste it is not possible to reach directly the defined objectives : the strong over saturation of a limited volume of interstitial liquid phase conceals a "global" DZP, since it does not reflect the surface heterogeneity.

In a diluted suspension, a very minute statistical analysis of the electrophoretic movement give a much better picture of the surface heterogeneity.

$C_3S$  and cement suspension have a negative DZP (that of  $C_3S$  is the weakest).  $C_3A$  seems to have a very strongly positive DZP.

Other tests are still necessary to confirm these results and to extend them to all pure minerals of the cement.

## I. INTRODUCTION

Compte tenu de la surface spécifique élevée des minéraux du ciment en cours d'hydratation, il est intéressant de prêter une attention particulière au rôle des charges électriques de surface, à l'origine d'interactions coulombiennes entre particules, qui influencent les comportements rhéologiques des bétons frais. De leurs connaissances on peut espérer une maîtrise plus efficace de l'emploi des adjuvants spécifiques des modifications de plasticité, maniabilité, teneur en eau, etc... Pour cette raison nous nous limiterons aux premières heures de l'hydratation, à l'exclusion du début de la prise.

Mais nous allons voir que les suspensions et les pâtes de ciment en cours d'hydratation sont assimilables à des systèmes colloïdaux évolutifs, hors d'équilibre auxquels le concept habituel de potentiel électrocinétique ZETA n'est pas applicable.

Le cas des systèmes quasi-hydratés et complètement durcis, où les interfaces sont en équilibre est mieux connu et de nombreux travaux concernent des phase minérales pures (1,2,3 et 4).

Dans cette communication préliminaire nous proposons d'établir une distinction entre les systèmes "statiques" constitués par les minéraux inertes en équilibre et les systèmes "dynamiques" en adoptant pour ces derniers le concept de "PZ dynamique" (PZD).

Enfin une bonne approche expérimentale de l'étude de l'interface dynamique passe par les suspensions diluées de minéraux inertes pour les systèmes statiques (par exemple QUARTZ-EAU) et des minéraux purs du Ciment Portland pour les systèmes dynamiques.

## II. POSITION DU PROBLEME

Dans le cas des surfaces solides en équilibre ionique stable (systèmes statiques) les phénomènes électrocinétiques sont bien connus. Ils font l'objet de nombreuses théories développées depuis 1910 et sans cesse affinées par l'introduction de nouveaux paramètres (5,6,7,8 et 9).

Dans un souci de simplification extrême, on rappellera que les charges électriques proviennent de l'ionisation de groupes hydratés, d'adsorption spécifique et aussi d'imperfections et lacunes du réseau cristallin ; elles constituent une couche rigide (de STERN) compensées dans la phase liquide par un environnement ionique perturbé (couche mobile diffuse). Une telle structure schématisée de la double couche ionique (FIGURE N° 1 A) permet de retenir que le PZ est une différence de potentiel (en mV) entre le plan de cisaillement et la phase liquide non perturbée. En d'autres termes, c'est aussi une grandeur numérique qui intègre la quantité de charges électriques et l'énergie électrostatique de répulsion entre les surfaces solides chargées de mêmes signes. Mais ces énergies d'interaction sont en réalité les bilans d'une composante répulsive et d'une composante de force de Van der Waals (d'attraction) qui peut l'emporter pour des distances entre solides assez petites.

Ainsi un PZ élevé caractérise un système colloïdal bien dispersé, l'état floculé correspondant à un PZ faible ou nul.

A partir d'une telle structure ionique de la double couche, tous les phénomènes électrocinétiques des systèmes colloïdaux n'ont pour origine que les déplacements relatifs de la phase solide et de la couche diffuse entraînés par la phase liquide. Il en résulte une dissymétrie statistique de la répartition des charges anioniques et cationiques. (FIGURE N° 1 B)

L'application d'un champ électrique provoque une mobilité électrophorétique des particules solides ou un déplacement électroosmotique du liquide interstitiel.

FIGURE 1 - STRUCTURE DE LA DOUBLE COUCHE IONIQUE

Par ailleurs, le déplacement forcé de cette dernière, sous l'action d'une contrainte physique (pression), donne naissance à des potentiels de filtration, d'écoulement, et même de sédimentation.

Par conséquent, un système colloïdal de type statique appelle déjà trois remarques importantes :

- 1°) La structure ionique d'une interface résulte d'un processus d'adsorption ionique très lent.
- 2°) Les paramètres utilisés pour calculer le PZ n'ont aucune signification tant que les conditions d'équilibre ioniques ne sont pas respectées.
- 3°) Le PZ est très sensible aux perturbations d'origine mécaniques en raison de la redistribution statistiques des ions de compensation.

Cela signifie que le concept PZ ne peut pas être appliqué sans discernement aux interfaces du type dynamique (ciments en cours d'hydratation), ceci pour plusieurs raisons :

- l'interface est toujours hors d'équilibre ionique,
- la force ionique de la phase liquide évolue durant l'hydratation,
- la transformation de phases hydratées nouvelles complique l'hétérogénéité des phases solides,
- en raison de la structure polyphasée des grains de ciment portland, au moins cinq minéraux sont présents à la surface :  $C_3S$ ,  $C_2S$ ,  $C_3A$ ,  $C_4AF$  et le gypse.

Enfin, parmi les facteurs et paramètres importants (mis à part les effets de la température sur les isothermes d'adsorption et les vitesses d'hydratation), l'influence du pH sur le PZ est la conséquence de l'adsorption spécifique des ions  $OH^-$  qui participent à la structure de la double couche. Par ailleurs cette dernière est comprimée par tout accroissement de la force ionique, ce qui entraîne un abaissement du PZ.

## III. SIGNIFICATION DU POTENTIEL ZETA DYNAMIQUE (PZD)

En pâte concentrée les variations de concentrations ioniques, dans la phase liquide ( $E/c = 0,3$  à  $0,5$ ) suivent en fonction de l'hydratation une loi bien connue et bien située par rapport aux échéances cruciales des limites de saturation et de sursaturation en  $Ca(OH)_2$ , quand on considère l'hydratation du  $C_3S$  pur (10). Un équilibre très stable subsiste entre les hydrates intermédiaires et la solution tant que la limite de saturation n'est pas atteinte. La sursaturation est une condition nécessaire et suffisante de la rupture de cet équilibre, et de l'évolution exothermique des hydrates précédents accompagnant la prise. En présence des minéraux du ciment portland, on retrouve sensiblement cette même loi malgré le recul de l'équilibre de concentration en ion  $Ca^{+}$  et  $OH^-$  en présence

des quantités d'ions alcalins  $\text{Na}_2\text{O}$  et  $\text{K}_2\text{O}$  (11). On a une bonne représentation, d'après les variations de conductivités  $\lambda$ , des variations relatives de concentration ioniques globales, en fonction de l'avancement de l'hydratation. (FIGURE N° 2 A).

FIGURE 2 - EVOLUTION IONIQUE DES PHASES LIQUIDES INTERSTITIELLES

Il est évident que les conditions d'hydratation sont très différentes en suspension diluée (très grand excès d'eau) : la saturation n'est jamais atteinte, ce qui privilégie les phases solides hydratées intermédiaires, moins représentatives de celles des bétons frais avant prise. (FIGURE N° 2 B).

Il en résulte que pour caractériser une interface hors d'équilibre dans ces systèmes dynamiques, il faut à chaque instant relever simultanément TROIS GRANDEURS en fonction du TEMPS D'HYDRATATION :

- 1° Les variations relatives, continues, du potentiel ZETA dynamique (PZD),
- 2° Le pH (indication spécifique de la concentration  $\text{OH}^-$ ),
- 3° La conductivité ( $\lambda$ ) indication de la concentration globale.

Nota :

Il va de soi que l'analyse élémentaire de la phase liquide devra être également suivie si l'on veut, en présence des adjuvants, faire le bilan des ions qui participent à la structure de la double couche.

Les mesures et les calculs du PZD appliquées à de tels systèmes colloïdaux nous placent devant un problème très difficile de choix et d'accessibilité des paramètres expérimentaux vis à vis des pâtes consistantes ou des suspensions diluées. (TABLEAU I).

En pâte, la phase solide est bloquée et la seule détection électrocinétique possible est liée au déplacement de la phase liquide. Ce dernier nécessairement global, ne tient pas compte de l'hétérogénéité de la surface solide en rapport avec les différents composants minéraux présents. De surcroît, le faible volume de liquide interstitiel favorise une sursaturation trop rapide par rapport aux moyens de détection électrocinétiques et la "conductivité de surface" apportée par les solides devient une composante non négligeable et difficile à estimer. S'agissant d'une localisation de l'action spécifique des adjuvants toute spéculation sur le PZD "global" est alors hasardeuse.

TABLEAU I			
PARAMETRES	MOYENS DE CONTROLES	INCIDENCES SUR L'HYDRATATION	REMARQUES
TEMPERATURE	Contrôle thermostatique des suspensions et de la cellule de mesure.	Vitesse d'hydratation et d'hydratation	Action sur : viscosité - Constante diélectrique - Mobilité - Déplacement des phases liquides
TEMPS D'HYDRATATION	STOCKAGE CONTINU DES DONNEES EXPERIMENTALES EN FONCTION DU TEMPS (PZD - pH - $\lambda$ )	Degré de transformation des hydrates - Degré de sursaturation - Force ionique (pH, $\lambda$ )	Evolution continue de : - PZD et charges électriques - Forces d'interactions interparticulaires.
E/C	SUSPENSIONS DILUEES	- Temps d'hydratation écoulé. - Force ionique (pH, $\lambda$ ) - Analyse élémentaire des ions en solution (en fonction du temps)	- Phase liquide très diluée (force ionique faible)
	PATES CONCENTREES	Force ionique	Phase liquide
PETURBATIONS MECANQUES MALAXAGE			FORCE IONIQUE ELUVEE (Compression DC et abaissement PZD).
			PZD modifié non mesurable

En raison de ce qui précède et malgré des conditions d'hydratation différentes, il nous a paru beaucoup plus intéressant de nous orienter vers les suspensions diluées. Les différences de déplacements électrophorétiques des particules solides fournissent notamment des informations beaucoup plus sélectives quant à l'influence des composants minéraux.

Ce sont les variations relatives du PZD qui sont importantes (non leurs valeurs absolues) : il est impératif de réaliser des essais à la fois comparatifs et parfaitement normalisés. Les résultats expérimentaux présentés dans cette communication préliminaire sont limités, dans un premier temps, uniquement aux suspensions diluées.

#### IV. FACTEURS ET METHODES

Il n'est pas possible de suivre en continu les changements apportés au niveau de l'interface par le passage des suspensions diluées aux pâtes consistantes, ni de relier directement les systèmes statiques et dynamiques. Les principales techniques électrocinétiques connues, qui sont rappelées dans le TABLEAU II, sont complémentaires, mais leurs domaines d'utilisation se recouvrent peu.

Dans le cas de la microélectrophorèse des particules en suspension diluée sous un champ électrique horizontal et uniforme  $H$ , nous rappelons ci-après les facteurs et paramètres fondamentaux :

TABLEAU II						
TECHNIQUE EXPERIMENTALE	DOMAINE D'UTILISATION	TAILLE DES PARTICULES	CONTAINTE APPLIQUEE	PHASE MOBILE	MODE DE DETECTION	REMARQUES
MICROELECTROPHORESE	SUSPENSIONS DILUEES	0-2 $\mu\text{m}$ 0-15 $\mu\text{m}$	Champ électrique $H$ (V stabilisé)	Particules solides	M.O.N. et A.L.D.	Fouche stationnaire cylindrique - Sédimentation possible dans le plan stationnaire
TRANSFERT DE MASSE	SUSPENSIONS CONCENTREES	0-50 $\mu\text{m}$	Champ électrique $H$ (stabilisé)	Particules solides	Concentration relative de "surface" et force ionique élevée	Utilisable en synergie "dynamique" et "statique"
ELECTROPHORESE	PATES SUSPENSIONS FLOCCULEES	400 $\mu\text{m}$ 8 1000 $\mu\text{m}$	Champ électrique $H$ Contrainte physique	Phase Liquide	M.O.N. A.L.D.	Erreur par courants de "surface" - Conductivités des surfaces solides élevées
POTENTIEL DE FILTRATION					Potentiel électrique	
M.O.N. : Microscopie Optique Manuelle						
A.L.D. : Anémométrie Doppler Laser						

#### IV.1 Influence statistique du comptage électrophorétique sur les calculs de PZ et dimension des particules.

Au départ l'application d'un champ électrique uniforme  $H$  sur UNE particule solide entraîne un mouvement électrophorétique à la vitesse  $V_e$  ( $\mu\text{m/s}$ ), sur

une trajectoire horizontale en direction de l'électrode de signe contraire (dans un milieu liquide immobile ou  $V_L = 0$ ).

La mobilité électrophorétique a la dimension d'une vitesse par unité de champ  $H$  :

$$M_e = V_e / H \text{ } \mu\text{m/s/V/cm}$$

Tant que la force ionique du milieu dispersant reste inférieure à  $10^{-3}M$ , on calcule le PZ à partir de l'équation de HENRY (I) uniquement sur les particules inférieures à  $0,1 \mu\text{m}$  ( $F$  est le facteur de HENRY). En milieu plus concentré et au-dessus de  $0,1 \mu\text{m}$ , seule l'équation d'HELMHOLTZ - SCHMOLUKOVSKI (II) est utilisable.

$$(I) \text{ PZ}_{mV} = \frac{6 \pi \eta}{D(1+F)} M_e \quad (II) \text{ PZ}_{mV} = \frac{4 \pi \eta}{D} M_e$$

L'influence multiple de la température se retrouve ici au niveau des coefficients de viscosité ( $\eta$ ) et de la constante diélectrique ( $D$ ) du milieu dispersant.

Mais, la mobilité  $M_e$  doit être UNE MOYENNE statistique de 50 à 100 particules pour une suspension statique ce qui est insuffisant pour un système dynamique hétérogène. Or avec un champ  $H$  de 5 à 20 V/cm et des durées d'électrophorèse de 5 à 30 S, le temps de comptage  $\Delta T$  de 25 particules consomme déjà 15 à 30 minutes au cours de l'enregistrement, point par point, du PZD en fonction du temps.

L'influence de la taille des particules a lieu à deux niveaux :

- 1°) Sur l'épaisseur relative de la double couche ionique à travers le facteur de HENRY utilisé dans l'équation I, ci-dessus,
- 2°) Avec la combinaison à l'électrophorèse, d'un mouvement vertical, lié à la sédimentation, notable à partir de  $5 \mu\text{m}$ .

#### IV.2 Parabole de l'électroendosmose :

En considérant les mouvements des particules, à travers l'épaisseur totale de suspension, il est bien connu que la vitesse apparente  $V_e$  de chacune d'elles est une fonction parabolique de leur distance à la paroi latérale (12). Les parois des cellules de mesures fermées sont toujours également chargées et il y a un double courant liquide superposé à l'électrophorèse (déplacement au voisinage de la paroi compensé par un retour au centre de la veine liquide).

Si les particules sont détectées uniquement dans le plan focal optique et si ce dernier coïncide exactement avec la couche stationnaire située dans le plan de cisaillement séparant les deux courants liquides contraires, le déplacement liquide est nul et les vitesses électrophorétiques mesurées sont les vitesses vraies, mais seulement dans ce plan.

Aucun moyen ne permet de vérifier si le plan stationnaire est respecté : il doit être calculé et localisé avec un très grand soin.

#### V. MATERIEL EXPERIMENTAL

Son développement a été conditionné par deux objectifs prioritaires : combiner l'électrophorèse avec la sédimentation et traiter automatiquement les données expérimentales :

- 1°) Le fait d'accepter la composante verticale des déplacements permet de travailler sur une étendue granulométrique plus importante, donc plus représentative : il suffit de remplacer la veine liquide cylindrique par une cellule de mesure plane à parois verticales : la couche stationnaire concentrique devient un plan stationnaire vertical (le plan de KOMAGATA (12). FIGURE N° 3 A et B. Pendant l'électrophorèse, les mouvements des particules sont des bilans des composantes verticales et horizontales. Ces dernières c'est-

à-dire  $V_e$ ) ne sont pas sensiblement modifiées pour des composantes de sédimentation relativement faibles.

FIGURE 3 - COMBINAISON DE L'ELECTROPHORESE ET DE LA SEDIMENTATION DES GRAINS SUPERIEURS A  $5 \mu\text{m}$

- 2°) Pour arriver à réduire au minimum la durée de comptage  $\Delta T$  il est impératif de réaliser un stockage très rapide et de traiter automatiquement les données expérimentales suivantes :  $V_e$ ,  $H$ ,  $\text{pH}$ ,  $\lambda$ , temps d'hydratation.

Pour y arriver, nous avons adopté comme élément de base un appareil de microélectrophorèse classique de RANK BROS (Type MK II) spécialement aménagé pour suivre en continu l'hydratation des suspensions de ciment sans une enceinte thermostatique. Une réserve de suspension-mère permet de renouveler la cellule de mesure de suivre le  $\text{pH}$  et la conductivité sans apporter de perturbation.

#### Remarque :

Un autre mode de traitement électrophorétique automatique est en cours de développement : il s'agit de l'anémométrie laser doppler (ALD), qui procède d'une exploitation électronique de la lumière laser diffusée par les suspensions. Avantages :  $\Delta T$  négligeable ; double application possible à l'électrophorèse et à l'électrosmose (détection du mouvement liquide interstitiel).

#### VI. RESULTATS EXPERIMENTAUX

Nous avions d'abord vérifié sur des suspensions statiques et homogènes (QUARTZ-EAU) l'influence du temps sur l'équilibre ionique et des écarts de  $\text{pH}$  sur la dérive du PZ, lorsque l'interface est maintenue hors d'équilibre. La durée de stabilisation du PZ correspondant à l'équilibre dépasse fréquemment 25 à 45 heures et l'écart type est inférieur à  $5 \text{ mV}$ .

Par ailleurs, lorsque l'on fait varier très rapidement le  $\text{pH}$ , les écarts de potentiels obtenus peuvent atteindre du 15 à 20  $\text{mV}$ . (FIGURE N° 4).

Nous avons étudié l'hydratation des surfaces solides à partir de différentes suspensions de ciments et de minéraux purs. Dans chaque cas les évolutions de PZD,  $\text{pH}$ , conductivité ont été établies en fonction de la durée de l'hydratation à  $25^\circ\text{C}$  (FIGURES N° 5, 6, 7 et 9).

FIGURE 4 - SIMULATION D'INTERFACE DYNAMIQUE ET DERIVE DU PZD PAR RAPPORT AU PZ.

FIGURE 7 - SUSPENSION DE  $C_3A$  DÉJÀ HYDRATÉ 1 MOIS

FIGURE 5 - HYDRATATION DU  $C_3S$

FIGURE 8 - HYDRATATION DU CPA 55 (EX CPA 400)

FIGURE 6 - HYDRATATION DU  $C_3A$

FIGURE 9 - HYDRATATION DU CIMENT ALUMINEUX FONDU

La conductivité ( $\lambda$ ) est un moyen commode de capter le sens des variations relatives de la force ionique du milieu dispersant alors que le pH permet de spécifier celui des seuls ions OH. Les augmentations de pH et de conductivité partant de force ionique, vont généralement dans le sens d'un abaissement (en valeur absolue) du PZD en raison d'une diminution (par "compression") de l'épaisseur de la double couche.

La corrélation systématique des minima de PZD avec les pics de conductivité traduit bien plus l'influence ionique du milieu dispersant qu'une modification brutale des propriétés électrocinétiques des surfaces solides.

Les suspensions de C<sub>3</sub>A sont très difficiles à étudier en raison de leur floculation immédiate. Le signe du PZD paraît nettement positif alors que la suspension d'un produit déjà préalablement hydraté (FIGURE N° 7) donne une surface négative. Ceci confirme bien la prudente distinction qu'il faut faire avec les différents degrés d'hydratation intermédiaire.

Les valeurs retenues pour les PZD des suspensions étudiées sont résumées dans le TABLEAU III suivant :

TABLEAU III	
QUARTZ	KCl 10 <sup>-3</sup> M (pH = 5,5) PZ = -40mV ± 5
ALUMINE	KCl 10 <sup>-3</sup> M (pH = 8,0) PZ = -20mV ± 5
C <sub>3</sub> S	De 0 à 24 h : PZD = -9 à -11 mV
C <sub>3</sub> A * anhydre ** hydrate	De 0 à 5 h PZD = +9 à +22mV * PZD = -12 à -20mV **
CPA 400	De 0 à 24 h : PZD = -14 à -17 mV
CIMENT ALUMINEUX	De 0 à 24 h : PZD = -10 à -15 mV

La valeur statistique des moyennes effectuées sur les temps d'électrophorèse ( $V_e$ ) doit être considéré avec une très grande prudence : les histogrammes sont des polygones de fréquence assymétriques et aléatoires dans le temps qui traduisent bien l'existence simultanée de plusieurs types de particules chargées (et des surfaces de signes contraires) et l'apparition incessante de nouvelles phases hydratées. Cependant malgré cela l'écart entre les moyennes arithmétiques et statistiques ne dépasse pas 2<sub>mV</sub> mais l'écart type est beaucoup plus étendu (3 à 5<sub>mV</sub>).

## VII. CONCLUSIONS

Au cours de l'hydratation du ciment portland au moins cinq phases minérales sont présentes à la surface : C<sub>3</sub>S, C<sub>2</sub>S, C<sub>3</sub>A, C<sub>4</sub>AF et le gypse.

Le cas des suspensions diluées correspond à une hydratation en présence d'un très grand excès d'eau et les hydrates intermédiaires présents à la surface ont un PZD négatif, celui du C<sub>3</sub>S étant le plus faible.

Le C<sub>3</sub>A, au contraire, semble présenter un PZD très fortement positif suivant les conditions initiales de contact avec l'eau.

Compte tenu de l'inévitable hétérogénéité des surfaces solides apportées par les ciments et de la contribution des différentes phases minéralogiques, l'expression globale du PZD apporte des informations sans doute intéressantes quant à la résultante des interactions particulières, mais reste sans signification au niveau des corrections spécifiques recherchées à partir des adjuvants pour la mise en oeuvre des bétons frais. Il nous paraît indispensable de mieux connaître l'évolution du PZD de chacune des phases minérales les plus importantes ainsi que les ions qui participent à la structure des interfaces correspondante. A cet égard la suspension diluée n'est qu'une

première étape, mais essentielle.

De très nombreuses expériences sont encore nécessaires pour confirmer ces premiers résultats et les perspectives offertes par informatisation des données électrophorétiques avec, si possible, l'anémométrie laser (ALD) permettent d'espérer une exploration beaucoup plus rapide des suspensions de minéraux purs et en mélange.

# Study of kinetics of industrial cements hydration

## *Vitesse d'hydratation des ciments industriels*

R. KRSTULOVIC, T. FERIC, P. KROLO, Split, Yougoslavie.

RESUME : Ce travail a comporté l'application des connaissances théoriques et expérimentales les plus récentes concernant la cinétique de l'hydratation des clinkers à l'hydratation des ciments industriels.

On s'est attaché spécialement à suivre la cinétique de l'hydratation par des méthodes thermo et électrocinétiques. L'hydratation d'échantillons de divers ciments industriels a été étudiée au moyen de ces méthodes. La méthodologie choisie s'est avérée être très utile à des fins pratiques.

La cinétique de l'hydratation appliquée à des échantillons variés de ciments industriels est parfaitement adaptée au processus de la théorie générale de l'hydratation des composants minéraux du clinker pur et du ciment. Certaines hypothèses théoriques sur les caractères et les processus d'hydratation ont été contrôlées expérimentalement.

SUMMARY : The aim of our work has been to apply up to date theoretical and experimental knowledge about kinetics of pure clinker minerals hydration to hydration of industrial cements.

Special attention has been paid when following the kinetics of hydration by thermo and electrokinetic methods. Hydration of samples of various industrial cements has been investigated by means of these methods. The methodology chosen has proved to be very useful for practical purposes.

The kinetics of hydration for various samples of industrial cements fits the general theory of hydration processes for pure clinker mineral systems and cement very well. Some theoretical hypotheses have been proved by means of criterion theory as applied in research into character and type of hydration process.

## INTRODUCTION

The study of the kinetics and the mechanisms of reactions in the cement hydration process has led to many new conclusions that have explained in a more exact way the already classical theory of hydration, setting and hardening of cement. These data and results apply to the study of pure clinker mineral systems. Abundant experimental methods and equipment indicate a wide range of approach to the hydration of binding materials in order to adjust this process to the needs of the builders. In short, the science has already explained much about the phenomena in the cement hydration and their mechanisms and has calculated these processes mathematically [1, 2]. But what and how much of this can apply to the study of the industrial cements hydration? The examinations should be simple in their methodology and the equipment used but exact in measurements, and they should not differ much from the tests carried out according to the cement certificates.

## EXPERIMENTAL

Investigations were carried out in order to have a systematical study of the hydration processes in various types and qualities of industrial cements with simple instruments, equipment and testing methods. At the same time the results obtained were coordinated to the laws and phenomena in hydration reactions in pure clinker minerals and cement in general.

The samples were: portland cement of varying quality with additives, the metallurgical cement, the asbestos cement. The cements were taken from the factory. An alite sample and the synthetic cement clinker made of pure components of clinker minerals were used in comparison.

Method of work: calorimetrical and electrochemical measurements and chemical analyses.

Equipment and measuring instruments: Hydration heat was determined with a thermos bot-

tle calorimeter. The tests were carried out according to the JUS standard B.C8.027 1975 with automatic temperature and time reader. The electromotor force (EMF) i.e. pH was measured with the pH-meter Radiometar M22. The cement pastes were examined continuously with metal indicator electrodes (In, Bi) at isothermic conditions (20°C) with a referent saturated calomel electrode [3]. Setting time was measured with the Pb-Cu electrode system in isothermic conditions (20°C) by means of the Radiometar M22. The Vicat apparatus was used in comparison. The water-cement ratio was the same in both measurements: W/C = 0.30. Conductivity ( $L_g$ ) was measured discontinuously in suspensions (W/C = 4) with a conductometer type Iskra Kranj MA 5960.

## RESULTS

As the measurements showed equal reproducibility and applicability the results obtained for the most characteristic samples will be given here.

The experiments were to examine quantitatively and qualitatively the cement hydration process. The portland cement PC-550, the clinker mineral alite and the synthetic cement clinker of approximately identical phase composition as the PC-550 (73%  $C_3S$ , 13.8%  $C_2S$ , 6.4%  $C_3A$ , 6.3%  $C_4AF$ , 0.5% CaO) were chosen. Calorimetrical and electrochemical methods were used in measurements. The results are shown graphically in the Fig.1 (a = PC-550, b = synthetic cement clinker, c = alite).

The curves in Fig.1 can give us the following information on the hydration process in the function of time: the thermokinetic curves give qualitative and quantitative data on the rate and intensity of the hydration process. Three main processes are clearly discernible, corresponding to those described by Lerch and other authors using this method of examination of the kinetics and mechanisms of the hydration process. EMF measurements show the change in  $OH^-$  ions.

Fig.1 Comparison of methods for examination of the cement hydration kinetics in A) paste, B) suspension

concentration as a consequence of hydration of main components of the cement clinker  $C_3S$  and  $C_2S$  [3, 12]. A good choice of the metal indicator electrode is very important in obtaining clear and sharp changes in potential with time. In the case on Fig.1 the peaks of the calorimetric and electrochemical curves ( $EMF_m$ ) are coordinated well. The comparative results of EMF measurements in industrial cement, synthetic cement clinker and alite show that the difference in the change of EMF with time indicates varying degree of quality of the samples, i.e. their reactivity and thus the characteristics of the hydration process development. Conductivity ( $L_s$ ) measurements and determination of pH and CaO concentration were carried out on the filtrates of the suspension as shown in Fig.1B. CaO was determined in a complexometrical chemical analysis.

A very good agreement was noticed in our work with suspensions with regard to the difference in the methods for determination of the hydration development.

Calorimetric and electrochemical methods are very useful in examination of the hydration kinetics when testing the influence of the additives on the acceleration or retardation of the hydration process and setting of the

cement. Fig.2 shows these phenomena in the same cement samples as those in the previous experiment. The comparative measurements were carried out with Bi and Mo electrodes and various types and quantities of additives. The results are shown in Fig.2 (a = PC-550, b = PC-550 + additive plastificator /0.3%, c = PC-550 + additive retarder /0.6%/).

The curves in Fig.2 indicate the similarity and correlation of the calorimetric and electrochemical examinations. Both methods record the changes in the hydration process very well, i.e. they clearly outline the acceleration or retardation of the process in time. Fig.2 also shows the individual stages of the hydration process equal to those in cements without additives. The EMF curves, obtained with Mo and Bi electrodes follow one another very well, i.e. the typical changes in the potential take place at the same time in both cases, although the changes in EMF are clearer when the Mo electrode is used. The measurements show that the change in the potential i.e. pH is very rapid at the beginning of the hydration process. The potential increases rapidly, reaches its peak value and then decreases and rises again to its final values. The sudden changes of the potential at the beginning of

the process indicate the intensity of the hydration reactions and formation of new structures.

Fig.2 Comparative measurements of the influence of the additives on the cement hydration process, PC-550 W/C = 0.30 T = 20°C

The Pb-Cu electrode system was used to determine the beginning and the end of setting. The results were compared to those obtained by the Vicat method. Fig.3 shows comparative measurements of the PC-550 cement with and without additives. The marks in Fig.3 correspond to those in Fig.2. The shaded areas correspond to the measurement with the Vicat

needle.

Fig.3 Comparative setting measurements carried out with electrochemical and Vicat methods

The above measuring methods are important in the control of the cement production process. The calorimetric method in particular, can determine well the influence of production factors on the quality of the same cement type at different times. Fig.4 shows the difference in quality in cements produced at different times. In the case "a" the thermokinetic curves apply to various samples of asbestos cement produced from PC-450 + 20% slag, and the asbestos added in the laboratory. Sample 1 is pure PC-450 + 20% slag. The "b" series of samples is metallurgical cement with addition of 50% of slag.

Fig.4

## ANALYSIS OF THE MEASURED DATA

The value for the hydration degree transformation ( $\alpha$ ) was calculated from the calorimetric data and used for calculation of the hydration process rate constant /4, 5/.

Table I shows the results of these calculations carried out with the samples of asbestos and metallurgical cements.

S A M P L E 6				S A M P L E 7		
(h)	$\alpha$	$k_1 \times 10^{-2}$ (h <sup>-1</sup> )	$k_2 \times 10^{-2}$ (h <sup>-1</sup> )	$\alpha$	$k_1 \times 10^{-2}$ (h <sup>-1</sup> )	$k_2 \times 10^{-2}$ (h <sup>-1</sup> )
5	0.0523	0.895	3.86	0.1374	2.46	6.41

Table I - Hydration degree ( $\alpha$ ) and rate constants ( $k_1$ ,  $k_2$ ) in asbestos and metallurgical cements in the function of time

The data on the hydration degree and rate constants make it possible to assume quantitatively the factors influencing the development of the hydration process.

Calorimetric measurements have made possible the mathematical approach to the determination of the number of individual processes in the first stages of the cement hydration. The possible number of typical processes is calculated by means of the criterion theory for determination of the number of

phases in a multiphase system /6, 7/. Final values of these calculations expressed by means of the reliability factor ( $\bar{R}$ ,  $\bar{\Delta R}$ ) have shown that during hydration three or four basic individual (isolated) processes take place, these processes being responsible for the speed and the mechanisms of the total hydration process /6, 7/. Table II shows the calculated values for the reliability factor for the PC 450 + 20% slag sample.

Number of combinations	$\bar{R}$	$\bar{\Delta R}$	Number of combinations	$\bar{R}$	$\bar{\Delta R}$
123	17.85	29.911	245	0.02	0.003
124	0.02	0.008	345	27.40	45.958
125	0.04	0.012	1234	0.01	0.008
134	0.12	0.061	1235	0.03	0.021
135	0.04	0.021	1245	0.01	0.002
145	0.03	0.006	1345	0.03	0.014
234	0.09	0.043	2345	0.02	0.008
235	0.02	0.008	12345	0.01	0.004

Table II - Reliability factors in determination of the number of processes during hydration of PC-450 + 20% slag

In these measurements, the necessary number of samples (always one more than the assumed number of processes) was prepared by varying the additive content in the cement. The tests resulted in the hypothesis of the four process system.

In examination of the process kinetics, the influence of the temperature on the hydration heat releasing process was observed and

the temperature difference i.e. temperature coefficient ( $\epsilon$ ) was calculated. In order to calculate the temperature factor a corrected Arrhenius' temperature function was used./8, 9/. Table III shows the measured data and values for the temperature coefficient in observed temperature intervals for the sample of metallurgical cement with 50% slag.

Q cal/g	Equivalent time (h) at the temperature ( $^{\circ}\text{C}$ )				$\epsilon$ in intervals of time		
	20 $^{\circ}\text{C}$	30 $^{\circ}\text{C}$	35 $^{\circ}\text{C}$	40 $^{\circ}\text{C}$	20-30	30-35	30-40 $^{\circ}\text{C}$
4	5	2.8	2.0	-	11.95	10.3	-
22	13	9.1	7.7	6.2	19.43	20.7	18.1
41	25	14.9	12.8	10.2	13.39	22.8	18.3
48	32	17.4	14.5	11.9	11.38	19.0	18.2
53	40	19.0	15.7	13.0	9.31	18.1	18.3
56	46	20.2	16.5	13.6	8.42	17.1	17.5
69	-	26.0	20.8	16.2	-	15.5	14.7

Table III - Temperature coefficient ( $\epsilon$ ) for the metallurgical cement

The results obtained for the temperature coefficient indicate a deviation from the Rustrup's relation /10/ which has adjusted Arrhenius' equation for the cement hydration process. At higher temperatures increases for more than 10 $^{\circ}\text{C}$ . So, the value of the tem-

perature factor depends on the time as well. Its value changes in the various stages of the process. It becomes monotonously reduced in the indicated temperature areas./9/.

#### CONCLUSIONS

The above presented experimental data and measurements make it possible to connect the theory and the practice. The standardized procedure for determination of the hydration heat with the thermos bottle method gives valuable results which may serve as a basis for more exact explanations and remarks on the hydration process development. The differential curves contain individual stages describing the whole process from the beginning of the contact of cement with water, i.e. from the hydration, setting and hardening reactions.

The transformation hydration degree and the

rate of the reaction constants, describing individual change phases in the differential curves, can be calculated from the calorimetric data. This is a simple approach and can be applied well in everyday practice. The description of the hydration process kinetics and mechanisms can be coordinated well with examinations carried out on clinker minerals and cement systems.

The number of individual processes in the whole cement hydration process, determined by means of the basic equation of the criterion theory, serves as a basis for calculating the reliability factors which should be

lower than 0.05. This confirms mathematically the number of individual processes described in the differential curves. In a two-process system, the reliability factor is much higher than that allowed, while in a three-phase system it ranges from 0.01 to 0.03. In a four-process system,  $R$  decreases to 0.01, which means that the measurements showed 3 i.e. 4 individual processes in the cement hydration, analogous to the graphic representations of the kinetics. The explanation of individual processes agrees with those found in literature [1/].

The temperature coefficient varied and differed from 10 in the examined temperature intervals up to 40°C in metallurgical cements.

The differential curves for the metallurgical cements (Fig.1) show a third peak which is not caused by a later hydration of  $C_3A$ . When compared to the data found in literature, the same explanation was reached: the hydration mechanism in the metallurgical cements is caused by other phenomena and reactions, different from those in portland cement. [11/].

The calorimetric results, processes in a computer, prove this method to be appropriate for scientific research, as well as for quick practical information on the influence of various factors on the initial phases of the cement hydration process.

To obtain comparative measurements, the electrochemical method which showed good agreement with calorimetric results was used. The electrochemical measurements are simple in their methodology and equipment. The change in the potential of the metal indicator electrodes depend linearly on the change in the pH of the environment, which is caused by cement components hydration. The potential varies with the type of addition and additive to the cement, so that pH measurements indicate well their influence on the process of setting and hardening of cement. The measurements of the electrical conducti-

vity on the cement suspension filtrates show the conductivity to be changing quickly at the beginning of the hydration process. The changes are most intensive in the very area where the most intensive changes in pH and the total CaO concentration occur [12/].

Thermo- and electrokinetic measurements indicate the peaks of differential and electrokinetic curves (EMF) to take place at the same time, while the conductivity curves, due to the fact that the examinations were carried out on the suspension filtrates, show certain deviations, i.e. shifts of the peak in time in recording the effects described.

# Influence of Water-Soluble Melamine Formaldehyde Resin on Hydration of $C_3S, C_3A + CaSO_4 \cdot 2H_2O$ Mixes and cement pastes

*L'influence de la résine hydrosoluble de mélamine-formaldéhyde sur l'hydratation des pâtes préparées de  $C_3S$ , du mélange de  $C_3A + CaSO_4 \cdot 2H_2O$  et des pâtes de ciment*

SLANICKA Stěfan - Tchécoslovaquie.

RESUME : A l'aide de l'analyse par les rayons X et de l'analyse thermique différentielle, l'auteur a découvert l'effet retardateur de la résine hydrosoluble sulfoyée de mélamine-formaldéhyde sur le développement de l'ettringite et sur sa transformation en monosulfate. Ce phénomène correspond aussi à une teneur élevée de  $C_3A$  non encore transformé. L'influence retardatrice de la résine est plus importante si sa dose s'élève à 4 % que si elle n'est que de 1 %. Dans les pâtes contenant 1 % de résine, cet effet est très prononcé au cours des premières 24 heures; plus tard il disparaît; au contraire, une légère accélération de l'hydratation est constatée. Ce phénomène se traduit par un retard du processus d'hydratation des pâtes de ciment, par le ralentissement du dégagement de la chaleur d'hydratation et par l'augmentation de la durée de prise; celle-ci est d'autant plus grande que la dose de l'agent et le rapport eau/ciment sont plus élevés. L'influence retardatrice de la résine sur les premières étapes de l'hydratation des pâtes mentionnées ci-dessus contribue à l'intensification de son effet plastifiant.

SUMMARY : In the case of  $C_3A$  and  $CaSO_4 \cdot 2H_2O$  mix a spectacular retardation effect of the water-soluble sulphonated melamine formaldehyde resin on the development of ettringite and its transformation to monosulphate was disclosed by the X-ray phase analysis and differential thermal analysis. To this phenomenon corresponds also the higher contents of non-reacted  $C_3A$ . The retardation influence of the resin is substantially higher if the dose amounts to 4 % than for the 1 % dose. In  $C_3S$  pastes with 1 % resin the retardation effect is clearly apparent during the first 24 hours, later on it disappears, on the contrary a slight acceleration of the hydration takes place. To this correspond the indications of the retardation of the cement pastes hydration process such as the retardation of the development of the hydration heat and prolongation of the setting period which are the more spectacular the higher the admixture dose and the w/c ratio. The retardation effect of the melamine formaldehyde resin on the first stages of the hydration process of the above mentioned pastes obviously contributes to the intensification of the plastification effect.

The water-soluble sulphonated melamine formaldehyde resins with plastification effects may be used for acceleration of concrete hardening, if their plastification effect is utilized for the reduction of the quality of mixing water and this applies also for heat treated concrete /3/. In spite of the reduction of the quantity of mixing water the acceleration effect is not achieved immediately but only after a certain time. For this reason it is advisable to contribute to the clarification of the influence of the water-soluble sulphonated melamine formaldehyde resins on the hydration of clinker minerals and portland cement.

#### Used materials:

The following materials were used for the tests:

- tricalcium silicate with specific surface of  $3\,148\text{ cm}^2/\text{g}$ ,
- tricalcium aluminate with specific surface of  $4\,452\text{ cm}^2/\text{g}$ ,
- gypsum with 46,3 % of  $\text{SO}_3$  and with specific surface of  $4\,501\text{ cm}^2/\text{g}$ ,
- distilled water,
- water-soluble sulphonated melamine formaldehyde resin in the form of 20 % solution<sup>x</sup> /further on it will be referred to only as melamine formaldehyde resin/ with molecular weight of  $2 \cdot 10^4$  /1/.

#### Preparation of specimens

For the tests the specimens were made of a mix of  $\text{C}_3\text{A}$  and  $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$  with molecular ratio 4 : 3. For a contents of 11 % of  $\text{C}_3\text{A}$  in the portland cement this ratio corresponds to the contents of 2,34 % of  $\text{SO}_3$ . After a homogenization of the dry components 0,8 part by weight of distilled water was added to 1 part by weight of the mix. To the pastes containing the melamine formaldehyde resin its solution was added. The water contained in the solution of the resin was reckoned with as a part of the mixing water. The paste was wrapped in plastic foils to prevent both evaporation of water and influence of atmospheric marketed under the name Melment L 10, a product of Süddeutsche Kalkstickstoffwerke, Trostberg, German Federal Republic.

$\text{CO}_2$ . This storage allows, at the same time, to change mechanically the orientation of the specimens until their perfect hardening to prevent bleeding of the mix.

The following pastes were manufactured for the tests:

- reference paste with water alone,
- paste including 1 % of dry substance of the melamine formaldehyde resin by weight of  $\text{C}_3\text{A} + \text{CaSO}_4 \cdot 2\text{H}_2\text{O}$
- paste including 4 % of dry substance of the melamine formaldehyde resin by weight of  $\text{C}_3\text{A} + \text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ .

The samples of the pastes were taken after 2, 4, 6, 24 and 48 hours, dried by washing in acetone and by subsequent washing in ether.

Furthermore, the following  $\text{C}_3\text{S}$  pastes were made for the tests:

- paste containing 1 part by weight of  $\text{C}_3\text{S}$  and 0,7 part by weight of water,
- paste containing 1 part by weight of  $\text{C}_3\text{S}$ , 0,7 part by weight of water and 0,32 % of dry substance of the resin by weight of  $\text{C}_3\text{S}$ ,
- paste containing 1 part by weight of  $\text{C}_3\text{S}$ , 0,7 part of water and 1 % of dry substance of the resin.

The pastes were sampled after 1, 3, 7 and 28 days, they were also dried by washing in acetone and ether.

#### Test results

The X-ray diffraction analysis was made with the Mikrometa 2 apparatus manufactured by Chirana, Czechoslovakia. The X-radiation was monochromatized by an Ni filter.

Figs 1 to 3 show the results obtained by testing pastes of  $\text{C}_3\text{A} + \text{CaSO}_4 \cdot 2\text{H}_2\text{O}$  mix.

Table II shows the results obtained by tests of  $\text{C}_3\text{S}$  pastes.

The complex thermal analysis was made using the apparatus Derivatograph made by the firm MOM, Budapest.

The results are tabulated. When evaluating the pastes made of the  $\text{C}_3\text{A} + \text{CaSO}_4 \cdot 2\text{H}_2\text{O}$  mix the endotherm used for evaluation was according to Midgley and Rosaman /2/ at about  $150^\circ\text{C}$  characteristic of ettringite and about

250° C characteristic of monosulphate.

Evaluation of results and their discussion.

Paste made of  $C_3A + CaSO_4 \cdot 2H_2O$  mix.

As early as after 2 hours of hydration of the paste without resin admixture the gypsum is practically absorbed by the formation of ettringite on the detriment of the initial components  $C_3A$  and the gypsum. The process goes on under intensive development of monosulphate so that successively after 24 hours and 48 hours  $C_3A$  is practically absorbed and similarly the ettringite contents

Fig. 1 Paste  $C_3A + CaSO_4 \cdot 2H_2O + H_2O$

has dropped whereas the monosulphate contents has increased /Fig. 1/.

As little as 1 % of dry substance of the resin retards the hydration /Fig. 2/, it is, however, not so spectacular as if the resin dose amounts to 4 % of the dry substance /Fig. 3/.

In this case the retardation of the monosulphate development is clearly visible; all over the period of 48 hours its contents varies only little. A pronounced retardation is visible as late as after 28 days. To this

		2,19	56	32	28	24
1 %	$Ca(OH)_2$ $C_3S$	4,90	7	40	60	80
		2,19	50	32	28	19

Table III.

$Ca(OH)_2$  contents in  $C_3S$  pastes according to thermal analysis results

Time /day/	$Ca(OH)_2$ contents in % by weight of paste		
	reference paste	paste containing resin admixture	
		0,32 %	1 %
1	13,0	11,0	1,4
3	16,5	17,2	17,2
7	19,9	21,0	20,9
28	21,9	22,0	22,3

fact corresponds the higher contents of the non-reacted  $C_3A$  in comparison with the preceding pastes. The melamine formaldehyde resin retards the hydration of the paste of  $C_3A + CaSO_4 \cdot 2H_2O$  mix as well as the ettringite to monosulphate transformation.

A comparison of Figs 1, 2 and 3 shows clearly that the retardation influence of the resin on the hydration process increases with increasing dose of the resin. The results of the thermal analysis /Tab. I/ roughly confirm the results of the X-ray analyses.

#### $C_3S$ paste

The admixture of 1 % of dry substance of the resin slows down the initial course of hydration of the  $C_3S$  pastes. The retardation effect of the melamine formaldehyde resin is accompanied with pronounced plastification effects on the fresh nonhardened paste. The retardation of the hydration of paste containing 1 % of the resin is spectacular during the first 24 hours which is also shown by the X-ray analyses /Tab. II/ as well as by the thermal analysis /Tab. III/.

Later, during the subsequent days, this retardation effect vanishes and in the case of pastes containing the resin certain marks of hydration acceleration in comparison with the pastes without resin admixture appear. The retardation effect of the resin on the hydration of the  $C_3S$  pastes depending on the admixture of the resin is, however, visible and if the doses of the resin amount to 0,32 % the results of the thermal analyses exhibit only an insignificant retardation after the first 24 hours.

#### Comparison with tests of cement pastes

Supplementary tests of initial set of two thirds of the portland cement pastes have shown that:

- if the w/c ratio is low /corresponding to normal density of the cement paste/ and if the plastification effect of the resin on the reduction of the quantity of the mixing water is used, the doses of the dry substance of the resin up to 1 % do not cause any changes in the initial set and the

period of setting,

- if the w/c ratio of the reference pastes and the pastes containing the resin is kept constant, the increasing resin dose and the increasing w/c ratio causes prolongation of the initial set and of the period of setting of cement pastes.

The supplementary tests have also shown that the admixture of the melamine formaldehyde resin slows down the development of the hydration heat of the cement.

The results obtained with the cement pastes correspond to the results obtained with  $C_3S$  and mixes of  $C_3A + CaSO_4 \cdot 2H_2O$  pastes.

#### Conclusion

The melamine formaldehyde resin slows down distinctly the hydration of pastes consisting of  $C_3A + CaSO_4 \cdot 2H_2O$  mix particularly the transformation of ettringite to monosulphate.

If the dose is higher /4 % of the dry substance of the resin/ this influence is substantially more spectacular than if the dose is lower /1 %/. The melamine formaldehyde resin slows down for a dose of 1 % the hydration of a paste of  $C_3S$  even after 24 hours, whereas during the subsequent days this retardation effect vanishes away and even certain indications of hydration acceleration appear.

If the admixture of the resin amounts to 0,32 % of the dry substance only, the retardation effect is hardly noticeable.

At the same time, a distinct plastification effect of the resin on fresh pastes has been recorded.

The retardation effect of the resin on the first hydration stages of the  $C_3S$  pastes and the  $C_3A + CaSO_4 \cdot 2H_2O$  mix contributes to the improvement of the plastification effect.

The above mentioned results agree with the results obtained during the investigation of the development of hydration heat and the process of setting of cement pastes.

# Agglutination (bridging) of Particles during Hydration Hardening and the Effect of Surface Active Additives

## *Agglutination des particules pendant l'hydratation et le durcissement des ciments. Influence des Ajouts tensio-actifs*

E.D. SHCHUKIN, Professor, Colloid Chemistry Dept. Moscow State University, USSR, The Institute of Physical Chemistry Acad. Sci. USSR,

E.A. AMELINA, Associate Professor, Colloid Chemistry Dept., Moscow State University,

E.P. ANDREEVA, Doctor of Chemical Sciences, Coll. Chem. Dept. MSU,

S.I. KONTOROVICH, Doctor of Chem. Sciences, Inst. of Phys. Chemistry Acad. Sci., USSR.

RESUME : La prise d'un liant minéral implique l'agglutination des particules individuelles. On a mesuré la force de cohésion entre ces particules (gypse, quartz, calcite ou silicate) dans diverses conditions de phase (amorphe ou cristallisée) dans des solutions sursaturées. On a observé une relation étroite entre la probabilité d'agglutination de particules semblables ou différentes et les paramètres physico-chimiques de base, responsables de la prise et du durcissement du ciment.

Le mécanisme de l'effet plastifiant des carbohydrates, au cours de l'hydratation des ciments Portland a été étudiée. On a observé que cet effet provient de l'adsorption des carbohydrates à la surface des grains anhydres et des nouveaux hydrates formés. On suggère que le mécanisme de l'adsorption du saccharose et du tregalose est commandé par leur capacité d'adsorption et leur effet plastifiant, compte tenu des nouveaux hydrates formés.

SUMMARY : The hydration hardening (setting) of mineral binding agents involves agglutination of individual particles. The force of cohesion between such particles (gypsum dihydrate, quartz, calcite and silica) was measured under the conditions of new phase (crystalline and amorphous) formation in supersaturated solutions. The results reveal the dependence of probability of agglutination of similar and different particles on the basic physico-chemical parameters responsible for the conditions of hardening.

The mechanism of the plastisizing effect of carbohydrates in hydration hardening of Portland cement constituents was studied. The effect was found to arise from the adsorption of carbohydrates on the surface of the anhydrous solid phase and newly formed hydrates. The suggested mechanism of adsorption of saccharose and tregalose accounts for their different adsorption capacity and plastisizing effect with respect to newly formed hydrates of various composition.

### 1. Experimental Study on Agglutination of Individual Particles.

Current physico-chemical theories of hardening attribute the formation of strong disperse structures (artificial stone) in plastic suspensions of mineral binding agents to the appearance of contacts, sometimes called bridging or agglutination, between particles of the newly formed phase (1). Thus the formation of individual contacts between particles during the emerging of a new phase attracts special interest. The corresponding studies should apparently be based on the ideas of the new phase formation put forward in the classical works of Gibbs and Volmer. A stage-by-stage theoretical description of the process of hardening has been given in (2).

This section of our paper deals with experimental investigations of elementary acts of agglutination of individual particles (crystalline and amorphous), i.e. the formation of primary contact bridges between them, under a variety of conditions depending on such parameters as supersaturation, the duration of contacting, the nature of particles and the presence of surfactants.

The instrument used was described elsewhere (3). It permits direct measurements of cohesion force in the individual contacts between particles over the range as wide as from  $10^{-5}$  to  $10^2$  dynes. The materials included  $5 \times 5 \times 0.5$  mm gypsum dihydrate crystals cleaved out of single crystals and particles of amorphous silica which were deposited onto the surface of fused quartz threads about 2 mm in diameter by means of precipitation from freshly prepared silicic acid sols. During the experiments two samples (gypsum crystals or silica-covered quartz threads) were brought into contact in the corresponding supersaturated solutions (of calcium sulphate or silicic acid) and were allowed to stay in a fixed position for a certain period. Measured was the force necessary to separate the samples. We shall call this force, which is equal to the cohesion force in the contact, the contact strength. Gypsum crystals were brought into contact by edges of certain crystallographic symbols (one edge normally to the other); silica-covered threads in the contact were mutually perpendicular.

Since the strength of contacts appearing under identical conditions is scattered over a wide range, it appeared necessary to carry out the statistical analysis of the results and to consider the corresponding distributions. Fig.1 presents some of our data in the form of histograms, i.e. the dependences of the differential function of distribution on the logarithm of strength (and are the current and the total number of measurements respectively). The analysis of the histograms shows that crystalline and amorphous particles alike form contacts of two types with sharply different strengths. These are "weak" contacts with  $10^{-2}$  dyne which correspond to the case when the particles merely touch one another and "strong" ones with  $10^{-1}$  dyne which cor-

Fig.1. Differential histograms of strength.

respond to agglutination (bridging) of the particles. The strength of the latter contacts arises from the short-range forces of cohesion acting on the area considerably exceeding that of a unit cell. The weak-to-strong contacts transition occurs in a jump-like manner and manifests as the second (right-hand) maximum in the histograms and the absence of contacts with strength from  $10^{-2}$  to  $10^{-1}$  dynes. The sharpness of the transition makes it possible to notice the fact of agglutination and thus study the probability of agglutination as a function of various physico-chemical factors. Such results may provide for deeper insight into the intimate mechanisms of agglutination (bridging), by probability of which we mean the ratio of the number of experimentally observed cases when it had taken place to the total number of experiments on bringing particles into contact and separating them under the given conditions.

As is seen from Fig.1, the probability of agglutination increases with the time the particles are staying in contact. Table 1 indicates that increases also with supersaturation of the solution (where and are the concentrations of the solutions supersaturated and saturated respectively with respect to gypsum and silica).

TABLE 1.  
Probability of agglutination of particles  
, %, at different supersaturations

Particles	1.2	1.4	1.5	1.8	3.0
Gypsum	17	-	24	49	83
SiO <sub>2</sub>	16	52	-	68	81

Such a dependence makes it possible to relate the elementary act of agglutination with the fluctuation formation of a nucleus-contact critical for the given supersaturation. The rapid growth of the nucleus-contact is the main process responsible for the jump-like change of the contact strength or, in other words, for the sharp transition to a different

type of contact.

We should note that in such experiments it is hardly possible to measure the strength due to the nucleus-contact itself (the primary contact bridge). Since the critical nucleus-contact is in mobile equilibrium with the supersaturated solution, a minor increase in its size results in spontaneous crystallization in the contact zone and in rapid growth of the contact strength. And the very fact of agglutination is well detectable from the sharp transition from "weak" contacts to the "strong" ones.

The analysis of experimental data on the basis of corresponding mathematical processing (3) has shown their qualitative agreement with the fundamentals of the fluctuation theory of new phase formation (4). This enabled us to estimate such energetical and geometrical parameters of the agglutination process as the work of formation ( ) and the size of the nucleus-contact and to establish the dependence of the probability of agglutination on the variable parameters of the experiments (3). Table 2 presents the values of calculated from the experimental data; also given are the values of the work of formation for gypsum two-dimensional (surface) nuclei calculated according to (2).

TABLE 2.

Agglutination of gypsum and silica particles: the works of nucleus-contact formation.

Particles	1.2	1.4	1.5	1.8	3.0
Silica	2.8	1.5	-	-	0.5
Gypsum	6.7	-	5.9	5.3	4.3
	45	-	22.5	15	8.5

Table 2 shows that the values of obtained are quite reasonable from the standpoint of the fluctuation theory of new phase formation. In particular, they are, as predicted by the theory, lower than the values of . The linear dimensions of the critical nucleus-contact in both systems at all the supersaturations studied were estimated as 4--9 Å.

Our results thus indicate that the formation of bridge contacts in supersaturated solutions obeys one and the same mechanism for both crystalline and amorphous particles.

Similar experiments were also performed for the case when different crystals were contacting (gypsum and calcite, fluorite or quartz), and when two quartz crystals were brought into contact in supersaturated calcium sulphate solutions. It was shown (3) that all these experiments involved agglutination of crystals and, as its first stage, the fluctuation formation of a nucleus-contact. These results suggest that the so-called inert fillers may actually behave as active structure-building elements taking part in the contact formation according to the contact bridge mechanism.

The process of hardening and the strength of the appearing structures are often controlled with the help of surfactants. Their effects are usually attributed to the influence on the dissolution kinetics, the level of supersaturation and the morphology of the newly formed crystals. In terms of contact formation, the role of surfactants may amount to changing the conditions of agglutination via chemical modification of the surface of the particles and affecting the properties of the solution. In our study the chemical modification of the surface was carried out so that the properties of the solution were virtually unchanged. It was shown that the process of agglutination may be hindered by octadecylamine and gelatine. For instance, the modification of gypsum crystals by octadecylamine and gelatine adsorption from aqueous solutions decreases the probability of agglutination from 67% (at  $t=1.8$  and  $t=1000$  sec) to 36% and 29% respectively. A similar effect is observed in agglutination of gypsum crystals with crystals of quartz previously hydrophobized by gaseous dimethyldichlorosilane, and in gypsum agglutination with quartz in the presence of octadecylamine and gelatine (3).

## 2. The Adsorption Effect of Plastisizing Carbohydrate Additives.

Owing to their capacity of affecting structure formation processes of mineral binding agents, surfactants are widely used in building industry. Carbohydrates belong to the surfactants exerting pronounced plastisizing effects, tregalose being a weaker decelerator than saccharose (5,6). In order to investigate the mechanism of the carbohydrate effects we have studied the processes of tregalose and saccharose adsorption in hydrating suspensions of individual binding agents such as tricalcium silicate  $3\text{CaO} \cdot \text{SiO}_2$  ( $\text{C}_2\text{S}$ ), tricalcium aluminate ( $\text{C}_3\text{A}$ ), tetracalcium aluminoferrite ( $\text{C}_4\text{AF}$ ) and monocalcium aluminate ( $\text{CA}$ ).

Data on the kinetics of concentration changes in the liquid phase of hydrating suspensions of various minerals indicate that the adsorption capacities of saccharose and tregalose may be either sharply different or virtually identical. As is seen from Fig. 2, in suspensions of  $\text{C}_2\text{S}$  and  $\text{C}_3\text{A}$  the decrease in saccharose concentration with time due to adsorption is far more pronounced than that of tregalose. In  $\text{C}_4\text{AF}$  suspensions, however, the adsorption of tregalose on the appearing hydrates is almost as high as that of saccharose. During the initial three hours of monocalcium aluminate hydration in solutions of either carbohydrate the adsorption is insignificant. In 24 hours the adsorption of saccharose (the decrease in concentration) comes to exceed that of tregalose.

Comparison of our data on the adsorption of carbohydrates with the information on hydration products in the systems studied (7,8) shows that the adsorption of tregalose in  $\text{CA}$  and  $\text{C}_4\text{AF}$  suspensions is likely to be so high (almost reaching the value of saccharose adsorption) because these systems contain  $\text{Al}(\text{OH})_3$  and  $\text{Fe}(\text{OH})_3$  hydrogels respectively. In con-

Fig. 2. The decrease in concentration of saccharose (o) and tregalose (□) in hydrating suspensions of binding agents  $C_2S$  (1,2),  $C_3A$  (3,4),  $C_4AF$  (5,6), CA (7,8). Initial carbohydrate concentration 0.01%. Composition of suspensions 2 g mineral in 100 ml carbohydrate solution.

fast to this, calcium-containing hydrates adsorb saccharose much more intensely than tregalose. To explain these facts let us consider the structure of the adsorbing molecules. The structural formulas of the two carbohydrates are rather similar, but the fructose ring in the saccharose molecule makes it asymmetrical, while tregalose has a symmetrical molecule. Adsorption on hydrophilic surfaces is markedly dependent on the hydroxy-groups of both molecules, which are capable of forming hydrogen bonds or even, if dissociation is involved, ionic bonds with the adsorbent surface (9,10). In the saccharose molecule the hydroxy-group in the vicinity of two oxygen atoms is very active and readily yields a proton. The tregalose molecule contains no group of similar activity. The evident consequence is the different capacity of forming ionic bonds with the adsorbent surface. Dissolved carbohydrate molecules may take different conformations. As they are approaching the surface, however, the conformation is determined by the orientation of the molecule and by the conditions of adsorption. In principle, a carbohydrate molecule may be oriented towards the surface of the adsorbent in either a "plane" or an "edge" manner (Figs. 3a and 3b). The "edge" orientation does not require any essential conformation changes, while the "plane" orientation is energetically favourable only provided the molecule takes a certain conformation. Namely, the pyranose ring should change its "chair" conformation, which is more favourable for the free molecule, for the "bath" conformation. Fig. 3a shows that in the "plane" orientation saccharose and tregalose face the ad-

Fig. 3. Schematic of saccharose (1) and tregalose (2) adsorption. (a) "Plane" orientation of the carbohydrate molecules towards the adsorbent surface, (b) "edge" orientation, (c) the adsorption of saccharate-cation  $CaC_{12}H_{21}O_{11}^+$  on a calcium-containing surface.

sorbent surface with approximately the same number of adsorption-active groups (hydroxy-groups and the oxygen atoms of the nuclei). In this orientation the carbohydrates considered should therefore manifest approximately the same adsorption capacity. It appears that the adsorption on hydrogel surfaces involves namely this orientation. In alkaline environment the negative surface charge of hydrogels promotes the formation of hydrogen bonds between the OH-groups of the carbohydrates and the oxygen atoms of the adsorbent. Apart from hydrogen bonds, coordination bonds are formed between the carbohydrate oxygen atoms and the metal atoms of the surface (Fig. 3a). The carbohydrate adsorption is the higher the greater is the complex formation capacity of the metal, i.e. adsorption on the  $Fe(OH)_3$  gel (in  $C_4AF$  suspensions) is greater than on  $Al(OH)_3$  (in CA suspensions). In the "edge" orientation the strength of saccharose bonds with the mineral surface is quite different from that of tregalose bonds (Fig. 3b). The above-mentioned asymmetry of saccharose and the presence of a particularly dissociable OH-group in its molecule promotes formation of ionic and hydrogen bonds with the host surface. Tregalose in this orientation can not form such strong bonds.

It seems likely that the adsorption of carbohydrates on the surface of calcium hydroaluminates and hydrosilicates requires the "edge" orientation in which the adsorbing active groups better fit the metal atoms of the lattice and the saccharose hydroxy-group may easier form a bond with the lattice calcium. The probability of formation of ionic bonds between the carbohydrate and the surface grows with the number of calcium atoms on the surface and with pH, since at higher pH the surface acquires a negative charge which favours saccharose dissociation as an acid.

In hydrating suspensions of mineral binding agents the pH is high and the liquid phase contains, along with neutral carbohydrate molecules, saccharate anions and calcium saccharates. Of these, only the  $\text{CaC}_{12}\text{H}_{21}\text{O}_{11}^+$  cation can compete with neutral saccharose molecules in active adsorption on the mineral surface. At the same pH tregalose, which contains no hydroxy-group as active as that of saccharose, is far less likely to form a similar cation. The adsorption of  $\text{CaC}_{12}\text{H}_{21}\text{O}_{11}^+$  on the surface of calcium-containing hydrates leads to the neutralization of the surface charge by virtue of formation of ionic bonds between calcium and the lattice oxygen (Fig.3c). The adsorption of these cations vs. that of neutral molecules is thus enhanced by electrostatic attraction. Therefore, at high concentrations of  $\text{CaC}_{12}\text{H}_{21}\text{O}_{11}^+$  (as by hydration of minerals in saccharose solutions saturated by  $\text{Ca}(\text{OH})_2$ ) its adsorption would somewhat suppress the adsorption of the neutral molecules. Bruere (5) suggested that tregalose is less effective than saccharose as a decelerator of Portland cement setting because of its higher stability in alkaline environment. He believes that the adsorption capacity of carbohydrates is determined by the presence of the  $\text{HO}-\text{C}-\text{C}=\text{O}$  group. In these terms any monosaccharide must be more active as an adsorbate than saccharose. Our results, however, indicate that glucose in hydrating suspensions of  $\text{C}_3\text{S}$  is less active than saccharose. Moreover, we have found that inversion of saccharose even in saturated  $\text{Ca}(\text{OH})_2$  solutions is low and the resulting minor amounts of glucose and fructose can not play any active part in adsorption.

Carbohydrates adsorb not only on the surface of hydrate phases, which causes their comminution and prevents recrystallization of metastable hydrates into stable ones, but also on the surface of anhydrous minerals. This is evidenced by our results on the adsorption of carbohydrates from alcohol solutions. The adsorption isotherms for saccharose are S-shaped and reversible; for tregalose they are of Z-shape. The adsorption of saccharose from alcohol solutions exceeds that of tregalose.

The carbohydrate-induced deceleration of dissolution of anhydrous hydrolyzable minerals may cause changes in the ionic composition of metastable solutions resulting from hydration and thus affect the chemical composition of the newly formed hydrates.

#### CONCLUSIONS

Analytical processing of the results of direct measurements of cohesion forces between individual particles (crystalline and amorphous) in supersaturated solutions supplies evidence that the initial stage of agglutination, i.e. the formation of the first bridge-contact, obeys the fluctuation mechanism. The dimensions of the nucleus-contact and the work of its formation have been estimated. The effect of surfactants on agglutination of gypsum dihydrate crystals has been studied.

The plastisizing effect of carbohydrates,

which consists in deceleration of dissolution of the anhydrous binding agent and the crystallization of newly formed hydrates, arises from the formation of screening layers from small crystals of newly formed hydrates and the adsorption layers of carbohydrates. The adsorption capacity of disaccharides (saccharose and tregalose) depends on the chemical nature of the adsorbent, on the orientation of the carbohydrate towards the surface (in a "plane" or "edge" manner) and on the capacity of yielding ions in alkaline media, which are capable of increased adsorption due to electrostatic attraction.

## The stiffening of mortar accompanied with the early hydration of cement

### *Le raidissement du mortier accompagnant l'hydratation initiale du ciment*

M. ONO, Senior Research Engineer, Research and Development Laboratory,  
M. NAGASHIMA, Senior Research Engineer, Mitsubishi Mining and Cement Co., Ltd.,  
M. SAITO, Research Engineer, Tokyo, Japan.

**RESUME :** Le raidissement, c'est à dire la diminution de plasticité du mortier frais, a été déterminé par l'essai de la pénétration, et on a étudié sa relation avec l'hydratation initiale du ciment.

La résistance à la pénétration, déterminée dans des conditions appropriées, est adoptée comme mesure du raidissement initial du ciment.

Les expériences ont été menées sur des mortiers et des pâtes préparées à partir des ciments de Portland, selon divers mélanges réalisés à partir des clinkers cuits dans les fours électriques du laboratoire.

Le raidissement du mortier est en corrélation avec la quantité d'eau de combinaison dans le ciment hydraté, c'est à dire le degré d'hydratation du ciment. Dans le cas du ciment sans alcali, la formation d'ettringite augmente principalement la quantité d'eau de combinaison.

$K_2O$  dans le ciment augmente la quantité d'ettringite, réduit sa dimension cristalline, et, par conséquent, provoque l'augmentation du raidissement.

**Summary :** Stiffening, i.e. decrease in plasticity of fresh mortar was determined with a penetration test and its dependence on the early hydration of cement was investigated. The penetration resistance determined under the appropriate condition is adopted as a measure of the stiffening accompanied with the early hydration of cement.

Experiments were carried out on the mortars and pastes prepared from portland cements with various composition which made of clinkers burned in the laboratory electric furnace.

The stiffening of the mortar correlates with the amount of the combined water of hydrating cement, i. e. the degree of hydration of cement.

In the case of alkali free cements, the combined water in the hydrated cement arises mainly from ettringite.

$K_2O$  in cement increases the amount of ettringite, reduces its crystal size and consequently brings about increasing the stiffening of the fresh mortar.

## INTRODUCTION

Fresh mortar or concrete stiffen gradually losing its plasticity. The decrease in plasticity is small quantity in the early hydration stage and it is rather difficult to detect its change in the short time. The modified penetration test of mortar was devised and the stiffening, i.e. the decrease in plasticity up to about an hour after the mixing of mortar was measured. The results were related to the early hydration of cement.

## THE MEASUREMENT OF THE STIFFENING

The plasticity of mortar was determined by the penetration resistance test.

The cylindrical plunger with the hemispherical bottom is caused to penetrate the mortar placed in the cylindrical container with a certain speed and the resistance is measured employing the load cell.

The ratio of the cross section of the plunger to that of the container is  $1/3$ . In a certain range of the penetration depth, the increase in the resistance is almost constant. When the resistance is determined at a definite depth under this condition, the ratio of the resistance,  $R$ , at any time up to about one hour to that,  $R_0$ , immediately after the mixing is dependent on cement used for mortar and usually almost independent of the mix proportion of mortar or the grading of sand.

Therefore, this resistance ratio is adopted as a measure of the stiffening accompanied with the hydration of cement. The resistance at 5 minutes after the gauging was used as  $R_0$  and that at 70 minutes as  $R$ , and the ratio of  $R/R_0$  was regarded as the measure of the stiffening.

## EXPERIMENT

Preliminary experiments carried out using cements with various composition which were made of clinkers burned in the laboratory electric furnace revealed that the  $C_3A$  and  $K_2O$  content of cement might influence the stiffening. Hence, the dependence of the

stiffening on the hydration of cement was investigated using cements with various  $C_3A$  and the  $K_2O$  content prepared in similar manner as above. Three experimental series are as follows.

Series A : The  $C_3A$  content of clinkers varies from 5% to 14% and alkali is free.

Series B : The  $C_3A$  content of clinkers is similar to that in series A and clinkers contain about 0.7%  $Na_2O$  and about 0.9%  $K_2O$ .

Series C : The  $K_2O$  content of clinkers varies from 0.4% to 1.1% and the  $Na_2O$  and  $C_3A$  content are respectively about 0.7% and 9%.

The mixture of the reagents were burned in the laboratory electric furnace and then clinkers were ground with 4.3 % gypsum to the Blaine value of  $3000 \text{ cm}^2/\text{g}$ . The mortars were made of Japanese sand for the strength test of cement. S/C and W/C of the mortars are respectively 1.0 and 0.35-0.40.

In addition to the mortars, cement pastes with W/C of 0.4 were prepared for the determination of the amount of combined water and ettringite in hydrating cement. The hydration was stopped at 5 and 70 minutes after the gauging.

The combined water was measured by the loss on ignition at  $1000^\circ\text{C}$ . The amount of ettringite was determined by quantitative XRD employing the X-ray diffractometer with a strong X-ray tube which has a rotating target. The calibration curve was made using the mixtures of a unhydrated cement and the ettringite which was prepared from  $C_3A$  and gypsum. The notation  $W_d$  and  $E_d$  will be used to designate the increment of the combined water and the ettringite from 5 to 70 minutes.

## RESULTS

The results of experiments on the resistance ratio of the mortar and the amount of the combined water ( $W_d$ ) in the cement paste are summarized in Fig. 1. As a whole the stiffening increases with the combined water. In both series A and B, the stiffening depends on the  $C_3A$  content and

alkali presence.

Fig. 1 Relationship between the ratio of penetration resistance and the amount of combined water

In series A, the stiffening increases with the  $C_3A$  content showing minimum at about 9 %  $C_3A$ , but in series B decreases linearly. Fig. 2 shows the relationship between the amount of ettringite ( $E_d$ ) and the amount of the combined water ( $W_d$ ) in the paste.

A dotted line represents the combined water upon ettringite. In series A where the cements contain no alkali, the amount of the combined water is directly proportional to that of the ettringite and line vicinity of the dotted line in Fig. 2. Therefore, the increase of the stiffening is mainly attributed to the formation of ettringite in the case of alkali free cement. However, the amount of ettringite scarcely varies in series B where the cements contain alkali, although the amount of the combined water varies considerably. Since both effect of alkali and  $C_3A$  exists in series B, the effect of alkali should be obtained in series C.

Fig. 3 shows the relationship between the amount of combined water ( $W_d$ ) in the paste and the  $K_2O$  content of clinker in series C. The combined water increases with the  $K_2O$  content. Since the combined water is composed of that upon ettringite and that upon hydrate except ettringite, they are

plotted separately in Fig. 3.

Fig. 2 The amount of ettringite against combined water

It is shown that  $K_2O$  increases mainly the combined water upon ettringite up to about 0.8 %  $K_2O$  and increases the combined water upon hydrate other than ettringite above about 0.8 %  $K_2O$ .

Because the stiffening increases with the combined water as shown in Fig. 1, it is suggested that  $K_2O$  in cements may increase the stiffening by the acceleration of the formation of ettringite and the other hydrate. As mentioned above, the resistance ratio increases with the amount of the combined water which varies with the  $C_3A$  content or the  $K_2O$  content in clinker.

Fig. 3 Relationship between the amount of combined water and  $K_2O$  content of clinker

As shown in Fig.1, the  $K_2O$  content of cements affects strongly on the relation

between the resistance ratio of mortars and the combined water. From the observation of the hydrated cement by SEM, it is shown that  $K_2O$  more than 0.5 % makes ettringite very fine. It is supposed from this fact that the increase in the surface area of the ettringite may make the mortar to stiffen.

#### CONCLUSION

The stiffening of the mortar up to about one hour after the mixing correlate with the increase in the combined water. Therefore, the stiffening arises from the hydration of cement. In the case of the alkali free cement, this hydration reaction is mainly the formation of ettringite.  $K_2O$  in cement increases the combined water upon ettringite and that upon the hydrate other than ettringite and reduces the crystal size of ettringite. As the result of these effects,  $K_2O$  in cement increases the stiffening of the mortar.

# On the mechanism of Hydration Hardening of Portland Cement Ferrite Phase

## *Mécanisme de l'hydratation et du durcissement de la phase ferritique des ciments Portland*

R. SANZHAASUREN, Professor, Ulan-Bator State University, Mongolia,  
E.P. ANDREEVA, Doctor of Chemical Science, Moscow State University, USSR,  
N. STUKALOVA, Candidate of Chemical Sciences, Moscow State University, USSR.

RESUME : Le processus de la formation d'une structure et les réactions chimiques dans les pâtes de  $C_4AF$  ont été étudiés à 5, 25 et 50°C. On a examiné l'action de l'hydroxyde de calcium, du gypse et du chlorure de calcium sur ce processus.

On a observé que  $C_4AF$  subit une hydratation rapide, suivie d'un lent durcissement dû à la recristallisation de l'hydroaluminoferrite tétracalcique  $C_4A.F_{1-x}H_{1.3}$ , dans la solution en aluminoferrite tricalcique  $C_3A.F_{1-x}H_6$ . La résistance de cette structure, d'apparence dispersée, dépend des facteurs affectant l'hydratation du  $C_4AF$  et de la cristallisation des hydrates (température, dispersion du  $C_4AF$  ...).

Le gypse et le chlorure de calcium modifient la composition chimique des hydrates et leur effet est alors commandé par la cinétique du développement des structures dispersées, à base d'hydro-sulfo ou d'hydrochloroaluminat ferritique de calcium. L'hydroxyde de calcium ralentit l'hydratation du  $C_4AF$  et les hydrates qui se forment successivement font la transition entre le métastable et le stable. Les résultats obtenus permettent de prévoir le comportement de la phase ferritique du ciment Portland, à divers âges d'hydratation, dans l'eau, et dans des solutions aqueuses de chaux, de gypse, et de chlorure de calcium.

SUMMARY : The structure formation processes and chemical interactions in tetracalcium aluminoferrite ( $C_4F$ ) pastes at 5, 25 and 50 C have been studied. The effect of calcium hydroxide, gypsum and calcium chloride on these processes has been investigated.

It was found that  $C_4AF$  undergoes rapid hydration followed by slow hardening due to the recrystallization of tetracalcium hydroaluminoferrite  $C_4A.F_{1-x}H_{1.3}$  through the solution into tricalcium aluminoferrite  $C_3A.F_{1-x}H_6$ . The strength of the appearing disperse structures depends on the factors affecting the hydration of  $C_4AF$  and the crystallization of hydrate phases (temperature, dispersity of  $C_4AF$ , etc.).

Gypsum and calcium chloride change the chemical composition of the hydrates and their effect is thus determined by the kinetics of development of disperse structures based upon calcium hydrosulpho- or hydrochloroaluminoferrites. Calcium hydroxide decelerates the hydration of  $C_4AF$  and the metastable-to-stable transition of newly formed hydrates. The results obtained make it possible to predict the behaviour of Portland cement ferrite phase at various stages of hydration in water and in aqueous solutions of calcium hydroxide, gypsum and calcium chloride.

The chemical processes involved in hydration of  $C_4AF$  have been extensively investigated by Carlson (1), Schwiete (2), Malquori and Cirielli (3) and other workers. However essential, their information yet does not suffice for the explanation of the very process of hardening. To develop a quantitative theory of hardening of mineral binding agents one has to know, as suggested in pioneer works by Reh binder and Segalova (4), the mechanism of disperse structure formation from newly formed hydrate phases. Thus our studies concerned with both structure formation and chemical interactions involved in  $C_4AF$  hydration under various conditions depending on the dispersity of  $C_4AF$  and on temperature.

According to our X-ray analysis and thermographic data the first product of  $C_4AF$  hydration in water at 5, 25 and 50 C is hexagonal tetracalcium hydroaluminoferrite which in due course recrystallizes into cubic tricalcium hydroaluminoferrite. Carbonate fillers do not stop the recrystallization as reported in (4) but rather decelerate it due to the epitaxional effect of calcite which stabilizes the hexagonal phase.

The  $Fe_2O_3/Fe_2O_3+Al_2O_3$  ratio in the mixed crystals of cubic hydroaluminoferrite decreases as the temperature is raised from 5 to 50 C (Table 1).

TABLE 1. Unit cell parameters and mole ratios  $Fe_2O_3/Fe_2O_3+Al_2O_3$  in cubic tricalcium hydroaluminoferrite resulting from the hydration of  $C_4AF$ .

This effect arises from the shift of the equilibrium  $FeO_2^- + 2H_2O \rightleftharpoons Fe(OH)_3 + OH^-$

to the right-hand side and the corresponding increase in  $FeO_2^-$  concentration in the liquid phase. On addition of calcium hydroxide to  $C_4AF$  pastes the  $F/A+F$  ratio in hexagonal and in cubic calcium hydroaluminoferrite increases. This is due to the fact that the solubility of iron in its anionic form grows with pH<sub>5</sub> (according to (5),  $HFeO_2^- / OH^- = 2.5 \cdot 10^{-5}$ ).

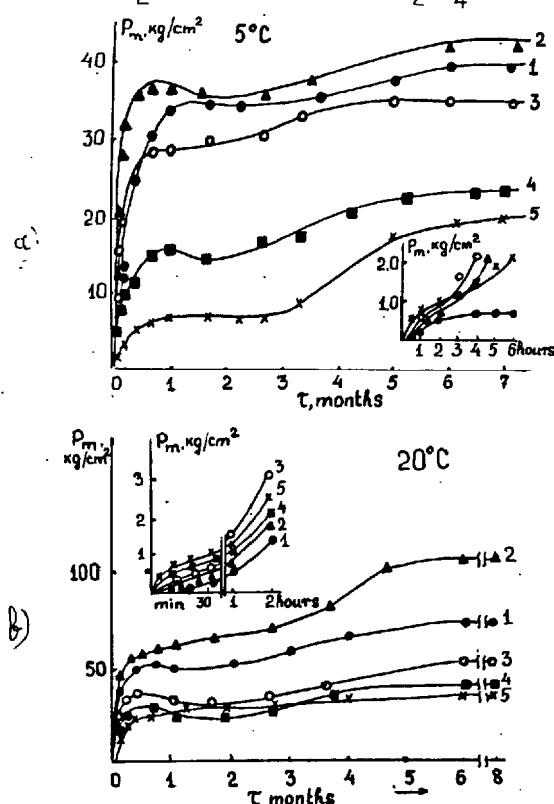

Hexagonal tetracalcium aluminoferrite which crystallizes in  $C_4AF$  suspensions with the molar ratio  $Ca(OH)_2/C_4AF = 2$  at 5 C has the parameter  $a = 5.82 \pm 0.02$  Å. According to (5) this value of  $a$  corresponds to the  $F/A+F$  molar ratio 0.48-0.52 (0.5 on the average). During the hydration process this ratio was constant over the range of  $C_4AF$  dispersities from  $1.9 \cdot 10^3$  to  $8.0 \cdot 10^3$  cm<sup>2</sup>/g. (Table 2).

Calcium hydroxide decelerates the hydration of  $C_4AF$  and the phase transitions of newly formed hydrates. By analogy with the  $CaO-Al_2O_3-H_2O$  system (6) it seems likely that the higher is the concentration of calcium hydroxide, the smaller is the difference between the solubilities of hexagonal and cubic hydroaluminoferrites. Therefore the dissolution of the hexagonal phase brings about lower supersaturations with respect to the cubic hydrate thus decelerating its crystallization and phase transitions. In saturated  $Ca(OH)_2$  solutions at temperatures below 50 C  $C_4A_0.5F_{0.5}H_{1.3}$  displays long-term stability and at 5 C no recrystallization into  $C_3A_0.5F_{0.5}H_{1.3}$  was observed for 8 months.

The process of  $C_4AF$  hydration involves the development of crystallization disperse structures of hardening (Fig. 1a, b and c).

Fig.1. Structure formation in 5%  $C_4AF$  pastes of various dispersity + 95% fine calcite powder + 28 ml  $H_2O$  at various temperatures. a - 5 C, b - 20 C, c - 50 C. The curves correspond to 1 -  $1 \cdot 10^3$ , 2 -  $1.9 \cdot 10^3$ , 3 -  $2.7 \cdot 10^3$ , 4 -  $5.5 \cdot 10^3$ , 5 -  $8.0 \cdot 10^3$   $cm^2/g$  dispersity.  $P_m$  is strength as measured by conical plastometer (16),  $P_m \sim R_{compr}$ .

The increase in strength due to the phase transitions of newly formed hydrates is uneven and continues when the hydration of anhydrous  $C_4AF$  is over. Depending on the temperature and on the dispersity of the binding agent  $C_4AF$  hydration in water takes from 1 to 15 days. The processes of post-hydration structure formation last for several months. During the post-hydration strength increase the role of the initial binding agent is played by the metastable hexagonal phase crystallized during the hydration of  $C_4AF$ . This is evidenced by the fact that destruction of  $C_4AF$  hardening suspensions after the hydration is over does not prevent the crystallization structure from further development. Moreover, such destruction increases the final strength of the system, apparently on account of partial relaxation of internal stresses emerging during hydration. Over the temperature range from 5 to 50 C not only the kinetics of strength development but also the final strength of the system based upon cubic and hexagonal calcium aluminoferrites are strongly affected by the dispersity of the initial  $C_4AF$ . The final strength vs. dispersity curve has a maximum whose position and shape are markedly dependent on active supersaturation in the liquid phase during and after the  $C_4AF$  hydration period. Our studies have shown that  $C_4AF$  belongs to the type of binding agents which display no metastable solubility during hydration (7). The supersaturation provided by such binding agents increases with the initial active surface. In  $C_4AF$  suspensions the increase in supersaturation leads to an increase in the specific surface of the crystallizing hexagonal phase and, accordingly, in the active supersaturation during the hexagonal-to-cubic phase recrystallization in the post-hydration period.

Supersaturation with respect to newly formed hydrates is responsible for the probability that the growing crystals agglutinate to form

a disperse structure. On the other hand, high supersaturations increase internal destructive stresses which result from the crystallization pressure of growing agglutinated crystals. Owing to this ambivalent effect of supersaturation there exists an optimum dispersity of  $C_4AF$  ( $1900 \text{ cm}^2/g$ ) which provides for the highest strength of the structures formed by metastable and stable phases.

During the initial period of hardening the strength growth rate increases with temperature, as does the hydration rate. Thus the strength of the structures of hardening is the greatest when they are formed at 20 C. The low final strength at 50 C results from the after-hydration strength drop which appears to be due to the increase in cubic hydroaluminoferrite solubility with temperature and, accordingly, to the dissolution of thermodynamically unstable crystallization contacts. Our results indicate that the hydration hardening of  $C_4AF$  is basically similar to that of tricalcium aluminate (4). Due to recrystallization of metastable hexagonal newly formed hydrates into stable cubic hydrates the strength in  $C_4AF$  systems grows unevenly and also has a maximum at a certain dispersity of the binding agent. In contrast to  $C_3A$ , however, the absolute values of  $C_4AF$  final strength are considerably higher and the phase transitions of newly formed hydrates do not involve such sharp strength drops as in the case of  $C_3A$ . This difference evidently arises from the formation of highly disperse hydroxides of iron and aluminium during  $C_4AF$  hydration. The hydroxides decrease the number of agglutination contacts between crystals and relax internal stresses thus promoting the formation of stronger structures.

In saturated  $Ca(OH)_2$  solution the crystallization of tetracalcium hydroaluminoferrite and its recrystallization into tricalcium hydroaluminoferrite also involves formation of disperse structures of hardening (8). In the light of current concepts of hardening of mineral binding agents this fact implies that the hexagonal-to-cubic recrystallization occurs via the liquid phase. Over the range of temperatures studied (from 5 to 50 C) the strength of the structures of hardening based on the hexagonal phase was a maximum when they had been formed at 5 C ( $Ca(OH)_2$  was added in an amount sufficient for binding all the initial  $C_4AF$  into  $C_4AF \cdot x \cdot aq$ ). The strength growth rate and the final strength of hexagonal phase structures were growing as the dispersity of  $C_4AF$  was increased from  $1 \cdot 10^3$  to  $8 \cdot 10^3 \text{ cm}^2/g$ . The final strength of these structures decreased as the temperature was raised from 5 to 20 and further to 50 C. This effect appears to arise from the decrease in active supersaturation with respect to  $Ca(OH)_2$  which, in its turn, is brought about by the decrease in equilibrium solubility of  $Ca(OH)_2$ .

The recrystallization of the hexagonal phase into the cubic phase at 20 and at 50 C leads to the increase in the strength of the system. In mixed structures based on the hexagonal and on the cubic phase the strength is a maximum when  $S=5500 \text{ cm}^2/g$  at 20 C and  $S=1900 \text{ cm}^2/g$  at

50°C (the initial mole ratio  $\text{Ca(OH)}_2/\text{C}_4\text{AF}$  was equal to 5). Thus the strength growth kinetics and the final strength of the structures resulting from  $\text{C}_4\text{AF}$  hydration in the presence of  $\text{Ca(OH)}_2$  depend on the phase composition of newly formed hydrates, on the ratio between them in the system, the temperature and dispersity of  $\text{C}_4\text{AF}$ .

X-ray phase and thermographic investigations of  $\text{C}_4\text{AF}$  hydration in the presence of gypsum performed in our laboratory (9) have shown, in agreement with (10,11) that the composition of newly formed hydrates is dependent on  $n$ , the initial molar ratio between gypsum and  $\text{C}_4\text{AF}$ . At  $n=4$  the trisulphate form of calcium hydroalumoferrite ( $\text{C}_3\text{A}_0.7\text{F}_0.3\text{S}_2\text{H}_2\text{O}$ ) crystallizes over the entire hydration period. The F/A ratio in this compound was inferred from X-ray analysis data with the help of the dependence of unit cell parameters  $a$  and  $b$  on this ratio reported by Bobrov (11). As long as free gypsum is present in the system, the only newly formed hydrate is the trisulphate. If the amount of gypsum added does not suffice to transfer all  $\text{C}_4\text{AF}$  into the trisulphate, a monosulphate form of calcium hydrosulphoalumoferrite starts to crystallize after all the gypsum is bound. The monosulphate may crystallize only provided simultaneous dissolution of the trisulphate and anhydrous  $\text{C}_4\text{AF}$  occurs:  $\text{C}_4\text{AF}$  supplies the necessary  $\text{Al}_2\text{O}_3$  while the trisulphate is a source of gypsum. As  $\text{C}_4\text{AF}$  dissolves more rapidly than the trisulphate, the initial  $\text{C}_4\text{AF}$  partially undergoes hydration and forms tetracalcium hydroalumoferrite which is isomorphic to the monosulphate form of calcium hydrosulphoalumoferrite and forms a solid solution with it as a result of simultaneous crystallization. Namely this solid solution and tetracalcium hydroalumoferrite are the products of crystallization of  $\text{C}_4\text{AF}$ +gypsum suspensions with  $n=4$  after all the gypsum is bound. The content of either component in the solid solution depends on the ratio between the hydration rates of the trisulphate form of calcium hydrosulphoalumoferrite and  $\text{C}_4\text{AF}$ . The solid solution, whose general formula is  $3\text{CaO} \cdot x\text{Al}_2\text{O}_3 \cdot (1-x)\text{Fe}_2\text{O}_3 \cdot y\text{CaSO}_4 \cdot (1-y)\text{Ca(OH)}_2 \cdot 12\text{H}_2\text{O}$  contains the more monosulphate the greater is the amount of the trisulphate resulting from the initial crystallization and, accordingly, the overall dissolution rate of the trisulphate. At  $n=1$   $y=0.92$ , at  $n=0.5$   $y=0.82$ . The composition of the crystallizing solid solution was evaluated on the grounds of comparing its unit cell parameter  $c$  with the corresponding parameter of various solid solutions of the monosulphate form of calcium hydroalumoferrite with tetracalcium hydroalumoferrite reported by Schwiete (10). No recrystallization of the monosulphate, of tetracalcium hydroalumoferrite or of their solid solution into tricalcium cubic hydroalumoferrite was observed in course of six months. In the simultaneous presence of gypsum and  $\text{Ca(OH)}_2$  the composition of the metastable and stable phases and the sequence of their crystallization during  $\text{C}_4\text{AF}$  hydration were the same as if only gypsum were present in the system (12). This fact becomes clear when one considers  $\text{C}_4\text{AF}$  hydration at low  $n$ , when the relative rate of gypsum binding is high. At

$n=0.25$  and  $0.5$  in the presence of  $\text{Ca(OH)}_2$  the first reaction product to crystallize is the trisulphate form of calcium hydroalumoferrite which in due course undergoes complete transformation into the monosulphate form (or its solid solution with  $\text{C}_4\text{AF}$ ,  $\text{H}_{1/2}$ ) and tetracalcium hydroalumoferrite,  $x_{1-x_{13}}$ .

The deceleration of  $\text{C}_4\text{AF}$  hydration and gypsum binding by  $\text{Ca(OH)}_2$ , in its turn, brings about the deceleration of phase transitions of the trisulphate into the monosulphate (or its solid solution with  $\text{C}_4\text{AF}$ ,  $\text{H}_{1/2}$ ). In the presence of  $\text{Ca(OH)}_2$  at  $n=1$  this process takes as long as two years (vs. four months without  $\text{Ca(OH)}_2$ ). At the same time the joint effect of  $\text{Ca(OH)}_2$  and gypsum consists in sharp deceleration of  $\text{C}_4\text{AF}$  hydration. For instance, at  $n=6$  and  $n=3$  the endothermic effects characteristic of gypsum dihydrate are present in the thermograms of the samples after two years of hydration, while in the absence of  $\text{Ca(OH)}_2$  these effects disappear in the thermograms in one month at  $n=3$  and in half a year at  $n=6$ .

In the presence of gypsum the hydration and hardening of  $\text{C}_4\text{AF}$  are dependent on the processes of formation of disperse structures from the trisulphate form of calcium hydroalumoferrite, tetracalcium hydroalumoferrite and its solid solution with the monosulphate form. They are also dependent on the phase transitions accompanying the decomposition of the trisulphate (Fig. 2 a and b).

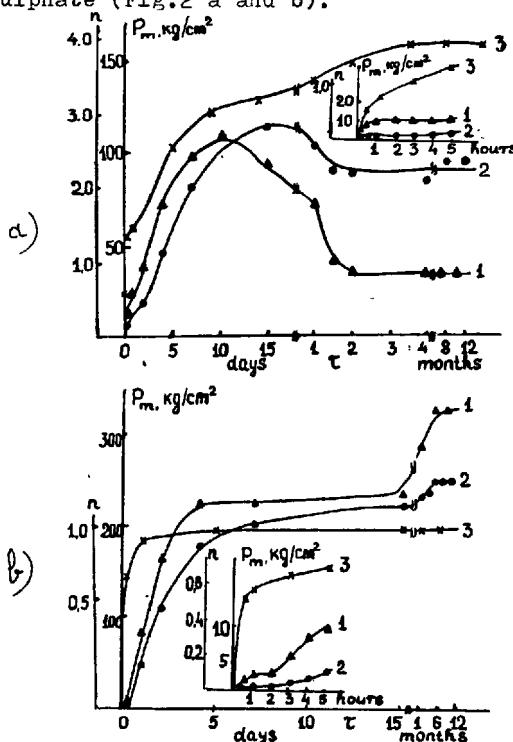

Fig. 2. Time dependences of strength (1,2) and  $n$ , the amount of bound gypsum (3) in  $\text{C}_4\text{AF}$  pastes with gypsum, calcite and water. The initial gypsum/ $\text{C}_4\text{AF}$  mole ratio  $m=4$  (Fig. 2a) and  $m=1$  (Fig. 2b). The water/solid ratio  $w/s=0.18$  (curve 1) and  $0.22$  (curve 2).

The formation of disperse structures of hardening from the trisulphate involves the development of appreciable internal stresses revealed by the strength "drops" observed until the  $C_4AF$  hydration is finished and increasing as the water/solid ratio decreases. In the beginning of  $C_4AF$  crystallization, when the supersaturation in the liquid phase is high, the trisulphate structure of hardening is formed by very small crystals connected by numerous contacts. Being thus relatively weak, it undergoes destruction under the effect of the internal stresses. At  $n = 4$  the initial crystallization of the trisulphate also does not lead to any appreciable strength increase. The strength grows primarily during the period of phase transitions involved in the decomposition of the trisulphate crystals in the course of  $C_4AF$  further hydration, when the solution yields the monosulphate form of calcium hydrosulphoalumoferrite, its solid solution with  $C_3A, F_1$  and  $C_4AF$  itself. The final structure of the hardened  $C_4AF$ +gypsum suspensions is determined by the phase composition of newly formed hydrates, their ratio in the mixture and the conditions of crystallization.

On addition of  $Ca(OH)_2$ , the general crystallization and hardening behavior of the structures based on the trisulphate form of calcium hydrosulphoalumoferrite, the monosulphate form and its solid solution or mixture with  $C_3A, F_1$  .aq does not essentially change (13). However, on formation of sulphate-rich films on the  $C_4AF$  surface its hydration sharply decelerates, as does the phase transition associated with decomposition of the complex salt. Thus the low strength period in the system becomes considerably longer.

In  $C_4AF$  suspensions containing gypsum the addition of  $Ca(OH)_2$  is not so detrimental to final strength as in  $C_3A$  suspensions. One may think in this case that the weakening effect of internal stresses which increase with active supersaturation with respect to  $Ca(OH)_2$  is counterbalanced by the increase in the amount of hydrate phases resulting from the reaction between  $Ca(OH)_2$  and  $Al_2O_3$ .aq (Fe $_2O_3$ .aq), the hydroxides being the product of the initial stage of  $C_4AF$  hydration.

It is widely believed that ettringite may be formed either by crystallization from the solution or by solid phase reactions. In the former case ettringite is thought to crystallize in the pores of the structure at early stages of hydration and to contribute to the strength of the system, while in the latter case a destructive effect is assumed. Our data, however, contradict to these ideas by indicating that at early stages of hydration ettringite is incapable of forming disperse structures of hardening.

In  $C_4AF$  pastes containing gypsum calcium chloride accelerates the crystallization of the trisulphate form of calcium hydrosulphoalumoferrite ( $n = 4$ ) and therefore causes a strength increase at early stages of hydration. On the other hand, in the presence of  $CaCl_2$  the supersaturation with respect to

the binary salt increases. The result is the increase in internal stresses and the decrease in final strength. At  $m = CaSO_4/C_4AF = 4$  the first product of hydration in the presence of  $CaCl_2$  is  $C_3A, F_1 \cdot Cs_2H_{12}$ . In the course of  $C_4AF$  further hydration this salt decomposes to yield calcium hydrochloroalumoferrite, the compound which is responsible for the basic increase in strength (like in the case of  $C_4AF$  hydration in  $CaCl_2$  solutions (14,15)).

#### CONCLUSION.

The information obtained in this study and concerning with the processes of structure formation, i.e. with the development of disperse structures of hardening based upon newly formed  $C_4AF$  newly formed hydrates crystallizing in water and in the solutions of calcium hydroxide, gypsum and calcium chloride, is in line with the theory presenting hydration hardening of mineral binding agents as a process consisting of consequent stages, namely the dissolution of the binding agent, the formation of solutions supersaturated with respect to the newly formed hydrates and the crystallization of the hydrates resulting in a crystalline agglomerate. The strength of disperse structures based on  $C_4AF$  (the ferrite phase of Portland cement) may be controlled by changing the conditions of  $C_4AF$  hydration and of crystallization of hydrate phases, as well as by changing the chemical composition of the hydrates.

## Early hydration of calcium silicates: surface phenomena

### *L'hydratation initiale des silicates de calcium: phénomènes de surface*

I. JAWED, D. MENETRIER and J. SKALNY Martin Marietta Laboratories, Baltimore, Maryland, U.S.A.

RESUME: Le mécanisme de l'hydratation initiale des silicates de calcium hydrauliques n'est pas encore bien élucidé. On tente d'interpréter des résultats expérimentaux obtenus par spectroscopie de photoélectrons (ESCA) et par microscopie électronique à haute résolution (STEM).

Les résultats montrent qu'il se forme une couche riche en silice à la surface des grains de  $\beta$ -C<sub>2</sub>S et C<sub>3</sub>S au cours des premiers instants de l'hydratation. Rien n'indique que cette couche est uniforme, par contre, on observe que la dissolution et la formation des hydrates sont localisées.

SUMMARY: The mechanism of the initial hydration of hydraulic calcium silicates is still inadequately understood. An attempt is made to interpret experimental data obtained by electron spectroscopy for chemical analysis (ESCA) and high-resolution electron microscopy (STEM, scanning mode).

The data show that in the very early stages of hydration, a Si-rich surface is obtained for both  $\beta$ -C<sub>2</sub>S and C<sub>3</sub>S. No evidence was found for the existence of a uniform layer of surface hydrate, but there was evidence of localized dissolution and formation of hydration products.

## INTRODUCTION

Performance of portland cement in concrete depends to a large degree on the interaction of calcium silicates with water because they constitute approximately 80 percent of the cement clinker. Although they react with water at very different rates, the mechanisms of their dissolution and the subsequent formation of hydration products are believed to be similar.

The cementing action of clinker minerals results from the products of their hydrolysis being less water-soluble and having a larger volume than the anhydrous phases. Thus, for calcium silicates, the hydration products, C-S-H and calcium hydroxide, precipitate into the water-filled space and consequently decrease the porosity of the system.

Details of the initial interaction of calcium silicates with water are complex and only partially understood. Several mechanisms have been proposed to explain these phenomena. They may be classified as protective hydrate theories (1,2), lattice defect theories (3,4), nucleation theories (5-7), and osmotic pressure theories (8,9). They differ in the interpretation of the dissolution phenomena, the reasons for the existence and termination of the induction period, and the sequence of formation and composition of hydration products. An attempt has been made recently by Taylor (10) to unify the various views.

The mechanism of the early stages of hydration clearly depends on the processes occurring on the solid-liquid interface and, thus, can be studied by appropriate physico-chemical techniques. The purpose of this paper is to interpret ESCA and high-resolution SEM results in view of the available data on the early hydration of  $C_3S$  and  $\beta\text{-}C_2S$ .

## EXPERIMENTAL

For spectroscopic studies, we used a Physical Electronics Model 548 Auger/ESCA spectrometer, featuring a double-pass cylindrical mirror analyzer, an ultra-high vacuum system, and a magnesium-anode X-ray source. The surface morphology was studied with a JEOL JEM-100 CX Scanning Transmission Electron Microscope (STEM), that has bright and dark fields, and microprobe and electron diffraction capabilities. In the present study, we used the SEM mode with 30 Å resolution. Other papers (11,12) give details of the  $C_3S$  and  $\beta\text{-}C_2S$  sample preparation, use of instrumentation, and data interpretation.

Whenever possible, the same samples were used for both the spectroscopic and electron optical experiments. To eliminate errors in interpretation due to sample preparation, we took precautions to avoid carbonation and to assure the reproducibility and accuracy of data.

## RESULTS AND DISCUSSION

Morphological Studies

It has been shown (11,12) that the surfaces of  $C_3S$  and  $\beta\text{-}C_2S$  prior to contact with water contain no impurities. Upon contact with water, minute hydration products (approximately 200-400 Å) form on the surface: with time, these particles grow in amount but not in size. In  $C_3S$  hydration, the particles cover — although not continuously — the whole surface, whereas their formation on  $\beta\text{-}C_2S$  surfaces seems to be more localized, both at room temperature and at 50°C (Fig. 1). Simultaneously, etching or corrosion of the surfaces becomes visible. This is more pronounced for  $C_3S$ , most probably because of its easy dissolution in water (Fig. 2).

Fig. 1.  $\beta\text{-}C_2S$  hydrated at 25°C for 15 seconds. Magnification: x20,000 (stereo).

Fig. 2.  $C_3S$  hydrated at 25°C for 15 minutes. Note the beginning of formation of Type II C-S-H and etching of surface. Magnification: x20,000.

$\beta\text{-}C_2S$  reacts at a lower rate — this is clearly shown by the much easier detectability

of the various surface phenomena. The minute hydration products are already visible after 15 seconds of hydration and are formed mostly, but not exclusively, at grain boundaries that became exposed by preferential dissolution. Only selected surface localities are covered by hydration products, and dissolution of the surface is not uniform. Some grains or their parts dissolve faster than others. At no time did we detect the existence of a uniform protective surface layer that has been claimed to be responsible for the induction period of  $\beta$ -C<sub>2</sub>S and C<sub>3</sub>S hydration (1,2).

As the hydration progresses, the surfaces of the two hydraulic calcium silicates become more etched, and hydration products resembling Type II C-S-H form (13). This happens for C<sub>3</sub>S at 25°C after about 30 minutes (Fig. 3), for  $\beta$ -C<sub>2</sub>S at 25°C after a few days, and for  $\beta$ -C<sub>2</sub>S at 50°C at about 18-24 hours (Fig. 4). These hydrates are not unlike the gel formed at initial stages of C<sub>3</sub>A hydration, as reported by Breval (14).

Fig. 3. Surface of C<sub>3</sub>S, hydrated at 25°C for 30 minutes, covered by Type II C-S-H. Magnification:  $\times 20,000$ .

Fig. 4.  $\beta$ -C<sub>2</sub>S hydrated at 50°C for 24 hours. Magnification:  $\times 30,000$ .

### ESCA Studies

ESCA scans of calcium silicates give peaks for oxygen, calcium, and silicon (Fig. 5).

Changes in the position, shape, and intensities of these peaks would indicate changes on the surface due to hydration. ESCA spectra show definite changes on the C<sub>3</sub>S and  $\beta$ -C<sub>2</sub>S surfaces as soon as they come in contact with water. This is most clearly indicated by changes in the position and shape of the O<sub>1s</sub> peak and the intensities of the Ca<sub>2p</sub> and Si<sub>2p</sub> peaks.

Fig. 5. ESCA spectrum of C<sub>3</sub>S.

In unhydrated and sputtered C<sub>3</sub>S samples, the O<sub>1s</sub> peak at  $532 \pm 0.2$  eV is symmetric and 2.7 eV wide, whereas in unsputtered samples, it is broader (3.2 eV) and slightly asymmetric. In hydrated samples, the O<sub>1s</sub> peak becomes broader, and its maximum shifts toward higher binding energy values. After about 10 minutes of hydration it becomes symmetrical and 3.5 eV wide, and its maximum shifts to  $533.5 \pm 0.2$  eV. Afterwards, up to 3 hours, the shape and position of the peak remain unchanged. For  $\beta$ -C<sub>2</sub>S, the O<sub>1s</sub> peak shows the same trend as for C<sub>3</sub>S (Fig. 6). The broadening of the O<sub>1s</sub> peak and the shift in its binding energy is the manifestation of the initiation of hydration of calcium silicates. These changes indicate that there are, at that point, more than one oxygen-containing species on the hydrated surface. Also, the new oxygen-containing species has higher binding energy, presumably due to the O-H bond since the oxygen in the O-H bond has a higher binding energy than in O-Ca and O-Si bonds.

Fig. 6. Changes in the  $O_{1s}$  peak of  $\beta$ - $C_2S$  as a result of hydration.

**Tricalcium Silicate:** Figure 7 gives typical results for an experiment that shows the change in the Ca/Si ratio on the  $C_3S$  surface as a function of hydration time.

Fig. 7. Ca/Si ratio on the  $C_3S$  surface as a function of hydration time.

As can be seen, the Ca/Si ratio drops to about 2.6 - 2.7 with only 2 seconds of hydration. It then passes through a minimum at about 2.5 and a maximum at about 2.8. From then on, it gradually decreases to a value of about 2.0 in 10 minutes, and 1.5 in 30 minutes. Afterwards, there is very little change, even up to 3 hours. It should be pointed out that the times when minima and maxima in the Ca/Si curves appeared were not exactly reproducible and probably depend on the fineness and thermal history of the  $C_3S$ .

The departure of the Ca/Si ratio from a value of 3.0 on the  $C_3S$  surface in the very early seconds of hydration shows that the first hydrates on the  $C_3S$  surface do not have a Ca/Si ratio of 3.0 as was believed previously. The probing depth of ESCA is about 20 Å. The hydrated layer in the early seconds of hydration is probably less than 20 Å but, in spite of this, a Ca/Si ratio close to 3.0 is not obtained. Thus, it may be concluded that the  $C_3S$  surface in the early stages of hydration is rich in Si (5-7). The significance of the minimum and maximum in the Ca/Si curves is not entirely clear. If we assume that the minimum represents a hydrated surface rich in Si, then the maximum may represent a surface on which  $Ca^{2+}$  ions have chemisorbed, supporting the views of Tadros *et al.* (7).

**Dicalcium Silicate:** It was found that both pure and stabilized  $C_2S$  gave very similar ESCA spectra and Ca/Si ratios. Variation in the Ca/Si ratio on the  $\beta$ - $C_2S$  surface is a function of hydration time, as shown in Fig. 8. Because of the very slow  $\beta$ - $C_2S$  hydration, samples were hydrated up to 24 hours, both at 25° and 50°C.

Fig. 8. Variation with time of the Ca/Si ratio for  $\beta$ - $C_2S$  hydrated at 25° and 50°C.

The shape of the Ca/Si-vs-hydration time curves is similar to those obtained for  $C_3S$ : a minimum is followed by a maximum in the very early stages of hydration. However, the fluctuations are less pronounced and appear somewhat later than for  $C_3S$ . They also appear earlier in samples hydrated at  $50^\circ C$  than in those hydrated at  $25^\circ C$ . These differences may be attributed to the higher hydration rate of  $C_3S$  and to the acceleration of  $\beta-C_2S$  hydration due to increased temperature.

The Ca/Si ratio for  $50^\circ C$  hydration reaches a value of about 1.6 in one minute, and then remains practically unchanged up to 6 hours. After 24 hours, it has decreased to about 1.3. At  $25^\circ C$ , the Ca/Si ratio reaches a value of about 1.5 in an hour, and from then on remains practically unchanged (1.50–1.55) up to 24 hours. The difference in the starting times of the plateaus in these Ca/Si curves is presumably due to the different hydration rates of  $\beta-C_2S$  at the two temperatures. The duration of these plateaus may have something to do with the induction period. If this is the case, then it also implies that the Ca/Si ratio on the surface hydrates does not change significantly during the induction period.

Although the probing depth of ESCA is only about 20 Å, bulk analyses can be obtained by sputtering the surface. Sputtering provides the possibility of estimating the thickness of the hydrated layer. Measurements were made on  $\beta-C_2S$  hydrated both at  $25^\circ$  and  $50^\circ C$ . For unhydrated  $\beta-C_2S$ , sputtering did not change the Ca/Si ratio from a value of 2.0 (Fig. 9). For samples

hydrated at  $50^\circ C$  for 24 hours, sputtering up to a depth of 150 Å did not change the Ca/Si ratio from 1.3. For other samples, the Ca/Si ratio eventually reached a value of 2.0 as a result of sputtering, but required deeper sputtering with increased hydration time or temperature. From these data, the depth of the hydrated layer for the  $25^\circ C$  samples is on the order of 50 Å after 15 seconds and about 100 Å after 6 hours.

Another interesting observation was made regarding the Ca/Si ratio of  $\beta-C_2S$  samples hydrated at  $50^\circ C$ . The surface Ca/Si ratios, after one minute and 6 hours of hydration, are 1.56 and 1.57, respectively. Sputtering to a depth of 50 Å changes these ratios to 1.80 and 1.68. The lower Ca/Si ratio beneath a depth of 50 Å for the 6-hour sample shows that hydration continues progressively beneath the surface, although it may not be noticeable at the surface during the induction period.

In addition to the information provided by the changes in the  $O_{1s}$  peak, some interesting conclusions can be drawn from the differences in the binding energies of  $Ca_{2p}$  and  $Si_{2p}$ . A decrease of 0.6 eV is observed for  $\beta-C_2S$  hydrated for 24 hours at  $50^\circ C$ . This is due to a shift of either  $Ca_{2p}$  towards lower, or  $Si_{2p}$  towards higher binding energies. The latter case is more probable, since the binding energy of  $Si_{2p}$  increases as the material goes from silicate to silica gel (15). Our results would then indicate that the monomer form of  $SiO_2$  in unhydrated  $\beta-C_2S$  is progressively transformed into dimeric or possibly higher polymeric forms upon hydration.

#### CONCLUSIONS

The present study clearly shows the usefulness of ESCA and high-resolution SEM in elucidating the mechanisms of early hydration of calcium silicates.

New information on the surface morphology of the hydrated calcium silicates has been obtained. Immediately upon contact with water, minute hydration products form on the surface. Simultaneously, dissolution or corrosion of the surface becomes visible. Both the dissolution of  $\beta-C_2S$  and  $C_3S$ , and the deposition of the hydrates are nonuniform, and are preferentially localized at grain boundaries. With the progress of hydration, what is believed to be honeycomb Type II C-S-H forms on the surface.

Surface analysis by ESCA revealed changes in the average Ca/Si ratio as a result of hydration. Immediately upon contact with water, the Ca/Si ratios drop for both of the calcium silicates and, following a maximum, continuously decrease. The data indicate the formation of a silica-rich hydrated surface in the early stages of hydration. Chemisorption of  $Ca^{2+}$  takes place on this surface. Sputtering of the hydrated surface enabled estimation of its depth as a function of hydration time.

Fig. 9. Ca/Si profile as a function of sputtering depth for hydrated  $\beta-C_2S$ .

## Materials from the Synthetic Tobermorite

### *Matériaux comportant de la tobermorite de synthèse*

T. CIACH, J. DYCZEK, M. PETRI, L. WESTFAL, Stanislaw Staszic Academy of Mining and Metallurgy, Cracow, Poland.

RESUME : La tobermorite de 11 Å, obtenue par traitement à l'autoclave de chaux et de silice en suspension aqueuse, se présente sous la forme de cristaux agglomérés en grains sphériques. La dimension moyenne des grains peut varier selon les particularités du traitement.

L'étude détaillée de la porosité des produits polycristallins obtenus par ce procédé de synthèse, avec diverses formes de granulats, a montré que la porosité totale et la distribution des pores pouvaient être très variés.

Nous avons étudié l'influence des propriétés d'aggrégation de la tobermorite de 11 Å sur les propriétés mécaniques, la porosité totale et la distribution des pores des produits obtenus.

SUMMARY : 11 Å tobermorite obtained in a hydrothermal processing of an aqueous solution of lime and silica has the shape of a spherical aggregate of crystallites. The average size of adjacent grains in particular synthesis may be different. The detailed study of porosity of polycrystalline products made of synthetic tobermorite /with different shapes of aggregates/, indicate the total porosity, although there is a very different pore size distribution to be observed. In this study we are trying explain the origin aggregate forming, the interactions of pore shapes and their influence on the observed porosity structure as well as mechanical factors of products made of 11 Å tobermorite.

## INTRODUCTION

Tobermorite is the main product of reaction derived during the course of autoclavisation of building materials such as: silicate bricks, autoclaved concrete and other materials. The optimal reception of these materials is often empirically treated. On the other hand as the main product of the reaction, tobermorite is responsible for the utilitarian properties of the product [1,2,3,4]. Established methods syntheses of 11 Å tobermorite was observed on the 50's [5,6,7], but not until recently were they applied to production, in particular to attractive products such as wollastonite, highly porous materials, insulation materials and so forth.

A particularly attractive method of obtaining calcium silicate hydrates in this and tobermorite is the hydrothermal treatment of quartz-lime water suspension.

It is easy to obtain a water suspension of tobermorite, and after removing water from it /pressing/ obtain light polycrystalline materials. They give evidence of their sufficient mechanical and insulative properties. A mixture of 11 Å tobermorite and CSH phase in the water suspension are usually products of lime and quartz hydrothermal syntheses, by which the quantitative ratio of the phase and stage of crystallisation of tobermorite differ in conditions of syntheses.

SEM microscopic observations proved the following:

- 1-in the water suspension appear aggregates composed of the tobermorite crystals cemented together by a CSH phase,
- 2-a dimension of these aggregates are different depending on the conditions of syntheses.

The following experimental description was carried out in the hope of explaining the influence of the aggregates dimensions on the form conditions and mechanical properties of the polycrystalline materials from synthetic 11 Å tobermorite.

## EXPERIMENTAL

The syntheses of tobermorite was carried out with CaO /analytical grade/ and SiO<sub>2</sub> in quartz form of specific surface area 160000 m<sup>2</sup>/kg in 0,01 m<sup>3</sup> volume of an autoclave with the agitator /120 rpm/ in the temperature of 448°K in saturated steam pressure. The molar ratio of CaO to SiO<sub>2</sub> was 0,87.

The amount of Al<sub>2</sub>O<sub>3</sub> present as kaolinite was 0,2 % on the weight of total solids. In the order of syntheses the change in time of the autoclavisation and the water to dry substance ratio /w:s/, in this cases was as following:

	w:s	time
syntheses A	10:1	10 hrs
syntheses B	7:1	7 hrs

X-ray diffraction showed that the product of syntheses A was 11 Å tobermorite and a small amount of CSH phase, the presence which resulted in a slightly raised background in the region of reflex /220/ /fig. 1/.

Fig. 1 - X-ray analyses of syntheses A

SEM macroscopic observation allowed to state that tobermorite appeared in a spherical aggregate form of dimension  $1+6 \cdot 10^{-6}$  m.

Fig. 2 - The aggregates of tobermorite A

X-ray analyses of syntheses B products showed also the presence of 11 Å tobermorite but less crystalline. It was stated also that in B material was a greater quantity of CSH phase /fig. 3/.

Fig. 3 - X-ray analyses of syntheses B

The aggregates observed on SEM microscope showed greater dimensions  $20+40 \cdot 10^{-6}$  m/ than in material A /fig. 4/.

Fig. 4 - The aggregates of tobermorite B

Samples of materials from both syntheses were heated to 673°K and X-ray diffraction showed a characteristic peak of 9,3 Å tobermorite. We may certify the obtained tobermorite as a "normal" variation at 11,3 Å tobermorite /8/.

Samples of 10x20x60·10<sup>-3</sup>m dimensions were formed from water suspensions of tobermorite by pressing, the top and bottom removing the water from it. The pressing conditions are in Table I. They were dried by superheated water steam a temperature of 393° C.

Dynamical Young's modulus  $E_d$  and Poisson's ratio  $\nu$  were determined by measuring the speed of transmission of ultrasonic wave. An ultrasonic generator was used with frequency of 11 Hz. Precision of measurement were 0,1 s.

$$E_d = \frac{C_L^2 \rho}{1 - \nu} \frac{1 + \nu / (1 - 2\nu)}{1 - \nu}$$

$C_L$  - speed wave  
 $\rho$  - bulk density

Values of crack initiation energy  $\gamma_I$  and crack propagation energy  $\gamma_F$  were determined by the "across bending bar with a notch" method /3,10,11,12,13/. The bars were deformed in three point bending at 4·10<sup>-2</sup> m span.

The samples of a=10<sup>-2</sup>m, b=6·10<sup>-2</sup>m, d=2·10<sup>-2</sup>m dimension were nothed to depth c. c/d ratio was as follows: 0,5; 0,6; 0,7; 0,8. Load deflection curves were recorded on an INSTRON machine operating at crossed speeds of 5·10<sup>-3</sup>m/min.

Using the following formulae were determined the values of  $\gamma_I$  /12/, and  $\gamma_F$  :

$$\gamma_I = \frac{9/1 - \nu^2 / P_F L^2 f/c/d/}{8Eb^2/d-c/3}$$

$P_F$  - fracture Load  
 $f/c/d/$  - values are in /12/

$$\gamma_F = \frac{U}{2b/d-c/}$$

U - fracture's total work

$\gamma_F$  is a function of c/d, decreasing with increasing notch depth. The true  $\gamma_F$  value are given by extrapolating the results to c/d = 1 /10/.

The values of Young's static modulus E, and bending strength  $\sigma_F$ , were determined by deforming the bars without notch under the mentioned conditions. Compressive strength  $\sigma_K$ , was determined on the cubic samples.

The value of critical defect C, was calculated from Griffith's equation /11/.

$$C_F = \left[ \frac{2\gamma_F}{\pi C} \right]^{1/2}$$

Data of the specimens:  $\nu, E_d, E, \sigma_F, \sigma_K, \gamma_I, \gamma_F, C$  are summarized in Table I.

Pores and pores size distribution were determined in 75 000 + 37,5 Å range, and were carried out by using mercury porosimeter /fig. 5 and 6/.

Total porosity was calculated. The results are tabulated in Table I.

Table I

	Material A	Material B
Pressing conditions N/m <sup>2</sup> · 10 <sup>6</sup>	20,89	15,94
Bulk density $\rho$ kg/m <sup>3</sup> · 10 <sup>-3</sup>	0,600	0,600
Total porosity m <sup>3</sup> /kg · 10 <sup>-3</sup>	1,4166	1,4166
Mercury porosity m <sup>3</sup> /kg · 10 <sup>-3</sup>	1,1135	1,1445
Poisson's ratio $\nu$	0,05	0,05
$E_d$ N/m <sup>2</sup> · 10 <sup>9</sup> $\frac{\perp}{\parallel}$	1,524 2,052	1,934 2,005
E N/m <sup>2</sup> · 10 <sup>8</sup>	4,562	3,544
$\sigma_F$ N/m <sup>2</sup> · 10 <sup>6</sup>	3,42	2,97
$\sigma_K$ N/m <sup>2</sup> · 10 <sup>6</sup>	10,86	9,21
$\gamma_I$ J/m <sup>2</sup>	4,02	7,04

Fig. 5 - Pores size distribution material A

Fig. 6 - Pores size distribution material B

## RESULTS

The mechanical properties of materials A and B show significant difference.

Material A has higher values of compressive strength  $\sigma_K$ , bending strength  $\sigma_F$ , and Young's static modulus  $E$ .

In both materials the values of compressive strength are much higher than of the bending strength. It is typical for brittle materials. Measurement of Young's Dynamic modulus  $E_d$  was determined vertically and horizontally with respect to the forming directions. The value differences of  $E_d$  depending on the direction of measurement indicate an anisotropic effect of the tested material.

If we can say that material B is isotropic, to the same extent material A showed significant anisotropic mechanical properties.

Material A was formed from a tobermorite water suspension with a small quantity of CSH concentrated in the aggregates having small dimensions.

For both materials it was found that the value of  $\gamma_K$  was greater than  $\gamma_F$ . So we use more energy for crack initiation than for crack propagation for the fracture of the material. It means that there is possibility of a catastrophic course of fracture process, in this case when a high deflection force is used. Material A was better, because it showed a higher resistance to fracture/ e.g.  $\gamma_F$  for A is greater than that for B/.

A pore determination allowed to say, that the total mercury porosity of both examined materials in range of  $75\ 000 \pm 37,5 \text{\AA}$  was almost identical. We have observed a difference in the pore size distribution. Material B was formed from a water suspension containing tobermorite aggregates with a larger quantity of CSH than material A, thus it can be said that material B has greater amount of small pores with radius less than  $500 \text{\AA}$ .

## CONCLUSIONS

- /1/ Obtaining tobermorite in a water suspension creates aggregates of  $11 \text{\AA}$  tobermorite cemented by the CSH phase. The stage of tobermorite crystallization and quantity of CSH combining has an influence on the extent of these aggregates and mechanical properties of the obtained products by pressing.

- 11 The obtained materials from the tobermorite water suspension of smaller aggregate dimensions and with smaller amounts of CSH phase showed better mechanical properties. However, to obtain such a suspension and form from these materials requires more energy for autoclavisation and formation.

- 111 When examining the mechanism of fracture on the samples it was stated that the amount of energy required for crack initiation is many times greater than energy necessary for fracture propagation. The practical results of this are, that the products from synthetic tobermorite ought to have a much smoother surface /with out cracks or notches/ and that the addition of reinforcing materials will fortify this tobermorite material.

# Hydration and strength of normal portland cement admixed with anhydrous calcium sulfate

## *Hydratation et résistance du ciment portland normal additionné d'anhydrite*

K. NAKAGAWA, Senior Research Manager, Denki Kagaku Kogyo Co., Ltd. R & D Department,  
K. ISOZAKI, Research Chemist, of Omi-Plant, Japan,  
Y. WATANABE, Research Chemist.

RESUME : Des recherches ont été entreprises sur l'hydratation et le durcissement de ciments composés de ciment portland normal et de sulfate de calcium anhydre du type II ou de silice activée; il s'agissait notamment de connaître l'influence des conditions de cure et des agents réducteurs d'eau.

L'addition d'une quantité appropriée de II  $\text{CaSO}_4$  retarde le début de l'hydratation du  $\text{C}_3\text{S}$ , mais plus tard augmente son taux d'hydratation. A température plus élevée, l'effet de cette addition d'anhydrite est augmenté. L'addition d'un agent réducteur d'eau (condensat de formol et de sulfonate  $\beta$ -naphthalénique de sodium) retarde l'hydratation du  $\text{C}_3\text{S}$  aux premiers âges, mais accélère la formation de l'ettringite.

L'addition d'une quantité optimale de II  $\text{CaSO}_4$  accélère l'hydratation du  $\text{C}_3\text{S}$  et la formation de l'ettringite, augmente la proportion d'eau non évaporable dans la pâte, et contribue ainsi à améliorer la structure de la pâte durcie. A température plus élevée, la cure est améliorée lorsque la proportion d'anhydrite ajoutée augmente; l'addition de silice activée peut alors compenser les inconvénients de l'anhydrite et améliorer la résistance à long terme et la stabilité.

SUMMARY: Investigations were made on the hydration process and the mechanism of strength development of cements composed of normal portland cement and Type II anhydrous calcium sulphate or further admixed with active silica to know the influences of the curing condition and the water reducing agent affecting thereon.

When an optimum quantity of II- $\text{CaSO}_4$  is added to normal portland cement, the early hydration of  $\text{C}_3\text{S}$  is retarded but the degree of hydration at the later age is increased. The effect of the admixture is noticeable so far at a high temperature. The addition of a water reducing agent (formalin condensates of  $\beta$ -naphthalene sodium sulfonate) promotes the retardation of  $\text{C}_3\text{S}$  hydration at the early stage, but accelerates the ettringite forming reaction.

The addition of an optimum quantity of II- $\text{CaSO}_4$  accelerates the hydration of  $\text{C}_3\text{S}$  and the formation of ettringite and the increase in non-evaporable water with attendant improvement of paste structure and strength development. It is considered that a high temperature curing is effective if the added quantity of II- $\text{CaSO}_4$  is large, and that the further addition of active silica compensates the disadvantage of II- $\text{CaSO}_4$  and contributes to the long-period strength and the stability.

## I. INTRODUCTION

Addition of gypsum to normal portland cement (NPC) is limited from the viewpoint of preventing the flash setting and the abnormal expansion (1). Important factors producing effects on these phenomena are the content of  $C_3A$ , the alkali content and the fineness of the cement. It has been known that the strength may be considerably increased by adding an optimum quantity of gypsum (1) (2), but it is supposed that if an excess quantity of gypsum is added to the cement, the unreacted  $SO_3$  and  $SO_3$  contained in the CSH gel will react with the aluminate components to accelerate the formation of ettringite or the growth of crystal, whereby the stability of the cement stone has been eventually lost for a long period of time (1) (3) (4).

On the other hand, regulated set cement and expansive cement etc. contain large amounts of calcium aluminate and gypsum and/or anhydrite (II-CS). In view of these background facts, this article reports the investigation which have been made on hydrate structure and mechanism of strength development of the cement admixed with II-CS to know the fundamental facts including the influences of curing conditions and water reducing agent.

## II. EXPERIMENTAL

Table I shows the mineral compositions of the admixtures, and Table II shows the chemical composition of NPC. In Table III, there are shown the curing methods. The high temperature curing was effected at  $65^\circ\text{C}$  for 6 hours by steam curing after pre-curing at  $20^\circ\text{C}$ , 80%rh and then left standing for spontaneous cooling.

TABLE I Mineral composition of admixtures (wt%)		
Name of admixture	II- $\text{CaSO}_4$	Activated $\text{SiO}_2$
C $\bar{\text{S}}$	100	0
C $\bar{\text{S}}$ +S	85	15

The water to cement ratio was 0.3 and 0.5% of the water reducing agent (formalin condensates of  $\beta$ -naphthalene sodium sulfonate) was added to cement (substituted for water).

Each of the paste specimens (4x4x16 cm beam) at the predetermined age was subjected to strength test. The crushed specimen was divided into a first group having the size of 5.0mm to 2.5mm and a second group having the size of less than 1.7mm. The former group was D-dried (for 48 hours) and used as samples for determining the evaporable water, the non-evaporable water, and the pore volume (measured by using mercury pressure porosimeter) and observing the morphology of hydrates by scanning electron microscope, whereas the latter group was washed with ethanol and subjected to X-ray diffraction analysis.

## III. RESULTS AND DISCUSSION

III-1. HYDRATION OF  $\text{C}_3\text{S}$  AND FORMATION OF ETTRINGITE

The differences in hydration degree of  $\text{C}_3\text{S}$  between the curing at  $20^\circ\text{C}$  and  $65^\circ\text{C}$  at the curing age of 24 hrs, were found about 10% for the NPC system wherein the admixture was not added, about 15% for the C $\bar{\text{S}}$  system wherein 10% of II-C $\bar{\text{S}}$  was added, and about 18% for the C $\bar{\text{S}}$ +S system wherein 10% of II-C $\bar{\text{S}}$  and activated silica were added. These results show that the effect of high temperature curing is remarkably promoted by the addition of the admixtures. (Fig. 1 (a) (b) (c))

The hydration of  $\text{C}_3\text{S}$  is accelerated by the admixtures. The difference in hydration degree of  $\text{C}_3\text{S}$  at the 24 hour age between the NPC and the systems of the admixtures added is increased by 5 to 10% when the curing is effected at  $20^\circ\text{C}$  and about 10% when the curing at  $65^\circ\text{C}$ .

Fig.1 Hydration process by X-ray analysis  
( Water curing after one day ).

However, the difference has been lessened at the 28 day age. In both of the C<sub>3</sub>S and C<sub>3</sub>S+S systems, when the added amounts of the admixtures are decreased to respectively 5% and 7.5%, the hydrations of C<sub>3</sub>S are more effectively accelerated as compared to the system wherein the added amount is 10%, whereas there is found tendency that the acceleration effect is decreased when the added amount is increased in excess of 10%.

The water reducing agent apparently retards the initial hydration of C<sub>3</sub>S in both of the C<sub>3</sub>S and C<sub>3</sub>S+S systems, but does slightly accelerate the hydration at the curing age of later than 24 hrs.

Although it had been recognized that the degree of super saturation of Ca<sup>2+</sup> in the liquid phase was promoted by adding gypsum to pure C<sub>3</sub>S alone to accelerate the initial hydration of it (5), the hydration of C<sub>3</sub>S contained

in the cement was found to be retarded. This is considered as related to the ettringite formation reaction which is activated by the addition of II-CS and in this activated period the nucleation for entering into the acceleration period of hydration of C<sub>3</sub>S becomes small. The added water reducing agent is adsorbed onto the surfaces of cement particles to facilitate this phenomenon. If the curing is effected at the high temperature of 65°C, this phenomenon is ceased and the hydration of C<sub>3</sub>S takes place actively concurrent with the formation of ettringite.

The formation of ettringite is appreciably affected by the action of the water reducing agent. The cement admixed with II-CS is particularly affected thereby, but similar actions are observed in the system of NPC alone and other systems referred to above irrespective of the curing temperature. As the mechanism attributing to this phenomenon, it may be assumed that the water reducing agent is partially adsorbed onto the surfaces of the calcium aluminate particles to render the organization of protective film, at which the ettringite is formed at the initial stage of hydration, to be coarse to facilitate the dissolution of Ca, Al ions.

In the C<sub>3</sub>S+S system, at both of the early and later curing ages, the difference in ettringite formation due to the curing temperature is small. Whereas in the C<sub>3</sub>S system, the amount of formed ettringite is relatively increased when the curing is effected at 65°C, and gradually increased further with the lapse of time. It is shown that active silica acts to form a large amount of ettringite at the early stage of curing. (Fig. 1(c) )

### III-2 MORPHOLOGY OF HYDRATION PRODUCTS

At the early age of curing at 20°C, the hydration does not proceed so far and the cement particles have the sizes of several to several tens microns and are dispersed to form a coarse matrix. Although no acicular or needle-like ettringite is visually confirmed at this stage, a relatively amount of ettringite has been found by X-ray analysis. It is, therefore, considered that the crystals of ettringite are not grown to have appreciable sizes and they form minute organizations adhering to the surfaces of calcium aluminate particles. (Fig. 2)

When the curing is effected at 65°C, a large numbers of needle-like ettringites are found in the voids of cement matrix at the 24 hour age, the diameter of such needle-like crystals being 0.2 to 0.4 μ and the length being several μ, and the crystals are grown to have diameters of 0.4 to 0.6 μ, but the lengths are not changed. The shapes of ettringite are characterized by the needle-like crystal and the hexagonal cross-section of prismatic crystal.

The hydrated particles form continuous gel as the hydration proceeds, and the matrix of 24 hrs age cured at 65°C shows the substan-

Fig.2 Observation of hydrates by scanning electron microscope. (water curing after one day.)

tially same state as that of the matrix of about the one month age at 20°C. It has been observed that ettringite crystals grow into the liquid phase presented in the voids of the gel from the surfaces of calcium aluminate particles.

### III-3 STRENGTH DEVELOPMENT AND HYDRATION DEGREE

Fig.3 Relation between compressive strength and admixture content.

In the  $\text{C}\bar{\text{S}}$  system cured at  $20^\circ\text{C}$ , the cement admixed with 5% of  $\text{C}\bar{\text{S}}$  has the highest strength throughout the curing ages of 1 to 28 days, and the strength at the curing age of 28 days of the cement admixed with 5% of  $\text{C}\bar{\text{S}}$  is about 1.4 times as high as that of the NPC. Those admixed with more than 5% of  $\text{C}\bar{\text{S}}$  have the strengths approximately equal to or slightly lower than that of the NPC. If the curing is effected at  $65^\circ\text{C}$ , the cement admixed with 7.5% of  $\text{C}\bar{\text{S}}$  has the maximum strength. The strengths of the cement admixed with larger amounts of  $\text{C}\bar{\text{S}}$  are somewhat different from the strengths of similar cement cured at  $20^\circ\text{C}$  so that the strengths of the cements cured at  $65^\circ\text{C}$  are increased by 10 to 20% as high as that of the NPC and inter alia the strengths in air curing are particularly improved (6). (Fig. 3(a))

In the  $\text{C}\bar{\text{S}}+\text{S}$  system cured at  $20^\circ\text{C}$ , the cement admixed with 5% of  $\text{C}\bar{\text{S}}+\text{S}$  has the maximum strength at the curing ages of 1 to 7 day, and the cement admixed with 7.5% of  $\text{C}\bar{\text{S}}+\text{S}$  has the maximum strength at the 28 day age. Although the strengths of the cements of the  $\text{C}\bar{\text{S}}$  system admixed with larger amount of  $\text{C}\bar{\text{S}}$  are not increased as compared to that of the NPC, the strengths of the cements admixed with larger amounts of  $\text{C}\bar{\text{S}}+\text{S}$  are increased by 10 to 15% as high as that of the NPC at the 28 day age. When the curing is effected at  $65^\circ\text{C}$ , the cement admixed with 7.5% of  $\text{C}\bar{\text{S}}+\text{S}$  has the maximum strength at the curing age of 28 days. No appreciable difference has been found between the strengths of the cements admixed with 5 to 20% of  $\text{C}\bar{\text{S}}+\text{S}$ , respectively, and the functional effect of the activated silica become obvious so that the developed strengths of the cements are approximately 1.4 times as high as that of the NPC. (Fig.3(b))

If an optimum quantity (5-7.5%) of II- $\text{C}\bar{\text{S}}$  is added, unreacted II- $\text{C}\bar{\text{S}}$  being scarcely present at an early age, the strength development is facilitated further effectively.

The rate of increase in strength in terms of the increase in non-evaporable water in each cement is obviously different in every system. In the NPC cured at  $20^\circ\text{C}$ , the strength is developed relatively rapidly with small increase in the quantity of non-evaporable water until it reaches to  $50 \text{ N/mm}^2$  but the rate of increase in strength at the later age is small. On the contrary, in the  $\text{C}\bar{\text{S}}$  and  $\text{C}\bar{\text{S}}+\text{S}$  systems, the rates of increase in strength are larger, and this tendency is more remarkable in the  $\text{C}\bar{\text{S}}+\text{S}$  system. When the curing is effected at  $65^\circ\text{C}$ , slightly difference is found between the rate of increase in strength of the  $\text{C}\bar{\text{S}}$  system and that of the NPC, whereas the rate of increase in strength of the  $\text{C}\bar{\text{S}}+\text{S}$  system is prominent. It is considered that the addition of activated silica serves to strengthen the matrix. (Fig.4(a)(b))

When the curing is effected at  $20^\circ\text{C}$ , the interrelation between the total pore volume and the strength may be plotted on a substantially straight line in either of the NPC and  $\text{C}\bar{\text{S}}$  and  $\text{C}\bar{\text{S}}+\text{S}$  systems irrespective of the

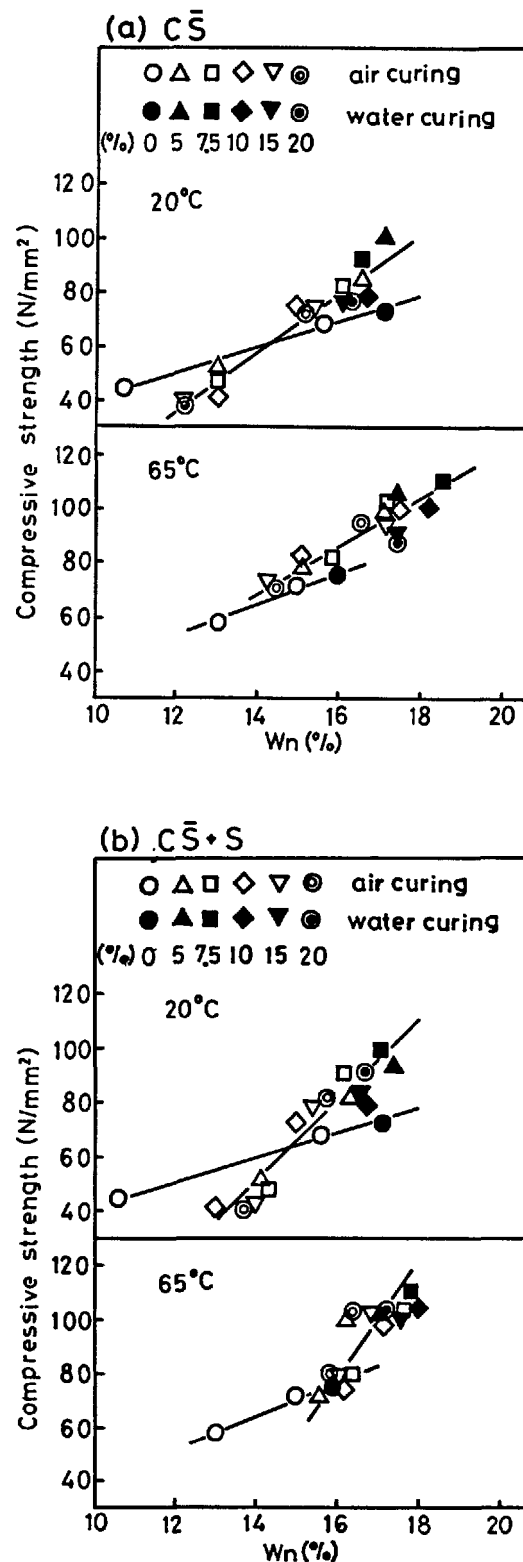

Fig.4 Relation between compressive strength and non-evaporable water ( $W_n$ ).

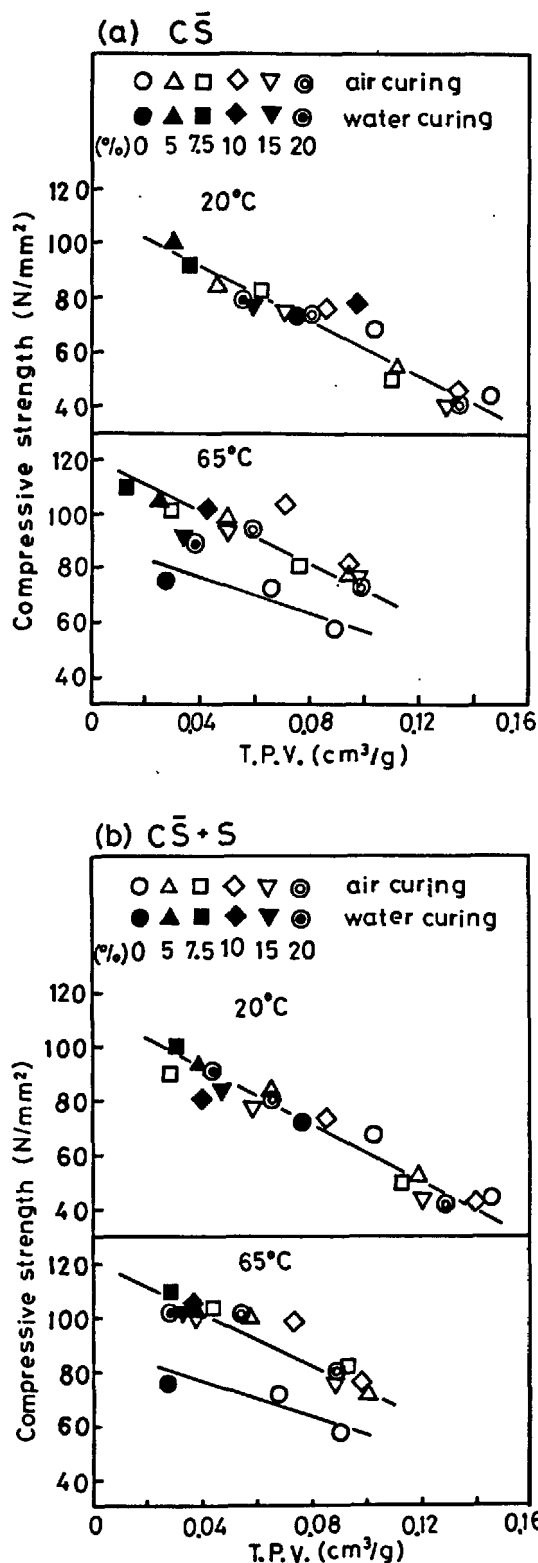

Fig.5 Relation between compressive strength and total pore volume (75-75000 Å).

quantities of the admixtures. However, when the curing is effected at 65°C, the cements admixed with admixtures have higher strengths as that of the NPC having the same total pore volume, and inter alia the strength in air curing are improved rather than the strengths in water. Different from the rate of increase in strength in terms of the increase in non-evaporable water, the rate of increase in strength in terms of the decrease in pore volume is not distinguishable between the  $\bar{C}\bar{S}$  system and the  $\bar{C}\bar{S}+S$  system. (Fig. 5 (a)(b) ) This aspect requires further investigation.

#### IV. CONCLUSION

When an optimum quantity of II- $\bar{C}\bar{S}$  (5-5.7%) is added to normal portland cement, the hydration of  $C_3S$  is retarded at the early stage but after aged for one day it is accelerated.

The addition of a water reducing agent ( formalin condensates of  $\beta$ -naphthalene sodium sulfonate) promotes the retardation of  $C_3S$  hydration at the early stage, but accelerates the ettringite formation reaction.

The addition of an optimum quantity of II- $\bar{C}\bar{S}$  facilitates the hydration of silicate phase and increases the formation of ettringite thereby to increase the amount of non-evaporable water and to strengthen the paste structure.

A higher temperature curing becomes effective with the increase in amount of II- $\bar{C}\bar{S}$ .

The activated silica serves to strengthen the paste structure and improve on the stability for a long period of time due to the promotive effect on ettringite formation at the early stage and the suppressive effect on it at the later age.

# Le rôle des aluminates et des sulfoaluminates de calcium dans l'élaboration de propriétés de la pierre de ciment

## *Part played by aluminates and calcium sulfoaluminate in formation of properties of cement stone*

T.V. KOUZNETSOVA, candidat ès sciences techniques,

I.V. KRAVTCHENKO, docteur ès sciences techniques, NIITzement, Moscou, U.R.S.S.

RESUME : On a étudié le phénomène d'hydratation du sulfoaluminate de calcium ainsi que de ses mélanges avec les silicates et les aluminates de calcium. On a démontré que la morphologie des cristaux formés ainsi que leur microstructure présentent des traits physiques propres au ciment hydraté. On a constaté que suivant le rapport quantitatif entre l'ettringite et les hydroaluminates de calcium dans la pierre de ciment en voie de durcissement il s'y forme soit une structure d'hydratation stable, soit des conditions favorables à son extension. La formation de structure d'hydratation, sa solidité, son extension et son auto-tension sont régies par la quantité d'aluminates et de sulfoaluminates de calcium contenue dans le ciment.

SUMMARY : Hydration of calcium sulfoaluminate and its mixtures with calcium silicates and aluminates has been investigated. It is shown that the morphology of novel formation crystals and microstructure characterise physical properties of hydrated cement. It has been found out that depending on the ratio in the amounts of ettringite and calcium hydroaluminates, a strong hydration structure is formed in the hardening cement stone, or conditions for its spreading are provided. Formation of the hydration structure, its strength, expanding and self-stressing are controlled by the amounts of aluminates and calcium sulfoaluminate in cement.

Les aluminates et les sulfoaluminates de calcium constituent justement les phases de clinker qui attirent l'attention lorsqu'on étudie les différents types de ciment : ciment portland, ciment alumineux à teneur élevée en alumine, ciment expansif. La cinétique de l'hydratation, la constitution des composés hydratés, la stabilité au cours d'un long durcissement, l'influence exercée sur la formation de la structure d'hydratation de la pierre de ciment sont l'objet de nombreuses études entreprises sur ces ciments.

L'analyse de données publiées sur la composition des hydroaluminates de calcium montre que le rapport entre  $\text{CaO}$  et  $\text{Al}_2\text{O}_3$  dans les composés hydratés est fonction de la composition des aluminates de calcium déshydratés (1-3), de la température et de la durée d'hydratation (4, 5), de la présence ou de l'absence de  $\text{Ca}(\text{OH})_2$  dans le milieu d'hydratation (6, 7). L'hydratation des aluminates de calcium en présence du gypse s'accompagne de la formation de l'hydro-sulfoaluminate de calcium dont la composition dépend de la quantité de sulfate de calcium contenue dans la phase liquide du mortier (8, 9).

L'hydratation du sulfoaluminate de calcium entraîne la formation de la variante monosulfate de l'hydro-sulfoaluminate de calcium et, en présence du gypse - de l'ettringite et de l'alumine hydratée (10).

La cinétique de l'hydratation d'aluminates et de sulfoaluminates de calcium est régie par de nombreux facteurs en conditionnant les particularités morphologiques des composés hydratés ainsi que la structure de la pâte de ciment qui durcit (11). La morphologie des produits d'hydratation et la microstructure de la pierre de ciment en voie de durcissement ainsi que ses interdépendances avec les propriétés physiques de la pâte de ciment ont été étudiées par de nombreux chercheurs. Cependant le nombre important de facteurs à actions réciproques sur la vitesse d'hydratation et la formation de la structure d'hydratation nécessite une étude détaillée de tous les stades d'hydratation du ciment et de durcissement de la pâte de ciment.

L'objet des recherches a été l'étude de l'hydratation du sulfoaluminate de calcium et de ses mélanges avec les aluminates, les silicates de calcium et le gypse ainsi que de l'influence réciproque des réactions d'hydratation sur la résistance et le gonflement du ciment en voie de durcissement.

L'étude du processus d'hydratation a été conduite par deux méthodes :  
- par agitation de la charge d'éprouvette dans l'eau pour un rapport  $S/L = 1/50$  durant 1, 7 heures, 1 à 28 jours ;  
- en éprouvettes de pâte de ciment dont le rapport  $E/C$  est égal à 0,4.

Par la première méthode étaient préparées les suspensions de sulfoaluminates de calcium qu'on conservait dans des ballons étanches. Le malaxage de la suspension

était conduit continûment durant 3 jours, puis trois fois par jour pendant une heure. Les délais prescrits écoulés les suspensions étaient filtrés et on déterminait la composition chimique de la phase liquide, tandis que le résidu de filtrage était soumis à l'analyse aux rayons X et à l'analyse thermique différentielle.

Tableau I			
Composition de la phase liquide au cours de l'hydratation du sulfoaluminate de calcium			
Délais de l'hydratation, jours	Concentration, mg/l		
	$\text{CaO}$	$\text{Al}_2\text{O}_3$	$\text{SO}_3$
0,04	851	1105	132
0,29	608	1053	74
1	600	1038	38
3	218	242	36
7	187	195	13
28	125	111	15

Comme il ressort des données figurant dans le tableau I la dissolution du sulfoaluminate de calcium s'effectue de façon non congruente. Une heure après sa mise en interaction avec l'eau, le rapport molaire d'oxydes dans la phase liquide ne correspond plus à la composition initiale du sulfoaluminate de calcium. Le rapport de  $\text{CaO}$  à  $\text{Al}_2\text{O}_3$  est voisin de l'unité durant les deux premiers jours d'hydratation. La solution est métastable et avec l'hydratation subséquente du sulfoaluminate de calcium le rapport  $\text{CaO}/\text{Al}_2\text{O}_3$  s'accroît jusqu'à 1,8-2.

Les études aux rayons X des phases solides après filtrage des suspensions ont montré qu'après une heure d'hydratation on détectait dans la composition des produits formés l'hydro-sulfoaluminate de calcium des variantes tri- et monosulfate. Le jour suivant l'hydratation se poursuivant, on observa sur le radiogramme, à côté de ces composés des raies de diffraction caractéristiques de l'aluminate de calcium de formule  $2\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot 8\text{H}_2\text{O}$ .

D'après les données fournies par l'analyse aux rayons X et l'analyse thermique différentielle l'hydratation du sulfoaluminate de calcium s'effectue de façon intense et, au bout de 28 jours, tout le  $3\text{CaO} \cdot 3\text{Al}_2\text{O}_3 \cdot \text{CaSO}_4$  est pratiquement hydraté.

Dans la seconde méthode l'étude de l'hydratation du sulfoaluminate de calcium avec une quantité restreinte d'eau a montré que dans ce cas l'hydratation se ralentit et après 28 jours, le degré d'hydratation du sulfoaluminate ne constitue que 71 % de la masse initiale. L'analyse aux rayons X et l'analyse thermique différentielle ont établi que la composition des produits d'hydratation contenait : l'alumine hydratée, l'ettringite, l'hydroaluminate de cal-

cium, hydromonosulfoaluminate de calcium (après trois jours de durcissement) et les hydrocarboaluminates de calcium (à 28 jours et plus de durcissement).

Les essais physiques et mécaniques d'éprouvettes ont montré (fig. 1) que l'hydratation du sulfoaluminate de calcium s'accompagne de la formation d'une structure d'hydratation solide qui en un jour de durcissement atteint une résistance de 337 kgf/cm<sup>2</sup>. Durant les temps de durcissement suivants l'accroissement de la résistance de la structure se ralentit et au bout de 28 jours la pierre de ciment acquiert une résistance de 500 kgf/cm<sup>2</sup>.

L'extension des éprouvettes est peu sensible de l'ordre de 0,05 à 0,08 %.

Fig. 1 - Résistance (a) et extension (b) d'éprouvettes durant le durcissement s'étendant sur 1 à 28 jours. 1 - du sulfoaluminate de calcium, 2 - idem avec addition de 10 % de gypse, 3 - idem avec addition de 36 % de gypse. On a montré en pointillé la désagréation de l'éprouvette.

L'étude de l'hydratation du sulfoaluminate de calcium en présence de gypse a permis d'établir que la composition des produits d'hydratation est fonction de la quantité de gypse introduit. Pour de petites additions de gypse (10 % de la masse du mélange avec le sulfoaluminate de calcium) la quantité d'ettringite monte quelque peu (fig. 2) par rapport à sa quantité obtenue

avec l'hydratation sans gypse. A côté de l'ettringite on rencontre dans la composition des produits d'hydratation des aluminates hydratés et des hydrocarboaluminates de calcium. Les premiers jours du durcissement la résistance des éprouvettes est beaucoup inférieure à celle de la pierre de ciment obtenue par hydratation du sulfoaluminate de calcium pur.

Avec l'adjonction au sulfoaluminate de calcium du gypse en quantité dosée pour la fixation complète du sulfoaluminate de calcium en ettringite, la résistance de la structure d'hydratation chute brusquement, et, après 7 jours de durcissement, les éprouvettes se désagrègent, par suite d'importantes contraintes au sein de la structure engendrées par la formation d'une grande quantité d'ettringite (sa quantité augmentant du double devant celle formée avec l'hydratation de  $3\text{CaO} \cdot 3\text{Al}_2\text{O}_3 \cdot \text{CaSO}_4$  en absence de gypse). Cela engendre une forte dilatation des éprouvettes et un abaissement de la résistance de la structure qui ne peut être maintenue devant les contraintes développées. Même une limitation de la dilatation (par armaturage biaxiale des éprouvettes) ne peut s'opposer aux efforts engendrés par la formation d'une grande quantité d'ettringite dans la pierre de ciment qui durcit.

Fig. 2 - Hauteurs des pics de diffraction de l'ettringite sur les diagrammes radio-graphiques d'éprouvettes dont le durcissement s'étale sur 1 à 28 jours. 1 - du sulfoaluminate de calcium, 2 - idem avec 10 % de gypse, 3 - idem avec 36 % de gypse.

Les études microscopiques d'éprouvettes par diffraction des électrons ont montré qu'avec l'hydratation du sulfoaluminate de calcium, à l'expiration d'un jour, il apparaît à côté de l'ettringite des cristaux lamellaires d'aluminate de calcium hydraté et du monosulfoaluminate de calcium hydra-

té. Les dimensions des cristaux d'ettringite s'accroissent au bout de 28 jours de durcissement. L'éprouvette manifeste une compacité élevée.

L'hydratation du sulfoaluminate de calcium avec l'addition de 10 % de gypse, un jour après, fait acquérir à l'éprouvette une nette structure cristalline de fins cristaux lamellaires d'aluminates de calcium hydratés et de gros cristaux d'ettringite de dimension atteignant  $6\ \mu\text{m}$ . La quantité d'ettringite et la dimension de ses cristaux augmentent durant 7 jours de durcissement. Les cristaux d'ettringite en s'allongeant repoussent les cristaux lamellaires voisins en engendrant des pores entre ces derniers. Au cours de l'hydratation ultérieure du mélange de sulfoaluminate de calcium et de gypse, la quantité d'ettringite et la dimension de ses cristaux demeurent invariables, les pores et les vides entre les cristaux d'ettringite se remplissant de cristaux lamellaires et de masse informe ; la compacité des éprouvettes durant cette période augmente.

La confrontation des résultats d'études physico-chimiques et des données d'essais physiques et mécaniques d'éprouvettes montre que suivant le rapport entre la quantité d'ettringite et d'aluminate de calcium hydraté dans le système en voie de durcissement il est possible soit d'augmenter la résistance, soit de provoquer l'expansion et l'autotension de la pierre de ciment. C'est ainsi que la pierre de ciment au cours de l'hydratation du sulfoaluminate de calcium possède une autotension de  $14\ \text{kgf/cm}^2$ , tandis qu'en présence de gypse elle s'élève à  $38\ \text{kgf/cm}^2$ .

Les études ont montré que pour obtenir des ciments à contraindre il est utile de combiner l'aluminate tricalcique au sulfoaluminate de calcium. Le tableau 2 nous fournit les résultats d'essais de ciments obtenus par broyage simultané du clinker-portland et du sulfoaluminate de calcium. Dans cette opération l'éprouvette 1 contenait 2 % de  $\text{C}_3\text{A}$ , tandis que l'éprouvette 2 - 7 % ; l'éprouvette 3 contenait 10 % de  $\text{C}_3\text{A}$ .

Tableau II			
Résultats d'essais de ciment à contraindre			
n <sup>os</sup> d'éprouvettes	Résistance, $\text{kgf/cm}^2$	Expansion, %	Autotension, $\text{kgf/cm}^2$
1	552	0,7	31
2	530	1,05	46
3	452	1,5	51

D'après les données fournies au tableau 2 on voit que l'augmentation de la quantité d'aluminate tricalcique dans le clinker-portland permet d'obtenir un ciment à autotension élevée. Comme il a été déjà men-

tionné (12) l'autotension de la pierre de ciment est le résultat de deux processus se déroulant au cours de l'hydratation du ciment : le compactage et le durcissement avec l'accentuation du degré d'hydratation du ciment et le gonflement dû à l'augmentation de la quantité et de la vitesse de formation de l'ettringite. Pour engendrer et conserver l'autotension au sein de la pierre de ciment, il faut que la résistance de la structure d'hydratation soit supérieure à l'effort créé par les cristaux d'ettringite en croissance. Il a été établi que la période de cristallisation spontanée de l'ettringite s'accompagne d'une extension maximale et de l'apparition de grandes contraintes au sein de la structure de la pierre de ciment qui conditionnent l'accroissement spontané des cristaux filiformes de l'ettringite renforçant la pierre de ciment. Mais l'auto-renforcement et la consolidation ne sont assurés qu'au cas d'un excès de la phase d'hydroaluminate devant celle nécessaire à la formation de l'ettringite. Cette condition est garantie par un rapport correspondant entre les aluminates et le sulfoaluminate de calcium dans le ciment.

Au cours de l'hydratation du mélange de sulfoaluminate de calcium et de gypse en présence du silicate tricalcique, le gypse est fixé dès le premier jour avec formation d'ettringite à côté duquel on observe dans l'éprouvette une importante quantité d'aluminates de calcium hydratés. Il a été établi que l'hydratation de  $\text{C}_2\text{S}$  en présence du sulfoaluminate de calcium s'accélère. Dans ce cas le degré d'hydratation de  $\text{C}_2\text{S}$  est au bout de 28 jours de 80 %, tandis qu'en absence de sulfoaluminate de calcium il est de 60 %. En qualité de corollaire on observe une élévation de résistance de la structure d'hydratation. Dans le premier cas la pierre de ciment se caractérise par une résistance de  $550\ \text{kgf/cm}^2$ , et dans le second de  $465\ \text{kgf/cm}^2$ .

L'hydratation du silicate bicalcique, du sulfoaluminate de calcium et du gypse s'accompagne de la formation de l'ettringite, d'hydrosilicates fibreux et d'aluminates de calcium hydratés en forme de lamelles écailleuses. Le degré d'hydratation de  $\text{C}_2\text{S}$  mélangé au sulfoaluminate de calcium et au gypse est supérieur à celui de l'hydratation de  $\text{C}_2\text{S}$  pur au cours de tous les stades de durcissement des éprouvettes. Il a été constaté qu'au cours de l'hydratation du mélange mentionné il s'établit une structure très résistante de beaucoup supérieure à celle de la pierre de ciment obtenu lors du durcissement de  $\text{C}_2\text{S}$  pur. On a utilisé cet effet pour la mise au point du ciment de sulfoaluminatobélite. Dans des conditions de production industrielle on a obtenu un clinker de sulfoaluminate composé de sulfoaluminate de calcium, d'aluminate de calcium de formule  $12\text{CaO} \cdot 7\text{Al}_2\text{O}_3$  et de silicate bicalcique (fig. 3).

Le clinker moulu avec et sans gypse a permis d'obtenir des ciments qui soumis aux

essais ont donné les résultats groupés au tableau 3.

Fig. 3 - Diagramme radiographique du clinker de sulfoaluminate. o -  $C_3A,CS$ , x -  $C_{12}A_7$ , . -  $C_2S$

Les études montrèrent que l'hydratation des phases de sulfoaluminates et de silicates s'effectue simultanément. Comme au cas d'études d'éprouvettes en laboratoire on a établi qu'au cours de l'hydratation du ciment de sulfoaluminatobelite il se forme des cristaux allongés d'ettringite, des hydrosilicates et des aluminates de calcium hydratés de forme fibreuse et lamellaire. La grande résistance de la pierre de ciment d'une telle microstructure a été notée maintes fois par V.V. Timachev et O.P. Mtchedlov-Petrosian.

Tableau III				
Désignation du ciment	Surface spécifique, $cm^2/g$	Résistance à la compression, $kgf/cm^2$		
		1 j.	3 j.	28 j.
De sulfoaluminatobelite	4000	352	400	620
Idem avec addition de gypse	4000	382	425	642

Mélangé au clinker-portland et au gypse le clinker de sulfoaluminate garantit une production de ciments expansifs et à contraindre se caractérisant par une extension égale à 0,1-1,0 % et une autotension de l'ordre de 20 à 38  $kgf/cm^2$  suivant le rapport entre les composants.

Donc la grande résistance ainsi que l'extension et l'autotension de la pierre de ciment sont des effets de la grande vitesse et du degré d'hydratation du ciment qui régissent la rapide formation de l'ettringite et d'aluminates de calcium hydratés

dès le premier jour de durcissement et, les jours suivants, d'hydrosilicates de calcium. Le rapport optimal entre la quantité d'ettringite et d'aluminates de calcium hydratés varie en fonction des besoins d'obtenir soit un ciment à haute résistance, soit un ciment expansif.

# Very early hydration of tricalcium silicate

## *L'hydratation aux premiers âges du silicate tricalcique*

E. SAKAI, Dr. Research Associate, M. DAIMON, Dr. Associate Professor and R. KONDO, Dr. Professor,  
Dept of Inorg. Materials, Faculty of Eng. Tokyo Institute of Technology, Japan.

RESUME : On a étudié l'hydratation aux premiers âges du silicate tricalcique anhydre, broyé à des finesses variées. Les propriétés du silicate tricalcique anhydre ont été déterminées par IR, par analyse aux rayons X, par Kr-adsorption, et par la mesure de la chaux libre. Le dégagement de chaleur de l'hydratation a été mesuré au moyen d'un calorimètre "isoperibol", à deux cellules associées dans un montage différentiel. D'autre part, on a recherché l'influence de  $\text{Ca(OH)}_2$  et de sulfonates aromatiques de soude ayant des structures moléculaires variées, sur la composition de la phase liquide. L'hydratation, aux tous premiers âges, du silicate tricalcique peut être divisée en deux phases: la première correspond à la libération immédiate d'ions  $\text{Ca}^{2+}$ , et la seconde, qui suit la première, correspond à la libération plus lente d'autres ions  $\text{Ca}^{2+}$ . Les résultats expérimentaux peuvent être expliqués par la théorie topochimique conventionnelle.

Après la première phase de l'hydratation, le sulfonate aromatique de soude ayant une longue chaîne hydrophobe, est adsorbé par le silicate tricalcique et ses premiers hydrates. Il s'en suit que la seconde phase du dégagement de chaleur est retardée, de même que la poursuite de l'hydratation du silicate tricalcique.

SUMMARY : Very early hydration of tricalcium silicate was studied using samples with various grinding times. Properties of unhydrated tricalcium silicate was determined by IR, X-ray diffraction, Kr-adsorption and free lime analysis. Heat liberation of hydration was measured by means of twin isoperibol calorimeter. Furthermore, influence of  $\text{Ca(OH)}_2$  and sodium aromatic sulfonates, with different molecular structures, were investigated in connection with the composition of liquid phase. The very early hydration of tricalcium silicate could be divided into two steps. The first corresponded to the immediate liberation of  $\text{Ca}^{2+}$  ion and the second following slower liberation of  $\text{Ca}^{2+}$  ion respectively. The experimental results could be explained by conventional topochemical theory.

After the first step of hydration, sodium aromatic sulfonate, having a long hydrophobic chain was adsorbed on tricalcium silicate or the first hydrates. Then the second step of heat liberation was retarded, and the further hydration of tricalcium silicate was retarded.

## INTRODUCTION

It has long been discussed whether the hydration of tricalcium silicate ( $C_3S$ ) takes place through solution or topochemically. A principle paper entitled "Phase composition of hardened cement paste" was contributed at the previous congress, and dealt with the mechanisms of cement hydration and the phase composition (1). However, the mechanisms of  $C_3S$  hydration have not been well known, and especially, the studies on the very early stages are insufficient.

Authors have investigated the kinetics and the mechanisms of hydration of  $C_3S$  using samples with narrow particle size distribution, and five stages were introduced as follows (2). In the  $S_I$  stage, the reaction took place immediately on contact with water. In the  $S_{II}$  stage, nucleation of C-S-H having low  $CaO/SiO_2$  (C/S) ratio with slow liberation of  $Ca^{2+}$  ion. In the  $S_{III}$  stage, the reaction took place very actively and was accelerated with time. In the  $S_{IV}$  stage, the rate of hydration decreased gradually,  $S_{IV}$  and  $S_V$  were the decay period. According to de Jong et al. (3), calcium silicate hydrate (C-S-H) coatings having high C/S ratio were formed on  $C_3S$  particles surface, thus prevented any further hydration of  $C_3S$ . With the passage of time, when C/S ratio of C-S-H decreased and the first hydrates converted into the second hydrates which were more permeable, the hydration of  $C_3S$  was accelerated. And Stein summarized the conventional studies of the mechanism of  $C_3S$  hydration and reconfirmed the validity of topochemical reaction theory (4).

Young et al., on the other hand, suggested that the induction period was controlled by the nucleation of calcium hydroxide (CH), and that the second peak of rate of heat liberation was controlled by the growth of CH (5). Fujii and Kondo (6) reported that when the maximum supersaturation of solution with calcium ions was attained, then the induction period would terminate and the reaction would proceed rapidly, probably as the result of propagative surface nucleation-growth of C-S-H(II). Maycock et al., who proposed the schematic model of  $C_3S$  hydration suggested that the induction period corresponded to nucleation of CH and the second hydrates (7). According to Tadros et al., calcium ions adsorbed on the Si-rich surface of  $C_3S$  particles, greatly reducing their further dissolution, thus initiating the induction period (8). Dent Glasser et al., recently, have studied the hydration of  $C_3S$  by means of analytical electron microscopy and trimethyl silylation, and they have postulated that initial protonic attack gave a surface layer of high C/S ratio and calcium ions was then lost and silicate tetrahedra condense gave dimer (9).

Very early hydration of  $C_3S$  had to be studied by considering the mechanochemical effect such as lattice defect or surface activity. Relations between surface activity, lattice

defect and the reactivity of cement were discussed (7,10,11). But the investigation of the correlation between the mechanochemical effect and the very early hydration of  $C_3S$  was scarce.

In this study, the mechanisms of the very early hydration of  $C_3S$  are investigated using samples which were ground for 15h, 30h, 48h, exposed to 100%RH for 1h, and the CH saturated solution or sodium aromatic sulfonates with different molecular structures were added. This study is also very important in considering the retarding mechanisms of organic compounds on the hydration of cement.

## EXPERIMENTAL

## Materials

$C_3S$  was synthesized based on the composition as shown in Table I (12). The synthesized  $C_3S$  was the so-called M phase or alite from the X-ray diffraction patterns.

Table I Chemical composition (%)

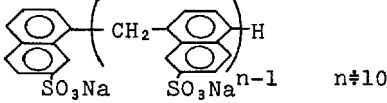

$SiO_2$	$Al_2O_3$	CaO	MgO	Total
25.8	1.2	72.0	1.0	100.0

The synthesized  $C_3S$  was crushed in an alumina mortar and was ground for 15, 30, 48h respectively. The properties of ground  $C_3S$  were analyzed as follows.  $B_{009}/B_{\theta} \cot \theta$  was measured using (009) of X-ray diffraction patterns. Specific surface area of ground  $C_3S$  was measured by Blaine's method and Kr adsorption. Particle size distribution of  $C_3S$  was measured by the photo-extinction method. The infrared spectrum of ground  $C_3S$  was observed by means of KBr disk method. The amount of free-CaO was measured by glycerol-alcohol method.

In the study of effect of sodium aromatic sulfonates, a large amount of  $C_3S$  was synthesized and was ground for 20h in order to study the effect of various organic compounds.

Additives, used in this study were sodium benzenesulfonate (BS) and sodium p-dodecylbenzenesulfonate (12N) made by TOKYO KASEI KOGYO CO. (Japan), and sodium salts of formaldehyde high condensate  $\beta$ -naphthalene-sulfonate (HCNS). The degree of polymerization of the latter was about 10, it was Mighty-150 made by KAO SOAP CO. (Japan). Table II shows the formulas of sodium aromatic sulfonates used in this study. BS has a hydrophilic group ( $-SO_3Na$ ) at an end of the molecule and a short hydrophobic group. 12N has a hydrophilic group at an end of the molecule and a long hydrophobic group. HCNS has many hydrophilic groups in the long molecule.

Table II Used sodium aromatic sulfonates

Sodium benzenesulfonate (BS)

Sodium p-dodecylbenzenesulfonate (12N)

Sodium salts of formaldehyde high condensate of $\beta$ -naphthalenesulfonate (HCNS)

Condition

The water to solid ratio was 10 and hydration temperature was 20°C. The amount of additives was 0.5% by weight of  $C_3S$ .

Calorimetry

Conduction calorimetry was highly suitable for measuring the heat liberation of cement hydration and was used by many investigators, but it is unsuitable for measuring the rapid change of heat. Therefore the twin isoperibol calorimeter (TOKYO RIKO CO., Japan) as shown in Fig.1 was used in this study.

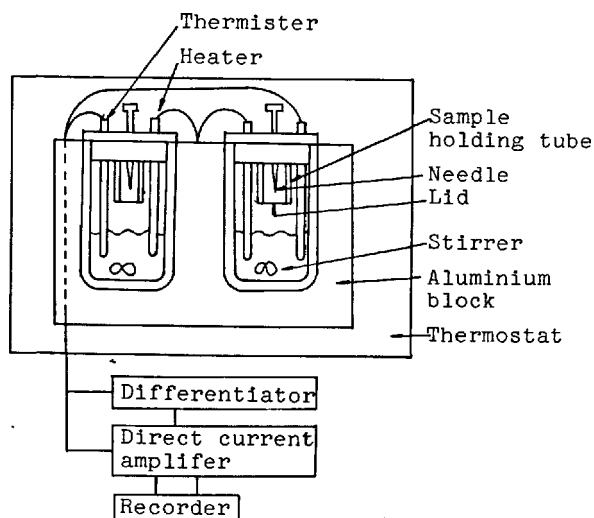

Fig.1 - The twin type of isoperibol calorimeter

Analysis of liquid phase

After  $C_3S$  was hydrated using the apparatus as shown in Fig.2, liquid phase was extracted by filtration. After adding  $Sr^{2+}$  ion as releaser,  $Ca^{2+}$  ion of liquid phase was analyzed by atomic absorption spectrophotometry. And pH changes of liquid phase were recorded continuously.

Fig.2 - The reaction apparatus

RESULTSProperties of ground  $C_3S$ 

The specific surface area of  $C_3S$  increases with grinding time as shown in Fig.3. The results of Kr adsorption do not agree well with and are larger than those of Blaine's method. Particle size distribution of  $C_3S$  is shown in Fig.4. The amount of  $C_3S$  having fine particle diameter increases with grinding time. The properties of ground  $C_3S$  are summarized in Table III. Free- $CaO$  and  $B_{900}/B_{940}$  increases with grinding time. IR spectra become broader with grinding time, and adsorption band of  $C_3S$  ground for 48h shifts to longer wave lengths (Absorption of  $930cm^{-1}$  shifts to  $940cm^{-1}$ ). Specific surface area of  $C_3S$  sample, used in the study of the effect of sodium aromatic sulfonates, as measured by Kr adsorption and Blaine's method are  $0.54m^2/g$  or  $0.41m^2/g$  respectively. In this case, free- $CaO$  is 0.02% and IR spectrum indicates the same results with 15h ground sample in Fig.3.

Fig.3 - Relation between grinding time and specific surface area

Fig. 4 - Relationship between particle size distribution of  $C_3S$  and grinding time

Table III The properties of ground  $C_3S$

Grinding time (h)	$B\cot\theta/B^0\cot\theta$	Free- $CaO$ (%)
0	1	0.019
15	1.025	0.027
30	1.058	0.049
48	1.064	0.055

#### Suspension hydration of $C_3S$

Heat liberation of very early hydration of  $C_3S$  is shown in Fig. 5. These heat liberation curves calculated from experimental data using equation (1).

$$\Delta T_{ad} = \Delta T_{ex} + \alpha \quad \dots\dots (1)$$

$$\Delta T_{ex} = T_2 - T_1$$

$$\alpha = \Delta T_{ex} \cdot \exp(t/\tau)$$

where  $\Delta T_{ad}$  is the adiabatic rise of temperature and  $\Delta T_{ex}$  is experimental value.  $T_2$  and  $T_1$  is experimental data of temperature.  $t$  is the time from  $T_1$  to  $T_2$ ,  $\tau$  is the time constant of the calorimeter (in this case, 60 min.).

The very early hydration of  $C_3S$  takes place by two steps. With the increase of grinding time, heat liberation in the first step ( $Q_1$ ) is increased and the appearance of the second step of heat liberation ( $Q_2$ ) is accelerated.

In 0h-ground sample, which is crushed in alumina mortar, it is not clear whether the reaction takes place by two steps. When  $C_3S$  hydrates in  $Ca(OH)_2$  saturated solution, the second step of heat liberation does not take place. The heat liberation of the first step

decreases when  $C_3S$  sample is exposed to 100%RH for 1h.

Fig. 5 - Heat liberation of  $C_3S$  hydration

#### Influence of sodium aromatic sulfonates on the very early hydration of $C_3S$

The heat liberation owing to  $C_3S$  hydration with sodium aromatic sulfonates is shown in Fig. 6. BS does not retard the very early hydration of  $C_3S$ . In the presence of 12N,  $Q_1$  is smaller than no addition case, and  $Q_2$  is not detected. The second step of very early hydration is found to be retarded by the addition of HCNS, and the main hydration of  $C_3S$  may be overlapped by the second step. The changes of  $Ca^{2+}$  concentration in liquid phase are shown in Fig. 7. As soon as  $C_3S$  contacts with water,  $Ca^{2+}$  ion of liquid phase increases rapidly, and thereafter, it increases gradually with processing time. In the case of 12N and HCNS addition,  $Ca^{2+}$  ion of liquid phase increases rapidly, but does not increase in the second step. The results of pH measurements show the parallel tendency with those of  $Ca^{2+}$  ion.

#### DISCUSSION

##### Mechanisms of the very early hydration of $C_3S$

Authors have reported that the very early hydration of  $C_3S$  using narrow particle size distribution, took place by two steps (2), the two-step reaction does not depend on the particle size distribution.

$Q_1$  and  $Q_2$  are larger than the heat of immersion of  $SiO_2$ ,  $TiO_2$ , and  $SnO_2$  which are about  $0.59J/m^2$ . Thus, it may be considered that the heat liberation depends on the

Fig. 6 - Influence of sodium aromatic sulfonates on the very early hydration of  $C_3S$

chemical reaction.  $Q_1$  increases with the increasing specific surface area and surface activity of  $C_3S$ , which increases with grinding time. The values of  $B\cot\theta/B^0\cot\theta$ , shown in Table III, are affected by crystallite size as well as lattice defects. But it is supposed to be true that surface activity of  $C_3S$  becomes higher with grinding time, because IR spectra become broad and free- $CaO$  increases.

The hydration of  $C_3S$  has been discussed based on topochemical theory.  $Q_1$  may be corresponded to the formation of the first hydrates with rapid release of  $Ca^{2+}$  ion. When  $C_3S$  is exposed to 100%RH for 1h,  $Q_1$  decreases as the first hydrates are already formed.

In the case of  $C_3S$ , hydrated in CH saturated solution,  $Q_2$  is not observed for liquid phase is saturated with CH, and main hydration of  $C_3S$  was retarded (2).  $Q_2$  should correspond to the nucleation of hydrates having low C/S ratio, that is, the formation of the second hydrates with release of  $Ca^{2+}$  ion. The mechanisms of  $C_3S$  hydration are illustrated in Fig. 8.

Fig. 8 - Illustration of  $C_3S$  very early hydration

Fig. 7 - The concentration of  $Ca^{2+}$  ion of a hydrating  $C_3S$  suspension with or without additives.

#### Retarding mechanisms

The influence of sodium aromatic sulfonates having different molecular structures on the main hydration of  $C_3S$  and portland cement has been reported in connection with the amount of adsorption (13). A certain type of surfactants having a long hydrophobic group and a hydrophilic group at the end of the molecule such as I2N, shows a critical amount of addition. The hydration of cement is significantly retarded only when the dosage exceeds a critical amount. I2N is, then, closely adsorbed on cement. HCNS gradually retards the hydration with the amount of addition. The retarding effect of BS having a short hydrophobic chain is low because the amount of adsorption is small, even if the concentration is high.

In all cases,  $Q_1$  takes place, but with the addition of I2N,  $Q_1$  is smaller than others.  $Q_2$  is retarded by the addition of I2N and HCNS. In the first step of very early hydration, the concentration of  $Ca^{2+}$  ion approximately reaches the point of zero charge range according to Stein's study of surface charge of calcium silicates and calcium silicate hydrates (14). Tadros et al. have suggested that calcium ions are adsorbed on Si-rich surface of  $C_3S$  particles (8).

Therefore, when the first step of very early hydration occurs, the surface charges of  $C_3S$  or the first hydrates become positive. Because anionic additives having a long hydrophobic chain is adsorbed on positive surface, the slow release of  $Ca^{2+}$  ion is prevented, and the formation of the second hydrates are prevented. Then the second step is retarded, and therefore the further hydration of  $C_3S$  is also retarded.

## CONCLUSION

Very early hydration of  $C_3S$  takes place by two steps. The heat liberation in the first step increases, and the appearance of the second step of heat liberation is accelerated with grinding time. The heat liberation of the first step decreases when  $C_3S$  was exposed to 100%RH for 1h before hydration. When  $C_3S$  hydrates in CH saturated solution, the second step of heat liberation ( $Q_2$ ) was not detected. The first step may be corresponded to the formation of the first hydrates with rapid release of  $Ca^{2+}$  ion, and the second step to the nucleation of hydrates having low C/S ratio, with slow release of  $Ca^{2+}$  ion.

Sodium aromatic sulfonates having a long hydrophobic chain are adsorbed onto the first hydrates of  $C_3S$ . Then the second step of very early hydration is retarded, and therefore the further hydration of  $C_3S$  is also retarded.

# Eventement et raidissement des ciments

## *Air aging and stiffening of Portland cements*

A. BONIN, ingénieur de recherche, laboratoire de recherche générale, Lafarge S.A., France.

RESUME : L'étude a été réalisée sur un CPA 55 R industriel ne présentant, en conservation prolongée à l'abri de l'air, aucun phénomène de raidissement lors de l'utilisation en pâtes ou mortiers.

Dans un premier temps, on a montré que des événements contrôlés du ciment à 20°C et 50 ou 80 % d'hygrométrie relative entraînaient des modifications néfastes plus ou moins marquées du comportement rhéologique. On a ensuite déterminé dans chaque cas de conservation la nature et la cinétique d'apparition, après gâchage, des premiers hydrates. Une corrélation entre ces cinétiques et l'effet passivateur de la vapeur d'eau sur la phase alumineuse du ciment a permis d'expliquer les anomalies d'écoulement observées dans le cas des ciments éventés.

SUMMARY : For this study a high early strength industrial Portland cement was used, which did not show any sign of stiffening, even after prolonged aging under dry air.

First, it was established that checked air agings of the cement at 50 or 80 % R.H. and 20°C result in more or less pernicious modifications of the rheological behaviour.

Then the nature and kinetics of formation of hydrates were determined in all cases of conservation. The surprising types of flow observed with pastes or mortars of wet air exposed cements are explained by comparing the kinetics of hydrates formation and the passivation effect of water vapour on aluminous phases.

## INTRODUCTION

L'événement ou exposition à l'air plus ou moins humide d'un ciment Portland ne présentant aucun phénomène de fausse prise, peut modifier de diverses manières le comportement rhéologique des pâtes, mortiers ou bétons dans les premières minutes de l'hydratation.

Nous écarterons d'office le cas bien connu de la fausse prise carbonate due à la carbonatation des alcalins pendant l'événement. Les carbonates alcalins qui en résultent réagissent au gâchage avec la chaux et précipitent de la calcite ; ce mécanisme est générateur de raidissement.

Dans le cas d'un clinker broyé non gypsé, tous les auteurs admettent que c'est l'hydratation immédiate du  $C_3A$  qui entraîne la prise rapide. La présence de gypse suffit à ralentir, et même à bloquer, l'hydratation de cette phase supprimant ainsi tout raidissement.

L'interprétation de l'action retardatrice du gypse ne fait pas contre pas encore l'unanimité :

SKALNY (1) pense que la dissolution du  $C_3A$  est incongruente. Avec un rapport C/A dans la solution supérieur à trois, il se formerait au contact du  $C_3A$  une couche riche en alumine sur laquelle s'adsorbent les ions calcium. Cette pellicule alors chargée positivement attirerait les ions  $SO_4^{--}$  et formerait ainsi une barrière à la diffusion de l'eau vers le  $C_3A$ .

FELDMAN et RAMACHANDRAN (2) font intervenir la cinétique de dissolution du  $C_3A$  qui serait contrôlée par la présence et le mouvement des dislocations cristallines, lesquelles seraient bloquées par l'adsorption superficielle des ions  $SO_4^{--}$  ralentissant ainsi la mise en solution.

GUPTA (3) envisage la formation d'une pellicule imperméable de  $C_4AH_x$  en présence de  $Ca(OH)_2$  et de  $SO_4Ca \cdot 2H_2O$  stable tant que la concentration en  $Ca(OH)_2$  reste assez élevée. Il n'exclut pas la formation de petites quantités d'ettringite, mais pense qu'elle précipite par réaction entre le  $C_4AH_x$  et le gypse avec libération de chaux hydratée qui renforcerait alors la stabilité du  $C_4AH_x$ .

Enfin STEINOUR (4), STEIN (5), COTTIN (6), COLLE-PARDI (7) admettent la formation directe d'une coquille d'ettringite par réaction  $C_3A$  - gypse. Cette capsule de tri-sulfoaluminate plus ou moins bien cristallisée serait assez imperméable à l'eau et aux ions  $SO_4^{--}$  pour isoler mécaniquement le  $C_3A$  du reste de la solution de gâchage.

En ce qui nous concerne, nous admettons cette interprétation et c'est avec ce modèle que nous expliquerons les comportements des ciments éventés.

Dans cette hypothèse, pour que le blocage du  $C_3A$  soit efficace, il faut que la coquille d'ettringite se forme rapidement sur les surfaces de  $C_3A$ . Son épaisseur minimale nécessaire sera de plus fonction de l'imperméabilité de la couche d'hydrate, donc de sa structure. Tout ce qui pourra dans le système  $C_3A$  - gypse - eau modifier la cinétique de formation et la structure de la couche d'ettringite, aura une influence certaine sur le comportement rhéologique des pâtes.

Dans cette optique, il faut citer les considérations de LOCHER (8) qui fait intervenir les réactivités relatives des deux phases principales que sont le  $C_3A$  et le sulfate. Par exemple, si le  $C_3A$  est plus actif que le sulfate (gypsage à l'anhydrite), il y aura possibilité de précipitation de  $C_4AH_x$  et de formation différée d'ettringite plus éloignée des sur-

faces de  $C_3A$  et par ce fait moins protectrice. Si par contre c'est le sulfate qui est plus actif (présence de semihydrate ou d'anhydrite soluble) la formation ralentie d'ettringite laisse la possibilité de précipitation de gypse entraînant le raidissement de type sulfate.

Enfin, si en présence de semi hydrate on a un  $C_3A$  super actif, la précipitation rapide d'ettringite consomme très vite tout le semi hydrate et élimine le risque de précipitation du gypse, tout en bloquant énergiquement le  $C_3A$ .

Ayant mis en évidence des comportements rhéologiques inhabituels d'un ciment industriel selon son mode de conservation, nous avons émis l'hypothèse que l'événement modifiait suffisamment la réactivité du  $C_3A$  pour provoquer des changements de fluidité. C'est pourquoi nous avons réalisé l'étude expérimentale de tels phénomènes.

## REALISATION DES ESSAIS

Choix du ciment

Nous avons choisi le CPA 55 R qui avait posé industriellement des problèmes de conservation. Le clinker a pour composition potentielle :

$C_3S = 66,3 \%$ ,  $C_2S = 15,4 \%$ ,  $C_3A = 0,5 \%$ ,  $C_4AF = 14,5 \%$   
Chaux libre : 1,55 %

$K_2O$  est le seul alcalin présent (0,25 %) entièrement combiné sous forme sulfate. Le ciment est obtenu par broyage industriel avec du gypse ( $SO_3 = 2,25 \%$ ) à la finesse de 4575  $cm^2/g$ . On a vérifié qu'il ne contenait pas de semi hydrate en proportion décelable.

On peut remarquer la forte teneur en  $C_4AF$  et la quasi absence de  $C_3A$  dans ce ciment mais nous savons par ailleurs que ce composé a dans le cas présent une très forte activité et que le ciment non gypsé raidit aussi fortement qu'un ciment contenant une proportion prépondérante de  $C_3A$ . Par ailleurs, en accord avec COLLEPARDI (9), nous savons que  $C_4AF$  en présence de gypse et de chaux (cas d'un ciment) a le même comportement que  $C_3A$  dans la première demi-heure d'hydratation (formation d'ettringite avec la même cinétique).

Eventement du ciment

Le ciment a été éventé pendant 24 heures, à 20°, en couche mince soit à 50 % d'hygrométrie relative, soit à 80 %. L'atmosphère n'étant pas exempte de  $CO_2$ , nous avons vérifié que les produits éventés ne contenaient pas de carbonates alcalins de manière décelable et susceptibles de provoquer une fausse prise carbonate. Dans les deux cas, quelques essais de durée d'événement différente ont été réalisés pour juger de la cinétique de passivation de l'aluminate de calcium.

Comportement rhéologique en présence d'eau

On a testé le comportement rhéologique après gâchage de deux manières :

- En pâte pure par la méthode de raidissement au bol : on gâche à la spatule dans un récipient appelé bol une certaine quantité de pâte qui ensuite est transvasée dans le moule tronconique des essais de consistance normalisés (NF P 15-414). La mesure consiste ensuite à déterminer à des temps fixés : 2 - 5 - 10 - 15 et 30 minutes, le refus d'enfoncement de la sonde de Vicat ( $\phi = 1$  cm). Le E/C d'obtention de la pâte dite normale est ajusté pour obtenir immédiatement après gâchage un refus de 4 à 5 mm. La hauteur du moule normalisé étant de 40 mm, le refus de la sonde ne

peut évidemment pas dépasser cette valeur.

- En mortier normalisé (norme NF P 15-403) par la technique du maniabilimètre LCPC où l'on mesure après 30 minutes de repos du mortier mis en place dans l'appareil, un temps d'écoulement sous vibration, dans des conditions standardisées (10).

#### Détermination des cinétiques d'hydratation

La cinétique d'hydratation a été suivie de deux manières :

- Par enregistrement à 20° de la chaleur d'hydratation avec un calorimètre à conduction. Le dégagement calorifique est mesuré dès le contact eau-ciment. Il n'y a pas de gâchage mécanique mais simple mouillage de la poudre par capillarité, l'eau étant introduite par une seringue.

- Par dosages en analyse thermique différentielle. A cet effet, on gâche des pâtes pures manuellement pendant une minute puis aux échéances de 0 - 2 - 5 - 10 - 15 minutes (décomptées immédiatement après la fin du gâchage) on prélève des échantillons dont on stoppe l'hydratation par lavage acétone-éther. L'examen de ces produits par ATD permet l'identification des hydrates et leur dosage quantitatif (moyennant un étalonnage préalable (11)). Quand la teneur en hydrate est suffisante, on peut confirmer par diffraction des rayons X leur nature minéralogique.

#### RESULTATS OBTENUS

##### Comportement rhéologique

Ciment	Écoulement au maniabilimètre LCPC		Essai de raidissement au bol						
	E/C	Temps après 30' de repos	E/C	Refus d'enfoncement de la sonde aux échéances de (mm)					
				0	2	5	10	15	30
Témoin	0,50	17 s.	0,275	6	22	26	27	27	28
24 h. à 50 % HR	0,50	168 s.	0,280	5	40	40	40	40	40
24 h. à 80 % HR	0,50	23 s.	0,306	7	15	20	21	25	30

TABLEAU N° 1 : Comportement Rhéologique des ciments.

Le tableau n° 1 montre que, par rapport au ciment témoin, celui éventé à 50 % d'hygrométrie relative accuse un très fort raidissement, alors que celui éventé à 80 % n'a pas vu ses caractéristiques rhéologiques sensiblement modifiées.

On note toutefois que le E/C nécessaire à l'obtention d'une pâte normale inchangé pour le produit éventé à 50 % HR augmente significativement pour celui éventé à 80 % HR.

On a aussi remarqué qu'en remalaxant la pâte ou le mortier après cinq minutes de repos, on détruit le raidissement du produit éventé à 50 % HR et celui-ci ne se régénère plus par la suite.

Ces mesures de raidissement après éventement sur un ciment à forte teneur en  $C_3A$  ont été reproduites de nombreuses fois sur des ciments à fortes teneurs comparées en  $C_3A$  et conduisent toujours au même comportement rhéologique des pâtes.

#### Nature et cinétique de formation des premiers hydrates

Les examens en analyse thermique différentielle et en diffraction des rayons X ont montré que l'ettringite était le seul hydrate présent pendant la première demi-heure d'hydratation. Le tableau n° 2 et le graphique n° 1 donnent les résultats de dosage de l'ettringite en fonction des temps d'hydratation.

Ciment	% d'ettringite aux échéances de (mn)							anhydre	
	dans l'an-hydré	0	2	5	10	15	30	% perte au feu à 1000°	% $CO_2$
Témoin	0	2,4	2,7	3,0	2,9	2,2	3,2	2,00	0,33
24 h. à 50 % HR	0	0,4	1,7	2,4	3,2	3,4	3,5	2,06	0,35
24 h. à 80 % HR	1,4	1,8	1,7	1,6	1,7	1,7	1,5	4,70	1,70

TABLEAU N° 2 : Dosage de l'ettringite en fonction du temps d'hydratation.

On remarque que :

- Au niveau du ciment anhydre le témoin et celui éventé 24h à 50 % HR sont très semblables : absence d'ettringite, même perte au feu à 1000° et même teneur en  $CO_2$ .

- En ce qui concerne les cinétiques d'hydratation en ettringite de ces deux ciments, on note une grande différence. D'une part, la quantité globale de trisulfoaluminate atteinte à l'équilibre est inférieure pour le témoin et d'autre part elle se forme à des moments différents. En effet, sur les 3,0 % d'ettringite du témoin, 80 % se forment au gâchage et seulement 20 % dans la période de repos qui suit. Le phénomène est inversé pour le ciment éventé 24 heures à 50 % HR puisque sur les 3,5 % d'hydrate formé à 15 minutes, 10 % seulement apparaissent au gâchage et les 90 % durant la période de repos.

GRAPHIQUE N° 1 : Cinétique de formation de l'ettringite

- Pour le ciment éventé 24 heures à 80 % HR, on voit que l'ettringite en quantité moindre (1,4 %) est déjà formée pendant l'événement et qu'au contact de l'eau de gâchage cette teneur évolue très peu. La formation d'ettringite est confirmée par l'accroissement de la perte au feu à 1000°. En tenant compte du  $\text{CO}_2$ , on trouve un accroissement de l'eau liée de 1,33 % exprimé par rapport à l'anhydre alors que la perte au feu à 1000°, due à l'ettringite, et exprimée dans les mêmes conditions est de 1,20 % pour 1,4 % d'ettringite. L'augmentation du  $\text{CO}_2$  est vraisemblablement due à la carbonatation de la chaux libre et en tout cas sans aucun effet sur le raidissement.

- Les courbes calorimétriques données par le graphique n° 2, sont en accord avec les résultats précédents à savoir un retard de dégagement de chaleur par rapport au témoin du ciment éventé à 50 % HR et une quasi absence de réaction pour celui éventé à 80 % HR.

GRAPHIQUE N° 2 : Microcalorimétrie des ciments

En faisant varier les temps d'événement, les courbes calorimétriques montrent que :

- à 50 % HR, il faut maintenir l'exposition au moins pendant 8 heures pour avoir un effet mesurable. A partir de 24 heures, les cinétiques de formation d'ettringite sont semblables, seule augmente la quantité finale d'ettringite globale.

- à 80 % HR, l'action est visible dès les premières heures d'exposition à l'air humide et se poursuit jusqu'à 16 heures, en restant stable par la suite.

#### INTERPRETATION DES RESULTATS

Nous avons mis en évidence que le seul hydrate présent pendant les premières minutes de contact avec l'eau était l'ettringite. De plus, on note de grandes différences de cinétique de formation selon les modes de conservation du ciment. C'est donc là qu'il faut chercher les causes des anomalies du comportement rhéologique constatées.

Lors de l'utilisation d'un ciment, il y a trois périodes importantes

- Son gâchage en présence de granulats plus ou moins gros
- Une période d'attente plus ou moins longue avant l'emploi

- La prise et le durcissement après la mise en place.

L'ettringite est susceptible, nous l'avons vu, de se former à n'importe lequel de ces moments : pendant le gâchage, nous l'appellerons ettringite de gâchage, et durant la période d'attente : ettringite de repos.

En admettant le modèle de protection de l'aluminate de calcium anhydre par une pellicule d'ettringite, il est clair que si deux grains de ciment se trouvent en contact au niveau de la matière interstitielle, les coquilles d'ettringite à cet endroit, auront une partie commune. Cette mise en commun de matière va assurer une liaison augmentant ainsi la rigidité de la pâte. Le raidissement sera d'autant plus intense que ces contacts seront plus nombreux et mieux consolidés. Lors du gâchage, où toutes les particules sont en mouvement, la probabilité pour que deux surfaces de matière interstitielle soient suffisamment longtemps en contact pour mettre leurs coquilles d'ettringite en commun, est relativement faible. Il s'ensuit un petit nombre de liaisons. De plus celles qui ont pu s'établir, ne sont pas très fortes et sont en quasi totalité détruites par l'énergie de malaxage. En d'autres termes, l'ettringite de gâchage tout en assurant son rôle bloquant de l'aluminate de calcium, n'est pas préjudiciable à la fluidité de la pâte.

Par contre, au repos, ces mises en commun de coquilles ont tout le temps de s'établir et de se consolider sans que rien ne vienne les briser. Il s'ensuit un raidissement important de la pâte que l'énergie des moyens de mise en place ne peut briser. L'ettringite de repos apparaît donc particulièrement néfaste pour la fluidité bien qu'elle remplit encore son rôle bloquant.

En revenant au cas concret du ciment étudié, on voit que :

- Le témoin a 80 % de son ettringite totale sous forme d'ettringite de gâchage non néfaste, et effectivement, il ne présente aucun raidissement.

- Le ciment éventé à 50 % HR a par contre 90 % de son ettringite sous forme d'ettringite de repos très néfaste et il présente bien un fort raidissement. Il est possible de transformer une grande partie de l'ettringite de repos en ettringite de gâchage. Il suffit pour cela, à l'échéance de 5 mn, de remalaxer la pâte ou le mortier. Nous sommes alors ramenés au cas du témoin et observons bien une fluidité normale retrouvée et stable.

- Le comportement du ciment éventé à 80 % HR est un peu plus particulier. Il ne présente ni ettringite de gâchage, ni de repos. Tout se passe comme si, dans cette atmosphère proche de la saturation, l'ettringite était capable de se former en surface de l'aluminate de calcium, l'encapsulant avant le gâchage. Il faut remarquer que l'imperméabilité de cette couche paraît excellente puisque 1,4 % d'ettringite suffisent pour passer le  $\text{C}_3\text{A}$ . L'eau de la pâte n'arrivant plus au contact de ces surfaces, il est normal de ne pas observer de raidissement.

Nous avons constaté que pour les ciments éventés à 80 % HR, il fallait, pour obtenir la fluidité normalisée, augmenter l'eau de gâchage de 10 % en pâte pure et qu'il n'était pas nécessaire de modifier celle du mortier.

Nous pouvons expliquer cette variation d'eau de gâchage si on considère que :

- L'événement à 80 % HR est susceptible de souder des grains entre eux par l'intermédiaire de l'ettringite.

- Dans la poudre de ciment, la distance moyenne des grains est très élevée (densité apparente inférieure à 1) comparée à celle obtenue dans les pâtes normales.

L'action du gâchage qui apparaît comme le moyen de permet-

tre aux grains de se distribuer pour rapprocher leurs centres au maximum dans un empilement le plus compact possible sera plus aisée pour des grains libres que pour des grains soudés entre eux.

Si donc, pour le ciment éventé, le gâchage est peu énergétique (cas des pâtes pures obtenues à la spatule), l'assemblage sera moins compact donc plus riche en eau. Par contre, en présence de granulats et au malaxeur mécanique, l'énergie est suffisante pour séparer les grains et permet d'obtenir la même compacité que pour le ciment non éventé.

En ce qui concerne les temps d'événement autres que 24 heures :

- à 50 % HR quand on poursuit jusqu'à 15 jours, on augmente de quelques points la teneur en ettringite de repos accentuant le raidissement. La cinétique de formation de l'ettringite étant inchangée, il faut croire que la coquille d'ettringite est moins imperméable (peut-être mieux cristallisée) et nécessite pour bloquer l'aluminate, des épaisseurs, donc des teneurs plus élevées.

- à 80 % HR, dès 16 heures, la coquille protectrice est formée et elle n'évolue plus par la suite. Elle protège donc l'aluminate anhydre aussi efficacement de la vapeur d'eau que de l'eau liquide du gâchage.

## CONCLUSION

Nous venons de montrer l'existence d'un nouveau type de raidissement des pâtes, mortiers et bétons. Ce raidissement, dû à une altération de la réactivité de l'aluminate de calcium de la matière interstitielle, n'est pas la conséquence de modification des réactions chimiques de cette dernière avec le gypse mais est induit par un changement de la cinétique de formation de l'ettringite permettant au repos, la formation d'un squelette rigide d'hydrate.

Accessoirement, le fait d'avoir pu expliquer simplement les comportements rhéologiques des ciments éventés à l'aide du modèle d'une coquille d'ettringite bloquant le  $C_3A$ , ne contredit pas cette hypothèse.

# Réactivité de l'aluminate monocalcique vis-à-vis de l'eau

## *Reactivity of monocalcium aluminate*

P. GALTIER et B. GUILHOT, Ecole Nationale Supérieure des Mines de Saint-Etienne,  
Laboratoire de Chimie-Physique,

M. MURAT, Institut National des Sciences Appliquées de Lyon, Département de Génie Energétique,

France.

**RESUME** : Dans le cadre d'un programme de travail interlaboratoire sur la réactivité des liants calciques, les auteurs ont étudié l'hydratation d'une préparation d'aluminate monocalcique synthétisé par réaction solide-solide à haute température (1360°C). En se basant sur les échéances d'hydratation mises en évidence par la courbe de calorimétrie, les prises d'essai ont été mélangées avec de l'eau (rapport eau/solide = 1), hydratées à 25°C, de 30 mn à 15 heures et analysées par différentes techniques (diffraction des R.X., spectroscopie I.R., thermoluminescence, analyse thermique différentielle et microscopie électronique à balayage). Il apparaît qu'une hydratation locale commence dans la "période de latence", mais ce phénomène semble grandement influencé par des hétérogénéités locales de composition (probablement inclusions de  $C_{12}A_7$ ) de l'aluminate anhydre et par le procédé employé pour stopper la réaction d'hydratation. La manifestation macroscopique du phénomène de croissance apparaît après 7 heures d'hydratation : l'hydrate formé de manière prédominante est  $C_2AH_8$ , mais il est accompagné de  $CAH_{10}$  et contaminé par du carboaluminate.

**SUMMARY** : Within the framework of an interlaboratory programme about reactivity of hydraulic binders, the authors have studied the hydration of a monocalcium aluminate sample prepared by solid state reaction at high temperature (1360°C). Basing on the calorimetric hydration curve, the sample was mixed with water (Water/solid ratio = 1) cured at 25°C from 30 minutes to 15 hours, and investigated by different techniques (X-ray diffraction, I.R. spectroscopy, thermoluminescence, differential thermal analysis and scanning electron microscopy). It was pointed out that local hydration begins during the "latent period" but it appears that this phenomenon may be largely influenced by local composition heterogeneities (probably  $C_{12}A_7$  inclusions) in the anhydrous aluminate and by the process employed to stop the hydration reaction. Macroscopically, after a curing of 7 hours,  $C_2AH_8$  is the predominant hydrated formed but it is accompanied by some  $CAH_{10}$  and contaminated by carboaluminate.

## I - INTRODUCTION

L'hydratation de l'aluminate monocalcique CA est un phénomène relativement complexe : à basse température il se forme  $\text{CAH}_{10}$  ( $\theta < 20^\circ\text{C}$ ) ; à température plus élevée ( $\theta > 35^\circ\text{C}$ ) on obtient  $\text{C}_2\text{AH}_8$  et de la gibbsite ; à l'ambiante ( $20-25^\circ\text{C}$ ) se forment simultanément  $\text{CAH}_{10}$  et  $\text{C}_2\text{AH}_8$ . Ces deux hydrates hexagonaux se transforment ensuite lentement en  $\text{C}_3\text{AH}_6$  cubique (1 à 3).

Compte tenu de cette complexité, une approche systématique de la réaction d'hydratation, en mettant en oeuvre sur une même préparation un maximum de techniques d'investigation, a été entreprise dans le cadre d'un programme interlaboratoire sur la réactivité des liants hydrauliques.

## II - PREPARATION ET CARACTERISATION DE L'ALUMINATE MONOCALCIQUE

II-1 - L'aluminate monocalcique est préparé à partir d'alumine  $\text{Al}_2\text{O}_3$  et de carbonate de calcium  $\text{CaCO}_3$  (réactifs purs Carlo Erba pour analyse).

Les deux réactifs sont mélangés dans le rapport stoechiométrique  $\text{Ca/Al} = 0,5$  pendant 24 heures dans un mélangeur rotatif à billes. Le mélange pulvérulent, légèrement tassé, est cuit pendant 6 h à l'air à  $1360^\circ\text{C}$ , température légèrement inférieure à celle de l'eutectique (4). Après cuisson, l'échantillon est broyé à  $\phi < 75 \mu$  puis repassé au mélangeur pendant 24 h et recuit pendant 6 h à  $1360^\circ\text{C}$ . L'opération est répétée encore une 3<sup>ème</sup> fois.

Le produit final est broyé à  $\phi < 75 \mu$  puis tamisé dans un appareil Alpine (5) qui permet d'obtenir deux fractions granulométriques :  $40 < \phi < 75 \mu$  et  $\phi < 40 \mu$ . Les essais ultérieurs seront essentiellement effectués sur la fraction  $40 < \phi < 75 \mu$ .

## II-2 - Caractérisation par diffraction X

La technique de diffraction a été utilisée pour caractériser les produits de cuisson obtenus selon le protocole de préparation décrit précédemment.

La première cuisson pendant 6 h conduit à un produit constitué d'aluminate monocalcique CA et d'aluminates  $\text{C}_{12}\text{A}_7$  et  $\text{CA}_2$ . On observe la présence d'alumine  $\text{Al}_2\text{O}_3$  et de chaux  $\text{CaO}$  résiduelles.

La seconde cuisson met en évidence la présence de  $\text{C}_{12}\text{A}_7$  résiduel. La troisième montre que le produit final (CA) contient encore des traces de  $\text{C}_{12}\text{A}_7$ .

## II-3 - Caractérisation par microscopie électronique à balayage et spectrométrie X.

Les clichés de microscopie électronique à balayage mettent en évidence une structure sphérolitique sans zone présentant des faciès cristallins nettement définis (Fig. 4, cliché 1). Une évaluation, par comptage, du rapport  $\text{Ca/Al}$  met en évidence des valeurs anormalement élevées de ce rapport (2 à 5 fois

supérieur à celui de CA pur) sur de très rares zones microcristallisées à faciès cubique.

## II-4 - Caractérisation par spectrographie I.R.

Les spectres d'absorption I.R. réalisés sur les produits de cuisson à 6h, 12h et 18h mettent en évidence une évolution vers un état de cristallisation marqué du produit final.

## II-5 - Caractérisation par thermoluminescence

Le composé préparé présente une thermoluminescence artificielle sous forme d'un pic intense dont le maximum apparaît à la température de 284 K (Fig. 1). Le pic qui apparaît aux très basses températures est dû à l'interaction solide-éthanol, l'éthanol étant utilisé pour étaler la poudre d'aluminate sur le porte-échantillon.

## II-6 - Surface spécifique

Les valeurs des surfaces spécifiques, déterminées par la méthode B.E.T., sont respectivement de  $0,1 \text{ m}^2 \cdot \text{g}^{-1}$  pour les fractions  $40/75 \mu$  et  $< 40 \mu$ .

FIG. 1 - Caractérisation de l'aluminate monocalcique par thermoluminescence.

### III - ETUDE DE L'HYDRATATION

#### III-1 - Etude cinétique par calorimétrie isotherme à 25°C

On observe généralement (6) une assez grande dispersion dans les courbes calorimétriques des aluminates monocalciques si on ne travaille pas sur un produit de granulométrie bien définie, dans des conditions de température et d'hydratation bien déterminées (7). Dans le cas considéré ici aussi, avec la fraction  $40/75\mu$  (Fig. 2) qui ont servi de base aux investigations ultérieures. Par contre, les fines ( $\phi < 40\mu$ ) donnent des courbes calorimétriques très dispersées.

Par ailleurs, comme cela a été observé par d'autres auteurs (8-9), une élévation de la température d'hydratation (dans la gamme de 19°C à 26°C explorée) se traduit par un ralentissement de la cinétique d'hydratation.

#### III-2 - Etude des produits d'hydratation à différentes échéances à 25°C

La courbe calorimétrique de la fraction  $40/75\mu$  à 25°C permet de définir les échéances auxquelles va être stoppée l'hydratation, à savoir : 30 min ; 2 h 30 mn ; 5 h ; 7 h ; 9 h ; 11 h ; 13 h ; et 15 h. Les poudres ont donc été conservées en présence d'eau (E/S = 1) à 25°C et la réaction d'hydratation a été stoppée de la façon suivante : l'eau est aspirée à la seringue à l'échéance choisie. Le solide est ensuite dispersé d'abord dans de l'éthanol et on élimine le solvant par aspiration à la seringue. L'opération est répétée trois fois avec l'éthanol puis trois fois à nouveau avec un mélange 1/1 éthanol-éther. Le produit est ensuite séché - soit par passage à l'étuve sous air pendant 6 heures à 40°C (mode A), - soit par vide primaire dynamique pendant 2 heures dans un dessiccateur (mode B).

Les produits d'hydratation sont ensuite examinés par différentes techniques.

#### III-2-1 - Résultats des analyses par diffraction X et analyse thermique différentielle.

Une certaine incertitude a concerné l'échéance

d'apparition des premières traces d'hydrate (en l'occurrence  $C_2AH_8$  hexagonal caractérisé par sa raie la plus intense (0001) à  $d = 10,5\text{ \AA}$ ) : si le séchage est réalisé selon le mode B, cet hydrate est à la limite de la détection par diffractométrie X dès l'échéance 2 h 30. La disparition aux échéances de 5 h et de 7 h de la raie  $d = 4,89\text{ \AA}$  de  $C_{12}A_7$  résiduel peut lever cette incertitude et confirmer la formation de petites quantités de  $C_2AH_8$  aux échéances faibles.

Les produits d'hydratation apparaissent très nettement au-delà de l'échéance de 7 h : à 9 h on observe la raie principale de  $C_2AH_8$  et plus faiblement celle de  $CAH_{10}$ . L'échantillon hydraté est cependant, comme tous ceux examinés aux échéances supérieures, contaminé par le monocarboaluminate. L'intensité de la raie la plus intense de  $C_2AH_8$  croît avec la durée de l'hydratation tandis que l'intensité des raies caractéristiques de  $CAH_{10}$  et du monocarboaluminate reste constante. A l'échéance de 9 h on décèle la présence de gibbsite.

L'analyse thermique différentielle confirme les résultats de diffraction X. Elle permet en outre, dans le cas du séchage selon le mode B, de mettre en évidence par son pic endothermique à 80°C (12), l'apparition de gel d'alumine dès l'échéance de 2 h 30, ce qui n'est pas détectable par diffraction X et par spectrographie I.R.

Ce petit pic, présent dès les premières minutes du séchage sous vide, ne peut être attribué ici (10) à une hydratation ultérieure par de l'eau résiduelle non éliminée par le séchage.

#### III-2-2 - Résultats de spectrographie I.R.

Les spectres d'absorption I.R. ont été réalisés sur pastilles d'iodure de potassium avec un rapport massique échantillon/iodure de potassium de 1/100. L'observation des spectres d'absorption a permis de tirer les conclusions suivantes :

- l'hydratation de l'aluminate monocalcique ne devient significative qu'à l'échéance de 9 h.

- une résolution suffisante des spectres des produits hydratés n'est obtenu que pour les échantillons hydratés 11 heures, échéance à partir de laquelle l'hydratation concerne la masse interne du

produit de départ.

- les bandes d'absorption entre 1500 et 1350  $\text{cm}^{-1}$  mettent en évidence de façon incontestable la formation de carboaluminate et ce, à partir de 9 h d'hydratation (11).

### III-2-3 - Résultats de thermoluminescence

La thermoluminescence met en évidence trois signaux (Fig. 3) :

FIG. 3 - Etude des produits d'hydratation par thermoluminescence.

- un pic principal dont le maximum se situe à 186 K (pic III)

- un épaulement sur le pic principal à 200 K (pic II)

- un pic de faible intensité lié à la présence d'éthanol lors du dépôt du composé sur le porte-échantillon (pic I).

L'évolution du pic III semble liée à la teneur en CA. Ce pic diminue à partir de l'échéance 9 h.

L'intensité du pic II passe par un maximum pour la même échéance. Le pic I lié à l'adsorption de l'éthanol sur le CA décroît régulièrement en fonction du temps d'hydratation.

L'évolution de l'intensité de ces pics marque bien la différence de part et d'autre de l'échéance 9 h qui correspond à la manifestation macroscopique du phénomène de croissance cristalline des hydrates. Dans la période dite "de latence" on peut penser que la thermoluminescence puisse apporter des informations toutes nouvelles sur les phénomènes de germination, mais ce point nécessite une expérimentation plus poussée avant de proposer une interprétation des résultats.

### III-2-4 - Résultats de microscopie électronique à balayage

Le fait le plus marquant de l'observation des échantillons par microscopie électronique à balayage est que même dans les conditions de séchage selon le mode A, une faible partie de l'aluminate de départ s'est déjà hydraté à l'échéance 5 h (fig. 4, cliché 2). Ce résultat n'est pas en désaccord avec les observations de spectrométrie X (existence locale de composés à rapport Ca/Al bien supérieur à celui de CA dans le solide de départ), de diffraction X (disparition du  $\text{C}_2\text{A}_7$  résiduel avant l'échéance 5 h), d'analyse thermique différentielle (apparition de gel d'alumine dès l'échéance 2 h 30) et de thermoluminescence.

### IV - CONCLUSION

Ce travail met en évidence la nécessité de définir de manière rigoureuse les conditions de préparation (synthèse, broyage, tamisage ...) et d'hydratation de l'aluminate monocalcique, tout au moins pour obtenir des échéances d'hydratation reproductibles et comparables entre différents laboratoires.

-La détection de produit hydraté dans la période de "latence" semble dépendre, de manière très sensible, du protocole adopté pour le stoppage de la réaction en cours d'hydratation.

-On peut également s'interroger sur le rôle que peuvent jouer les microhétérogénéités de composition sur la manifestation de ces phénomènes.

Ces différents problèmes font l'objet d'études complémentaires.

# Cinétique de l'hydratation du ciment Portland

## *Hydration kinetics of Portland cement*

C. VERNET, E. DÉMOULIAN, P. GOURDIN, F. HAWTHORN, Société des Ciments Français,  
CEREG, France.

### RESUME

Les auteurs ont étudié la séquence et la cinétique de l'hydratation de 7 clinkers industriels et des ciments portland correspondants à l'aide d'un appareillage permettant des mesures ioniques en continu, des analyses chimiques et physico-chimiques séquentielles, sur des suspensions de rapport (eau/ciment)  $E/C = 4$ . Cette étude montre l'interdépendance des vitesses de réaction des phases du clinker, par l'intermédiaire de couplages thermiques et chimiques, ainsi que les différences de comportement des ciments en fonction de leurs particularités (type de  $C_3A$ , quantité de sulfates alcalins). La séquence de l'hydratation reste la même à  $E/C = 4$  qu'en pâte pure mais l'échelle des temps est modifiée car, en suspension, l'influence de la diffusion sur la diminution de vitesse de réaction est moindre. Les mécanismes d'influence du  $K_2SO_4$  sur les vitesses de réaction de  $C_3A$  et  $C_3S$  sont étudiés dans le cadre des mécanismes généraux de dissolution-cristallisation.

La méthode aboutit à l'étude directe de la cinétique d'hydratation des ciments industriels, des ajouts et des adjuvants.

### SUMMARY

The authors have studied the sequence and kinetics of the hydration of 7 clinkers and the corresponding portland cements, on suspensions of water/cement ratio  $(W/C) = 4$ , using an apparatus which measures continuously the ions contents, and sequential physico-chemical analysis.

This study points out the interdependance of the reaction speeds of the clinker phases, through thermic and physico couplings and the different behaviours of the cements according to their particularities such as  $C_3A$  type and alkali-sulphates contents.

The sequence of hydration for  $W/C = 4$  is the same as in cement pastes, but the time scale is modified because in a suspension, the influence of the diffusion on the slowing down of the reaction speed is less than in the cement pastes.

The mechanism of  $K_2SO_4$  influence on  $C_3A$  and  $C_3S$  reactions are developed, according to general dissolution-crystallization mechanisms.

The method leads to a direct study of the kinetics of industrial cements, adds and admixtures.

## INTRODUCTION

Nous avons montré dans une étude des mécanismes réactionnels de l'hydratation (1) que les phénomènes de dissolution-précipitation, envisagés par LE CHATELIER (2) dès 1887, sont prépondérants pendant la prise. Ceci implique une correspondance permanente entre la composition de la solution au contact, l'apparition ou la disparition des phases solides, l'ensemble des vitesses de dissolution des anhydres et de précipitation des hydrates. A chaque instant, les concentrations ioniques résultent de la différence de ces vitesses et les hydrates formés ne sont pas en équilibre thermodynamique : cet équilibre n'étant atteint que lorsque leur vitesse de précipitation tend vers zéro. L'énergie libérable par les anhydres est donc utilisée à maintenir en permanence un certain taux de sursaturation, moteur de la cristallisation et de l'évolution des résistances. Nous avons introduit le concept de distance de précipitation, qui permet une interprétation cinétique du mode particulier de cristallisation du CSH et de ses variations de structure. Il est donc théoriquement possible de mesurer indirectement les vitesses de réaction des phases à partir des mesures de concentrations ioniques. Nous tentons ici de mettre cette théorie en pratique : pour cela, nous avons conçu et réalisé un appareillage original permettant :

- de mesurer en CONTINU la composition ionique de la solution, par des méthodes chimiques et électrochimiques ;
  - d'effectuer séquentiellement des dosages simultanés des anhydres et hydrates, pendant une durée suffisante pour observer l'ensemble des réactions ;
  - d'effectuer des mesures thermiques simultanées.
- Pour des raisons pratiques, ces mesures ne pouvant être effectuées facilement sur des pâtes de ciment, on est amené à utiliser des suspensions agitées. Nous avons choisi un rapport eau/ciment (E/C) égal à 4, ce qui constitue un minimum compatible avec le bon déroulement des essais et des dosages. D'autre part, cette valeur du E/C permet d'accélérer considérablement les réactions finales, qui dans les pâtes, sont limitées par la diffusion à travers les hydrates. A la fin de chaque essai nous pouvons alors tracer un diagramme de l'évolution chimique du système solide-solution, montrant la séquence de l'hydratation de la manière la plus complète possible.

## 1/ METHODOLOGIE

## 1.1 - Méthodes d'analyse et appareillage :

Nous ne pouvons décrire ici dans le détail l'ensemble des méthodes d'analyse utilisées. Ceci fait l'objet d'une communication séparée (3). L'appareillage (fig.1) comprend les éléments suivants :

- un réacteur étanche en acier inoxydable d'une contenance de 5 l, comportant un système d'agitation et un système de filtration en continu ;
- une double enveloppe thermostatique à circulation d'eau, entourant complètement le réacteur ;
- un système de recyclage du filtrat, le long duquel on place un certain nombre de capteurs électrochimiques (conductance, pH,  $pK^+$ ,  $pNa^+$  ...) ;
- un système de prélèvement de suspension pour analyses séquentielles ;
- des capteurs de température et de température différentielle ;
- un thermostat à circulation ;
- une batterie d'appareils de mesure, renvoyant les informations issues des capteurs vers un enregistreur à 12 voies.

Un essai se déroule de la manière suivante :

- 1) étalonnage des capteurs à l'aide de solution étalon ;

- 2) remplissage du réacteur par le volume d'eau distillée ;
- 3) mise en température du réacteur (25°C) ;
- 4) introduction rapide de la masse  $m$  du ciment ( $V/m=4$ ) au temps  $t_0$ . L'évolution ionique et thermique se traduit alors par les courbes sur l'enregistreur ;
- 5) à des échéances  $t_1, t_2 \dots t_n$  variables selon les vitesses de réactions observées, prélèvements de petites quantités en suspension ;
- 6) filtration des aliquotes prélevées, analyse chimique du filtrat. Analyse cristallographique des phases solides (diffraction X, ATG, ATD).

Nous avons également effectué des essais complémentaires dans un autre réacteur pour des mesures particulières comme celle de la viscosité dynamique de la suspension en fonction du temps.

Fig. 1 - Schéma du réacteur filtrant

Les précautions suivantes ont été prises pour obtenir des analyses représentatives :

- 1) Prélèvements et analyses séquentielles :
    - essais entièrement conduits en atmosphère d'azote,
    - forte agitation de manière à obtenir une suspension homogène et des prélèvements instantanés représentatifs
    - filtration ultra rapide des prélèvements de suspension, lyophilisation rapide d'une petite partie du gâteau de filtration, rinçage du reste du gâteau au méthanol immédiatement après récupération du filtrat aqueux, qui est filtré une deuxième fois sur filtre micropore à l'abri de l'air.
  - 2) Circuit d'analyse automatique :
    - volume du filtrat circulant à l'extérieur du réacteur négligeable par rapport au volume total,
    - étalonnage périodique des électrodes par analyse chimique séquentielle du filtrat,
    - suppression des interférences entre capteurs par cellules à circulation spéciales.
- L'appareillage et les méthodes utilisées ici permettent donc de ne laisser échapper aucun phénomène rapide ou transitoire, grâce à l'analyse en continu, dont le principal défaut, à savoir le manque de fiabilité dans le temps est corrigé par les analyses ponctuelles.

## 2/ CHOIX DES ECHANTILLONS

Nous avons sélectionné parmi un lot plus important de clinkers de la SOCIÉTÉ DES CEMENTS FRANÇAIS, un groupe de 7 clinkers choisis pour leur composition minéralogique et leurs propriétés hydrauliques différentes, de manière à obtenir l'éventail le plus large possible des comportements des clinkers industriels. Pour chaque clinker, un ciment portland à 3,2 % de  $SO_3$  a été réalisé et nous avons effectué les mesures, d'une part sur le clinker et d'autre part sur le ciment. Les clinkers sélectionnés ont la composition suivante (tableau 1), (analyse élémentaire par fluorescence X - Analyse cristallographique par diffraction X) :

TABLEAU I

## 3/ RESULTATS

La même séquence de l'hydratation se répète pour tous les clinkers d'une part et pour tous les CPA d'autre part. Nous nous proposons donc de décrire cette séquence pour un clinker et pour le CPA correspondant, à titre d'exemple. L'interprétation des courbes obtenues sera donnée pour chaque étape de l'hydratation. Nous décrirons simultanément les différences observées pour les autres échantillons en fonction de la minéralogie et de la teneur en éléments mineurs solubles (CaO libre, sulfates alcalins).

## 3.1 - Suspensions de clinkers (fig.2)

1ère étape : dissolution rapide exothermique (durée 10 à 20 minutes). On observe une augmentation rapide des concentrations en Ca<sup>++</sup> et OH<sup>-</sup> et une dissolution quasi instantanée des sulfates alcalins, se traduisant par un palier des concentrations en K<sup>+</sup> et Na<sup>+</sup>. La concentration en SiO<sub>2</sub> passe en 15 minutes d'une valeur élevée à moins de 30 micromoles/l.

Pour les clinkers contenant K<sub>2</sub>SO<sub>4</sub>, le sulfate réagit très rapidement dans les premières minutes, pour former de l'ettringite. La vitesse de réaction semble liée au rapport E/C et à la quantité de sulfate du clinker, ainsi qu'à des facteurs modifiant la diffusion comme l'agitation et la température : la réaction ralentit jusqu'à une vitesse très faible, du fait de l'intervention d'un effet de barrière. Le sulfate disparaît alors au bout d'un temps croissant avec la teneur initiale (plusieurs heures pour C5, 20 minutes pour C6). Pendant toute cette période, K<sup>+</sup> est supérieur à la valeur correspondant à la solubilisation totale de K<sub>2</sub>SO<sub>4</sub>, ce qui montre que C<sub>3</sub>A a réagi très rapidement au départ, en libérant le potassium contenu dans son réseau. L'alumine devient presque instantanément indosable dans la solution en présence de sulfates. En leur absence, on peut encore en trouver quelques micromoles/l au bout de 10 minutes : ceci est dû à la solubilité de l'ettringite beaucoup plus faible que celle des aluminates hydratés. La chaux libre est consommée par formation de CSH<sub>II</sub> et d'ettringite en présence de sulfates.

Fig. 2 - Diagramme d'hydratation du clinker C4

## 2ème étape : Sursaturation en chaux, "période dormante"

En présence de K<sub>2</sub>SO<sub>4</sub>, après consommation du calcium de la chaux libre, la formation d'ettringite ne peut se poursuivre que par consommation du calcium libéré par l'alite selon :

On observe effectivement des teneurs en calcium d'autant plus basses au départ que la teneur en K<sub>2</sub>SO<sub>4</sub> est élevée. La réaction ci-dessus déplace la solubilité de l'alite et le taux de réaction est alors inhabituellement élevé durant la période dormante. Dans le cas des mortiers, l'alite ainsi consommée ne peut évidemment plus servir à produire de la portlandite et du CSH<sub>II</sub> dans les périodes suivantes : ce facteur s'ajoute à la modification de structure du CSH<sub>II</sub> et contribue à un manque de résistance à long terme.

Le flux thermique et la concentration en SiO<sub>2</sub> restent très faibles. OH<sup>-</sup> et Ca<sup>++</sup> augmentent ensemble et l'on atteint des sursaturations en chaux de 1,4 à 1,6 lorsqu'on parvient au maximum de conductance.

Comme nous l'avons montré par ailleurs (1) pendant cette 2ème période on observe un ralentissement des vitesses de dissolution de l'alite et de précipitation du CSH et l'on tend vers un état stationnaire caractérisé par une croissance quasi-linéaire de la concentration en chaux. La germination de la portlandite est ralentie par un inhibiteur qui pourrait être l'ion silicate (4)(5). La vitesse de sursaturation mesurée par la pente de la courbe de conductance est fonction de l'alcalinité, de la forme et de la quantité d'alite. Les flux instantanés de dissolution de l'alite s'échelonnent entre 2,76 et 0,14 μm·m<sup>-2</sup>·s<sup>-1</sup> (calcul d'après le modèle mathématique que nous avons établi par ailleurs) (1).

La fin de la "période dormante" se produit à l'apparition de la portlandite, très peu de temps avant le maximum de conductance. Malgré les teneurs extrêmement variables en alcalis des clinkers et donc les basicités très variables en début de période, cette précipitation se produit à un pH sensiblement constant pour tous les clinkers (pH 12,9 ± 0,2).

3ème étape : Au bout de quelques heures, la précipitation de la portlandite, très rapide au départ, puis stationnaire, produit une violente reprise de la dissolution de l'alite : le flux de dissolution varie

alors, d'après notre estimation, entre 5 et 50  $\mu\text{M}\cdot\text{m}^{-2}\cdot\text{s}^{-1}$  selon les cas. Le flux thermique augmente rapidement et une déformation du pic indique l'effet endothermique de précipitation de  $\text{Ca}(\text{OH})_2$ . On observe une légère augmentation de la teneur en  $\text{SiO}_2$ , due à un écart plus grand entre vitesses de dissolution de l'alite et de précipitation du CSH, ce que nous avons montré par ailleurs (1). Après le palier de concentration en chaux caractérisant l'état stationnaire, on observe un maximum de teneur en  $\text{SiO}_2$ , correspondant au maximum de flux thermique. Il se produit alors une reprise de l'hydratation du  $\text{C}_3\text{A}$  détectable grâce à l'augmentation du pH, des teneurs en  $\text{K}^+$  et  $\text{Na}^+$  et de la conductance (effet particulièrement visible avec  $\text{C}_3\text{A}$  tétragonal). Cette réaction n'est pas nécessairement la même pour tous les clinkers : la séquence de réaction des aluminates dépend en effet du rapport molaire  $\text{SO}_3/\text{C}_3\text{A}$  au départ (fig.3) qui conditionne le nombre de transformations des sulfoaluminates pour arriver à l'état stable final.

Fig. 3 - Schémas de transformations des sulfoaluminates pour 3 rapports  $\text{K}_2\text{SO}_4 / \text{C}_3\text{A}$ .

TS : ettringite  
 MS : monosulfoaluminate  
 BTS : solution solide à 0,5 mole  $\text{CaSO}_4$   
 $t_1$  : disparition du sulfate en solution, fin de la formation d'ettringite, début de formation de monosulfoaluminate  
 $t_2$  : disparition de l'ettringite, fin de la formation de monosulfoaluminate  
 $t_3$  : disparition du monosulfoaluminate  
 $t_M$  : 2ème pic de flux de chaleur d'hydratation  
 $t_f$  : fin de réaction.

Les %  $\text{C}_3\text{A}$  consommé indiqués sur les échelles correspondent aux quantités stoechiométriques (calculées d'après le  $\text{SO}_3$ ) de chaque sulfoaluminate.  
 L'échelle des temps correspond aux mesures expérimentales des temps de réaction.

Le flux thermique fourni par l'alite augmente les vitesses de ces réactions qui sont toutes lentes.

On voit que lorsque  $\text{SO}_4^{2-}$  n'est pas consommé pendant les premières minutes, il faut alors attendre le 2ème pic de flux thermique pour observer la formation de monosulfoaluminate. Dans le cas contraire, c'est la réaction  $\text{MS} \rightarrow \text{BTS}$  qui se produit avec retard. Par son effet thermique l'hydratation de  $\text{C}_3\text{A}$  relance l'hydratation de l'alite. Pour les clinkers riches en  $\text{K}_2\text{SO}_4$ , la teneur en calcium étant systématiquement plus faible pendant la période d'hydratation du  $\text{C}_3\text{A}$ , la distance de précipitation (1) augmente et le CSH aura donc tendance à prendre une structure d'autant plus cristalline. Au bout de 50 à 70 heures, le système évolue de plus en plus lentement sans que l'on puisse détecter de nouveaux changements de composition de la phase solide : les hydrates obtenus alors sont essentiellement constitués du  $\text{CSH}_{II}$  et soit de  $\text{C}_3\text{A}$  hydraté ( $\text{C}_4\text{AH}_x$ ) soit de sulfoaluminates dans les clinkers contenant du  $\text{K}_2\text{SO}_4$ . Les taux d'hydratation atteignent des valeurs très élevées après 100 heures pour l'alite et le  $\text{C}_3\text{A}$ . Le  $\text{C}_4\text{AF}$  et la bélite sont peu hydratés. La solution reste sursaturée par rapport à tous les hydrates. Les trajets des points figuratifs des solutions dans les diagrammes ( $\text{CaO} - \text{SiO}_2 - \text{H}_2\text{O}$ ) ( $\text{CaO} - \text{SO}_3 - \text{H}_2\text{O}$ ) ( $\text{Ca}^{++} - \text{OH}^-$ ) sont du même type : Après une période de sursaturation rapide, le point figuratif atteint un point de rebroussement et longe la courbe d'équilibre en suivant un trajet sensiblement parallèle. Le mécanisme est donc du même type que pour l'alite (dissolution-précipitation).

### 3.2 - Suspensions de ciments portland (Fig.4 et 5)

Fig.4 - Mesures ionométriques et thermiques (ciment C4)

Fig.5 - Allure de composition du solide (ciment C4)

La figure 4 représente l'évolution chimique de la solution et la figure 5 montre les variations correspondantes des phases (périodes 2, 3 et 4). La présence de gypse produit ici la formation systématique d'ettringite aux premiers instants. La séquence de l'hydratation de l'alite n'est pas modifiée.

#### Pendant la 1ère période

Nous n'avons pas observé la formation de syngénite pour les clinkers riches en  $K_2SO_4$  (le produit de solubilité de ce sel n'est pas atteint dans nos conditions opératoires).

Le gypse bloque beaucoup plus rapidement l'hydratation du  $C_3A$ , que le  $K_2SO_4$  : la teneur en aluminium de la solution est beaucoup plus faible dès le départ, de même que le flux de chaleur.

Pendant la 2ème période, comme le montre la fig. 4, on n'observe pas de modifications sensibles des réactions. Comme pour les clinkers, la solution se sursature progressivement en chaux, les teneurs en alcalins restent sensiblement constantes et la teneur en silice décroît jusqu'à des valeurs très faibles, difficilement dosables sans concentration du filtrat ou extraction.

La teneur en sulfate n'évolue pratiquement pas (légère diminution avec l'augmentation du calcium) le flux thermique est faible, mais jamais nul. Les taux de réaction sont tous faibles. Les vitesses de sursaturation sont systématiquement plus élevées pour les CPA que pour les clinkers correspondants, en fin de période dormante et plus faibles au début, ce qui aboutit souvent à des échéances très voisines pour l'apparition de  $Ca(OH)_2$  dans les deux cas. Ceci est en parfait accord avec nos mesures faites par ailleurs en système ouvert (1) et montrant qu'en présence de solutions de chaux + gypse, la dissolution de l'alite est ralentie par le calcium. On précipite ensuite des CSH beaucoup moins solubles, ce qui augmente la vitesse de dissolution. L'influence accélératrice du gypse sur l'hydratation de l'alite ne se manifeste donc qu'en fin de période dormante et ne doit pas modifier beaucoup le temps de prise rhéologique.

Pendant la 3ème période, la fig. 4 montre une augmentation simultanée du flux thermique et de la teneur en  $SiO_2$  en solution, la chute de conductance accompagnant la précipitation de  $Ca(OH)_2$  est plus élevée que pour les clinkers : la formation de CSH moins solubles en présence de gypse augmente leur vitesse de précipitation et déplace la solubilité de l'alite dans le sens d'une dissolution plus rapide. A la fin de la période quasi-stationnaire de précipitation rapide de la portlandite, la conductance diminue et le flux thermique commence à décroître : la dissolution de l'alite se ralentit. On aboutit alors à un minimum de conductance suivi peu après d'un second maximum. Pendant cette courte remontée de conductance, les concentrations en  $Ca^{++}$ ,  $OH^-$ ,  $SiO_2$ ,  $Na^+$ ,  $K^+$  augmentent (fig.4). Le flux thermique et la viscosité de la suspension forment un pic pointu pour les fortes teneurs en  $C_3A$ . La concentration en  $SO_4^{--}$  chute brutalement et parvient à une valeur très faible. La teneur en  $C_3A$  diminue rapidement (fig.5) et il y a reprise de l'hydratation de l'alite. L'ensemble de ces phénomènes montre de manière remarquable l'interdépendance des vitesses de réaction, à la fois par des effets de couplage thermique (la chaleur de réaction de l'alite augmente la vitesse de formation de l'ettringite, puis la chaleur de réaction de  $C_3A$  produit une reprise de l'hydratation de l'alite) et par des effets de couplage chimique : l'épuisement du gypse et la chute de  $SO_4^{--}$  provoquent la transformation ettringite + monosulfate et la reprise

de l'hydratation de  $C_3A$ .

Comme dans le cas des clinkers, la séquence de l'hydratation de  $C_3A$  dépend du rapport initial  $C_3A/SO_3$ . La transition ettringite-monosulfate ne peut donc avoir lieu que si la quantité de  $C_3A$  est suffisante. Or, pour les 2 ciments contenant très peu d'aluminates, nous observons vers 30-40h la disparition de  $SO_4^{--}$  (qui devrait rester en excès) et les hydrates obtenus à 100 h sont l'ettringite et le monosulfatealuminat. Bien que  $C_4AF$  réagisse simultanément, son taux de réaction reste beaucoup trop faible pour expliquer cette anomalie. Nous sommes donc amenés à conclure à l'entrée de l'ion  $SO_4^{--}$  en solution solide dans le CSH<sub>II</sub> : ceci contribue à l'épuisement rapide du gypse pendant la période d'hydratation intense de l'alite. Pour les ciments à forte teneur en  $C_3A$ , les transformations successives des sulfoaluminates en des formes de teneur de plus en plus faible en sulfate peuvent être détectées par notre appareillage, à condition que la teneur en alcalins du  $C_3A$  soit suffisante. Ces transformations se produisent en général vers 50 heures puis vers 70 heures et sont accompagnées de petites reprises de l'hydratation et de petits pics exothermiques.

Comparaison des vitesses de réaction des différentes formes de  $C_3A$ . Nos essais montrent bien que, dans le milieu complexe du ciment industriel, la réactivité intrinsèque du  $C_3A$  n'est que l'un des nombreux facteurs influençant sa vitesse d'hydratation. Il faut en effet tenir compte également du rapport gypse/ $C_3A$ , de la chaleur d'hydratation de l'alite, du sulfate entrant dans le CSH, de la quantité d'alite, de la quantité de  $C_3A$ , de sa chaleur d'hydratation, et de la quantité d'alcalins qui modifient le pH et les vitesses de précipitation. Au cours de nos essais, nous avons observé des temps de disparition du gypse variant de 9h à 20h pour C4. Ces temps varient fortement avec la température et la vitesse d'agitation : ceci montre qu'il existe un mécanisme diffusionnel empêchant la dissolution du  $C_3A$  en présence de gypse. D'une manière générale, on peut dire que la disparition du sulfate est d'autant plus tardive que :  
- la chaleur d'hydratation, la teneur en  $C_3A$  et la teneur en sulfate alcalins sont faibles et que la teneur en alcalins du  $C_3A$  est élevée. Ces facteurs influencent de la même manière, par le biais d'effets thermiques, les temps de prise rhéologique et les durées des périodes dormantes définies par les courbes de conductance. C'est ainsi que le ciment C3, qui contient 5,6 % de  $C_3A$  tétragonal a une vitesse de montée en résistance faible, le temps de prise et les temps de réaction les plus longs en suspension : apparition de la portlandite à 6h, disparition du gypse à 40 h. Ceci ne l'empêche pas à 6 mois de montrer d'excellentes performances mécaniques, bien meilleures que celles de C2 et C4, qui sont riches en  $C_3A$ . Lorsque l'on vise des résistances élevées à long terme, on peut donc tenter de reculer au maximum la transformation de l'ettringite de manière que les contraintes mécaniques qu'elle provoque puissent être absorbées par le CSH suffisamment résistant. Par contre, si l'on repousse trop loin ou si l'on supprime cette transformation, on perd alors le bénéfice de la reprise thermique de l'hydratation de l'alite. Il faut trouver un compromis : l'optimum de gypse sera toujours un peu supérieur à la quantité nécessaire à la transformation totale du  $C_3A$  en ettringite, du fait de la consommation de sulfate par le CSH. Cet optimum sera variable selon la pente de montée de résistances désirée. Un rapport gypse/ $C_3A$  élevé favorisera les résistances à long terme. Inversement, un rapport faible augmentera plutôt les résistances initiales, aux

dépens des résistances finales.

Les diagrammes d'évolution chimique montrent pour les ciments C4 (15,8 %  $C_3A_T$ ) et C2 (12,5 %  $C_3A_C$ ) des temps d'épuisement du gypse de 10 h pour C2 et 13 à 20h pour C4 selon la vitesse d'agitation. Ceci montre que le  $K_2SO_4$  du ciment C4 (0,8 %) accélère notablement l'hydratation du  $C_3A$  tétragonal (6) et lui permet presque de rattraper la vitesse de C2 : ce qui est parfaitement logique car nous avons vu que  $K_2SO_4$  agit par couplage chimique, en déplaçant par formation d'ettringite la dissolution de l'alite qui à son tour accélère l'hydratation de  $C_3A$ .

#### 4/ CONSEQUENCES

##### Lien avec les réactions à faible E/C

Ayant montré que la séquence de l'hydratation reste la même en suspension à  $E/C = 4$  qu'en pâte pure, on en vient à rechercher des correspondances de temps de réaction entre ces deux cas. Compte tenu des connaissances actuelles sur les réactions en pâte pure, on peut remarquer que les paramètres qui différencient les réactions en pâte pure et à  $E/C = 4$ , sont principalement : l'intervention de la diffusion à travers les hydrates qui est considérablement facilitée à  $E/C = 4$  sous forte agitation et les effets thermiques qui sont plus faibles à  $E/C = 4$  qu'en pâte pure (mais ils seraient du même ordre en mortier normal). On peut donc s'attendre à une liaison entre échelles des temps du type parabolique : nous obtenons effectivement à 100 h, à  $E/C = 4$  des taux de réaction équivalents à 1 an en pâte pure.

L'effet de barrière intense de l'ettringite a tendance à annuler l'influence de l'agitation et du  $E/C$  élevé sur les temps de réaction, tant que cette influence n'est pas suffisante pour briser ou diminuer la couche d'hydrates. On doit donc observer un décalage du temps plus faible pour les aluminates que pour les silicates.

Le temps mis pour parvenir au maximum de sursaturation en chaux (1er pic de conductance) est en relation étroite avec le début de prise. Les véritables réactions de la prise commencent en effet avec la précipitation de la portlandite, peu avant ce maximum. Nous trouvons à  $E/C = 4$  des temps à peu près doubles des temps de prise mesurés sur pâte pure, les écarts étant liés à des effets thermiques et rhéologiques des aluminates. A ce titre, le temps de sursaturation limite mérite bien le nom de "début de prise chimique", par opposition au début de prise "rhéologique", lié à la consommation rapide de l'eau libre. En pâte pure, le maximum de conductance signalant la précipitation de la portlandite a lieu avant cet effet rhéologique, alors que la pâte est encore plastique : il ne faut donc pas confondre début de prise "rhéologique" et précipitation de la portlandite.

L'influence des éléments mineurs comme  $K_2SO_4$  sera encore plus grande à  $E/C = 0,3$  qu'à  $E/C = 4$ . En toute rigueur, il faut donc essayer de reproduire à  $E/C = 4$  les concentrations de la solution de départ que l'on obtiendrait à  $E/C = 0,30$ . Mais ce faisant, on modifierait énormément les quantités par rapport au clinker : il faut donc rechercher un compromis.

#### CONCLUSIONS

L'ensemble des phénomènes que nous décrivons montre que, par l'intermédiaire des couplages de vitesse de réaction, chaque ciment portland forme un système particulier où chaque constituant intervient sur la dynamique de l'ensemble. Les mêmes mécanismes s'appliquent à tous indifféremment. Parmi ceux-ci, le mécanisme de dissolution-cristallisation tient une place très importante.

Notre démarche d'étude simultanée de toutes les réactions est à ce titre parfaitement bien adaptée, car elle permet l'examen direct de l'influence d'un paramètre sur l'ensemble du comportement. En particulier nous avons dégagé ici le mécanisme de l'action simultanée des sulfates alcalins sur la vitesse de réaction de  $C_3A$  et sur l'hydratation de l'alite. Ce mécanisme aboutit dans ses conséquences, aux effets bien connus sur l'évolution des résistances et sur la structure des hydrates.

La même méthode peut permettre de déterminer l'influence des caractéristiques propres du clinker et d'éventuelles anomalies sur la cinétique de l'hydratation. Le mécanisme d'action d'un grand nombre d'ajouts et d'adjuvants peut également être mis en évidence. Ces études peuvent être faites de manière rationnelle et rapide en utilisant des méthodes d'analyse chimique automatique combinées aux méthodes classiques d'analyse cristallographique.

# Influence of pretreatment on the microstructure of calcium silicate hydrate gels

## *Influence du prétraitement sur la microstructure des gels de silicate de calcium hydraté*

F.G.R. GIMBLETT, Lecturer in Chemistry,

Z. MOHD. AMIN, Research Student and K.S.W. SING, Professor of Chemistry, School of Chemistry, Brunel University, Uxbridge, England.

**RESUME :** Le gel de silicate de calcium hydraté est l'un des principaux composés intervenant dans l'hydratation des ciments. Des échantillons de gel, préparés par réaction à l'hydroxyde de calcium sur le métasilicate de sodium, dans un rapport molaire de 1:1, en solution aqueuse à un pH de 12,5, ont été étudiés par porosimétrie au mercure, adsorption d'azote et de vapeur d'eau, complétées par l'étude de la diffraction des rayons X et la microscopie électronique à balayage.

L'adsorption d'azote et d'eau par les gels dépend du prétraitement; la microstructure du matériau étant conditionnée par la méthode de séchage et par le (ou les) solvant organique utilisé dans la procédure de séchage par déplacement de l'eau par un solvant.

L'adsorption d'azote à  $-196^{\circ}\text{C}$  est réversible jusqu'à une pression relative de 0,45, alors que l'adsorption d'eau est caractérisée par une hystérésis s'étendant jusqu'à des faibles valeurs de pression relative. En général, les aires spécifiques B.E.T. obtenues à partir de l'adsorption d'azote sont bien inférieures à celles obtenues avec l'eau, bien que, sous certaines conditions, il soit possible d'obtenir des valeurs ayant le même ordre de grandeur.

L'influence du séchage, et d'autres facteurs, sur la porosité et l'aire spécifique du matériau sont discutés; une explication de la spécificité de l'eau est proposée, basée sur son interaction avec les sphères de coordination des ions calcium de la structure.

**SUMMARY:** Calcium silicate hydrate gel is one of the major products in the hydration of cement. Samples of the gel, prepared by the interaction of calcium hydroxide and sodium metasilicate at 1:1 molar ratio in aqueous solution at pH 12.5, have been studied by mercury porosimetry and nitrogen and water vapour sorption supplemented by X-ray diffraction and scanning electron microscopy studies.

The adsorption of nitrogen or water by the gel is very dependent on its pretreatment, the microstructure of the material being influenced both by the method of drying and by the organic solvent(s) used in the solvent displacement drying procedure.

Nitrogen adsorption at  $-196^{\circ}\text{C}$  is reversible up to a relative pressure of 0.45, whereas water sorption is characterised by open hysteresis loops down to low relative pressures. In general, the BET surface areas for nitrogen adsorption are substantially less than those obtained with water, although under certain special conditions it is possible to obtain values of approximately similar magnitude.

The influence of drying, and other factors, on the porosity and surface area of the material is discussed, and an explanation advanced for the high specificity of water based on its interaction with the coordination spheres of the calcium ions in the structure.

## INTRODUCTION

Extensive studies have been made of the adsorption of nitrogen and water vapour on cement pastes and related calcium silicates (1). However, in most cases, both the pore volumes (2) and the BET surface areas (3,4) computed from the water sorption isotherms have proved to be much higher than those calculated from the nitrogen isotherm (5-8). Two principal explanations have been advanced for these differences: the presence in the samples of "ink-bottle" pores, i.e. pores with wide bodies and constricted entrances, accessible to water but not to nitrogen (6,8), or the possibility that nitrogen measures the surface area and porosity correctly while the increased values with water are a consequence of the penetration of water vapour into the layer structure of the calcium silicate hydrate gel common in these hydrated systems (9,10).

Recently, Litvan (11) has demonstrated that these differences are removed, certainly as far as cement pastes are concerned, if special techniques are employed for drying the samples. The main features of such methods were the use of a solvent displacement method during the washing procedure and the use of vacuum distillation to remove final traces of the solvent from the sample. Using methyl alcohol as the solvent, Litvan obtained a value of approximately  $200 \text{ m}^2 \text{ g}^{-1}$  for both the nitrogen and water surface areas of his specially dried cement pastes.

One of the problems associated with the study of cement pastes is the degree of inhomogeneity, both chemical and physical, frequently encountered in these materials. Since the surface characteristics of such pastes are controlled by the calcium silicate hydrate gel they contain, the present systematic study was undertaken on samples of calcium silicate hydrate gel prepared in a manner to ensure, as far as possible, chemical and physical uniformity.

## EXPERIMENTAL

Materials

Polythene containers were used throughout to eliminate any stray contamination arising from the use of glass vessels, and all experiments were conducted in a nitrogen-flushed glove box to avoid, as far as possible, interference from atmospheric carbon dioxide.

Aqueous solutions of sodium metasilicate were prepared by dissolving AR sodium hydroxide in conductivity water and slowly adding, with constant stirring, an appropriate amount of silica gel (Merck kiesel gel 60HR). The resulting solution was further diluted and stored in a well-stoppered vessel to exclude carbon dioxide. The silicate content of the final solution was analysed using methods described by Vogel (12).

Calcium hydroxide solution was prepared by dissolving the AR grade solid in conductivity water. The calcium content was determined by EDTA titration using Eriochrome Black T as an indicator (13).

Calcium silicate hydrate gel (CSH(I)) was prepared by adding an aqueous solution of calcium hydroxide ( $18 \text{ mmol dm}^{-3}$ ) to a sodium metasilicate solution of the same concentration. Constant stirring was employed

throughout to avoid fluctuations of pH, the latter being continuously monitored as 12.5. The resulting gel ( $\text{CaO}:\text{SiO}_2 = 1:1$ ) was stored for various lengths of time in the mother liquor before being transferred to a stoppered stainless steel vessel, frozen overnight at  $-196^\circ\text{C}$  and then allowed to thaw to room temperature. The sample was centrifuged, the mother liquor decanted and the solid gel shaken for 5 min with  $50 \text{ cm}^3$  of a given organic solvent. Decantation of the organic solvent was followed by similar treatment with the same volume of acetone and the washed sample was then initially dried by brief suction over a laboratory pump. Further drying was effected through the use of various drying agents (see below) and the final samples were stored in tightly capped bottles sealed with paraffin wax contained in a vacuum desiccator.

Conductivity water was prepared by passage of distilled water through a mixed-bed ion-exchange column, and all the organic solvents were of AR purity as were the solid desiccants employed.

Methods

The CSH(I) samples were dried before examination by a variety of methods. When solid desiccants were employed, drying was effected by storage of the sample for various lengths of time over the desiccant in a vacuum desiccator. Alternatively, reduction of the ambient water vapour pressure of samples to a constant value of  $5 \times 10^{-4}$  Torr (the so-called method of D-drying) was achieved through the use of a conventional vacuum line, involving a liquid nitrogen trap in conjunction with a rotary oil pump and a mercury diffusion pump, the pressure being continuously monitored by a Pirani gauge.

The volumetric apparatus used to study the adsorption of nitrogen at  $-196^\circ\text{C}$  was similar to that described by Harris and Sing (14). Nitrogen gas of 99.9% purity was employed, being first dried by slow passage through a cold trap. Outgassing of the solid under investigation was carefully controlled at  $2 \times 10^{-4}$  Torr, a slightly lower pressure than that achieved during D-drying but chosen to compensate for the possible small uptake of moisture by the sample during its introduction into the apparatus. Where the solid was heated before adsorption of nitrogen, this was only commenced after the attainment of the above pressure to eliminate any possible contamination of the sample by residual gas or vapour in the system. Equilibrium gas pressures were measured with a pressure-sensitive transducer gauge and a mercury manometer (to  $\pm 0.001 \text{ cm}$ ). An oxygen vapour pressure thermometer was used to measure the adsorbent temperature.

Water sorption was measured gravimetrically using a quartz spring balance of the McBain-Bakr type (15), whose operation has been described by Carruthers *et al.* (16). Care was again taken regarding outgassing the sample and, where necessary, its heating. Water vapour was admitted slowly into the apparatus to reach the solid at the desired relative pressure, sorption being allowed to proceed until the pressure reached a steady value and no further extension of the quartz spring had occurred over a period of 30 min. The time necessary to attain this condition varied with the solid employed and the relative pressure in the system.

Mercury porosimetry measurements were made with a Carlo Erba 225 Pressure Porosimeter. Gel samples were outgassed for 30 min at room temperature to a pressure less than  $10^{-2}$  Torr and the mercury pressure increased

from 1 atm to 2000 kg cm<sup>-2</sup> at a fairly constant rate over a period of 1-2 h.

## RESULTS

### Coding of samples

The narrative has been simplified by coding the samples to provide a complete summary of their pretreatment prior to surface investigation. For the particular sample CSH/18/1A/D(8)/100, reading from left to right tells us that this is a sample of CSH(I) gel (information before the first solidus), stored for 18 days in the mother liquor before filtration (information between first and second solidi), washed with propan-2-ol (I) followed by acetone (A) (information between second and third solidi), dried to a constant water vapour pressure of  $5 \times 10^{-4}$  Torr (D-drying) for 8 days (information between third and fourth solidi) and heated to 100°C before being investigated either by nitrogen or water vapour sorption. Variants of this code refer mainly to organic solvents used in the solvent displacement method (M = methanol; E = ethanol) and to the various desiccants employed (Ca = calcium chloride; Mg = magnesium perchlorate; P = phosphorus pentoxide) or water vapour pressure attained (D or D\*). In the last case the symbol D\*(8) indicates that the sample was initially dried for 4 days at a water vapour pressure of  $2 \times 10^{-2}$  Torr followed by a further 4 days at  $5 \times 10^{-4}$  Torr, making a total of 8 days drying in all.

### Description of isotherms

Typical examples of nitrogen and water vapour sorption isotherms are illustrated in Figure 1(a) and (b), respectively. Nitrogen adsorption at -196°C is

Fig. 1 - Typical isotherms for CSH(I) gels: (a) nitrogen adsorption; (b) water sorption. O - adsorption; ● - desorption branch.

reversible to a relative pressure of 0.45, while water sorption is characterised by open loops down to low relative pressures. The isotherms illustrated were obtained using samples washed with propan-2-ol and acetone and outgassed at 25°C prior to investigation, but similar results were obtained for samples pre-washed with other organic solvents and outgassed at higher temperatures.

### Influence of drying conditions

Preliminary experiments were conducted to investigate the effect of the drying conditions on the surface properties of prepared CSH(I) gels. The results obtained from porosimetry are illustrated in Figure 2, while the nitrogen and water surface areas for some of the same samples, as well as those computed from the porosimetry data are listed in Table I.

From the table it will be seen that a wide variety of drying conditions and methods of pretreatment were employed during the preparation of the samples.

Fig. 2 - Influence of drying agent on porosity of CSH(I) gels. A - CSH/18/1A/D(8)/25; B - CSH/30/A/D(8)/25; C - CSH/2/A/P(3)/25; D - CSH/7/A/Ca(8)/25; E - CSH/2/A/Ca(8)/25; F - CSH/2/A/Mg(3)/25.

Of the results quoted, those relating to the use of solid desiccants show the widest variation in surface area (nitrogen and water) but the least variation in porosity with change of conditions. Thus the porosimetry results show that pores with the smallest radii are generated by storage over phosphorus pent-

oxide, with calcium chloride being the next most efficient drying agent, and magnesium perchlorate the least efficient in this particular sequence. Increasing the storage time in the mother liquor before drying seems to increase the percentage of smaller pores in the sample although, as the results discussed below indicate, this is by no means clear-cut.

All of the solid desiccants studied suffer from a major defect in that their efficiency is drastically reduced on prolonged exposure to water vapour. As a result, samples "dried" in the presence of phosphorus pentoxide, calcium chloride or magnesium perchlorate are not really dry, but contain traces of moisture capable of catalysing ageing processes when the samples are stored for prolonged lengths of time. Such ageing processes lead to considerable decreases in the

<sup>b</sup>Low value attributed to carbonation before examination, as demonstrated by X-ray diffraction and scanning electron microscopy studies.

in the nitrogen surface areas of samples (cf. the  $S_{\text{BET}}^{\text{N}}$  values in Table I for CSH/2/A/Ca(8)/25 and CSH/2/A/P(3)/25 stored for seven and 323 days, respectively) but have little effect on the water surface areas (cf. the  $S_{\text{BET}}^{\text{H}_2\text{O}}$  values for the same samples stored for 757 and 295 days, respectively). The  $S_{\text{BET}}^{\text{H}_2\text{O}}$  value recorded for CSH/7/A/Ca(8)/25 is anomalous and is attributed to interaction between the sample and atmospheric carbon dioxide before examination as shown by X-ray diffraction data, which clearly indicate the presence of calcite in the sample, and scanning electron microscopy, which shows that on storage the surface of the sample changed from an open porous form to one consisting of close-packed spherical nodules.

Because of the deficiencies of powdered solid desiccants, all systematic studies of the influence of various conditions have been made on samples whose ambient water vapour pressure had been reduced to a constant value ( $2 \times 10^{-2}$  Torr and/or  $5 \times 10^{-4}$  Torr) during drying. The latter pressure is that attained by the so-called D-drying method and this term is used here. Typical results obtained for D-dried samples are illustrated in Figure 2 and listed in Table I as CSH/2/A/D(8)/25 and CSH/4/IA/D(8)/25, respectively. Figure 2 shows that D-drying induces a much higher proportion of smaller pores while Table I indicates that the nitrogen surface areas are much higher for D-dried samples than for those exposed to solid desiccants. What is also important is that samples dried by this method show none of the instabilities and inconsistencies in surface area mentioned above for samples dried over phosphorus pentoxide, calcium chloride and magnesium perchlorate. Thus D-dried samples have surface areas which appear to be independent of the length of storage time between drying and experimental examination, i.e. they are free from ageing processes, and as has been demonstrated on numerous occasions in this laboratory, using the same method of preparation and pretreatment always leads to a constant value for the surface area (to within  $\pm 5\%$ ) for a given adsorbent.

#### Influence of solvent displacement

The curves for samples CSH/2/A/D(8)/25 and CSH/4/IA/D(8)/25 illustrated in Figure 2 indicate that the inclusion of propan-2-ol as a solvent for the displacement of water prior to D-drying appreciably influences the porosity of the final sample, while the results tabulated in Table I show that the nitrogen and water surface areas for such a sample approach each other in the manner described by Litvan (11) for methanol-treated cement pastes.

To see whether such changes may be related to the nature of the organic solvent, studies have been made on a series of samples prepared in an exactly similar manner except that different alcohols have been employed for solvent displacement prior to D-drying. The mercury porosimetry results obtained for such samples are illustrated in Figure 3, while Table II lists their corresponding  $S_{\text{BET}}^{\text{N}}$ ,  $S_{\text{BET}}^{\text{H}_2\text{O}}$  and  $S_{\text{Hg}}$  values.

Fig. 3 - Influence of solvent on porosity of CSH(I) gels. A - CSH/10/EA/D\*(8)/25; B - CSH/10/MA/D\*(8)/25; and C - CSH/10/IA/D\*(8)/25.

Of the three alcohols studied, propan-2-ol yields samples with the highest percentage of smaller pores as well as nitrogen surface areas substantially closer to those measured by water sorption. However, it is interesting to note that both the porosity and nitrogen surface area of the propan-2-ol washed sample listed in Table II are appreciably different from those recorded in Figure 2 and Table I for a similar sample washed with the same solvent. These differences may be attributed to the variation in the length of storage of the two samples in the mother liquor before filtration and to the different mode of drying employed in the two cases. These points are pursued in greater detail below.

In contrast to the nitrogen surface areas, those measured with water are approximately constant for the three samples listed in Table II, being apparently independent of the alcohol used in the solvent displacement procedure and of the length of storage time prior to examination. The surface area determined by mercury porosimetry appears to be more closely related to the value for nitrogen than for water, as far as the results recorded in Tables I and II are

concerned, in agreement with observations reported for macroporous alumina gels (17).

#### Influence of storage of mother liquor

Mention has been made above of the apparent influence of the length of storage in the mother liquor before drying on the porosity and nitrogen surface areas of both propan-2-ol/acetone- and acetone-washed samples. For this reason, studies have been made of the porosity and surface areas of a number of samples where the only difference in pretreatment before drying was in their storage time in the mother liquor.

No simple relationship seems to exist between the porosity of the samples and their length of storage, and this could possibly be attributed to the increasing crystallinity of the samples on storage, as demonstrated by the sharpening of lines observed in the X-ray diffraction patterns of these solids. Such crystallinity would lead to increasing inhomogeneity as crystalline regions grow at the expense of amorphous areas, and affect the porosity of the materials in an

erratic manner.

In contrast, the nitrogen and water surface areas of the samples listed in Table III follow a regular pattern, with the water surface area being substantially unchanged while the nitrogen surface area shows a steady decline until after 30 days storage it is less than one-half of that recorded after 4 days of the same treatment.

#### Influence of outgassing temperature

In all the work discussed above, outgassing of the samples immediately before the commencement of nitrogen and water vapour sorption was always undertaken at 25°C. As the results recorded in Table IV show, increasing the outgassing temperature to 200°C makes little difference to the nitrogen surface area of the samples, the value remaining virtually unchanged within experimental error. However, over the same temperature range, the water surface area is drastically reduced until at 200°C it is only one-quarter of the value attained at 25°C.

#### Influence of outgassing pressure

Although most of the systematic work recorded in this report has been undertaken on D-dried samples, some results (recorded in Table II) have been obtained on samples which although ultimately outgassed at  $5 \times 10^{-4}$  Torr have attained this pressure in stages rather than in one progressive process. This raises the question as to whether the outgassing pressure has any significant effect on the surface properties of the resulting solid, similar to that observed for the rate of drying on the surface area of cement pastes (18).

Fig. 4 - Influence of outgassing pressure on porosity of CSH(I) gels. Sample CSH/4/IA/-/25 outgassed (A) at  $5 \times 10^{-4}$  Torr and (B) at  $1 \times 10^{-2}$  Torr.

The porosimetry results depicted in Figure 4 indicate that decreasing the outgassing pressure from  $1 \times 10^{-2}$  Torr to  $5 \times 10^{-4}$  Torr increases the porosity of the sample, with a much higher percentage of smaller pores being generated at lower pressure - an observation supported by scanning electron microscopy. Whether the surface area is affected to the same extent is doubtful however. Certainly, outgassing in stages rather than continuously down to  $5 \times 10^{-4}$  Torr has little effect on the surface area of the final sample when measured by nitrogen or water sorption, as shown by a comparison of the results listed for samples CSH/10/EA/D\*(8)/25, CSH/10/EA/D(8)/25, CSH/10/IA/D\*(8)/25 and CSH/10/IA/D(8)/25 in Tables II, III and IV. In this respect, the behaviour of CSH(I) gel appears to differ from that of cement pastes, although it must be stressed that the pressure range studied was rather small and the rate of drying was far from rapid.

#### DISCUSSION

The results reported here clearly show that the surface characteristics of CSH(I) gels are very dependent on their pretreatment before examination. Thus, five principal factors; method of drying; treatment with organic solvents; storage in mother liquor; heating; and outgassing pressure, have been identified in this work, with two other factors, viz. the influence of atmospheric carbon dioxide and the ageing of samples containing traces of moisture, noted but not studied in any great detail.

The existence of so many factors calls into question the value of much of the previous work on the surface chemistry of CSH(I) gels and also, by implication, of cement pastes. Too often work in this field has been characterised by the use of poorly defined materials whose pretreatment has been largely ignored - certainly as far as published accounts are concerned - and

subjected to a variety of drying procedures including an arbitrary selection of organic solvents. Under these circumstances it is little wonder that widely divergent results have been obtained by different groups of workers.

However, despite these divergencies, there has always been general agreement between workers that surface areas measured by nitrogen adsorption are much less than those determined through the use of water on the same samples. This observation is sustained by the work described here, where it has been shown that it is only a coincidence of factors which leads to the nitrogen and water surface areas being approximately equal. These are short storage in mother liquor, washing with propan-2-ol followed by acetone, D-drying and outgassing at elevated temperatures (ca  $100^{\circ}\text{C}$ ) prior to examination.

Like other workers in this field, we have been tempted to speculate on the reason(s) for the normally observed differences between the nitrogen and water surface areas. The results obtained point to the enhanced specificity of water and suggest that a more accurate estimate of surface area is obtained from nitrogen adsorption. The decrease in the nitrogen surface area observed for CSH/2/A/P(3)/25 on storage for 323 days, which has been attributed to ageing processes catalysed by traces of moisture, indicates that water interacts with the material of the gel, and the general shape of the water isotherm (Figure 1(b)) with its open hysteresis loop down to low relative pressures shows that water is trapped and retained in the sample on desorption.

As mentioned above, other workers have suggested that trapping of water occurs in "ink-bottle" pores (6,8) or through penetration into the layer structure of CSH(I) gel (9,10). We would like to advance a third suggestion involving the assumption that the structure of CSH(I) gel consists of a silicate framework whose intrinsic negative charge is balanced by the presence of an appropriate number of ancillary calcium counterions. Drying the gel at low ambient water vapour pressure (D-drying) removes bulk water from the silicate framework (a process which is enhanced by the use of an appropriate solvent) as well as some water from the coordination spheres of the calcium ions in the system. This leaves pores in the silicate framework accessible to both nitrogen and water, and vacancies in coordination spheres accessible only to water where the adsorbate is retained.

Provided that relatively mild drying conditions are employed, there is no danger of collapsing the coordination spheres; hence, reducing the outgassing pressure from  $1 \times 10^{-2}$  Torr to  $5 \times 10^{-4}$  Torr in stages, although increasing the porosity of the overall material, has little effect on either its nitrogen or water surface areas. However, increasing the length of storage in the mother liquor increases the crystallinity of the sample; this, in turn, introduces a measure of order into the silicate framework thus reducing the number of pores accessible to nitrogen in the bulk material, although penetration of water into the framework remains unchanged. The nitrogen surface area of the material is correspondingly reduced but the water surface area remains unchanged since the water content of the coordination spheres is unaltered by crystallisation, being determined solely by the drying process employed.

Heating the samples to elevated temperatures has a drastic effect on coordinated water, and leads to the successive collapse of coordination spheres as the temperature is raised. This process is irreversible and causes a decrease in the water surface area as well as a change in the shape of the desorption branch of the isotherm, indicating an approach to a closed loop at sufficiently high temperatures (19). In contrast, the nitrogen surface area remains virtually constant as the temperature is raised indicating that the number of pores accessible to nitrogen in the silicate framework is much less affected by heating (certainly in the range to 200°C) than the coordination spheres of the calcium ions.

# Etude analytique des C-S-H obtenus par action de la chaux sur la silice

## *Analytical study of C-S-H obtained by the action of lime on silica*

- D. MENETRIER, docteur ès sciences, attachée de recherches CNRS (L.A. 23), Faculté des Sciences de Dijon,  
 B. COTTIN, ingénieur de l'Ecole Centrale, Société des Ciments Lafarge, Centre de Recherches de Trappes,  
 P. BARRET, professeur à l'Université de Dijon, directeur du L.A. 23 (Réactivité des Solides), France.

RESUME : L'étude cinétique de la réaction à 21°C de l'eau de chaux de diverses concentrations initiales (0 à  $35.10^{-3}$  mol.kg<sup>-1</sup>) avec la silice amorphe (aérosil) a été faite systématiquement pour établir les courbes d'évolution en fonction du temps des concentrations en chaux et silice. Les produits solides de réaction ont été analysés aux instants successifs ainsi qu'à l'état d'équilibre final par diffraction X et spectrométrie de vibration IR. Il a été établi que le dosage de la silice solide résiduelle pouvait être effectué quantitativement par cette dernière méthode et la possibilité d'un dosage simultané du CSH global a été précisée.

Les résultats mettent en évidence la rapide diminution initiale de la concentration en chaux due à la fixation superficielle d'ions  $Ca^{2+}$  par les groupes silanols, suivie, après passage par un minimum, de la remontée de concentration des ions  $Ca^{2+}$  vraisemblablement sous l'influence de l'enrichissement simultané de la solution en silice totale ( $H_4SiO_4$ ,  $H_3SiO_4^-$ ,  $H_2SiO_4^{2-}$ ).

Un maximum de concentration des ions  $Ca^{2+}$  est alors atteint. Il est le point de départ d'une décroissance régulière jusqu'à l'équilibre en raison de la précipitation des hydrosilicates dont la composition stoechiométrique pour C/S = 0,5 et plus encore pour C/S = 1 reçoit l'appui d'arguments expérimentaux à condition d'admettre simultanément l'existence d'une solution solide avec la chaux s'étendant au moins jusqu'à C/S = 2.

Le report sur le diagramme chaux-silice-eau des variations de composition des solutions accompagnant l'évolution des systèmes étudiés montre que les chemins cinétiques se développent parallèlement aux courbes d'équilibre de solubilité.

SUMMARY : The kinetic study of the reaction, at 21°C, of lime water with various initial concentrations (0 to  $35.10^{-3}$  mol.kg<sup>-1</sup>) with amorphous silica (aerosil) was carried out to establish the evolution curves versus time of lime and silica concentration. The solid products of the reaction were analysed at successive times as well as at final equilibrium state by X-diffraction and IR vibration spectrometry. It was established that dosing residual solid silica could be quantitatively performed by the latter method and the possibility of a simultaneous titration of the bulk CSH was clarified.

The results show the rapid diminution of initial lime concentration due to the surface fixation of  $Ca^{2+}$  ions by the silanol groups, followed, after passing through a minimum, by the concentration increase of  $Ca^{2+}$  ions probably under the influence of the simultaneous enrichment of the solution in total silica ( $H_4SiO_4$ ,  $H_3SiO_4^-$ ,  $H_2SiO_4^{2-}$ ).

A concentration maximum of  $Ca^{2+}$  ions is then reached. It is the starting point of a regular decrease until equilibrium due to the precipitation of hydrosilicates whose stoichiometric composition for C/S = 0.5 and even more for C/S = 1 is validated by experimental arguments providing it is simultaneously assumed that there is a solid solution with lime extending to at least C/S = 2.

Reporting the compositions changes in the solutions accompanying the evolution of the systems investigated on the lime-silica-water diagram shows that kinetic paths develop in parallel to the solubility equilibrium curves.

## INTRODUCTION

La compréhension des processus de prise et de durcissement du ciment Portland suppose une bonne connaissance des diagrammes d'équilibre de solubilité qui permettent de relier la composition des hydrates à celle des solutions. Les variations de composition que subissent celles-ci en fonction du temps par suite de la dissolution des phases solides anhydres et de la précipitation des hydrates peuvent être représentées par une construction graphique simple (1) sur les diagrammes d'équilibre, aussi bien dans le cas des silicates de calcium que dans celui des aluminates. Or, les deux diagrammes du système  $\text{CaO-SiO}_2\text{-H}_2\text{O}$  publiés antérieurement (2, 3) offrent entre eux de notables différences. L'un des objectifs de ce travail a été de préparer des C-S-H purs et de développer des techniques d'analyse pour mieux les caractériser.

Steinour a fait, dès 1947, une synthèse des travaux déjà publiés sur le système  $\text{CaO-SiO}_2\text{-H}_2\text{O}$  (4). Beaucoup d'entre eux démontrent l'existence d'une relation entre le rapport molaire global  $[\text{C/S}]_s$  des phases solides et la concentration en chaux des solutions avec lesquelles elles sont en équilibre ; cette courbe  $[\text{C/S}]_s = f [\text{CaO}]_l$  traduit toutefois les résultats de façon incomplète - elle ne tient pas compte de la concentration en silice des solutions - et cela a été une source de désaccords entre les auteurs : le rapport  $[\text{C/S}]_s$  est un rapport global ; il peut donc être interprété soit par l'existence de deux hydrates, C-S-H (I) et C-S-H (II) de composition variable dans un large domaine (5), soit par le mélange dans des proportions différentes de plusieurs hydrates de composition définie (3).

Dans deux articles seulement, ceux de Flint et Wells (2) et de Greenberg (3) les données sur la composition des solutions en chaux et en silice sont suffisantes pour établir le diagramme d'équilibre du système  $\text{CaO-SiO}_2\text{-H}_2\text{O}$ . Récemment, Dron (6) a calculé le diagramme théorique et a conclu à la validité de l'hypothèse de Greenberg sur l'existence d'un hydrate  $\text{CaH}_2\text{SiO}_4 \cdot n\text{H}_2\text{O}$ .

Malgré les nombreuses recherches faites à leur sujet, la nature de ces hydrates n'est pas bien élucidée et ils sont toujours écrits dans la forme C-S-H pour montrer qu'ils n'ont pas de composition définie. Les méthodes classiques d'analyse apportent peu de renseignements dans le cas de ces produits de faible cristallinité ; il faut cependant mentionner que le développement récent de la méthode de triméthylsilylation a permis de progresser dans la distinction des anions silicates (7). Nous avons essayé de tirer parti de la spectrométrie de vibration infrarouge.

## Méthodes expérimentales :

A l'instant initial, 1,00 g de silice amorphe (Aérosil 200) est mélangé avec 1 litre de solution de chaux dont la concentration est différente à chaque essai (colonne 2 - tableau I). Les solutions sursaturées de chaux sont obtenues soit par filtration de suspensions de  $\text{C}_3\text{S}$  dans l'eau, soit à l'aide de résines échangeuses d'ions (essais n, o, p, q). Pour les essais r, s, t, de la chaux vive fraîchement décarbonatée est ajoutée à des solutions de chaux saturées.

Le flacon est placé dans un bain thermostaté à  $21^\circ\text{C}$  et le mélange est agité à vitesse constante, sous courant d'azote. Des échantillons sont prélevés à intervalles de temps réguliers. La concentration en chaux et en silice des filtrats est déterminée par

TABLEAU I

spectrophotométrie d'absorption atomique ; la fraction solide est d'abord séchée (acétone puis éther) avant d'être soumise à une série d'examen, diffraction des rayons X, microscopie électronique à balayage, spectroscopie infrarouge en particulier. En vue de l'utilisation de cette dernière technique, les échantillons sont pastillés avec KBr dans la proportion de 1,20 mg pour 500 mg de KBr ; trois pastilles de 100 mg sont préparées chaque fois, afin d'assurer une bonne reproductibilité des résultats.

## Résultats expérimentaux - Discussion :

Il est impossible de rapporter ici les résultats détaillés de tous les essais ; ils sont explicités dans une thèse (8).

Etude des solutions : Nous avons sélectionné quelques courbes pour montrer l'évolution en fonction du temps des concentrations en chaux notée [C] et en silice notée [S] des solutions. (Figure 1).

Au cours des premières minutes, [C] baisse de 2 à 4 millimoles en raison, probablement, d'une fixation d'ions  $\text{Ca}^{++}$  sur les groupes silanols de la surface de la silice ; chaque  $\text{Ca}^{++}$  doit réagir avec 2 groupes silanols. Nos résultats sont en bon accord avec ceux de Fripiat et col. (9) qui ont montré que l'aérosil 200 contenait  $2,90 \cdot 10^{-3}$  mol de groupes silanols par gramme de silice. Dans les essais r, s, t, où de la chaux solide a été ajoutée, ce phénomène, s'il existe, est masqué par le passage d'un peu de chaux dans la phase liquide tendant à donner des solutions saturées. L'augmentation de [C] souvent observée

Fig. 1 - Evolution en fonction du temps des concentrations en chaux et silice des solutions.

ultérieurement, peut s'expliquer par le passage en solution, sous l'influence de changements dans le milieu réactionnel : modification de pH, dissolution de silice ...), d'une partie des ions  $\text{Ca}^{2+}$  chimisorbés.

Dans la période suivante, les courbes  $[\text{C}]$  sont parallèles (la longueur et les limites de cette période dépendent du titre initial de la solution de chaux). La vitesse moyenne de consommation est de  $0,0125 \mu\text{mol.kg}^{-1}.\text{sec}^{-1}$ . L'essai a est exclu :  $[\text{C}]$  ne varie plus. La courbe de l'essai u, réalisé à partir de 0,5 gramme de silice n'est pas parallèle à celle des autres essais, tous effectués avec 1 gramme : la pente de la courbe est moins forte et la vitesse de consommation de la chaux est réduite de moitié environ. La vitesse de précipitation des C-S-H est indépendante de la concentration initiale de la solution de chaux, elle est directement proportionnelle à la quantité de silice présente, donc à la surface de la silice.

A l'opposé des courbes  $[\text{C}]$  qui présentent une évolution générale commune, celles de la silice se divisent en plusieurs groupes. La courbe (a) peut être utilisée comme base de comparaison ; en effet, après quelques minutes,  $[\text{C}]$  ne varie plus et il y a seulement une dissolution de silice sous forme  $\text{H}_4\text{SiO}_4$ , accompagnée d'une transformation partielle de l'acide monosilicique  $\text{H}_4\text{SiO}_4$  en  $\text{H}_3\text{SiO}_4^-$ ,  $\text{H}_2\text{SiO}_4^{2-}$ . La courbe de l'essai (d) a la même forme que celle de (a) mais les valeurs de  $[\text{S}]$  sont inférieures à celles obtenues lors de l'essai (a), pour des temps identiques. Une nouvelle forme de courbe apparaît dans les essais (e) et (f) : après avoir suivi le même trajet qu'en (a) et (d), (40 min.), les courbes se séparent :  $[\text{S}]$  décroît puis réaugmente soit rapidement comme dans (e), soit après quelques heures, comme dans (f).

Ceci reste valable pour l'essai (g), mais, les deux premières périodes de la courbe d'évolution durent très peu de temps. Pour (h) et (i),  $[\text{S}]$  conserve une valeur faible (environ  $0,1 \cdot 10^{-3} \text{ mol.kg}^{-1}$ ) pendant de nombreuses heures, puis croît brusquement au bout de 18 h dans le cas de l'essai (h) et de 20 h dans celui de (i), alors que dans les deux cas,  $[\text{C}]$  passe par la valeur  $2 \cdot 10^{-3} \text{ mol.kg}^{-1}$ .

De la comparaison des résultats obtenus pour  $[\text{C}]$  et  $[\text{S}]$ , il est possible de tirer des conclusions importantes quant au mécanisme de formation des C-S-H. La décroissance continue de  $[\text{C}]$ , et la forme des courbes  $[\text{S}]$  suggère l'existence d'une compétition entre le passage en solution de la silice et la précipitation des C-S-H à partir des ions de la phase liquide. Dans l'essai (d), la vitesse de précipitation des hydrates reste faible ; par suite,  $[\text{S}]$  ne s'arrête pas de croître ; en revanche, à partir de l'essai (l), la vitesse de précipitation des hydrates croît rapidement par rapport à la vitesse de dissolution de la silice ce qui permet d'expliquer les deux premières parties de la courbe : apparition de  $\text{SiO}_2$  en solution puis sa diminution. Pour les essais (g), (h), (i), la vitesse de précipitation des C-S-H est grande depuis le début ; la concentration de la silice en solution reste faible car la dissolution de la silice est l'étape déterminante de la cinétique de la réaction. On peut penser, sans toutefois en apporter de preuve formelle, que le même mécanisme reste valable lors des essais effectués avec des solutions sursaturées de chaux. On retrouve là l'un des problèmes majeurs posés par l'hydratation de  $\text{C}_3\text{S}$ . La formation des C-S-H a-t-elle lieu par précipitation à partir des ions en solution ou bien est-elle de nature topochimique en entendant par là la fixation directe des molécules d'eau dans la phase solide et la transformation structurale aboutissant à C-S-H.

Au bout de plusieurs mois d'évolution, chaque système atteint un état d'équilibre métastable, caractérisé partiellement par sa concentration en chaux et en silice en solution (colonnes 3 et 4 du tableau I) et par le rapport global  $[\text{C}/\text{S}]_s$  des phases solides (colonne 5). Chaque couple de valeurs  $[\text{C}]_f$ ,  $[\text{S}]_f$  définit un point d'une courbe de solubilité des C-S-H, ce qui nous a permis de reconstruire le diagramme d'équilibre du système  $\text{CaO-SiO}_2\text{-H}_2\text{O}$  (8). Il est particulièrement instructif de reporter sur ce diagramme les variations de composition des solutions accompagnant l'évolution des systèmes : on remarque alors que ces "chemins cinétiques" se développent parallèlement aux courbes d'équilibre de solubilité. La conséquence intéressante qui en découle est qu'il suffit de connaître les concentrations initiale  $[\text{C}]_i$  et finale  $[\text{C}]_f$  en chaux de la solution pour savoir qu'elle sera l'évolution de  $[\text{S}]$  tout au long d'un essai.

**Etude des phases solides :** Les spectres de diffraction X d'échantillons prélevés pendant les essais (a), (b), (c), (d) ne montrent guère qu'une bosse de diffusion due au gel de silice ; la première raie de C-S-H (I) à  $3,07 \text{ \AA}$  apparaît sur le spectre final de l'essai (d), mais elle est très large et peu intense ; un épaulement à  $2,83 \text{ \AA}$  [2ème raie de C-S-H(I)] apparaît sur celui de (e). Si l'on déshydrate ces produits finals à  $1000^\circ\text{C}$ , on obtient le spectre du quartz pour (a), (b), (c), celui du quartz et de la parawollastonite pour (d), (e) et (h). Les trois raies principales sont présentes sur le spectre final de (h), mais seule la raie à  $3,07 \text{ \AA}$  est fine. Les trois raies deviennent fines quand  $[\text{C}/\text{S}]_s$  atteint l'unité (essai m) ; le fond continu que donnait la silice a alors complètement disparu.

Fig. 2 - Spectres d'absorption infrarouge dans le domaine des vibrations de valence Si-O des phases solides obtenues à l'équilibre.

La spectroscopie infrarouge confirme ces premiers résultats et apporte des informations supplémentaires. Nous ne donnerons ici que les résultats relatifs au domaine  $1200 \text{ cm}^{-1} - 400 \text{ cm}^{-1}$ . La silice amorphe y présente des bandes caractéristiques à  $1100 \text{ cm}^{-1}$ ,  $805 \text{ cm}^{-1}$  et  $468 \text{ cm}^{-1}$  ; elles sont respectivement attribuées aux vibrations de valence des liaisons Si-O et Si et à la vibration de déformation asymétrique des liaisons Si-O (10). Les C-S-H sont caractérisés essentiellement par une bande large et intense à  $970 \text{ cm}^{-1}$  et par une bande à  $450 \text{ cm}^{-1}$  ; l'intensité de la bande à  $805 \text{ cm}^{-1}$  est beaucoup plus faible. Les spectres des produits finals de quelques essais ont été tracés sur une même figure pour comparaison (figure 2). Le spectre de (a) est identique à celui de l'aérosil ; ceux des échantillons (b), (c), (d) ( $C/S < 0,20$ ) présentent un élargissement progressif de la bande à  $1100 \text{ cm}^{-1}$  vers les nombres d'onde inférieurs. Un épaulement à  $970 \text{ cm}^{-1}$  apparaît sur le spectre de (d) ; la bande n'apparaît vraiment que sur le spectre de l'échantillon (e), mais la bande à  $1100 \text{ cm}^{-1}$  de la silice reste la plus intense. La présence de la silice est encore décelable sur le spectre du produit se caractérisant par  $[C/S]_s = 0,94$  (essai l), mais elle a complètement disparu du spectre de (m), pour lequel  $[C/S]_s = 1,0$  ; ceci est donc un argument en faveur de l'existence d'un hydrate défini, de rapport  $[C/S]_s = 1$ . En revanche, on n'observe pas de modifications sur les spectres IR et X de tous les échantillons pour lesquels  $1,0 \leq [C/S]_s \leq 1,50$ . Il faut donc reconnaître que l'hydrate précédent est capable de fixer un excès important de calcium dans son réseau.

Dans les essais où de la chaux solide a été ajoutée

Fig. 3 - Etude cinétique par spectroscopie infrarouge de la transformation des phases solides (essai m).

(r), (s), (t), un précipité de  $\text{Ca(OH)}_2$  accompagne au début la précipitation des C-S-H. Ses raies apparaissent sur les spectres de rayons X et infrarouge ; leurs intensités s'affaiblissent progressivement alors que celles des raies de C-S-H augmentent.  $\text{Ca(OH)}_2$  n'est plus détecté dans les échantillons finals (r) et (s) ( $C/S = 1,26$  et  $1,53$ ), mais il est présent à côté de C-S-H (l) dans le produit (t) pour lequel  $C/S = 2,19$ .

Des analogies radiocristallographiques et infrarouges des phases solides, jointes à celles des solutions apportent les résultats suivants :

#### 1/ Rapport $[C/S]_s$ global des phases solides $\leq 0,23$ :

Ces phases sont de la silice amorphe et de petites quantités de C-S-H ; elles sont en équilibre avec des solutions dont la concentration en chaux demeure faible ( $1 - 1,50 \cdot 10^{-3} \text{ mol.kg}^{-1}$ ) alors que la concentration en silice va en croissant à cause de la formation d'ions  $\text{H}_3\text{SiO}_4^-$  quand le pH augmente.

#### 2/ $0,20 \leq [C/S]_s \leq 1,00$ :

Il s'agit d'un mélange de silice et de C-S-H (l) dans des proportions croissantes. La concentration en chaux des solutions varie peu mais celle de la silice décroît jusqu'à la valeur  $0,1 \cdot 10^{-3} \text{ mol.kg}^{-1}$  [essais (f) à (m)].

#### 3/ $1,00 \leq [C/S]_s \leq 1,50$ :

La chaux excédentaire se répartit entre le solide (sans qu'il y ait apparition d'une nouvelle phase) et la solution,  $[C]_f$  atteint  $15,47 \cdot 10^{-3} \text{ mol.kg}^{-1}$  quand  $[C/S]_s = 1,53$ , alors que  $[C]_f = 3,70 \cdot 10^{-3} \text{ mol.kg}^{-1}$  seulement pour  $[C/S]_s = 1,01$ .

4/  $[C/S]_s > 1,50$  : l'hydroxyde de calcium précipite en même temps que C-S-H qui a fixé une partie de la chaux excédentaire. Ces phases solides sont en équilibre avec une solution saturée de chaux.

Là encore, il est intéressant de remarquer les analogies dans les résultats que donne l'ensemble des systèmes à l'équilibre (figure 2) et ceux que donne un système particulier en cours d'évolution. On a choisi comme exemple l'essai (m) et rassemblé sur la figure 3 quelques spectres d'échantillons représentatifs de l'évolution du système. Au cours des premières heures, la bande à  $1100\text{ cm}^{-1}$  se déforme progressivement vers les nombres d'ondes plus petits et son intensité diminue légèrement (1h30) ; un épaulement à  $970\text{ cm}^{-1}$  apparaît au bout de 6 heures puis s'accroît (9h), la séparation en deux bandes distinctes se produit vers 12 heures et on note la variation, en sens inverse des deux bandes à  $1100$  et  $970\text{ cm}^{-1}$ , ce qui permet d'envisager un dosage quantitatif des C-S-H.

#### CONCLUSIONS

Dans cette étude des réactions entre silice amorphe et solutions de chaux, la méthode adoptée a été l'analyse simultanée des phases solides et des solutions en contact avec elles, au cours de l'étude cinétique aussi bien que de celle des états d'équilibre. Il a ainsi été mis en évidence que les C-S-H précipitent à partir des ions en solution et que l'étape qui gouverne la cinétique globale des réactions est celle du passage en solution de la silice. On a également construit les courbes de solubilité du système  $\text{CaO}, \text{SiO}_2, \text{H}_2\text{O}$  et associé, à chaque point définissant la composition des solutions, le rapport  $[C/S]_s$  des phases solides avec lesquelles elles sont en équilibre. La spectroscopie infrarouge a apporté des informations nouvelles en permettant de différencier les produits finals des réactions et de suivre la cinétique de formation des hydrosilicates de calcium.

D'autre part, l'étude du système  $\text{CaO}-\text{SiO}_2-\text{H}_2\text{O}$  sous deux aspects généralement étudiés séparément - cinétique et états d'équilibre -, a montré qu'ils sont en fait étroitement liés : les chemins cinétiques représentant la variation de composition des solutions au cours de leur évolution se développent parallèlement aux courbes d'équilibre de solubilité.

# Calorimétrie des liants

## *Calorimetry of binders*

A.V. OUCHEROV-MARCHAK, collaborateur scientifique, candidat ès sciences techniques,  
KHICI, A.M. OURJENKO, collaborateur scientifique,  
O.P. MTCHEDLOV-PETROSSIAN, professeur, docteur ès sciences techniques, U.R.S.S.

RESUME : Cet exposé constitue un examen des objectifs concernant l'application de l'analyse calorimétrique à la chimie et à la technologie du ciment. Il fait état de la mise au point d'une méthode de microcalorimétrie isotherme différentielle. Les études portent sur la suppression des erreurs qui ont pour cause des interactions hétérogènes et la correction dynamique de l'inertie des instruments de mesure, ainsi que le dépouillement automatique des données finales et l'interprétation cinétique des relations obtenues pour des liants modèles monominéraux. Les auteurs mettent en évidence l'apport, dans l'effet thermique général, de la chaleur des processus élémentaires de durcissement : adsorption, dissolution et cristallisation. On y trouve également des données concernant les possibilités de régulation technologique et l'obtention de ciments aux propriétés voulues sur la base des données de l'analyse calorimétrique. Celle-ci englobent la composition chimique et minéralogique, la granulométrie, l'addition d'adjuvants et de germes cristallins, les conditions de durcissement et d'exploitation.

SUMMARY : The problems of using calorimetric analysis in the chemistry and technology of cement are considered. The results of development of the isothermic differential microcalorimetry method are presented. The developments comprise elimination of errors connected with the heterogeneous nature of interaction and dynamic correction of the time-lag of the instruments, as well as automatic processing of results and kinetic interpretation of the relationships obtained for model monomineral binders. Contributions of the elementary hardening processes (adsorption, dissolving and crystallization) in the total thermal effect are established. The possibility of technological control and preparation of cement with required properties on the basis of the calorimetric data is discussed. The data cover the chemical and mineral composition, granulometry, introduction of additives and crystal seeds, conditions of hardening and of exploitation.

Le dégagement calorifique est un des plus importants phénomènes qui accompagnent le durcissement des ciments. Ses caractéristiques sont utiles pour les recherches sur le mécanisme et la cinétique d'hydratation, on y fait recours lors du choix et de la prescription des paramètres dans la technologie des ciments et des bétons. La calorimétrie joue un rôle toujours croissant dans l'ensemble des méthodes chimiques et physiques de la recherche sur la chimie des ciments. Ceci s'explique par une grande capacité d'information de la méthode. Les données sur l'effet thermique global  $Q$ , la vitesse de dégagement thermique  $dQ/d\tau = f(\tau)$  lors de la réaction d'hydratation, permettent, dans le cas de leur interprétation à l'aide de l'appareil cinétique des processus hétérogènes, d'obtenir des renseignements quantitatifs sur le degré  $\alpha$  et la vitesse  $d\alpha/d\tau$  de transformation des liants. En dépit de certaines contradictions, on connaît fort bien les possibilités de l'analyse calorimétrique à laquelle on fait recours pendant les investigations des voies de régulation technologique et des modalités de conférer au ciment des propriétés nécessaires par une modification de la capacité de dispersion et de la granulométrie, de la composition de phase et chimique, et l'addition d'adjuvants et de germes chimiques.

A des fins scientifiques et pratiques, on utilise la calorimétrie de dissolution, les méthodes adiabatique et isothermique, ou bien leurs variétés. La calorimétrie isothermique différentielle permet d'enregistrer de faibles variations de la puissance thermique d'un système en état de durcissement dès le contact avec de l'eau, ce qui est important pour les études sur des stades initiaux de durcissement, puisqu'en cette période le degré d'hydratation est minime, alors que la vitesse d'hydratation est grande.

On a plus d'une fois attiré, dans des ouvrages scientifiques, l'attention sur la nécessité de franchir des obstacles, sur le plan méthodologique, créés par la spécificité de l'interaction hétérogène dans les systèmes dispersés en voie de durcissement, ainsi que sur la nécessité de surmonter les difficultés d'interprétation quantitative des résultats de mesures, dues à la disproportion des vitesses de dégagement calorifique et d'hydratation aux divers stades de durcissement.

L'évolution de la technique des expérimentations a permis d'assurer la suppression de toute une série d'erreurs. Nous utilisons pendant nos travaux des calorimètres munis d'un dispositif d'introduction automatique des liants en poudre dans la cellule de la réaction et d'un malaxage des réactifs par vibration lors de leur combinaison. On a envisagé la suppression de l'effet de la température sur la poudre du liant et sur l'eau. Ces dispositifs réduisent au minimum les erreurs qui ont lieu à cause de l'hydratation préliminaire des liants dans les vapeurs d'eau, de l'évaporation des liquides et de l'homogénéité insuffi-

sante d'un mélange. On applique également un dispositif électronique de correction dynamique de l'inertie de la partie mesurage du calorimètre. Le microcalorimètre isothermique différentiel est muni d'un potentiomètre d'enregistrement des rapports  $dQ/d\tau = f(\tau)$ , d'un intégrateur de leur transformation en rapport  $Q - \Phi(\tau)$  et d'un potentiomètre à double orientation d'enregistrement des courbes  $dQ/d\tau = F(Q)$ . La sensibilité du potentiomètre est de  $10^{-5} W$ , la constante du temps, de 120 sec. La construction automatique des rapports modèles et le dépouillement des résultats d'expérimentation à l'aide d'un ordinateur facilitent dans une grande mesure l'interprétation des données d'analyse calorimétrique. L'objet des recherches calorimétriques quantitatives sont essentiellement des liants monominéraux  $3CaO \cdot Al_2O_3$  et  $CaSO_4 \cdot 0,5H_2O$ . Pendant des recherches sur l'hydratation du silicate tricalcique, R.Kondo, M.Daimon (1) P.Longuet (2) et N.Stein (3) se sont heurtés à des difficultés quant à l'utilisation des données calorimétriques à cause de la disproportion des indices  $dQ/d\tau$  et  $d\alpha/d\tau$ , de la différence de précision lors de l'évaluation de la vitesse d'hydratation par les méthodes chimique, radiologique et calorimétrique. Cependant, Stein (3) estime l'utilisation des résultats d'analyse possible lorsque la composition d'un hydrosilicate au cours du processus reste invariable ou bien quand on observe le rapport constant entre les hydrosilicates de haute et basse basicité. D'une façon générale, on a su mettre en évidence et décrire certains stades du processus, évaluer le rôle de la formation des noyaux et de la pellicule, la possibilité d'application des équations cinétiques essentielles, de la règle de Van't Hoff lors des variations de température, de l'introduction des additifs, etc. Les recherches sur le gypse semi-hydraté en tant que modèle d'un liant sont plus avantageuses, puisque le gypse est hydraté sans former des produits intermédiaires et la valeur  $Q/\alpha$  demeure constante au cours du processus. Par ailleurs, la chaleur d'adsorption d'eau par des produits cristallins d'hydratation du gypse est incomparablement plus basse que celle par des hydrosilicates.

Nous avons étudié certaines équations cinétiques utilisées pour décrire le phénomène d'hydratation (4). La figure 1 présente les rapports  $d\alpha/d\tau = f(\alpha)$  pour les équations Kolmogorov - Avrami - Eroféev

$$d\alpha/d\tau = (1-\alpha) [-\ln(1-\alpha)]^{3/4} \quad (1)$$

$$\text{Reedje } d\alpha/d\tau = \alpha(1-\alpha)^{2/3} \quad (2)$$

$$\text{Comb et d'autres } d\alpha/d\tau = 3(1-\alpha) \ln(1-\alpha)^{1/3} \quad (3)$$

Les valeurs calculées du degré de transformation  $\alpha_{\max}$  où la vitesse du processus atteint son maximum constituent respectivement 0,52; 0,60 et 0,28. En même temps, pour

Fig. 1. Rapports théoriques entre la vitesse et le degré de transformation calculés sur les équations (1), (2) et (3).

l'équation (1)  $n = 4$ .

Les calculs de  $\alpha_{\max}$  d'après les résultats d'analyse calorimétrique pour  $\alpha$  - forme et  $\beta$  - forme du semi-hydrate (Fig.2) montrent que sa valeur de l'ordre de 0,4 est bien au-dessous des prévisions théoriques. La meilleure concordance des données théoriques et expérimentales doit être observée quand la valeur  $\alpha_{\max}$  est plus basse ce qui peut être expliqué par le fait que les germes d'hydrate adoptés pour les équations (1) et (2) sont de forme lamellaire ou aciculaire, et non sphérique tridimensionnelle. La meilleure explication des données des expérimentations offrent les équations qui tiennent compte de deux constantes cinétiques (vitesse de dissolution et cristallisation) puisque la vitesse maximale du processus doit varier en fonction des variations du rapport de ces constantes.

La conclusion essentielle de cette analyse tient à ce que la relation linéaire de  $d\alpha/d\tau = k\alpha$  même si la valeur  $\alpha_{\max}$  est minime, n'est pas observée et la formation et l'accroissement d'une phase nouvelle sont régis plutôt par la fonction puissance et non par la fonction exponentielle ce qui est propre pour la plupart des réactions hétérogènes. Par ailleurs, pour expliquer le caractère des courbes cinétiques pendant la période de ralentissement de la vitesse d'hydratation (rapport 2, Fig.2), il conviendrait d'adopter, dans l'équation du type  $d\alpha/d\tau = k(1-\alpha)^m$ , la valeur de  $m \gg 2/3$

Fig.2. Rapport entre le dégagement calorifique et la chaleur d'hydratation de  $\alpha$  - forme (1,2,3) et  $\beta$  - forme du gypse semi-hydraté (4).

et d'expliquer le phénomène par une large distribution de particules selon les dimensions.

Les recherches calorimétriques ont permis d'élucider toute une série de questions concernant le mécanisme et la cinétique d'interaction entre les additifs chimiques et, notamment, les amorces et les minéraux de clinker (5). On a découvert une différence d'action des amorces pendant le durcissement de divers minéraux (Fig.3).

On enregistre sur les courbes thermocinétiques d'hydratation de  $3\text{CaO} \cdot \text{SiO}_2$  (Fig.3,A) un accroissement de la valeur du premier exo-effet dans les éprouvettes avec amorce dû à la chaleur d'adsorption d'eau par la surface bien développée d'hydrosilicates de calcium similaires à des tobermorites. La différence calculée en valeurs de l'effet thermique pour une éprouvette de contrôle et des mélanges avec amorce constitue 7,79 Joules; le taux de chaleur étant de 97,13 J pour un gramme de  $3\text{CaO} \cdot \text{SiO}_2$ , ce qui est bien conforme au taux de chaleur d'adsorption par le gel tobermorite.

Lors de l'introduction des amorces, il est nécessaire de créer un contact intime avec liant.

Ceci est obtenu pendant nos expérimentations grâce à la trituration du mélange pendant 1 ou 2 minutes. Dans ce cas, la période d'hydratation essentielle évaluée sur la va-

leur du deuxième exo-effet se réalise plus amplement. Cela se produit, paraît-il, pour le compte de l'augmentation de la réactivité par activation mécano-chimique, puisqu'on dispose de données sur l'effet insignifiant de  $4\text{CaO} \cdot 5\text{SO}_2 \cdot 5\text{H}_2\text{O}$  sur la cinétique de durcissement du silicate tricalcique. Un résultat analogue a été obtenu pendant les recherches sur l'influence de l'amorce d'afwillite sur l'hydratation et le développement de la résistance du silicate tricalcique (6).

La nature de l'hydratation de  $3\text{CaO} \cdot \text{Al}_2\text{O}_3$  (Fig. 3, B), appartenant à la catégorie des liants qui durcissent rapidement, reste invariable à l'usage d'une amorce d'aluminate hydraté Ca, quoique son action sur le dégagement calorifique est très efficace, surtout lorsqu'elle est introduite par la méthode de trituration. L'accélération de la vitesse de durcissement dès le gâchage provoque la réduction de la période, pour l'essentiel à cause de l'effet écran de l'enveloppe d'hydrate.

L'action d'activation des amorce la plus efficace se manifeste pendant l'hydratation de  $4\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{Fe}_2\text{O}_3$  (Fig. 3, C). La courbe thermocinétique du durcissement de ce minéral enregistre la présence d'une période d'induction de la cristallisation. L'introduction de l'amorce (produit d'hydratation de  $4\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{Fe}_2\text{O}_3$ ) réduit la période d'induction de 6 à 2 heures pendant le malaxage ordinaire et jusqu'à une heure quand on assure un contact serré du minéral et de l'amorce.

L'analyse thermique différentielle, l'analyse des phases au rayons X ainsi qu'au microscope électronique ont confirmé la différence qui existe dans la constitution et la structure de nouvelles formations, cependant les données de l'analyse calorimétrique sont particulièrement appréciables vu l'existence des informations concernant l'effet des amorce sur le mécanisme et la cinétique de l'hydratation au stade initial. L'interprétation quantitative des données de l'analyse thermocinétique pour des poudres polyminérales et polydispersées des ciments est limitée, bien que, on l'a noté ci-dessus, leur importance pour la régulation technologique soit grande.

Une importance particulière est attribuée aux recherches sur la cinétique d'hydratation d'une série de ciments modèles spéciaux.

Ainsi, par exemple, les investigations dans le domaine du dégagement thermique des systèmes de dilatation à base de  $3\text{CaO} \cdot \text{Al}_2\text{O}_3$  et  $\text{CaO} \cdot \text{Al}_2\text{O}_3$ , du gypse et de la chaux, ont montré que la haute sensibilité de la méthode permettait d'enregistrer des variations thermiques insignifiantes qui accompagnent la formation et les transformations des aluminates hydratés et des hydrosulfoaluminates. On a établi des différences principales quant à l'influence du gypse et de la chaux sur la cinétique d'hydratation des aluminates.

Fig. 3. Intensité du dégagement calorifique pour  $3\text{CaO} \cdot \text{SiO}_2$  (A),  $3\text{CaO} \cdot \text{Al}_2\text{O}_3$  (B) et  $4\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{Fe}_2\text{O}_3$  (C). 1 - matière de base, 2 - mélange avec amorce introduite par malaxage, 3 - mélange avec amorce introduite par trituration.

Lors de l'introduction du gypse dans C3A, on relève une baisse de 2 fois de la valeur absolue du premier exo-effet, une extension de la période d'induction et une extinction de la vitesse du dégagement calorifique, ce qui s'explique par un effet atténuant des enveloppes d'hydrosulfoaluminate de calcium. L'addition de  $\text{Ca}(\text{OH})_2$  freine davantage l'action thermocinétique du système.

Tout comme H. Mori et K. Minegishi (7), nous avons enregistré la fission du deuxième exo-effet et sa transformation en doublet, ce qui est lié à la formation du monosulfate et sa transformation en solution solide et  $\text{C}_4\text{AH}_{13}$ .

Par contre, l'hydratation et le dégagement calorifique des systèmes à base de  $\text{CaO} \cdot \text{Al}_2\text{O}_3$  se déroulent d'une autre façon. A l'interaction de CA avec gypse qui s'effectue dans les conditions d'une saturation plus faible, il se produit une cristallisation rapide de l'ettringite qui s'achève au bout de 14-16 heures.

A ce moment près, la valeur  $dQ/dt$  devient minimale et s'approche d'une manière asymptotique du zéro. L'addition du gypse accélère l'hydratation de CA. La valeur des deux exo-effets s'accroît avec augmentation de la teneur en gypse, l'effet thermique total augmente, le degré d'hydratation s'élève. La présence de la chaux accélère la

cristallisation de l'ettringite, et l'augmentation de sa teneur provoque une augmentation de l'effet thermique total. Il est clair que dans les ciments expansifs à base de  $\text{CaO} \cdot \text{Al}_2\text{O}_3$ , il est assuré une synchronisation des indices de vitesse des réactions chimiques et de la formation des structures, alors que l'expansion, au stade initial est compensée par une plus profonde hydratation et par une consolidation de la structure du matériau.

Jusqu'ici nous avons examiné les aspects d'application des données de l'analyse calorimétrique au stade de la préparation des liants. Des résultats fort appréciables ont été obtenus également lors de l'application de la calorimétrie à la fabrication des pièces et constructions préfabriquées. Dans ce cas, c'est le principe de la conformité de l'ensemble des caractéristiques du liant (technologiques, cinétiques, thermodynamiques et d'autres) aux paramètres des effets appliqués lors du durcissement pour recevoir un matériau à composition de phases et à structure désirées. Ce principe est formulé par O.P. Mtchedlov-Petrosian. La durée, l'intensité et le moment d'application d'un de ces effets (thermique, mécanique, chimique ou de leurs combinaisons) doivent être choisis compte tenu de l'utilisation optimale des propriétés potentielles des ciments.

Les questions de l'influence de la température sur le dégagement thermique et de la prise en considération du dégagement thermique lors du choix des régimes de traitement thermique ont été examinées dans une communication, faite au séminaire "E" du présent Congrès.

On sait que les caractéristiques technologiques des liants, telles que la composition chimique et minéralogique, la dispersité, etc., sont liées étroitement à l'utilisation très répandue de l'effet chimique sur des mélanges en voie de durcissement au moyen de l'introduction d'additifs différents. Nous avons analysé l'influence de divers adjuvants - accélérateurs, retardateurs, porophores, plastificateurs - sur la cinétique du dégagement calorifique des minéraux de clinker et des ciments.

Auparavant (8), on a confirmé le fait de l'effet sélectif des additions sur les processus élémentaires d'hydratation et de durcissement - adsorption, hydrolyse, cristallisation - que nous avons appelé EFFET LE SELECTIVITE CINETIQUE de l'activité des composés chimiques. Utilisant les données sur la constante de la vitesse et l'énergie d'activation on a établi les séries d'activité des additions minérales les plus répandues avec anion commun  $\text{SO}_4^{2-}$ ,  $\text{Cl}^-$ ,  $\text{NO}_3^-$ ,  $\text{OH}^-$  et avec cation commun  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$  et d'autres. Cette conception a permis d'étayer d'une façon quantitative des séries d'additions chimiques complexes qui sont utilisées avec succès dans le bâtiment. Ces derniers temps, sont en cours de réalisation toute une série de travaux de recherche sur la cinétique du dégagement calorifique des ci-

ments avec addition de plastificateurs de forte action.

On a analysé l'effet de l'additif "Melment" et de certaines modifications des lignosulfonates. Une relation a été établie entre l'efficacité de l'action plastifiante et la modification successive de la vitesse d'hydratation qui se traduit par la baisse d'intensité du dégagement calorifique. Ainsi donc, les résultats des recherches sur les processus de durcissement, obtenus par la méthode de la microcalorimétrie isothermique différentielle, permettent, au stade de la préparation et de l'utilisation des liants, d'approfondir les connaissances sur le mécanisme et la cinétique d'hydratation, d'étudier, d'une façon rationnelle, sur la base expérimentale et théorique, les modalités de perfectionnement de la technologie des liants et des bétons.

## Effects of Admixtures upon Electrokinetic Phenomena During Hydration of $C_3S$ , $C_3A$ and Cement

### *Effets des adjuvants sur les phénomènes électrocinétiques au cours de l'hydratation de $C_3S$ , $C_3A$ et du ciment*

RESUME : On a étudié le rôle des adjuvants superplastifiants utilisés pour réduire l'eau de gâchage des ciments dans des applications spéciales. Pour comprendre leur action, on a étudié les phénomènes provoqués par l'hydratation du  $C_3S$  (alite) et du  $C_3A$  de divers ciments (type I, type V, classe C et classe H), lorsque ces ciments sont malaxés avec de l'eau contenant des proportions variées de ces superplastifiants ainsi que divers ions. Les techniques d'électrofiltration et d'électrophorèse ont été utilisées pour déterminer le potentiel zêta, produit à l'interface liquide-solide. Par la suite l'électrophorèse a été utilisée de préférence. La peptisation des grains de ciment, sous l'action de superplastifiants constitués par des condensats de formaldéhyde de naphthalène sulfoné et de formaldéhyde de mélamine sulfoné, semble due à la formation d'un potentiel zêta fortement négatif à la surface des cristaux d'alite et de  $C_3A$ . D'autres ions peuvent modifier ces effets, mais le phénomène reste le même en général, bien que son intensité puisse varier. Les variations systématiques du potentiel zêta ont été mesurées en fonction de la concentration en ajouts et en fonction du temps; ces variations sont importantes, notamment pour le  $C_3A$ . Ces variations semblent dues à l'adsorption des adjuvants à la surface des grains du ciment et du granulat. Il suffit de concentrations plus faibles en adjuvants pour créer ce potentiel zêta, si le ciment contient des cendres volantes. Ont aussi été examinées les relations entre ces phénomènes et d'autres facteurs physiques, comme la rhéologie du mortier et l'adsorption isotherme.

SUMMARY: The actions of superplasticizing admixtures, utilized for reducing the required water contents of cementitious mixes for special applications, have been investigated. To understand their effects, electrokinetic phenomena have been investigated for  $C_3S$  (alite),  $C_3A$  and cement particles (Type I, Type V, Class C and Class H) in contact with water containing different concentrations of superplasticizing admixtures and other ions. Streaming potential and electrophoresis techniques were explored to determine the zeta potential generated at the liquid-solid interface. Subsequently the electrophoresis technique was used primarily for measurements. The dispersion of cement particles through use of superplasticizing admixtures of the sulfonated naphthalene formaldehyde condensate and sulfonated melamine formaldehyde condensate families is apparently related to the generation of a strongly negative zeta potential at the surfaces of both alite and  $C_3A$  particles. Other ions in solution modify the effects, but the phenomena generally remain similar, though having differing magnitudes. Systematic changes in the magnitude of the zeta potential with concentration of admixture and time have been determined, and are significant, particularly with  $C_3A$ . The changes observed are related to adsorption of the admixture species upon the surfaces of the individual cement compounds and their admixtures. Smaller concentrations of admixtures are required to generate strong negative zeta potentials with flyash particles in similar suspension. Relations to other measurements such as mortar flow, viscosity and adsorption isotherms are also discussed.

## INTRODUCTION

The achievement of optimally dense very low permeability hardened cement composites is important for applications requiring high performances, such as plugging, because such materials have superior mechanical properties, and potential for chemical stability. Admixtures such as superplasticizers are employed for the purpose of decreasing the water-to-cement ratio, without decreasing the fluidity of the mixture. Zeta-potentials of cements in suspension have been studied (1), and the surface generated forces thus quantified were used to explain some of the effects of the superplasticizers upon the rheological properties of pastes and slurries. Recently, studies have been made of the related viscometric properties as well (2-4). The use of so-called superplasticizers or super-water-reducers have recently attracted the attention of concrete engineers (5) and for predictability, it is important to understand the mechanisms of their behavior. Significant attractive forces exist between cement particles in cement-water suspensions, and in time the particles link together to build rigid networks. Water reducing admixtures are effective in breaking the cement particle networks and dispersing them (6), preventing premature agglomeration minimizing the amount of water required to suspend the particles and render the mix workable for the required period of time. The admixtures control the forces between particles and increase fluidity of the mix (1).

Until recently (1), very little experimental work was carried out to apply zeta potential measurements to calcium silicates or cement (7,8). Ernsberger and France (9) studied the effect of calcium lignosulfonate, concluding that cement suspension viscosity reduction took place due to an electrostatic repulsion between cement particles in the presence of surface-adsorbed surfactant molecules. Petrie (6) reported that the attractive charge on cement particle surfaces was neutralized by adsorption (onto active sites), when an anionic surfactant based on certain naphthalenesulfonic acid condensates was present. Hattori (10) recently showed results fundamentally similar to those of Ernsberger and France, on one kind of superplasticizer.

Following the suggestion that potentially more than one mechanism may be applicable for generating a stable colloid (11) preliminary capillary rise experiments (1a) demonstrated that solid-liquid affinity played little role in the action of typical superplasticizers; the zeta potential was shown to have a dominant role; but the additional effect of steric hindrance could not be entirely discounted (1).

## EXPERIMENTAL

Two techniques were utilized at first for determination of zeta potential: streaming potential\* and electrophoresis (1). After preliminary experiments by both methods, primarily the electrophoretic method was utilized (1a).

The electrophoresis technique involved measurement of the velocity of a charged particle moving through a fluid under the influence of an electric field. According to Akers (13) the electrophoretic mobility of a particle suspended in an electrolyte is given (in  $\mu\text{m.cm.sec}^{-1}.\text{v}^{-1}$ ) by

$$v_e = \frac{\Delta W \lambda}{t I \phi (1 - \phi) (\rho_s - \rho_L)}$$

where  $\Delta W$  is the change in weight of particles,  $\lambda$  is specific conductance of the dispersion,  $t$  = time,  $I$  = current,  $\phi$  = volume fraction of dispersed solid,  $\rho_s$  = density of solid,  $\rho_L$  = density of electrolyte. Henry (in ref. 13) related the zeta potential to the electrophoretic mobility ( $v_e$ ) from which the zeta potential is calculated as follows:

$$\zeta = \frac{v_e \eta \pi}{f \epsilon}$$

where  $\eta$  is the viscosity of the electrolyte, and  $f$  depends on the value of the product  $k\alpha$  where  $k$  is the Debye-Huckel double layer reciprocal thickness and  $\alpha$  is the radius of the spherical particles. The admixtures used are listed in Table I.

Table I - Superplasticizers

designation	form	density (g/ml)	concentration (wt % solid)
A9 <sup>x</sup>	sulfonated naphthalene formaldehyde condensate	--	100.0
M1 <sup>*</sup>	sulfonated melamine formaldehyde condensate	1.125	20.0
A3 <sup>+</sup>	sulfonated naphthalene formaldehyde condensate	1.21	43.0
A4	sulfonated naphthalene plus retarder		45.4
A14	sulfonated melamine formaldehyde condensate	1.11	24.8
A28	sulfonated naphthalene formaldehyde condensate		

x #3 in Table I ref. (1a)

\* #1 in Table I ref. (1a)

+ #2 in Table I ref. (1a)

\*\* Where liquids were used in mixture preparations concentrations were expressed as vol. % liquid, as received (except in Fig. 1). Thus, the effective component concentration is higher in A3 and A4 than in M1 and A14.

## ZETA POTENTIAL RESULTS

**Cements.** The negative zeta potential generated on the cement particle surfaces is illustrated in Fig. 1, using the naphthalene-based admixture A3 in deionized water. Slightly lower magnitudes of negative zeta potentials were found with tap water than deionized water (1b). A general decrease in the

Fig. 1 - Change in zeta potential of Type I cement with concentration of A3.

\*In apparatus constructed by N. Macmillan

magnitude of the negative potential is shown with time, but it remains strong even after 1200 minutes. Similar though not identical behaviors have been shown with admixtures A1 and A2 as well (1).

Zeta potential measurements have been continued comparing the results with a naphthalene-based admixture containing a retarder (A4) to that without a retarder (A3). The maximum negative zeta potential similarly was reached at ~ 1% admixture concentration upon the same cement (14). Measurements for additional comparisons have been continued with a class C (HSR) cement [Fig. 2], a type V (HSR) [Fig. 3] and a class H (MSR) cement [Fig. 4]. Though the results were in general similar in all, some differences were found. The presence of the retarder in A4 allowed a smaller change in the zeta potential as a function of time, with the HSR class C and V cements; and a smaller magnitude of zeta potential for the type V cement. Further measurements were made using a newer melamine-based admixture (A14) with the Type I cement as shown in Fig. 5. These show less change with time in the magnitude of zeta potential than in previous measurements with M1 [Fig. 4 in Ref 1(b)]. The higher concentration of admixture (2%) is more effective than the 1% concentration, after 2 hours time. Similarly, with class H cement (Fig. 6) admixture A14 appears to require higher concentrations, at least 2% for greatest effectiveness. One additional naphthalene-based admixture A28 was studied in combination with the Class H cement [Fig. 7], showing a slightly different relationship than that shown in Fig. 4 for admixture A4.

**Effect of Mixing Water.** Since the mixing water in a cement slurry is saturated with  $\text{Ca(OH)}_2$  early in the cement hydration process, the behavior of admixtures in a saturated solution of  $\text{Ca(OH)}_2$  was also investigated (15). In addition, the specific conductance of the binary system of a saturated  $\text{Ca(OH)}_2$  solution with both a 10 percent and 1 percent admixture A4 was measured. The specific conductance of 0.2 normal solution of NaCl with 10 percent of admixture A4 was also measured (15). The specific conductance of the saturated  $\text{Ca(OH)}_2$  solution was 7375  $\mu\text{mho/cm}$ , larger than any specific conductance measured thus far. The liquid phase in which the cement zeta potentials were measured could not have been saturated with  $\text{Ca(OH)}_2$ ; because of the lower conductances reflecting the large w/c ratios.

**$\text{Ca(OH)}_2$ .** The zeta potential of  $\text{Ca(OH)}_2$  crystals was measured in a saturated solution to be +33.5 mv. (15) In the presence of admixtures A3 or A4 the zeta potential of  $\text{Ca(OH)}_2$  crystals changed from plus to a minus; indicating that the admixture is adsorbed on the surface of  $\text{Ca(OH)}_2$  particles. However, the exact amount could not be determined because water decomposition began to take place at the high specific conductivity values.

**Alite and  $\text{C}_3\text{A}$ .** The zeta potentials of alite and  $\text{C}_3\text{A}$  were measured with admixtures A3 and A4 (Figs. 8 and 9).  $\text{C}_3\text{A}$  developed higher negative zeta potentials, which in general showed greater concentration dependence. The presence of retarder A4 caused an increase in the magnitude of alite's zeta potential with increasing time, in contrast to the behavior of A3 in alite, or in type I cement (1b). The effects with  $\text{C}_3\text{A}$  were similar with and without retarder, diminishing with time, in both instances. Further measure-

ments were made in a saturated vs a non-saturated solution of  $\text{Ca(OH)}_2$ , and compared. In the saturated solution the zeta potential had a smaller negative value compared with that of the non-saturated solution for both the A3 and the A4 admixtures. Additionally, there appears to be a reaction between the admixtures and  $\text{Ca}^{++}$  ions which varies directly with the concentration of  $\text{Ca(OH)}_2$ , especially at higher concentrations. Specific conductance measurements of mixed solutions of varying concentrations in liquids, of admixture vs NaCl and admixture vs saturated  $\text{Ca(OH)}_2$  revealed departures from theoretical linearity (15), in the latter case, correlating with the same phenomenon.

**Fly Ash.** The zeta potential of a fly ash (B15) which is used for partial replacement of cement was measured in a naphthalene-based admixture, A-28 as shown in Fig. 10. It is noted that a smaller magnitude zeta potential (-16 mv) is generated in tap water, vs -22 mv in deionized water, for the pure fly ash. A highly negative zeta potential was generated with a very small admixture addition, 0.05%, indicating that some superplasticizer is adsorbed on the fly ash surface, but that a saturation effect is reached with very low levels.

## DISCUSSION AND CONCLUSIONS

The effectiveness of superplasticizing admixtures in their fluidifying cement-based mixes has been investigated by a combination of methods, including studying their adsorption characteristics on cement particle surfaces, the flow characteristics of mortars (1), the zeta potentials generated at the cement-liquid interface, and quantitative viscometric measurements (2-4). From the overall results to date it is apparent that the water reducing effect of the superplasticizers investigated (both of the sulfonated melamine and naphthalene formaldehyde condensate types) is caused mainly by their dispersion abilities which are in general correlated with a change in zeta potential as a function of surfactant adsorption onto the cement particle surfaces.  $\text{C}_3\text{S}$  (alite),  $\text{C}_3\text{A}$ , mixed cements and even  $\text{Ca(OH)}_2$  are subject to generation of high magnitude (-30 mv to -50 mv) negative zeta potentials in the presence of increasing admixture concentration, generally reaching a saturation value at 1-2%. The ionic content of the mix solutions (including degree of  $\text{Ca(OH)}_2$  saturation) affects their specific conductivities and the magnitude of the zeta potentials, though within the range of usual mixing waters, the general phenomena observed are similar. The fly ash studied required much smaller quantities of superplasticizer to generate a very negative zeta potential. Thus, the latter may be largely neglected when calculating amounts of superplasticizer required for a mix. The adsorption characteristics and the zeta potentials generated in cement-water-superplasticizer suspensions are among their most important characteristics, reflecting the generation of strong repulsive forces, causing dispersion. Additional and detailed viscometric studies are in progress to further elaborate these characteristics, and provide more adequate prediction of the flow properties of slurries containing superplasticizers.

# Modifications of Structure and Properties of Cement Stone

## *La modification de la structure et propriétés des ciments hydratés*

V.M. KOLBASOV, Doctor of technology, Assistant professor, MCTI n.a. Mendeleev, Miusskaja sq.,  
9 Moscow, USSR,

N.A. KOZYREVA, Doctor of Technology, Head of the Laboratory MCTI n.a. Mendeleev, U.R.S.S.

**RESUME :** Cette communication montre que la formation des structures du ciment et le durcissement de ce dernier dépendent du développement des processus initiaux de la cristallisation des hydrates. Ce processus est déterminé par le milieu où il a lieu.

Les formes initiales de la croissance cristallographique des nouvelles formations des hydrates sont liées à la composition de la phase liquide dans le système durcissant "ciment-eau" et dans une grande mesure influent sur le processus postérieur de l'hydratation de la formation des structures ainsi que sur les propriétés du ciment hydraté.

En agissant sur les processus initiaux d'hydratation du ciment, il est possible de diriger efficacement la formation des structures du ciment hydraté et ses propriétés techniques. En particulier cela peut être réalisé au moyen d'additions solubles dans l'eau.

**SUMMARY:** The interdependence of structure forming and cement hardening with the development of initial stages of hydrates crystallization is traced. The initial process of crystallization is determined by the medium in which it is carried out.

The initial crystallographic forms of hydrates new formations growth are connected with the composition of the liquid phase in the hardening system "cement-water" and influence sufficiently the further process of hydration, structure and properties of formation of cement stone.

The directed influence on the initial processes of interaction of cement with water gives an opportunity of effective ruling of processes of structure forming on cement stone and its industrial properties. For instance it may be done by means of chemical additives soluble in water.

The process of crystal formation during the initial period of cement hydration which in many respects determines further stages of its character, is not thoroughly studied [1].

The process of initial mass growth of crystal hydrates which helps us to form full understanding of their ontogenesis, formation mechanism and their interdependence with the hydration system medium is also studied not carefully.

In order to find out the interdependence of structure formation and cement hardening with the initial processes of crystal formation in MCTI named after Mendeleev were carried out some experiments in "cement-water" systems and some systems modeling these processes [2].

These experiments were carried out by means of transmission and scanning microscop- ing including micro-diffraction and other methods of phase analysis. The works were made using the electronic microscopes VEMHV and JSM-50-A.

The investigations of the very initial stage of phase formation (when Portland cement and its components hydration is taking place) helps us to detalize some aspects of the process of the initial processes of hydration in "cement-water system and to imagine the beginning of these processes in the following way.

After cement and water interaction just at the moment of coming into contact of water molecules and the most active parts of the surface of clinker minerals (dislocations, outlets, picks and edges of crystals and so on) takes place their solving and the transfer of hydrated ions into the adjoining layer of the liquid phase. And in the local volumes of the system in the layer less than 0.1 mm thick momentary conditions are created. They are favourable for the formation of new phases and the crystallisation from the surface of basic grains which form the separating line for hydrate formation.

The formation of hydrates is seen a second later and that's why it is evident that the mechanism of initial crystallization of cement hardening is in action.

Phase composition of new formations, their morphology and characters of their growth depend directly on the qualities of the liquid phase which is formed in the local volumes of the system.

Depending on the concrete conditions which are created in the layer of the liquid phase adjoining the basic particle, certain hydration phases are formed. They have the form of filamentous, prismatic, skeleton and anti-skeleton crystals, hexagonal plates and round particles of irregular form with dimensions of hydrates from 5 mc to 1 mm.

New formations which include ions of  $\text{SO}_4^{2-}$  and  $\text{Al}(\text{OH})_3^-$  are formed near the grains of any clinker mineral. Hydrate phases are seen not all over the surface of the basic clinker grains. Analysis of a number of electro-

no-diffraction photographs of the surface of grains of Portland cement clinker made in the following time intervals 1, 5, 15 seconds and one minute, which have reflections of about 8.06; 5.27; 4.54; 4.17; 3.38-3.22; 3-23-3.07; 2.98; 2.84-2.78; 2.78-2.70; 2.22; 2.08-2.04; 2.00; 1.96-1.76; 1.67-1.64; 1.59; 1.49; 1.43-1.41; 1.39-1.37 Å support the fact that there is a variety of phases and crystals of hydrate phases.

The reflections mentioned above are typical for hydrociliates and hydroaluminates of calcium of different composition, attrin-gitt, calcium monosulphoaluminate, hydro-gematite, portlandite and aluminium hydroxide.

The process of two-water gypsum grains solving dominates the process of hydrate phases formation near them at the first moments of interaction. A high diffusion coefficient let the ions of  $\text{Ca}^{2+}$  and  $\text{SO}_4^{2-}$  diffuse easily into liquid phase of the system and thus creates favourable conditions for newformations crystallization in actively growing forms [3].

Initial crystallographic forms of new formations influence greatly the process of hydration. Crystalhydrates formed in actively growing crystallographic forms-filamentous, skeleton and anti-skeleton - favour rapid decrease of solving products in the adjoining layer of the liquid phase thus stimulating the processes of further solving of the basic adhesive and the recrystallization of meta-stable (under certain conditions) new formations into stable ones.

Phase composition of new formations of Portland cement clinker in hydration period (up to 24 hours) is rather various with the domination of the formation of calcium hydrociliates  $\text{CSH}(\text{B})$  and  $\text{C}_2\text{SH}(\text{A})$ .

The connection between different clinker particles is carried out by means of prismatic, filamentous and fine-filamentous mass of hydrates consisting of round particles of irregular form and also by means of filling of spaces between the newformations of poorly crystallized hydrates.

The analyses revealed the dependence of cement structure formation and cement hardening on the development of initial process of crystal-formation. And the initial process of crystal formation in turn depends on the initial conditions of the medium.

The action directed of the initial processes of cement and water interaction (for instance on the initial conditions) determines the efficiency of ruling the processes of cement stone structure formation and its industrial properties.

A well-known method of influencing the medium (beginning with the moment of cement and water interaction) is the use of chemical additives soluble in water.

As a result of this use the additives change meta-stable solubility of Portland cement clinker relating to  $\text{CaO}$  (mainly alite); ba-

lance concentration and consequently the extent of oversaturation of the liquid phase by different ions.

Additives influence the solubility of the basic adhesive and the products of its hydration, change and interaction of ions of the solution and the extent of initial oversaturation of the system which determines the crystallization nucleus, the rate of formation, morphology, dispersion, the extent crystallization of hydrates, the rate and their capacity of grow.

The medium of the system "cement-water" is originally connected with the physical processes of crystallization of hydrates which in turn influence the processes of solving of the basic clinker that is the kinetics of cement hydration. For instance it is shown that the formation on hydrates having filamentous, skeleton, dendrite-like crystals which is connected with the ion composition and oversaturation of the liquid phase intensifies the solving of basic grains of cement and its components, fastens the process of crystallization of "primary" hydrates which are formed at the first moment of cement and liquid phase of the system contacting and, on the contrary, slows the process of mass crystallization of the "secondary" hydrates, especially in the poorly crystallized forms thus favouring the increase of general amount of hydrates and improving the conditions of grows of crystal hydrates.

All this in turn determines the development of constructive processes of formation of optimal micropore cement stone structure which is more or less strengthened by the filamentous hydrosilicates arming the structure. Or, on the contrary, it may initiate the destructive processes lying in the basis of stressed hardening structure, formed as a result of initial stressed crystallization of hydrated phases. The initial stress of structure is emphasized by further processes of hydrates recrystallization and by growth of crystallization pressure.

Chemical additives added to water for its mixing with cement give an opportunity from the very beginning of the process of hydration to exercise directed influence on the formation of the structure of hardening cement anticipating its quality, structural density and durability of cement stone.

Thus for example chemical additives in common use  $\text{CaCl}_2$  and  $\text{NaNO}_2$  added with water for mixing increase the meta-stable solubility of clinker phases of Portland cement  $\text{CaO}$  concentration in the liquid phase in the presence of these additives is higher than in cement hydration in clear water. But if to take into consideration balance concentrations of this oxide in water ( $1.13\text{g/l}$   $\text{CaO}$  at  $20^\circ\text{C}$ ) and its corresponding concentrations in the solutions of  $\text{CaCl}_2$  and  $\text{NaNO}_2$  ( $1.06\text{ g/l}$   $\text{CaO}$  in 4% solution of  $\text{CaCl}_2$  and  $1.7\text{ g/l}$   $\text{CaO}$  in 4% solution of  $\text{NaNO}_2$  at  $20^\circ\text{C}$ ) one can see that the adding of  $\text{CaCl}_2$  increases the oversaturation of the liquid phase relating to  $\text{CaO}$  from 1.49 to 1.79 and

$\text{NaNO}_2$  on the contrary decreases the oversaturation in such conditions to 1.28.

Thus changing the properties of the liquid phase these additives create quite different conditions for the crystallization of new formations and the formation of structures of cement hardening.

Illustrations 1,2,3 demonstrate the structure of the surface of grains  $\text{C}_3\text{S}$  after 5 sec of hydration in 4% solutions of  $\text{CaCl}_2$  and  $\text{NaNO}_2$ , and the illustration 3 -  $\text{C}_3\text{S}$  acted by water.

Fig.1. The surface of grains  $\text{C}_3\text{S}$  after 5 sec of hydration in the system  $\text{C}_3\text{S}-\text{H}_2\text{O}$  ( $\times 12000$ ).

It is known that is the presence of  $\text{CaCl}_2$  new formations in cement stone are represented by well crystallized hydrated phases. It is supposed that quick and time-consuming active cement hydration in the presence of  $\text{CaCl}_2$  leads to the formation of hydrates in the forms tending to recrystallization processes and this is accompanied by the development of sufficient internal pressures. Illustration 4 depicts the structure of grains  $\text{C}_3\text{S}$  which had been hydrated in the paste for 6 hours (the mixing was carried out by a corresponding solution  $\text{CaCl}_2$ ).

One can see a substantial amount of skeleton crystals tending to the processes of recrystallization in case of the decrease of the number of constructive particles in the liquid phase. It reaffirms that the liquid phase of the system is highly oversaturated even after 6 hours of hydration.

The results reflecting durability comparison given in the Table I are in full accordance with all said above i.e. various levels of oversaturation of the liquid phase relating  $\text{CaO}$  favour the formation of structures differing in durability.

Cement stone with  $\text{CaCl}_2$  additive has a higher level of durability under pressure, but it renders small resistance to following pressures; as to the resistance of cement stone with  $\text{NaNO}_2$  additive it is greater. It proves that the structure in this case can endure even higher folding pressures and actually cement stone structure

Fig.2. The surface of grains  $C_3S$  after 5 sec of hydration in 4% solutions of  $CaCl_2$  ( $\times 40\,000$ ).

Fig.3. The surface of grains  $C_3S$  after 5 sec of hydration in 4% solutions of  $NaNO_2$  ( $\times 45\,000$ ).

Fig.4. The surface of grains  $C_3S$  after 6 hours of hydration in the paste in 4% solutions of  $CaCl_2$  ( $\times 20\,000$ ).

Fig.5. The surface of grains  $C_3S$  after 6 hours of hydration in the paste in 4% solutions of  $NaNO_2$  ( $\times 35\,000$ ).

given at the illustration 5 after 6 hours of hydration is the evidence of this fact. And the presence of large amount of pin-like hydrates makes the system stronger this particularly refers to folding pressures.

Table I

The Influence of  $CaCl_2$  and  $NaNO_2$  Additives on the Strength Properties of Cement Stone

Additives: parameters	Strength: MPa	Sample age, hours				
		24	72	168	672	8640
$CaCl_2$	$R_{com}$	21.9	50.0	40.0	51.1	47.0
	$R_{bend}$	3.6	4.5	3.7	4.2	5.1
$NaNO_2$	$R_{com}$	13.3	37.5	41.0	47.5	48.0
	$R_{bend}$	2.9	4.3	5.2	5.8	7.0

The possibility of substantial increase of strength of cement stone (concerning bending pressures) due to chemical additives influencing the hardening structure formation in a necessary direction is of great importance. It is known that the rising of quality of cement on one grade ( $R_{pr}$  to 10 MPa which is reached at cement producing factories by means of great efforts gives only insignificant increase of strength level concerning bending pressure). (0.5-1.0 MPa). Even more with the improving of cement grade ratio  $R_{fold}/R_{pres}$  decreases (see Table 2). So we may say that the further increase of cement grades doesn't ensure desirable growth of cement strength (folding pressures).

That is why the rising of  $R_{bend}$  of cement stone by other ways including the directed structure formation when hardening is the most important problem. The solution of this problem is available using chemical additives - structure modifications.

Table II

The Standard Properties of Cements

Cement type	$R_{comp}$ : 672 hours: : MPa	$R_{bend}$ : 672 hours: : MPa	$R_{bend}/R_{comp}$ : in %
300	30.0	4.5	15.0
400	40.0	5.5	14.0
500	50.0	6.0	12.0
550	55.0	6.2	11.0
600	60.0	6.5	11.0

Cement stone investigation with the application of scanning electronic microscopy revealed substantial differences in the morphology of hydration phases, which are formed under the influence of  $CaCl_2$  and  $NaNO_2$ . Sample without additives had a large-pore structure and poorly expressed crystallization of new formations.

In the pores of cement stone hydration without additives one can trace the hydrates which have the form of round irregular particles with dimensions 0.1-0.5 mm with  $CaCl_2$  additive. Calcium hydrosilicates are crystallized in the form of the plates with dimensions up to 3 mm (and with the  $NaNO_2$  additive crystals of filamentous structure dominate).

Fig. 6. The surface of grains  $C_2S$  after 6 hours of hydration in the paste when mixing (x 45 000).

Table III gives the data, characterising micropore structure of cement stone with  $CaCl_2$  and  $NaNO_2$  additives. As one can see from the data given above in the presence of the mentioned additives are formed some structures of hardening. They differ from the structure of cement stone which doesn't contain additives from the very moment of cement and water interaction.

Table III

The influence of  $CaCl_2$  and  $NaNO_2$  on the Quantitative and Qualitative Pore Structure of the Hardened Cement

Additions:	The total porosity : $kg/m^3$ :	Distribution of pore size in radii : $10^3 nm$ : $10^3 - 10^2$ : $10^2 - 10^1$ : $10^1 - 10^0$ : $10^2 nm$ : $10 nm$ : $1 nm$				
$H_2O$	122.0	3.0	1.6	3.4	2.0	
$CaCl_2$	94.0	2.6	2.3	3.8	1.4	
$NaNO_2$	113.0	1.6	1.9	4.5	2.0	

CONCLUSION The experiments carried out revealed a certain dependence of the initial processes of crystallization of hydrates on the medium of cement and water interaction, and the influence of initial crystallographic forms of "primary" hydrates on the further process of structure formation and cement hardening.

Crystalline hydrates found in the actively growing forms (pin-like, skeleton, dendrite-like and anti-skeleton) favours rapid thinning of the adjoining layer of the liquid phase by solution products, stimulating the process of the further, solving of basic clinker and recrystallization of unstable new formations, thus favouring the formation of the most stable and durable hardening structures of cement stone.

# Comportement de l'aluminate tricalcique en milieu glycol - comparaison avec l'hydratation

## *Tricalcium aluminate behaviour in glycol - comparison with water*

P. LONGUET, G. BELLINA - C.E.R.I.L.H. Paris, France.

### RESUME

La base  $O^{2-}$  de  $C_3A$  réagit avec le glycol en formant deux particules distinctes:

tandis qu'avec l'eau, dans l'hydratation classique, on forme deux particules identiques:

Cette particularité liée à la formation de molécules  $H_2O$  dans le milieu initial glycol anhydre permet de suivre la cinétique des réactions et de mettre en évidence le mode de formation et la nature des produits solvatés.

### SUMMARY

The base  $O^{2-}$  of  $C_3A$  is reacting with glycol to create two different particles:

whereas with water, for usual hydration, two identical particles are created:

This particularity relied on the creation of molecules of water from the anhydrous glycol initial medium allows us to follow the speed of these reactions and to clear up the way of formation and the kind of solvated products.

## INTRODUCTION

L'espèce chimique  $\text{OH}^-$  présente dans les phases du système eau-ciment, à un moment donné de son évolution, provient:

- soit de la dissociation du solvant  
 $\text{H}_2\text{O} \rightleftharpoons \text{H}^+ + \text{OH}^-$
- soit de la réaction du proton avec la base oxygène  $\text{O}^{2-}$  des constituants anhydres initiaux  
 $\text{O}^{2-} + \text{H}^+ \rightleftharpoons \text{OH}^-$ .

Cette particularité caractéristique de l'eau limite beaucoup l'interprétation des bilans réactionnels relatifs à l'hydratation.

Des études antérieures nous ont montré que des réactions comparables à celles mises en jeu dans l'hydratation des ciments pouvaient se développer en milieu glycol (1) (2). Dans ce cas, la dissociation ionique globale du solvant:

libère la base glycol  $(\text{CH}_2\text{O})_2^{2-}$  différente de celle provenant de la réaction du proton avec la base oxygène.

Cette caractéristique du glycol doit permettre de lever l'incertitude apportée par l'eau dans l'étude des mécanismes de l'hydratation des liants hydrauliques.

Dans cet exposé nous examinerons uniquement le cas de l'aluminate tricalcique  $\text{Al}_2\text{O}_3\text{Ca}_3$  ( $\text{C}_3\text{A}$ ) en milieu glycol. Après un rappel de l'essentiel des résultats déjà obtenus (1) (2) nous proposerons une interprétation dégagant des hypothèses sur le mécanisme de la solvatation dans ce milieu non aqueux.

## DONNEES EXPERIMENTALES

Le glycol est un dialcool (éthane diol 1,2). C'est un solvant polaire, sa constante diélectrique est environ la moitié de celle de l'eau. Il donne lieu à des équilibres de dissociation acido-basiques du même type que ceux de l'eau (solvant amphiprotique). Son produit ionique est de  $10^{-11}$  à  $20^\circ\text{C}$ . Il dissout les substances minérales polaires.

Dans nos études seul l'équilibre d'ionisation global suivant a été pris en considération:

Avec  $\text{CaO}$  le glycol réagit selon l'équation:

La solvolysé de la base oxygène  $\text{O}^{2-}$  de l'oxyde de calcium par le glycol est pratiquement complète

A chaque mole  $\text{O}^{2-}$  solvolysée correspond une mole de base glycol et une mole d'eau.

La solution obtenue conduit le courant électrique.

Le dosage acidimétrique de la base  $(\text{CH}_2\text{O})_2^{2-}$  est facilement réalisé avec un acide titré en repérant le point équivalent par conductimétrie.

L'eau provenant de la solvolysé peut être déterminée selon la méthode de KARL FISHER.

Ces deux dosages permettent de suivre les cinétiques de solvolysé et d'établir les bilans réactionnels.

L'aluminate tricalcique  $\text{Al}_2\text{O}_3\text{Ca}_3$  ( $\text{C}_3\text{A}$ ) réagit avec le glycol. D'ailleurs c'est l'observation expérimentale de la prise et du durcissement d'une pâte de  $\text{C}_3\text{A}$  dans le glycol qui est à la base de tous nos travaux dans ce domaine.

Deux séries générales d'essais ont été réalisées. L'une sur des suspensions dans le glycol à 1,5 g pour cent environ de  $\text{C}_3\text{A}$  à  $25$  et  $70^\circ\text{C}$  dans le cadre du dosage de la chaux libre, l'autre sur des pâtes de rapport solvant/solide de 0,3 environ pour vérifier la généralisation des conclusions déduites de l'étude sur les suspensions.

Une suspension de  $\text{C}_3\text{A}$  dans le glycol conduit le courant électrique et son évolution en fonction du temps peut-être suivie par un conductimètre enregistreur.

Sur la solution au contact du solide les teneurs en  $\text{H}_2\text{O}$ ,  $\text{Ca}^{2+}$ ,  $\text{Al}^{3+}$  et la basicité ont été déterminées à différents moments de l'évolution de la suspension.

Ces valeurs mettent en évidence la formation au sein de la suspension de nouvelles phases solides qui ne peuvent prendre naissance qu'avec consommation de base glycol  $(\text{CH}_2\text{O})_2^{2-}$ . Pour vérifier cette hypothèse nous avons séparé le solide présent dans la suspension après un long contact (24 heures), puis nous avons extrait le  $\text{C}_3\text{A}$  n'ayant pas réagi avec une adaptation de la méthode de TAKASHIMA (2) et analysé le précipité solvaté restant [ $\text{Al}^{3+}$ ,  $\text{Ca}^{2+}$ , carbone, hydrogène et oxygène (par différence)]. A partir de ces dosages nous avons pu calculer une composition molaire moyenne du type  $(\text{Al}, \text{Ca}, \text{C}_6, \text{H}_{13}, \text{O}_6)$  aux erreurs expérimentales près. Ces valeurs complétées par l'analyse thermopondérale permettent de calculer la formule suivante:

Le composé solvaté obtenu est cristallisé, la diffraction X montre des raies nettes dont aucune ne correspond aux raies connues des aluminates de calcium hydratés.

La formule proposée est évidemment hypothétique, elle ne traduit que des bilans réactionnels et ne représente aucunement la structure du composé. Elle montre essentiellement que le composé solvaté se forme à partir de la base  $(\text{CH}_2\text{O})_2^{2-}$  présente dans la phase liquide au contact du solide. Cette remarque importante est d'ailleurs complétée par l'étude acidimétrique de cette phase liquide qui permet de mettre en évidence l'existence d'ions organominéraux en solution comme:

et même:

$[2\text{Al}, 2(\text{CH}_2\text{O})_2]^{2+}$  qui met en évidence l'importance de l'affinité entre l'ion aluminium  $\text{Al}^{3+}$  et la base glycol  $(\text{CH}_2\text{O})_2^{2-}$ .

Notons encore que les produits solvatés qui précipitent au cours de l'évolution de la suspension ont un rapport  $(\text{CH}_2\text{O})_2^{2-}/2\text{Al}$  qui croît régulièrement d'environ 3 à la valeur 5 (valeur correspondant à la formule proposée plus haut) et que d'autre part la cinétique de l'évolution de la suspension enregistrée par conductimétrie indique une augmentation de la vitesse de réaction aux environs du début de la précipitation du composé solvaté.

Les résultats précédents obtenus sur des suspensions prennent tout leur intérêt si on peut les transposer aux pâtes.

Les essais ont été réalisés à 25°C sur micro-éprouvettes de 1 cm<sup>3</sup> en pâte pure de rapport glycol/ $\text{Al}_2\text{O}_3\text{Ca}_3 = 0,3$ . On obtient ainsi:

- à l'échéance 2 jours une éprouvette subissant une forte déformation plastique avant de se rompre aux environs de 450 bar.

- à 7 jours on observe une rupture plus franche vers 550 bar.

- à 28 jours c'est une rupture classique à 650 bar.

Les éprouvettes à 28 jours ont été reprises après rupture et dispersées par broyage dans du méthanol anhydre. La suspension a été filtrée. Le filtrat et le précipité séparé ont été analysés comme nous l'avons indiqué pour les suspensions. Les résultats obtenus sont tout à fait comparables à ceux obtenus sur les suspensions et conduisent aux mêmes conclusions.

#### INTERPRETATION DES DONNEES EXPERIMENTALES

Il convient d'abord de rappeler brièvement les conceptions actuelles sur la formation des solutions. Le passage en solution d'un solide dans un solvant suppose que des particules se séparent de la masse du solide pour venir s'insérer parmi les molécules du solvant. Cette première étape définit la dissolution.

Dans le cas d'un solvant polaire et d'un solide possédant des liaisons ioniques la dissolution s'accompagne d'une dissociation électrolytique, les particules en solution sont alors des ions. Ces ions s'entourent par attraction électrostatique d'un cortège de molécules du solvant polaire qui assure la stabilité de la dissolution. C'est le phénomène de solvation. Cette solvation s'accompagne d'interactions plus ou moins importantes entre les ions et les molécules du solvant. La gamme des actions possibles peut s'étendre d'attractions électrostatiques pratiquement négligeables (le solvant joue alors un rôle d'espace) jusqu'à des liaisons chimiques définies, on parle alors de solvolysse. Il apparaît alors dans le milieu de nouvelles espèces chimiques renfermant une ou plusieurs particules provenant du solvant. Il est alors possible que les nouvelles espèces formées puissent donner lieu à de nouvelles réactions, par exemple à des précipitations si l'évolution du système amène à des concentrations correspondant au produit de solubilité d'un composé peu soluble.

Compte tenu de ces conceptions nos études peuvent s'interpréter de la manière suivante. Pour le système  $\text{CaO}$ -glycol la dissolution provoque la formation des ions  $\text{Ca}^{2+}$  et  $\text{O}^{2-}$ . La solvation de ces ions se fait sans solvolysse pour  $\text{Ca}^{2+}$  et avec solvolysse pour  $\text{O}^{2-}$  soit:

Les teneurs en eau et en base glycol du milieu sont proportionnelles à la quantité de  $\text{CaO}$  passée en solution.

Pour  $\text{Al}_2\text{O}_3\text{Ca}_3$  un raisonnement analogue conduit à la formation d'ions solvatés avec  $\text{Al}^{3+}$ ,  $\text{Ca}^{2+}$  et  $\text{O}^{2-}$ .  $\text{O}^{2-}$  se solvolysse comme précédemment, la concentration en base glycol  $(\text{CH}_2\text{O})_2^{2-}$  augmente en fonction de cette solvolysse.

L'ion  $\text{Al}^{3+}$  donne en général des complexes hexacoordinés par exemple:

Cet ion solvaté peut se dissocier dans le milieu basique en perdant successivement tous les protons disponibles de ses molécules de glycol en fonction de la concentration en  $(\text{CH}_2\text{O})_2^{2-}$  en formant des anions. Citons:

qui sont, à la solvation près, ceux mis en évidence dans nos études.

Le milieu s'enrichit aussi par ailleurs en ions calcium solvatés. Si un composé insoluble est susceptible de se former il précipite lorsque les concentrations des différents ions présents dans le milieu vérifient le produit de solubilité du composé peu soluble. Dans notre cas il s'agit vraisemblablement de l'aluminate bicalcique pour lequel nous avons proposé la formule:

Cette précipitation rompt l'équilibre ionique du milieu et permet la poursuite de l'évolution du système vers son état final.

Bien que cette interprétation soit présentée sous une forme simplifiée (bien des facteurs ne sont pas pris en considération: concentrations au lieu d'activités, condensation ou polymérisation possibles des anions, influence des liaisons hydrogène, dissociations successives du solvant, viscosité, utilisation d'autres solvants polaires de constantes diélectriques ou de dissociations différentes...).

Il est intéressant de constater que les hypothèses ainsi avancées s'accordent et viennent compléter la théorie de Le CHATELIER sur l'hydratation des liants hydrauliques. Elles permettent de plus une généralisation des mécanismes de "l'hydraulicité": la réactivité d'un composé hydraulique apparaît liée à sa teneur en  $\text{O}^{2-}$  solvolysable par les protons d'un solvant polaire amphiprotique. Cette solvolysse

libère la base du solvant et permet la formation d'anions avec les ions amphotères présents ( $\text{Al}^{3+}$ ,  $\text{Si}^{4+}$  ...). Ces anions en précipitant des sels de calcium insolubles assurent la prise et le durcissement.

#### CONCLUSION

Nous souhaitons d'abord que le lecteur ne nous tienne pas trop rigueur de cet exposé spécialisé assez inhabituel dans la chimie des ciments.

L'étude du système C<sub>3</sub>A-glycol permet de proposer une généralisation des phénomènes particuliers à l'hydraulicité et fournit une version actualisée de la théorie de Le CHATELIER. Il est évident que nos études apportent une modeste et bien incomplète contribution à cette chimie des ciments en milieu non aqueux; nous espérons cependant en avoir montré l'intérêt sur le plan fondamental et sur le plan technologique.

# The Hydration of Portland Cement. Evidence for an Osmotic Mechanism

## *L'hydratation des ciments Portland. Intervention évidente d'un processus osmotique*

D.D. DOUBLE, N.L. THOMAS and D.A. JAMESON, Grande-Bretagne.

RESUME : Il est proposé d'expliquer l'hydratation des ciments Portland par l'intervention évidente d'un processus osmotique. Ce modèle osmotique permet de prévoir, avec un plein succès, les valeurs calorimétriques et la composition chimique des produits en solution; il est confirmé par des études faites sur des matériaux synthétiques analogues. La microscopie électronique apporte la preuve des similitudes qui existent entre les gels synthétiques de C.S.H. et les produits d'hydratation du ciment; et les caractéristiques osmotiques de tels gels peuvent être mises en évidence par le phénomène des "jardins chimiques".

### Abstract

An osmotic mechanism of Portland cement hydration has been proposed, and evidence for the model is reviewed. The model successfully accounts for observed calorimetric and solution chemistry data, and is reinforced by studies of analogous synthetic systems. Electron microscopy provides collaborative evidence of similarities between synthetic C-S-H gels and cement hydration products, while the osmotic characteristics of such gels can be demonstrated by the phenomenon of "chemical gardens".

## 1. Introduction

Almost 20 years ago, Powers put forward the suggestion that osmotic effects might play an important role in the hydration of Portland cement (1). For reasons that are not clear, this proposal was not developed further - until recently, when two groups of researchers published articles reinforcing the original idea and elaborating on it further to provide a viable model explaining the mechanism of hydration of cement (2-4). This osmotic/membrane model has been the subject of some discussion in the literature (5-8) and it seems an appropriate time to review the points in its favour and to consider its wider implications.

## 2. Colloidal Membranes

The feature that makes the hydration of Portland cement rather different from a simple dissolution and crystallisation process (i.e. a 'through solution' mechanism such as has been proposed for the hydration of Plaster of Paris, for example) is that the main reaction product is a colloidal gel and it is precipitated by local reaction at the surfaces of the cement grains. In a hydrated cement paste there are crystalline hydration products (viz.  $\text{Ca}(\text{OH})_2$  and various complex aluminate hydrates) but the main constituent of the hydrated matrix responsible for the strength development is the calcium-silicate-hydrate (C-S-H) gel phase. Diamond (9) in a recent review of cement hydration refers to "the unusual compositional flexibility and quasi-amorphous character" of the gel. Only very poorly defined and diffuse peaks are obtained by X-ray/electron diffraction observations compatible with a colloidal microstructure in which the unit particle sizes are extremely small (of the order  $100\text{\AA}$ ).

In general, when metal ion silicates are precipitated from aqueous solution at ordinary temperatures, an amorphous colloidal solid is usually the result. Crystalline silicates may be obtained through slow growth from dilute solution or after prolonged aging, particularly at elevated temperatures. The reason lies in the stereochemical difficulty that the molecular silicate units (generally in varying degrees of polymerisation) have in arranging themselves into a repeatable three-dimensional lattice. As is noted by Iler (10), essentially the process is one of mutual coagulation of the hydroxides of the metal ion and the silica. These principles should apply equally to the C-S-H gel in cement, (compare figures 1(a) and (b)).

Figure 1(a): Colloidal C-S-H gel in hydrated Portland cement.

Transmission electron micrographs.

Figure 1(b): C-S-H gel obtained by precipitation between aqueous solutions of calcium chloride and sodium silicate.

An important property of silicate gels is that, when precipitated as a continuous membrane between two solutions of different compositions, they can display osmotic phenomena. A good example of this occurs in so-called 'silicate gardens', obtained when metal ion salt crystals are immersed in dilute aqueous sodium silicate solution (figure 2). Double et al. (2,3) and Birchall et al. (4) have drawn attention to the striking visual analogy between the growth sequence in silicate gardens and the morphological developments occurring during the hydration of Portland cement. The point of this analogy was to illustrate that:

- (a) osmotic pressure effects can be generated across metal-silicate gel membranes (including C-S-H gel membranes) by virtue of their selective permeability to ions in aqueous solution,
- (b) the osmotic properties derive mainly from the colloidal gel character of the membrane. The effect is not restricted to silicates but also occurs for gel membranes formed from ferrocyanides (refer to Pfeffer's experiments for example (11)), large oxyanion species such as aluminates/borates/zincates, and even oxalates and carbonates (12,13).

Clearly, there are some points of difference between the growth of silicate gardens and the hydration of Portland cement. The analogy is not exact but the fundamental features (i.e. the preferential diffusion of species through a colloidal gel membrane) are essentially the same. This inevitably leads one to the conclusion that osmotic effects ought to play a significant part during the hydration of cement.

Figure 2: Tubular fibre growth from a 'silicate garden' obtained from a crystal of cobalt nitrate immersed in dilute aqueous sodium silicate solution. Optical micrograph.

### 3. The Mechanism of Hydration of Portland Cement

In the osmotic model of cement hydration, one visualises the sequence of events illustrated diagrammatically in figure 3.

**Initial reaction.** There is ample evidence to show that gelatinous coatings (possibly involving both silicate and aluminate) are formed on the surface of cement grains very soon after contact with water. The development of these coatings has been directly observed in 'in situ' experiments in the environmental cell in the high voltage electron microscope (3,6). It has been postulated that the formation of the coatings is responsible for the onset of the induction period following the initial rapid hydrolysis of the anhydrous clinker (1,14). Essentially, a membrane is formed which inhibits access of water to the reactive cement constituents. Some insight into the way that these membranes are formed has been provided by recent SEM/ESCA studies by Ménétrier et al. (15) of the composition of surface hydrates on  $C_3S$  grains exposed to water for short time intervals. These showed a sharp initial decrease in the Ca/Si ratio followed by a rapid rise, reaching a maximum within 15 seconds. At the same time, fine-grained reaction products were observed to cover the surface. This behaviour is consistent with (i) an initial leaching of lime from the  $C_3S$  structure by hydrolysis, followed by (ii) recombination between the calcium ions released into solution and the hydrosilicate residue left on the surface of the cement grains to precipitate a C-S-H gel membrane.

**Induction period.** Calorimetric measurements of the rate of heat evolution during the induction period suggest that little is happening at this stage of hydration. However the situation is not quiescent because, as studies by various workers have shown (16,17), the concentration of the bulk aqueous phase is rapidly rising with respect to dissolved  $Ca^{++}$  and  $OH^-$  ions - and indeed exceeds the saturation level for the precipitation of  $Ca(OH)_2$  by a factor of 1.5 - 2.0. Significantly, the silicate concentration in solution remains negligibly small (less than 5 ppm). These observations would imply (i) that hydrolysis of the clinker is still continuing and (ii) that there is preferential diffusion through the membrane coating (ingress of water and egress of  $Ca^{++}$  and  $OH^-$  ions). The inability of the hydrolysed silicate to diffuse out through the membrane is reconcilable with its large molecular size, particularly because of its tendency to polymerise into configurations larger than the basic  $SiO_4^{4-}$  unit. This preferential diffusion process is precisely the situation that will lead to the development of an osmotic pressure within the membrane coating around the cement grains. Powers cited these pressure effects as being responsible for the transient dilation that occurs in cement pastes at early stages of hydration (1).

Figure 3: Diagrammatic representation of the sequence of hydration of cement. (a) Cement grains in water, (b) initial gel coatings around cement grains, (c) secondary growth of C-S-H gel after osmotic rupture of gel coatings and (d) long term infilling and consolidation of microstructure.

**Post-induction period.** The end of the induction period is considered to occur when the gel coatings around the cement grains rupture because of osmotic pressure effects. Hydrosilicate material is extruded through the ruptured membrane and combines with the calcium ions in solution to precipitate C-S-H gel as excrescences on the surfaces of the cement grains. These growths constitute the secondary hydration products. In this way, one accounts for the drop in the calcium ion concentration in the bulk aqueous solution that is observed to occur at the end of the induction period (6,17).

By analogy with silicate gardens, these excrescences may be expected to develop a tubular morphology. Indeed, observations by several workers have shown that the fibrillar gel growths on the surface of cement grains have a hollow structure (3,6,8). Pratt and Jennings (6) have observed enhanced growth of tubular fibres when partially hydrated cement pastes were subsequently immersed in distilled water. This effect can readily be understood in terms of an osmotic process in which the driving force for secondary growth (the difference in chemical potential between the dissolved species on either side of gel membrane) is promoted by sudden dilution of the aqueous phase.

Tubular morphologies are by no means the only type of secondary growths to be expected. Since the hydrosilicate material is forced out through a ruptured membrane, the form assumed by the outer precipitate will be governed by the local conditions under which the combination between the calcium and the silicate occurs. The extrusion process could easily give rise to hollow or solid fibres, and even sheet and foil-like structures - as has been observed (figure 4). In any case, it is possible to reconcile the variety of morphologies of the hydrated cement gel with an osmotically driven hydration process such as has been described.

While one visualises that osmotic effects are important in the early stages of hydration, it seems likely that as the gel coatings thicken and become increasingly difficult to rupture, other precipitation processes become more important in the progressive infilling and consolidation of the cement microstructure.

#### 4. Conclusions

A model has been proposed to explain the mechanism at early stages of the hydration of Portland cement. This is based on osmotic effects associated with the colloidal C-S-H membrane formed around the cement grains. The evidence for this model is circumstantial but it has the advantage of explaining the following facts:

- (a) It gives a reason for the onset and eventual termination of the induction period.
- (b) It explains the morphology of growth of the outer C-S-H products - tubular fibres and other forms.
- (c) It is compatible with the variations that occur in the composition of the bulk aqueous phase during hydration.
- (d) It provides a transport mechanism for the silicate material from the anhydrous cement core to the outer hydration products - without having to postulate diffusion through the bulk aqueous solution, where its concentration is known to be extremely low.

By emphasising the colloidal nature of the C-S-H gel and its inherent properties, the model provides a different insight into the hydration mechanism as opposed to other theories which invoke conventional nucleation and growth processes.

# Etude comparée de la formation de C-S-H à partir de solutions sursaturées et de mélanges C<sub>3</sub>S-solution

## *Comparative study of C-S-H formation from supersaturated solutions and C<sub>3</sub>S solution mixtures*

P. BARRET, professeur, directeur du Laboratoire de Recherches sur la Réactivité des Solides (L.A. 23)  
Université de Dijon (France),

D. BERTRANDIE, docteur de l'Université de Dijon, CNRS (L.A. 23),

D. MENETRIER, docteur ès sciences physiques, attaché de recherches (L.A. 23), France.

**RESUME :** En système fermé, l'évolution de mélanges hétérogènes (C<sub>3</sub>S-eau ou solutions aqueuses de composition initiale donnée) a été comparée à celle des milieux homogènes obtenus par filtration ou par mélange initial de deux solutions et sursaturés par rapport au C-S-H. Des données complémentaires ont été fournies par l'étude en système ouvert de la composition initiale et de l'évolution de filtrats obtenus par flux d'une solution de chaux et de silice à travers une couche de C<sub>3</sub>S sur filtre et par mélange de deux solutions de chaux et de silice de compositions appropriées, sur filtre. Le report sur le diagramme chaux-silice-eau (C,S,H) des variations de composition en CaO et SiO<sub>2</sub> (chemins cinétiques), accompagnant l'évolution de ces différents systèmes, a permis de constater qu'il n'y avait pas de différence, au point de vue cinétique, entre la vitesse de précipitation de C-S-H à partir de milieux homogènes sursaturés et la vitesse de formation du C-S-H à partir de mélanges hétérogènes C<sub>3</sub>S-eau ou C<sub>3</sub>S-solution. Ces chemins cinétiques sont tous situés dans le domaine sursaturé délimité supérieurement par la courbe de supersolubilité du C-S-H construite par les auteurs (2) et qui correspond à une nucléation immédiate, inférieurement par la courbe d'équilibre de solubilité de C-S-H. On peut donc conclure que le C-S-H formé à partir de mélanges hétérogènes C<sub>3</sub>S-eau ou solution tire également son origine d'un processus de précipitation. Des constructions graphiques fondées sur les expressions du bilan analytique permettent de rendre compte de la forme de ces "chemins cinétiques" dans le cas des milieux homogènes aussi bien que dans celui des mélanges hétérogènes et pour ces derniers, par la mise en œuvre de la dissolution congruente de C<sub>3</sub>S superficiellement hydroxylé, suivie de la précipitation de C-S-H de rapport  $[C/S]_s$  variables suivant la concentration en chaux du milieu.

**SUMMARY :** The evolution of heterogeneous mixtures (C<sub>3</sub>S water or aqueous solutions with a given initial composition) was compared in a closed system with that of homogeneous media obtained by filtration or initial mixture of two solutions supersaturated with respect to C-S-H. The open system study yielded further data on the initial composition and evolution of filtrates obtained by pouring a silica and lime solution through a C<sub>3</sub>S layer on a filter and by mixing on filter two solutions of lime and silica of appropriate compositions. Reporting the CaO and SiO<sub>2</sub> composition variations (kinetic path), on the lime-water-silica diagram (C,S,H), and accompanying the evolution of these different systems allowed to note that there was no difference, from the kinetic viewpoint, between the C-S-H precipitation rate from supersaturated homogeneous media and the formation rate of C-S-H from heterogeneous C<sub>3</sub>S water or C<sub>3</sub>S solution mixtures. These kinetic paths are all in the supersaturated domain delimited in its upper part by the C-S-H supersolubility curve plotted by the authors (2) and corresponding to immediate nucleation, and in its lower part by the C-S-H solubility equilibrium curve. It may thus be concluded that the C-S-H formed from heterogeneous C<sub>3</sub>S water or solution mixtures also derives from a process of precipitation. Plots resulting from the expressions of the analytical balance allow to account for the profile of these "kinetic paths" in the case of homogeneous and heterogeneous media as well, and for the latter by performing congruent dissolution of superficially hydroxylated C<sub>3</sub>S followed by the precipitation of C-S-H with variable  $[C/S]_s$  ratios depending on the lime concentration in the medium.

## INTRODUCTION

Nous postulons une analogie fondamentale entre le mécanisme de formation des hydrosilicates de calcium et celui des hydroaluminates (1), pensant que, dans un cas comme dans l'autre, ces hydrates résultent d'un processus de précipitation à partir d'une solution sursaturée (processus du type Le Chatelier). Notre position est donc défavorable à l'idée d'une formation "topochimique" de ces hydrates (2). Encore convient-il de définir avec précision ce que l'on entend par ce terme.

En revanche, nous posons comme principe qu'il ne faut pas confondre hydratation et précipitation. En effet, nous considérons que tout ou partie de l'hydratation des phases anhydres qui interviennent comme constituants des ciments se produit au cours d'étapes cinétiques élémentaires, consistant en l'hydroxylation des ions négatifs superficiels par interaction directe de la surface du solide anhydre avec les molécules d'eau (3,4). Ce processus d'hydroxylation, par protonation dans le cas de  $C_3S$ , par addition dans celui de CA, est une étape nécessaire pour permettre le passage en solution de ces ions. Ainsi, à notre point de vue, cette étape d'hydroxylation est suivie d'étapes de transfert en solution des anions hydroxylés et des cations. La précipitation des C-S-H, comme celle des aluminates hydratés, introduit seulement une fraction d'eau supplémentaire, ou pas du tout.

Ce que nous entendons par "formation topochimique des hydrates" consisterait en une accumulation des défauts superficiels que constituent, dans la structure de la phase anhydre, les ions hydroxylés, suivie d'une réorganisation structurale directe de ceux-ci, en l'édifice des différents hydrates, sans passage par la phase liquide. Il s'agirait d'une transformation solide-solide, qui à aucun moment, ne mettrait en jeu la phase liquide pour se réaliser. Notre opinion est que ce processus n'intervient pas ou que, s'il intervient, il est beaucoup moins rapide que le processus de dissolution-précipitation avec lequel il est en compétition.

Pour étayer ce point de vue, nous avons procédé à un ensemble d'expériences. Celles que nous rapporterons ici sont fondées sur la comparaison de la cinétique d'évolution en système fermé, d'une part de mélanges phase solide anhydre-solution, d'autre part de phases liquides, soit séparées par filtration du solide anhydre et des hydrates, soit résultant, à l'instant initial, du mélange de deux solutions. Pour faciliter la rédaction, les expériences du premier type seront désignées par la lettre W et celles du second, par la lettre B. En outre, nos idées sont fondées sur un ensemble de considérations thermodynamiques et cinétiques.

Dans des travaux antérieurs, (5) la comparaison des courbes d'évolution de mélanges solides-solutions et de solutions pures nous avait amenés à conclure au caractère non hétérogène de la nucléation des phases hydratées, la période d'induction précédant la précipitation des aluminates de calcium hydratés à partir de CA étant du même ordre de grandeur (une vingtaine d'heures) dans les deux cas. Il semble en être de même dans la précipitation à partir de  $C_3S$  de  $Ca(OH)_2$  dont la période d'induction n'est pas sensiblement plus courte en présence des grains de  $C_3S$  qu'à partir d'une solution sursaturée pure (6).

## ETUDE EXPERIMENTALE

Pour bien situer les expériences plus particulière-

ment concernées dans cet article par rapport à notre approche expérimentale du problème des mécanismes d'hydratation, on se reportera au tableau I où l'on distingue les expériences de type W et B :

TABLEAU I				
Bilans analytiques				
syst. fermé	$s + l$	eau	stagnant	
		solution		
		initiale		
		initiale		
		$l$ (filtrat)(B); $l+l$ initial puis B.		
syst. ouvert	$s/f + l$	eau	bref	versé
		solution		
			long	pulvérisé
		$(l + l)/f + B$ (fermé)		

Le principe de ces expériences est de suivre la cinétique en faisant un bilan analytique aussi complet que possible, portant à la fois sur les phases solides et sur les solutions. Les essais en système fermé sont ceux où aucun constituant n'est ajouté ni retranché au cours d'une expérience. Dans les essais de type W où une phase solide  $s$  est agitée dans une phase liquide  $l$  qu'il s'agisse initialement d'eau ou d'une solution de composition déterminée, le mélange de rapport pondéral  $l/s$  est placé dans un ballon sous atmosphère d'azote décarbonaté et à une température maintenue constante grâce à un thermostat. Dans les essais de type B, les conditions sont les mêmes mis à part le fait qu'initialement, le système est homogène : filtrat  $l$  ou mélange de deux solutions  $l+l$ . La cinétique d'évolution est suivie par prélèvements, filtration et analyse du filtrat et des constituants solides au moyen de la spectrométrie d'absorption atomique, de la diffraction X et éventuellement de méthodes complémentaires : analyse colorimétrique de la silice par réduction du complexe silico-molybdique, microscopie électronique à balayage et sonde à dispersion X, spectrométrie IR. Naturellement, tous ces essais sont effectués sans que les solutions ne soient jamais au contact du verre ou d'un matériau susceptible de libérer de la silice.

Les essais en système ouvert sont ceux durant lesquels un ou plusieurs constituants sont ajoutés ou retranchés au cours d'une expérience. La lettre  $f$  indique que l'essai est effectué sur filtre. Initialement, un solide  $s$  (constituant anhydre d'un ciment) peut être étalé en couche mince sur le filtre et le réactif liquide  $l$  peut le traverser pendant une durée soit très brève soit longue, auquel cas le système évolue en régime stationnaire. Le liquide peut être, ou versé sur le filtre, ou finement pulvérisé. Dans des expériences d'un autre type, c'est un mélange initialement homogène qui est réalisé sur filtre en versant simultanément deux liquides ; le précipité qu'ils sont susceptibles de donner par réaction est retenu sur le filtre et le filtrat est éventuellement soumis à une expérience de type B, en système fermé, afin de suivre la cinétique de précipitation. Les variations de composition entraînées par cette précipitation sont reportées systématiquement sur les diagrammes d'équilibre correspondant : chaux-alumine-eau ou chaux-silice-eau. Dans cet article, l'attention sera principalement attirée sur la

cinétique d'évolution en système fermé de mélanges de  $C_3S$  agité soit dans l'eau, soit comparativement, dans une solution préparée indépendamment et de concentrations données en silice  $[S]$  et en chaux  $[C]$  avec plusieurs valeurs du rapport  $\ell/s$  initial.

## RESULTATS

La première série d'expériences (8) avait pour but de comparer la cinétique d'évolution en système fermé des systèmes définis par les conditions initiales suivantes :

Exp. 1)  $s + \ell$  (tableau I); avec  $s$  : 1g de  $C_3S$   $T_1$  (triclinique  $T_1$ ) ;  $\ell$  : 1000 g d'eau ( $\ell/s = 1000$ ).  
Courbes  $W_C$  :  $[C] = f(t)$  et  $W_S$  :  $[S] = g(t)$  Figure 1.

Exp. 2)  $s + \ell$  avec :  $s = 1g$  de  $C_3S$ ,  $\ell = 1000 g$  de solution contenant :  $[C]^0 = 3,95 \cdot 10^{-3} \text{ mol.kg}^{-1}$  ;  $[S]^0 = 1,19 \cdot 10^{-3} \text{ mol.kg}^{-1}$  ;  $[C/S]_\ell = 3,32$  ; courbe  $W'$  (figure 2).

Exp. 3)  $\ell$  (tableau I) avec :  $[C]^0 = 3,95 \cdot 10^{-3} \text{ mol.kg}^{-1}$  ;  $[S]^0 = 1,19 \cdot 10^{-3} \text{ mol.kg}^{-1}$ . Courbes  $B$  :  $[C] = f(t)$  ;  $[S] = g(t)$  (figure 1).

Fig. 1 - Evolutions comparées en fonction du temps : - - - - , courbes  $W_C$  et  $W_S$  (exp. 1) ; — courbes  $W'_C$  et  $W'_S$  (exp. 2) ; - - - courbes  $B_C$  et  $B_S$  (exp. 3).  
..... courbes  $B'_C$  et  $B'_S$ ,  $B''_C$  et  $B''_S$  après  $\ell + \ell$  (exp. 8,9) avec, respectivement de fortes ou de faibles concentrations dans le mélange initial.

Il convient de souligner la grande différence entre les courbes  $W$  et  $W'$  et la similitude entre les courbes  $W'$  et  $B$ .

Des expériences du même type :  $s + \ell$  (courbe  $W$ ), ont été faites dans un rapport  $\ell/s = 10$  avec comme conditions initiales :

Exp. 4)  $s$  : 10 g de  $C_3S$  ;  $\ell$  : 1000 g d'eau. La figure 2 donne les courbes  $W_C$  et  $W_S$  obtenues dans deux expériences différentes en dosant les faibles concentrations  $[S]$  par la méthode de réduction du complexe silico-molybdique. En effet, par spectrométrie d'absorption atomique, on ne peut espérer doser la silice avec une incertitude inférieure à  $0,1 \cdot 10^{-3}$

$\text{mol.kg}^{-1}$ . C'est pourquoi la courbe de la silice n'est généralement pas tracée et certains auteurs croient même pouvoir affirmer qu'à  $\ell/s = 10$ , il n'y a pas de silice en solution sauf dans la période initiale, ce qui est une erreur. Une courbe de variation de  $[S]$  à  $\ell/s = 10$  a été établie également par J.F. Young et col. (7). Mais il semble que les valeurs trouvées soient entachées d'une erreur par excès.

Exp. 5)  $s$  : 10 g de  $C_3S$  ;  $\ell$  : 1000 g de solution préparée indépendamment par agitation pendant 75h de silice (aérosil) dans l'eau de chaux diluée. Après filtration, la composition de cette solution était :  $[C]^0 = 1,75 \cdot 10^{-3} \text{ mol.kg}^{-1}$ ,  $[S]^0 = 4,70 \cdot 10^{-3} \text{ mol.kg}^{-1}$ . Les courbes obtenues  $W'_C$  et  $W'_S$  ont été reportées sur la figure 2 en même temps que les courbes  $W_C$  et  $W_S$ . Il est remarquable de constater que, dans sa partie initiale, la courbe  $W'_C$  est décroissante,  $[C]$  passant de  $3,65 \cdot 10^{-3} \text{ mol.kg}^{-1}$  à  $t = 1 \text{ mn}$  à  $1,85 \cdot 10^{-3} \text{ mol.kg}^{-1}$  à  $t = 15 \text{ mn}$ , ce qui est pratiquement  $[C]^0$ . Après ce minimum,  $W'_C$  amorce une remontée, d'abord lente ( $[C]$  passe de  $1,85$  à  $2,20 \cdot 10^{-3} \text{ mol.kg}^{-1}$  à 15 et 25 mn), puis plus rapide ( $[C]$  prend les valeurs  $5,40$  et  $11,12 \cdot 10^{-3} \text{ mol.kg}^{-1}$  à 30 et 45 mn). Simultanément,  $[S]$  décroît, passant de  $3,83$  à  $0,38 \cdot 10^{-3} \text{ mol.kg}^{-1}$  quand  $t$  passe de 1 à 30 mn ; cette décroissance est moins rapide dans la seconde demi-heure, mais au bout d'une heure, la courbe  $W'_S$  rejoint la courbe  $W_S$  à  $[S] = 0,063 \cdot 10^{-3} \text{ mol.kg}^{-1}$  et par la suite, les deux courbes coïncident. On peut donc dire que toute la silice présente à l'origine dans le solvant a été éliminée.  $[S]$  continue à décroître lentement avec des valeurs telles que  $0,020$ ,  $0,0175$ ,  $0,0130 \cdot 10^{-3} \text{ mol.kg}^{-1}$  respectivement pour  $t = 4 \text{ h } 30$ ,  $7 \text{ h } 30$ ,  $24 \text{ h}$ .

Si l'on revient à la branche ascendante de la courbe  $W'_C$ , on constate qu'elle reste décalée par rapport à celle de  $W_C$  et qu'il en est de même pour la branche descendante, le début de la chute de concentration en  $CaO$  intervenant avec un retard de 1h environ.

Fig. 2 - Courbes d'évolution de mélanges  $C_3S$  + eau ( $\ell/s = 10$ ). • Courbe  $W_C$  :  $[C] = f(t)$ , ▲ courbe  $W_S$  :  $[S] = g(t)$  (D. Bertrandie, Réactivité des Solides, Dijon) ; o courbe  $W'_C$ , Δ courbe  $W'_S$  (D. Ménétrier, Martin Marietta Laboratories, Baltimore). Courbes d'évolution de mélanges  $C_3S$  + solution de composition  $[C]^0 = 1,75 \cdot 10^{-3} \text{ mol.kg}^{-1}$ ,  $[S]^0 = 4,70 \cdot 10^{-3} \text{ mol.kg}^{-1}$ . x courbe  $W'_C$  ; + courbe  $W'_S$  (D. Bertrandie, Dijon).

De cette dernière expérience, est à rapprocher un essai effectué également avec un rapport  $l/s = 10$ , mais dans les conditions initiales suivantes (8) :

Exp. 6)  $[C]^0 = 34.10^{-3} \text{ mol.kg}^{-1}$ ,  $[S]^0 = 0,012.10^{-3} \text{ mol.kg}^{-1}$ , c'est-à-dire en utilisant comme solvant le filtrat prélevé peu avant le maximum de  $W_C$  d'un essai antérieur à  $l/s = 10$  avec de l'eau comme solvant.

La figure 3 présente la courbe  $W_C'$  obtenue comparée à la courbe  $W_C$  normale (avec l'eau) ainsi que, en pointillé, les courbes de variation concomitante du pourcentage d'eau liée déterminée par perte au feu.

Fig. 3 - — A et B : Courbes d'évolution  $W_C$  à  $l/s = 10$  avec comme solvant  $l$  : (exp. 4) de l'eau, (exp. 6) une solution à  $[C]^0 = 34.10^{-3} \text{ mol.kg}^{-1}$ . - - - a) et b) Courbes de pourcentage d'eau liée correspondantes.

Il convient de noter une baisse initiale de  $[C]$  d'une amplitude de  $2.10^{-3} \text{ mol.kg}^{-1}$  environ, au début de la courbe  $W_C'$ , puis à  $t \approx 30 \text{ mn}$ , une remontée ramenant  $[C]$  approximativement à sa valeur primitive, suivie à  $t \approx 4\text{h}30$  d'une décroissance continue.

La baisse initiale de  $[C]$  représente un retrait de 120 mg de  $\text{CaO}$  pour 100 g de  $\text{C}_3\text{S}$ . Quant au pourcentage d'eau liée, il est clair qu'il est très amoindri pendant les 4 ou 5 premières heures du cas b par rapport à la même période du cas a ; la masse d'eau liée est au maximum de 500 à 700 mg dans le cas b contre au moins 2000 mg dans le cas a et l'on doit constater que ce décalage se maintient dans la suite de l'évolution. La présence de C-S-H reconnaissables à leur morphologie en nid d'abeilles est facilement détectée par microscopie électronique à balayage durant cette période, au bout d'une heure par exemple dans le cas a, mais non dans le cas b.

Des expériences du type  $s/f+l$  en système ouvert,  $l+l$  initial + B en système fermé et  $(l+l)/f+B$  en système fermé apportent des résultats complémentaires très intéressants (8). Les essais du premier type (exp. 7) consistent à faire passer à travers une couche de 20 g de  $\text{C}_3\text{S}$  étalée sur filtre, 14 l d'une solution de composition :  $[C]^0 = 3,80.10^{-3} \text{ mol.kg}^{-1}$ ,  $[S]^0 = 1,17.10^{-3} \text{ mol.kg}^{-1}$  avec un débit de 1 l.mn<sup>-1</sup>.

La composition du filtrat est :  $[C] = 4,03.10^{-3} \text{ mol.kg}^{-1}$ ,  $[S] = 1,11.10^{-3} \text{ mol.kg}^{-1}$  et le pourcentage d'eau liée 0,88 (figure 4) :

Fig. 4 - L point du diagramme C,S,H correspondant à la composition de la solution versée sur filtre à débit constant à travers une couche de  $\text{C}_3\text{S}$ . N : composition du filtrat. La construction graphique montre que la quantité de chaux et de silice transformées en C-S-H sont données par les projections du vecteur  $\overline{NM}$ ; soit  $r$  la silice engagée dans le C-S-H : la partie  $r' = -\Delta q$  provient de la silice préexistante en solution ; la partie  $r''$  de la silice provenant de  $\text{C}_3\text{S}$ . Une partie de la chaux complémentaire  $(3-\alpha)$  est utilisée entre P et N. Elle le serait totalement si N était en  $N'$  et de la chaux préexistante serait consommée si N était en  $N''$  (exp. 2 et 5).

Les essais du second type ont pour but d'étudier la cinétique d'évolution du mélange de deux solutions dont le titre était calculé de façon que la composition initiale du mélange appartienne soit au domaine s'étendant au-dessus et à droite de la courbe (I) (figure 5) dont la construction expérimentale est décrite dans de précédentes publications (8, 9, 10), par exemple (exp. 8) :  $[C]^0 = 6,47.10^{-3} \text{ mol.kg}^{-1}$ ,  $[S]^0 = 2,20.10^{-3} \text{ mol.kg}^{-1}$ , soit à celui situé au-dessous et à gauche de cette courbe, par exemple (exp. 9) :  $[C]^0 = 3,0.10^{-3} \text{ mol.kg}^{-1}$ ,  $[S]^0 = 1,05.10^{-3} \text{ mol.kg}^{-1}$ . Les courbes de variation de ces concentrations en fonction du temps sont reportées sur la figure 1 et les changements de composition correspondants sur le diagramme C,S,H (figure 5).

Sur cette dernière figure, ont été portés également les résultats des essais du 3ème type en système ouvert (exp. 10) : le mélange des deux solutions sur filtre à la composition théorique suivante :  $[C]^0 = 7,02.10^{-3} \text{ mol.kg}^{-1}$ ,  $[S]^0 = 2,20.10^{-3} \text{ mol.kg}^{-1}$ ,  $[C/S]_t = 3,62$  ; celle du filtrat est :  $[C] = 5,31.10^{-3} \text{ mol.kg}^{-1}$ ,  $[S] = 1,47.10^{-3} \text{ mol.kg}^{-1}$ ,  $[C/S]_t = 3,62$ .

#### DISCUSSION

Pour faire apparaître les conséquences intéressantes de l'ensemble des résultats, il est utile, lorsque l'évolution en fonction du temps du système fermé est accompagnée d'un changement de composition de la phase liquide, de reporter sur le diagramme C,S,H les trajectoires du point représentatif de la composition. A chaque point de ces "chemins cinétiques", correspond une valeur du degré de sursaturation du

Fig. 5 - Report sur le diagramme C,S,H des changements de composition accompagnant l'évolution en fonction du temps dans les expériences 1, 2, 3, 4, 5, 8, 9, 10. Les trajectoires obtenues portent le même numéro que les expériences citées. (1' : W à  $\ell/s = 100$ ).

milieu calculable, ou tout au moins évaluable, par rapport aux courbes d'équilibre de solubilité des C-S-H. Des indications peuvent également être tirées de la pente en chaque point de ces courbes.

Ainsi, sur le diagramme de la figure 5 la courbe 1) relie les valeurs au même instant de  $[C]$  et  $[S]$  des courbes  $W_C$  et  $W_S$  de l'expérience 1 à  $\ell/s = 1000$ . Avec cette dilution, la sursaturation en  $Ca(OH)_2$  n'est jamais atteinte puisque 1 g de  $C_3S$  représente  $4,30 \cdot 10^{-3}$  mol.kg $^{-1}$  soit  $13,10^{-3}$  mol.kg $^{-1}$  en  $CaO$  si tout passait en solution. Alors que  $[C]$  est constamment croissante,  $[S]$  passe par un maximum au bout de 15 mn ( $[S] = 1,19 \cdot 10^{-3}$  mol.kg $^{-1}$ ,  $[C/S]_l = 3,12$ ) et commence à décroître au-delà de la 31ème minute. Du 13ème au 25ème jour,  $[C]$  et  $[S]$  se sont stabilisées respectivement à  $6,32$  et  $0,040 \cdot 10^{-3}$  mol.kg $^{-1}$  sur la courbe d'équilibre de C-S-H. La formule du bilan (8, 9, 2) exprimant que toute la chaux (en solution et à l'état solide) est dans le même rapport avec toute la silice (en solution et à l'état solide) que dans  $C_3S$ , permet de calculer le nombre de millimoles  $r$  de silice engagées dans un C-S-H de rapport  $[C/S]_s = \alpha$  :

$$r = \frac{\beta q - 3q}{3 - \alpha} \quad (1)$$

Dans cette relation,  $\beta$  est la valeur du rapport  $[C/S]_l$  et  $q$  celle de la concentration  $[S]$  de la silice en solution. En admettant que la totalité de  $C_3S$  ait été transformée, cela donnerait :  $r = 4,35 \cdot 10^{-3}$  mol. et compte tenu des valeurs ci-dessus de  $\beta q$  et  $q$ , la valeur moyenne de  $\alpha$  serait :  $\alpha = 1,57$ .

En fait le C-S-H commence à être aisément détecté en microscopie électronique à balayage par son aspect en nid d'abeilles, au bout de 2 h (8,9). Il est remarquable de constater que la trajectoire sur le diagramme C,S,H est constituée du segment de la droite  $[C/S] = 3$  allant de l'origine au point A et de la courbe (I) approximativement parallèle à la courbe (I) que nous avons définie expérimentalement (8, 9, 2) comme la limite entre la cinétique rapide et la cinétique lente de nucléation des C-S-H. A titre indicatif, la courbe 1'), obtenue avec  $\ell/s = 100$  est légèrement décalée en direction de (I) donc, dans un domaine un peu plus sursaturé.

Si à la trajectoire 1), nous comparons la trajectoire 2) (exp. 2), la partie OA ne doit pas être prise en compte puisque la solution a, au départ, la composition correspondant au point B. Ce qui prévaut, c'est la décroissance de  $[C]$  en même temps que celle de  $[S]$ , à peu près parallèlement à  $[C/S]_l = 1$ , jusqu'à  $t = 20h$ ; au-delà,  $[C]$  commence à croître pour atteindre  $5,7 \cdot 10^{-3}$  mol.kg $^{-1}$  au 20ème jour alors que  $[S]$  continue à décroître jusqu'à  $0,07 \cdot 10^{-3}$  mol.kg $^{-1}$ . Le début de la courbe 2) rappelle ainsi les courbes telles que 3) 8) 9) 10) qui sont des trajectoires correspondant aux courbes de type B des expériences de même numéro d'ordre, c'est-à-dire de solutions de rapport  $[C/S]^0 = \beta^0$  dont S et C consommées ne sont pas renouvelées par dissolution de  $C_3S$ . En outre, leur tangente en chaque point est parallèle à la droite de  $[C/S]_s = \alpha$  du C-S-H précipité. Dans le cas de l'expérience 2) en présence de  $C_3S$ , celui-ci peut bien se dissoudre pour renouveler C et S, mais l'expérience montre que le C-S-H qui se forme consomme non seulement toute cette silice et la chaux correspondante dans le rapport  $\alpha$ , mais aussi la chaux complémentaire ( $3 - \alpha$ ), plus une partie de la chaux préexistante, (figure 4) puisque  $[C] \leq [C]^0$ . Cela implique que le processus de précipitation est au moins aussi rapide que tout autre processus de formation du C-S-H, notamment topochimique, qui pourrait intervenir avec  $C_3S$ .

Considérons à présent les expériences 4 et 5 à  $\ell/s = 10$ . Il apparaît une très grande similitude avec les expériences 1 et 2 à  $\ell/s = 1000$  lorsque l'on considère les trajectoires correspondantes sur le diagramme C,S,H (figure 5). Avec l'eau comme solvant (exp. 4), la branche OC est initialement parcourue, puis la branche 4) se développe aussi parallèlement à la courbe (I) mais beaucoup plus près d'elle, dans un domaine plus fortement sursaturé que pour la courbe 1). Cela est explicable par la plus grande densité de grains dans le liquide permettant une compensation plus rapide de S et C consommées. La seule différence avec le cas à  $\ell/s = 1000$  est qu'ici le rapport  $\ell/s$  est assez petit pour que la sursaturation en chaux soit possible. Lorsque celle-ci est suffisante pour que s'amorce la nucléation de  $Ca(OH)_2$ , l'accumulation de ce constituant en solution cesse et un état quasi stationnaire du système entre dissolution et précipitation permet à  $[C]$  de ne décroître que très lentement vers la saturation.

La détermination expérimentale de  $[S]$  que nous avons faite montre que même à la plus forte sursaturation en chaux, la silice reste dosable, avec  $[S] > 0,018 \cdot 10^{-3}$  mol.kg $^{-1}$ . Il convient de remarquer que la formule du bilan (1) permet de calculer de façon simplifiée dès lors que  $q \ll \beta q$  le nombre  $r$  de millimoles de silice transformée en CSH de rapport  $[C/S]_s = \alpha$ . A  $\alpha$  constant,  $r$  est donc proportionnel à  $\beta q$ , par exemple si  $\alpha = 2$ ,  $r = \beta q$  et la branche ascendante de  $W_C$  (figure 2) représente aussi l'accroissement en fonction du temps du nombre de millimoles de silice transformées en CSH. La tangente en un point de cette courbe renseigne donc sur la vitesse au temps  $t$  de formation des C-S-H. Ceci n'est plus valable naturellement après le maximum de  $W_C$  lorsque la précipitation de portlandite s'est amorcée. On voit que la vitesse de formation de CSH diminue, mais pas considérablement, lorsque  $[C]$  croît.

En ce qui concerne l'expérience 5, elle diffère de l'expérience 2, hormis la valeur de  $\ell/s$ , par la forte valeur de  $[S]^0$  par rapport à  $[C]^0$ , de sorte que la trajectoire sur le diagramme C,S,H (figure 5) ne comporte pas de branche OC, mais commence en D qui est

pratiquement sur la courbe d'équilibre. Il n'est donc pas étonnant que, dans un premier stade (branche DE) le processus de dissolution de  $C_3S$  avec formation de CSH soit le plus rapide et contribue à accroître  $[C]$  et à abaisser  $[S]$ . Mais de ce fait, le degré de sur-saturation créée incite à précipiter en C-S-H, avec la silice préexistante, non seulement le reliquat de chaux  $(3 - \alpha)$  non engagé dans un C-S-H, provenant de la dissolution de  $C_3S$ , mais aussi une fraction de la chaux préexistante et accumulée. Il est donc manifeste que ce processus est plus rapide que la formation de CSH aux dépens de  $C_3S$  quel que soit son mécanisme (topochimique ou non) et ramène le point figuratif vers la courbe d'équilibre en F ce qui correspond au minimum de  $W'_C$  (figure 2) et à l'élimination de pratiquement toute la silice préexistante. On observe alors une discontinuité des vitesses avec une brusque remontée de  $[C]$  suivant une branche  $W'_C$  parallèle à  $W_C$  alors que  $W'_S$  rejoint  $W_S$  et se confond avec elle. Il en résulte une situation de la branche FG de la trajectoire sur le diagramme C,S,H (figure 5) dans la partie beaucoup moins sursaturée du domaine à gauche de (I). Au cours de la partie DEF de la trajectoire,  $16/(3-\alpha)$  millimoles de silice dont les 4,39 millimoles préexistantes sont rentrées dans le C-S-H et comme cela ramène au début de la branche ascendante  $W'_C$ , cet excédent se conserve aux instants ultérieurs par rapport à la courbe normale  $W_C$ . Comme dans l'expérience 2, il est donc manifeste que le processus de précipitation de C-S-H à partir de l'excédent de silice en solution est au moins aussi rapide que la formation de C-S-H à partir de  $C_3S$  et qu'il ne laisse pas plus de silice dans la phase liquide.

La conclusion la plus simple que l'on peut en tirer est que les deux processus sont identiques c'est-à-dire que la formation de C-S-H à partir de  $C_3S$  est aussi le résultat d'un processus de précipitation.

Fig. 6 - Constructions graphiques illustrant dans le cas B et le cas W, les formules de bilan (2) et (3) correspondantes et rendant compte des "chemins cinétiques" sur le diagramme C-S-H.

Les trajectoires du point N représentatif de la composition sur le diagramme C,S,H peuvent être analysées à l'aide de constructions qui transcrivent graphiquement les formules de bilan dans les cas B et W.

La composition initiale de la solution est dans les deux cas :  $[C]^0 = \beta_0 q_0$ ,  $[S]^0 = q_0$  (points L et L') ;

$[C] = \beta q$ ,  $[S] = q$  est la composition finale dans le cas B (point N') et la composition au temps t de la solution agitée avec  $C_3S$  dans le cas W ;  $\alpha_1, \alpha_2, \dots, \alpha_i$  sont les  $[C/S]_i$  du C-S-H,  $r_i$  les quantités correspondantes de silice fixées dans le C-S-H ; les coordonnées  $\beta_i q_i$ , sont exprimées par rapport aux axes d'origines L,  $N_1, N_2, \dots, N_i, \dots$ , (figure 6). Les expressions du bilan s'écrivent alors :

Cas B : (relation 2)

Cas W : (relation 3)

$$\beta q + \sum_i \alpha_i r_i$$

$$\sum_i \beta_i q_i + \sum_i \alpha_i r_i$$

$$\frac{\beta q + \sum_i \alpha_i r_i}{q + \sum_i r_i} = \beta_0$$

$$\frac{\sum_i \beta_i q_i + \sum_i \alpha_i r_i}{\sum_i q_i + \sum_i r_i} = 3$$

$$\text{avec : } \sum_i \beta_i q_i = \beta q - \beta_0 q_0 \quad \text{et} \quad \sum_i q_i = q - q_0$$

## CONCLUSIONS

Les "chemins cinétiques" tracés sur le diagramme C,S,H à partir des essais de types B et W sont instructifs, du fait qu'ils se situent tous dans le domaine sursaturé compris entre la courbe I dont l'origine cinétique (nucléation très rapide des C-S-H) est bien illustrée par la comparaison des expériences 8) et 10) et la courbe de solubilité du C-S-H. Cela suggère l'unicité du mécanisme : la formation du C-S-H par précipitation.

## Remerciements

Ces travaux ont été faits en coopération avec la Société Lafarge à laquelle nous exprimons notre gratitude.

# Mécanismes réactionnels de l'hydratation

## *Mechanisms of hydration reactions*

C. VERNET, E. DEMOULIAN, P. GOURDIN, F. HAWTHORN, Société des Ciments Français, CEREG, France.

### RESUME

Dans le but de comparer les vitesses de réaction des ciments dans des conditions standard, les auteurs ont réalisé un appareillage permettant de mesurer en continu les flux ioniques pendant l'hydratation. Les courbes obtenues démontrent l'existence d'un mécanisme de dissolution-cristallisation du type proposé par LE CHATELIER. Pour évaluer la contribution de ce mécanisme relativement à tout autre susceptible d'agir simultanément, ils ont réalisé des mesures de vitesse de précipitation des CSH, dont les résultats montrent la prépondérance du mécanisme de LE CHATELIER.

Ils décrivent ensuite les différentes étapes de l'hydratation, en montrant que, dans ses conséquences, le mécanisme de LE CHATELIER n'est pas en contradiction avec l'ensemble des observations connues.

Ils présentent enfin un modèle mathématique de la cinétique d'hydratation, basé sur ce mécanisme et permettant d'expliquer les influences observables des autres réactions chimiques sur la vitesse de l'hydratation. Les applications pratiques de ce modèle s'étendront à l'étude de l'influence des adjuvants et des ajouts du ciment, ainsi qu'à la mesure physique de l'hydraulicité des clinkers.

### SUMMARY

In order to compare the reaction speeds of the cements in standard conditions, the authors have constructed an apparatus which measures continuously the ionic fluxes during the hydration. The curves obtained show the existence of a dissolution-crystallization mechanism as proposed by LE CHATELIER.

For estimating the rôle of this mechanism in hydration, the authors have determined the CSH precipitation speed. The results demonstrate the preponderance of the LE CHATELIER mechanism over all the others put forward.

They also describe four hydration periods and show the agreement of the proposed mechanism with all the known data.

Finally on the basis of this mechanism, they give a mathematical model of the hydration kinetics, which can be applied successfully in the presence of other chemical reactions during hydration. In practice, this model will be used for the study of admixtures and adds in cement, and also for the physical evaluation of clinker hydraulicity.

## INTRODUCTION

Pendant l'hydratation de l'alite on distingue quatre périodes :

- 1ère période : réaction rapide et exothermique, débutant par une chimisorption d'eau (1) ;
- 2ème période dite "période dormante" : lente, presque athermique, avec sursaturation progressive en chaux de la solution, sans modifications rhéologiques ;
- 3ème période caractérisée par la précipitation de la portlandite, l'accélération brutale des réactions, l'augmentation du flux thermique ;
- 4ème période : ralentissement progressif des réactions. Dans le cas des ciments portland, les réactions secondaires des aluminates, aluminoferrites et du gypse se produisent, sans modifier la séquence ci-dessus. Malgré de très nombreuses publications, les mécanismes réactionnels des ciments portland restent mal connus : on trouve dans la bibliographie des théories différentes, que l'on peut classer en 3 groupes :
  - théories du type "LE CHATELIER" basées sur l'hypothèse de la dissolution congruente de l'alite et la cristallisation d'hydrates, de rapports  $\text{CaO/SiO}_2(\text{C/S})$  plus faibles (7) ;
  - théories du type "topochimique" basées sur l'action directe de l'eau entrant dans le réseau de l'alite, avec formation d'hydrates in situ, par réorganisation structurale et libération de la chaux excédentaire par diffusion ;
  - théories mixtes, combinant les deux précédentes en leur attribuant plus ou moins d'importance.

Du point de vue cinétique, l'approche des phénomènes est différente selon l'hypothèse de départ :

. dans l'hypothèse "topochimique", le flux de chaux libérée dépend de l'énergie libérable par l'alite et de la stoechiométrie des CSH. Il ne peut exister aucun flux de silice vers la solution. La concentration en  $\text{SiO}_2$  est alors régie par la solubilité de l'hydrate le plus externe, la mesure du flux de  $\text{CaO}$  et du  $\text{C/S}$  du CSH permet d'accéder directement à la vitesse d'hydrolyse de l'alite ;

. dans l'hypothèse de LE CHATELIER, le flux de silice libérée est la différence des flux de dissolution et de précipitation et la solution est d'autant plus sursaturée que cette différence est grande. Pour obtenir la vitesse de réaction de l'alite, il faut donc mesurer par ailleurs la vitesse de précipitation, en calculer le flux, pour le déduire du flux mesuré : on obtient ainsi la vitesse de dissolution.

Sans préjuger de la validité de telle ou telle hypothèse, nous avons effectué des mesures précises de flux ioniques, afin de comparer les vitesses de réaction des ciments dans des conditions standard et de rechercher des éclaircissements sur les mécanismes réactionnels. Nos essais ont été effectués : d'une part à l'aide d'un appareillage de lixiviation spécialement étudié, permettant d'extraire en permanence une partie des ions libérés par le système ciment-eau, ce qui rend possible la mesure du flux de silice (système ouvert) d'autre part, en vase clos (système fermé) pour étudier la cinétique de précipitation des CSH.

## 1 - MESURES EN SYSTEME OUVERT

## 1.1 - Appareillage (fig.1)

Principe : Une suspension de ciment dans une solution à choisir est agitée dans le réacteur (R) dans lequel circule la solution de lixiviation, pompée à travers le filtre micropore en téflon (F), puis injectée dans un circuit comportant une série de capteurs ioniques. Le filtrat est, soit recyclé, soit recueilli et dosé séquentiellement. Ce montage, réalisé au début de 1977 diffère de celui qu'ont publié BARRET et MENETRIER en 1978, par son degré poussé d'automatisme et l'utilisation de capteurs électrochimiques, dans le but de

mesurer en continu les flux ioniques et non pas de faire des bilans en fin d'essai.

Equations de fonctionnement du réacteur : Soient

- $m$  : la masse de ciment en suspension,
- $s$  : la surface spécifique du ciment ( $\text{m}^2/\text{g}$ ),
- $S$  : la surface totale du ciment ( $\text{m}^2$ ),  $S' = dS/dt$
- $Q_h$  : la quantité en mmoles d'un ion libéré,
- $\phi_h$  : le flux résultant (en  $\text{mM}/\text{m}^2$ ),
- $I_h$  : Intensité résultante de libération (en  $\text{mM}/\text{mn}$ ),
- $\Delta_h$  : flux instantané (en  $\text{mM}/\text{m}^2 \cdot \text{mn}$ ),  $= d\phi_h/dt$
- $C_\ell$  : concentration du réactif de lixiviation ( $\text{mM}/\text{l}$ ),
- $C$  : concentration à la sortie du réacteur (en  $\text{mM}/\text{l}$ ),
- $h$  : débit de lixiviation ( $\text{ml}/\text{mn}$ ),
- $V$  : volume total du filtrat (en  $\text{ml}$ ),
- $v$  : volume du réacteur (en  $\text{ml}$ ).

Fig. 1- Montage de lixiviation avec capteurs électrochimiques.

L'équation générale du réacteur s'écrit :

$$10^3 I_h = v \frac{dC}{dt} + h(C - C_\ell) \quad \text{[I]}$$

$$\text{or } I_h = \frac{S d\phi_h}{dt} + \phi_h \frac{dS}{dt} = S \Delta_h + \phi S'$$

d'où le flux résultant :

$$\Delta_h = \frac{10^{-3}}{S} v \frac{dC}{dt} + h(C - C_\ell) - \phi \frac{S'}{S} \quad \text{[II]}$$

Dans le cas particulier d'une lixiviation par l'eau avec une surface sensiblement constante  $s_0$  :

$$10^3 I_h = v \frac{dC}{dt} + hC = 10^3 m_0 s_0 \Delta_h \quad \text{[III]}$$

Dans le cas de la dissolution-précipitation, le flux de dissolution sera obtenu en faisant la différence :  $a\Delta_d = \Delta_h - b\Delta_p$  (où  $a$  et  $b$  sont des coefficients stoechiométriques de  $\text{C}_3\text{S}$  et CSH), des flux résultant et de précipitation.

Si  $dX/dt$  est la vitesse de précipitation (en  $\text{mM}/\text{l} \cdot \text{mn}$ )

$$b \Delta_p = \frac{bv}{1000 S} \frac{dX}{dt}$$

La formule III se ramène alors à :

$$10^3 a\Delta_d = \frac{v}{m_0 s_0} \left( \frac{dC}{dt} - b \frac{dX}{dt} \right) + \frac{h}{m_0 s_0} C \quad \text{[IV]}$$

Le terme  $v \frac{dC}{dt}$  traduit l'existence d'une constante de temps du montage : on prendra donc le volume  $v$  du réacteur suffisamment faible si l'on veut rendre la concentration  $C$  proportionnelle à l'intensité  $I_h$ .

Dans le cas d'un flux  $\Delta$  constant, on voit que l'expression de  $C$  sera très simple :

$$C(t) = \frac{m}{v} \Delta s_0 10^3 \left( 1 - \exp. - \frac{ht}{v} \right) \quad \text{[V]}$$

$$t \rightarrow +\infty \quad C \rightarrow c_\infty = 10^3 \frac{m}{h} s_0$$

$$t \rightarrow 0 \quad \frac{dC}{dt} \rightarrow 10^3 \frac{m}{v} \Delta s_0$$

ce qui montre bien l'influence des rapports  $\frac{m}{v}$  et  $\frac{h}{v}$  sur la concentration  $C$ .

La constante de temps est ici  $\frac{v}{h}$  (mn)

Pour  $h = 0$ , c'est-à-dire en système fermé,

$$I_h = 10^{-3} v \frac{dC}{dt} \quad \text{[VI]}$$

le flux peut alors être obtenu par dérivation de la courbe de concentration.

## 1.2 - Mesures

Les précautions suivantes ont été prises pour que nos mesures soient significatives :

- asservissement électronique du débit de lixiviation,
- commande électronique de l'agitation,
- contrôle de la réponse des capteurs par analyse chimique séquentielle du filtrat,
- dans le domaine des traces, prise en compte uniquement des résultats d'analyse supérieurs au triple de l'incertitude,
- thermostatisation à 25°C.

Vingt-deux essais ont été réalisés dans diverses conditions opératoires (rapport m/v, débit, agitation) pour une alite de synthèse et un clinker industriel. Le réactif de lixiviation étant, soit de l'eau, soit de la chaux saturée, soit un mélange chaux + gypse, ce qui permet de se placer dans des conditions très proches de l'hydratation des pâtes de ciment.

Nous avons tracé les courbes d'évolution des concentrations et calculé les flux ioniques correspondants, à l'aide des formules du réacteur.

En reportant les valeurs des concentrations instantanées dans le diagramme d'équilibre  $\text{CaO}$ ,  $\text{SiO}_2$ ,  $\text{H}_2\text{O}$ , nous avons tracé le trajet du point figuratif (F) de la solution, pendant la réaction. Peu de chercheurs ayant calculé la courbe de solubilité des CSH en tenant compte à la fois des équilibres entre  $\text{H}_2\text{SiO}_4^{2-}$ ,  $\text{H}_3\text{SiO}_4^-$ ,  $\text{Ca}^{++}$  et  $\text{CaOH}^+$  et de la force ionique, nous avons donc calculé un nouvel abaque donnant une série de courbes d'équilibre avec  $\text{OH}^-$  comme paramètre.

Fig.2 - Diagramme des flux

Fig.3 - Trajet du point figuratif F

## 1.3 - Résultats - Description des phénomènes

L'ensemble des essais donne des courbes analogues à celles de l'exemple (fig.2 et 3). On distingue toujours 3 étapes dans le mécanisme, chacune comportant une cinétique particulière :

1ère étape : (Trajet  $\text{OR}_1$  sur le diagramme)

Le point figuratif F se déplace très rapidement et entre dans le domaine sursaturé. Pour les ciments, le C/S de départ est très supérieur à 3 (présence des phases mineures solubles). Pour l'alite, le point F s'éloigne rapidement de l'axe C/S = 3, dont il est d'autant plus proche au départ que le débit et le rapport v/m sont élevés.

En quelques minutes, F atteint donc le point de rebroussement  $\text{R}_1$ , où le taux de sursaturation prend sa

valeur maximum. Simultanément, les flux de silice et de calcium atteignent une valeur très basse.

2ème étape : (Trajet  $\text{R}_1\text{R}_2$  sur le diagramme)

Le trajet de F s'incurve de manière à s'approcher tangentielllement de la courbe (1) établie par MENETRIER par une méthode différente (2). Le flux de calcium augmente jusqu'à un maximum et le flux de silice diminue jusqu'à un minimum lorsque F atteint le point  $\text{R}_2$ , proche de la courbe d'équilibre.

## 3ème étape :

Le point F remonte selon une courbe voisine de la courbe d'équilibre, située dans le domaine sursaturé. Pendant tout le trajet, on observe alors l'existence d'un "produit de solubilité apparent"  $\text{P}_{\text{CSH}} = a_{\text{Ca}^{++}} \cdot a_{\text{H}_2\text{SiO}_4^{2-}}$  traduisant un taux de sursaturation pratiquement constant. Dans un seul cas sur 22, où le débit de lixiviation et le rapport v/m étaient élevés, le trajet de F passe dans le sous-saturé, au cours de cette 3ème étape. Dans tous les autres cas, au bout d'un temps suffisamment long,  $\text{P}_{\text{CSH}}$  tend vers une limite commune à chaque essai, un peu supérieure à la valeur d'équilibre pour le CSH précipité ( $1,3 \cdot 10^{-7}$ ) au lieu de ( $7,22 \cdot 10^{-8}$ ).

Ce schéma se répète également lorsqu'on utilise des solutions de chaux ou chaux + gypse : les étapes sont alors parcourues plus rapidement et les flux ioniques plus faibles qu'avec l'eau. Le point  $\text{R}_2$  est situé plus bas, ce qui indique une solubilité plus faible des hydrates. Les dosages de  $\text{SiO}_2$  deviennent rapidement difficiles. Dans la 3ème étape, la concentration en chaux tend vers celle de la solution de lixiviation.

## 1.4 - Interprétations

Le niveau de sursaturation en CSH, maintenu malgré la dilution permanente par l'eau de lixiviation, la chute brutale, dès le départ, des flux de silice et de calcium, dans l'étape 1, le trajet suivi par le point F le long de la courbe (1), entre  $\text{R}_1$  et  $\text{R}_2$ , tout cela ne peut s'expliquer selon le mécanisme topochimique seul. Il faut donc admettre qu'il y a une contribution du mécanisme de LE CHATELIER à la réaction. Le trajet  $\text{R}_1\text{R}_2$  soit, en moyenne, la courbe I, apparaît alors comme la résultante d'une famille de trajets instantanés que l'on peut représenter vectoriellement sur le diagramme chaux-silice-eau (fig.4).

Fig.4 - Diagramme chaux-silice-eau

Vecteurs  $\text{OA}$ ,  $\text{BS}$ ,  $\text{DE}$ ,  $\text{FG}$  ... dissolution congruente  
Vecteurs  $\text{AB}$ ,  $\text{CD}$ ,  $\text{EF}$ ,  $\text{GH}$ ,  $\text{IJ}$  ... précipitation de CSH.  
La forme de ce trajet implique l'existence pour l'alite d'un produit de solubilité, ce que BARRET (3) a montré par des considérations thermodynamiques.  
La diminution du flux de calcium dans la 3ème étape peut s'expliquer par l'évolution de la surface spécifique (état stationnaire final avec concentration proportionnelle à la surface S). L'allure nettement diffusionnelle observée nous a cependant conduit à étudier la vitesse de précipitation des CSH et leur composition afin d'évaluer la part d'un éventuel mécanisme topochimique coexistant avec le mécanisme de LE CHATELIER (S2.1)

1.5 - Phénomènes secondaires - Réactions entre phases  
Ayant observé des taux de réaction anormalement bas pour le C<sub>3</sub>A lors des lixiviations par l'eau, nous avons dosé l'aluminium dans les filtrats pour plusieurs essais : l'hydratation du C<sub>3</sub>A, dont la période rapide se traduit par une augmentation du flux d'ions AlO<sub>2</sub><sup>-</sup>, ne commence que lorsque la concentration en SiO<sub>2</sub> a atteint une valeur suffisamment basse, en fin de 1ère étape de l'hydratation de l'alite. Ceci est en parfaite concordance avec l'existence de silico-aluminates mis en évidence par Mme. REGOURD (4) autour des grains de C<sub>3</sub>A, et empêchant son hydratation.

## 2 - MESURES EN SYSTEME FERME

### 2.1 - Cinétique de précipitation des CSH

Ayant confirmé l'existence réelle du mécanisme de LE CHATELIER, il reste à voir son importance par rapport à un éventuel 2ème mécanisme simultané : nous avons donc cherché à mesurer la vitesse de précipitation des CSH dans divers domaines de sursaturation. En utilisant des solutions pures de chaux et de silice, nous avons effectué 15 essais en plusieurs étapes permettant de suivre l'évolution de la composition chimique de la solution et du CSH précipité. L'ensemble des opérations a été conduit sous atmosphère d'azote. Les précipités de CSH ont été lyophilisés. Les vitesses de précipitation initiales ont été mesurées par conductimétrie et analyse chimique.

#### Résultats

Les vitesses observées sont très élevées. Elles augmentent avec les concentrations initiales en chaux et en silice, en suivant approximativement la relation :

$$-\left(\frac{dC}{dt}\right)_i = k (C_i)^{1/2} (S_i)$$

Les vitesses initiales sont donc proportionnelles au taux de sursaturation.

La courbe (I) correspondrait, d'après nos essais à des vitesses initiales de précipitation voisines de 4 mM/l.mn.

Ce chiffre nous donne un flux de précipitation extrêmement voisin du flux de dissolution, d'où la faiblesse de la concentration en SiO<sub>2</sub> en solution. La contribution du mécanisme de LE CHATELIER est donc très importante par rapport à tout autre mécanisme.

L'application de la formule IV du § 2.1 nous conduit à un flux maximum de dissolution de 58 μM/m<sup>2</sup>.mn, au maximum de l'exemple, résultat extrêmement voisin de celui de MENETRIER (2) obtenu par des méthodes différentes (60 μM/m<sup>2</sup>.mn).

Aux alentours de la courbe (I), la précipitation est limitée par la diffusion et on vérifie avec une bonne approximation la relation :

$$-\frac{d(SiO_2)}{dt} = 3,5 [(SiO_2) - (SiO_2)^*]$$

où SiO<sub>2</sub><sup>\*</sup> est la teneur à la saturation.

Cette relation permet de calculer la loi de variation de la distance d parcourue par les ions silicate, depuis l'interface réactionnelle jusqu'au site de précipitation. On obtient :

$$d = \frac{v}{3,5} \ln \left( \frac{X_0 - X^*}{X_d - X^*} \right)$$

où v = volume de solution      X<sup>\*</sup> = concentration à la saturation  
X<sub>d</sub> = concentration en SiO<sub>2</sub> à la distance d      X<sub>0</sub> = concentration à l'interface

Le rapport  $\alpha = \frac{X_d - X^*}{X_0 - X^*}$  représente la fraction non précipitée à la distance d, la précipitation étant totale lorsque X<sub>d</sub> = X<sup>\*</sup>. La fraction précipitée est donc (1 - α), fonction que nous avons représentée (fig.5) pour les conditions opératoires utilisées.

Fig.5 - Relation (1-r) = f(d)

En conclusion, la vitesse de précipitation est suffisamment grande pour que la majeure partie des CSH se forme à une très faible distance des grains, de l'ordre de l'épaisseur de la couche de diffusion, une faible proportion d'hydrates peut cependant se former à distance plus grande, à une vitesse plus faible, là où la solution est moins sursaturée.

On peut s'attendre à une différence de structure et de composition entre ces hydrates, formés dans des zones où les concentrations sont très différentes. En effet, nos résultats montrent bien la croissance du C/S avec les concentrations (le C/S varie linéairement entre 1,25 et 2 lorsque la teneur en chaux passe de 5 à 20 mM/l).

### 2.2 - Courbes de WELLS - Relation avec les courbes de lixiviation

Les courbes d'évolution ionique des suspensions de ciment en fonction du temps sont souvent appelées courbes de WELLS. Elles présentent des points remarquables bien connus (fig.6).

Fig.6 - Diagramme des flux en système fermé

- A<sub>1</sub> = fin de dissolution rapide
- A<sub>1</sub>A<sub>2</sub> = faible flux de calcium
- A<sub>2</sub>B = "période dormante"
- B = maximum de saturation ( 36 mM/l Ca)  
début de précipitation de Ca(OH)<sub>2</sub>
- B<sub>c</sub> = période de réaction rapide donnant lieu à la prise lorsque E/C est suffisamment bas.

Dans le cas des ciments, des points singuliers s'ajoutent à chaque apparition ou disparition d'une phase. Nous les avons étudiés par ailleurs (5).

Pendant la réaction en système fermé, le point figuratif F décrit un trajet parallèle à la courbe (I) à une distance dépendant du rapport v/m.

Lorsque l'on compare les diagrammes en système fermé et en système ouvert, on constate que la courbe inté-

grale du flux de calcium (système ouvert) redonne bien une courbe homologue de la courbe de concentration en système fermé, à la différence près, qu'en système fermé, la précipitation de la portlandite interrompt l'augmentation de la teneur en chaux. Par contre, l'intégrale du flux de silice donne une courbe différente de celle du système fermé, où le flux de silice prend une valeur négative dès les premières secondes : cette allure, obtenue aussi pour les faibles débits de lixiviation, indique une vitesse de précipitation supérieure à la vitesse de dissolution. Pendant la période dormante, c'est donc la lenteur de la dissolution de l'alite qui freine la réaction : la vitesse de dissolution diminue avec la sursaturation en chaux tandis que la vitesse de précipitation n'évolue plus au bout de quelques minutes : on se rapproche donc de plus en plus de l'équilibre. Le taux de sursaturation en CSH diminue et si rien ne vient perturber le quasi-équilibre obtenu, le taux d'hydratation restera faible.

### 3 - CONSEQUENCES = MODE DE CROISSANCE DES CSH

L'ensemble de nos observations nous amène à décrire le mode de développement des CSH au cours de chaque étape de l'hydratation de la manière suivante :

1) Hydroxylation superficielle de l'alite. Dissolution congruente rapide et formation des premiers germes de CSH au voisinage des défauts de réseau, où la vitesse de dissolution est maximum. La distance de précipitation passe par un minimum ; la croissance de CSH est surtout superficielle.

2) La vitesse de précipitation diminue. La vitesse de dissolution diminue beaucoup plus vite. La croissance des CSH est de plus en plus verticale au fur et à mesure que la silice en solution diminue ( $\text{SiO}_2 + \text{SiO}_2^2$ ). Le taux de réaction n'augmente pratiquement plus : c'est la "période dormante". Pendant cette période, les défauts de réseau ont fait place à des fissures d'où s'échappent les flux d'ions et les CSH, formés lentement, sont assez bien cristallisés. Leur C/S est relativement faible, car ils ont cristallisé dans une zone assez éloignée de l'interface, zone où la teneur en chaux est moins élevée.

3) La portlandite précipite, ce qui produit une brutale reprise de la dissolution de l'alite. La vitesse de précipitation de  $\text{Ca}(\text{OH})_2$  est plus faible que celle de CSH : elle cristallise en gros cristaux loin de l'interface. Le CSH est plus mal cristallisé et précipite plus vite et plus près de l'interface que précédemment : son C/S est plus élevé. Les fissures de l'alite s'agrandissent et forment des pores ouverts où le CSH cristallise. D'autres fissures les remplacent et fournissent des flux d'ions intenses : peu à peu la surface initiale est totalement remplacée par le CSH.

4) La réaction ralentit à nouveau, suite au recouvrement complet des grains d'alite par le CSH, laissant encore passer un faible flux d'ions. La vitesse de précipitation de  $\text{Ca}(\text{OH})_2$  diminue considérablement. La sursaturation en CSH diminue et la distance de précipitation augmente. La croissance du CSH se poursuit de plus en plus lentement selon un arrangement de type "corallien". Le C/S de ce CSH "externe" devient plus faible, sa structure est plus cristalline et il tend à combler les pores et à produire des ponts entre les grains, tandis que le mécanisme se poursuit (fig.7).

Fig. 7 - Croissance du CSH

### 4 - RECHERCHE D'UN MODELE MATHEMATIQUE DE LA CINETIQUE D'HYDRATATION

Après en avoir précisé les mécanismes, nous sommes maintenant en mesure de construire un modèle mathématique dont la forme sera adaptée à chaque étape de la réaction.

1ère étape : Dissolution congruente de l'alite avant le début de précipitation du CSH.

La précipitation du CSH ne peut intervenir qu'au moment où son produit de solubilité est atteint : le point figuratif de la solution se trouve alors à l'intersection de l'axe C/S = 3 et de la courbe de solubilité du CSH. L'alite va se dissoudre selon :

La vitesse de dissolution sera limitée seulement par la diffusion, selon une loi du type :

$$k_d = \frac{D_d}{e_d} (X_d^* - X) = \frac{\Delta}{v} = \frac{1}{S} \cdot \frac{dX}{dt} \quad \text{IX}$$

où  $k_d$  = vitesse de dissolution spécifique ( $\text{Ml}^{-1}\text{mn}^{-1}\text{m}^{-2}$ )

$D_d$  = coefficient de diffusion de l'ion X ( $\text{mn}^{-1}\text{m}^{-1}$ )

$e_d$  = épaisseur de la zone de diffusion (m)

$X_d^*$  = valeur de X à la saturation (M/l)

X = concentration de l'ion (M/l)

( $\Delta$ , S et v sont définis précédemment).

L'équation [IX] associée aux équations liant les concentrations permet de tirer

$$X = [B(1 - e^{-At})]^{1/3} \quad \text{[X]}$$

avec  $A \neq S \frac{D_d}{e_d} = 4,2 \text{ mn}^{-1}$   $B \neq 9,61 \cdot 10^{-21} = \frac{3PC_3S}{5}$

on constate que la saturation en CSH, qui est obtenue au point F<sub>1</sub> du diagramme, où  $(\text{CaO}) = 1,88 \text{ mM/l}$ ,  $\text{SiO}_2 = 0,627 \text{ mM/l}$  est atteinte quasi-instantanément ( $t < 10^{-3} \text{ s}$ ). Au delà de ce point, le rapport C/S de la solution sera alors de plus en plus supérieur à 3 (système fermé).

2ème étape : Au mécanisme de dissolution s'ajoute maintenant la précipitation dont la vitesse sera également limitée par la diffusion et suivra une loi du type (même terminologie que IX. Indices CSH)

$$k_p = \frac{D_p}{e_p} (X - X_p) = \frac{1}{S'} \cdot \frac{dX}{dt} \quad \text{[XII]}$$

La quantité  $dn_d$  d'alite dissoute pendant le temps  $dt$  va produire  $dn_p$  moles de CSH et  $dn_s$  moles de  $\text{SiO}_2$  en solution. Posons  $X = (\text{SiO}_2)$  totale en solution C = chaux totale et  $\alpha = \text{C/S}$  du CSH.

$$dn_s = dn_d - dn_p = \frac{v}{1000} \frac{dX}{dt}$$

$$\frac{dX}{dt} = \frac{1000}{v} (dn_d - dn_p) = S k_d - S' k_p$$

$$\frac{dX}{dt} = S \frac{D_d}{e_d} (X_d - X) - S' \frac{D_p}{e_p} (X - X_p) \quad \text{[XI]}$$

De même que pour la chaux :

$$\frac{dC}{dt} = 3 S \frac{D_d}{e_d} (X_d - X) - S' \alpha \frac{D_p}{e_p} (X - X_p) \quad \text{[XIII]}$$

En posant  $A = S \frac{D_d}{e_d}$   $B = S' \frac{D_p}{e_p}$ , on peut écrire l'équation [XI] sous la forme :

$$x = \frac{\frac{A}{B} X_d + X_p}{\frac{A}{B} + 1} - \frac{1}{A+B} \frac{dx}{dt}$$

qui montre bien que lorsque  $A/B \rightarrow 0$   $x \rightarrow X_p$  et  $A/B \rightarrow \infty$   $x \rightarrow X_d$

A/B étant le rapport des constantes de vitesse de dissolution et de précipitation.

On aura également :

$$\frac{dC}{dt} = 3 S \frac{D_d}{e_d} (C_d - C) - S \frac{D_p}{e_d} (C - C_p) \quad [\text{XIII}]$$

où  $D_d, D_p$  sont les coefficients de diffusion pour  $\text{Ca}^{++}$ . Pour chacune de ces relations différentielles, les conditions initiales sont définies par :  $C_0 = 3 X_0$ ,  $X_0 = X_p$ . Théoriquement,  $X_p$  et  $X_d$  sont données par les lois des équilibres de CSH et  $\text{C}_3\text{S}$ , liant les constantes thermodynamiques et les concentrations :

$$X_d = \frac{P_{\text{C}_3\text{S}} \left(1 + \frac{K_B}{(\text{OH}^-)}\right) \left(1 + \frac{(\text{OH}^-)^3}{K_3}\right)}{C^3 (\text{OH}^-)^5} \quad [\text{XIV}]$$

$$X_p = \frac{P_{\text{CSH}} [K_3 + (\text{OH}^-)] [K_B + (\text{OH}^-)]}{K_3 C (\text{OH}^-)} \quad [\text{XV}]$$

En pratique, on ne pourra définir un produit de solubilité théorique pour le CSH dont la composition est variable. On utilisera plutôt des relations expérimentales comme  $X_p \cdot C^{1/3} \cdot 10^{-13.36}$ , obtenue avec une très bonne approximation. Ainsi, connaissant l'équation approchée du trajet du point figuratif : pour la courbe (I)  $X \cdot C^{1/3} \cdot 10^{-13.36}$ , on débouche sur l'utilisation pratique du modèle (les valeurs de  $C_d$  et  $X_d$  peuvent être mesurées directement en fonction du pH).

Les formules ci-dessus montrent que toute réaction chimique consommant les ions calcium et  $\text{OH}^-$  va permettre d'augmenter la solubilité de l'alite : formation de complexes, que nous avons étudié par ailleurs (8) précipitations, dont le meilleur exemple est la précipitation de la portlandite.

3ème étape : Bien que manquant de données expérimentales sur la cinétique de précipitation de la portlandite permettant de compléter le modèle, on peut voir d'après les relations XIV et XV que la diminution de teneur en  $\text{Ca}^{++}$  et  $\text{OH}^-$  va augmenter plus rapidement  $X_d$  que  $X_p$ . Le système sera donc déplacé vers un nouvel état beaucoup plus sursaturé en CSH, où la vitesse de dissolution de l'alite est plus grande. De même, en présence d'ajouts comme le laitier qui consomment de la chaux durant cette étape, l'équilibre de solubilité de l'alite sera déplacé, ce que nous avons étudié par ailleurs (6).

4ème étape : Pendant cette étape, les vitesses sont fortement diminuées par la diffusion à travers les hydrates et le calcium en solution est peu à peu remplacé par des alcalins, ce qui augmente le pH et freine encore la dissolution de l'alite ( $X_d$  diminue). Pour utiliser les relations précédentes, il reste à déterminer  $X_d$ ,  $X_p$  et  $C$ , dans des milieux de composition chimique voisine.

#### CONCLUSION GENERALE

La méthode expérimentale indirecte par laquelle nous avons abordé le mécanisme de l'hydratation s'est révélée très fructueuse : les résultats obtenus démontrent la prépondérance du mécanisme de dissolution-cristallisation imaginé par LE CHATELIER.

Seul ce mécanisme permet en effet d'expliquer le comportement des concentrations pendant la réaction. Il explique également l'existence de la "période dormante" des ciments et les phénomènes de couplages chimiques entre les réactions d'hydratation des constituants des ciments, que nous avons observé ici, et étudié en

détail par ailleurs (5). A ce titre, la précipitation de la portlandite apparaît comme indispensable à la reprise de l'hydratation produisant la prise et permettant l'évolution des résistances. D'autre part, nos mesures montrent que la vitesse de précipitation est très élevée et qu'en conséquence, le CSH cristallise au voisinage immédiat de l'interface, à une distance variable selon le taux de sursaturation. Cette observation permet d'expliquer le mode de croissance particulier du CSH, selon une progression "corallienne". Disposant d'une théorie globale cohérente reliant le comportement cinétique des ciments en système ouvert à celui en système fermé et en parfait accord avec toutes les observations connues, nous en avons tiré un modèle mathématique théorique possédant une véritable signification physique. L'application pratique de ce modèle permet actuellement de prévoir l'action de certaines variables chimiques sur la vitesse d'hydratation et d'expliquer ainsi, de manière qualitative, l'influence des constituants mineurs solubles, des adjuvants, et des anomalies de l'eau de gâchage.

Après avoir précisé par des mesures expérimentales les constantes de vitesse et les relations entre paramètres, cette théorie doit nous permettre de déterminer les caractéristiques intrinsèques de solubilité des ciments, dans des conditions à choisir. Ces caractéristiques, définissant de manière précise le terme d'hydraulicité pourront être reliées à des caractéristiques de structure et de forme allotropique des phases, établissant ainsi un lien entre l'histoire thermique du produit au cours de la cuisson et son histoire cinétique au cours de l'hydratation.

#### REMERCIEMENTS

Les auteurs remercient M. MAES, technicien au CEREG, pour sa contribution importante à l'étude, en ce qui concerne les analyses quantitatives en diffraction X.

# La régularité et la théorie d'hydratation des liants

## *Regularity and theory of binder hydration*

V.V. KAPRANOV, docteur, chef de la chaire de la Construction, l'Institut Polytechnique de Tchéliabinsk, av. Lénine, 76, 454080, U.R.S.S.

**RESUME:** Cette communication est consacrée à l'étude de la nouvelle voie scientifique dans la recherche des processus d'hydratation. L'auteur a essayé de mettre en évidence la régularité et de donner la théorie mathématique d'hydratation se basant principalement sur la recherche des forces motrices intérieures et sur la direction énergétique des stades à part du processus. On développe les modèles physiques et mathématiques des stades à part du processus d'hydratation, on déduit les relations pour l'étude de l'interaction des particules des phases liquides et solides compte tenu de la structure, des tailles, des charges des ions et des autres propriétés physico-chimiques de la substances. La régularité de chaque processus élémentaire reflète la liaison des phénomènes d'hydratation avec les propriétés des substances avec l'abaissement ininterrompu du niveau de libre énergie du système. La théorie d'hydratation permet de révéler le mécanisme du processus et de déterminer les traits particuliers du processus et les voies d'influence sur lui en changeant les paramètres du système. La théorie proposée montre les voies de perfectionnement de la technologie du ciment et du béton, la création des substances dont la structure est donnée avant. La coïncidence des caractéristiques de calcul du processus avec l'expérience confirme la régularité révélée.

Comme il est impossible de donner les calculs précis du système étudié, l'auteur propose de considérer les résultats obtenus comme la première approximation, dont la précision revendique la création des méthodes de calcul plus précises et l'obtention des données supplémentaires suivant la structure des substances, la distribution de la densité électronique etc.

**SUMMARY :** The paper is devoted to development of a new scientific trend dealing with research into hydration processes. An attempt has been made to reveal objective laws governing hydration and to elaborate a mathematic theory of the latter on a completely new basis - that of research into internal motive forces and power directivity of some phases of the process.

There have been worked out physical analogs and mathematical models of the hydration process. Formulas have been derived for investigation of interaction of liquid and solid particles in view of their structure, size, ionic charges, and other physical-and-chemical properties of substances.

Objective laws governing each elementary process reflect the connection between the phenomena occurring through hydration and basic properties of reacting substances as well as constant decrease in the free energy level of the system.

The elaborated hydration theory makes it possible not only to reveal the process mechanism but also to theoretically determine the process characteristics as well as the ways of influencing the process by change of specific parameters. The theory shows the means of improving cement and concrete technology as well as of creating materials with a preset structure. Good coincidence of the process design characteristics with experimental data proves the objectivity of the revealed laws and a sufficient reliability of the theory.

Accurate calculations for a very complex system under investigation being impossible, the results obtained should be regarded as the first approximation. To make it more accurate more perfect methods of calculation should be elaborated and additional data on the structure of substances, electronic density distribution and others should be obtained.

Il est à noter que le 7<sup>e</sup> Congrès International sur la Chimie des Ciments se passe à Paris, où il y a cent ans Le Chatelier publia ses premiers travaux concernant la théorie de durcissement. (1,2). Il écrit: "Cette théorie peut encore expliquer la prise de tous les autres ciments et mastics, dont le durcissement ne résulte plus d'une simple hydratation, mais de la combinaison des différents corps déjà plus ou moins hydratés" (2, p.1056).

Dans la communication présente on donne les résultats des études sur le développement et le perfectionnement de la théorie de Le Chatelier et des travaux théoriques des autres savants (Brumauer, Mohedlov-Petrosyan, Sytchov, Polak etc). On se base sur les revendications modernes prévoyant la direction de la réaction, sa régularité essentielle, la structure du liant et les voies d'influence sur le processus.

L'hydratation - c'est le processus de la liaison d'eau par des agents chimiques. En somme, la marche de n'importe quel processus chimique est causée par les interactions électromagnétiques entre les particules du système (les ions, les molécules).

Ainsi, la base méthodologique des études est la détermination théorique des forces motrices intérieures du processus et sa directions énergétique sur toutes les étapes: de l'adsorption à la formation de la structure.

La série des relations d'énergie d'interaction entre les particules du système était exposée au 6-e Congrès (3) et plus tard (4).

Au temps dernier on a réussi à calculer le processus d'hydratation du plâtre semi-hydraté et mettre en évidence sa régularité particulière, déduire la relation de la résistance théorique de la pâte de ciment etc. On donne ci-après les relations essentielles de calcul à l'aide desquelles on peut étudier le processus élémentaire d'hydratation des liants, la régularité et le mécanisme des stades à part.

L'adsorption des particules des phases liquides sur la surface du liant est le premier processus élémentaire d'hydratation. Pour calculer l'énergie d'interaction de l'ion ( $H^+$ ,  $OH^-$ , les ions du soluté) avec le cristal on peut utiliser la relation déduite dans le travail (3) basée sur la méthode quantique.

Mais la relation

$$U = - \frac{q^2 (\epsilon_2 - \epsilon_1)}{8\pi \epsilon_0 \epsilon_1 (\epsilon_2 + \epsilon_1) r} \quad (1)$$

est aussi valable, où  $\epsilon_0$ ,  $\epsilon_1$ ,  $\epsilon_2$  - constante diélectrique du vide par rapport à l'eau et au cristal,  $q$  - charge des ions de la phase liquide,  $r$  - distance entre le cristal et l'ion. On utilise également la relation déduite sur la base de l'équation de Borne

$$U = - \frac{0,728 q_1 q_2}{4\pi \epsilon_0 \epsilon_2} \sum \frac{N_1}{r_1} \quad (2)$$

où  $N_1$  - quantité des ions du cristal (compte tenu de signe) disposés à la distance  $r_1$  de l'ion de la phase liquide. On a obtenu les relations analogiques pour le système molécule cristal-dipôle  $H_2O$ , de la molécule PAV.

L'analyse des relations montre que l'énergie de l'adsorption monte avec l'augmentation de la charge d'ion ou avec le moment dipôle de la molécule, de la constante diélectrique du cristal et avec la diminution de la constante diélectrique de l'eau. L'énergie d'adsorption d'ion dépasse celle-ci de la molécule. A partir de cette régularité le processus active d'adsorption sera la dissociation électrolytique de l'eau. L'effet d'écran PAV accroit avec l'augmentation du moment dipôle et avec la diminution des tailles des molécules PAV. Le calcul théorique de l'épaisseur de la couche diffusante aux limites de laquelle les particules de la phase liquide possèdent l'énergie de liaison avec le cristal pas moins que  $KT$ , c'est-à-dire de l'énergie thermique moyenne de la molécule, est conduit à la valeur de 10-12 Å ce qui s'accorde bien avec l'expérience.

#### LA DISSOLUTION DES LIANTS

Dans les différentes théories de durcissement ce processus ainsi que ceux de la surface se discute beaucoup, mais en même temps il est peu étudié. La régularité révélée des processus sur la surface des cristaux ioniques (les liants sont les représentants) lors de l'interaction avec l'eau montre l'inévitabilité d'hydratation superficielle. Le fait le plus important est celui que l'interaction des ions  $O^{2-}$  (ou  $SO_4^{2-}$ ) et  $Ca^{2+}$  avec l'eau conduit au dégagement de l'énergie dépassant celle des liaisons ioniques avec le cristal.

Ce n'est que cela qui détermine la possibilité d'arrachage d'ion du cristal et leur passage à la phase liquide c'est-à-dire - la dissolution. La condition générale de la dissolution est le dépassement d'énergie d'hydratation superficielle sur celle de la liaison de la particule avec le cristal:  $U_{h.s.} >$

$U_1$ . Ceci est montré par des calculs pour les cristaux ioniques du type sodium chlorure dont le trait particulier est le dégagement des paires ioniques dans la phase liquide. Pour le plâtre les calculs montreraient que la dissolution passe les étapes suivantes:

- l'adsorption de l'eau sur la surface du cristal avec le dégagement d'énergie 122 kJ/Mol (ici et plus loin on donne les effets moyens énergétiques) obtenu lors de la déduction des relations (1) ou (2);

- les processus sur la surface avec le dégagement d'énergie en quantité de 587 kJ/Mol suivant la méthode expliquée dans (4) (la formation des liaisons chimiques, la dissociation de la molécule d'eau  $H_2O \rightarrow H^+ + OH^-$ , le passage des électrons des ions  $SO_4^{2-}$  de

- la surface aux ions  $H^+$  de la phase liquide et des ions  $OH^-$  aux ions  $Ca^{2+}$  de la surface;
- l'arrachage des produits de la réaction du cristal sous l'influence d'énergie dégagée en excès (l'énergie de liaison des molécules

CaSO<sub>4</sub> avec le cristal) obtenu par le calcul électrostatique du réseau suivant la relation (2) est égale à 697 kJ/Mol; - le dégagement des produits moléculaires de la réaction dans le volume de la phase liquide.

Ce mécanisme de la dissolution est plus avantageux et conduit au dégagement d'énergie en quantité de  $122 + 587 - 697 = 12$  kJ/Mol ce qui est proche à l'expérience (19,2 kJ/Mol). Les calculs ont montré que pour CaO se passe la rupture de liaison Ca - O dans les produits de la réaction sur la surface et le dégagement des ions CaOH<sup>+</sup> et OH<sup>-</sup> dans le volume de la phase liquide. Le dégagement général d'énergie - 56 kJ/Mol (suivant l'expérience  $54 \div 65$  kJ/Mol). L'excès d'énergie favorise l'arrachage et la transition des produits de la réaction dans le volume de la phase liquide. Suivant la relation d'énergie de transition on déduit cette voie:

$$A = E_n = \int_{r_1}^{r_2} \frac{q_1 q_{\text{cond}}}{4\pi \epsilon_0 \epsilon_1} dr = \frac{q_1 q_{\text{cond}}}{4\pi \epsilon_0 \epsilon_1} \left( \frac{1}{r_1} - \frac{1}{r_2} \right), \quad (3)$$

où  $q_{\text{cond}}$  - charge conditionnée superficielle du cristal (déduite suivant la relation (1))  
où on suppose que :  $q_1$  - charge d'ion arraché,  
 $U$  - énergie calculée de liaison,  $q_2 = q_{\text{cond}}$ ;  
 $E_n$  - énergie dégagée lors de la réaction;  
 $r_2$  - rayon d'ion superficiel arraché. La voie de déplacement de la surface ( $r_1 - r_2$ ) est égale 3-15 Å, après quoi le mouvement est conditionné par les lois de diffusion.

Comme au ciment les restes du groupes d'ions (autre CaO) s'hydratent pratiquement sans dégagement d'énergie, leur dissolution du clinker ne se passe qu'après l'élimination des ions, Ca<sup>2+</sup> et O<sup>2-</sup> étant la combinaison. Leur déplacement du grain du ciment est négligeable. Ainsi, nous voyons que les tétraèdres SiO<sub>4</sub> restent sur la surface ou près d'elle et se polymérisent (5,6). Les calculs théoriques montrent pourquoi dans la phase liquide du ciment durcissant le contenu des ions Ca dépasse à 10-100 celui de la silice. Avec ce caractère de la dissolution du ciment la surface de la réaction se déplace à l'intérieur du grain. Le passage de la phase liquide à cette surface et l'élimination des produits de la réaction se passe dans les conditions de la diffusion en solide. Pour cette dissolution incongruente des liants (le ciment et le monominéral) la relation de la cinétique d'hydratation est déduite

$$C = C_0 \left[ 1 - \frac{4 \sin \xi}{\pi \xi} \exp\left(-\frac{t}{\tau}\right) \right], \quad (4)$$

où  $C$  - Concentration des molécules d'eau dans la couche du grain du ciment,  $C_0$  - concentration des molécules au dehors de la particule (qu'elle soit égale à 1),  $\xi = r/R_2$  - rayon adimensionnel de la particule,  $\tau = R^2/D$  - paramètre temporaire de la relaxation du processus. ( $R$  - rayon de particule,  $D$  - coefficient

de diffusion),  $t$  - temps. Pour les liants dissolutifs d'une manière congruente (plâtre, chaux, monominéraux aux conditions déterminées) on déduit la relation de cinétique d'hydratation:

$$N_t = N_0 \sqrt{\frac{t}{\tau}} \exp \frac{R^2}{4D} \left( \frac{1}{\tau} - \frac{1}{t} \right), \quad 0 < t < \tau, \quad (5)$$

où  $N_t$  - nombre des ions diffusés vers le liquide;  $N_0$  - nombre des ions dans le grain,  $\tau = R^2/4D$  - paramètre temporaire de la relaxation du processus.

Les calculs suivant des relations (4) et (5) montrent le processus d'hydratation. Ils donnent la possibilité de faire la courbe de la cinétique d'hydratation et de déterminer le temps d'hydratation. Pour les particules du ciment de  $10^{-5}$  à  $10^{-7}$  m: il se change de quelques heures à une année. Pour le plâtre le temps d'hydratation est de quelques secondes à la dizaine de minutes. Les résultats obtenus correspondent à ceux de l'expérience.

#### LA FORMATION DE LA SOLUTION SATURÉE

L'étude énergétique montre que la condition limitée inférieure de la formation de solution saturée est l'égalité d'énergie d'interaction des ions dissous et de la moyenne thermique :  $U = KT$ . Suivant cette condition de la relation

$$r = \frac{q_1 q_2}{4\pi \epsilon_0 \epsilon_1^m U} \quad (6)$$

on peut déterminer la distance entre les ions de la solution saturée et de cette manière sa concentration. La condition  $U = KT$  se garde aux distances de 21, 30 et 40 Å pour l'interaction ionique des homocharges, homocharges avec bicharges et bicharges. Ayant appris les charges des ions et les distances entre eux il est facile de déterminer la concentration de la solution saturée. Pour le plâtre et l'oxyde de calcium elle est 12,7 et 5 g/l (suivant l'expérience 8-11 et 3,6 - 7,2 g/l respectivement).

#### LA GERMINATION CRISTALLINE

La relation déduite

$$R_{g.c} = \frac{(\epsilon_2 - \epsilon_1) q^2}{4\pi(\epsilon_2 + 1,5\epsilon_1)\epsilon_0\epsilon_1} \cdot \frac{(\epsilon_2 - \epsilon_1) q^2}{8\pi(\epsilon_2 + 1,5\epsilon_1)\epsilon_0\epsilon_1 r} - U \quad (7)$$

donne la grosseur du germe cristallin, où  $q$  - charge d'ion décantant sur le germe (sur la surface du petit cristal dans le cas général);  $r$  - distance entre le germe et l'ion;  $U$  - énergie d'interaction entre les mêmes composants, égale à l'énergie de la liaison intermoléculaire de la structure de l'eau  
1.1. si, pendant la cristallisation les ions ne se dégagent pas de l'enveloppe hydratée, ou égale à l'énergie d'interaction des ions avec la molécule dipôle de l'eau  
"ion-dipôle" si les ions se dégagent de l'en-

veloppe hydratée. Dans ces conditions la valeur des rayons du germe critique compose quelques angstroms (5-16).

Le résultat le plus important est celui qui permet de déterminer suivant (7) la sphère d'attraction  $r$  des ions par les cristaux de tailles différentes. La sphère d'attraction c'est la distance de la surface du cristal vers lequel tous les ions dissous s'attirent. Il est évident qu'avec la taille du cristal la sphère d'attraction s'accroît. La régularité découverte de la germination montre que la diminution de la rayon du germe critique est possible lors de l'augmentation des charges des ions de la substance cristalline, lors de l'augmentation de sa constante diélectrique mais aussi lors de la diminution de cette dernière du solvant. Ce phénomène est lié à la sursaturation suivant la relation de Tomson et diminue avec l'augmentation de la sursaturation, mais ce phénomène montre encore des autres voies: l'introduction des additions chimiques - les électrolytes, l'action des champs électriques et magnétiques.

#### LA PERIODE D'INDUCTION DU DURCISSEMENT

Se basant sur les connaissances énergétiques la période inductive est conditionnée par le mécanisme de la germination des cristaux, pendant lequel se passe non seulement la cristallisation, mais encore la dissolution des cristaux, n'ayant pas de tailles critiques. Ceci se confirme: aux conditions que  $U = U_{l.1}$  on peut trouver le volume et la masse<sup>1.1</sup> des germes dont la quantité est

$$N = \frac{1}{(2R_{g.c.} + 1)^3} \quad (8)$$

où  $R_{g.c.}$  - rayon du germe critique; 1 - épaisseur<sup>g.c.</sup> de la couche d'eau entre les surfaces des germes, déduite suivant la relation (6)  $1 = r - (R_1 + R_2)$  où  $R_1$  et  $R_2$  - rayons des ions de la surface des germes. Pour les ciment la masse des germes est 5-7% de tout le liant ce qui s'accorde bien avec l'expérience d'hydratation, correspondante à la fin de la prise du ciment et au commencement du deuxième pic exothermique du dégagement de chaleur.

#### LA CROISSANCE DES CRISTAUX DE L'HYDRATE

est conditionnée par le fait que, outre le gradient de concentration, la force motrice pour les ions des substances dissoutes est le dépassement d'énergie d'attraction vers les cristaux des hydrates par rapport au grain du liant jusqu'à 50%, déduit suivant la relation (7), lors de l'augmentation simultanée de la sphère d'attraction jusqu'à 150%. Ceci explique que la constante diélectrique des hydrates est supérieure de celle-ci du liant initial et compose 10,6 contre 7,47 pour le ciment.

Il est naturel que la régularité de croissance des cristaux est évident après la formation des germes de tailles critiques et notamment après que la couche d'eau entre le

grain du liant et les hydrates cristallins est devenue moins que les deux sphères d'attraction des particules; déduite suivant la relation (7) par rapport à  $r$ . Suivant la croissance des particules des hydrates cristallins, l'énergie de liaison ionique de la substance dissoute grandit ce qui provoque l'accélération du mouvement et l'augmentation du volume de la substance du ciment initial par rapport aux particules hydratées. Les calculs énergétiques confirment le caractère sigmatique de la courbe cinétique de l'hydratation. Dans la période initiale on n'observe pas leur croissance quand la distance entre les germes cristallins de l'hydrate est grande. Mais à mesure que la distance entre les particules différentes et la structure diminue, apparaissent les conditions pour la croissance prépondérante des cristaux ayant la grande valeur de la distance diélectrique. Par exemple, les hydrocillates du Ca (C-S-H) dans le rapport  $\text{CaO/SiO}_2$  étant 2, 1,5 et 0,83 ont la constante diélectrique atteignant 13, 14,2, 19 respectivement. Donc, la diminution de la basicité des hydrocillates pendant l'hydratation conforme à la régularité, ce qui correspond à l'expérience.

#### LE CHANGEMENT D'ETAT DE LA PHASE LIQUIDE

Le fait essentiel, déterminant l'énergie d'attraction des particules dissoutes, causant la dissolution, la germination et le durcissement est la constante diélectrique du solvant: Se basant sur la théorie du changement de la constante diélectrique de l'eau  $\epsilon$ , tout près d'ion, proposée par Debye (7), on a révélé l'expression de la constante diélectrique moyenne de l'eau entre les ions:

$$\epsilon_1^m = \frac{2}{r} \int_0^r f(r) dr \quad (9)$$

où  $f(r)$  - fonction  $\epsilon$ , de  $r$  suivant la théorie de Debye,  $r$  - distance entre les ions. On a déduit les valeurs  $\epsilon_1^m$  pour les ions dont la distance est différente (tableau). On ne prêtait aucune attention au changement d'état de la phase liquide, outre les travaux de M. Sychev (8), bien que cet état influe sur le mécanisme d'hydratation.

TABEAU 1

$r, \text{\AA}$	0	2	6	10	20	40	50
$\epsilon_1^m$	1	1,8	2,2	6,3	24,5	57	78

La particularité de l'eau changer la constante diélectrique près d'ion et de la surface ionique est la base pour la dissolution. Ceci est bien prouvé par les calculs énergétiques réfutant l'opinion que le pouvoir dissolvant de l'eau est conditionné par la haute constante diélectrique. Il s'est trouvé que l'eau d'un côté assure la bonne dissolution des substances en diminuant la constante diélectrique dans la zone du contact avec le cristal jusqu'à 1. D'un autre côté l'eau assure la conservation du

SOLvant aux grandes distances entre les ions, puisque la constante diélectrique de l'eau augmente (à 80) ce qui diminue l'énergie d'attraction entre les ions dissous. Le changement du contenu ionique  $H^+$  et  $OH^-$  a la grande importance puisqu'il détermine le mécanisme d'hydratation, surtout pour les substances difficile à dissoudre. Il est montré que l'influence des températures sentent à travers l'augmentation de la dissociation électrolytique mais non pas à travers l'augmentation du contenu des molécules actives déquites suivant la loi de distribution de Boltzman. Il est prouvé que le coefficient d'accélération de réaction est corrélatif avec celui d'augmentation de la concentration des ions  $H^+$  et  $OH^-$ . Suivant la relation  $f = C_x/C_0$  on déduit le coefficient de température d'accélération de réaction, où  $C_x$  et  $C_0$  - concentrations des ions  $H^+$  respectivement aux températures  $T_x$  et  $T_0$ .
