## **SUB-THEME I - 1**

**Influence of the nature  
and preparation  
of raw materials  
on the reactivity of raw mix**

**R. BUCCHI,  
Italcementi spa, ITALIA**

## 1. INTRODUCTION.

It is said that a cement factory arises where a market of such a product exists and where deposits of raw materials suitable for production are available. In the practice the first condition always (or almost always) keeps its strictness whereas the second one is often compromised by other needs till to be reduced to the banal requisite to merely give the four fundamental oxides in the proportions demanded.

However experience shows that nature and characteristics of rocks and, generally, of the materials used for the raw meal involve important consequences on investments, operating costs and quality of the cement produced.

It seems therefore reasonable that the cement industry devotes greater attention to the study of raw materials and the methods used for their preparation.

## 2. REACTIVITY AND BURNABILITY.

**2.1 Definitions.** The raw mix is a system consisting of several components in finely dispersed phases. It transforms into clinker through a series of reactions between about 400° and 1450°C. Its reactivity is defined by the overall rate of these reactions at the temperatures completing them in practically suitable times. So as is defined with reference to a given mix, the reactivity prescind from every quality attribute of the obtained clinker. On the contrary it has a considerable influence on the energy consumption of the process and the capacity of the plant.

The concept of reactivity differs from that of burnability, as the derivative of a function differs from the function itself (or from the value which the latter takes for given values of the variables).

**2.2 Expression of CaO in the mix during burning.** Since the fundamental constituents of clinker are all calcium compounds, the transformed CaO gives a suitable measure of the advancement of the overall process. The amount  $\Gamma$  of CaO, in a given form of combination present at any moment and temperature, can be expressed in different terms (the formulas without mark represent concentrations of the corresponding chemical species in the raw meal, in homogeneous unities of mass %):

between about 400°C and 1000°C, as degree of decarbonation  $\varphi$  (1, 2):

$$\varphi = 1 - \frac{CO_2'}{CO_2}, \text{ undim.} \quad [1]$$

where  $CO_2'$  is the mass % of  $CO_2$  in the transforming mix;

forming mix;

- between about 700°C and 1450°C, as free CaO:
- $CaO_f$ , in the l.o.i.-free mix, mass %;
- $F_{CaO_f}$ , fraction of  $CaO_f$  with respect to total  $CaO_t$  ( $F_{CaO_f} = CaO_f / CaO_t$ ), undim.;
- $S_{CaO_f}$ , fraction of  $CaO_f$  with respect to the saturation CaO calculated according to Lea and Parker (see TAB. II), undim.;
- $H_{CaO_f}$ , fraction of  $CaO_f$  with respect to the hydraulic factors ( $H_{CaO_f} = CaO_f / (SiO_2 + Al_2O_3 + Fe_2O_3)$ ), undim.;

- between about 400°C and 1450°C, as burning degree  $\alpha$  (2):

$$\alpha = 1 - \frac{1.27 CO_2' + 0.7 SO_3' + CaO_f}{CaO_t}, \text{ undim.} \quad [2]$$

where  $CO_2'$  and  $SO_3'$  are the mass % of  $CO_2$  and  $SO_3$  in the transforming mix, in unities homogeneous with those of  $CaO_f$  and  $CaO_t$ . (The term  $0.7 SO_3'$  must be neglected when  $SO_3 \neq K_2O + Na_2O$ , in molar concentrations).

Only  $\alpha$ ,  $\varphi$  and  $F_{CaO_f}$  versus the processing time and temperature correctly express a measure of the burnability of the mix. Their derivatives versus time (or, on the average, the ratio of the finite variations of functions to the time intervals when these variations occur) measure the reactivity, for given constant temperatures. The quantities  $S_{CaO_f}$  and  $H_{CaO_f}$ , considered by Longuet & Courtault (3) and Pfrunder and Wickert (4) respectively, concern in some way the burnability of the components of the mix rather than that of the mix itself.

## 2.3 Course of the CaO transformation.

**2.3.1**  $\alpha = f(t, \theta)$  describes the CaO transformation versus the temperature  $t$  and the reaction time  $\theta$ . It is represented, in the space  $(\alpha; t; \theta)$ , by a curved surface whose intersections by planes almost parallel to  $(\alpha; \theta)$  for  $t_1 \approx \text{const.}$  and to  $(\alpha; t)$  for  $\theta_1 \approx \text{const.}$  (pseudo-isotherms and pseudo-isochrones of reaction respectively (\*)) are experimentally determined.

**2.3.2** The trend deducible from the literature data (5, 6) of a pseudo-isochrone is schematically represented in FIG. 1. The reaction velocity increases in two temperature ranges:

between  $t_1$  and  $t_2$  (about 850°C and 950°C) when  $K_p$  of the  $CaCO_3$  dissociation sharply increases (7). The first free CaO appears

(\*) Actually, in practice, these planes result not strictly  $t = \text{const.}$  or  $\theta = \text{const.}$ , but more or less inclined with respect to  $(\alpha; \theta)$  or  $(\alpha; t)$  because of the variability (with  $t_1$ ) of the time and the temperatures reached to bring a sample to the test temperature  $t_1$ .

in this interval whereas  $\text{CaCO}_3$  has already disappeared at  $t_2$  (8);

- between  $t_3$  and  $t_4$  (about  $1250^\circ\text{C}$  and  $1300^\circ\text{C}$ ) where the  $\text{C}_3\text{S}$  formation starts.

The values  $t_1$ ,  $t_2$ ,  $t_3$  and  $t_4$  and those of the corresponding ordinates are typical of the reactive properties of the mix.

2.3.3 The portion of pseudo-isochrone  $\varphi=f(t)$  for  $\theta_i \approx \text{const.}$  between about  $400^\circ\text{C}$  and  $t_2$  is called decarbonation function (9). FIG. 2 shows some examples derived from Vogel's (2) and Ritzman's (9) papers. These functions, characterizing the decarbonation and the first reactions in the solid phase,

FIG. 1. PSEUDO-ISOCCHRONE OF REACTION.

are greatly important in the study of the calcining processes outside the kiln (10).

2.3.4 The portion of pseudo-isochrone between  $t_2$  and about  $1450^\circ\text{C}$ , expressed by  $\text{CaO}_f=f(t, \theta)$  for  $\theta \approx \text{const.}$ , is exponential:

$$\text{CaO}_f = e^{a-bt} (\theta_i \approx \text{const.}), \text{ mass \%} \quad [3]$$

and it has two different trends (different couples of the constants  $a$  and  $b$ ) in the  $t_2 - t_3$  and  $t_3 - 1450^\circ\text{C}$  ranges. These trends characterize the diffusion processes in the solid phase and in the presence of the liquid phase, respectively. FIGS. 3 and 4

show the functions of four typical mixes of which the literature (11, 12) and other sources (13, 14) give the necessary number of couples of values ( $\text{CaO}_f$ ,  $t_i$ ).

TAB. 1 summarizes the values of  $a$ ,  $b$  and  $t_3$ .

2.3.5 The portion of pseudo-isotherm between  $t_2$  and about  $1450^\circ\text{C}$ , expressed by  $\text{CaO}_f=f(\theta, t)$  for  $t \approx \text{const.}$ , is a logarithmic function (4, 13):

$$\text{CaO}_f = k - h \ln \theta \quad (t_i \approx \text{const.}), \text{ mass \%} \quad [4]$$

(with constant  $k$  and  $h$ ), at least in the  $0' \leq \theta \leq 30'$  range for  $t_i = 1380^\circ\text{C}$  (4). FIG. 5 shows some examples (12, 13).

2.4 Measure of burnability. It is expressed by one

FIG. 2. FUNCTIONS OF DECARBONATION. AFTER VOGEL (2) AND RITZMANN (9).

of the following quantities (determined under strictly reproducible conditions):

- measure of  $\text{CaO}_f$  of a pseudo-isochrone at given  $t_i$ . Examples:  $30'$  and  $1300^\circ\text{C}$  or  $1400^\circ\text{C}$  (15);  $45'$  and  $1450^\circ\text{C}$  (16);  $42'$  and  $1450^\circ\text{C}$  (13);  $15'$  and  $1450^\circ\text{C}$  (3);  $15'$  and  $1370^\circ\text{C}$  (4);  $15'$  and  $1400^\circ\text{C}$  (17); a.s.o. Increasing values of  $\text{CaO}_f$  correspond to decreasing reactivities (\*);
- measure of  $\theta_i$  of a pseudo-isotherm, necessary so as  $\text{CaO}_f$  becomes equal to or lower than a fixed value. Example:  $\theta_i$  for  $\text{CaO}_f \leq 2\%$  at  $1350^\circ\text{C}$  (18). Increasing values of  $\theta_i$  correspond to decreasing reactivities (\*);

(\*) Therefore this quantity expresses more precisely a reluctance to burning (13).

factor  $K_{su}$ . Sulikowski (11) characterizes the burnability as the ratio of  $CaO_f$  to the maximum of  $CaO_f = f(t)$  in the  $700^\circ C \leq t \leq 1400^\circ C$  range,  $\theta$  being of few seconds:

$$K_{su} = \frac{CaO_f}{CaO_{fmax.}}, \text{ undim.} \quad [5]$$

The measure is based on the thesis that the maximum quantity of  $CaO_f$  released during the process should be the lower the more reactive the mix.  $K_{su}$ , always  $> 1$ , increases as the reactivity rises;

factor AC. Blaise et Al. (12) rightly think that the evaluation of the burnability demands

FIG. 3. FUNCTIONS  $CaO_f = e^{a-bt}$  IN LINEAR CO-ORDINATES.

a quantitative expression related to the  $CaO_f = f(t, \theta)$  trend in the overall  $1000^\circ$  et  $1450^\circ C$  range. This requirement is satisfied by the ratio of a constant (=600) reference surface ( $CaO_f$ ; t) area to the one integral (\*) of the abo-

FIG. 4. FUNCTIONS  $CaO_f = e^{a-bt}$  IN SEMILOGARITHMIC CO-ORDINATES.

ve function for fixed  $\theta_i$  in the aforesaid temperature range:

$$AC = \frac{600}{C_0 + 2C_1 + 2C_2 + 3C_3 + 4C_4 + 4C_5 + 2C_6}, \text{ undim.} \quad [6]$$

where  $C_0 \dots C_6$  are the values of  $CaO_f$  at seven different increasing  $t_i$ , for  $\theta_0 = 20'$ ,  $\theta_1 = 20' + 20' \dots \theta_6 = (6 \times 20') + 20' (**)$ . The reproduci-

(\*) see factor AC in paragraph 2.4.

(\*) Suitably enlarged for the highest temperatures.

(\*\*) The times necessary to pass from each level of temperature to the next higher one are added to these times. Consequently a  $CaO_f = f(t, \theta)$  quite different from both the isochrones and the isotherms is obviously used.

bility of the measure is ensured by strictly controlled working modes.

The inadequacy of the first three methods, expressing the measure of the burnability by means of the co-ordinates of an only point of  $\text{CaO}_f = f(t, \theta)$  is obvious. On the contrary, the factor AC seems to be more interesting in this connection. It has the advantage of considering the overall course of the  $\text{CaO}$  combination in the presence of liquid, the trend of the reactions in the solid phase as well as (by the value  $\text{C}_0$ ) the extreme portion of the decarbonation function.

It is also clear that the examined measures of burnability give results whose significance, method by me

FIG. 5 . FUNCTIONS  $\text{CaO}_f = k - h \cdot \ln \theta$  IN LINEAR CO-ORDINATES.

thod, does not exceed that of the relative comparison, since the technological process develops under quite different conditions from the laboratory ones and different from one another depending on the type of plant.

## 2.5 Evaluations of the burnability by calculation.

At least three methods allow the burnability of the

mix to be calculated (in the absence of mineralizers and other specific additions), by its chemical, mineralogical and physical parameters. These procedures are important since they explain, to some extent, the influence of the different chemical and physical parameters on the burning process.

2.5.1 Ludwig and Ruckenstein (18, 19, 20) showed that the practical burnability (\*)  $B_{pr}$  of a mix, determined as time of reaction at 1350°C needed to reduce the  $\text{CaO}_f$  content to a value  $\pm 2\%$ :

$$\theta_{1350^\circ\text{C}} \approx e^{\frac{k-2}{h}}, \text{ min.} \quad [7]$$

coincides (correlation coefficient  $r=0.985$  for 12 mixes) with the value of the theoretical burnability,  $B_{th}$ , so called since it can be calculated from:

$$B_{th} = 55.5 + 11.9H_{K90} + 1.55(K_{stIII} - 90)^2 - 0.43(SA)^2, \text{ min.} \quad [8]$$

This equation is obviously valid for  $K_{stIII} \geq 90$ . It has been extended to the temperatures of 1375°C and 1400°C in a following paper (21).

The significances of the symbols are:

$H_{R90}$ , "heterogeneity  $> 90 \mu\text{m}$ ", measured as the amount of raw meal retained on  $90 \mu\text{m}$  sieve lessened of the quantity of multiminerall aggregations of elements  $< 90 \mu\text{m}$  present in this oversize, mass % of the mix;

$SA$ , amount of liquid phase at 1350°C after Dahl (22), mass % of the l.o.i.-free mix;

$K_{stIII}$ , Kalkstandard after Spohn et Al. (23), undim.

The hypothesis on which the determination of  $H_{R90}$  is based - namely that the ratio of  $\text{CaO}$  to hydraulic factors in the multiminerall aggregations  $> 90 \mu\text{m}$  is equal to the one in the mix - may not occur in all cases.

2.5.2 Kock et Al. (17) determined the correlation between burnability ( $\text{CaO}_f$  for  $t_i = 1400^\circ\text{C}$  and  $\theta_i = 15'$ ) of 168 industrial mixes (raw materials of 15 different deposits) and 10 parameters resulted significant out of 15 examined. From a 3<sup>rd</sup> order-regression it results (correlation coefficient  $r=0.949$ ):

$$\text{CaO}_{f1400^\circ\text{C}}^{15'} = \frac{0.022y - 1 - \sqrt{(0.022y - 1)^2 + 0.0188y^2}}{0.008y} + 5, \text{ mass \%} \quad [9]$$

$$y = y_{\text{ref.}} + \sum_{i=1}^{10} a_i x_i, \text{ mass \%} \quad [10]$$

(\*) "Practical" means "experimental", without any reference to the technological process.

$$y_{\text{ref.}} = \frac{\text{CaO}_{\text{ref.}} - 5}{-0.004(\text{CaO}_{\text{ref.}} - 5)^2 + 0.022(\text{CaO}_{\text{ref.}} - 5) + 1.174}, \text{ mass \% [11]}$$

where:

$\text{CaO}_{\text{ref.}}$  = value of reference  $\text{CaO}_f$ , obtained by burning any mix of the studied raw materials at  $1400^\circ\text{C}$  and  $15'$ , provided it has values of the parameters within defined limits;

$x_i$  = differences between the value of each parameters and the value of the same for the reference mix;

$a_i$  = (constant) coefficients of  $x_i$  defining the regression.

TAB. II. PARAMETERS OF COMPOSITION OF THE RAW MEAL AND CLINKER.

symbol	parameter	denomination	ref.
OG	$2.8S+1.65A+0.35F$	max. combinable CaO after Guttman and Gille	(35)
SP	$2.8S+1.1A+0.70F$	max. combinable CaO after Spohn	(36)
LP	$2.8S+1.18A+0.65F$	max. combinable CaO after Lea and Parker	(37)
BO	% of $\text{C}_3\text{S}$ , $\text{C}_2\text{S}$ , $\text{C}_3\text{A}$ ( $\text{C}_2\text{F}$ ) and $\text{C}_4\text{AF}$	"potential composition" after Bogue	(38)
SA	% of liquid at $t_f$ °C	"liquid phase" after Dahl "diagrams of clinkering"	(22) (39)
SM	$S : (A+F)$	silica modulus	(40)
TM	$A : F$	iron modulus	(41)
CM	$C^* : S$	calcium modulus	(35)
MSO <sub>3</sub>	$\bar{S} : 0.85 \bar{K}$	sulphate modulus	(42)

NOTES.  $S, A, F, C, \bar{S}$  and  $\bar{K}$  are mass % of  $\text{SiO}_2$ ,  $\text{Al}_2\text{O}_3$ ,  $\text{Fe}_2\text{O}_3$ ,  $\text{CaO}$ ,  $\text{SO}_3$  and  $\text{K}_2\text{O} + \text{Na}_2\text{O}$  equiv. respectively in the 1.0-1.-free raw meal (or in clinker).  $C^*$  is mass % of CaO in the 1.0-1.-free raw meal (or in clinker), combined in silicates.

The limits of the variables within which the correlation is valid are stated [9].

2.5.3 Christensen (24) reports an empiric relation enabling  $\text{CaO}_{f1400^\circ\text{C}}$  to be calculated versus the chemical composition, as well as the content in particles of calcite  $> 125 \mu\text{m}$  and quartz and flint  $> 44 \mu\text{m}$ . This relation is consistent with Ludwig and Ruckenstein's.

### 3. CHEMICAL COMPOSITION.

**3.1 Composition in raw materials.** The mass quantities of  $n$  raw materials, having independent chemical composition (\*), necessary for the mass unit of raw meal are solutions of linear systems of  $n$  simultaneous equations expressing the  $n-1$  conditions of chemical composition assigned to the mix. The methods of algebraic solution, among which (25, 26, 27, 28, 29) and the graphic procedures, out of which Fenaroli's (30, 31, 32) and Glauser's (33) ones are reminded, are based on this principle. A method of optimized solution (for the minimum consumption of fuel for burning) was developed by Xirokostas and Zoppas (34).

**3.2 Composition in oxides.** The chemical composition of the mix is defined by assigned values of one or more characteristic parameters (TAB. II) suitably chosen on the basis of the composition of the available raw materials.

**3.2.1** In the system C - A - S - F, the compositions of the plane  $\text{C}_3\text{S} - \text{C}_3\text{A} - \text{C}_4\text{AF}$  (the latter expressed numerically as  $\text{C}_2\text{A} + \text{CF}$ ), contain GG mass % of CaO. GG is fully combinable only under conditions of equilibrium cooling ensuring a complete reaction between free CaO and liquid during the cooling itself. Therefore GG is a limit practically unattainable in any case.

An identical situation occurs for all the BO compositions without  $\text{C}_2\text{S}$ .

According to Spohn (36) SP is the maximum amount (mass %) of CaO combinable in the clinker cooled not in equilibrium. The straight line  $2.8S + 1.1A - C = 0$  joins  $\text{C}_3\text{S}$  with  $(\text{C}_2\text{A})$  in the plane C - A - S and it is called Wetzel line (43) (\*\*). In the space C - A - S - F, the plane  $2.8S + 1.1A + 0.7F - C = 0$  contains  $\text{C}_3\text{S}$ ,  $(\text{C}_2\text{A})$  and  $\text{C}_4\text{AF}$  (this time expressed numerically as  $\text{C}_2\text{A} + \text{C}_2\text{F}$ ). Kühl (44, 45) defined Kalkstandard, ( $\text{K}_{st}$ ), as the  $\text{CaO} : \text{SP}$  ratio (of a clinker or a raw meal). LP is the maximum quantity of CaO combinable in the clinker cooled not in equilibrium, according to Lea and Parker (37). In the space C - A -

(\*) The independence of chemical composition of any raw material (with respect to the compositions of any number of others) is verified by the non-identity condition between suitable ratios of % of oxides expressing the chemical analysis and the homologous ratios of all the other raw materials, including those obtainable by addition or subtraction from one another.

(\*\*) This line is near (but does not coincide with) the line joining  $\text{C}_3\text{S}$  to point Z (Z = invariant at  $1470^\circ\text{C}$  among liquid, CaO,  $\text{C}_3\text{S}$  and  $\text{C}_3\text{A}$ , having composition 54.8% CaO, 22.7%  $\text{Al}_2\text{O}_3$ , 6%  $\text{SiO}_2$ , 16.5%  $\text{Fe}_2\text{O}_3$ ).

S - F, the plane  $2.8S + 1.18A + 0.65F - C = 0$  contains  $C_3S$ , invariant Z at  $1470^\circ\text{C}$  and  $C_4AF$  ( $\text{CaO}$  combined with F is  $4\text{CaO} - 1.18\text{Al}_2\text{O}_3$ ). The compositions containing  $\text{CaO} \neq \text{LP}$  are deprived of equilibrium free  $\text{CaO}$ . The  $\text{CaO} : \text{LP}$  ratio is called lime saturation factor (LSF) or also modified Kalkstaud ( $K_{\text{stII}}$ ).

Spohn et Al. (23) showed that  $\text{MgO}$  combines in clinker up to the limit of about 2 mass % (of clinker) by releasing 0.75 mass %  $\text{CaO}$  for each 1 mass %  $\text{MgO}$ , as a rule. In most cases the amount exceeding 2% does not affect the  $\text{CaO}$  combinations. For such a reason these Authors proposed  $K_{\text{stIII}}$  as  $(\text{CaO} - 0.75 \text{MgO}) : \text{LP}$  ratio, or  $(\text{CaO} - 1.5) : \text{LP}$  when  $\text{MgO} \neq 2\%$  or  $\text{MgO} \geq 2\%$  respectively.

Christensen (46) attained a very similar expression of LSF corrected by the presence of  $\text{MgO}$  (not exceeding  $\sim 2\%$ ) on the basis of the phase relations in the system C - A - S - F - M:

$$\text{LSF} = \frac{\text{CaO} - 0.77 \text{MgO}}{2.8S + 1.18A + 0.66F}, \text{ undim.} \quad [12]$$

3.2.2 The sulphate modulus, recently introduced by Osbaeck (42), determines the fraction of soluble alkalis with respect to the total alkalis in clinker according to the results of Pollit and Brown's research (47).

3.2.3 The reason why the potential compound composition according to Bogue (38) does not correspond to the mineralogical composition of clinker determined by microscope and/or X-ray diffraction is well-known. Above all the calculated amounts of  $C_3S$  and  $C_2S$  deviate, being the former higher than that of alite and the latter lower than that of belite (23, 48, 49, 50). Nevertheless Bogue's model is a simple and clear reference of unnegligible practical utility. Therefore Hansen (51) proposed its revision by calculating the aluminate as  $C_3A_{0.9}F_{0.1}$  and the aluminoferrite as  $C_2A_{0.54}F_{0.46}$  (52, 53, 54).

The interpretation of SM, TM and CM in terms of the potential compound composition was given by Bucchi and Buzzetti (55).

3.3 Chemical composition and reactivity. The effects due to the minor compounds are discussed in Chaps. 6 and 7.

3.3.1 As the lime saturation of the mix increases, the number of  $\text{CaCO}_3$  particles sterically "co-ordi-

nated" by each particle of acidic oxides increases and therefore the mass fraction of  $\text{CaO}$  (of the total one present), diffusing into these oxides in the time unit for each temperature below about  $1300^\circ\text{C}$ , decreases. All the values of the functions  $\varphi = f(t, \theta)$  and  $\alpha = f(t, \theta)$ , expressing burnability and reactivity decrease.

On the contrary, as the liquid phase appears (above  $\sim 1300^\circ\text{C}$ ), the kinetics of the dissolution processes in the liquid is affected only to a slight extent - any other condition unchanged by the mass of the present solid  $\text{CaO}$ . The graphs of the functions  $\alpha = f(t, \theta)$  and  $\text{CaO}_f = f(t, \theta)$  of mixes differing only in the lime saturation, between about  $1300^\circ$  and  $1400^\circ\text{C}$ , are roughly parallel and distant from one another of an ordinate value equal (case of  $\text{CaO}_f$ ) or about proportional (case of  $\alpha$ ) to the difference of free  $\text{CaO}$  present at temperature and time ( $t_i, \theta_i$ ) when the liquid appears. This trend seems to be confirmed by the data derived and calculated from Heilmann's (56), Toropov and Luginina's (57), Pfrunder and Wickert's (4), Blaise et Al.'s (12) papers. Also Musgnug (15), Ludwig and Ruckenstein (19), Kock et Al.'s (17) equations - even if with different dependence - express the increase in  $\text{CaO}_f$  (for given  $t_i, \theta_i$ ) or in  $\theta_i$  for  $\text{CaO}_f \neq 2\%$ , when the lime saturation increases.

Therefore above  $1300^\circ\text{C}$ , the increase in this parameter determines a decrease in burnability whereas it does not practically affect the reactivity.

3.3.2 The processes occurring in the presence of liquid phase are clearly affected by the amount composition and properties of the latter. The liquid appearing at  $1338^\circ\text{C}$  in the system C - A - S - F ( $1301^\circ\text{C}$ , under  $\text{MgO}$  saturation conditions) has  $A : F = 1.23$  (1.63 under  $\text{MgO}$  saturation conditions) (58). Therefore  $\text{Al}_2\text{O}_3$  and  $\text{Fe}_2\text{O}_3$  act as agents of first melting for raw meals having  $\text{TM} < 1.23$  ( $< 1.63$ ) or  $\text{TM} > 1.23$  ( $> 1.63$ ) respectively. At the same SM, the amount of liquid is maximum at  $\text{TM} = 1.23$  ( $= 1.63$ ); at the same TM, the amount of liquid increases (22) as SM decreases (\*). At constant temperature, the viscosity of the liquid phase decreases as  $A : F$  reduces (50) with consequent increase in the rate of the dissolution processes.

These circumstances, and other examined in Chap. 6, explain why the increasing silica modulus-mixes show worse and worse reactivities, at  $K_{\text{st}}$ , TM and any other condition unchanged (4, 15, 61) (\*\*). On the contra-

(\*) Dahl's (22) equations are based on a composition of the liquid, at  $1338^\circ\text{C}$ , having  $A : F = 1.38$  (59) instead of 1.23 (or 1.63 under  $\text{MgO}$  saturation conditions). This difference does not change the kind of reasoning.

(\*\*) Musgnug (15) showed that the function  $\text{CaO}_f = f(\text{KS})$  ( $\text{KS} = S : A$ , Kieselsäuremodul) linearly increases with KS, for constant  $t_i$  and  $\theta_i$ .  $\text{CaO}_f = f(\text{SM})$  coincides with  $\text{CaO}_f = f(\text{KS})$ , when the angular coefficient of the first function is multiplied by the value  $\frac{\text{TM} + 1}{\text{TM}}$ .

ry the deductions on the influence of the TM variations badly agree with the results of Musgnug's (15) and Lehmann et Al.'s (8) works. Nevertheless it is observed in this connection that raw meals having TM between 1.3 and 1.6 are almost universally judged as the easiest to burn, at any other condition unchanged.

#### 4. PARTICLE SIZE.

##### 4.1 Demolition of the structure of the clayey minerals. $\text{CaCO}_3$ decarbonation.

4.1.1 Both processes proceed according to first order-reactions and they are governed by the rates of this type of reactions. The research of many Authors (62, 63, 64, 65, 66, 67) shows that the time for the dissociation of a  $\text{CaCO}_3$  particle is a linear function of the particle diameter, in the range of the usual sizes that they have in the raw meal.

4.1.2 The time  $\theta'_M$  demanded for the isothermal demolition of the mass unit of clayey mineral, distributed in quasi-spherical particles having narrow grading interval, is approximatively proportional to the reciprocal of the specific surface  $S'_M$  of these particles:

$$\theta'_M \approx \frac{k'}{S'_M}, \text{ s} \cdot \text{g}^{-1} \quad [13]$$

where  $k'$  is constant ( $\text{s} \cdot \text{cm}^2 \cdot \text{g}^{-1}$ ) at constant temperature and activation energy.

4.1.3 Similarly, the time demanded for the decarbonation of the mass unit of quasi-spherical  $\text{CaCO}_3$  particles having narrow grading interval is expressed by a [13] type function (except for the different numerical value of  $k'$ ) in that stage of the process when the dissociation rate is higher than the diffusion rate of CaO in the acidic oxides. This occurs starting from the first appearance-temperature of free CaO as far as the temperature of complete disappearance of  $\text{CaCO}_3$  ( $\leq t_2$ ). Below the former temperature, the early decarbonation supplies CaO to the reactions with  $\text{SiO}_2$ ,  $\text{Al}_2\text{O}_3$  and  $\text{Fe}_2\text{O}_3$  (absence of free CaO); in this stage of the process the dissociation times are controlled by the diffusion rate of CaO in the acidic solid phases.

##### 4.2 Reactions between solid phases.

4.2.1 In the simple processes of binary diffusion between the fundamental oxides, the direction of transfer of matter follows De Keyser's rule (68):

(the affinity values of oxygen after Katelaar are within brackets) according to which the oxide having less affinity for the oxygen diffuses on and inside the oxide having a greater affinity (acceptor oxide). The diffusion proceeds by three ways (69):

- transfer of matter on the external surface of the particle of acceptor oxide (surface diffusion);
- transfer of matter along the surfaces joining the grains of the particles of the acceptor oxide (diffusion at the joints);
- transfer of matter inside the grains of the acceptor oxide (lattice or volume diffusion).

The weaker bonds of the atoms and/or ions at the surface and the greater disorder existing at the joints of the grains determine, in these sites, a higher level of free energy than that present inside the lattice. Consequently the activation energies of the process at the surface  $Q_s$ , at the joints  $Q_j$  and inside the lattice  $Q_r$ , increase according to the following order under isothermal conditions (70):

$$Q_s < Q_j < Q_r, \text{ cal} \cdot \text{moles}^{-1} \quad [14]$$

with corresponding decrease, in the same order - from [15] and [18] - of the diffusion rate of each process. Therefore the processes (a) and (b) are by-pass of (c). The latter being the slowest one, controls the overall stationary process under isothermal conditions when the grains of the acceptor oxide have size higher by several orders of magnitude than the thickness of the surface layer of matter concerned in the diffusion according to (a) (equal to some atomic distances of the acceptor).

4.2.2 Under stationary isothermal conditions, the advancement of the front of the diffusion inside the lattice is described by:

$$\frac{dn}{d\theta} = -DA \frac{dc}{dy}, \text{ moles} \cdot \text{s}^{-1} \quad [15]$$

where  $n$  is expressed in moles,  $\theta$  in s;  $c$  in moles  $\cdot \text{cm}^{-3}$ ,  $D$  in  $\text{cm}^2 \cdot \text{s}^{-1}$ ,  $y$  in cm (direction of propagation of the front) and  $A$  in  $\text{cm}^2$  (surface across the direction of propagation). The negative sign indicates the propagation towards the lowest concentrations. If the diffusion front travels  $y_i$  cm in  $\theta_i$  s, from [15] it results:

$$y_i^2 = k\theta_i, \text{ cm}^2 \quad [16]$$

or

$$\frac{y_i}{\theta_i} = \frac{k}{y_i}, \text{ cm} \cdot \text{s}^{-1} \quad [17]$$

where  $k$  is constant at constant temperature and activation energy (\*).

(\*) Only formally the dimensions of  $k$  are the same as  $D$ .

In the portion of plane  $(+\frac{y}{\theta}; +y)$ , the average rate [17] of propagation along  $y$  is represented by a branch of equilateral hyperbola having asymptotes coinciding with the reference axes (FIG. 6).

The diffusion coefficient  $D$  (and therefore the rate  $dn/d\theta$  of the process) varies according to Hevesy's equation:

$$D = D_0 \exp - \frac{Q}{RT}, \text{ cm}^2 \cdot \text{s}^{-1} \quad [18]$$

where  $Q$  ( $\text{cal} \cdot \text{moles}^{-1}$ ) represents the activation energy of the type of diffusional process considered,  $T$  ( $^{\circ}\text{K}$ ) is the temperature at which this process occurs, and  $D_0$  ( $\text{cm}^2 \cdot \text{s}^{-1}$ ) is a (quasi-) constant, cal-

FIG. 6 . AVERAGE RATE OF THE PROGRESSIVE ADVANCEMENT OF THE REACTION FRONT VERSUS THE THICKNESS OF THE MATTER TRANSFORMED ( LATTICE DIFFUSION ).

led pre-exponential factor or frequency factor (of the atomic oscillations) formally equal to  $D$  when  $T = \infty$ .

4.2.3 From [14] the reactivity in the solid phase is mainly controlled by the size of the grains of  $\text{CaO}$  acceptors, that is the acidic oxides,  $\text{SiO}_2$ ,  $\text{Al}_2\text{O}_3$  and  $\text{Fe}_2\text{O}_3$ .

The time  $\theta_M''$  demanded for the isothermal reaction of the mass unit of acceptor oxide (distributed in quasi-spherical grains having narrow grading inter-

val) is approximately proportional to the reciprocal of the square of the specific surface of the grains  $S_M''$ :

$$\theta_M'' \approx \frac{k''}{S_M''^2}, \text{ s} \cdot \text{g}^{-1} \quad [19]$$

where  $k''$  ( $\text{s} \cdot \text{cm}^4 \cdot \text{g}^{-3}$ ) is constant at constant temperature and activation energy  $Q_r$ .

As seen, the validity of [19] is based on the hypotheses that the volume diffusion is the bottle neck of the overall process and the grains of acceptor oxides have quasi-spherical shape of very narrow grading interval. Consequently the description of the influence of  $S_M''$  on  $\theta_M''$  the more deviates from [19] the larger the grading interval, the more different the shape of the grains from the spherical one, and the smaller their shortest dimension.

Two remarks on the quantity  $S_M''$  are necessary:

- $S_M''$  measures the surface of the mass unit of portions of single-phase matter (acceptor oxides) delimited by crystal joints where the diffusion coefficient  $D_j$  is higher than  $D_r$ . Briefly,  $S_M''$  represents the specific surface of single-phase grains delimited by active joints. Its value can be represented by the results obtained from the usual measure of specific surface of powdered matter only when the particles consist of a single grain of a single mineralogical species. Ludwig and Ruckenstein's (18) concept of heterogeneity  $> 90 \mu\text{m}$ ,  $H_{90}$ , already seen in 2.5.1, takes into account this criterion.
- $S_M''$  refers to the fineness that the acceptor oxides have when the reactions develop, instant by instant during the process (and not necessarily to the fineness that they have in the raw meal before the thermal process).

From what considered in 4.2.1, the surface of the free particles, consisting of single - or multi-phase grains, (that is the one referable to the usual measures of specific surface) affects the kinetics of the overall diffusion process in that it is an extent of the by-pass of the lattice process.

#### 4.3 Reactions of clinkerization.

4.3.1 Clinkerization is controlled by the diffusion process in the liquid phase (71, 72).

4.3.2 Rumyantsev (73) and Kondo and Choi (74) showed that the isothermal dissolution of  $\text{C}_2\text{S}$  and  $\text{CaO}$  in the liquid phase at the temperature of clinkerization is described by equations of the same type as [15], [16], [17], [18] and [19] governing the lattice diffusion (\*).

(\*) Rumyantsev's equation (73) does not differ from Kondo's and Choi's (74) and both of them do not differ from [16] when, in the former, the due size ( $\text{s} \cdot \text{cm}^{-1}$ ) is assigned to  $\tau$  and in the latter  $\alpha$  is expressed as the distance covered by the diffusion with regard to the radius of the grain or particle.

Nevertheless, in the isothermal dissolution,  $S_M''$  represents the surface of the mass unit of the  $C_2S$  and CaO grains wetted by the liquid phase, whereas  $dc : dy$  is the gradient of concentration in the contact solution.

4.3.3 Therefore the process rate is controlled by:

- the grain size of the phases produced in the previous reactions between solid phases;
- the size of the CaO grains resulting from decarbonation; (differently from what occurs for the latter process, the time for the dissolution of CaO is proportional to the fourth power of the grain diameter);
- the wetting power (surface tension) of the liquid phase.

4.4 Technological considerations. The described model is an approach that, as such, has only a beginning-value. Nevertheless it allows some deductions useful for the practice to be drawn.

4.4.1 The diameter of the grains of the acidic oxides - at the fourth power in [19] - would have a decisive effect, according to this model, on the kinetics of the reactions both in the solid phase and in the presence of liquid. Thus the considerable importance, for the reactivity of a mix, of the size of quartz here contained is explained. On the contrary, in the reactions in the solid phase, the diameter of the pure  $CaCO_3$  particles would have a reduced influence, merely proportioned to the square of its size (see equation [13]). During the dissolution process in the liquid, the diameter of the CaO grains from the decarbonation of  $CaCO_3$  would have the same importance as that of the acidic oxides.

These deductions are directly or indirectly confirmed by several data of the literature (56, 16, 75, 76, 77, 78, 79, 80, 81), but not by others (82, 8).

4.4.2 The particles consisting of coarser single-phase grains in the industrial raw meals, are the last to complete the reactions. It becomes obvious that the reactivity is increased by the reduced grading interval, at the same specific surface. In this connection, therefore, methods and equipment to - day used for grinding the raw meal in the technological practice do not seem the most suitable to produce the most reactive grading at the lowest energy consumption. Clearly this inadequacy must be attributed to the poor separation precision of the equipment "cutting" the feed produced in the closed-circuit mills. It is also due to the indifferenced application of the mechanical grinding energy to materials having different grindability which, because of this, are differently distributed into the different grading intervals (83).

This problem can be solved by separately grinding the component the most difficult to grind (for ex. quartz) (76, 84), according to a method already

used in some modern cement factories (85, 86).

## 5. MINERALOGICAL SPECIES AND THEIR REACTIVITY.

### 5.1 Activity state of solids.

5.1.1 The ease or hardness of an industrial raw meal to burn must be referred to the petrographic characteristics of the rocks composing it, the present mineralogical species and their state of activity just before being attributed to the different technological parameters, such as chemical composition, fineness of grinding, homogeneity a.s.o.

The two expressions of the previous chapter:

$$D = D_0 \exp - \frac{Q}{RT}, \text{ cm}^2 \cdot \text{s}^{-1} \quad [18]$$

$$Q_s < Q_j < Q_r, \text{ cal} \cdot \text{moles}^{-1} \quad [14]$$

(of which significance and symbols are specified in 4.2.2 and 4.2.1 respectively) allows the interpretation of the different behaviour that different solids show in the solid-phase reactions and in the presence of liquid. The energy of diffusional activation  $Q$  of [18] (or  $Q_s$ ,  $Q_j$  or  $Q_r$ , if the elementary processes, on the external surface of the grains, at the joints or inside the lattice are considered) is, to some extent, a measure of the chemical rigidity of the lattice: it is the lower (that is the process is the faster) the higher the level of free energy related to the lattice (or the zone of lattice) involved in the process or - as is briefly said - the higher the activity state of the portion of solid matter considered. Moreover the equation [14] expresses that the active state of a portion of a same solid species is maximum at the delimiting surface, lower at the junctions between grains and minimum inside the lattice.

5.1.1 The active state of solids is evidenced by the measure of suitable quantities which are directly or indirectly related to the lattice disorder as:

- distortions inside the lattice (87, 88, 89);
- concentration of punctual faults (broadness and intensity of the lines of EPR spectra) (89, 90);
- position, shape and area of DTA effects (82, 91);
- enthalpy and rate of reaction and/or dissolution (88, 6);
- a.s.o.

5.1.3 The aforesaid type of approach justifies a great deal of well-known phenomena (69, 92, 93, 94, 95, 96, 18, 97, 89, 98):

- a mean value of  $Q$ , characteristic of the species, is due to each solid matter or mineralogical species carrying one or more oxides into the raw meal. Each mineral, or solid mat-

ter, reacts with its own rate, all the other conditions unchanged;

- for a same species of matter, the value of  $Q$  is a function of the particular state of activity that this species assumes from its formation and elapsed vicissitudes. Faults, defective structures and disorder of any origin in the lattice, increase active state and reactivity. Even if not as a rule, higher levels of free energy are often related to the condition of solid solution of substitutive type (especially among ions of different charge and at the limit of the dimensions of replaceability), interstitial and subtractive type. The pseudo-solids and the matter badly crystallized or having limited lattice periodicity (glasses, colloids, a.s.o.) owe the high reactivity to the high content in free energy of these structures;
- similarly the solids in transient state of structural modification (especially if it results from a deep rearrangement) and the chemical species in the nascent state are exceptionally reactive. The "ageing" of the structures, on the contrary, reduces the concentration of their crystalline faults, increases their stability and grain sizes, and so makes them less reactive;
- the surface extension of an exposed phase as well as the concentration of junctions among the grains, are liable for great variations in the active state where the same crystalline species, or the same minerals of a rock, can be found.

5.1.4 The application of suitable mechanical stresses to the solid matter can cause distortions inside the lattice and/or changes to the structural arrangement in the proximity of the free surfaces, which increase its state of activity (mechanical activation) (99, 4, 6, 100).

## 5.2 Carrier of acidic oxides.

5.2.1 The main minerals, and most of the accessory ones, of argillaceous materials (clays, shales, slates), phyllites, schists, flysh, marls, sandstones are carriers of acidic oxides. The use of metastable glassy volcanic rocks, such as tuffs, pözzolanas, trass, pumice and industrial wastes, such as fly-ashes and blastfurnace slags, is less frequent. When necessary, the raw meal is corrected by small amounts of siliceous materials, laterites, terra rossa, bauxite, limonite, siderite or pyrite cinders, depending on the lacking oxide and the material available at the lowest cost. An exhaustive review of these materials is contained in Wolfe's (101) paper. Kiefer (102) published a synthesis on the structure and properties of the main clay minerals. Of the latter Beutelspacher and Van der Marel (103) presented over 250 electron micrographs of rare evidence. Leroux (104) reported significant notes on the different textures of clayey and marly rocks.

5.2.2  $\text{SiO}_2$  released through thermal amorphization of phyllosilicates has great dispersion and considerable activity because of its nascent state. Therefore it is much more reactive than the several types of natural silica.

As for the clastic quartz of clays, sandstones, sands and veins in limestones, as for chalcedony and/or opal of flint, as well as gels of "aged" natural silica, it is the dispersion and the size of grains, the type of structure and the degree of disorder inside the lattice at the temperature of reaction which control their reactivity anyhow low. The results of Dyckerhoff's (16) and Akatsu and Ikeda's (91) works are very instructive on this subject. According to Makashev (97) the reactivity of the different types of  $\text{SiO}_2$ , free and combined, increases in the order:

quartz < chalcedony < opal <  $\alpha$ -cristobalite;  
 $\alpha$ -tridymite < silica of feldspars (orthoclase;  
 albite; anorthite) < silica of micas and amphiboles < silica of clay minerals < silica of glassy slags;

whereas Michedlov-Petrosyan et Al. (89) found that silica of volcanic glasses and that of clayey minerals are more reactive than that of blastfurnace slags;

5.2.3 It can be reasonably assumed that an analogous situation to that of  $\text{SiO}_2$  occurs for  $\text{Al}_2\text{O}_3$  and  $\text{Fe}_2\text{O}_3$ . The thermal demolition of the structure of a phyllosilicate gives these oxides in the nascent state at temperatures at which their reaction with  $\text{CaCO}_3$  can begin and develop at practically useful rates. Gibbsite, bohemite, diaspore, goethite, a.s.o. - present as accessory minerals in clays, or as main constituents of residual sediments (laterite, terra rossa, bauxites, limonites a.s.o.) - contain, "at the green state", the hydroxides under conditions of poor crystallinity and high configurational energy. However they are unable to offer these hydroxides under this very condition to the reaction with  $\text{CaCO}_3$  over  $500^\circ\text{C}$  during the conventional process of burning. In fact the gradual heating of the raw meal dehydrates these compounds prematurely and it favours their structural rearrangement. Consequently the latter reduces their energy content, activity and reactivity.

In the light of these concepts, the pyrite cinders are the worst carriers of  $\text{Fe}_2\text{O}_3$ , because of the high temperatures at which they form.

5.2.4 Generally the most abundant phyllosilicates in the clayey fraction of the raw meal are illite, chlorite and muscovite (102, 105, 106, 16). Kaolinite is frequent but less abundant. According to Lehmann et Al. (8) montmorillonite would be rare even if it appears to be present and sometimes abundant in raw materials and raw meals examined by other Authors (107, 81). It is mainly found in the alteration products of volcanic ashes and as accessory mineral of recent marls. More common carriers of octahedral layer- $\text{Fe}^{3+}$  are glauconite (ferric illite)

and nontronite (ferric montmorillonite). Detailed information on the presence of the different phyllosilicates in the sediments of different origin and nature is found in Grim's (108, 109) and Millot's (110) classical texts.

The lattice stability of these minerals is related to the temperatures of initial and final hydroxyl dehydration. The stability decreases - all the other conditions unchanged - as the symmetry of the sheet decreases and, for a same type of structure, by moving from the alumina terms to the iron ones (102). As Goerg (111), Hill and Schwiete (112), Ludwig et Al. (113), Bereczky (114), Lehmann and Thormann (7) and Mchedlov-Petrosyan et Al. (115) show, it is thought that, as the stability of phyllosilicates decreases, the reactivity with  $\text{CaCO}_3$  increases, as a rule, according to the order:

muscovite < montmorillonite < chlorite < illite < kaolinite.

Nevertheless there are disagreeing experimental results (116, 117) and opinions (101, 118). Actually, it would seem right to relate the reactivity of a phyllosilicate towards  $\text{CaCO}_3$  not to the activity of the structure before the demolition of the latter, but more properly to the temperature at which  $\text{SiO}_2$ ,  $\text{Al}_2\text{O}_3$  and  $\text{Fe}_2\text{O}_3$  are offered in the nascent state with respect to the temperature at which the  $\text{CaCO}_3$  dissociation, in their presence, attains practically useful values. Therefore the different phyllosilicates are likely to show different degrees of relative reactivity depending on the nature and texture of the carbonatic rock with which they react.

Anyhow, if the requirements of chemical composition of the industrial raw meals are considered, it must be concluded that the three layer-sialites of pyrophyllitic structure (montmorillonite, a.s.o.), having Si : (Al, Fe) atomic ratio equal to or slightly lower than 2 ( $\text{SM} \approx 2.3$ ), give more reactive raw meals than those containing other sialites (kaolinite, illite, chlorites, muscovite a.s.o.) which, even if of very different nature, have Si : (Al, Fe) atomic ratio  $\neq 1$  ( $\text{SM} \approx 1.2$ ). In fact the latter ones must always be accompanied, in the raw meal, by higher contents in poorly reactive free  $\text{SiO}_2$  (or combined in another tectosilicate) than the former ones.

### 5.3 Carriers of CaO.

5.3.1 Calcite (rarely and in negligible amounts, aragonite and ankerite) of the carbonatic rocks is the main carrier of CaO in the raw meal. A contribution in CaO can be sometimes given by blastfurnace slags and wastes from other industries in the form of silicate, hydroxide or oxide. The supply of CaO from dolomite, gypsum, magmatic rocks, and phyllic silicates having adsorbed or reticular  $\text{Ca}^{2+}$  is always poor.

The case of raw meals containing quicklime obtained by burning limestone (119) is exceptional.

5.3.2 The state of activity (and therefore the reac-

tivity) of calcium oxide released from  $\text{CaCO}_3$  for the diffusion in the acidic oxides is determined by the disorder and concentration of defective structures present in the dissociation product which, in their turn, depend on (93, 120, 121, 5, 11, 122, 123, 97, 90):

- the microstructure of the carbonatic rock;
- the temperature of formation of CaO;
- the temperatures and the times during which the produced CaO "ages" before reacting with the other solid phases, or before dissolving in the liquid phase.

The most influential variable is the size of the calcite crystals. As it decreases, the concentration

FIG. 7 . GRAIN SIZES OF THE DIAGENETIC CARBONATE SEDIMENTS AND NON-CARBONATE FRACTION ( $< 6.3 \mu\text{m}$ ). ELABORATION FROM MARSCHNER'S PAPER (124).

of the defective structures of the dissociation CaO increases and the temperature at which - for a given equilibrium of solid phases -  $p_{\text{CO}_2}$  attains practically useful values, decreases. On the other hand, Marschner (124) proved that, for diagenetic limestones, the sizes of the grains are inversely proportional to the content of clayey minerals (FIG. 7) whose protective coating would prevent the formation of large crystals during the diagenesis.

5.3.3 These concepts explain the great burnability of marls and the preference that the cement manufacturers generally give to limestones of "polluted" microstructure rather than to pure or very pure carbonatic rocks. Subordinately, among these, micrites and micro- and cryptocrystalline limestones are more reactive; the middle-grained sediments are ac-

ceptable. Clearly the worst carbonates used for cement are pure limestones deeply diagenized and containing large crystals, such as marbles.

## 5. MINOR COMPOUNDS.

### 6.1 Concentrations of minor compounds in the raw meal. Admixtures.

Minor compounds (\*) are chemical species different from the four fundamental oxides which participate in the transformation process of the raw meal into clinker. As a rule, they derive from the accessory minerals of rocks, fuels, refractories, wear parts of equipment; they can also result from admixtures added to the raw meal for specific purposes. Blai-

The main purposes that have been stimulating the research on the minor compounds and admixtures for several years are:

- production of more reactive raw mixes;
- improvement of particular technological conditions in order to increase efficiency of the process;
- increase in the allowable levels of impurities and consequently enlargement of the availability of raw materials and types of fuel. There is also the possibility of using industrial wastes or the ones of different source for ecological decontamination purposes;

TAB. III. CONTENTS IN MINOR COMPOUNDS OF INDUSTRIAL RAW MEALS (127, 128, 129, 130)

minor compound	number of samples	$\Delta C_E$ extremes of conc. mass %	$\Delta C_{fo}$ interval of fo mass %	fo frequency of $\Delta C_{fo}$ %	$C_M$ median content mass %	$C_m$ mean content mass %

ne et Al. (125, 126) published the frequency distribution of 17 minor elements into 186 portland cements as well as the results of a research concerning their effects on the properties of cement.

TAB. III gives the significant statistical quantities of the concentrations of 11 minor compounds in 141 industrial raw meals (127, 128, 129, 130). The median values of the concentrations decrease in the order:

the frequency distribution is of normal-logarithm type (except for that of TiO<sub>2</sub>, approaching the normal one).

- production of cements having better quality.

### 6.2 Modifiers of the properties of the liquid phase.

These are the minor compounds called fluxes and mineralizers acting in the liquid and/or liquid-solid phase. Fluxes are substances which lower the first appearance-temperature of the liquid phase (131). Mineralizers are substances which, through any mechanism, accelerate the rate of the process or reaction between solid phases, or in the liquid phase or at the liquid-solid interface (131). Attributing (84) both properties to fluxes - that is the lowering of the first-melting point and the reduction in the viscosity of the liquid-must be avoided because not always the same substance produces the two effects simultaneously. It does not

(\*) Also called: minor components, minor constituents, minor elements, impurities, traces.

even seem suitable to assign (132) the role of mineralizers only to fluxes, since many of these act just in the solid phase.

TAB. IV. COMPOSITION OF THE LIQUIDS OF WHICH BUTT AND TIMASHEV (137) STUDIED THE VARIATIONS OF  $\sigma$  AND  $\eta$ .

	liquid 1 peritectic at 1338°C	liquid 2 saturated at 1450°C
CaO	54.8	57.0
SiO <sub>2</sub>	6.0	7.5
Al <sub>2</sub> O <sub>3</sub>	22.7	22.6
Fe <sub>2</sub> O <sub>3</sub>	16.5	12.9
a	2.76	2.78
b	0.016	0.025

6.2.1 The important role that fluxes play on the transformation of the raw mix must be referred:

- first of all, to the necessity of the presence of a liquid phase for the rapid C<sub>3</sub>S formation (peritectic reaction);

FIG. 8 .POLYTHERMS OF  $\sigma$  OF THE LIQUID PHASES 1 AND 2 OF TAB. IV .AFTER BUTT AND TIMASHEV (137).

- afterwards, to the need to avoid the "ageing" of the CaO and C<sub>2</sub>S crystals before dissolving in the liquid;
- finally, to the energy saving of the process, which results to be the higher the lower the first appearance-temperature of the liquid.

It has already been mentioned (paragraph 3.3.2) that this temperature is 1338°C in the most basic part of the system C - S - A - F (59); 1301°C in the same in the presence of 5% MgO (58); 1280°C in the system C - S - A - F - M - N (133). All the minor compounds dissolving in the liquid phase decrease its first appearance-temperature. Nevertheless, since C<sub>3</sub>S does not form below 1250°C, this temperature must be considered the lowest (also theoretical) limit for clinkerization.

6.2.2 The substances able to modify the kinetics of the C<sub>2</sub>S and CaO dissolution and the rate of ionic diffusion in the same, affect the rate of the peritectic reaction (134, 135, 136, 73). Butt and Timashev

FIG. 9 .ISOTHERMS (1450 °C) OF  $\sigma$  OF THE LIQUID PHASE 2 OF TAB. IV FOR INCREASING CONTENTS IN DIFFERENT MINOR COMPOUNDS. AFTER BUTT AND TIMASHEV (137).

(137) have exhaustively reported on the mechanism of formation of clinker. The mineralizers act, at the solid-liquid interface, by increasing the wetting power of the liquid phase - that is by reducing its surface tension - and they increase the fraction of exposed surface of the solid phase which dissolve. On the contrary, the mineralizers in the liquid phase accelerate the ionic diffusion by reducing the viscosity.

The surface tension  $\sigma$  of the liquid phase of clinker is of the order of hundreds of dynes·cm<sup>-1</sup>, between 1300°C and 1450°C (138); the viscosity  $\eta$  is of the order of poises (60). According to Butt and Timashev (137):

$$\log_{10} \sigma = a - \frac{b}{\eta}, \text{ undim.} \quad [20]$$

is valid between 1400°C et 1500°C for the quaternary

ry liquids having the composition given in TAB. IV. The values of the constant a and b are also shown in the same TAB. IV.

FIG. 10 .POLYTHERMS OF  $\eta$  OF THE LIQUID PHASES 1 AND 2 OF TAB. IV. AFTER BUTT AND TIMASHEV (137).

The variation of  $\sigma$  versus the temperature is shown in FIG. 8, whereas FIG. 9 gives the isotherms  $\sigma$

FIG. 11 .ISOTHERMS (1450 °C) OF  $\eta$  OF THE LIQUID PHASE 2 OF TAB. IV FOR INCREASING CONTENTS IN DIFFERENT MINOR COMPOUNDS. AFTER BUTT AND TIMASHEV (137).

of liquid 2 at 1450 °C for increasing concentrations

in different minor compounds.

The viscosity is caused by the mobility of the ions  $\text{Si}_x\text{O}_y^{z-}$ .

In the presence of minor compounds the values of  $\eta$  depend on the equilibrium displacement between the co-ordinative structures of the amphoteric elements:

FIGS. 10 and 11 show the variations of  $\eta$  versus the temperature and the concentration of different minor compounds. It must be pointed out that increasing  $\text{K}_2\text{O}$  and  $\text{Na}_2\text{O}$  reduce  $\sigma$  but increase  $\eta$ , at the same temperature.

$a_0$  = sum of the cation radius and  $\text{O}^{2-}$ .

$a$  = cationic RVI after Whittaker and Muntus (142).

$Z$  = number of ionic charge.

6.2.3 The ability of an ion to modify the characteristics of the liquid is a property of the electron configuration of the ion itself. The effectiveness by which the viscosity is reduced, at the same temperature, increases as the electronegativity  $X$ , or the field force  $Z/a_0^2$ , or the ionic potential  $Z/a$  of the ion increase (137, 139, 140), as shown by the values of TAB. V. Ions like  $\text{K}^{1+}$  and  $\text{Na}^{1+}$  having large radius and low charge do not reduce but increase  $\eta$  (137). Also the mineralizing effectiveness, measured by the degree of combination of  $\text{CaO}$  through the liquid phase, increases as  $X$ ,  $Z/a_0^2$  and  $Z/a$  increase (143,

144, 145, 146, 147, 148) (FIG. 12); in fact ions having small radius and high charge (Cr, V, Ti, Mn, a.s.o.) are the most effective mineralizers.

This behaviour towards the liquid phase of clinker must be considered as a particular case of a more general rule, valid for all the silicatic magmas (149).

### 6.3 Equilibrium modifiers between phase and structure modifiers of the clinker minerals.

6.3.1 The minor compounds distribute differently into the clinker phases at high temperature and they determine displacements of the equilibria among the phases. New solid solutions and new compounds often form. In any case the evaluation of the effects

FIG. 12. MINERALIZING EFFECTIVENESS OF DIFFERENT CATIONS FOR CLINKER LSF=0.96 SM=2.2 AND TM=2.0 BURNT AT 1350°C UNDER LOAD OF 9100 WITH ADDITION OF 0.01g-% EQUIV. OF F<sup>-</sup>. AFTER TEOREANU AND TRAN VAN HUYNH (146).

of one or more minor compounds presume the knowledge of the resulting phase relations, out of which the most important are reported in Chap. 7.

6.3.2 These minor compounds that, in adequate concentration, increase the hydraulic properties of clinker and/or its minerals, are called activators (of hydraulicity) (150, 151, 152). The fundamental pa-

pers (137, 138, 153, 154, 155, 156, 49, 157, 158) published on this subject allow two types of model of activation to be designed:

- the presence of an isomorphogeneous substitute in a lattice causes disorder and often increases the concentration of defective structures of any kind (punctual, linear and superficial). This rise can increase the free energy of the structure by reducing its stability and by activating its hydraulicity (\*). There are, however, some exceptions: for instance the impurities do not increase the concentration of the imperfections inside the lattice of C<sub>2</sub>S (160). Foreign ions, depending on their ionic potential, can make the structure of β-C<sub>2</sub>S more stable (and decrease its hydraulic activity) (161);
- when ions having high value of Z/a vary the surface tension, the ionic mobility and the concentration gradients in the liquid, they modify the conditions of formation and growth of the crystals at the same time. In this way the microstructure of clinker varies with possible increase in the relative hydraulic activity (162).

6.4 Mineralizers between solid phases and through formation of atypical liquid phase (\*\*). These are the minor compounds which increase, at the same temperature, the dissociation tension of CaCO<sub>3</sub>, the rate of the diffusion processes in the solid phase and/or give intermediate compounds favouring or accelerating the C<sub>3</sub>S formation.

The mineralizers of this type (NaCl, CaCl<sub>2</sub>, B<sub>2</sub>O<sub>3</sub>, Na<sub>2</sub>B<sub>2</sub>O<sub>7</sub>, NaNO<sub>3</sub>, phosphates, fluorides, sulphates, a.s.o.), which gave interesting laboratory results, are numerous. Nevertheless most of them have the disadvantage of yielding technological conditions unfavourable for other aspects, or they involve costs not repaid by the advantages obtained. For this reason, today, the cement industry utilizes only fluorite and gypsum (or anhydrite), in particular cases and for specific purposes.

### 6.5 Minor volatile compounds.

6.5.1 The minor chemical species, whose vapor tension is unnegligible at the burning temperatures and, at the same time, not high enough at the temperature of the exhaust gases, volatilize in the hotter zones of the kiln and condense in the cooler ones (on the raw mix, on the walls, on the recuperators,

(\*) The stability of a structure corresponds to a minimum of the free energy F at temperatures > 0°K (F=U-TS, for isothermal and isochoral systems). Disorder and imperfections increase both the internal energy U and the entropy S. The stability decreases when ΔU > TΔS (159).

(\*\*) Liquid phase different from the typical liquid phase of clinkerization as for composition and properties (i.e. liquid phases of chlorides, sulphates, nitrates, a.s.o.).

a.s.o.). Thus, a cycle of these compounds is established (163, 164, 165, 166, 167, 168, 169, 170, 171, 172, 173, 174). It increases the concentration in the processed material up to the (maximum) level  $X_i$  needed to balance the entering and the coming out amounts.

With respect to the concentrations  $A_i$  and  $A_{ki}$  of the chemical species  $i$ , in the fresh raw meal and in the fuel respectively,  $X_i$  expresses the intensity of the cycle of that chemical species by the recycling factor  $K_i$  (167):

$$K_i = \frac{X_i}{A_i + A_{ki}}, \text{ undim.} \quad [22]$$

with  $X_i$ ,  $A_i$  and  $A_{ki}$  in homogeneous units of mass concentration.

$K_i$  depends on the type of process (171) and other different parameters, among which the coefficients of primary volatility  $\epsilon_{1i}$  and cycle volatility  $\epsilon_{2i}$  of the considered species (167):

$\epsilon_{1i}$  = mass fraction, with respect to the total one, of the species  $i$  volatilized from the fresh raw meal having concentration  $A_i$  (undim.);

$\epsilon_{2i}$  = mass fraction, with respect to the total one, of the species  $i$  volatilized from the burning raw meal having concentration  $X_i$  (undim.).

The two coefficients are referred to given temperatures.

Ritzman (172) published the quantitative relations from which  $X_i$  and the concentration of  $i$  in clinker, at steady condition, are calculated versus  $A_i$ ,  $A_{ki}$ ,  $\epsilon_{1i}$ ,  $\epsilon_{2i}$  and other variables of the process. From Locher et Al.'s (170) equations, it is possible to calculate  $X_i$  versus the time of recycle, as well as the time necessary to attain the equilibrium concentration  $X_i$  in the burning material.

6.5.2  $\text{Cl}^{1-}$ ,  $\text{Br}^{1-}$ ,  $\text{J}^{1-}$ , alkalis, sulphates, fluorides and zinc compounds produce cycles.  $K_i$  of the two latter species are very low. There is little information on the cycles of  $\text{Br}^{1-}$  and  $\text{J}^{1-}$  even if there is evidence of the aggressiveness of these halogens on the electrofilters and their ducts.  $K_i$  (and therefore  $X_i$ ) of chlorides, sulphates and alkalis are high and liable for the direct or indirect formation of most coatings and rings which jeopardize the regularity and the operation continuity of kilns.

In the technological practice, three methods allow the coming out amounts of volatile compounds to be increased in order to reduce  $X_i$ :

- shut off of the cycle generally by total elimination of the dust of electrofilter (and sometimes of grate in the lepol kilns) when the volatile compound concentrates in the dust (170, 175). The latter condition, and the necessity to reutilize the recovered dust, limit the prac-

tability of the method only to the kilns producing very reduced amounts of dust ( $0.04 + 0.06 \text{ kg/kgcli.}$ ), that is to the lepol and the nodule-fed kilns. (In order to reduce the production of dust the characteristics of the nodules can be improved by avoiding the presence, in the raw meal, of compounds hydrolyzable in  $\text{Ca}^{2+}$ , by adding  $\text{Na}_2\text{CO}_3$ , a.s.o.);

- shut off of the cycle by (partial or total) bypass of the exit gases in the suspension preheater kilns (165, 166), especially when they are equipped with precalciner (176, 177, 178, 10);
- reduction in the volatilization of the chemical species which recycles by addition of suitable compounds to the raw meal (see paragraphs 7.3.4 and 7.6.3) and by adopting the measures which enable the burning at lower temperatures. Obviously, in this way, clinker becomes richer in volatile compound. This method is favoured by the semi-dry process since the nodules release fewer compounds than the raw meal, at any other condition unchanged (164, 171).

## 7. BEHAVIOUR OF SOME MINOR COMPOUNDS.

### 7.1 Sulphates.

7.1.1 Sulphates (gypsum, anhydrite, celestine, baritine), and exceptionally elementary sulphur, are often present in the evaporitic limestones. On the contrary the ancient limestones can be mineralized by sulphides (prevailing blende and galena). Clayey sediments, marls, detrital rocks contain both sulphides (pyrites and marcassite) and sulphates. Gypsum and anhydrite are sometimes added to the raw mix as mineralizers and modifiers of the recycle of alkalis (170). Sulphides and sulphur of the raw meal and the fuel are oxidized to sulphates and combined, as such, in the solid phases during burning (179, 169).

7.1.2 Fundamental knowledge of the sulphate-containing systems:

- $\text{SO}_3$  preferably combines as  $(\text{K}, \text{Na})_2\text{SO}_4$ . At ordinary temperature, the solid solution contains the two sulphates in the same ratio of the present oxides if (in moles)  $\text{SO}_3 \rightleftharpoons \text{K}_2\text{O} + \text{Na}_2\text{O}$ ; on the contrary it corresponds to about  $3\text{K}_2\text{SO}_4 \cdot \text{Na}_2\text{SO}_4$  in the opposite case (180);
- $2\text{CaSO}_4 \cdot \text{K}_2\text{SO}_4$  is stable up to  $1011^\circ\text{C}$  in the system  $\text{CaSO}_4\text{-K}_2\text{SO}_4$ . The compound can form during the cooling of high potassium and sulphate clinkers (181);
- $3\text{CA} \cdot \text{CaSO}_4$  (182, 183) is stable up to about  $1400^\circ\text{C}$ . Kostov (184) explains how to calculate its amount, eventually together with  $\text{C}_3\text{A}$ , in the clinkers rich in  $\text{CaSO}_4$ . Alkalis (185) and low A : F ratios ( $\leq 0.64$ ) (186) prevent its formation;

- $2C_2S \cdot CaSO_4$  (187) forms from the oxides already at  $900^\circ C$ . Above  $1298^\circ C$  it decomposes in  $\alpha - CaSO_4$  and  $\alpha' - C_2S$  containing 1.1 mole %  $CaSO_4$ ;
- $C_3S$  coexists with  $CaSO_4$  in the system  $CaO - C_2S - CaSO_4$  (188). The saturated solid solution of  $CaSO_4$  in  $C_3S$  contains about 2.9%  $SO_3$  (at  $1310^\circ C$ ) (189). Sulphatic  $C_3S$  has lower hydraulicity (189) and decreasing mechanical strengths as the  $SO_3$  content increases (190);
- the compatibility (coexistence at the equilibrium) among  $CaSO_4$ ,  $2C_2S \cdot CaSO_4$  and  $3CA \cdot CaSO_4$  and  $SCA \cdot CaSO_4$  with  $CaO$ ,  $C_2S$ ,  $C_12A_7$  and  $Ca$  - in the  $950^\circ/1150^\circ C$  range and in the

lower alkali content than  $SO_3$  (including the one of fuel), in the absence of  $Cl^{1-}$ , allows the alkalis to be "fixed" in clinker as sulphates and therefore it reduces the internal cycle of the kilns (FIG. 13). Generally the quality (early mechanical strengths) of clinker is favoured by the condition (in moles)  $SO_3 > K_2O + Na_2O$  - at least for limited amounts of  $SO_3$  in excess (200, 201, 202, 203, 204). The most effective action of  $CaSO_4$  is obtained on raw meals having low A : F ratio ( $1.2 + 1.5$ ) and moderate lime saturation ( $\sim 0.8$ ), for contents of  $2.3 + 2.5\%$   $SO_3$  in clinker (186).

Alkali sulphates are less active mineralizers than  $CaSO_4$ . On the other hand they promote-similarly

FIG. 13 .FORMATION OF ALKALI SULPHATES IN CEMENT KILNS. AFTER LOCHER ET AL. ( 170 ).

absence of  $K_2SO_4$  and  $C_3S$  - was established by Pliego Cuervo et Al. (191).

**7.1.3** The advantages of the addition of calcium sulphate to the raw meals have repeatedly been reported, especially by Russian Authors (192, 193, 194, 195, 196, 197, 198, 199).  $CaSO_4$  is an effective flux and mineralizer: it lowers the appearance temperature of the liquid phase by over  $100^\circ C$ , it decreases its viscosity and surface tension and increases the mobility of  $Ca^{2+}$ ,  $Si_xO_y^{2-}$ ,  $Al^{3+}$ ,  $AlO_4^{2-}$ ,  $Fe^{3+}$  (137).

The addition of  $CaSO_4$  to raw meals having molarly

FIG. 14 .SO<sub>2</sub> EMISSIONS WITH THE GASES OF SUSPENSION PREHEATER AND LEPOL KILNS. AFTER LOCHER ET AL. (170).

to  $F^{1-}$  and  $Cl^{1-}$  - the formation of  $C_3S$  (181).

**7.1.4** Nevertheless the use of calcium sulphate must be cautious. One must consider the lower hydraulicity of sulphatic alite, as well as the fact that the simultaneous presence of  $Al^{3+}$  and  $SO_4^{2-}$ , in the absence of  $MgO$ , impoverishes the clinker in  $C_3S$ , whose formation can even be prevented (189). Still in the absence of suitable concentration in  $MgO$ , also  $Na_2SO_4$  and high contents in  $K_2SO_4$  can avoid the  $C_3S$  formation (181). The unfavourable effect of the combined action of  $Al^{3+}$  and  $SO_4^{2-}$  is eliminated, or strongly weakened, by the presence of a sufficient

quantity of MgO. These phenomena are likely to be related to the particular "wetting and penetrating" properties of the liquid phases containing high amounts of alkali sulphates which, in this way, would be able to "mineralize" a very rapid decomposition of  $C_3S$  at 1250°C, during the clinker cooling (205). Finally one must remember the role of sulphates in the formation of rings and coatings (206, 207) which, in the upper parts of kilns, prevailing consist of sulposilicate,  $2CaSO_4 \cdot K_2SO_4$  and  $Na_2SO_4$ .

7.1.5 The  $SO_2$  emissions with the kiln gases which process, under normal condition, raw meals and fuels containing sulphur compounds are poor (179, 170, 208, 209). The graph of FIG. 14 shows the  $SO_2$  concentrations in the gases, calculated by Locher et Al. (170) versus the overall amounts of sulphur entering the kiln.

## 7.2 Fluorides.

7.2.1 The vicariance between  $F^{1-}$  and  $OH^{1-}$  makes fluorine the most important halogen of the sedimentary rocks. It is contained in carbonatic rocks (100 + 600 ppm F), combined as fluorite and fluorapatite; in marls, clays, shales (300 + 2500 ppm F); in sandstones, calcareous sands, loess (80 + 360 ppm F). The minerals of the most rich clays are illite ( $0.1 \pm 0.3\%$  F), micas ( $0.1 \pm 0.2\%$  F), montmorillonite ( $\sim 0.03\%$  F). Fluorine is always present in the cement raw mix and it is often added to improve its reactivity.

7.2.2 Some aspects of the equilibria in the  $CaF_2$  containing-systems are interesting for the practical implications:

- in the system C - S -  $CaF_2$ ,  $(C_2S)_2 \cdot CaF_2$  forms at 950°C and decomposes at 1040°C in  $\alpha'$ - $C_2S$  and  $CaF_2$  (210). The compound  $11CaO \cdot 4SiO_2 \cdot CaF_2$  (211), or more precisely  $19CaO \cdot 7SiO_2 \cdot 2CaF_2$  (212), also called " $(C_3S)_3 \cdot CaF_2$ " is stable between 1110°C and 1185°C. Its incongruent melting gives trigonal  $C_3S$ ,  $\alpha'$ - $C_2S$  and liquid, at 1185°C;
- in  $C_{12}A_7$ ,  $O^{2-}$  is replaced by  $F^{1-}$  at 1300°C in a continuous series of solid solutions (213),  $C_{12-x}A_7 \cdot (CaF_2)_x$  ( $0 \leq x \leq 1$ ), whose extreme term contains 2.7% F. The singular term, when  $x=0.8$ , contains 2.3% F. In the most basic part of the system C - A -  $CaF_2$ , the solid solutions of the interval  $0.8 \leq x \leq 1.0$  are in equilibrium with CaO at 1300°C; those of the interval  $0 \leq x \leq 0.8$ , with  $C_3A$  (214). In the most basic and F-poorest part of the system C - A - S -  $CaF_2$  (215) the solutions of the interval  $0.8 \leq x \leq 1.0$  are compatible, each time, with  $C_2S$  and  $C_3S$  at 1300°C, or with  $C_3S$  and CaO, but not with  $C_3A$ . On the contrary, the latter is in equilibrium with the solutions of the interval  $0 \leq x \leq 0.8$ ,  $C_2S$  and  $C_3S$  (FIG. 15). It is therefore wrong to think that, in every case,  $CaF_2$  decompo-

ses  $C_3A$  in CaO and a solid solution of F in  $C_{12}A_7$  (216); really this occurs only for higher contents in  $CaF_2$  than those of the plane  $C_2S$ - $C_3S$ - $C_{11.2}A_7 \cdot (CaF_2)_{0.8}$ . In the practice the fluoridized clinkers contain  $C_3A$  or  $C_{12-x}A_7 \cdot (CaF_2)_x$ , or both, depending on the F content and the cooling conditions (217);

- the system C - A - F -  $CaF_2$  at 1250°C (218), in its most basic part, has not quaternary compounds but only solid solutions containing a small amount of fluoride;
- in the system C -  $C_2S$  -  $CaSO_4$  -  $CaF_2$  between 1000°C and 1150°C (212), an only quaternary compound  $3C_2S \cdot 3CaSO_4 \cdot CaF_2$  (fluorellestadi-

FIG. 15 . MOST BASIC PART OF THE SYSTEM C-A-S- $CaF_2$  (NOT TO SCALE). AFTER MASSAZZA AND PEZZUOLI (215).

te) is present. It is incompatible with both  $C_2S$  not saturated with  $CaSO_4$  (1000°C) and " $(C_3S)_3 \cdot CaF_2$ " (1150°C). The two silico-fluorides  $(C_2S)_2 \cdot CaF_2$  and " $(C_3S)_2 \cdot CaF_2$ " would only form in the raw meals containing F :  $SO_3$  (mass %)  $> 0.158$ .

7.2.3 Even small amounts ( $< 0.3\%$   $CaF_2$ ) of fluorides in the raw meal increase the values of  $p_{CO_2} = f(t)$  of the carbonatic phase and they modify the kinetics of all the burning reactions deeply (2, 219, 82, 3, 220, 221, 222). The amount of  $\beta$ - $C_2S$ , which forms as from 750°C, increases and a liquid phase, which favours the diffusion processes among the reacting solid phases, appears already at 800°C (223). Therefore, at 850°C ( $p_{CO_2} = 1$  atm), the presence of  $CaF_2$  determines the formation of  $(C_2S)_2 \cdot CaCO_3$  which, at 960°C ( $p_{CO_2} = 1$  atm), decomposes by separating  $CO_2$ ,  $C_2S$  and CaO, the two latter in a particularly active state to be combined in  $C_3S$ : in this way, spurrite would play a role of intermediate phase which accelerates the formation of alite. These phenomena are evidenced, in the DTA graphs, by the variations in height or area of the thermal effects of the transformations versus the content in  $CaF_2$  (82) (FIG. 16). The de-

creases in the specific effectiveness of fluoride as its concentration increases is also clear, as area-

FIG. 16 DTA EFFECTS OF THE RAW MEAL VERSUS  $\text{CaF}_2$  CONTENT. AFTER COURTAULT (82).

dy pointed out by Vogel (2) and recently reconfirmed by Johansen et Al. (224).

Similarly to spurrite, also  $(\text{C}_2\text{S})_2 \cdot \text{CaF}_2$  and  $\text{C}_{19}\text{S}_7 \cdot 2\text{CaF}_2$  would give rise, between 950 and 1200°C approx., to a mechanism of formation of alite through incongruent melting of  $\text{C}_{19}\text{S}_7 \cdot 2\text{CaF}_2$ , according to a scheme proposed by Gutt (220). The higher rate of formation of  $\text{C}_3\text{S}$  in the presence of  $\text{CaF}_2$  is also attributed (224) to the larger extension of the primary phase field of  $\text{C}_3\text{S}$  in the C-S- $\text{CaF}_2$  and C-S-A systems. In any case the  $\text{C}_3\text{S}$  formation begins at lower temperatures by at least 150° + 200°C than those in the absence of fluorides.

On the contrary the existence of  $\text{C}_{19}\text{S}_7 \cdot 2\text{CaF}_2$  involves - during the clinker cooling - the attack of alite and belite by the liquid, with separation of  $\text{C}_{19}\text{S}_7 \cdot 2\text{CaF}_2$  because of the peripheral reaction at 1185°C (225). In the practice the rate of cooling is always fast enough so that the reaction does not occur; nevertheless the case of fluoridized clinkers containing  $\text{C}_{19}\text{S}_7 \cdot 2\text{CaF}_2$  (as a coating of alite) is not rare. The poor hydraulicity of  $\text{C}_3\text{S}$  fluoridized (226) would explain the low mechanical strengths of clinkers containing more than 0.5 + 0.6% F (227).

7.2.4 The mineralizing action of fluorine compounds is attributed to their influence on the stability of the rhombohedral structure of  $\text{CaCO}_3$  and on the mobility of the  $(\text{SiO}_4)^{\text{IV}}$  groups of silicates (82). This influence increases as the lattice energy of fluoride increases and therefore, in first approach,

as the radius of the cation decreases. For this reason, at the same concentration in F,  $\text{MgF}_2$  and  $\text{LiF}$  have higher effectivenesses and (in decreasing order)  $\text{NaF}$ ,  $\text{CaF}_2$ ,  $\text{SrF}_2$  the lower ones.  $\text{BaF}_2$  and  $\text{KF}$  are the less active (82, 147). The fluosilicates, having the same ionic species and equal content in F, have equal (82) or slightly lower (228) effectiveness than that of fluorides.

7.2.5 Fluorite is generally used in the technological practice for its lower cost and its easy handling. In the last few years its use has extended not only to the manufacture of white clinkers but also of normal ones because of the fuel saving and the increase in the kiln capacity that this mineralizer and flux often enables. The advantages obtainable, at the same amount added, are not equal for all the raw meals and all the types of kiln: as a rule, the harder raw meals to burn, containing macrocrystalline rocks, and the short processing-kilns, above all the lepol ones, take the most advantage. The internal cycle of fluorine in the burning plants is weak and such that only traces are found in the gases (229). The losses correspond to the eventual shut off of the cycle by extraction of the electrofilter dust which generally has higher (10 + 20%) concentration in fluoride than that of the raw meal (values referred to the calcined matter).

Experience suggests to limit the additions of fluorite not above 0.5 + 0.6% F of clinker, in order to avoid the dangerous decrease in mechanical strengths. Within this limit the hydraulicity and the strengths of clinker are quite normal if it still contains 1 + 2% free  $\text{CaO}$  or anyhow it is intended for the production of high fineness cement.

### 7.3 Phosphates.

7.3.1 The organogen sedimentary rocks (fossiliferous limestones, marls and clays of shore-sea facies, a.s.o.) contain varying and sometimes considerable amounts of phosphates. These minerals are also present in sandstones, sands, and prevailingly detrital clays. Phosphorus compounds are contained in the by-products of the siderurgical industry (blastfurnace slags, slags from electric furnaces, from converters, a.s.o.) often used in the cement raw meal.

7.3.2 The fundamental knowledge on the phosphatic clinkers is mainly due to the Researchers (230, 231, 232, 227, 233, 220) of the Building Research Station of Garston (United Kingdom). Schlaudt (234), V'lkov and Tabakova (235), Fix et Al. (236), Salge and Thormann (237) gave further contributions.

$\text{P}_2\text{O}_5$  preferably concentrates in belite to the detriment of alite and the intersital phase (237): the concentrations in the three phases are in the ratio 4: 2: 1 approximatively.

In the system  $\text{CaO} - \text{SiO}_2 - \text{P}_2\text{O}_5$ , a series of solid solutions of  $\text{CaO}$  and  $\text{P}_2\text{O}_5$  in  $\text{C}_3\text{S}$  (233) appears as

a primary phase of crystallization. The compositions given in TAB. VI have been assigned to the saturated term (called  $C_3S''$ ) (233, 234, 237).  $C_3S''$

TAB. VI. APPROXIMATE COMPOSITIONS (MASS %) OF  $C_3S''$  AFTER DIFFERENT AUTHORS (233, 234, 237).

	Gutt (1963)	Schauldt (1964)	Salge and Thormann (*) (1973)
CaO %	74.0	73.4	72.9
SiO <sub>2</sub> %	25.5	25.5	25.1
P <sub>2</sub> O <sub>5</sub> %	0.5	1.1	2.0
$C_3S$ %	96.9	96.9	95.4
CaO %	2.6	2.0	2.6
P <sub>2</sub> O <sub>5</sub> %	0.5	1.1	2.0
(*) in the presence of Al <sub>2</sub> O <sub>3</sub> , Fe <sub>2</sub> O <sub>3</sub> , MgO and alkalis.			

has trigonal structure; with respect to  $C_3S$ , it shows a distorted elementary cell having reduced dimensions (227). The hydraulic activity ought to be slightly higher than that of  $C_3S$ .

Phosphatic belite is a solid solution of  $\bar{\alpha}$ - $C_3P$  in  $\beta$ - $C_2S$  (for contents  $\leq 2\%$  P<sub>2</sub>O<sub>5</sub>) and in  $\alpha'$  and  $\alpha$ - $C_2S$  (for higher contents in P<sub>2</sub>O<sub>5</sub>) (227). Since the series of solid solutions  $C_2S$ - $C_3P$  shows a lack of subsolid miscibility, a limiting composition called PSS' is in equilibrium with  $C_3S''$  at 1500°C. There are still considerable uncertainties for the practical consequences on the composition of PSS' (TAB. VII). It must not even be excluded that it falls outside the line joining  $C_2S$  to  $C_3P$ , towards higher lime contents, because of the marked aptitude of this solution to take hyperstoichiometric CaO (236, 237). The composition of PSS' found by Nurse (230) confirms this hypothesis.

7.3.3 The portion of the system CaO- $C_2S$ - $C_3P$  near  $C_2S$  and  $C_3S$ , at 1500°C, is shown in FIG. 17 where the compositions deducible from the paper (237) have been assigned to  $C_3S''$  and PSS'.

The phases in equilibrium are:

- $C_3S$  and solid solution  $C_2S$ -PSS', for lower content in P<sub>2</sub>O<sub>5</sub> than the line  $C_3S$ -PSS';
- solid solution  $C_3S$ - $C_3S''$  and PSS', for content in P<sub>2</sub>O<sub>5</sub> between the line  $C_3S$ -PSS' and the line  $C_3S''$ -PSS';
- CaO, solid solution  $C_3S$ - $C_3S''$  and PSS' for higher content in P<sub>2</sub>O<sub>5</sub> than the line  $C_3S''$ -PSS'.

$C_3S''$  disappears, as an equilibrium solid phase, for higher contents in P<sub>2</sub>O<sub>5</sub> than the line CaO-PSS'. In the  $C_3S$ - $C_2S$ -PSS'- $C_3S''$  field, the amounts of  $C_3S$  and/or  $C_3S''$  decrease and that of solid solu -

tion between  $C_2S$  and PSS' increases as the % of P<sub>2</sub>O<sub>5</sub> increases: an experimental confirmation was obtained by Salge and Thormann (237). The opportunity of using very high values of lime saturation (or even supersaturation) for the phosphatic raw meals, consistently with the present content in P<sub>2</sub>O<sub>5</sub>, is clear.

The hydraulicity of the phosphatic clinkers shows a

slight increase for low contents in P<sub>2</sub>O<sub>5</sub> (0.5+1.0%) (235, 237, 238, 239), probably due to the peculiar structure of  $C_3S''$ ; afterwards it considerably decreases as the content in P<sub>2</sub>O<sub>5</sub> increases. This drop must be related to the decrease in the  $C_3S/C_2S$

FIG. 17. MOST BASIC PART OF THE SYSTEM CaO- $C_2S$ - $C_3P$  AT 1500 °C (NOT TO SCALE).

ratio, as well as to the progressive increase in the amount of the structures  $\alpha'$  and  $\alpha$ C<sub>2</sub>S, to the detriment of the  $\beta$ -form.

7.3.4 It is recognized (235, 240, 241, 242) that phosphates have a strong accelerating action on all the reactions occurring during the burning of clinker. The process of combination of CaO in the solid phase is facilitated; conditions favourable for a rapid crystallization of the clinker minerals occur in the presence of liquid phase.

The presence of hydroxyapatite in raw meals containing chlorides ought to reduce their intensity of internal recycle in the kilns and in this way it should avoid (or minimize) the formation of spurrite coa -

lime saturation	maximum content	optimum content
0.74	2.0	1.5
0.84	1.5	1.0
0.94	1.0	0.3

tings (207). Therefore the correction of raw meals with suitable amounts of phosphatic additions can be an effective means to improve some technological conditions of the clinker burning.

The uncertainty of the compositions of C<sub>3</sub>S" and, above all, of PSS' does not allow the calculation of the maximum content in P<sub>2</sub>O<sub>5</sub>, practically allowable in a raw meal. V'lkov and Tabakova (235) suggest the limits shown in TAB. VIII.

7.3.5 The favourable influence of CaF<sub>2</sub> on the raw meals containing P<sub>2</sub>O<sub>5</sub> was examined by several authors among whom Simanovskaya and Vodzinskaya (243) and Gutt (220). Tymashev et Al. (244) studied the effects of concentrations of 0.8-1.5% P<sub>2</sub>O<sub>5</sub> on the raw meals containing high amounts of alkalis.

#### 7.4 Titanium compounds.

7.4.1 Titanium is present in the clayey sediments and in the detrital ones as both hydrolysis product coprecipitated with Al, Fe, Be and Zr (bauxites, laterites, a.s.o.) and combined in less alterable residual minerals, such as ilmenite, rutile and titanite.

7.4.2 Owing to the great proximity of the ionic rays and the strong energy of the bond Ti-O, Ti<sup>4+</sup> is vicariant of Fe<sup>3+</sup> in the tetrahedra (FeO<sub>4</sub>)<sup>V</sup> of calcium aluminoferrite (245, 246, 247, 248). It also replaces Al<sup>3+</sup> in the same aluminoferrite and the aluminate (orthorhombic, cubic and tetragonal forms)

TiO <sub>2</sub> of clinker	0.24 + 0.34	0.78	-	1.00

NOTES. (\*) Arithmetical mean of the determinations on four industrial clinkers.  
 (\*\*) Clinker 1 of (158).  
 (\*\*\*) Mean of six determinations on one laboratory clinker.

(158, 249). In alite, the vicariance between (TiO<sub>2</sub>)<sup>IV</sup> and (SiO<sub>2</sub>)<sup>IV</sup> is limited (1500°C) at 13 mole %, equal to 4.53 mass % TiO<sub>2</sub> of C<sub>3</sub>(S, T). The form M<sub>II</sub> and the form R remain stabilized up to 7 mole % (2.45 mass % TiO<sub>2</sub>) and for higher contents respectively (250). The limit of the solid solution in belite corresponds to 0.76 mass % TiO<sub>2</sub> (251). The limits of vicariance of Ti<sup>4+</sup> instead of Si<sup>4+</sup>, Al<sup>3+</sup> and Fe<sup>3+</sup> in the minerals of pure clinker result from a recent research (252):

	TiO <sub>2</sub> mass %
C <sub>3</sub> (S, T)	5.0 ± 0.3
C <sub>2</sub> (S, T)	0.7 ± 0.1
C <sub>3</sub> (A, T)	1.1 ± 0.2
C <sub>4</sub> (AF, T)	18.5 ± 0.5

The distribution in the different phases of clinker appears to be varying (253, 49, 254, 158); nevertheless the tendency to the enrichment in aluminoferrite is clear (TAB. IX).

It was reported (254) that increasing amounts (up to 4%) of TiO<sub>2</sub> in a clinker having K<sub>st</sub> = 90, SM = 2, TM = 1 - not in equivalent replacement of SiO<sub>2</sub> - determine a sharp reduction in the alite content with equal gain in belite without, however, appreciable variations in the amounts of the other phases (FIG. 18).

Variations of the same type are much more restrained when TiO<sub>2</sub> is added in place of equivalent amounts of SiO<sub>2</sub>. It is assumed that either the solid solution of TiO<sub>2</sub> in belite contains hyperstoichiometric CaO (as is assumed for phosphatic belite) or

the presence of TiO<sub>2</sub> displaces the compositions of the invariants at 1338°C and 1341°C of the system C - S - A - F.

In any case, in the practice, it seems suitable to cal

culate the saturation of the raw meals containing  $\text{TiO}_2$  (not exceeding  $\sim 2.5\%$ ) by summing the % of  $\text{SiO}_2$  to the % of  $\text{TiO}_2$  (in equivalent amounts).

FIG. 18 .PHASES IN THE  $\text{TiO}_2$  CLINKERS, AFTER KNÖFEL(254).

7.4.3 1% (of clinker) of  $\text{TiO}_2$  is enough to reduce the temperature of incipient melting of the raw meal by  $50^\circ - 100^\circ\text{C}$  (254).  $\text{TiO}_2$  reduces the surface tension of the liquid phase (138) and causes a drop in the viscosity proportional to its concentration (at least within 4%  $\text{TiO}_2$ ) (255). These conditions facilitate the  $\text{CaO}$  combination and the alite formation, which are however considerably favoured also by the intermediate formation of  $\text{CaO} - \text{TiO}_2$  and solid solutions of  $\text{CaO}$  in the same. The effectiveness of the mechanism of  $\text{C}_3\text{S}$  production would even exceed the one occurring in the presence of  $\text{CaF}_2$  (256). The presence of  $\text{TiO}_2$  gives clinker a darker colour than the usual one.

7.4.4  $\text{TiO}_2$  retards the initial rate of the clinker hydration (250, 49, 254, 257) with slower setting times and lower early strengths (1 and 2 days). Nevertheless Kondo (250) showed that alite containing  $\text{TiO}_2$  has a higher hydraulic activity than ordinary alite for ages over three days. The  $\text{TiO}_2$  clinkers examined by Knöfel (254, 252) confirm higher (up to 20%) strengths between 3 and 90 days, for  $\text{TiO}_2$  contents of about 1%. The highest increases occur in clinkers having very high lime saturation and high SM (252).

## 7.5 Chrome compounds.

7.5.1 Generally limestones contain only traces of chrome. Since Cr is an isomorphogenous substitute

in the feric silicates, it is found in the sediments from basic and ultrabasic rocks and in the sedimentary products of hydrolysis (laterites, bauxites, a. s.o.). Chrome is sometimes present in the raw meals containing siderurgical slags. The wear of the grinding media and the linings of the raw mix mills as well as the one of the refractory inside the kilns produce only traces.

7.5.2 Although there is a certain disagreement (258, 259, 155, 260) about whether chrome replaces  $\text{Ca}^{2+}$  or  $\text{Si}^{4+}$  in  $\text{C}_3\text{S}$ , or both, the latest research (261, 262) seems to indicate that tetrahedra  $(\text{CrO}_4)^{\text{III}}$  and  $(\text{CrO}_4)^{\text{IV}}$  replace  $(\text{SiO}_4)^{\text{IV}}$  according to:

( $\text{Ca}^{2-}$  = lattice vacancy of Ca), with mean state of oxidation of Cr +4.6 (155). Different Authors fix the limit of solubility at 0.9 (263), 1.4 (264), 1.5 (265, 266), 1.7 (155), 2.0 (259) of  $\text{Cr}_2\text{O}_3$  mass % of solid solution. The  $\text{Cr}_2\text{O}_3$  saturation increases the solubility of  $\text{Al}_2\text{O}_3$  (1.1 to 1.3%) in  $\text{C}_3\text{S}$  and it decreases that of  $\text{Fe}_2\text{O}_3$  (0.9 to 0.7%) (155).  $\text{Cr}_2\text{O}_3$  in excess with respect to saturation decomposes  $\text{C}_3\text{S}$  in  $\text{C}_2\text{S}$  and  $\text{CaO}$  (155, 265, 138). According to Sakurai et Al. (155) the forms  $\text{T}_\text{I}$  and  $\text{T}_\text{II}$  (for  $\text{Cr}_2\text{O}_3 \leq 1.4\%$  and  $\text{Cr}_2\text{O}_3 > 1.4\%$ , respectively) remain stabilized at ordinary temperature; according to Hornain (49), on the contrary, the hexagonal forms and  $\text{M}_\text{Iado}$ .

$\text{Cr}^{5+}$  replaces  $\text{Si}^{4+}$  in  $\text{C}_2\text{S}$  at  $1100^\circ\text{C} + 1250^\circ\text{C}$ , by stabilizing the form  $\beta$  at ordinary temperature; the limit of solubility attains at least 8.6 of  $\text{Cr}_2\text{O}_3\%$  solid solution (267, 261).

$\text{Cr}^{6+}$  replaces  $\text{Al}^{3+}$  in  $\text{C}_3\text{A}$  (49, 150).

In  $\text{C}_6\text{A}_p\text{F}_{1-p}$  ( $0 \leq p \leq 0.7$ )  $\text{Cr}^{6+}$  occupies octahedric sites instead of  $\text{Fe}^{3+}$  and  $\text{Al}^{3+}$  (247).

Peters and Hummel (268) studied the relations of subsolid phase in the systems  $\text{CaO} - \text{Al}_2\text{O}_3 - 3\text{CaO} \cdot 3\text{Al}_2\text{O}_3 \cdot \text{CaCrO}_4 - \text{Al}_2\text{O}_3$  at  $1300^\circ\text{C}$  and  $\text{SrO} \cdot \text{Al}_2\text{O}_3 - 3\text{SrO} \cdot 3\text{Al}_2\text{O}_3 \cdot \text{SrCrO}_4 - \text{Al}_2\text{O}_3$  at  $1400^\circ\text{C}$ .

In a typical clinker containing 0.55%  $\text{Cr}_2\text{O}_3$ , 76.3%  $\text{C}_3\text{S}$ , 9.1%  $\text{C}_2\text{S}$ , 5.3%  $\text{C}_3\text{A}$  and 8%  $\text{C}_4\text{AF}$ , Hornain (49) found the following distribution of chrome into the different phases (ratios among mass concentrations of  $\text{Cr}_2\text{O}_3$  in the phases):

alite	: belite	: aluminate	: alumino-ferrite
1	: 2	: 0.1	: 1.4

The limit of solubility of  $\text{Cr}_2\text{O}_3$  in clinker is about 2% (under oxidizing conditions): considera-

ble amounts of free CaO appear above this concentration (241).

7.5.3 The viscosity of the liquid decreases, at the same temperature, for concentrations up to 2%  $\text{Cr}_2\text{O}_3$  of liquid (138). Increasing contents of  $\text{Cr}_2\text{O}_3$  up to 4 mass% cause also a reduction in the surface tension; this reduction is the greater the higher the A : F ratio (269).

Therefore the lime combinations is favoured in the raw meals which are difficult to burn and have high A : F ratio (270).

Alite forms more rapidly and its crystals become larger (49).

However, also as regards the kinetics of the clinker formation, it is suitable that the  $\text{Cr}_2\text{O}_3$  content does not exceed  $0.5 \pm 1.0\%$  of clinker (154, 137).

7.5.4 The solid solution of chrome in  $\text{C}_3\text{S}$  contains, in the lattice, punctual defects due to vacancies and linear faults which, during the reaction with water, favour the detachment of  $\text{Ca}^{2+}$  from the latyice sites.

Although the data of the literature are discordant on the minimum amount of  $\text{Cr}_2\text{O}_3$  needed, nevertheless it is ascertained that the presence of  $0.25 \pm 0.50\%$   $\text{Cr}_2\text{O}_3$  increase the initial hydraulic activity of clinker (155, 260, 138, 49, 241, 271, 152).

The effect mainly concerns the mechanical strengths at very short ages (270) of clinkers having high lime saturation (154) and high A : F ratio (270).

Strengths at longer ages are not affected or are negatively influenced (270).

The presence of small amounts of fluorine and manganese favours the action of chrome (272).

## 7.6 Potassium and sodium.

7.6.1 The main carriers of alkalis into clayey rocks and clastic sediments are orthoclase, albite and plagioclase of magmatic rocks.

K and Na are also contained in the structure of some phyllosilicates, above all the three layer-sialites such as micas, illite, montmorillonite, montronite, a.s.o.

All the sediments, including the carbonatic ones, sometimes contain soluble alkali salts which are residues of the deposit environnement.

$\text{K}_2\text{O}$  and  $\text{Na}_2\text{O}$  in the raw meals of European cement factories (170) range between 0.5 and 2.0% and between 0.05 and 0.6% respectively (ratio of the mass concentrations between 3 and 10).

Jawed and Skalny (273) have recently revised the

knowledge about alkalis in clinker.

7.6.2 Because of their marked volatility, alkalis give rise to a cycle, inside the kilns, which increases their concentration in the processed material with possible danger to the regular course of the process (164, 167, 169, 170, 274).

The intensity of the recycle more concerns the potassium compounds than the sodium ones, being the former more volatile than the latter, at the same temperatures (FIG. 19) (164, 275, 276).

Moreover this intensity depends on the nature of the present alkali minerals and anionic species, on the chemical composition of the raw meal, on the characteristics of the process as well as on the type of kiln (173).

Under normal conditions, the alkali volatility of the raw meals increases, in the order, for feldspars, micas, illite and montmorillonite, that is as the bond energy of the considered silicate decreases (164).

Sulphates determine less intense cycles than carbonates, and these than chlorides (164) (FIG.19). The nodule-fed kilns (lepol and long with internal recuperators) have poorer recycles than the dry meal-fed ones (both with suspension preheater and long with internal recuperators) and than the wet kilns (171).

7.6.3 Although they act as fluxes, alkalis are the technologically less desirable compounds among the minor ones. They can be eliminated from the internal cycle through the three systems already men-

FIG. 19 VAPOR PRESSURE OF SODIUM AND POTASSIUM SULPHATES AND CHLORIDES (164, 275, 276).

ned in the paragraph 6.5.2:

- through shut off of the cycle by (total or partial) elimination of the electrofilter dust. This technique is not practicable with the suspension preheater kilns;
- through shut off of the cycle by (partial or total) bypass of the external recuperator. Unfortunately the method involves the wasting of an amount of energy which is proportional to the amount of bypass; this loss can substantially be reduced by the technique of the calcination outside the kiln (10).  
Today the total bypass of the kiln gases with a nearly full precalcination, enables low alkali clinkers to be cheaply produced also from raw meals rich in alkalis (277), eventually by using addition of calcium chloride (278, 279, 280, 281);
- through clinker. The method can be used in all the kilns and demands the conversion of alkalis to sulphates (279, 282). It involves fairly high amounts of recycling phase in the burning material and the production of clinkers having all the alkalis contained in the raw meal and fuel. Therefore it is not practicable with raw meals too rich in alkalis ( $K_2O + Na_2O > \text{about } 1.0\%$  of the calcined material) because of the forming coatings and rings. Moreover it is not even practicable with raw meals not very poor in alkalis ( $\leq 0.6\% Na_2O + K_2O$  equiv. of the calcined material) if they are intended for low alkali clinkers. The presence of Cl ( $> 50$  ppm of the calcined material) makes the system ineffective.

7.6.4 The alkalis present in clinker as sulphates, particularly  $K_2SO_4$ , favourably affect its strengths at early ages (up to 3 days) whereas they lower those at 28 days and over (42, 283).

## 7.7 Magnesium.

7.7.1 In the practice there are not calcareous rocks deprived of magnesium, which replaces  $Ca^{2+}$ , also at random. Generally limestones of the oldest formation are richer. Magnesium is also present in clayey and detrital sediments as a carbonate, as a silicate of primary rocks and finally as an isomorphogenous substitute in some phyllosilicates.

7.7.2  $MgO$  distributes, in the solid solution, into the clinker minerals as far as saturation; the excess remains uncombined as periclase.

In alite, the solid solution is of substitutive type

$Mg^{2+} \rightarrow Ca^{2+}$  (284, 158). Its content in  $MgO$  is a constant fraction of  $MgO$  of clinker, within the  $0 \leq MgO_{cli} \leq 3\%$  range; this fraction is 0.74 according to Yamaguchi and Takagi (285) and 0.63 according to Kristmann (50). As a rule, the richest alites are monoclinic (286); the poorest ones are trigonal (158, 50). The  $MgO$  content in belite is  $0.25 \pm 0.35$   $MgO$  of clinker, within the  $0 \leq MgO_{cli} \leq 2\%$  range (50). The presence of high concentrations in  $MgO$  would reduce the activation energy of the conversion  $\alpha - C_2S \rightarrow \alpha' - C_2S$ , with consequent stabilization, during cooling, of the hydraulically less active form  $\beta$  (287). Although the liquid phase can contain up to 8%  $MgO$  ( $A:F = 1.3$ ) (288), the replacement of  $Ca^{2+}$  and  $Fe^{3+}$  by  $Mg^{2+}$ , in  $C_3A$  and  $C_2A_pF_{1-p}$  ( $0 \leq p \leq 0.7$ ), generally yields matrixes containing 3.5%  $MgO$ . In some cases, concentrations of 6% and over have been found (50). The presence of magnesia favours compositions of  $C_2A_pF_{1-p}$  having higher values of  $p$ , with decrease in  $C_3A$  and corresponding increase in  $C_3S$ , to the detriment of  $C_2S$  (288, 289, 290, 48, 291).

Periclase appears as an independent phase in clinkers containing over 2%  $MgO$  (23, 50): depending

FIG. 20. AUTOCLAVE EXPANSION FOR INCREASING  $MgO$  CONTENT (297, 298, 299).

on its excess and the rate of cooling, it appears in large roundish crystals arranged in clusters as well as in dendritic shape, finely dispersed and well-distributed into the mass (292, 293, 294).

7.7.3 The reactivity of raw meals is favoured by the presence of MgO only in the range of the higher temperatures (about 1300°C) (228). At any other variable unchanged, the first appearance-temperature of the liquid drops by some tens of °C; viscosity and surface tension of the liquid reduce whereas the mobility of all the present ionic structures increases (137). Under these conditions, the dissolutions in the liquid of C<sub>2</sub>S and CaO are more rapid and C<sub>3</sub>S forms more quickly (228). Unfortunately - as known - the presence of periclase (especially the one in the form of large crystals in clusters) makes the cement unstable. Therefore the standards of several countries (295) limit its content and/or prescribe a test of unsoundness in autoclave (296).

The results achievable by this test with regard to the % of MgO in clinker, reported by different Authors (297, 298, 299) are shown in FIG. 20.

Nevertheless it is recognized that the test is not probative with every type of cement (288, 298).

Moreover the decrease in the mechanical strengths at medium ages, that some cements containing a limited amount of MgO (< 4 + 5%) show, also with quite normal volume stability, is worrying (291, 287, 288). According to Soda et Al. (287) this phenomenon would be limited only to clinkers very rich in C<sub>2</sub>S, containing over 2% MgO, and it would be attributed to the conversion of α-C<sub>2</sub>S to β-C<sub>2</sub>S.

7.7.4 Finally it must be noticed a curious relation between MgO and SO<sub>3</sub> present in clinker. It was seen (paragraph 7.1.4) that the impoverishment in C<sub>3</sub>S caused by the combined action of SO<sub>4</sub><sup>2-</sup> and Al<sup>3+</sup> is hampered by a suitable concentration in MgO. On the other hand, Schmitt-Hencko (299) showed that the volume instability of cements containing over 2% MgO is neutralized by the presence of an amount of SO<sub>3</sub> (in clinker) equal to:

$$\% \text{SO}_3 = 0.67 (\% \text{MgO} - 2) \quad [25]$$

when  $2 \leq \% \text{MgO} \leq 6$  about.

## 7.8 Strontium.

7.8.1 As a rule, strontium is present in minimum amounts in ancient limestones (and marls), attributable to sediments of skeletons and shells of organisms. On the contrary, even important contents (up to 10% SrO and over) are sometimes found in recent limestones (and marls), especially of evaporitic and chemical origin. The more frequent mineral is celestine (SrSO<sub>4</sub>). This (together with other evaporitic minerals) is also present, as a

cement, in the calcareous and siliceous detrital sediments (sandstones, grauwackes, a.s.o.). Strontianite is relatively rare; it is generally found in veins of limestones and marls.

7.8.2 The phase equilibria of the system CaO - SrO - SiO<sub>2</sub> were reexamined and completed by Brisi and Appendino (300) at 1200°C and, in the most basic part, at 1350°C.

In Ca<sub>2</sub>SiO<sub>4</sub>, Sr<sup>2+</sup> is vicariant of Ca<sup>2+</sup> in all the proportions (with stabilization of the form α'), whereas in Ca<sub>3</sub>SiO<sub>5</sub> the vicariance is limited to 1 + 2 atomic % Sr, roughly corresponding to (Ca<sub>2.95</sub>Sr<sub>0.05</sub>)SiO<sub>5</sub> (point N of FIG. 21). The structures

FIG. 21 . MOST BASIC PART OF THE SYSTEM CaO - SrO - SiO<sub>2</sub> (NOT TO SCALE) AFTER BRISI AND APPENDINO (300).

T<sub>I</sub> and T<sub>II</sub> remain stabilized, at room temperature, up to 1 atomic % Sr and at the limiting concentration respectively (301). In the two-phase field C<sub>2</sub>S - M - N - C<sub>3</sub>S, the solid solutions of SrO in C<sub>2</sub>S and SrO in C<sub>3</sub>S coexist, whereas in the three-phase field C - M - N, (Ca<sub>2.95</sub>Sr<sub>0.05</sub>)SiO<sub>5</sub> is in equilibrium with the solid solution (Ca<sub>1.8</sub>Sr<sub>0.2</sub>)SiO<sub>4</sub> (point M) and free CaO. It is deduced that the mixes of C<sub>3</sub>S + C<sub>2</sub>S can carry not more than 2.25 + 11.40% SrO (segment NM) in the solid solution, depending on the C<sub>3</sub>S : C<sub>2</sub>S ratio; for contents exceeding these limits, free CaO of equilibrium (coexisting with N and M) always appears. When SrO exceeds a value between 11.40% (point M) and 8.71% (point W) depending on the C<sub>3</sub>S : C<sub>2</sub>S ratio, the solid solution of 3SrO · SiO<sub>2</sub> in C<sub>3</sub>S disappears and only (Ca, Sr)<sub>2</sub>SiO<sub>4</sub> and (Ca, Sr)O remain in equilibrium (in the case concerning the composition of portland cement clinker, (Ca, Sr)O is practically pure CaO).

7.8.3 Gilioli, Massazza and Pezzuoli (302, 303) studied the equilibria of the systems CaO-SrO-SiO<sub>2</sub>-SO<sub>3</sub> and CaO-SrO-Al<sub>2</sub>O<sub>3</sub>-SO<sub>3</sub> at 1330°C. They

found in the former, on the segment  $\text{CaSO}_4\text{-SrSO}_4$ , three series of solid solutions separated by two lacks of miscibility, and the compound  $\text{CaSO}_4 \cdot 2\text{SrSO}_4$  (304) as a singular term (for  $x = 0.336$ ) of the series  $(\text{Ca}_{1-x}\text{Sr}_x)\text{SO}_4$  with  $0.6 \leq x \leq 0.7$ . The saturated solution N in the presence of  $\text{SO}_3$  is in equilibrium with M,  $\text{CaO}$  and a solid solution  $\text{SrSO}_4\text{-CaSO}_4$ : for this reason, the limits  $2.25 \pm 11.40\%$   $\text{SrO}$  become higher in the presence of  $\text{SO}_3$  (in fact, as FIG. 22 shows, a part of  $\text{SrO}$  forms a solid solution with  $\text{CaSO}_4$ ).

The equilibria of the systems  $\text{CaO-SrO-Al}_2\text{O}_3\text{-SO}_3$  (FIG. 23) evidenced incompatibilities between solid solutions  $\text{C}_3\text{A-3SrO}\cdot\text{Al}_2\text{O}_3$  and all the sulphate

FIG. 22 .MOST BASIC PART OF THE SYSTEM  $\text{CaO-SrO-SiO}_2\text{-SO}_3$ . AFTER GILIOLI ET AL. (302).

tic phases, except for the extreme term  $3\text{SrO}\cdot\text{Al}_2\text{O}_3$  with  $\text{SrSO}_4$ : therefore the solid solutions  $3(\text{CaO}, \text{SrO})\cdot\text{Al}_2\text{O}_3$  decompose in the presence of  $\text{SO}_3$  to form free  $\text{CaO}$  and a solid solution of the series  $4(\text{CaO}, \text{SrO})\cdot 3\text{Al}_2\text{O}_3\cdot\text{SO}_3$ , having the compound  $3\text{CA}\cdot\text{CaSO}_4$  (305, 183, 306, 307) and the compound  $3(\text{SrO}\cdot\text{Al}_2\text{O}_3)\cdot\text{SrSO}_4$  (308) as extremes.

The direct measurements (electron microanalysis) carried out by Massazza and Pezzuoli (309) on industrial and laboratory clinkers confirmed that, for contents of  $4 \pm 5\%$   $\text{SrO}$ , this element preferably distributes into belite and, to a lesser extent, into alite. Free  $\text{CaO}$  is just contaminated.

7.8.4 Although celestine (and probably strontianite) have an accelerating action on the combination reactions of  $\text{CaO}$  in the solid phase (310) and they lower the appearance-temperature of the liquid (302), their presence in the raw meals is not desirable since they are liable for the release of free  $\text{CaO}$  of equilibrium and - over certain limits - for

the destruction of alite. From this standpoint,  $\text{SrCO}_3$  is more dangerous than  $\text{SrSO}_4$  and the clinkers having high degree of lime saturation are more vulnerable than the prevailingly belitic ones.

FIG. 23 .MOST BASIC PART OF THE SYSTEM  $\text{CaO-SrO-Al}_2\text{O}_3\text{-SO}_3$ . AFTER GILIOLI ET AL. (303).

On the other hand  $\text{SrSO}_4$  - at least in the absence of alkalis - decomposes the solid solutions  $3(\text{CaO}, \text{SrO})\cdot\text{Al}_2\text{O}_3$  by releasing  $\text{CaO}$  in this case too. The limits of acceptability of the  $\text{SrO}$  concentration in two typical raw meals are given in TAB. X. It would seem that higher concentrations can be allowed in the presence of  $\text{CaF}_2$  (310).

Butt et Al. (311) found that hydraulicity and strengths developed by strontium alites are considerable

TAB. X. .ACCEPTANCE LIMITS OF  $\text{SrO}$  CONTENT IN THE RAW MEALS, MASS % OF  $\text{SrO}$  ON BURNT MATTER (309).

form of combination	$K_{st} I=0.76$	$K_{st} I=0.96$
celestine ( $\text{SrSO}_4$ )	8	3
strontianite ( $\text{SrCO}_3$ )	6	3

rably lower than those of the ordinary ones; they attributed this fact to the lower number and the smaller sizes of the lattice voids in strontium alite.

## 7.9 Barium.

7.9.1 Limestones contain varying amounts of ba -

rium (10,600 ppm Ba), essentially as barite. Evaporitic limestones are rich (up to 1000 ppm) or, exceptionally, very rich. Barium can concentrate in the hydrolysis minerals of clayey sediments also in appreciable amounts. It is found in the detrital rocks, besides as a sulphate, also as a residual femic mineral (amphiboles and pyroxenes).

7.9.2  $Ba^{2+}$  replaces  $Ca^{2+}$  in all the minerals of clinker, except for aluminoferrite (152). FIG. 24 shows (312) the portion richest in lime of the system  $CaO - BaO - SiO_2$ .

It results that:

FIG. 24 . MOST BASIC PART OF THE SYSTEM  $CaO-BaO-SiO_2$  (NOT TO SCALE). AFTER BRISI(312).

- in the two-phase field  $C_3S - C_2S - Q - R$ : solid solutions  $(C, B)_2S$  and solid solutions  $(C, B)_3S$ ;
- in the two-phase field  $C_3S - R - CaO$ : solid solutions  $(C, B)_3S$  and  $CaO$ ;
- in the three-phase field  $CaO - Q - R$ : solid solution  $(C, B)_2S$  having composition Q, saturated solid solution  $(C, B)_3S$  having composition R, and  $CaO$ ;
- on the right of the  $Q - CaO$  line: solid solutions  $(C, B)_2S$  and  $CaO$ ;

coexist in equilibrium, in each of these times.

The limiting solid solution R of  $BaO$  in  $C_3S$  contains 1.5 mole %  $BaO$  (2.96 mass %) (313), or 1.0 mole %  $BaO$  (1.99 mass %) (301), at 1600°C and 1450°C respectively.

The stabilized form is TII (in the presence of  $MgO$  + 2% moles,  $M_{INV}$ ) (301). The solid solution Q of  $BaO$  in  $C_2S$ , in equilibrium with R and  $CaO$ , contains 7 mole %  $BaO$  (11.55 mass %) at 1350°C (312).

The form  $\alpha'$  remains stabilized (314, 315). The limiting solid solution of  $BaO$  in  $C_3A$  contains about 1.5 mole %  $BaO$  (about 2.5 mass %) (152).

7.9.3 In disagreement with other Authors (316, 317), Suleimenov et Al. (318) and Kurdowski (152) believe that the presence of  $BaO$  - also in limited amount - affects neither the characteristics of the liquid phase nor the rate of the lime combination.

On the contrary, barium appears to be one of the most effective "activators" of the hydraulicity and strengths of clinker; the latter are higher by 10 + 20% at any age, all the other conditions unchanged (152, 271, 150, 319, 320).

The optimum concentration is between 0.3 and 0.5 mass %  $BaO$  and the clinkers containing few fluxes ( $SM > 3.0$ ) (152) and having high content in  $C_2S$  (150) are more favoured by this concentration. Barium cements demand suitable additions of gypsum and eventually of  $K_2SO_4$  (320).

This behaviour of clinker is strangely different from that of the solid solution of  $BaO$  in  $C_3S$ ; for this solution, in fact - because of the larger ionic radius of  $Ba^{2+}$  with respect to  $Ca^{2+}$  - Butt et Al. (311) theorized and experimentally confirmed a reduced hydraulic activity.

The action of  $BaCl_2$  on  $C_3A$ , between 900°C and 1000°C, was studied by Muminov and Akhmedov (321).

## 7.10 Zinc.

7.10.1 The content in zinc in the sedimentary rocks does not exceed the tens of ppm, as a rule. It is mainly contained in the detrital and clayey rocks (magnetite and chlorite vectors). Sprung and Rechenberg (322) found amounts ranging between 25 and 62.10<sup>-4</sup>%  $ZnO$  in 23 raw meals from German cement factories. Nevertheless higher concentrations must be expected in raw meals containing limestones mineralized by sulphides or corrected with pyrite cinders rich in blende.

7.10.2 During the burning process, 80 + 90%  $ZnO$  (or  $ZnS$ ) in the raw meal is combined in clinker (322, 323). Therefore clinkers contain between 30 and 100.10<sup>-4</sup>%  $ZnO$ , depending on the content in the raw meal and the amount of electrofilter dust rejected out of the cycle.

Roughly half zinc distributes into silicates (with sharp preference for alite, to the detriment of belite) and the other half does into the matrix (with preference for the ferritic phase) (323, 293). Therefore, for a normal composition of clinker, alumi

no-ferrite and aluminate, alite and belite should result less rich in the decreasing order two by two.

Hornain (49) found concentrations (ZnO mass % of phase) resulting in the ratios:

belite	:	aluminate	:	alite	:	alumino-ferrite
1	:	4	:	8	:	17

According to Knöfel (323), the saturation attains 5 + 6% ZnO in alumino-ferrite, 4 + 5% in aluminate, about 1% in alite, 0.3% in belite.

According to Ono et Al. (324) and Tsuboi et Al. (293), trigonal  $C_3S$  would be stabilized; according to Knöfel (323)  $C_3S_{MII}$  and  $\beta$ - $C_2S$ , and according to Hornain (49)  $C_3S_{MIB}$  and  $\beta$ - $C_2S$  would.

In the clinkers studied by Knöfel (323) - also containing only 1% ZnO - a new phase probably consisting of free ZnO (zincite) appears together with zinc containing-minerals.

The presence of ZnO reduces the amount of aluminate in favour of alumino-ferrite (323, 293, 325): each 1% ZnO reduces the former and increases the latter by little less than 2%.

Strangely, an increase in alite does not correspond to this variation (323).

7.10.3 Zinc is a very effective flux and mineralizer (323, 293): it lowers the clinkerization temperature and accelerates the lime absorption. Nevertheless the effect on the properties of clinker (except for a darker colour) are not quite clear. According to Aktsu (325) just 0.3% ZnO would negatively affect the hydraulicity.

On the contrary, Knöfel's (323) research show that limited contents in ZnO (< 1 + 2%) in a typical clinker having  $K_{st} = 95$ ,  $SM = 2.2$  and  $TM = 2.5$  determine an improvement in its mechanical strengths by up to 20% and over (especially at short ages).

## 8. CONCLUSIONS.

8.1 It is important to distinguish reactivity from burnability of a raw mix. In the present paper, the concept of reactivity has been associated to that of rate of reaction, or of a set of reactions, for given conditions of temperature.

On the contrary, burnability expresses an amount of matter transformed or still to transform, at any instant and temperature of the process.

This distinction seems particularly useful to compare raw meals having different lime saturation.

8.2 Reactivity and burnability are fundamental properties having important effects on the capacity of plants and the energy needs of the process.

The choice of the type of kiln and its dimensions, the proportioning of the raw meal, the more suitable admixtures cannot prescind from a right evaluation of such properties.

Nevertheless the knowledge on this matter is not satisfactory, above all for want of a suitable methodology of measurement, universally adopted.

The methods entrusting the evaluation of burnability to the value of  $CaO_f$ , that the function  $CaO_f = f(t, \theta)$  assumes for only a couple ( $t_i; \theta_i$ ), or to the values  $t'_i$  and  $\theta'_i$ , for which the quantity of  $CaO_f$  becomes equal to or lower than an established amount, prove to be insufficient.

On the contrary, Blaise et Al.'s method seems to be rational. It evaluates burnability on the basis of the course of the reactions in the overall range between 1000°C and 1450°C.

For practical purposes, the characterization of the raw mix by three values of average reactivity relevant to three significant temperature intervals (for instance, 500°C + 1000°C, 1000°C + 1300°C, 1300°C + 1450°C), under standard conditions of temperature and time gradients, could result even more useful.

8.3 Reactivity and lime saturation affect the value of the burnability.

In its turn, reactivity is a function of  $SM$ ,  $TM$ , fineness, present mineralogical species and activity state of such species.

The laws governing the diffusion processes among solids and between solids and liquid well explain the influence that those variables have on the reactivity.

Particularly, the dependence of the diffusion coefficients on the activation energy, and the dependence of the value of the latter on the concentrations of defective structures in the solid matter, constitute the basis for a satisfactory model of interpretation of the phenomena. This model also explains the interesting possibilities offered by the so called mechanical, thermal, and chemical activations of the raw meal.

8.4 It seems right to expect that the chemical activation (or however one prefers to call, or must interpret, the action of the minor compounds acting as mineralizers and/or fluxes) constitute the more promising field for the development of new technological methods. The knowledge on the mechanism of action of these compounds, and on the phase relations that they yield, more and more frequently allow higher capacities of the equipment and energy savings to be obtained. Thanks to this knowledge, also the limits of exploitability of raw materials as well as of wastes, which are sometimes introduced into the raw meal for ecological decontamination purposes, are enlarging.

## **SUB-THEME I-2**

**Effect of the Burning Process  
on the formation  
and properties of the clinker**

**S. SPRUNG,  
Forschungsinstitut der Zementindustrie  
Düsseldorf, R.F.A.**

### 1. Introduction

The properties of the cement are essentially influenced by the composition and thermal treatment of the clinker. The clinker composition mainly depends on the composition of the raw material mixture. Besides, it can be affected by the type of fuel used and the ash constituents of the fuel. Depending on the type of burning process applied, material circulations in the kiln and preheater will frequently lead to an enrichment or depletion of volatile substances and thus to a change in composition.

During the thermal treatment the properties of the clinker are mainly determined by the temperature, heating rate and burning period. Equally important are the interactions between the material to be burnt and the furnace atmosphere as well as the cooling rate of the clinker.

The underlying report presents a summary of the recent findings that have been published since 1973/74. Only in a few cases reference is made to older publications. In its first part the report deals with the composition of fuels as far as they have an influence on the properties of the clinker. Subsequently the reactions during heating and sintering of the kiln feed and its interactions with the kiln atmosphere and the resulting material circulations are being discussed. In the last part of the report the influence of the cooling rate is described.

### 2. Fuels for Cement Production

#### 2.1 Fuel Oil

Mineral oil still is the most important source of energy for the production of cement. For burning heavy oil is used most frequently. In 1978 heavy oil accounted for 64 % of the total fuel consumption in the German cement industry (1). The composition of fuel oils differs according to the origin of the crude oil. The composition of the cement is mainly influenced by the sulphur content which may amount to anything between 1 and 2,5 wt.-% (2) in fuel oil grade S. In fuel oil with residues from cracking even higher sulphur contents have to be expected. During combustion sulphur is converted to  $\text{SO}_2$  which reacts with the alkalis and the calcium oxide of the cement raw materials.

Moreover, fuel oils contain small quantities of ash which may amount to .01 to .1 wt.-%, depending on the origin of the oil. The ash constituents mainly are  $\text{SiO}_2$ ,  $\text{Al}_2\text{O}_3$ ,  $\text{K}_2\text{O}$ ,  $\text{Na}_2\text{O}$  and  $\text{Ni}$ . If the V-content amounts to .0001 to .0109 wt.-% in the crude oil (3), similar concentrations may be expected in the fuel oil. As far as we know today, other heavy metals, such as Pb and Zn, occur in concentrations of .0016 and .0020 wt.-% (12).

#### 2.2 Coal

Hard coal and lignite are used more and more frequently as sources of energy. Depending on the conditions of its formation, coal may vary in composition very much. Important characteristics are the ash and sulphur con-

tent.

The coal ash forms from the mineral admixtures such as the clay minerals of kaolite and illite, some quartz, carbonate minerals and pyrite. The ranges over which the composition of coal ashes may vary in the USA, the U.K. and Germany are shown in Table I (4).

Table I: Composition of Coal Ashes (acc. W. Gunz) (4)

	Hard Coal			Lignite
	USA	U.K.	Germany	Germany
	wt.-%			
$\text{SiO}_2$	20-60	25-50	25-45	8-18
$\text{Al}_2\text{O}_3$	10-35	20-40	15-21	4-9
$\text{TiO}_2$	0,5-2,5	0-3	-	-
$\text{Fe}_2\text{O}_3$	5-35	0-30	20-45	2-6
$\text{CaO}$	1-20	1-10	2-4	25-40
$\text{MgO}$	0,3-4	0,5-5	0,5-1	0,5-6
$\text{Na}_2\text{O}+\text{K}_2\text{O}$	1-4	1-6	3-4 (6)	0-1 (6)
$\text{SO}_2$	0,1-12	1-12	4-10	0-50

The ash content of coals may vary between about 3 and 30 wt.-%. Acid coal ashes tend to form melts of low viscosity which react with the material to be burnt in the kiln. In this way the tendency of coating and ring formation in cement kilns is enhanced (5).

Besides, the coal ash will change the clinker composition. If high-ash coals with high  $\text{SiO}_2$ ,  $\text{Al}_2\text{O}_3$  and  $\text{Fe}_2\text{O}_3$  contents are fired in the kiln, the  $\text{CaCO}_3$  content of the raw meal must therefore be increased proportionately in order to maintain the standard lime factor or the LSF of the clinker. The homogeneous blending of the ash with the kiln feed is also important. Kilns working as suspension-type preheater kilns offer the most favorable conditions for homogeneous blending. In kilns with grate preheater ash may accumulate on the pellet surface which increases the formation of C,S and melting phases. This, however, does not seem to change the technical characteristics of the cement (7). A very homogeneous distribution of the ash can be achieved if coal is used as fuel for precalcination. This is the reason why according to E. Steinbiss (8) low-grade fuels from waste materials can be used profitably and without impairing the clinker quality. However, the use of such fuels is limited due to the emission of organic carbon compounds and  $\text{CO}$ .

Of special importance for the burning process are sulphur and chloride and occasionally alkalis. The sulphur content of the coal frequently amounts to .5 to 1,2 wt.-%. Most of the sulphur is bound in pyrite or marcasite ( $\text{FeS}_2$ ). The proportion of sulphur bound in the organic substance is not significant. Lignite may contain sulphur in the form of calcium sulphate or alkali sulphate. In coals with a higher  $\text{FeS}_2$  content the sulphur may also rise to values of more than 2 wt.-% (4).

Contrary to fuel oil, coal may contain as much as .01 to .1 wt.-% of chloride. In coals that are particularly rich in ash and salt, chloride contents of up to .4 wt.-% have been measured (9). A high supply of chloride in the kiln enhances the tendency of coating and ring formation (10).

The amount of alkali fed into the kiln with the coal is low, i.e. about .1 wt.-% at an ash content of 20 wt.-%. The alkalis from the coal together with the alkalis from the raw meal have an effect on the emission of sulphur dioxide (10). Coal also contains traces of other pollutants, i.e. heavy metals such as Pb, Zn, Ni, V, Co, Cr, As and Tl. In coal from West Germany concentrations of .00010 to .0150 wt.-% (10 to 150 ppm) of such elements were found (3, 11, 12). The Pb and Zn contents that have so far been measured in West German lignite amounted to about .0010 to .0030 wt.-% (10 to 30 ppm) (12).

### 2.3 Alternative fuels

The alternative fuels that are being tested with the purpose of saving fuel oil consist of burnable waste materials from production processes and municipal waste. The calorific value should amount to at least 12,600 to 16,800 kJ/kg (3,000 to 4,000 kcal/kg) (13-18). In general alternative fuels are able to produce 10 to 30 % of the heat supply today.

As far as the composition and properties of the clinker are concerned, it is the ash content of those alternative materials, the ash composition and the content of alkalis, chloride and sulphur that is of importance. No reliable statements can be made about the average composition of alternative fuels. Analytic data that have so far been published are summarized in Table II.

Table II: Composition of Alternative Fuels (13-18)

	Ash	S	K <sub>2</sub> O	Na <sub>2</sub> O
	wt.-%			
Bleaching earth	48-52	1,0-1,5	0,6	1,2
Acid sludge	2-6	10-15	-	-
Used tyres	4-6	1-2,1	-	-
Delayed coke (Canada)	2,5-4	5-6	0,1	-

Bleaching earths containing about 50 wt.-% of ash require a correction of the CaCO<sub>3</sub> content in the raw meal because the ash primarily consists of SiO<sub>2</sub> and Al<sub>2</sub>O<sub>3</sub>. The ash contents of the other alternative fuels are below 10 wt.-%. Municipal waste, however, may contain more ash depending on the water content (15).

Alternative fuels contain various amounts of sulphur depending on their origin; in the case of acid sludge the sulphur content may rise to as much as 15 wt.-%. In order to avoid SO<sub>2</sub> emissions, the sulphur supply to the kiln must be adjusted to the supply of

alkali. For this reason, acid sludge can only be used to a limited extent. The alkali and chloride contents in the materials mentioned in Table II are insignificant with respect to kiln operation and clinker composition. Other alternative fuels, such as shredder waste (13) or chlorinated hydrocarbons (17), were less desirable because the chloride content led to an increase in the chloride circulations in the kiln and interfered with the kiln operation due to coating and ring formation.

The influence of heavy metals on the clinker quality and the emission is not yet known. According to the results of studies made so far, alternative fuels may contain .0100 to 2 wt.-% of Pb, Zn, Cu, Sn, Ni and V. Concentrations of less than .01 wt.-% are reported for Cd, B, Mo and Cr (12, 13, 16, 18). In used oil a bromine content of .15 wt.-% was found (16). The contents of other elements, such as Tl, As and Se, have not yet been studied in a systematic way.

### 2.4 Fuels with a high content of inert materials

Such fuels that are more and more being used as a substitute for high-grade sources of energy, are oil shale, coal-containing shale, low-grade coal with a high inerts content and charcoal. The typical characteristics of such fuels are the low content of natural burnable substances and, consequently, a high ash content. Therefore these fuels have a low calorific value which, according to B. Mayer (19), amounts to only 9,300 kJ/kg (2,200 kcal/kg) in a Corean coal shale or to as little as 3,900 kJ/kg (930 kcal/kg) in oil shale (Dotternhausen), according to R. Rohrbach (20). Flotation slimes formed during coal preparation have an ash content of 53 to 74 wt.-%, according to W. Poersch (21). The calorific values are low, i.e. 6,500 to 15,800 kJ/kg (1,548 to 3,762 kcal/kg). The values given for the composition of such fuels are summarized in Table III; they may differ so widely from each other that an average composition cannot be stated.

Table III: Composition of Fuels with a High Content of (6, 19-22) Inert Materials

	Ash	K <sub>2</sub> O	Na <sub>2</sub> O	S	Cl
	wt.-%				
Oil shale	80	2,0	0,3	3,0	-
Coal shale	69	2,7	0,2	1,95	0,04
Coal slime (flotation)	53-74	-	-	1,1-1,3	-

Due to their high content of ash rich in SiO<sub>2</sub> and Al<sub>2</sub>O<sub>3</sub>, the use of such fuels requires a correction of the CaCO<sub>3</sub> content in the raw meal. In addition to continuous monitoring of the raw meal composition, homogenization of the coal in mixed beds and continuous checking of the ash content and ash composition would also be desi-

rable (19).

Coal with a high inerts content can be used as primary fuel up to an ash supply of 50 to 75 kg/t clinker (in all following cases metric ton), according to J. Parisi (23), without coating or ring formation in the transition zone from sintering to calcination. If the coal is very finely ground and injected at high speed, even an ash quantity of 100 to 150 kg/t clinker is considered acceptable. In kilns with grate preheater high-ash coals can usually not be used.

From the angle of process engineering, the use of coal with a high inerts content is more advantageous for precalcination of the raw meal. If enough excess air is present, complete combustion will occur due to high meal and gas temperatures of about 700 to 1,000 °C. The released heat is immediately used for dissociation of the raw meal. Besides, the ash mixes homogeneously with the kiln feed, as the experience with several kilns equipped with a suspension-type preheater has shown. Obviously, complete mixing even occurs if the suspension-type preheater is only charged with limestone meal and the required quantities of  $\text{SiO}_2$ ,  $\text{Al}_2\text{O}_3$  and  $\text{Fe}_2\text{O}_3$  are exclusively supplied from the burnt up secondary fuel such as oil shale, bituminous lime marl or washery refuse (19-20, 22-25).

According to Table III, fuels with a high content of inert materials may contain major sulphur quantities which may rise to 3 wt.-% and mainly occur in a chemically bound form as pyrite or marcasite ( $\text{FeS}_2$ ). On the basis of geochemical studies (3), higher contents of heavy metals than in prepared coal and lignite must be expected in such fuels. It is therefore necessary to analyze their composition and decide whether they can be used.

### 3. Burning of the Clinker

When the cement raw meal is heated,  $\text{CaCO}_3$  and the clay minerals dissociate first. Even before this reaction is completed, the formation of the clinker phases begins which is accelerated at higher temperatures by the clinker melt. The reaction rate is important for reducing the heat requirements and for the properties of the cement clinker. For this reason, it has often been attempted to predict the burnability of raw meals and to influence it by suitable measures. During burning the clinker composition can be influenced by the kiln atmosphere and may be changed by the type of fuel used and by circulations. Besides, the cooling rate of the clinker which was slowed down by the use of planetary coolers may have an effect on the setting and development of strength in the cement.

#### 3.1 Burnability

##### 3.1.1 Dissociation of raw meal constituents

The dissociation reactions of raw meal constituents occur at temperatures of less than 1,000 °C. When pure calcium carbonate is heated in a  $\text{CO}_2$  atmosphere, decomposition will

start at a temperature of about 900 °C. With decreasing  $\text{CO}_2$  partial pressure, the dissociation occurs at lower temperatures, according to the equilibrium conditions. For technical-scale processes, the reaction time required for complete dissociation is of special importance. In addition to  $\text{CO}_2$  partial pressure and temperature, also the particle size and crystalline structure of the calcium carbonate and the reactions of the  $\text{CaCO}_3$  with the other main constituents of the raw meal are major factors of influence. According to a summary by F.W. Locher (26), the reactions already begin at a temperature of about 550 °C. Due to the reaction of  $\text{SiO}_2$ ,  $\text{Al}_2\text{O}_3$  and  $\text{Fe}_2\text{O}_3$ , the dissociation pressure of the  $\text{CaCO}_3$  which is still very low in this temperature range will start to rise. As reaction products  $\text{C}_2\text{S}$ , aluminates with lower calcium content and calcium aluminate ferrite will be formed. Free  $\text{CaO}$  only forms at temperatures above 900 °C.

The dissociation rate of the raw meal constituents is particularly important from the angle of process engineering. In the modern heat saving kiln installations operating on the basis of the half-wet or dry process, the raw meal is mainly preheated in the grate and suspension-type preheaters in counterflow to the hot kiln exhaust gases; decomposition only amounts to 20 to 40 % in the preheater (27). Dissociation is taking place subsequently in the rotary kiln. According to a summarizing description of the state of the art in the field of process engineering by L. Kwech (28), the output of the kiln could only be improved to a significant extent while maintaining nearly unchanged favorable energy consumption figures when precalcination was introduced. The higher kiln output was due to the fact that, after raw meal preheating in the heat exchanger, an almost complete calcination in an additional calcinator step with secondary firing was taking place so that the only process occurring in the rotary tube was the sintering process. Essential prerequisite for the precalcination technique are an improved heat transfer and a rapid dissociation of the raw meal constituents.

Other possibilities of saving energy may arise from a better burnability of the raw meal. The kinetics of the  $\text{CaCO}_3$  dissociation were studied in detail by B. Vösten (29). More recent studies with a laboratory reactor about which A. Müller, B. Dahm and J. Stark (30) reported in a summarized form, showed that the time required for complete dissociation of the  $\text{CaCO}_3$  decreases with increasing temperature of the kiln feed, declining  $\text{CO}_2$  partial pressure in the combustion gases, decreasing load of solid particles in the gas flow, decreasing mean particle size of the  $\text{CaCO}_3$  and decreasing crystallinity. Although the test results and the mathematical formulas for precalculating the degree of dissociation or the dissociation rate derived from them cannot automatically be transferred to practical conditions, they might be useful for estimating how an in-

crease in material temperature in the calcinator step of the preheater, a decline of the  $\text{CO}_2$  content in the combustion gas, if natural gas is used instead of fuel oil, or a greater fineness of the ground  $\text{CaCO}_3$  in the raw meal would affect the acceleration of precalcination in technical scale installations. The influence of clay minerals and quartz on the dissociation rate of the  $\text{CaCO}_3$ , however, is not considered in this approach.

The impact of the heating-up velocity on the dissociation rate of limestone and cement raw meal was studied by K. Volke (31) in the temperature range of about 100 to 2000 K/min. The heating velocity in technical installations is estimated to amount to a few hundred K per minute. From studies made on a laboratory scale with  $\text{N}_2$  as carrier gas it appears that in the case of low heating velocities the dissociation rate of limestone meal mainly depends on the mass transfer. With rising heating velocities and increasing calcite particle size, the inadequate thermal conductivity and a mounting  $\text{CO}_2$  partial pressure inside the particle will slow up the dissociation rate. In cement raw meal and a high heating gradient of more than 450 K/min. the  $\text{CaCO}_3$  dissociation is enhanced by the reaction with the clay containing raw meal constituents, and the delaying effect of the inadequate thermal conductivity is partially offset. Similarly, Y. Nygardas (32) found that by slightly reducing the number of rotations of the kiln to .92 r.p.m. as compared to 1.33 r.p.m., higher heating velocities were observed on the particle surface of the kiln feed which led to a higher degree of calcination at the same mean material temperature. B. Vosteen (35) has developed a formula for precalculating the retention time of cement raw meal for complete decomposition taking into consideration the heat transfer in a suspension-type preheater with a downstream calcination step. These calculations, however, are based on the dissociation equilibrium of pure  $\text{CaCO}_3$  so that they will only lead to an approximation to the actual conditions even if a large number of parameters are included.

An accelerated heating rate also favors the reactivity of  $\text{CaO}$  and thus the rate at which clinker phases will form. According to studies by O.P. Mtschedlow-Petrosian and co-workers (33), the increased reactivity of  $\text{CaO}$  which is formed at 800 to 900 °C and does not recrystallize at short retention periods, is due to a high content of lattice defects and lattice voids. U. Ludwig (34) also emphasizes the technical advantage of a high heating gradient in the temperature range below 1000 °C for the sintering reaction.

K.P. Kacker, R.C. Satiya and D. Chandra (36) as well as H.J. Wächtler (37) have studied the influence of clay minerals and other foreign oxides on the thermal dissociation and dissociation rate of calcite. According to these studies, the lowering of the dissociation temperature of the calcite in the

clay containing raw meal by about 90 to 130 K is supposed to be exclusively due to water vapor (36). H.J. Wächtler (37), however found that besides clay minerals alkali salts occurring in quantities of up to 2 wt.-% will reduce the activation energy of the  $\text{CaCO}_3$  dissociation. Their effect is due to the formation of salt melts or easily melting compounds at the reaction front of the  $\text{CaCO}_3$ . During technical-scale operation alkali compounds are carried into the raw meal by the kiln dust. The most effective substance for reducing the activation energy in cement raw meals is  $\text{Na}_2\text{SiF}_6$ . Additives such as basalt, lead and copper slag, apatite, triphosphate, phosphorite and phosphorous slag have a similar effect. V.V. Timasev, J.A. Fridman and A.L. Polanskij (38) were able to accelerate the raw meal decomposition and increase the kiln output by adding  $\text{FeCO}_3$  (Siderite).

These investigations thus lead to the conclusion that a high dissociation rate of the raw meal constituents has a favorable effect on the rate of clinker phase formation and, thus, on the output of the kiln. Additives to the raw meal also expedite dissociation. A similar behaviour can be expected of foreign substances which are carried into the kiln system mainly by way of alternative fuels, although this still requires detailed and comprehensive studies. Since, in practice, the retention time of the material in the rotary tube often is too long, the technical benefit of the quick dissociation of the raw meal constituents will be partly or fully lost unless such parameters as length and number of rotations of the kiln are fully adjusted to the conditions of precalcination.

### 3.1.2 Sintering

The sintering reactions accelerate at temperatures of more than 900 to 1000 °C. Mainly dicalcium silicate, calcium aluminate and calcium aluminate ferrite as well as free  $\text{CaO}$  are formed in the process. The content of free  $\text{CaO}$  decreases when clinker melt is formed and  $\text{C}_3\text{S}$  formation may occur at a faster rate at temperatures above 1250 °C. The significance of melt quantity, melt composition and the equilibria that occur as well as the kinetics of the sintering reactions are discussed by V.V. Timasev in his report.

The temperature at which the clinker is burnt must be above 1250 °C to promote the formation of  $\text{C}_3\text{S}$  which is important for the development of strength. In rotary cement kilns the burning temperature usually amounts to about 1450 °C. Higher burning temperatures of up to 1700 °C may be disadvantageous and therefore are of no technical importance for the time being (26). Previous studies by J.M. Butt and V.V. Timasev (30) show in principle the advantage of a high sintering temperature for the rate of clinker phase formation. Below 1450 °C  $\text{C}_3\text{S}$  formation mainly occurs as solid body reaction when the quantity of clinker melt is still relatively small. At a higher temperature the

sintering time is reduced to a few minutes because the amount of melt increases and its viscosity decreases. Japanese studies (40) have led to similar conclusions. If, however, the isothermal holding time at burning temperatures of more than 1350 °C is extended to the extreme value of 120 minutes, the  $C_2S$  content will decline. The reason for this is the dissolution of the  $C_2S$  in the enlarged amount of melt (41). It is questionable whether sintering at temperatures exceeding 1500 °C will be of any interest at all in future, since substantial energy savings cannot be expected from the acceleration of the sintering process and the rotary kilns with the present types of linings cannot be automatically used for such processes. Of much greater technical interest might be those processes in future that permit to burn clinker also at temperatures below 1400 °C. Indications in this direction were given by N.P. Kogan, O.P. Mtschedlov-Petrossian and V.I. Satarin (42). It might be worth-while to study the influence of the heating rate in this context.

According to O. Philipp (47), a high heating velocity promotes the sintering of the cement raw meal at temperatures of up to 1450 °C, since the CaO and the other oxides show a high activity due to the fact that no recrystallization occurs; this activity leads to the fast formation of clinker phases at temperatures as low as 1000 °C as soon as the melt begins to form. Studies by J. Stark and D.Q. Phu (48) as well as studies by J.M. Butt, V.V. Timasev and J. Stark (49) on a laboratory scale at temperatures of up to about 1700 °C also show that the clinker obviously has good strength characteristics which are mainly due to a higher  $C_2S$  content and a reduced particle size of the  $C_2S$  as a function of burning time. The technical significance of the process cannot yet be estimated because no data have so far been given with regard to the energy requirements.

Of a more practical importance for burning is the small particle size of the raw meal constituents and their homogeneous distribution. Sintering is mainly promoted by fine grinding and homogeneous distribution of the raw meal constituents (26,44). At temperatures above 1450 °C the particle size distribution is less important, as studies by U. Ludwig and G. Ruckenstein (43) have shown. Coarse quartz and calcite particles of a diameter larger than 100 microns should not amount to more than 1 and 6 wt.-%, respectively. H. Lehmann and P. Thormann (45) found that the  $C_2S$  forms fastest if the average particle size of the calcite is 15 microns. When standard treatment methods are used, however, quartz sand which is added to the raw mixture is rarely ground more finely than to an average diameter of 50 to 100 microns (46). Due to the poor grinding characteristics of quartz sand, cements from lime stone and quartz with a reduced amount of clinker melt cannot be produced economically, as calculations by F.W. Locher (26)

have shown. The energy required for grinding the quartz would be higher than the energy saving that could be made as a result of the better grinding characteristics of a clinker with a lower melt proportion. Similar statements may be made for experiments aiming at a better decomposition and sintering behaviour by mechanical activation and grinding to maximum fineness in vibration mills (50, 51).

The burning of cement clinker may also be promoted by fluxes and mineralizers. Whereas fluxes reduce the temperature at which melt will begin to form and change its viscosity, mineralizers enhance the  $C_2S$  formation without any melt. Fluorides act as both fluxes and mineralizers. A summary on the use of fluxes and mineralizers was given by W.A. Klemm and J. Skalny (60). It appears from this summary that not only oxides but also fluorides and silicofluorides have proved to be effective in laboratory and industrial scale studies. Similar conclusions are reported by J. Stark (52) for the production of quick burnt clinker in the laboratory.

Additions of Ba, P, Cr,  $SO_2$ , Na, Ti and other elements are supposed to have a mineralizing effect, whereby A.K. Chatterjee (44) mentions an optimum concentration of .2 to 1 wt.-% in most cases. In laboratory scale burning tests a mineralizing effect of the elements Cu, Cr, Mn, Ti, Zn and Pb was observed if these were added in quantities of up to 4 wt.-% (55-59). Substances that act as a flux or mineralizer and which especially promote  $C_2S$  formation, are often contained in industrial waste materials. In this context A.M. Dmitriev, M.T. Wlasowa und B.E. Judowitsch (53) as well as Th. Uschold and E. Giesa (54) refer to blast furnace slag, nepheline sludge, phosphorous slag, wollastonite, basalt, power plant ash and heavy metal containing waste such as copper slag and lead slag as raw meal constituents.

In summary, it appears from all these studies that little is known about whether the industrial scale use of such materials, esp. in comparison with modern production methods, would lead to cost and energy savings, production increases or to a marked improvement of the cement quality. When burning mixtures of natural raw materials and standard composition with an  $Al_2O_3$  ratio of 1.38, the optimum quantity of melt will be formed at the lowest possible temperature that leads to complete sintering, according to studies by H.R.M. Banda and F.P. Glasser (61). In such cases the additional expenditures for buying, storing and dosing of the fluxes or mineralizers do not appear to be economically justified. Such expenditures might possibly be useful if raw material mixtures with a high content of lime and a low melt formation are to be burnt which would otherwise require a very high sintering temperature (26).

### 3.1.3 Testing procedures

For planning new cement kiln installations and deciding about operational measures for reducing the heat requirements of older installations or making specific changes in the clinker quality, it is very important to determine the burnability of the raw meal. The burnability or sinterability depends on the material properties of the raw meal and the process engineering conditions. The material properties include the chemical and mineralogical composition of the raw meal, the particle size distribution and the degree of interstratification of the constituents. The process engineering parameters are the temperature rise over time up to sintering temperature, temperature differentials in the raw meal particle, sintering temperature, retention time at sintering temperature, kiln atmosphere and cooling rate. Tests for characterizing the burnability or sinterability are therefore made with the objective to verify the success of the thermal treatment by examining the clinker or to burn the raw meal under controlled conditions and observe the process of the reactions.

An appraisal of the burning behaviour by microscopic methods is suggested by Y. Ono (62), M. Kristmann (63), F.A. DeLisle (64) and by J.D. Dorn (65). The influence of the fineness of the calcite and quartz particles, the heating and cooling conditions and the kiln atmosphere on the sinterability can be qualitatively recognized from the micrograph. On certain conditions it is also considered possible to classify the clinker in quality categories (62).

A summary of the studies made so far for the appraisal of burnability was given by E. Rauschenfels (66). The methods used for testing the burnability are characterized by steady-state or dynamic burning conditions, and in some cases the burnability of unknown raw meals is computed on the basis of regression analyses determined previously. In experimental processes using steady-state burning conditions the success of burning is usually measured by the free lime content. The burning temperatures amount to between 1000 and 1500 °C and the retention time remains constant (67-70). In a comparison with a standard meal of known burning behaviour relative conclusions can be drawn with respect to a deviating burning behaviour, and the duration of the sintering process, the rate constant or the activation energy can be computed. The kiln atmosphere and heating rate often are neglected in such calculations.

The experimental procedure suggested by U. Ludwig and G. Ruckenstein (71) for determining the burnability permits the calculatory prediction of the sintering behaviour ( $B_p$ ) of raw meals made from limestone, clay and sand, since there is a proved correlation between the practical burnability  $B_p$  in minutes at 1350 °C determined experimentally under steady-state burning condi-

tions and the theoretical burnability  $B_{th}$ . For such a prediction data on the lime standard III, the proportion of melt including the proportion of alkalis and  $SO_3$  (72) and the particle size distribution of the raw meal constituents are required. With rising burning temperature the burning period ( $B_p$ ) decreases in a non-linear way (73). The effects of the heating velocity, motions of the kiln feed and kiln atmosphere on the burning period  $B_p$  are still unknown.

The studies by N.H. Christensen (74), V. Johansen (75) and E. Fundal (76) basically lead to a similar definition and computation of burnability. The free lime content determined after a 30 minute burning period at 1400 °C shows a linear correlation with the lime saturation factor (LSF), the silica module and the proportion of calcite > 125 microns and of quartz > 44 microns in raw meals that do not very much differ in composition. The influence of the alumina module (.5 to 4) is obviously excluded by the choice of the burning conditions. The alumina module essentially determines the melt point temperature of the clinker melt (61). The effects of the motions of the kiln feed, heating rate and kiln atmosphere are also neglected.

Dynamic methods for testing the burnability of stationary raw meal specimens were suggested by H.-J. Wächtler (77, 78), J. Kieser, A. Krähner and B. Gathemann (79) as well as by H. Hoffmann (80). Such processes are based on thermoanalytical and thermogravimetric studies for determining the raw meal activity and raw meal decomposition rate and the use of a gradient kiln for determining the sinterability or the degree of lime binding. The laboratory burning equipment permits to adjust the heating rate to the temperature curve of a technical-scale kiln installation and the creation of a  $CO_2$  containing atmosphere. This process was also applied for studying the effect of alkali salts and spurrite formations on the burnability by way of a model (79). As with other processes, the burnability of raw meal was calculated on the basis of the standard lime, silicate module, alumina module, screen retainings and heating gradient which are the factors that have an effect on and are correlated to the free lime content (80).

From these studies the conclusion can be drawn that there obviously is a considerable interest in predetermining, by means of suitable testing methods, the burnability and sinterability of raw meals and the effect that additives may have on both. However, with all testing procedures known today simplifications must be made so that a number of parameters that are known from practical burning operations are neglected. Thus, for instance, the motions of the kiln feed, the reactions between the kiln feed and the gas atmosphere and the heat transfer cannot fully be taken into consideration in laboratory tests as yet. Therefore it is to be assumed that the test values found in the

way described can only be considered as relative values to which the burnability of the raw meals is to be compared with practical experience. This means that even with very complex and sophisticated testing procedures only a relative measure might be found for the burnability which could also be found by simpler means.

### 3.2 Composition

The composition of the raw meal essentially determines its behaviour during calcination and sintering, the economy of the burning process and the properties of the clinker. The most important criterion for the clinker properties is the strength of the cement made from it and its workability characteristics. The economy of the burning process mainly depends on the kiln output and the heat consumption. Besides, the grinding characteristics of the clinker also influence the energy requirements of cement production.

Usually the sinterability of cement raw meals is created in practice by an adequate fineness of grinding, reduction of the silicate module ( $S_r = \text{SiO}_2 / (\text{Al}_2\text{O}_3 + \text{Fe}_2\text{O}_3)$ ) and standard lime ( $M_{\text{KST}} = 100 \text{ CaO} / (2.80 \text{ SiO}_2 + 1.18 \text{ Al}_2\text{O}_3 + .65 \text{ Fe}_2\text{O}_3)$ ) and by increasing the melt quantity and lowering the melting point temperature of the clinker. The lowest melting temperature occurs at an alumina module ( $T_m = \text{Al}_2\text{O}_3 / \text{Fe}_2\text{O}_3$ ) of 1.38 (61). Further details as to the influence of the main and minor constituents on raw meal sintering can be found in the literature (66-80). G. Gouda listed the various technical requirements to be met by the raw materials and the raw meal composition (81). Of critical importance is the chemical and mineralogical composition of the raw materials, the energy required for crushing and homogenizing and for drying and burning. Due to the different characteristics of the raw materials, the optimum production conditions have to be determined for each plant separately, whereby the procedures used for testing the burnability may supply the first indications. In this connection attention must be paid to the fact that an improvement of the sintering characteristics due to a higher proportion of melting phase may lead to a decrease of the grinding characteristics of the clinker which is directly proportional to the extent of melting phase. Complete sintering should therefore take place at the lowest possible temperature and the minimum quantity of melting phase (82).

The influence of the clinker composition on the development of strength and workability characteristics of the cement produced on a technical scale was studied by C. Schmitt-Henco (83) and by B. Sutej and K. Vrgoc (84). According to these studies, the setting time can be prolonged and in this way the workability characteristics of the cement can be improved if the  $C_3A$  content of the clinker is increased at the expense of the  $C_2A$  content and no change is made in the amount of

melting phase. It was observed that the strength of industrially made clinker increased with rising standard lime (KST). A silicate module rising from 2 to 3.2 may lead to particularly high 28 d strength properties if the quartz is present in a finely dispersed form and complete sintering is achieved. Under comparable conditions a rising alumina module will lead to a slight increase in the early strength. The test results obtained in factory-made clinkers can only be transferred to other raw material compositions, factories or even kilns as far as their general tendency is concerned, since in most cases the sinterability and burning conditions (heat transfer, kiln temperature curves, kiln atmosphere and cooling rate) are different. This also applies to tests for determining the strength development in advance on the basis of the chemical composition of the clinker by means of a multiple regression analysis (84) or quantitative phase analysis (85).

The minor constituents also have an effect on the workability and strength characteristics of the cement. Increasing quantities of free lime will reduce the soundness and strength if the CaO has formed in a primary way and recrystallized (83). Free CaO in quantities of up to about 6 wt.-% from weakly burnt shaft kiln clinker, however, did not impair the properties of the cement, according to tests made by K. Nagy (86).

The effect of alkalis bound in the clinker as described by I. Jawed and J. Skalny (87) may differ according to the prevailing conditions. Alkalis that are mainly bound in the  $C_3A$  usually increase its reactivity and may therefore contribute to quick setting of clinker that is rich in  $C_3A$  and to higher early strength but lower 28 d strength (88). In clinkers in which the alkalis are essentially bound as sulphates (sulphurization) by  $\text{CaSO}_4$  additions or by burning with high-sulphur fuels, the early strength will increase. The final strength remains unaffected up to a total alkali content of about .8 wt.-% ( $\text{Na}_2\text{O}$  - equivalent). If, however, the total alkali content rises to values of more than 1 wt.-% ( $\text{Na}_2\text{O}$  equivalent) as a result of sulphurization, the 28 d strength may decline (89).

In natural raw meal heavy metals only occur in trace amounts, and it may be assumed that they have no major effect on the clinker properties. However, it is not yet known what the effect of those heavy metals may be that are carried into the cement kiln when substitute or alternative fuels are used. That seems to be of interest assuming that most of the heavy metals are bound in the cement clinker. According to the experiences made so far, clinker may contain heavy metal concentrations of up to about 200 ppm (12 - 18).

A large number of studies many of which, however, were only made in the laboratory, deal with the effect of higher heavy metal

and fluoride quantities added in the form of mineralizers or fluxes. In the older literature (60) the effects of fluorides on the cement properties are assessed in very different ways. According to P. Tewari and P.K. Mehta (90) as well as W. Gutt and M.A. Smith (91), a marked increase in the final strength was observed when fluoride was bound in the clinker. Studies concerning the practical use of fluoride sludge in the cement factory showed a considerable improvement of the 3 d and 28 d strength values, according to G. Stampendahl, H. Tauchmann and Ch. Engelmann (92).

However, the specific energy consumption for cement grinding was 16 to 22 % higher than the energy required for grinding cement which was free of fluxes.

Elements such as Ba, Sr, Ce, Cr, F, Ti and Zn that were added to the clinker in concentrations of up to 3 wt.-% or contained in the raw materials had more or less the same effect on setting and strength. With the exception of Ce which obviously did not influence the properties of the clinker in any way, and Cr which led to higher early strength values, all those elements delayed the hydration of the cement. Besides, it is being assumed that .5 wt.-% of  $V_2O_5$ ,  $Cr_2O_3$  or BaO in the clinker may improve the grindability (94).

The conclusion to be drawn from those studies is that the effects of trace elements or minor constituents cannot be appraised in a quantitative way. It is practically impossible to compare the results because the production conditions of the various cements differ too much from one another.

### 3.3 Kiln atmosphere

Experience has shown that, for quality reasons, the burning of the clinker requires an oxidizing atmosphere. This means that especially in the sintering and cooling zone of the kiln there must be an adequately high excess of air. The oxygen content of the kiln atmosphere cannot be controlled by simple means during the burning process in the sintering zone of the kiln.  $O_2$  contents of 1 to 2 vol.-% measured in the kiln exhaust gas before it enters the preheater very often are no reliable indications of the absence of reducing conditions in the sintering zone. This largely depends on the shape of the flame, optimum atomization of the fuel, complete combustion of the fuel after mixing with hot air before it comes in contact with the kiln feed.

The results of older studies dealing with the influence that burning under reducing conditions has on the clinker quality were discussed in a summarized form by F.W. Locher (7) and H.-M. Sylla (98). Sylla again studied these correlations in a systematic way under laboratory conditions. The raw meals were burnt for 30 minutes at 1450 °C in air and in a  $CO_2$  and CO atmosphere. The most striking characteristic of a clinker

burnt in a reducing atmosphere was its brown color. This, however, only occurred if the clinker was cooled slowly to 1200 °C also in a reducing atmosphere. Cements made from clinker burnt in a reducing atmosphere and cooled slowly had a shorter setting time and also a considerably lower final strength. The early strength was not affected as strongly. The reason for the fast setting was the much higher  $C_2A$  content in the clinker than would have been expected in view of the composition and phase calculations according to Bogue. The increase in  $C_2A$  formation is due to the fact that part of the iron is reduced and can therefore not contribute to the formation of aluminates ferrite. The loss of strength is mainly caused by the fact that the  $C_2S$  takes up bivalent iron in its lattice during burning and becomes unstable as a result. The increase in the  $C_2A$  content and the decrease in the  $C_2S$  content is promoted by slow cooling in the temperature range between 1450 °C and 1200 °C.

The conclusion to be drawn from these studies is that, under normal operating conditions, the clinker quality will not deteriorate because in most cases the burning is done with an adequately high excess of air. Reducing burning conditions that may occasionally exist will only affect the clinker properties to any extent if, at the same time, the cooling zone of the kiln is longer and the clinker therefore is not cooled quickly enough.

### 3.4 Circulations

The gas in the cement kiln which flows in the direction opposite to the direction of the kiln feed, not only contains  $CO_2$ ,  $O_2$ , CO,  $N_2$  and water vapor but also dust from the kiln feed and a number of other gaseous and vaporous compounds. Most of the nitrogen oxides NO and  $NO_2$  formed during combustion are emitted with the exhaust gas (99).

The kiln gas also contains alkali, sulphur, chloride and fluoride compounds which are formed from vapourized and dissociated constituents of the kiln feed and the fuel by reactions in the gas phase. When they react with the kiln feed or condense again in the cooler parts of the kiln, the preheater or in the hot-air drying and grinding plant, an inner circulation is created. An outer circulation is formed when dusts which are separated in the electrical precipitator containing the condensed compounds are added again to the raw meal and fed into the kiln. The circulation is interrupted when separated dusts are rejected.

The reactions of the volatile constituents in the kiln atmosphere were discussed in a summarized form at the 1971 VDZ Congress (10). The most important statement made in the paper was that the alkalis and the sulphur are mainly bound as alkali sulphates in the clinker and in the dust. The  $SO_2$  emission of cement kilns is therefore low if

a stoichiometric alkali surplus exists. Forty investigations of kilns resulted in a mean  $\text{SO}_2$  concentration of  $30 \text{ mg/m}^3$  ( $1013 \text{ mbar}$ ,  $273^\circ \text{K}$ , dry). When the raw material and fuel composition are changed or when new installations are planned, the  $\text{SO}_2$  emission can be predicted by approximation.<sup>2</sup> However, a higher  $\text{SO}_2$  emission must be expected if there is an excess of sulphur or when burning is done in a reducing atmosphere. In agreement with R. Frankenberger and J. Matejka (100) it was found that a surplus of sulphur also enhances the tendency of sulphate spurrite coating ( $2 \text{ CaO} \cdot \text{SiO}_2 \cdot \text{CaSO}_4$ ). This often occurs if the cement raw materials are low in alkalis and high-sulphur fuels are used. The use of raw materials richer in alkalis leads to an increased sulphur absorption in the clinker, and thus represents an effective remedial measure in production.

Contrary to the less volatile alkali sulphates, the alkali chlorides evaporate more easily. Only very little of them is bound in the clinker. The mean  $\text{Cl}^-$  concentration in the clinker amounts to about .01 wt.-%. In clinker with a high proportion of melting phase it may rise to levels of up to .03 wt.-%. Alkali chlorides therefore often build up an inner circulation in the kiln and must be removed via a bypass, if necessary. Studies on suspension-type preheater kilns have shown that a bypass is required whenever the  $\text{Cl}^-$  content in the raw meal amounts to more than .015 wt.-% and the  $\text{K}_2\text{O}$  supply exceeds  $20 \text{ g/kg}$  clinker.

The  $\text{Cl}^-$  concentration in the kiln feed near the kiln inlet may rise to values of 1 to 2 wt.-%. Such a chloride enrichment favours coating and ring formation in the cement kiln and in the area of the lower stage of the preheater (10, 101). According to studies by H.-M. Sylla (102), A.E. Moore (103) and I.G. Luginina (104), this is mainly caused by the formation of salt melts and spurrite and a number of other compounds. W. Danowski and J. Kieser (105) found that in the rotary kiln with shaft preheater the risk of coating is low even if the alkali content amounts to  $20 \text{ g K}_2\text{O/kg}$  clinker and the chloride content is five times higher (106). These studies, however, also indicate that the balances show relatively high deficits on the output side. These may be due to an emission of  $\text{KCl}$ . An emission of chlorides, however, would have the same effect as a bypass because it would interrupt the circulation. This agrees with later findings by P. Rösner, F. Feige, W. Danowski and J. Kieser (107) according to which the  $\text{Cl}^-$  concentration in the kiln feed at the kiln inlet was not higher than only 1 to 2 wt.-% and permitted trouble-free kiln operation although the  $\text{Cl}^-$  content in the raw meal amounted to .05 wt.-%.

Contrary to the reactions of sulphur, chloride and water vapor in the kiln atmosphere lead to an increase in the volatility of the alkalis. It is therefore possible to

volatilize alkalis by adding  $\text{Cl}^-$ , to remove the alkali chlorides via bypass and to reduce the alkali content of the clinker in this way. Tests of this kind were made among others by R. Bohmann (108). However, it was found that the addition of  $\text{CaCl}_2$  leads to relatively high operating expenses. Additionally, the alkali chlorides in the bypass reduce the efficiency of the electric precipitator which increases the dust emissions (109).

Other measures for reducing the alkali content in the clinker which are easier to carry out from the technical point of view would be to remove dusts with a high alkali load from the kiln system. Especially in grate preheaters with a high alkali supply of over 12 to  $15 \text{ g K}_2\text{O/kg}$  clinker this measure has a chance of success (110). In suspension-type preheater kilns with precalcination, contrary to kilns without precalcination the size of the bypass can be varied in a wide range. In special cases the use of the kiln exhaust gases for raw meal preheating can be entirely dispensed with (100 % bypass). The design and operation of such kiln systems were described by J. Svendsen (111), J. Warshawsky and E.S. Porter (112) and H. Ritzmann (113). They also gave data as to the amount of energy required for reducing the total alkali content to values below .6 wt.-%  $\text{Na}_2\text{O}$  equivalent. A study made by the Portland Cement Association, USA (114) also contains information about the energy costs to be expected for bypass installations.

Minor alkali and alkali sulphate contents in the cement lead to an increase of the 28 d strength, as investigations by V. Johansen (115) and B. Osbaeck (116) have shown. Besides, the storage and processing characteristics are improved (117-118, 88). If the total alkali content is less than .6 wt.-%  $\text{Na}_2\text{O}$  equivalent, the cement may be used for the production of concrete with alkali-reactive aggregates.

Besides the circulations of alkalis, sulphur and chloride the fluoride and some heavy metal circulations were also studied. It was found that most of the fluoride is bound in the clinker. Gaseous fluorides are not emitted. The emission is limited to fluorides, that are bound predominantly as  $\text{CaF}_2$  in the dust of the waste gas having passed the precipitator.

Heavy metals are contained in the raw materials and fuels at lower concentrations. By using substitute or alternativ fuels larger quantities of heavy metals may be supplied to the kiln. So far only the reactions of lead and zinc in the cement kiln have been studied (12). It turned out that, depending on the kiln system, 80 to 95 % of the zinc is bound in the clinker and 5 to 20 % in the dust respectively. Lead shows a behaviour similar to the one of zinc. More recent investigations, however, indicate that the degree of lead bindings in the clinker may

also be somewhat lower so that the lead content in the kiln dust increases and consequently the inner circuit too. In kilns with grate preheaters and in the case of a high chloride load this seems to be a frequent observation.

According to the studies made so far, lead and zinc can only be emitted with the dust which means that the lead and zinc emission depends on the efficiency of the precipitating system of the kiln (12, 16-18). The effects of binding fairly low concentrations of Pb and Zn in the clinker on the properties of the cement have not yet been studied in a complete way. Systematic studies of the reactions of other heavy metals that are contained in the raw materials and especially in the fuels and substitute fuels, have not yet been made. However, it may be assumed that these reactions might prove to be more important in connection with the emissions to the environment than they are to the properties of the cement.

#### 4. Cooling of Cement Clinker

The cooling rate and kiln atmosphere influence the strength development and setting behaviour of the cement. In this part of the report only the effect of the cooling rate on the cement properties will be discussed.

The test results described in older publications (7, 26) show unanimously that fast cooling of the clinker generally leads to higher strength values. Fast cooling has a positive influence on both the early and the final strength. Fast cooling from sintering temperature is required in order to prevent reduction of the  $C_2S$  content by reabsorption which would lead to an increase in the  $C_2S$  and  $C_3A$  content. Fast cooling is also required to avoid decomposition of  $C_2S$  to  $C_3S$  and  $CaO$  and to obtain a fine-grained periclase crystallization. According to K. Mohan and F.P. Glasser (120), the  $C_2S$  decomposition is initiated by slow cooling in the temperature range between 1210 °C and 1025 °C by the formation of  $C_3S$  and  $CaO$  nuclei on the  $C_2S$  surface. The  $C_3S$  and  $CaO$  in the clinker accelerate the decomposition rate. Only by quenching the reactivity of the  $C_3A$  which is essential for setting behaviour can also be reduced. From a technical standpoint, however, quenching is not practical and would lead to a loss of strength.

Recent studies by H.-M. Sylla (98, 121) have shown that cooling in an oxygen-containing atmosphere generally leads to higher final strength values than cooling in a reducing atmosphere. The effect on the early strength values is less important. Losses of strength will occur if the clinker is cooled from sintering temperature to room temperature by quenching. When the clinker was shortly quenched with water at a temperature level of 1450 °C and then slowly cooled by air without impairing the crystallization of the melt, the highest 28 d strength values were

obtained in laboratory-made clinkers. Medium 28 d strength values were reached when the clinker was cooled from 1450 °C to 1250 °C within 30 minutes and then cooled faster by air. The explanation can probably be found in the reactivity of the  $C_2S$  which can obviously be influenced more strongly in the temperature range between 1450 °C and 1250 °C. However, these processes have not yet been fully clarified. Evidently the decisive phase of the cooling process still occurs in the kiln between the end of the sintering zone and the entry of the clinker into the cooler. The cooling zone varies in length depending on whether the kiln is equipped with a planetary or grate cooler. The length of the cooler also depends on the insertion length of the burner lance. However, so far no significant differences in strength have been found in technical scale cements that would have been due to different conditions during clinker cooling (7). Similar conclusions are to be drawn from the investigations by T. Enkegaard (122) and O.L. Jebsen (123) who compared the effects of the cooling rates of grate and planetary coolers. The samples taken at the inlet of the cooler and at the cooler outlet, however, primarily characterized the influence of the different cooling zone length in the kiln rather than the effect of the cooler design on the strength of the cement.

The conclusions to be drawn from the results available today show that the difference in the cooling rates may lead to significant changes especially in the final strength of the cement, as laboratory tests have indicated. In this connection only the temperature range from 1450 °C to 1250 °C is of interest. In technical-scale clinkers no effects on the strength could be observed despite the differences that existed in the cooling conditions in the kiln. This, however, may only apply if the clinker is burnt and cooled in an oxidizing atmosphere. In a reducing atmosphere longer cooling periods in the high-temperature range may impair the development of strength and the setting behaviour of industrially made cements.

## **SUB-THEME I-3**

# **The Kinetics of Clinker Formation The Structure and Composition of Clinker and its Phases**

**V.V. TIMASHEV,  
Professor,  
Moscow Mendeleev Chemical Engineering Institute  
Moscow, USSR**

The problem of the catalysis of the synthesis of Portland cement clinker, especially at the liquid-phase stage, is becoming more and more topical because of the general tendency towards the reduction of energy consumption in chemical engineering. Since the formation of the phase composition and of the micro- and macro-structure of clinker grains depends, to a considerable extent, on the amount of the melt in the sintering system and its physico-chemical properties, the control of these parameters is a very important task. No substantial change in the properties of the melt formed in the C-S-A-F system can be achieved by the control of the modular characteristics of clinker (1). In this connection, many investigators are searching for elements or their combinations that would have an efficient influence on

the structure and properties of the melt in the sintering grains of the material, on the microstructure and composition of the crystalline phases in clinker.

#### THE ACID-BASE EQUILIBRIUM IN THE MELT

The clinker liquid phase belongs to the class of slightly associated and high-basic aluminosilicate melts. The low degree of polymerization is confirmed by the low values of viscosity (0.1 to 0.3 Pa · s) and by its nearly exponential dependence on temperature and also by the absence of relaxation effects. The ionic nature of the melt is evidenced by the results of investigations of its physico-chemical characteristics, such as electrical conductivity and surface tension, the values of which correspond to the pa-

rameters characteristic of typical electrolytes—molten salts.

The skeleton structure of the melt is built up of silicon-oxygen radicals which are present predominantly in the form of the complex  $\text{SiO}_4^{4-}$ ,  $\text{Ca}^{2+}$  ions and amphoteric Al and Fe, which enter, depending on the conditions, into the composition of the groupings  $[\text{MeO}_4^{5-}]$  or  $[\text{MeO}_6^{9-}]$ . By forming the complex  $[\text{MeO}_4^{5-}]$ , the ions  $\text{Al}^{3+}$  and  $\text{Fe}^{3+}$  display the properties of acids, and when they remain as free cations with an octahedral oxygen environment of  $[\text{MeO}_6^{9-}]$  the ions  $\text{Al}^{3+}$  and  $\text{Fe}^{3+}$  exhibit the properties of bases.

In the low-oxygen complexes  $[\text{MeO}_4^{5-}]$  the Me-O bond is more stable than in the octahedral groupings  $[\text{MeO}_6^{9-}]$ , as a consequence of which the complex  $[\text{MeO}_4^{5-}]$  moves in the melt predominantly in the undissociated state, whereas the complex  $[\text{MeO}_6^{9-}]$  dissociates into  $\text{Me}^{3+}$  and  $6\text{O}^{2-}$ , whose mobility is high.

In the melt there must exist an acid-base equilibrium between the various coordination forms of amphoteric elements:

$$K = \frac{[\text{Me}^{3+}][\text{O}^{2-}]^4}{[\text{MeO}_4^{5-}]} \quad (2)$$

The elements S, P, B, etc., which form stable silicon-oxygen complexes,  $[\text{SiO}_4^{4-}]$ ,  $[\text{PO}_4^{3-}]$ , and  $[\text{BO}_3^{3-}]$ , bind  $\text{O}^{2-}$ , thereby decreasing its concentration in the melt, which causes the dissociation of such an amount of the complexes  $[\text{MeO}_4^{5-}]$  which is required to restore the upset acid-base equilibrium (1). As a result of the breakdown of part of the complexes  $[\text{MeO}_4^{5-}]$ , the viscosity of the melt is decreased and the diffusion coefficients of its structural units are increased. The elements Ti, Cr, Mn, F, Cl, Ni, etc., combine with  $\text{O}^{2-}$  in the melt to give groupings, the type of which depends on the value of the Me-O bond energy. For example, the presence of F, Cl, B, and Mo increases the absorption in the region of valence vibrations ( $400-700 \text{ cm}^{-1}$ ), which is evidence of the increase of the number of  $[\text{AlO}_6^{9-}]$  groupings in the melt and of the shift of the equilibrium (1) in the melt to the right. The ions  $\text{Ba}^{2+}$  and  $\text{Sr}^{2+}$ , on the contrary, caused a decrease in the absorption in the spectral region indicated, i.e. caused the shift of the equilibrium (1) to the left.

Belov and coworkers (2,3) assume the formation in the melt of neutral angular  $\text{O}=\text{S}=\text{O}$  molecules at a deficiency of free oxygen

ions in it, which participate in the building-up of the crystal lattices of  $\text{C}_2\text{S}$  and  $\text{C}_3\text{S}$ .

#### THE STRUCTURE AND PROPERTIES OF A MELT WITH A HIGH CALCIUM CONTENT

The effect of various elements on the properties of the melt which is formed in clinker at  $1450^\circ\text{C}$  and which has the following composition (per cent by mass):  $\text{CaO} = 57$ ,  $\text{SiO}_2 = 7.5$ ,  $\text{Al}_2\text{O}_3 = 22.6$ ,  $\text{Fe}_2\text{O}_3 = 12.9$ , has been studied (Fig. 1).

The experimental procedures have been described in the literature (5). The elements were introduced into the melt in an amount of 0.1M in the form of oxides, carbonates and ammonium salts. The viscosity of the melt in the presence of s-elements decreased in the order of their decreasing basic properties:  $\text{K} \rightarrow \text{Ba} \rightarrow \text{Na} \rightarrow \text{Sr} \rightarrow \text{Ca} \rightarrow \text{Mg}$ .

Accordingly, the quantity decreased with increasing acidity of p-elements in the sequence:  $\text{Al} \rightarrow \text{P} \rightarrow \text{B} \rightarrow \text{S} \rightarrow \text{Cl} \rightarrow \text{F}$  (Fig. 2).

Fig. 2. Effect of the electronegativity of s- and p-elements on the viscosity and surface tension of the melt.

That is, there exists a linear dependence of the viscosity on electronegativity of elements with the same structure of their outer electron shells. In the presence of d-elements the viscosity,  $\eta$ , increased with decreasing state of oxidation (Fig.3) of the elements, which corresponds

Fig. 3. The viscosity of the melt against the ratio of cationic charge to cationic radius  $Z/r$  (1) and against the energy of the bond between the cation and oxygen  $Me - O$  (2).

(according to the Kossel scheme) to the weakening of their acidic properties in the sequence:  $Mo \rightarrow W \rightarrow V \rightarrow Cr \rightarrow Ti \rightarrow Mn \rightarrow Fe \rightarrow Co \rightarrow Cu \rightarrow Ni \rightarrow Zn \rightarrow Cd$ .

As the charge-to-radius ratio of the ion and the  $Me - O$  bond energy diminishes the decreasing effect of the element on the viscosity of the melt is weakened. This dependence is characteristic of s- and p-elements as well as of d-elements (Fig.3)

When comparing the effect, on the viscosity  $\eta$ , of s- and p-elements which are situated in the periodic table in the same period but in different groups, it has been established that the viscosity decreases with increasing nuclear charge (Fig.4). An insignificant difference in

Fig. 4. Effect of the nuclear charge of the element introduced on the surface tension and viscosity of the melt.

the properties of d-elements of the same period, which is accounted for by the identical structure of their outer electron shell (2 s-electrons), is responsible for the fact that the properties of the melt differ little in the presence of these elements. Thus, for example, in the series  $Mn-Fe-Co-Ni$  the viscosity of the melt increased from 0.129 (Mn) to 0.143 Pa.s (Ni), and in the series  $Ti-V-Cr$  it increased from 0.123 to 0.128 Pa.s. With increase of the cationic radius in their comparable series, which corresponds to the increase of basic properties, the viscosity of the melt diminishes to a lesser extent.

The activation energy of the viscous flow of the melt,  $E_\eta$ , was equal to 364 kJ/mole. In the presence of s-elements  $E_\eta$  decreased with increasing basicity of the cation within the limits of 317 (Mg) and 193 kJ/mole (K). The quantity  $E_\eta$  of melts containing Cr, Ni, Mo, Mn, V, Cu, W, Ti and Co varied within the limits of 113-155 kJ/mole; in the presence of Zn and Cd the activation energy increased abnormally up to 193 and 251 kJ/mole, respectively. The values of  $E_\eta$  of the melt in the presence of p-elements were very low: from 84 to 147 kJ/mole. An exception is a system with phosphorus, whose  $E_\eta$  increased up to 251 kJ/mole.

The departures of the function  $\log \eta = f(1/T)$  from the exponential law, the appear-

range of points of inflection on the curve and the increase of the quantity  $E_{\eta}$  can be explained by the onset of crystallization of the melt in the presence of the corresponding

elements. The following temperatures of the onset of crystallization of the melt in the presence of individual elements are as follows (in °C): 1432 for P, 1427 for Ni, 1406 for V, 1402 for Cr and Cl, 1400 for Cd and Mn, 1397 for Zn, 1387 for Cu, and 1386 for Co. The viscosity  $\eta$  is decreased most strongly under the influence of elements when their concentration in the melt is 2-3 per cent; higher concentrations of the elements may bring about negative results.

When several elements are jointly present in the melt, the properties of the melt are not additively changed by the ion concentration. The negative effect of  $K^+$  and  $Na^+$  on the viscosity of the melt is well compensated for by  $Mg^{2+}$ . According to the data obtained by Osokin and Mironov, the effect of 1.5 per cent of  $(K_2O + Na_2O)$  is fully compensated for by 6.5 per cent of  $MgO$ . Further increase of the amount of  $MgO$  causes the viscosity to decrease due probably to the oversaturation of the melt with  $Mg^{2+}$  and to the onset of the crystallization of the latter. The positive effect of  $SO_4^{2-}$  on the viscosity of the melt is weakened by  $Na^+$  and  $K^+$ ; but if these cations are

present together in the ratio corresponding to the compounds  $Na_2SO_4$  and  $K_2SO_4$ , the viscosity of the melt  $\eta$  is nevertheless considerably diminished. After the stoichiometry is exceeded there is observed an intensive increase of  $\eta$  with increasing amount of  $Na^+$  and  $K^+$  in the melt. In such cases the melt undergoes microliquation. The joint presence of  $Na^+$ ,  $K^+$ ,  $Mg^{2+}$ , and  $SO_4^{2-}$  in the melt is accompanied by the change of  $\eta$  from 0.08 to 1.65 Pa·s, depending on the ratio of the ions. The microliquation of the melt in the presence of the given group of elements is retained (Fig. 5)

The effect of a complex consisting of  $Ti^{4+}$ ,  $Mn^{3+}$ , and  $SO_4^{2-}$  on the viscosity of the melt is more complicated: in the respective concentration triangle the viscosity isocoms are broken. A considerable decrease of the viscosity of a melt containing an increased amount of  $SO_4^{2-}$  and  $Mn^{3+}$  combines with zones of increased viscosity, which are situated closer to the side of  $Ti-Mn$ . The increase of the viscosity at a certain ratio of the elements may be accounted for by the formation of stable complexes in the melt. To the lowest  $\eta$  value (0.085 Pa·s) of a melt containing the complex  $(Mg^{2+} + Ba^{2+} + Mn^{3+})$  there corresponds the maximum content of  $Mn^{3+}$  and  $Mg^{2+}$  and the minimum content of  $Ba^{2+}$ . The above-given examples of the effect of a group of elements on the viscosity of the melt are in agreement with the character and specificity of the action of the corresponding individual elements.

The surface tension of the melt is governed by its structure in the bulk and also by the composition and structure of the surface layer. In the presence of various elements the value of  $\sigma$  is changed not only as a result of the change of the activity of the matrix ions of the melt but also because of the high absorption capacity of the ions introduced, which, as compared with viscosity, complicates the dependence of the variation of  $\sigma$  on the nature of the element.

With increasing electronegativity of s-elements there is observed an increase of  $\sigma$ , and, on the contrary, the increase of the electronegativity of p-elements is accompanied by the decrease of the surface tension of the melt (Fig. 2). True, in view of a wide spread of experimental data, one should speak only of a tendency in the manifestation of the above-discussed regularities. As the values of ratio  $Z/r$  and the Me - O bond energy of elements increase, the following effect of elements is observed: the alkali and alkaline-earth cations increase and acid cations, on the contrary, decrease  $\sigma$ , this being in agreement with the data obtained by Yesin. The cations  $K^+$  and  $Na^+$  are weakly bonded with  $O^{2-}$ , which leads to their displacement into the surface layer of the melt, whose  $\sigma$  decreases from 0.58 to 0.35-0.40 N/m with increasing concentration of these cations (Fig. 6). As the values of the Me - O

Fig. 5. The isocoms of the viscosity of the melt in the presence of the complex  $MgO-R_2O-SO_3$ .

Fig. 6. The isotherms (1450°C) of the surface tension of the melt in the presence of s-elements (a) and p-elements (b).

bond energy and  $Z/r$  of p-elements increase, their surface activity is enhanced (Fig. 6), this being due to the stability of the complex ions  $PO_4^{3-}$ ,  $SO_4^{2-}$ , and  $BO_3^{3-}$ , which cannot be held in the bulk of the liquid and are displaced into its surface layer. The anomalies in the behaviour of  $F^-$  and  $SO_4^{2-}$  (Fig. 4) are accounted for by the liquation phenomena that occur in the melt. The increase of  $\sigma$  caused by the addition of more than 1.5 per cent of  $Al_2O_3$  may be associated with the saturation of the melt with the complex  $[AlO_5^{5-}]$  and with the increase of its viscosity. With increase of the acidity of d-elements there is observed the tendency towards the decrease of the surface tension of the melt (Fig. 7), just as is the case with the

Fig. 7. The surface tension of the melt against the cationic charge-to-radius ratio  $Z/r$  (1) and the energy of the bond between the cation and oxygen Me - O (2).

regularity obtained for  $\eta$  (Fig. 3). The order of arrangement of elements is evidence that for ions having close ratio the surface activity increases with increasing state of oxidation, i.e., with increase of acidic properties:  $Co \rightarrow V \rightarrow Cr \rightarrow Mo$ .

According to Appen (6), the introduction of a component having a smaller value of  $\sigma$  brings about a decrease in the surface tension of the system. Such a mode of change of  $\sigma$  caused by mutual replacements of s-, p-, and d-elements in the melt occurs rather regularly.

When the ions  $K^+$ ,  $Na^+$ , and  $SO_4^{2-}$  ions are present together in the melt, the observed decrease of the surface tension of the melt is described by the empirical equations (1). In the presence of a group of the elements  $K^+$ ,  $Na^+$ ,  $Mg^{2+}$  and  $SO_4^{2-}$ , because of the screening of the cations  $Na^+$  and especially of  $K^+$  by the anion  $SO_4^{2-}$ , there arises an extensive liquation zone with the formation of a liquid characterized by the decrease of  $\sigma$  down to values of the order of 0.1-0.25 N/m (Fig. 8).

Fig. 8. The isocoms of the surface tension of the melt in the presence of the complex  $\text{Mn}_2\text{O}_3\text{-TiO}_2\text{-SO}_3$ .

The Mn-Ti complex contributes to the increase of  $\sigma$  up to 0.54-0.60 N/m, but upon addition of S to it and with an optimum ratio of all the three elements the surface tension of the melt may be diminished down to 0.34-0.36 N/m.

The sizes of vacancies (microcavities) in the melt, as calculated from the values of  $\sigma$ , are as follows: at 1450°C the radius of vacancies is 1.1 Å, and at 1525°C it is equal to 1.15 Å, which is an indication of the increase of the free volume of the melt upon heating it above the liquidus temperature. The density of the melt at 1450°C is 3020 kg/m<sup>3</sup>. As the temperature rises from 1450 to 1475°C the value of  $\rho$  drops to 2900 kg/m<sup>3</sup>, which confirms that the structure of the melt in the pre-liquidus region has undergone considerable changes.

The clinker melt is characterized by the electronic-ionic conductivity (1). The electronic component is due to the exchange of electrons between the iron ions, and the ionic component is due to the high mobility of the  $\text{Ca}^{2+}$  cations and also due to the transport of electricity by the octahedrally coordinated ions  $\text{Fe}^{3+}$  and  $\text{Al}^{3+}$ . The nature of the effect of the ions introduced into the melt depends on many factors: the size of the ion and its charge, the strength of the Me-O bond, the mutual polarization of oxygen and several cations, the viscometric properties of the melt and the change of the electronic component of conductivity. The joint presence of several charge-transfer agents and the presence of the electronic component complicates the interpretation of

the results obtained.

In the presence of the ions of Mg, Sr, and Ba the electrical conductivity of the melt, which is equal to 63.7 S/m at 1450°C, increases proportionately to their concentration, its value increasing with decreasing field strength of the cation (Fig. 9).

Fig. 9. The electrical conductivity of the melt versus the charge-to-radius ratio  $Z/r$  of s- and d-elements.

The observed increase of  $\sigma$  with increasing radius of the cation is accounted for by the fact that the size of vacancies (microcavities) in the clinker melt, which is equal to 1.1 Å at 1450°C, is commensurate with the size of the cations of Mg, Sr, and Ba. Therefore, the most probable mechanism of diffusion for them is the vacancy mechanism and in this case the geometric factor (the quantity  $r$ ) has no substantial effect. The predominating effect is exerted by the energy factor—as the field strength increases, so does the attractive energy of the cation  $\text{O}^{2-}$ , which is what lowers the probability of the vacancy mechanism. This increases the mobility of the cation  $\text{Ca}^{2+}$ .

The  $\text{Na}^+$  ions contribute to the growth of  $\sigma$  due to the increase of the concentration of current carrier in the melt, and the  $\text{K}^+$  ions reduce  $\sigma$  due to the decrease of the mobility of  $\text{Ca}^{2+}$  and the reduction of the electronic conductivity (there are formed  $\text{FeO}_4^-$  ions which are less capable of exchanging electrons).

An analogous dependence is observed for the majority of the d-elements studied (Fig. 9). The abnormally high electrical conductivity of melts containing the ions of V (79), Mo (94), W (97), Fe (87 S/m) is explained by the increase of the electronic conductivity, which has been observed for molten glasses and slags (6). An increase in the content of chromium increases  $\sigma$ , because the energy levels of the transitions  $\text{Fe}^{2+} \rightarrow \text{Fe}^{3+}$  and  $\text{Cr}^{2+} \rightarrow \text{Cr}^{3+}$  are practically identical and the increase of the

content of Cr increases the number of vacancies and the probability of electronic transitions. But, judging by the results of viscosity measurements, one could have expected a more substantial decrease of electrical resistance in the presence of Cr, but the electrical conductivity increased only up to 76 S/m with the concentration of  $\text{Cr}_2\text{O}_3$  being 4 per cent.

The incorporation of p-elements into the melt leads to an increase of  $\alpha$  due to the decrease of the viscosity of the system and the attending increase of the mobility of the cation  $\text{Ca}^{2+}$ . In the presence of phosphorus ions the electrical resistance increases in proportion to the concentration of  $\text{P}_2\text{O}_5$ , which is accounted for by the formation of complex anions of the type  $(-\text{O}-\text{Si}-\text{O}-\text{Ca}-\text{O}-\text{P}-\text{O})$ , which reduces the number of current carriers.

The electrical conductivity of the melt is enhanced within the temperature range from 1400 to 1500°C, it increasing most intensively in the pre-liquidus region. The activation energy of electrical conduction in the melt, which is equal to 50 kJ/mole, is 3 times lower than  $E_{\text{Ca}}$  (163 kJ/mole), which supports the fact of transport of electricity in the melt both by ions and electrons.

The diffusion coefficients of the structural components of the melt over the temperature range 1450-1525°C are as follows:  $D_{\text{Ca}} = (5.31 \text{ to } 8.55) \times 10^{-9}$ ;  $D_{\text{Fe}} = (5.70 \text{ to } 14.2) \times 10^{-10}$ ;  $D_{\text{Al}} = (2.35 \text{ to } 7.10) \times 10^{-10}$ ;  $D_{\text{Si}} = (4.73 \text{ to } 15.8) \times 10^{-11}$   $\text{m}^2/\text{s}$ . The diffusion coefficients increase with rise of temperature. A comparison of the size of vacancies in the melt (1.1 to 1.15 Å) with the effective radii of the cations  $\text{Ca}^{2+}$ ,  $\text{Al}^{3+}$ , and  $\text{Fe}^{3+}$  (ca. 1 Å) suggests the vacancy mechanism of their diffusion; larger anions, such as  $[\text{SiO}_4]^-$ ,  $[\text{FeO}_4]^-$ , and  $[\text{AlO}_4]^-$  diffuse by way of exchanging places upon rotation of the corresponding groupings relative to each other. In the presence of  $\text{Na}^+$  and  $\text{K}^+$  ions the diffusion coefficients of all the structural units of the melt were diminished; they increased under the influence of  $\text{Mg}^{2+}$  and  $\text{SO}_4^{2-}$ .

The high surface activity of p-elements (F, Cl, Si, P, S) causes the formation in the melt of micro- and macroliquetation regions which differ considerably in acidic-basic properties. The segregation of the composition of the liquid phase results from the adsorption of the anionic groupings by the surface layer of the melt and also from the low mobility of the silicon-oxygen complexes, which leads to an increase in their concentration in the melt regions adjacent to the dissolving silicon-containing phases ( $\text{SiO}_2$ ,  $\text{C}_2\text{S}$ ,  $\text{C}_3\text{AS}$ , etc.). The tendency of the ions of Si, Al, and Fe to form a coordination sphere leads to the follow-

ing: elements such as F, Cl, and S, especially in combination with Ba, Cd, Sr, Na, and K, enhance the liquation phenomena.

According to the theory developed by Weyl (6), the degree of shielding of cations increases with increasing polarizability of anions. Since the  $\text{F}^-$  ion has a lower polarizability ( $0.96 \text{ Å}^3$ ) than  $\text{O}^{2-}$  ( $2.74 \text{ Å}^3$ ), it is readily displaced from the coordination sphere of the complex-formers (Si, Al) into the coordination sphere of  $\text{Ca}^{2+}$ ,  $\text{Na}^+$  and  $\text{K}^+$ . Therefore, even at a fluorine concentration of about 1 per cent in the melt there is observed the appearance of liquation zones (Fig. 10) which are

Fig. 10. The liquation regions in the clincker melt at the following concentrations: a — 1.0 per cent  $\text{F}^-$  by mass; b — 3.0 per cent  $\text{Cl}^-$  by mass (magnification  $\times 10000$ ).

(2 to 3)  $\times 10^3$  Å in size. The appearance of non-miscibility in a fluorine-containing melt has also been confirmed by the appearance of the exo-effect on the thermograms at 850°C, which results from the crystallization of liquating drops and from the presence of two endothermic effects (1200 and 1380°C), which has also been observed in the case of glass-forming systems (7). The fact that the  $\text{F}^-$  ion is close to  $\text{Ca}^{2+}$  contributes to the microheterogenization of the melt to regions enriched with groups containing the bonds  $\text{Si}-\text{O}$  and  $\text{Al}-\text{O}$  and to the zones with an increased concentration of modifying cations, where the  $\text{Me}-\text{O}$  bond is predominating.

The chloride ions exhibit a higher polarizability than do the fluoride ions and therefore in their presence the degree of shielding is increased and microliquetation

appears at higher concentrations of Cl (2-3 per cent) with the formation of li-  
quation regions of a smaller size. The  
ions  $S^{6+}$  are even more polarizable and  
therefore in this case the liquation is  
observed only in the presence of  $Na^+$  and,  
especially, of  $K^+$ . Thus, for example, when  
the total content of  $SO_3$  and  $Na_2O$  in the  
melt is 2.7 per cent, the observed micro-  
liquation (the size of drops being  $10^3 \text{ \AA}$ )  
changed to complete immiscibility at a 5-  
per cent concentration of the oxides. In  
the presence of the complex  $SO_3-K_2O$ , ma-  
croliquation appeared even when their tot-  
al concentration was 2.4 per cent. The  
addition of  $Mg^{2+}$  to a melt containing the  
complex  $R_2O-SO_3$  contributes to the sup-  
pression of the liquation phenomena and  
the phase separation occurs only at high  
concentrations of sulphur and alkalis in  
the melt.

Liquation salt melts enriched with F, Cl,  
K, Na, and S have a viscosity which is  
lower by about two orders than the visco-  
sity of the matrix liquid phase and low  
values of surface tension (0.15 to 0.19  
N/m). Therefore, the macrosegregation in  
the system alters, to a considerable ex-  
tent, the kinetics of dissolution of gra-  
ins of  $CaO$ ,  $C_2S$  and other minerals, and  
also hinders the aggregation of the par-  
ticles of the materials in the sintering  
zone where clinker grains are formed.

#### DISSOLUTION AND CRYSTALLIZATION

The liquid phase formed in the sample of  
the material being burned fills separate  
pores and capillaries, forming thin films  
on the particles. Some authors (8-10) pre-  
sume that the melt in the sintering sam-  
ples is a continuous phase in which grains  
of  $CaO$ ,  $C_2S$  and  $C_3S$  are distributed. The  
interaction of the minerals indicated  
above with the melt takes place in con-  
strained conditions when the diffusion of  
the ions required for the growth of  $C_3S$   
crystals limits the course of the syn-  
thesis reaction.

At lower temperatures (1000-1200°C) there  
are formed non-equilibrium melts of acidic  
nature (11), which arrange themselves in  
the form of small drops predominantly  
near the softening quartz grains and which  
contains the ions of S, F, Cl, Na, K, Ca,  
Si, Al, Fe, and O. It is through these  
melts that the  $Ca^{2+}$  ion is transferred  
to the surface of the  $SiO_2$  grains and  $C_2S$   
is synthesized. In spheres consisting  
of a shell having the  $C_2S$  composition and  
a kernel of  $SiO_2$  the acidic melts are  
retained until they are absorbed (pulled)  
by the melt enriched with  $Ca^{2+}$  as a result  
of the countercurrent diffusion of  $Ca^{2+}$   
and  $Si_2O_7^{4-}$  (a pore is left in place of the  
 $SiO_2$  kernel). Between the grains of  $CaO$ -  
 $C_2S$ ,  $CaO$ - $C_3S$ ,  $CaO$ - $C_2S$ - $C_3S$  there are formed  
zones of the melt enriched with  $Ca^{2+}$ , in  
which crystals of  $C_3S$  are generated. The  
zonally arranged melts characterized by  
concentration gradients and different aci-

dic-basic properties when brought into con-  
tact with each other exchange their ions  
at the interface, tending to the equilibri-  
um composition. When the melts have large  
volumes, the averaging of their composition  
is contributed by convection, but in thin  
capillaries and films the transport of a  
substance is accomplished only by diffusion.  
The retainment of molten volumes of differ-  
ent composition in clinker grains (metas-  
table microliquation) and the development  
of liquation processes in the presence of  
impurities lead to the separation of solid  
phases which are at equilibrium with these  
liquids.

The kinetics of the dissolution of sintered  
samples of  $CaO$  and  $C_2S$  in melts of differ-  
ent composition have been investigated by  
the equally-accessible-surface through the  
control of the thickness of the diffusion  
layer by altering the intensity of rotation  
of the sample. At 1450°C the rate of disso-  
lution of  $C_2S$  in the main melt ( $n = 600$  to  
1400 r.p.m.) was equal to  $(1.94 \text{ to } 2.78) \times 10^{-8}$   
m/s and that of  $CaO$  was  $(6.10 \text{ to } 8.34) \times 10^{-8}$   
m/s, i.e., higher by 3 times. The  
activation energy of the dissolution process  
is as follows:  $E_{CaO} = 264 \text{ kJ/mole}$  and  $E_{C_2S}$   
= 419 kJ/mole. The rate of dissolution of  
 $CaO$  is commensurate with  $D_{Ca}$  ( $E_{Ca} = 163$   
kJ/mole) and that of  $C_2S$  is commensurate  
with  $D_{Si}$  ( $E_{Si} = 368 \text{ kJ/mole}$ ). The differen-  
ce in the values of  $E_{CaO}$  and  $E_{Ca}$  and  
also in the values of  $E_{C_2S}$  and  $E_{Si}$  may be  
attributed to the complex mechanism of the  
multi-component diffusion (8,10) within  
the thin films of the melt. The diffusion  
mechanism of the dissolution process con-  
firms the dependence of the rate of dissolu-  
tion of  $CaO$  and  $C_2S$  on the viscosity of the  
melt (Fig. 11). The fact the dissolution is

Fig. 11. The rate of dissolution of  $C_2S$  and  $CaO$  cakes versus the viscosity of the melt.

speeded up with decrease of  $\eta$  is associated with the decrease of the thickness of the diffusion films on the particles being dissolved.

The sulphur, chloride and fluoride ions, which render the melt acidic and lower its viscosity, speed up the dissolution of CaO (by 1.5-2 times) and of  $C_2S$ . In the presence of  $Ba^{2+}$  and  $Sr^{2+}$  the rates of dissolution of CaO and  $C_2S$  ( $I_{CaO}$  and  $I_{C_2S}$ ) are somewhat diminished. The rate of dissolution  $I_{CaO}$  is very strongly decreased in a melt containing  $Na^+$  and  $K^+$  (by 2 to 4 times at 3-4 per cent  $R_2O$ ) due to the increase of  $\eta$ . The rate of dissolution of  $C_2S$  in an alkali-containing melt increases anomalously: by 3 to 7 times with the content of  $K_2O$  being 0.5-1.9 per cent by mass and by 30 to 50 times with the content of  $Na_2O$  being 2.2-4 per cent by mass; the rates of dissolution in the latter case are 78 and  $133 \times 10^{-8} m/s$ , respectively. The special role of the ions  $Na^+$  and  $K^+$  may consist in the following: being concentrated in the diffusion layer on a particle of  $C_2S$ , they also speed up the transport of the low-mobile ions  $SiO_4^{2-}$ . The difference in the effect of Na and K may be ascribed to the sizes of their ions:  $Na = 0.97 \text{ \AA}$  and  $K = 1.33 \text{ \AA}$ . When  $R_2O$  and  $SO_3$  are present together in the melt, this leading to the microliquation of the melt,  $I_{C_2S}$  is lower than in the presence of  $R_2O$  alone, but it exceeds  $I_{CaO}$  by 3 to 5 times. The kinetics of the expansion of the  $C_3S$  zone at the point of contact between of the layers of the composition  $CaO + C_3S + \text{melt}$  and  $C_3S + C_2S + \text{melt}$  ( $1500^\circ C$ ) referred to the rate of formation of  $C_3S$  is expressed, according to the literature data (8, 10), by the following parabolic relation:

$$x^2 = Kt \quad (3)$$

where  $x$  is the width of the  $C_3S$  zone,  $t$  is the reaction time, and  $K$  is a constant ( $cm^2/s$ ). The reaction rate constant increased with increasing amount of the melt from 10 to 30 per cent, upon replacement of part of  $Al_2O_3$  by  $Fe_2O_3$  and with rise of temperature. The proportionality between the amount of the melt and the rate of the processes of binding of CaO in the preparation of clinker has also been established by Butt, Timashev and Osokin (1). The positive effect of the replacement of  $Al^{3+}$  by  $Fe^{3+}$  is due to the decrease of the viscosity of the melt involved (Figs. 2 and 4). It has been found (12, 13) that with increasing size of the particles of CaO,  $SiO_2$ ,  $C_2S$ , etc., apart from the decrease of the rate of their dissolution, the following anomaly is observed: the process takes place in cycles, this being caused by the formation, on the reacting grains, of fringes of the reaction products ( $C_2S$  and  $C_3S$ ), which retard the synthesis, the formation of these fringes being followed by the rupture of the shell and the onset of a new cycle of the accelerated

reaction. The cyclic course of the reaction correlates well with the existence of local melts which differ in composition.

In the zones of the acidic melt ( $C_2S + \text{liquid}$ ) the formation of  $C_3S$  is controlled by the rate of diffusion of  $Ca^{2+}$  ions from the regions with a larger content of lime to the crystal nuclei and also by the rate of dissolution of  $C_2S$ , the alite crystals growing in the direction of the  $C_2S$  particles. In basic melts and especially in the presence of  $Na^+$  and  $K^+$  the rate of dissolution of  $C_2S$  is high, and the process is limited by the rate of dissolution of CaO grains, the  $C_3S$  crystals being formed at various points in the volume of the melt. After the grains of CaO (and also of  $CSiO_2$ ) are dissolved there are left pores in their place.

For a model system composed of particles of CaO,  $C_2S$  and glass, it has been established (20) that the concentration of the liquid phase undergoes change in the direction of the dissolving particles and, for example, at  $1450^\circ C$  the portions of the melt in the CaO-melt and  $C_2S$ -melt zones are characterized by different concentrations of Ca and Si because of the difference between the diffusion coefficients of the ions of these elements. The  $\eta$  values of the melts are different: with increasing concentration of  $Ca^{2+}$  the viscosity of the melt is decreased. During the course of the synthesis there takes place a mutual diffusion of the melts until there are formed zones of supersaturation with respect to portions of the melt saturated with  $C_3S$ . In the supersaturated zones there occurs the crystallization of  $C_3S$  with the formation of a saturated melt.

Since the rate of the reaction of formation of  $C_3S$  is usually proportional to the concentration gradient ( $\Delta C$ ) in the diffusion layer and the surface area of the latter is equal to that of the dissolving particles (20, 37, 38), the kinetics of the process, at least at the initial stage, is satisfactorily described by diffusion equations of the following type:

$$(1 - \sqrt[3]{1 - \alpha})^n = \frac{2D \Delta C}{r^2} \tau = K\tau$$

where  $\alpha$  is the fraction of the reacted substance and  $\tau$  is the time. The fraction of the reacted substance has been found to be proportional to the viscosity of the melt.

In comparing models for the process of sintering from the preliminarily synthesized  $C_2S$ , CaO, and  $C_3S$ , one should bear in mind that under the influence of the capillary pressure of the melt the porous grains of the minerals can be dispersed, thereby distorting the kinetics of the dissolution process (1, 8).

The presence of 1 per cent of  $TiO_2$  in the batch results in an increase of the amount of the melt and a decrease in the temperature, at which the process of binding of CaO is completed, by  $50-100^\circ C$ , but with a

higher content of titanium the amount of  $C_3S$  is diminished (51). The catalytic properties of the complex ( $R_2O + MgO + SO_3$ ), which is usually present in the composition of raw mix have been analyzed (52-54). According to the literature data (52), the process of binding of  $CaO$  is speeded up with the following content of the components: 0.2-1.2%  $MgO + 1-4\% SO_3 + 0-0.3\% R_2O$ ; the effect of a complex consisting of 3-5%  $MgO + 1-1.5\% SO_3 + 1\% MnO$  has been found to be positive (53). Complexes having a more complicated composition have also been found to be effective (54); two examples are ( $MgO + CaCl_2 + CaF_2 + CaSO_4 + P_2O_5$ ), ( $MgO + SO_3 + R_2O + MnO + BaO$ ).

In order to prepare a clinker with a saturation coefficient of 0.88 at  $1400^\circ C$ , the original clinker containing 1 per cent of  $CaO$ , the optimum concentrations of the components of the complex  $MgO-CaSO_4-R_2O$  (where  $R_2O = K_2O/Na_2O = 3/1$ ) must be in the

Fig. 12. The region of the optimum ratios of the components of the complex  $MgO-CaSO_4-R_2O$  (where  $R_2O = K_2O/Na_2O = 3/1$ ) for producing the clinker with  $SC = 0.88$ ,  $n = 2.1$ ,  $p = 1.2$  at  $1400^\circ C$ , containing less than 1 per cent of free  $CaO$ .

range presented in Fig. 12. With the increase of the saturation coefficient from 0.88 to 0.96 and of the burning temperature the limiting concentration of  $R_2O$  is decreased.

The presence of several elements often has a positive effect on the binding of  $CaO$  upon burning. A complex consisting of  $Na_2SO_4$  (0.3%) and  $MgO$  (3%), while causing the viscosity of the melt to decrease, contributes to the binding of  $CaO$ , though the microliquation of the liquid has also been observed (22). The process of binding of  $CaO$  is catalyzed by the complex ( $BaSO_4 + MgO + R_2O$ ), this leading to the decrease of  $\eta$  and the temperature at which a melt is formed (23). The addition of magnesium oxide to

$R_2O$  and  $P_2O_5$  eliminates the unfavourable effect of  $P_2O_5$  alkalis and phosphorus (24).

Under the action of a flux of accelerated neutrons ( $200-400 \text{ kGy/s}$ ) the rate of binding of  $CaO$  increased by about 100 times (14), and the process of alite formation is completed at  $1100-1300^\circ C$  in 5-15 seconds with an energy consumption of about  $3300 \text{ J/g}$ .

#### THE LIQUID-PHASE SINTERING OF CLINKER

The mechanism of the formation of the micro- and macrostructure of clinker granules obeys the general regularities of the process of liquid-phase sintering (15, 16). The process of formation of clinker grains in the presence of an equilibrium melt may be subdivided into three stages: (1) the combination and rearrangement of particles; (2) the packing of granules due to dissolution-crystallization reactions; and (3) the cooling stage followed by the crystallization and freezing of the melt.

**The Combination and Rearrangement Stage.** When a melt is formed, the particles of the material being fired and their aggregates enter into random contact interactions and combine with one another due to the surface tension of the melt. The rearrangement of the particles in the grain is made possible by the high value of  $\sigma$  ( $0.5-0.6 \text{ N/m}$ ) of the melt and its low viscosity ( $0.1-0.2 \text{ Pa}\cdot\text{s}$ ), and also by the compression of the grains by the overlying layer of the material being burned in the furnace. The intensive rearrangement of the particles, which takes place in the initial period (stage 1) results in the shrinkage of the granules (Fig. 13). Stage 2 is characteriz-

Fig. 13. The relative linear shrinkage of pressed samples against the time of thermal treatment at various temperatures: 1 —  $1450^\circ C$ ; 2 —  $1400^\circ C$ ; 3 —  $1350^\circ C$ .

ed by the reduced rate of shrinkage and its

lower absolute value; its mechanism consists of dissolution-crystallization reactions. With rise of temperature the amount of the melt increases and there is required less and less time for the rearrangement process to be complete.

The capillary force  $F$ , which draws the particles together at the rearrangement stage, is determined by two components:  $F_1$  and  $F_2$ . The force  $F_1$  is due to the difference between the pressures on both sides of the meniscus of the melt in the particle contact zone (the Laplace law): the pressure inside the liquid ring is lower than that outside, and the particles are brought nearer to one another. The force  $F_2$  is due to the tendency of the free surface of the liquid to contract and depends on the surface tension of the melt. Having calculated the total driving force of the process,  $F$ , one can derive an equation for the kinetics of shrinkage of the sintering grain of the material ( $dl/l_0$ ), which characterizes the rate of the rearrangement process (17, 18):

$$dl/l_0 = \frac{\sigma}{\eta r \sin \varphi} \left\{ \sin \varphi \left[ \frac{\cos(\varphi + \theta)}{1 - \cos \varphi} - \frac{1}{\sin \varphi} - \frac{(1 - \cos \varphi)[1 - \sin(\varphi + \theta)]}{\cos(\varphi + \theta)} \right] + 2 \sin \varphi \cdot \sin(\varphi + \theta) \right\} \cdot d\tau \quad (4)$$

Equation (4) takes account of the dependence of the rate of shrinkage of grains on the properties of the liquid phase, such as  $\sigma$ ,  $\eta$  and  $\theta$  (the angle of wetting and its amount  $\varphi$  (the angle depending on the amount of the melt) at a certain particle size. After substituting  $\Delta l/l_0$  by the total driving force of the process of drawing of particles together (17) Eq. (4) can be used for the computation of the kinetics of the aggregation of the particles of the material being burned into clinker grains in the sintering zone of the rotary furnace. By changing the properties of the melt, the process of aggregation of particles of different mass can be influenced in any desirable way.

The dependence of the predominating size of the clinker grain, as calculated from the modified equation (4), on the surface tension of the melt (Fig. 14) is al-

Fig. 14. Dependence of the final size of clinker grains formed in the rotary furnace on the surface tension of the clinker melt.

most linear. An appreciable decrease in the surface tension of the melt achieved under certain conditions in the presence of  $K^+$ ,  $Na^+$ ,  $Sr^{2+}$ ,  $Mo^{3+}$ , and  $Sb^{3+}$  was accompanied by a decrease in the final size of the agglomerate (17). A slight decrease of  $\sigma$ , the more so its increase, observed in the presence of  $Ti^{4+}$ ,  $Al^{3+}$ ,  $Fe^{3+}$ ,  $Mn^{3+}$ , and  $Mg^{2+}$ , contributed to the progress of the aggregation process. The effect of the joint presence of several elements satisfactorily obeys the dependence of  $F$  on  $\sigma$  (Fig. 14). Anomalies arise in those cases where the melt undergoes liquation in the presence of impurities. For example, in the presence of  $nSO_3 + mR_2O$ , as a result of the liquation, there is formed a sulphate-alkaline liquid with a low surface tension (0.3 to 0.35 N/m), which lowers the driving force  $F$  of the process of aggregation. The final size of the clinker grain is reduced almost by half in the presence of  $F^-$  and  $Cl^-$ , which also causes liquation with the formation of salt zones in the melt with decreasing  $\sigma$ . The indicated dependences of the grain size,  $R$ , on the surface tension of the melt ( $\sigma$ ) are well reproducible in industrial conditions. But in such cases it is necessary to take into account the effect of many technological factors on the process of aggregation: the fluctuations in temperature in the sintering zone; the particle-size distribution of the material before it enters the zone of intensive aggregation; the dimensions of the sintering zone, and the shape of the flame.

The dissolution-crystallization stage involves the formation of stable crystals of minerals and the compaction of the system due to a more compact packing of cry-

stals and to the decrease of the pore volume. At this stage there takes place the crystallization of  $C_3S$  from the melt. This is accompanied by the convective transport of the melt between zones with temperature gradients and also the diffusion averaging of the composition of the melts characterized by concentration gradients. The driving force  $F$  of the process of rearrangement of crystals and of their approach (i.e., the shrinkage process) is the same as that at the first stage, but with a small correction introduced for the non-spherical shape of the crystals formed.

The kinetics of the shrinkage of clinker grains at the second sintering stage may be expressed by the following equations (15, 20):

$$\Delta l/l_0 = (6 K_2 \delta D_0 C_0 \sigma V_0 / K_1 RT)^{1/3} r^{-4/3}.$$

$$\tau^{1/3}$$

(5)

where  $K_1$  is the ratio of the pore radius to the radius of the particles;  $K_2$  is the proportionality factor;  $C_0$  is the equilibrium solubility of  $C_3S$ ,  $m/m^3$ ;  $D_0$  is the diffusion coefficient for  $SiO_4$  in the melt,  $m^2/s$ ;  $V_0$  is the molar volume of  $C_3S$ ,  $m^3/kmole$ ;  $\delta$  is the thickness of the film of the melt between the  $C_3S$  crystals,  $m$ ;  $R$  is the universal gas constant,  $J/kmole$ ;  $T$  is the absolute temperature,  $^{\circ}K$ ;  $r$  is the size of  $C_3S$  crystals,  $m$ ;  $\tau$  is the duration of heat treatment, seconds.

At a constant temperature ( $T$ ) the values of  $C_0$  and  $\sigma$  are sufficiently stable, and therefore the amount of shrinkage will depend on the rate of the growth of the volume fraction of  $C_3S$  ( $V_0$ ,  $\delta$ ,  $D_0$ ), which determines the time of the process,  $\tau$ . As the grain structure becomes more and more compact the diffusion of the most slowly moving ions  $SiO_4^{4-}$  to the crystal nuclei of  $C_3S$  becomes the rate-limiting factor of the process. The decrease of the viscosity of the melt attained in various ways contributes to the increase of  $D_{SiO_4^{4-}}$  and speeds up the process of  $SiO_4^{4-}$  synthesis. The dependence of the clinker microstructure on the viscosity of the melt containing  $Ti$ ,  $V$ , and  $Cr$  has been deduced by Kurdowski (21).

Since the packing of the sample at the second sintering stage is associated with the formation and growth of  $C_3S$  crystals ( $r$ ), one can predict, by solving Eq. (5) for  $r$ , the size of the crystals of the mineral during the occurrence of the process of shrinkage of the clinker grain.

At the cooling stage (stage 3), the convection of the liquid is increased in the clinker grain (because of the large  $\Delta T$ ), as a result of which there may appear in

it zones of increased porosity (usually, a surface layer) in it, and, on the contrary, compact zones (zones in the middle portion). The specific volume of the eutectic melt is lowered when it is frozen to glass. The volume of the hardened melt containing  $R_2O$  and  $Cr_2O_3$  also decreases; in the presence of  $SO_3$ ,  $MgO$ , and  $CaF_2$  it is increased (19). The increase of the specific volume of the cooled melt occurs due to the formation of pores in the solid phase of the pores upon crystallization. The compression and expansion deformations that take place upon cooling the melt, especially if they are alternating in the various zones of the grain, develop mechanical stresses in it. These stresses are enhanced by the difference in the thermal linear expansion coefficients of the crystals of the minerals (as determined on sintered samples at 25-600 $^{\circ}C$ ):  $C_2S = 19.5$

$x$ ;  $C_3S = 13 x$ ;  $C_4AF = 10 x$ ; glass = 10.8  $\times 10^{-6} K^{-1}$ . Solid solutions of  $C_2S$  with  $P_2O_5$  (2.5-3 per cent) are characterized by even higher thermal linear expansion coefficients ( $39 \times 10^{-6} K^{-1}$ ); the thermal linear expansion coefficient also increases upon dissolution of  $K_2O$  in the lattice of the mineral and when  $Cr^{3+}$  and  $Ti^{4+}$  are incorporated the linear expansion coefficient decreases. The crystals of solid solutions formed in the non-equilibrium regions of the melt exhibit, when cooled slowly, the tendency towards chemical and physical breakdown. These processes may lead to a partial (dusting) and complete (crumbling) destruction of clinker grains. Melts with a high content of iron, with a temperature above the liquidus temperature are prone to overcooling by 100-130 $^{\circ}C$  below the solidus temperature (55). The crystallization of the overcooled liquid proceeds spontaneously. It has been shown (56) that on the DTA curves for glass phases being cooled there appear endothermal effects caused by the pre-crystallization nucleation. The heat of crystallization of minerals is as follows: 436 kJ/kg for  $C_3A$ ; 109-197 kJ/kg for  $C_6A_2F_3$ ; 34 kJ/kg for  $C_2S$ ; the pre-crystallization effect of the crystallization of  $C_3S$  is 155 kJ/kg.

#### THE STRUCTURE AND COMPOSITION OF CLINKER AND ITS PHASES

The crystallization of minerals from a melt containing various chemical elements as impurities is accompanied by the formation of non-equilibrium multi-component solid solutions. A comparatively large number of elements (about 12-15) are distributed non-uniformly among the main phases of clinker (25, 40-43). Belov and Boikova (25, 40) have found that the least amount of impurities is contained in the crystals of alite (4 per cent), and the largest amount, in the aluminate phase (13 per cent); the belite phase contains 6 per cent of impurities, and the aluminoferrite phase contains 10 per cent. The  $Mg^{2+}$  ion is preferentially dissolved in the alumin-

oferrite phase (1.9-3.2 per cent) and enters, in a considerable amount, into the composition of  $C_3S$  and  $C_3A$  (41). The  $Na^+$  ions are concentrated in  $C_3A$  (0.3-4.6 per cent), and the  $K^+$  ions are concentrated in  $C_2S$ . In crystals of  $C_3S$  and  $C_2S$  there are more  $Na^+$  and  $K^+$  ions in the centre than in the surface layers (27). The concentration of  $Al^{3+}$  and  $Fe^{3+}$  is considerable in  $C_3S$  and  $C_2S$ , but their concentration in the belite phase is two times higher. The elements Ti, Mn, and Cr dissolve predominantly in the aluminoferrite phase, and  $S^{6+}$ ,  $P^{5+}$ ,  $Ba^{2+}$ , and  $Sr^{2+}$  dissolve in  $C_2S$ .

**Solid Solutions of Minerals.** A new monoclinic modification  $M_3$  of  $C_3S$  has been detected by the microscopic method (26):  $T_1$  (ca. 620°C),  $T_2$  (620-920°C),  $T_3$  (920-980°C  $M_1$  (980-990°C),  $M_2$  (990-1060°C),  $M_3$  (1060-1070°C),  $R$  (1070°C).<sup>\*</sup> It exists in a narrow temperature range of about 10°C between  $M_2$  and  $R$ . The transitions  $T_1 \rightleftharpoons T_2$ ,

$T_3 \rightleftharpoons M_1$ ,  $M_2 \rightleftharpoons M_3$  and  $M_3 \rightleftharpoons R$  differ from each other by their optical properties, such as birefringence and the orientation of axes, and  $T_3 \rightleftharpoons M_1$ ,  $M_2 \rightleftharpoons M_3$  and  $M_3 \rightleftharpoons R$  differ by twinning. The transition  $M_1 \rightleftharpoons M_2$ , which cannot be determined by heating optical microscopy has been identified by the X-ray spectral analysis ( $\beta = 90^\circ$  for  $M_2$  and  $\beta < 90^\circ$  for  $M_1$ ).

The modification  $M_3$  has also been identified in a solid solution of  $C_3S + 0.5\%$  ZnO in the temperature range from 1020 to 1090°C (27). It is stabilized in clinker in a solid solution of  $C_3S + MgO$  with a content of MgO being equal to or greater than 2 per cent (23). With a lower concentration of MgO there is observed a zonal structure in the alite crystal with  $M_1$  and  $M_3$ : a high concentration of  $Mg^{2+}$  in the peripheral portions stabilizes the lattice structure corresponding to  $M_3$ , and in the central portion, which is impoverished in  $Mg^{2+}$ , there is retained the  $M_1$  modification. Here the zonal boundary is parallel to the outer hexagonal boundaries of the crystal. The transition  $R \rightarrow M_3$  is accompanied, at a temperature of about 1000°C, by the formation of a cyclic twin structure along  $\{11\bar{2}0\}$  for monoclinic crystals of  $C_3S$ . The phase transition  $M_3 \rightarrow M_1$  is one of the processes of activation of the lattice.

If the content of MgO is low, the stability of monoclinic forms of  $C_3S$  depends on the rate of cooling of clinker (43). In the slowly cooled clinker,  $M_{1a}$  or  $M_{11a}$  is stabilized, and in the rapidly cooled clinker the  $M_{1a}$  modification is stabilized in the central portion of the alite crystal, whereas in the surface layer it is the  $M_{1b}$  modification which is stabilized ( $M_{1b}$  is the monoclinic modification of a solid solution containing  $Al_2O_3$  and MgO).

In monocystals (single crystals) of solid solutions of  $C_3S$  with  $MgO$ ,  $Al_2O_3$  and  $Fe_2O_3$  grown by the Nurse procedure there have been detected a block (39) and a domain structure (29) with the impurity ions being distributed along the domain boundaries. A solid solution of Al and Cl in  $C_3S$  has been synthesized in the form of single crystals, which has the composition  $C_{11}(Si, Al)_4O_{18}Cl$  or  $6Ca_3SiO_5 \cdot 4CaO \cdot 2AlOCl$  (30). The chromium spurrite has been identified:  $2Ca_2SiO_5 \cdot CaCrO_4$  (46). In the system  $CaO-SiO_2-CaCl_2$  there have been isolated (48)  $Ca_3SiO_4Cl_2$  in the form of needle-prismatic and monoclinic crystals and  $Ca_2SiO_5Cl$  in the form of transparent, almost fibrous crystals. Chlorocalite melts at 1040°C and chloro-orthosilicate melts at 920°C. In the system  $CaO-SiO_2-Al_2O_3-CaSO_4$  the mineral  $C_3S$  is decomposed by the action of  $Al_2O_3$  and  $SO_3$ , but in the presence of MgO the decomposition process is slowed down.

Heterovalent replacement of  $Ca^{2+}$  ions by  $Cr^{3+}$  and of  $Si^{4+}$  ions by  $Cr^{6+}$  in the system  $C_3S-Cr_2O_3$  bring about the stabilization of the  $T_{III}$  modification of  $C_3S$  over the entire concentration range up to 2.5 per cent of  $Cr_2O_3$  by mass. At 3 per cent of  $Cr_2O_3$  the  $M_1$  modification is stabilized. The volume of the unit cell attains a maximum value for a solid solution of  $C_3S$  with 1.75 per cent of  $Cr_2O_3$ . In the binary systems  $C_3S-TiO_2$ ,  $C_3S-Mn_2O_3$  and  $C_3S-SO_3$  there are formed solid solutions of the substitution type at concentrations of the added impurity reaching 3 per cent by mass. Upon replacement of  $Ca^{2+}$  ions by  $Mn^{3+}$ , of  $Si^{4+}$  by  $Mn^{3+}$ , and of  $Si^{4+}$  by  $Ti^{4+}$  and of the complex ion  $SiO_4^{4-}$  by  $SO_4^{2-}$  there takes place the stabilization of the  $T_{II}$  modification of  $C_3S$ . The presence, in the composition of solid solutions, of complexes containing (0.5%  $TiO_2 + 0.5\%$   $Mn_2O_3 + 0.5\%$   $SO_3$ ) and (2.0%  $TiO_2 + 1.0\%$   $Mn_2O_3$ ) leads to the stabilization of the  $M_1$  modification of  $C_3S$ . When the contents of oxides in ternary complexes is increased and also with titanium-sulphur, manganese-sulphur combinations there is formed a triclinic modification of  $C_3S$ .

Calcium orthosilicate at an  $Mn_2O_3$  content of more than 1% by mass in a solid solution is stabilized in the  $\beta$ - and  $\alpha$ -forms; as the content of  $Mn_2O_3$  increases up to 7 per cent the fraction of the  $\alpha$ -form of  $C_3S$  increases up to 60 per cent. This enhances the degree of disorientation of fragments of the block-mosaic structure of belite crystals (44). Sulphosilicate

<sup>\*</sup>In some works (27,43) the polymorphic forms of  $C_3S$  are designated as follows:  $T_I$ ,  $T_{II}$ ,  $T_{III}$ ,  $M_{1a}$ ,  $M_{11a}$ ,  $M_{1b}$ ,  $R$ .

$2(2\text{CaO} \cdot \text{SiO}_2) \cdot \text{CaSO}_4(\text{C}_6\text{S}_2\text{Si})$  formed at low temperatures is decomposed at  $1298^\circ\text{C}$  into  $\alpha\text{-C}_2\text{S}$  and  $\alpha\text{-CaSO}_4$ . In the presence of the complex  $\text{BaSO}_4 \cdot \text{Mn}_2\text{O}_3$  there is formed  $2(\text{BaO} \cdot \text{CaO}) \cdot \text{SiO}_2$  (45).

A study of the symmetry and coordination of the structural units of  $\text{C}_3\text{A}$  and  $\text{C}_{12}\text{A}_7$  has shown that the  $\text{Al}^{3+}$  ion entering into the composition of these minerals gives rise to tetrahedral complexes which perform the function of anions (31). Belov and Boikova (25) assume the occurrence of a "feldspar" balanced substitution  $\text{Ca}^{2+}\text{Al}^{3+} \rightleftharpoons \text{Na}^+\text{Si}^{4+}$  during the formation of solid solutions in  $\text{C}_3\text{A}$  and calcium aluminoferrites. In this substitution the maximum amount of  $\text{Na}_2\text{O}$  in  $\text{C}_3\text{A}$  will be lower than during the formation of a saturated solid solution of  $\text{NC}_3\text{A}_3$ .

There have been synthesized the following halogen-containing compounds:  $\text{C}_{11}\text{A}_7\text{CaF}_2$  ( $T_{\text{melt}} = 1550^\circ\text{C}$ ),  $\text{C}_{11}\text{A}_7\text{CaCl}_2$  ( $T_{\text{melt}} \approx 1520^\circ\text{C}$ ),  $\text{C}_{11}\text{A}_7\text{CaBr}_2$  ( $T_{\text{melt}} \approx 1420^\circ\text{C}$ ),  $\text{C}_{11}\text{A}_7\text{CaI}_2$  ( $T_{\text{melt}} = 1410^\circ\text{C}$ ),  $3(\text{CA}) \cdot \text{CaF}_2$  ( $T_{\text{melt}} = 1505^\circ\text{C}$ ),  $3(\text{CA}) \cdot \text{CaCl}_2$  ( $T_{\text{melt}} = 1540^\circ\text{C}$ ),  $3(\text{CA}) \cdot \text{CaBr}_2$  ( $T_{\text{melt}} = 1580^\circ\text{C}$ ) and solid solutions of the type  $\text{C}_{11}\text{A}_7\text{-xFe}_x \cdot \text{CaF}_2$  ( $0 \leq x \leq 0.7$ ). The stability of the minerals decreases in the following sequence:  $\text{F} \rightarrow \text{Cl} \rightarrow \text{Br} \rightarrow \text{I}$ . Minerals that contain Br and I are readily decomposed in air with the evolution of bromine and iodine vapours. Like the compound  $3(\text{CA}) \cdot \text{CaSO}_4$ , the mineral  $3(\text{CA}) \cdot \text{CaF}_2$  is formed at low temperatures ( $1100\text{--}1150^\circ\text{C}$ ) (47). In order to prevent the volatilization of the halogens during the firing process, to raw mix there are added salts (say,  $\text{NaCl-AlCl}_3$ ,  $\text{NaF-MgF}_2$ ), which form thermally stable compounds. A solid solution of  $3(\text{Ca}_{1-x}\text{Ba}_x\text{A}) \cdot \text{CaSO}_4$  has been produced (50). The analysis of the Mössbauer spectra of a complete series of solid solutions of calcium aluminoferrites (32) has shown that the  $\text{Fe}^{3+}$  ions are uniformly distributed in tetrahedral and octahedral cavities of the crystal lattice of calcium aluminoferrites. The same sites are occupied by the  $\text{Al}^{3+}$  ions which replace the  $\text{Fe}^{3+}$  ions. The incorporation of the  $\text{Fe}^{3+}$  and  $\text{Mg}^{2+}$  ions in place of  $\text{Al}^{3+}$  and  $\text{Fe}^{3+}$  into the crystal lattice of calcium aluminoferrites causes the appearance of ionic vacancies in place of  $\text{Al}^{3+}$  (33). The incorporation of  $\text{Cr}^{3+}$  and  $\text{Cr}^{2+}$  ions alters the composition of solid solutions from  $\text{C}_6\text{A}_2\text{F}$  to  $\text{C}_4\text{AF}$ ; the iron and aluminium have predominantly coordination number of 4 in  $\text{C}_4\text{AF}$  and a coordination number of 6 in  $\text{C}_6\text{A}_2\text{F}$ . Upon replacement of  $\text{Fe}^{3+}$  with  $\text{Mn}^{2+}$  there are formed solid solutions of the composition  $\text{C}_2\text{A}_p(\text{F}, \text{Mn})_{1-p}$ ; the limiting composition is  $\text{pC}_4\text{AF}_{0.3}\text{Mn}_{0.7}$  (34, 35). Crystals of  $\text{C}_6\text{A}_x\text{F}_y$  have been found to grow in a helical manner (44). In the presence of  $\text{P}_2\text{O}_5$ ,

calcium aluminoferrite becomes impoverished in iron because of the replacement  $\text{FeO}^{2-} \rightleftharpoons \text{PO}_4^{3-}$ , and in the presence of  $\text{F}^-$ , on the contrary, the content of iron increases in it. The  $\text{Ba}^{2+}$  ions favour the separation of  $\text{Fe}_2\text{O}_3$ -enriched calcium aluminoferrites from the melt, and the acidic components  $\text{ZnO}$ ,  $\text{CuO}$ ,  $\text{P}_2\text{O}_5$  favour the separation of  $\text{Fe}_2\text{O}_3$ -impoverished calcium aluminoferrites (36). The  $\text{Na}^+$  ions contribute to the formation of a high-iron aluminoferrite phase and  $\text{C}_3\text{A}$ . The abovementioned changes in the composition of the aluminoferrite phase conform with the acid-base equilibrium (1) of the melt.

**Crystal Defects.** Real crystals of minerals, the more so their solid solutions, have imperfections or defects. The stresses that arise in crystals upon rapid cooling may be responsible for the formation of supersaturated metastable structures and for the occurrence of the processes of replacement of ions, say, of  $\text{Ca}^{2+}$  by  $\text{Mg}^{2+}$  (49). Prolonged annealing reduces the number of defects and stresses in crystals. The mineral  $\text{C}_3\text{S}$  cooled from  $1550^\circ\text{C}$  to  $25^\circ\text{C}$  was found to display a prominent thermoluminescence peak and high reactivity. The magnitude of the peak decreased upon slow cooling and when the mineral was allowed to stand in air for a prolonged period of time (58). This increased the degree of binding of electrons in traps.

Several types of electron-hole defects have been detected in the formation of solid solutions of clinker minerals;

1. Electron-hole paramagnetic centres on cationic and anionic vacancies, which have been detected from the spectra of gamma-irradiated solid solutions of calcium silicate (57).
2. Free charge carriers-electrons (n-type) and holes (p-type).
3. Thermoluminescence centres, which have been detected for  $\text{C}_3\text{S}$  after heat treatment and ultraviolet irradiation (58).

The changes of the concentration of point defects of the first two types are interconnected and depend not only on the specific features of the crystal lattice structure and the type and chemical nature of the impurity added but also on the arrangement of impurity ions in the crystal lattice of minerals.

The magnitude of electrical conductivity of solid solutions of  $\text{C}_3\text{S}$ ,  $\text{C}_2\text{S}$ , and  $\text{C}_3\text{A}$  ranges from  $10^{-7}$  to  $10^{-10}$  ( $\text{S}^{-1} \cdot \text{m}^{-1}$ ), which is characteristic of dielectrics. Even when its value is increased by addition of impurities, the materials under study cannot be assigned to the class of typical semiconductors. On the basis of measurements of the parameters of the Hall effect in alternating electric and magne-

tic fields carried out by the four-probe method it has been found, however, that solid solutions of clinker minerals exhibit the properties of semiconductors; the properties of semiconductors; in the case of impurity-free minerals the p-type conduction can be changed to the opposite type by introducing certain additives, say  $\text{Fe}_2\text{O}_3$ ,  $\text{NiO}$ , or  $\text{CaO}$ . The concentration of holes in pure  $\text{C}_3\text{S}$  and  $\text{C}_3\text{A}$  is  $2.6 \times 10^{15}$  and  $2.1 \times 10^{18} \text{ 1/m}^3$ , respectively, with the same mobility of charge-carriers ( $1.2 \times 10^{-6} \text{ m}^2/\text{V}\cdot\text{s}$ ), which is probably caused by departures from stoichiometry, the presence of cationic and anionic vacancies and by the unsaturation of valence bonds. The introduction of impurities leads not only to an increase in the concentration of charge carriers but also to a change in their mobility, which is evidently associated with the spreading of charges over structural defects, such as dislocations, twins, grain boundaries, etc. It has been established that the mobility of charge carriers ranges from  $10^{-5}$  to  $10^{-8} \text{ m}^2/\text{V}\cdot\text{s}$ . The concentration of charge carriers and their mobility for the  $\beta$ - and  $\alpha'$ -forms of  $\text{C}_2\text{S}$  depend on the nature and content of modifying additives. It should be noted that the concentration of charge carriers is practically always higher in samples of  $\alpha'$ - $\text{C}_2\text{S}$  since for the high-temperature forms to be stabilized, there is required a larger amount of the impurity, which causes additional structural distortions. This regularity is also characteristic of solid solutions of  $\text{C}_3\text{S}$ . The concentration of charge carriers, however, decreases in the following sequence of polymorphic forms: rhombohedral  $\rightarrow$  triclinic  $\rightarrow$  monoclinic.

Two types of conduction have been established for the formation of solid solutions of  $\text{C}_3\text{S}$ :

1. Electronic Conduction. In the systems  $\text{C}_3\text{S}-\text{Fe}_2\text{O}_3$ ,  $\text{C}_3\text{S}-\text{CoO}$ , and  $\text{C}_3\text{S}-\text{NiO}$  upon iso- and heterovalent substitutions, the concentration of charge carriers increases with increasing concentration of additives (up to 1 per cent by weight) (Fig. 15).

Fig. 15. The concentration of charge-carriers ( $N$ ) and their mobility ( $\mu$ ) versus the content of the elements dissolved in  $\text{C}_3\text{S}$

The electronic type of conduction in solid solutions with Fe is associated with the redistribution of the electron density of valence bonds with the  $\text{Si}^{4+}$  ions being predominantly replaced by  $\text{Fe}^{3+}$  and the

structural cavities being occupied by  $\text{Fe}^{3+}$  ions. In other cases, perhaps, not only the replacement of  $\text{Si}^{4+}$  and  $\text{Ca}^{2+}$  ions is a decisive factor, but the type of conduction also greatly depends on the specific features of the electronic shell structure, the departures from stoichiometry, and the changes in the concentration of other types of defects, which are difficult to take into account. Sing has determined (59) the electronic conduction in the system  $\text{C}_3\text{S}-\text{NiO}$  but the concentration of charge carriers and their mobility differ significantly from the data obtained by the author of the present paper.

2. Hole Conduction. The majority of solid solutions of  $\text{C}_3\text{S}$  of varying composition the display p-type conduction. Upon iso- and heterovalent replacements of  $\text{Ca}^{2+}$  and  $\text{Si}^{4+}$  ions by the ions  $\text{Zn}^{2+}$ ,  $\text{Ba}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{Mn}^{3+}$ ,  $\text{Cd}^{2+}$ ,  $\text{Al}^{3+}$ ,  $\text{Cr}^{3+}$ ,  $\text{Cr}^{6+}$ , and  $\text{Cu}^{2+}$ , and also upon incorporation of  $\text{Na}^+$ ,  $\text{Ba}^{2+}$ , etc., into the crystal lattice of the matrix the concentration of charge carriers increases as a result of a change in the density of valence bonds, different degrees of substitution in the non-equilibrium crystal lattice, the presence of defects, etc. The concentrations of free charge carriers is influenced especially strongly by the replacement of  $\text{Ca}^{2+}$  by  $\text{Mg}^{2+}$ , the incorporation of  $\text{Na}^+$  into the structure of  $\text{C}_3\text{S}$  and the addition of complex additives of the type ( $0.3\%$  by mass of  $\text{SO}_3 + 0.7\%$  by mass of  $\text{Na}_2\text{O}$ ) which exert a simultaneous effect on the anionic and cationic parts of the structure. The largest concentration of charge carriers has been found in solid solutions of  $\text{C}_3\text{S} + 0.7\% \text{Na}_2\text{O}$  and  $\text{C}_3\text{S} + 1\% \text{MgO}$  (from  $1.8 \times 10^{19}$  to  $3.2 \times 10^{19} \text{ l/m}^3$ , respectively). The changes in the galvanomagnetic characteristics that take place in the solid solution systems  $\text{C}_3\text{S}-\text{Mn}_2\text{O}_3$  and  $\text{C}_3\text{S}-\text{Cr}_2\text{O}_3$  are presented in Fig. 15 as examples of what results from heterovalent substitutions.

The density of dislocations in alite crystals ranges from  $5 \times 10^{12}$  to  $5 \times 10^{13} \text{ m}^{-2}$  (60), and the area occupied by dislocations on the surface of crystals of minerals is as follows, as evidenced by microphotographs: ( $1/3-1/2$ ) for  $\text{C}_3\text{S}$  and ( $1/6-1/3$ ) for  $\text{C}_2\text{S}$  (61). The Burgers vector of screw dislocations in alite should be expected to have a value of  $0.05$  to  $0.1 \mu\text{m}$  since the nucleus of alite upon its crystallization from the melt is of the same order of magnitude (1). As the concentration of dislocations increases, so does the number of surface-active centres on which the hydration starts. The high rate of hydration of  $\alpha'-\text{C}_2\text{S}$  as compared with  $\beta-\text{C}_2\text{S}$  has been accounted for (62) by the difference in the structure of the crystals and also by the presence of linear dislocations in  $\alpha'-\text{C}_2\text{S}$ . According to Boikova (63), the density of etched pits on the surface of crystals of  $\alpha'$ - and  $\alpha$ - $\text{C}_2\text{S}$  is, however, lower by a factor of 2 and 3.5, respectively,

than in crystals of  $\beta-\text{C}_2\text{S}$ . No direct relationship between the amount of impurities in a crystal and the density of etched pits on its surface has been established by Boikova.

Point defects, thermoluminescent centres, and electron-hole defects contribute to the adsorption of charged particles from aqueous solutions on crystal surfaces.

## **SUB-THEME I - 4**

**Influence of grinding  
and storage conditions  
of clinker**

**J.P. MÉRIC  
Général Manager  
Centre d'Études et de Recherches  
de l'Industrie des Liants Hydrauliques  
Paris, FRANCE**

The grinding of clinker and secondary components is the ultimate stage in cement manufacture. It is the grinding which, by freeing the surfaces necessary for clinker hydration, give the final product the reactivity to water leading to high strengths. Research on grinding was focused on the manufacture of high strength cements for many years.

Since this objective has now been reached, recent research on grinding has concentrated more on the regularity of cement manufacture and towards a reduction in grinding energy consumption. In these two fields, results have been obtained only through reflexion on the physics of comminution applied to cement and after a thorough study of the properties of ground material. These three topics : physics of comminution applied to cement, properties of the ground material and energy utilization are developed in the following paragraphs.

#### 1.- PHYSICAL PRINCIPLES OF COMMINUTION

The physics of comminution is a complex scientific field devoted to the study of modifications in the structure of a material subjected to mechanical stresses.

The most important parameters concerning these stresses are their distribution and the rate at which they are applied, taking into account the mechanical properties specific to the material. Structural modifications include the setting up of free surfaces and defects in the molecular organization within the material.

The surfaces defined by comminution have very different characteristics from those set up by sublimation, diffusion or condensation. The physics of comminution aims at studying these particular features.

The defects in molecular organization caused by comminution also show specific characteristics very different from those induced by temperature variations, chemical actions, ionic bombing. Study of these features constitutes the second aspect of the physics of comminution.

##### 1.1.- Fracture mechanics

Fracture mechanics was introduced by Griffith (1) in 1920. His work underlined the importance of structural defects in the understanding of fracture phenomena, and promoted understanding of why former theoretical calculations, which failed to take structural faults into consideration, revealed strengths 100 to 1000 times higher than those observed in testing of the strongest natural materials. These strengths are only some tens of MPa under tensile stress, whereas calculation founded on chemical energy gives results up to 1000 MPa. Moreover it is only recently that flawless materials were manufactured, revealing the

tensile strengths forecast by these calculations. Such materials are essentially fibres produced in such a way that microcracks do not occur.

With fracture mechanics it is possible to determine the mechanical stress conditions in which the microcracks can develop and give rise to fracture of the material. It is possible in this way to calculate the strength of materials with structural flaws, however provided that two determining microcrack propagation parameters are known : the mean dimension of microcracks and the specific fracture energy  $\gamma_F$ .

The specific fracture energy is the energy which has to be used per freed unit surface to propagate the crack. This energy is much higher than the surface energy, that is to say the energy needed to break the molecular bonds present on the surface. Indeed, surface energy is around 0.05 to 0.5 Joule per m<sup>2</sup>, whilst fracture energy is around 5 Joules per m<sup>2</sup> for brittle materials, 10 Joules per m<sup>2</sup> for plastics and 500 Joules per m<sup>2</sup> for metals. The differences between surface energy and specific fracture energy show that more energy must be used to develop a crack by opening the two edges than is needed to break the molecular surface bonds by an ideal means. This difference finds its explanation in the setting up of high stress concentration near the edge of the crack ; this concentration is due to the application of forces necessary to the propagation of the crack and brings about plastic deformations in the material, themselves sources of irreversible energy losses. These losses are all the higher the more plastic the mechanical behaviour of the material as is shown in the preceding values.

Crack propagation energy is provided by the field of elastic stresses applied to the material. As propagation develops, this stress field decreases in intensity, that is to say in energy, part of energy being transformed into specific fracture energy. This transfer of mechanical stress field towards fracture energy corresponds to a deterioration of mechanical energy into heat. The orders of magnitude involved are as follows.

Q the section, L the length. Transverse fracture requires  $2Q\gamma_F$  which must come from this stress field. Consequently it is necessary that

$$2Q\gamma_F < \frac{\sigma^2}{2E} QL$$

$$\text{or again } L > 4 \frac{E\gamma_F}{\sigma^2}$$

that is to say that the propagation of a crack starting from an elastic stress field is possibly only above a certain dimension of the volume in which this stress is exerted. As an example for glass the preceding

formula gives an order of magnitude to the micron and for a plastic material to the millimeter.

These examples illustrate a point which will be reconsidered later ; the difficulty of fine grinding and the importance of a precise determination of  $\gamma_F$  to fix the grinding limits. This parameter can be determined with mechanical tests by applying to the material an appropriately chosen stress field where all the energy transforms into fracture energy. Huet (2) has studied these techniques and applied them to a large number of materials to determine their  $\gamma_F$  coefficient. The values obtained are given in detail in table I.

Material	$\gamma_F$ Joules/m <sup>2</sup>
Fired clays	5,5 to 40
Plate glass	3,5
Ceramics	20 to 60
Natural stones	3,7 to 59
Dried clays	7,3 to 25,3
Al <sub>2</sub> O <sub>3</sub>	20 to 50
Refractory bricks	30 to 50
NaCl + fibres	200

TABLE I

Another particularly important parameter in the study of comminution is the mean size of structural flaws which are responsible for cracking onset. Weber (3) shows that stressing a cylinder by simple compression leads to unstable cracking, that is to say that an excess of elastic energy must be provided to obtain crack propagation, this then occurs in an uncontrolled way and the excess energy is transformed into kinetic energy of fragments. Weber indicates that the effectiveness of the operation, that is to say the proportion of elastic energy transformed into fracture energy, is proportional to  $a_0$ , mean dimension of the onsets of fracture in a material.

The overall fracture behaviour of a material can consequently be described by two intrinsic parameters  $\gamma_F$  and  $a_0$ .

Table II provides as example the values of these parameters for two common materials.

Material	$\gamma_F$ Joules/m <sup>2</sup>	$a_0$ microns
Fired clays	5,5 to 40	100 to 1500
Glass	3,5	20

TABLE II

For clinkers very little work has been undertaken up to present to determine  $\gamma_F$  and  $a_0$  according to the composition of the material and taking into account its thermal treatment. It would be appropriate to undertake this research with the aim of correlating the manufacturing parameters with the specific fracture energy along the lines of work carried out on alumina by Simpson (12). It would then be possible to explain more thoroughly the differences in grindability observed on industrial clinkers and focus attention on producing more grindable materials.

#### 1.2.- Grinding methods

Crack propagation occurs through stressing of material. This stressing can be brought about in three ways (figures 1, 2 and 3).

Fig. 1 - By slow compression between two jaws

Fig. 2 - By impact compression of a falling body

Fig. 3 - By projection against an anvil

These three means of stressing material correspond to three grinding modes which have

defined three technological approaches :

- . roller mills,
- . rod or ball mills,
- . impact or impeller mills.

Rumpf (4) and his school have analysed these grinding modes, giving a very exact description of the stress field in these three cases. Theoretical investigations and testing carried out on glass beads have revealed only few differences in the stress field, even when the kinetic effects linked to the rapidity of stressing were expected as in grinding by projection. This research was carried out by crushing the material grain by grain and measuring the surfaces freed as well as the grinding energy used for this. The grinding energy is the deformation or kinetic energy supplied to the grain.

In this way, Rumpf (5) checks on grain by grain testing the proportionality of the freed surface to the energy spent, that is to say that the Rittinger law, known since the nineteenth century and currently used in the cement industry is still applicable, with a certain approximation to the individual grain scale.

The Rittinger law stipulates more generally that, for a given grinding process, the grinding energy is proportional to the surfaces set up or, in other words, that the output of a grinding process is constant and consequently independent of the fineness of the material. This law proves correct for common finenesses, but it is found that for high finenesses the grinding efficiency falls. This was been attributed to clustering but it happens even when this is prevented. The explanation of this fall in output is undoubtedly dual :

- . on one hand, the areas of plastic deformation become extensive compared with the sizes of the grains and the grinding by transfer of elastic energy into surface energy is no longer possible, as was shown previously ;
- . on the other hand, successive grinding exhausts the microcracks in the material and when a certain size is reached, the useful microcracks have all been freed. The material is then a monocrystal medium difficult to grind.

The two phenomena limit the law of Rittinger towards the high finenesses. Rumpf (5) by undertaking a dimension analysis has given this phenomenon a new law which takes into account the size of grains in the application of the Rittinger law.

Haese (6) reports on systematic grinding tests on clinker grain by grain. In the light of tests carried out with different modes of grinding the author determines the parameters

which indicate the aptitude of a clinker to comminution. He especially studies in detail an essential magnitude : the probability of fracture of a grain of given size according to the load applied on it. He also examines the aspect of grading distributions of ground material and gives a formulation deduced from the testing.

### 1.3.- Surfaces freed by grinding

The surfaces freed by grinding are generally measured by two methods : the Blaine method which gives an envelope surface and the BET surface which gives the total surface taking into account all the dislocations and surface fractures. Comparison of the two methods gives useful informations on the structure of surface set up by grinding.

Schwenk (72) has found (5) that with vacuum grinding, it is possible to obtain very active surfaces. Grinding was undertaken at  $10^{-5}$  Torr ; the surfaces freed were measured before and after being in contact with the air. This revealed that the action of the air and of its humidity especially lead to a decrease of these surfaces by closing of cracks. The reduction factor was 1,6 in the case of quartz and about 2,6 for glass, therefore the surface reactions during the very grinding are of considerable importance.

This importance has led research scientists to study the influence of the surroundings on grinding performance. Schönert (7) has shown that grinding with liquid water or steam leads to a decrease in specific fracture energy. The decrease only occurs however with low rates of crack propagation :  $10^{-3}$  m/s. When the rate of propagation is higher, the specific fracture energy is identical in vacuum or in water vapour. This gives an evaluation of the kinetics for the fixing of water molecules in the heart of the crack. The very active surfaces set up by grinding can weld together again, this is the phenomenon of clustering which can be avoided by covering the surfaces with a surface active product. This phenomenon will be described later in the case of cement. The structure of the surface set up by grinding is amorphous (8). This statement is explained by the plastic deformations which occur with the crack propagation and also by the very high temperatures which prevail in the crack neighbourhood. Weichert and Schönert (9) have measured these temperatures by basing their calculations on the light emission of grains during grinding and they have found in certain cases temperatures of several thousand degrees.

Other surface phenomena have also been studied by various authors. These phenomena are surface loads and triboluminescence.

Surfaces obtained by grinding have numerous properties ; research scientists have exa-

mined the variations in these properties according to the grinding mode. Schönert (10) has considered that all the grinding modes lead to similar fracture phenomena, therefore to identical surface properties. This conclusion is however challenged by fine grinding where marked differences in surface aspect (11) have been revealed by scanning electron microscopy between impact compression grinding and projection grinding.

#### 1.4.- Structural flaws induced by grinding

It is commonly accepted that fracture onset is necessary for material fragmentation and none the less disputable that grinding can induce extensive dislocations and disorders in the crystalline networks.

Numerous investigations have been undertaken on this subject. Sciora (13) examines the effect of grinding on hydrates and shows that the mechanical forces bring about modifications in the network identifiable by the dehydration temperature variations. Certain network modifications can also be made easy to identify by a widening of diffraction X rays. Tekiz (14) studies the zinc oxide and zinc sulphur network modifications. The widening of rays makes it possible to obtain an order of magnitude of dislocations which occur during the grinding and which can be later suppressed by a thermal treatment. Legrand and Nicolas (15) have applied these techniques to clays and have also found extensive transformations in the crystalline network. Opoczky (16) points out similar phenomena for  $\beta\text{C}_2\text{S}$  to which grinding confers a certain amorphization and therefore a certain activation which must be taken into account in the grinding work index. Using calorimetric tests (16) it has been possible to indicate an order of magnitude of this energy.

The importance of a thorough study of the fundamentals of comminution for the chemistry of cement is also clearly obvious since cement hydration is first of all a surface reaction; it therefore varies with the quantity of surface freed and the physical nature of these surfaces (73). It is also a transformation reaction of the anhydrous phase transformation whose kinetics is linked to structure. However grinding can modify this structure towards greater activity (16) and consequently, towards an improvement of transformation kinetics.

## 2.- THE ROLE OF COMMINUTION IN THE CHEMISTRY OF CEMENT

### 2.1.- Particle size distribution of ground clinker

The aim of grinding is to free the surfaces necessary for the hydration reaction. Measuring these surfaces according to the Blaine method has for a long time constituted the most used parameter to identify the ground state of a cement. However it became

obvious that the particle size distribution was also a capital indication towards knowledge of cement properties. The grading curves after comminution do not comply with any theoretical formulae which have been drawn up in the past. So it is necessary to manage with approaching these actual distributions by approximate formulae.

The most used functions are as follows ( $D(a)$  is the proportion of undersize at diameter  $a$ ):

Function of Gaudin and Schuhmann :

$$D(a) = \left(\frac{a}{k}\right)^m$$

Log-normal function :

$$D(a) = \Phi \left[ \ln\left(\frac{a}{a_0}\right) \right]^p$$

where  $\Phi$  represents the integral of the Gauss function.

Rosin-Rammler function :

$$D(a) = 1 - \exp - \left(\frac{a}{a_0}\right)^n$$

This later function is widely used. The mean value of the distribution is :

$$A = a_0 \frac{1}{\Gamma(n)}$$

The standard deviation is :

$$\sigma = a_0 \sqrt{\frac{2}{\Gamma(n)} - \left(\frac{1}{\Gamma(n)}\right)^2}$$

The maximum frequency of the grading distribution corresponds to the diameter :

$$a_m = a_0 \left(\frac{n-1}{n}\right)^{\frac{1}{n}}$$

When this function is represented in logarithmic coordinates in

$$\ln a \text{ and } \ln \ln \frac{1}{1-D}$$

a straight line is obtained

$$Y = n(x - x_0) \quad \text{where } x_0 = \ln a_0$$

$n$  is the slope of the straight line and notifies the smaller range grading distribution, whilst  $x_0$  represents the degree of fineness.

Theoretically the grading distribution should make it possible to calculate the specific surface thanks to the following formula :

$$S = \frac{6}{\rho} \int_0^1 \frac{dD}{a} \quad \text{where } \rho \text{ is the density}$$

In the case of Rosin-Rammler distribution we find :

$$S = \frac{6}{a_0 \rho} \Gamma \frac{n-1}{n}$$

This function is not defined for  $n \leq 1$  and for  $n > 1$  it gives values which are very different from surfaces determined by the Blaine method. The two other formulae proposed bring us no closer to obtaining correlation between theory and experience. This is due to the ever approximate nature of the functions proposed, this nature above all obvious for the lower extremity of the grading curve, that is to say for the very low values of  $a$ . These are the frequencies corresponding to these values which have the highest weight in calculating  $S$ . It is not surprising therefore to find the disagreement mentioned previously. In spite of this, the Rosin-Rammler formula is very useful since, thanks to two parameters  $a_0$  and  $n$ , it is possible to identify a grading distribution with enough accuracy for routine grinding.

Closer study must be made on complete grading determinations carried out by sieving with the elutriator or the Andreasen pipette. With a more recent method [17] it is possible to carry out a complete grading determination in a few minutes by using laser beam diffraction. Thanks to this method, grading determination has become routine in laboratories.

The grading curve is used to calculate the specific surface with the formula :

$$S = \frac{6}{\rho} \sum \frac{\Delta D}{a}$$

where  $\rho$  is the density and  $\Delta D$  the proportion of grains in the class characterized by the diameter  $a$ . This gives a value of the specific surface which is generally close to that determined by the Blaine method.

It is then possible to compare experimentally as Slegten did [18] this new determination of the specific surface with that carried out according to Blaine and to look for the determination which gives the closest definition of the cement characteristics. In spite of the interest of this research, recent work emphasizes more the grading distribution than the surface determinations to evaluate the cement properties. Indeed it is obvious that the specific surface depends essentially on the finest grains ; however these grains hydrate very quickly and if they play an important part, this remains limited to the initial properties of cements and cannot be extended entirely to their future development.

## 2.2.- Relation between grading distribution, rate of hydration and strength

According to zur Strassen [19] hydration is a diffusion reaction which propagates on a uniform front of the clinker grain surface towards the core. Measurements carried out on portland cement and on pure  $C_3S$  give the

following values for depths of penetration of the reaction

1 day	0,5 $\mu m$
3 days	2 $\mu m$
7 days	3 - 4 $\mu m$
28 days	6 - 7 $\mu m$

For  $C_2S$  zur Strassen admits the following values :

30 days	1 $\mu m$
60 days	2 $\mu m$
80 days	3 $\mu m$

This shows that in a cement rich in alite the 30 micron grains are hydrated at 87,5% at 28 days and that the grains smaller than 3 microns undergo complete hydration shortly after mixing.

This points to two conclusions :

- first, that the 0-3 micron fraction grains (and these contribute to giving the cement a high specific surface) are indispensable for initial strength but make no contribution to final strengths.
- secondly, that the 0-3 micron fraction grains are the only ones to contribute meaningfully to final strength. Grains over 30 microns only partially hydrate ; consequently their contribution to strength is very low.

Beke [20] has checked these conclusions on blends of different classes of cements by replacing missing classes by an inert powder. From this work, he was able to draw useful conclusions on mill adjustment.

Ritzmann [21] checks the relation between the time-dependent development of strength and the grading curve by blending about thirty cements from ten distinct grading classes. This relation can be expressed as a satisfactory theoretical formulation with the hypothesis which zur Strassen used that the hydration reaction is a diffusion reaction. Using a grading curve it is then possible to determine the quantity of hydrated cement as a function of time. Ritzmann shows that quantity determined by calculation is linked to strength by a linear law, however provided that the water/cement ratio is constant. If the cement is mixed at normal consistency, the excess water brings about falls in strength for a given rate of hydration. Nevertheless such decreases in strength can be forecast by calculation taking this excess water into account.

Locher, Sprung and Korf [22] come to the conclusion that with equal specific surface it is the cements with a narrow grading spectrum which offer the best final strength, whilst initial strengths are equivalent. These findings can again be explained by the concept of depth of hydration. The laws drawn from these tests are not however gene-

ral, they are based on the chemistry of cements : so with an identical curve, a cement rich in alkalis will offer an initial strength higher than a cement without alkalis whereas its final strength will be lower. The obvious conclusion is that the increase in specific surface with the aim of improving initial strengths will be more marked for a cement with low alkali content.

Kelenburg (33) takes three distinct clinkers to study the relationships between the grading curve, the hydrated fraction of the clinker and the normal mechanical strengths. The quantity of clinker hydrated is determined by measuring the non-evaporable water. Consequently this quantity is no longer dealt with as a calculation intermediary, but as a physical factor whose correlation with strengths has been checked. This work underlines how the zur Strassen diffusion model explains the correlations between grading curve and quantity of hydrates. The relation between quantity of hydrates and strengths may be linear for a given cement but nevertheless varies a great deal with the composition and structure of hydrated cement. It is shown that with a given composition, the whole kinetic formation process of strengths could be described by two points on the grading curve 10 and 50 microns for example ; but this information is to be added to the specific surface.

The great importance of the structure of hardened pastes in explaining the relationships between rates of hydration and strengths is underlined by Syrkin and co-workers (23) as well as by Butt, Kolbasow and Berlin (24) who have linked fineness to hardened paste porosity. It has been found that the increase in cement fineness beyond a certain threshold would not lead to a marked transformation of cement structure and that the grains more than 10 microns in diameter offer favorable conditions for porosity of the order of the micrometer.

The concept of depth of hydration penetration makes it possible to explain the influence of grading distribution on the quantity of cement hydrated. Explaining the relation between the quantity of hydrated cement and strengths is found more difficult. However we can consider certain facts that for a cement of given composition and for a fixed water/cement ratio, the rate of hydration is an excellent indication of strengths. It still remains that the structure of hydrates vary with their growth kinetics and that the knowledge of this structure could complete the determination of the hydration rate for improved forecasting of strengths according to grain size. Research on porosity already quoted can open an approach to bring light on this question.

### 2.3.- Clustering and the role of grinding aids

When grinding in a ball mill is pursued to very high specific surfaces, it is found that beyond a certain limit the specific surface no longer increases in spite of the energy input.

This phenomenon has been interpreted by the recaking of grains whose active surfaces bond together to form large size composite grains. Papadakis (25) has drawn up a formula showing the influence of the ball mill and ball sizes in the understanding of the phenomenon which seems linked to the grinding tool and its working. In extreme cases, continuing grinding will imply a decrease in specific surface (figure 4) and an unacceptable waste of energy.

Fig. 4 - Development of specific surface plotted against grinding energy in a ball mill

The phenomenon has been studied in detail by Beks (26) who has measured the development of grading curves in a ball mill plotted against grinding time and energy used. As the grinding progresses, three stages become obvious :

1. The coefficient of uniformity remains constant ; the straight lines represent the grading distribution moving parallel to themselves.
2. The coefficient of uniformity increases; the finest grains are monocrystals difficult to grind ; grinding continues only thanks to failure onsets in the largest grains. The specific surface tends to stagnate at a ceiling.
3. The coefficient of uniformity falls since the fine grains cake together to form larger grains. The specific surface tends to decrease.

Figure 5 shows this development plotted against energy supplied to the material.

Fig. 5 - Development of the coefficient of uniformity plotted against the number of impacts  $N$ , the diameter of the mill  $D$  and the mass of balls  $G$  according to Beke.

Clustering can be lessened by adding grinding aids. The products used are generally polar surface active which saturate the fresh surfaces set up by grinding. These surfaces consist of free links and electric charges which encourage the grains to come together. The additives composed of polar organic molecules bind with the oxygen ions of these surfaces by hydrogen links. This phenomenon is analysed by Iwabuchi (27) who also comes to the conclusion about a possible action on failure onsets, action which would have a positive effect on grinding efficiency. Von Seebach (28) has carried out grinding in different atmospheres without succeeding in revealing an influence of organic substances of these atmospheres on the grinding output. We must conclude that grinding aids act essentially on the caking and this point of view is properly confirmed (29)(30) by rheology studies on dry powders obtained with and without grinding aids.

Grinding aids of the glycol or ethanolamine type have considerable practical importance since they offer the possibility of pursuing grinding to its technological limits (fixed by sizes or the energy of milling bodies) or its physical limits (limit of plasticity of the material).

Grinding aids also influence the hydration reactions. The covering over of active surfaces by a monomolecular layer of organic material also affects the hydration kinetics and the morphology of hydrates. This influence has been studied on pozzolanas (31) by grinding the material to the same degree of fineness without and with grinding aids. The influence of the aid is then examined according to whether it is added to grinding or in the mixing water. Differences thus become obvious in the kinetics of hydration and in the morphology of hydrates which seem more pronounced when the aid is added during grinding. The mechanisms of this influence are as yet incompletely known; it is however probable (32) that the hydrogen links

set up by the organic molecules with the crystal surfaces orientate the crystalline growth as well as the dissolution of crystals.

It seems then that the role of grinding aids is complex. Their influence is obvious on several parameters:

- . the caking rate,
- . the Blaine fineness,
- . the grading distribution,
- . the reactivity of surfaces.

All these parameters influence the kinetics of hydration.

#### 2.4.- Grindability of clinker according to its chemical composition, thermal treatment and storage conditions

The grindability of different clinker phases has been extensively investigated. Beke and Opoczky (34) especially have ground separately synthetic preparations of  $C_3A$ ,  $C_4AF$ ,  $C_2S$  and  $C_3S$ . Grinding carried out in a ball mill has shown how the behaviour of the various cement phases is differentiated.  $C_3S$  was particularly grindable, showing only a slight tendency to caking, whilst  $BC_2S$  was more difficult to grind with more accentuated likelihood of caking in spite of grinding aids being added.  $BC_2S$  was ground a long time but it was impossible to exceed a 5000 Blaine surface. This surface moreover fluctuates during grinding, the phases of increasing surface being followed by caking phases during which the surface decreases. With pure  $C_3S$ , 10000 Blaine surfaces were obtained.  $C_4AF$  and  $C_2A$  show intermediate behaviour.  $C_4A$  is close to  $C_3S$  and  $C_4AF$  similar to  $BC_2S$ . X-ray diffraction studies reveal a distinct tendency to amorphization of all phases, except  $C_3S$  when grinding is pursued to an extreme limit. It is however noted that when grinding of the phases is simultaneous, this amorphization then also extends to  $C_3S$ , which proves an interaction between the phases during grinding in a ball mill. This interaction undeniably leads to less effective grinding of  $C_3S$  in the presence of the other phases.

Gouda (35) carries out investigations on four factory clinkers whose grindability improves the lower the liquid phase concentration. Consequently it is advisable to keep to a low liquid phase concentration and a  $C_2S$  content as high as possible to improve clinker grindability.

Deckers (36) also studies the influence of physical parameters of clinker on its grindability and especially the influence of its porosity. This parameter has a very marked influence for primary grinding below 2000  $cm^2/g$  Blaine.

The presence of free lime which indicates firing conditions and consequently the

structure of clinker, influences grindability to produce an increase in this property with higher free lime content, an increase obvious in the ranges of fine or primary grinding. The influence of cooling systems has been examined by Regourd (supplementary paper) working on industrial and synthetic clinker tempered in air and water. Regourd observes significant differences in the crack network and in grindability. Differences in the latter property which reach 10% can especially be explained by elastic energy stored in a grain put to thermal shock. Hasselman (37) has calculated this energy which corresponds to the gain in elastic energy which has been revealed by experimenting.

Storage conditions act on clinker structure and therefore on its grindability. Exposure has a negative influence on clinker grindability. Cussino and Pintor (38) have analysed the causes of this phenomenon. First it is observed that the specific surface variations no longer follow the grading spectra variations since the very fine particles caused by exposure show a very high specific surface which superposes that of the cement proper. Moreover during grinding the particles formed by exposure cake around clinker grains and absorb a high fraction of grinding energy. Exposure therefore reduces mill efficiency especially ball mills and causes overestimation of the specific surface still hydratable. So it is not surprising that grinding evaporated clinker in a ball mill leads to lower strengths if the fine particles are not extracted from the mill as grinding proceeds and if the fineness determination is not corrected from the specific surface of these same particles. Clinker deterioration through exposure can be avoided by immediate grinding as soon as it leaves the furnace. Schweindig (39) proposes grinding clinker as it leaves the cooler at 400°C and using the roller mill as an exchange unit capable of lowering the clinker temperature to 100°C whilst generating hot gases. Pospisil (40) has investigated the effectiveness of grinding at different temperatures. Using laboratory equipment he finds that grinding energy increases when clinker temperature rises from 20°C to 200°C. This increase is not surprising in so much as it expresses a decrease in the brittleness of the materials with the increase in temperature. The author also notes that clinker grindability decreases with storage time. This fall is attributed to the relaxation of internal stresses whose potential encouraged grinding; it can also be due to a slow reorganization of microstructures leading to microcrack consolidation. It seems therefore that clinker as it leaves the kiln retains a capacity of development which leads it towards a greater stability as grinding tests show. This stabilization is detrimental to grindability especially if it combines with deterioration through exposure to air.

## 2.5.- Chemical reactions in the ball mill and mineral releasing of clinker phases

The ball mill must be considered as a chemical reactor where complex phenomena occur liable to modify the behaviour of cements.

Up to now this paper has only mentioned clinker proper. In reality grinding clinker in a ball mill is generally carried out simultaneously with that of gypsum and with a certain proportion of alkaline sulphates within the clinker itself. These components definitely tend to be unstable when the temperature of the material increases during grinding following degradation of an extensive part of the mechanical energy of grinding accompanied by heat. This rise in heat must be controlled; in the case of ball mills it can be limited by energetic ventilation or by injecting water. The strong steam-generating heat helps to absorb the surplus thermal units. The thermal work index of such a process has been drawn up by Reuss (41). Hansen and Clausen (42) have checked its harmlessness on the cement properties.

The regulating role of gypsum rests with grinding conditions. Research has shown that when grinding is carried out in a selective way to produce monodimensional grains, the optimal gypsum proportioning is appreciably higher than during traditional grinding in a ball mill. Pöijärvi and Matikkala (43) have ground cements in a ball mill, but so as to obtain a clear grading restricted to 30 microns. They found that the optimum gypsum proportioning lies between 9 and 12%. A similar result is found with cements ground in a vacuum spinner type mill grinding by projection (11). This phenomenon had been attributed to more thorough mineral release obtained by projection grinding and especially the mineral release of  $C_3A$ . Regourd, Hornain and Mortureux (44) examined the hydration of these cements, showing that projection grinding made it possible to achieve more complete hydration of the different cement phases. They have also found that the texture of these hydrated cements is different from that usually observed, which seems to confirm that the modification of the gypsum optimum corresponds to extensive modifications in the hydration of cements undergoing selective grinding, whether in a ball mill or put to projection grinding.

The increased importance of gypsum for these cements leads to studying the role of dissolution kinetics which varies with its fineness and degree of hydration. These factors were the subject of interest in a study by Kato and Hirose (45) who prepared 27 samples varying the clinker grading distribution, the gypsum proportioning and its degree of hydration. These tests confirm

the negative effects of an excessive solubility of gypsum and the importance of a high proportioning in gypsum for cements with a various grading spectrum.

Gypsum solubility can be checked by regulating the mill atmosphere (temperature and humidity). The complex role of this atmosphere has been examined especially by Sprung (46) who investigated the reactions liable to occur between the aluminates, the gypsum and the alkaline sulphates and leading in particular to ettringite  $3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot 3\text{CaSO}_4 \cdot 32\text{H}_2\text{O}$ , to the semi-hydrate and the syngenite  $\text{CaSO}_4 \cdot \text{K}_2\text{SO}_4 \cdot \text{H}_2\text{O}$ . These reactions exert an influence not only on the setting of the cement, but also on its hardening and strengths. They vary with the quantities of alkaline sulphates, gypsum and water present, but also with the quantity of aluminates released by grinding and the degree of activation of these aluminates by grinding. Work in progress in different laboratories should make it possible to define more clearly the role of these different parameters and especially their contribution in the rheology and durability of concretes.

### 3.- GRINDING EFFICIENCY

Grinding consumes large quantities of energy. It is therefore important to study ways of fulfilling grinding objectives with the minimum consumption of energy.

These objectives may include :

- . a given specific surface,
- . grading distribution,
- . strengths on standardized test-pieces,
- . concrete strengths.

This last objective is the most important one for industry.

Figure 6, drawn from (47), gives as an example the relationships observed between grinding energy and concrete strength.

Cleemann and Modeweg-Hansen (47) have observed that the different parameters : surface, grading curve, standardized strengths and concrete strengths show precise correlations between them for a given type of grinding. However these correlations are no longer respected when the grinding system is modified, even if there are only minor modifications such as the running of a separator for example. When the grinding mode is basically changed, the relationships between the preceding parameters undergo even more extensive changes. Research on these modifications which has just entered an active stage will lead to improved knowledge of grinding and important technological development in this field.

Fig. 6 - Grinding energy plotted against strength measured on concrete, based on results by Cleemann and Modeweg-Hansen

#### 3.1.- Comparison of energy consumed by different modes of grinding clinker

The three modes of grinding mentioned in 1.2 were investigated thoroughly by Rumpf, Schönert and their co-workers. These tests were first carried out grain by grain and then mechanized in the appropriate equipment. The amount of energy consumed is measured for each test.

Haese (6) and Schönert (10) have published these results for clinker.

Figure 7 drawn from (48) sums up results obtained by different authors on quartz.

The tests carried out are :

- . slow compression
  - on isolated grains,
  - on a set of grains between a cylinder and a piston,
  - in a roller mill,
- . impact compression by a falling mass
  - on isolated grains,
  - in a ball mill,
- . projection against an anvil
  - grain by grain,
  - by a plate revolving in vacuum.

For each test measurements were taken of the energy supplied and the surface freed. The surface set up per unit of energy is plotted on the ordinate and the surface on the abscissa.

Fig. 7 - Efficiency of different grinding processes expressed in square meters of surface set up per Joule consumed (and in efficiency compared with the theoretical surface energy) plotted against fineness of ground material expressed in square centimeters per gramme using the Blaine method

Since this graph sums up tests carried out in different laboratories, the indications should be taken cautiously. Extrapolating tests carried out on quartz to results obtained on clinker can not be done without taking precautions.

However this graph can be used as a reference to illustrate the general conclusions drawn from the most recent research in the field of grinding.

These conclusions are as follows :

- The efficiency of all the methods in respect to surface energy is low and in any case close or below 1%.
- The efficiency as regards specific cracking energy is around 10%.
- The different modes of grinding and the mechanical equipment implementing these modes fall in a range of efficiency whose extreme values are in an approximate ratio of ten.

The best output is obtained with slow compression grain by grain. The grinding energy here is the compression work of crushing bodies. Unfortunately this process cannot be undertaken industrially : it would lead

to minute output. Collective crushing of grains reveals a loss compared with crushing isolated grains but remains one of the best methods from the energy point of view. Moreover it seems possible to mechanize it, which encourages Schönert (10) to consider its application to the cement industry. The roller mill, compared with the preceding process introduces additional losses due to roller friction, but this process proves to be much better than the ball mill. This explains the present development of the latter for clinker grinding (49)(50)(51).

Impact compression by falling mass offers good efficiency for low values of fineness, as shown in the diagram obtained by crushing a 2 mm grain with a falling mass. Here the crushing energy is the kinetic energy behind this mass. If improved fineness is required, the crushing body energy must be increased. It is then found that the efficiency of this grinding mode drops. It moreover joins the efficiency of a ball mill which remains constant for a certain range of fineness. This fall in efficiency can be attenuated if the mass of the crushing body is reduced with naturally lowering the incident energy. This essential adaptation of the size of the crushing bodies to the fineness of the material has been studied by Bombléd (52). It is also at the origin of the recent development in small size finishing ball mills (53)(54).

Generally speaking experience has shown that grinding equipment - a ball mill just as a roller mill - reaches maximum efficiency for a well defined grain size. Now, grinding produces a wide spectrum of sizes. It therefore seems advisable to extract the fine particles from the grinder as soon as they have reached the required size to avoid overgrinding and therefore waste of energy. The air separators offer this possibility. In the case of roller mills, the separator is built into the grinder casing ; with the ball mill, it is generally a turbo-separator (55) connected on to the grinder.

The optimal configurations mill-separator, preparatory grinder-mill, mill-finishing mill have been thoroughly studied based on mathematical modelization (56)(57)(58)(59)(60)(61)(62). Beke (63) however states that the development of ball mills now seems to suffer from a limitation due to the principle which results from the impossibility of increasing the concentration of energy to obtain finer grinding at higher outputs.

Projection grinding is not subject to this limitation because the rate of projection of material can be increased to high speeds. Here the grinding energy is the kinetic energy of the material. The graph in figure 7 shows that the efficiency of this grinding mode is high if compared with ball milling. Mechanization of this grinding mode only brings about a slight fall in efficien-

cy if it is carried out according to the process advocated by Planiol (64) who has succeeded in fine grinding by accelerating the material with a wheel turning in vacuum. However this solution raises a certain number of technological difficulties which still have to be faced. It is also possible to accelerate the material by a jet of gas (65) but the transfer of compressive energy of the gas into kinetic energy in the material occurs with a much more mediocre efficiency than in the device advocated by Planiol. The satisfactory output of this grinding mode offers the possibility of planning developing an industrial-scale projection mill which would constitute a third generation of mills after the ball mills and the roller mills.

Having surveyed the output of different grinding processes, it is now possible to check the energy losses which bring down the overall grinding efficiency.

- . The first source of losses must be attributed to the propagation of cracks. This mechanism brings about a dissipation of energy by plastic deformation near the surfaces. It was analysed in paragraph 1.
- . The second source of losses comes from the surplus elastic energy which must be transmitted to the material for crack propagation. This phenomenon requires a certain amount of energy which is taken from this elastic energy, the surplus is generally lost in the shape of kinetic energy through chipping.
- . The third source of losses is a lack of selectivity in the crushing body action. These masses transfer to the material more energy than necessary to obtain the critical elastic energy, that is to say the energy which leads to failure. This lack of selectivity can lead to the material clustering or caking.

Grinding by slow compression is very selective especially if it is carried out grain by grain and at low rates of reduction.

Grinding by projection in a vacuum centrifugal mill is also selective ; since the speed is constant, the kinetic energy varies with the mass of particles. In this way a large grain is worked on more than a fine grain.

Ball milling on the other hand is not selective, the ball falls with the same energy on a large or small grain. This explains the modest output of ball mills which can however be improved by a separator eliminating the fine grains. This elimination makes the lack of selectivity of this equipment less important.

The three sources of losses are traced on the graph figure 7 where the areas in which they exert influence are numbered 1, 2 and 3.

To evaluate the total energy consumption of a mill, those losses due to the machine must be added to the preceding causes. They are analyzed by Sillem (66).

### 3.2.- Optimization of clinker hydraulic activity by different grinding modes

The preceding comparisons were carried out based on the specific surface. In paragraph 2 the importance of the grading curve was underlined for forecasting the behaviour of clinkers and especially the 3-30 micron class. A precise comparison of the advantages of different grinding modes must consequently be found not only on their capacity to set up surfaces, but also on their aptitude to produce grains in the 3-30 micron range. This approach was adopted by Schönert (10) and has made it possible to emphasize the advantage of slow and collective compression used with declustering equipment and a separator to produce a cement in compliance with the preceding grading criteria.

The selectivity of the projection mill makes it possible to produce cements with various grading spectra. As formally stated, there is a greater probability of the larger grains being crushed than the smaller ones. The comminution modes of these mills therefore makes it possible to obtain narrow spectra (11) which satisfy criteria of not containing grains over 30 microns, that is to say grains which only hydrate partially, at the same time showing no excess of fine grains where hydration would occur too early to really contribute to strengths. These fine grains which have the highest specific surface require high crushing energy out of proportion with their contribution to the quantity of the crushed material. This aspect of crushing effectiveness has been developed in mathematical form by Reuss ((67)(68) with an aim to obtaining maximum clinker hydraulic activity with minimum energy consumption.

Cleemann and Modeweg-Hansen (47) have carried out experimental study on a ball mill working with a separator with an aim to relating the strengths measured on standardized test-pieces to the grinding energy. This research has proved that the most effective crushing equipment from the point of view of mortar strengths is the mill producing 3-30 micron grains with maximum selectivity.

### 3.3.- Optimization of cement properties by selective crushing of its ingredients

Secondary constituents are of increasing importance in present day cements. They are

generally incorporated in the cement during crushing in a ball mill. This process offers great advantages through its simplicity because the mill also serves as a homogeniser. On the other hand, this process is not very satisfactory from the physico-chemical point of view since there is no possibility of controlling the grain sizes of the various cement ingredients. This control is only carried out on the finished product for which the total grading curve can be imposed as well as the specific surface, but it is impossible to control the curves of each of the different ingredients which vary in the grading ranges according to their specific grindability.

In this way, by grinding a blend of clinker and slag (which is less grindable than clinker) (69) a range of grading will be obtained containing large proportions of slag in the coarse sizes and a large quantity of clinker in the finest sizes. Since clinker is intrinsically more active than slag, it is the latter which should be ground finer to develop its hydraulic potential properly. Simultaneous grinding of ingredients leads to the opposite result and consequently to a waste of the hydraulic potential of the materials. To avoid such waste research scientists have explored the possibility of separated or selective grinding, each ingredient being ground according to its reactivity, that is to say the higher the reactivity, the coarser the grinding. As far back as 1965 Bombléd (70) carried out separate grindings of slag and clinker, finding improved tensile strengths. Recent X-ray diffraction research attributes this increase to the presence of a high proportion of ettringite.

Iwabuchi and Okaue (71) have studied the parameters which influence the behaviour of cements with slag ground simultaneously or apart, with an aim to determining the influence of the grinding mode on the optimal gypsum content.

When clinker and a very soft pozzolana are ground simultaneously, the latter becomes much finer than the clinker but in this case this fineness is preferable because a pozzolana is improved when activated by thorough grinding, so simultaneous grinding contributes to an optimization of the cement characteristics. However this is a specific case where selectivity is obtained naturally by a fortunate coincidence between the activity of the materials and grindability.

As for fillers, their role can be essential as secondary constituents of a very narrow grading spectrum clinker. Research has shown that such cements (whose grains are monodimensional, therefore impeding an optimal grading filling) hydrate, leaving a porosity of the order of a micrometer (24)

This porosity can be filled in by adding a fine filler which thus becomes a granular complement of a narrow spectrum. This combination of a narrow spectrum for the active matter and of a complement of fine and inert material could be an optimal solution for making up a cement which, together with good strengths, offers the possibility of noticeable saving in clinker and therefore in energy. It is hardly likely that simultaneous grinding leads to the required result. Selective grinding of the different ingredients is necessary along with reformulating the cement by blending the ground materials.

### 3.4.- Optimization of concrete quality in accordance with the cement

The behaviour of cements is usually tested on standardized test-pieces which are mixed with a constant quantity of water, in weight half that of the cement quantity. The concrete test-pieces are made with constant workability, that is to say that the quantity of water to add to the concrete to obtain a given consistency is determined. The influence of water on concrete strengths is capital. Excess water quickly brings down concrete strengths, so cements must give concretes the required rheological properties with as low water contents as possible. Cements which comply best with this objective (74) are those which show a continuous grading curve to ensure optimal filling. If this is so, instead of accumulating in the microcavities, the water moves between the grains and promotes their relative displacement. Good rheological properties are thus obtained with a minimal water content. From this point of view the ideal grading curve is undoubtedly close to a curve described by

$$D(x) = \sqrt{\frac{x}{\phi}}$$

where  $x$  is the grain diameter,  $D(x)$  the undersize at this diameter and  $\phi$  the maximum diameter. The ball mill working in open circuit tends to produce curves of this type. This is not surprising because the ball falling on the material compacts it and contributes to grinding, whilst there are voids in the layer of material. Through its internal working such a mill tends to produce a curve without voids, therefore an optimal curve for rheological behaviour.

Paragraph 2 pointed out that the optimum curve for hydration is on the contrary a narrow grading spectrum curve. So there is opposition between the two imperative requirements : maximum hydraulic activity and optimum rheological properties. This opposition has been noticed by numerous research scientists either on narrow grading spectrum cements made up from separate classes (21), or on narrow spectrum cements obtained in ball mill separators (47), or in roller mills (50) or gas-jet mills (75).

The rheological differences noted usually imply a requirement for a greater quantity of water. This excess water however exerts only limited influence on strengths because of the additional activation of the clinker. The result is generally positive (50); it could undoubtedly be still further improved by better knowledge of the physical parameters which influence the rheology, that is to say apart from the grading distribution, the grain shape, their surface activity, the composition of pore liquid and especially the dissolution of gypsum in this liquid.

It also appears timely to investigate the role of appropriate fillers which could exert a positive influence on rheology as is the case with fly ash. There is reason to hope that fillers which contribute to the compactness of hardened pastes (3.3.) have a favourable influence on rheological properties. This is a field where research has available an extensive field of investigation and where the work to be undertaken will make it possible at one and the same time to reach a better understanding of cements and achieve savings in the manufacture of these products by discerning replacement of certain clinker gradings by less energy-intensive materials.

## 1. INTRODUCTION

This paper presents a review of the literature on the mechanisms of hydration of individual portland cement clinker minerals and portland cements at normal temperatures (i.e., hydration above 60°C is not discussed). The paper is not intended to be comprehensive; rather, it will discuss selected works on the mechanistic aspects of hydration reactions, especially those published after the 1974 Congress in Moscow. Papers discussing hydration in terms of mechanical properties are generally not included, and the structure, morphology, and influence of the various hydration products and their modifications on the engineering properties of cement pastes, mortars, and concretes will be reviewed by other authors. Therefore, these subjects will be addressed only when they bear on mechanistic interpretations.

Our review will consider the mechanisms of hydration with respect to the crystal form of the minerals; the presence of impurities (e.g., solid solutions), minor components (e.g., alkali sulfates), and chemical admixtures (e.g., accelerators, water reducers); and special treatments (e.g., carbonation). The scope of the interpretations given will depend on the importance of the particular mechanism to overall cement performance and on the availability in the literature of appropriate experimental and theoretical data.

## 2. HYDRATION OF CLINKER MINERALS

2.1 Tricalcium Silicate

We shall pay special attention to the hydration of tricalcium silicate,  $C_3S$ , because it is the most important component of portland cements, responsible for most of the engineering properties of hardened cement paste (e.g., strength, dimensional stability).  $C_3S$  hydration is also often used as a model for explaining the hydration of cement — an approach that is acceptable after the first few hours of hydration, when the most important reactions of the aluminate and sulfate phases have occurred. Scientific literature published on the subject of tricalcium silicate hydration after 1974 is reviewed yearly in Cements Research Progress. In addition, several review papers discussing the controversial views on the mechanism of  $C_3S$ -water interaction have been published (1-3).

2.1.1 Hydration Mechanism

There is a vast amount of literature discussing the basic mechanism of  $C_3S$  hydration. This is due to 1) the recognition of  $C_3S$  as the main component of portland cements, and 2) the extremely complex and still unresolved details of its reaction mechanism with water. As is the case with other cementitious compounds, hydration

of  $C_3S$  involves a sequence of overlapping reactions, some slow and others fast. All of these contribute to the technical importance of portland cement concrete: workability at early stages, strength development, and volume stability and durability at mature ages.

$C_3S$  reacts immediately upon contact with water in a short exothermic reaction (pre-induction period), followed by a so-called induction or dormant period of relative inactivity. During the induction period, an exchange of ionic species between the solution and solid anhydrous  $C_3S$  occurs, leading to reaction conditions that cause an autocatalytic increase in reaction rate — referred to as the acceleration period. During this reaction stage, large amounts of hydration products with lower density and larger volume than the anhydrous phases deposit into the available (water-filled) space, causing an overall decrease in system porosity, decreased transport of ionic species on the solid-liquid interface, and overall deceleration of hydration. This stage is referred to in the literature as the diffusion-controlled stage of hydration.

Numerous attempts have been made to explain the complex  $C_3S$  hydration processes. Calorimetry, analysis of the liquid phase composition, surface area measurements, and electron microscopy have been the most commonly used experimental approaches. In recent years, these have been supplemented by thermoluminescence, spectroscopy (e.g., Raman, ESCA/Auger), electron microscopy (STEM, AEM, high-voltage EM), silicate polymerization analysis, and other techniques. Based on data obtained with these high-precision methods, new mechanisms are being proposed.

The Pre-Induction and Induction Periods

Protective Hydrate Theories. de Jong et al. (4) have proposed the formation of a protective hydrate layer, which inhibits further hydration of  $C_3S$  and thus starts the induction period. The "first hydrate",  $C_3SH_n$ , which is not readily detectable by direct observation, is converted into a "second hydrate" with a lower C/S ratio (~0.8-1.5) and a thin-film morphology. Since this hydrate is more permeable to diffusion of ionic species to and from the  $C_3S$  surface, its formation signals the end of the induction period. Later, during the post-induction acceleration period, it transforms to a fibrous "third hydrate" (C/S = 1.5-2.0).

This proposed sequence embodies many of the ideas of Brunauer and Kantro (5), and a somewhat similar mechanism has been adopted by others (6-9). Barret et al. (10) concluded from a study of concentrations of ions in solution that congruent dissolution occurs initially; but, because the first C-S-H precipitate has C/S < 3, the C/S ratio in solution tends to increase indefinitely. However, in our opinion, congruent dissolution in  $C_3S$  pastes is at best a transient state, and a truly congruent solution cannot be said to occur with certainty in the bulk solution. Andreeva

and Keshelava (11) report data indicating the transient nature of congruent dissolution at high solids contents of suspensions.

Shpynova *et al.* (7) also postulate initial congruent dissolution with subsequent precipitation of  $C_3SH_n$ , which is based on a calcium hydroxide structure containing  $SiO_4$  tetrahedra. This material is unstable, and the silica condenses first to  $Si_2O_7$  units and then to infinite silicate chains (as in wollastonite or xonotlite) with the simultaneous release of  $CaO$  as  $Ca(OH)_2$ . Magnan *et al.* (9) agree that silicate polymerization occurs concomitantly with liberation of lime from the primary C-S-H (first hydrate). Condensation of isolated silicate tetrahedra forms a gel structure which, by pozzolanic effect, reacts with lime in solution to form the final silicate hydrates. Both Rebinder *et al.* (8) and Andreeva and Keshelava (11) consider the ionic concentrations to be important in crystallizing new C-S-H phases and subsequent structure formation.

Magnan *et al.* (9) could not detect the formation of a primary hydrate directly, but Fujii and Kondo (12) were able to locate hydration products on the  $C_3S$  surface after 20 minutes of hydration. Menetrier *et al.* (13) also observed the development of hydration products in the first 20 minutes of  $C_3S$  hydration; after the initial formation of minute, round or rod-like particles, Type II C-S-H developed on the surface (Fig. 1).

Fig. 1  $C_3S$  hydration products after 1 hour at 25°C (ref. 13).

**Lattice Defect Theories.** Maycock and co-workers (14) explored the influence of lattice defects on the initial reactions of  $C_3S$  with water. They concluded that the number of lattice defects (the degree of crystal disorder), introduced by mechanical grinding or heating and quenching, was directly related to the length of the in-

duction stage of hydration. Using a fast-response calorimeter, they were able to separate the first heat evolution peak into two (believed to correspond to physical adsorption of water and formation of a hydrate) and to show that the induction period shortens with increased concentration of lattice defects. They postulated that this effect was controlled by solid state diffusion within the anhydrous grain rather than by diffusion of species through a "first hydrate" that (and this was considered important) was formed after the introduction of the defects and thus could not be the reason for initiation of the induction period.

In related studies, but with different experimental approaches and interpretations, Fierens and Verhaegen (15-19) attempted to correlate lattice defects, introduced by u.v. excitation, to the early reactivity of  $C_3S$ . Using calorimetry and thermoluminescence as the main experimental tools, they found that irradiated  $C_3S$  gave two thermoluminescence peaks; however, for  $C_3S$  hydrated with water vapor or liquid, one peak diminished with hydration time while the other remained unchanged. The time for complete disappearance of the first thermoluminescence peak was about the same as the induction period determined by calorimetry. The higher the probability of the escape of electrons trapped in the defect structure, as measured by thermoluminescence, the shorter was the induction period. They therefore concluded that the main reaction during the induction period involved participation of the trapped electrons. Using ESR, they showed that the active sites on the surface, originating from lattice defects, were highly nucleophilic and provided preferential sites for chemisorption of water molecules during hydration of  $C_3S$ . Menetrier *et al.* (13), using high-resolution SEM, observed non-uniform attack of the  $C_3S$  surface exposed to water. According to Fierens and Verhaegen, the absence of any intensity change in the second peak indicates that the process does not involve the whole  $C_3S$  surface.

Fierens and Verhaegen have proposed the following mechanism for  $C_3S$  hydration: 1) rapid chemisorption of water on  $C_3S$  particles, 2) simultaneous formation of hydrated nuclei on the active sites and dissolution of a small quantity of  $C_3S$ , and 3) exothermal growth of C-S-H. The induction period ends when C-S-H nuclei reach their critical size and start growing according to the laws of nucleation kinetics, i.e., as the result of a potential barrier corresponding to the critical size of the C-S-H nuclei on the  $C_3S$  surface and not because of a protective layer which would prevent further contact with water. Exposing  $C_3S$  to water vapor prior to paste hydration decreases the induction period, apparently because the water vapor produces nuclei, or at least potential nuclei, on the active sites, which can be used in the final step of exothermal growth of C-S-H. The induction period, i.e., the time required for appearance of a sufficient number of stable nuclei, is thus ap-

preciably reduced. Fujii and Kondo (12) also believe that the induction period is terminated by propagative surface nucleation growth of C-S-H initiated by high  $\text{Ca}^{2+}$  concentration.

According to Stein (3), the above mechanism — although incorrectly interpreted from experimental data — is not necessarily incompatible with the hypothesis of de Jong *et al.* For instance, if one kind of lattice imperfection is due to an ion that is significantly displaced during the inward diffusion of water into  $\text{C}_3\text{S}$  to form the first hydrate, whereas a different kind of lattice defect is due to an ion unaltered by the first hydrate formation, then the Fierens-Verhaegen and de Jong *et al.* mechanisms are complementary. A possible model, according to Stein, involves displaced calcium ions on the one hand and imperfections related to silicate ions on the other.

**Calcium Hydroxide Nucleation Theories.** The arguments of Fierens and Verhaegen and Maycock *et al.* favor a "delayed nucleation" rather than "protective layer" explanation for the early hydration mechanism. Additional arguments in favor of this view were given recently by Young (20), Young *et al.* (21), Tadros *et al.* (22), Dent Glasser *et al.* (23) and others, but these concentrate more on the question of the nucleation of calcium hydroxide than of C-S-H.

Young *et al.* (21) have studied the composition of the liquid phase of hydrating  $\text{C}_3\text{S}$  pastes. The ionic product for calcium and hydroxyl ions,  $[\text{Ca}^{2+}][\text{OH}^-]^2$ , was calculated as a function of time and correlated with CH crystal growth data and calorimetric measurements of  $\text{C}_3\text{S}$  hydration. The results confirmed that the maximum  $\text{Ca}^{2+}$  concentration corresponds to the end of the induction period and coincides with the onset of initial nucleation of CH. The onset of maximum crystal growth correlated closely with the period of maximum reactivity (heat evolution). The increase of ionic products after CH nucleation began was attributed to the dominant role of the  $[\text{OH}^-]^2$  factor, which did not decrease during the subsequent growth of CH. This continued increase in  $[\text{OH}^-]$  may have resulted from the polymerization of silicate species, which were formed during renewed activity of  $\text{C}_3\text{S}$  at the end of the induction period. According to Young *et al.*, the following scheme for  $\text{C}_3\text{S}$  hydration seems plausible:

Initial hydrolysis:

(where "C<sub>2</sub>S" can be considered a lime-deficient  $\text{C}_3\text{S}$  structure after undergoing initial hydrolysis)

At the end of the induction period:

Young *et al.* did not have any evidence for  $\text{C/S} = 2$  in reaction (1b). It is also unknown if  $\text{Si}_2\text{O}_7^{6-}$  would be unprotonated in reactions (1a) and (2b), but this does not affect their argument. "C<sub>2</sub>S" was deduced solely from relative concentrations in solution rather than from experimental evidence, but it could be the "first hydrate" of Stein (3). The end of the induction period may be inferred from both the crystallization of CH and the formation of acicular C-S-H (second hydration product) from "C<sub>2</sub>S." A major reaction occurring during the growth of the second hydration product may be the polymerization of mono-silicate ions (in  $\text{C}_3\text{S}$ ) to disilicate and higher polymers (in C-S-H). As pointed out by Magnan *et al.* (9), this gel structure of polymers can react with lime solution to form the final hydration products.

Changes in the  $\text{Ca}^{2+}$  ion concentration with time have also been studied by Fierens and Verhaegen (24) and Slegers and Rouxhet (25). Fierens and Verhaegen observed that initial release of  $\text{Ca}^{2+}$  was independent of the reactivity of  $\text{C}_3\text{S}$  as measured by thermoluminescence, but that the  $[\text{Ca}^{2+}]$  increase depended on the specimen treatment used (Fig. 2). In contrast to Young *et al.* (21), they found the  $[\text{Ca}^{2+}]$  peak not to coincide with the end of the induction period. Slegers and Rouxhet (25) have confirmed that the  $\text{Ca}^{2+}$  ion concentration peak is a real supersaturation peak. However, crystalline CH was detected long before the appearance of this peak. This is surprising but could be due to the crystallization of CH near the grain surfaces. Crystallization of CH at or near grain surfaces of hydrating  $\text{C}_3\text{S}$ , where a high concentration of  $\text{Ca}^{2+}$  ions would be expected, has also been noted by others (7,26,27).

Fig. 2 Variation of  $\text{Ca}^{2+}$  concentration with time for five different samples of  $\text{C}_3\text{S}$ . Arrows indicate the end of the induction period, determined by conduction calorimetry (ref. 24).

New data by Tadros *et al.* (22) point to a similar  $C_3S$  hydration mechanism. At the beginning of hydration, the Ca/Si ratio in the liquid phase was found to be much higher than 3, and zeta-potential measurements showed the presence of a positive charge on the surface of the  $C_3S$  particles. Additionally, CH crystal growth studies showed that the presence of silicate ions retarded the nucleation and growth of CH crystals and, thus, led to supersaturated CH solutions. Based on these observations, Tadros *et al.* suggested the following mechanism for early hydration of  $C_3S$ . Upon contact with water,  $C_3S$  undergoes a rapid hydrolysis, releasing  $Ca^{2+}$  and  $SiO_4^{4-}$  into solution. The ratio of C/S is much greater than 3, implying that the surface of the original  $C_3S$  becomes deficient in calcium. As indicated by zeta-potential data, calcium ions chemisorb on the Si-rich surface, giving it a positive charge:

Using ESCA for analysis of surface layers, Thomassin *et al.* (28) and Menetrier *et al.* (13) found evidence to support this view. Initially, the C/S ratio at the surface falls rapidly to about 2.5, but quickly rises again to about 2.75 after 1 minute (see Fig. 3). Thereafter, a slow, but continual decrease in C/S ratio with time is observed over several hours. The high  $Ca^{2+}$  concentration in the interfacial region, perhaps aided by the underlying Si-rich layer, reduces further the dissolution of  $C_3S$ , thus initiating the induction period (22). The  $Ca^{2+}$  and  $OH^-$  ions continue to dissolve at lower rates and, since the growth of CH crystals is inhibited by silicate ions, the liquid phases become supersaturated with respect to CH. When the supersaturation reaches a certain limit (1.5–2.0 times the saturation value), CH nuclei are formed and rapid precipitation of CH begins. This marks the end of the induction period. The precipitating ions act as a sink for ions in solution, which, in turn, enhances the further dissolution and reaction of  $C_3S$ . The CH crystals incorporate sili-

Fig. 3 Changes in C/S of surface of hydrating  $C_3S$  as a function of time (ref. 28).

cate ions and therefore may also act as nuclei for C-S-H. The dissolution of  $C_3S$  marks the beginning of the acceleration period.

Stein (3) disagrees with the above interpretations; he believes that these observations — a molar C/S  $\gg 3$  after 1 minute of hydration, a positive zeta-potential indicating an outer layer of chemisorbed  $Ca^{2+}$ , and initiation of CH crystallization simultaneous with the end of the induction period — can be more satisfactorily accounted for by using the hypothesis of de Jong *et al.* (4). He considers the end of the induction period to be the cause rather than the effect of CH crystallization, and feels that the Tadros *et al.* mechanism cannot explain the experimentally found accelerating effect of amorphous silica on the hydration of  $C_3S$ .

**Other Theories.** The question of the induction period of  $C_3S$  hydration is discussed also by Odler and Dorr (29). According to these authors, upon  $C_3S$  contact with water, the  $Ca^{2+}$  ions are leached out from the surface to form CH in solution. Water molecules are simultaneously taken up by the surface to form a C-S-H of low C/S and high H/S ("first hydrate"). This initial, topochemical reaction terminates upon supersaturation of the liquid phase with respect to CH, so that no more  $Ca^{2+}$  can be accommodated. At this point, the degree of reaction has reached about 1–2 percent. Almost simultaneously, nuclei of a "second hydrate" form on preferential  $C_3S$  surface sites. The exact reasons for the induction period are not clear. During this period, neither the "first" nor the "second" hydrate can form because of, respectively, the supersaturation of the liquid phase with respect to CH and the size of nuclei, which are smaller than critical. The induction period terminates when the second hydrate nuclei reach the critical size, enabling rapid propagative surface nucleation. The reaction continues until it is decelerated by consumption of anhydrous  $C_3S$  and the diffusion-controlled character of the process. The "second hydrate" has a lower H/S and higher C/S than the "first hydrate." However, since both C-S-H forms have a C/S  $< 3$ , liberation of free lime is occurring simultaneously. During the formation of the "second" C-S-H, amorphous CH is formed, which, upon conversion to crystalline form, is initially effective in nucleation and growth of CH. During this time, the supersaturation of the liquid phase with respect to CH decreases to the saturation concentration. Formation of detectable solid CH at the beginning of the acceleration period is considered to be the consequence of rather than the reason for the termination of the induction period.

The considerable variation in estimates of the C/S ratio for a "first hydrate" emphasizes the difficulty of obtaining a good measure of its stoichiometry. Dent Glasser *et al.* (23) noted an apparent discrepancy between the C/S ratios of the C-S-H obtained by the direct and indirect

methods at early ages: for pastes a few days old, their own results from the indirect method gave low values, around 1.0, while direct analyses by analytical electron microscopy gave a mean C/S of about 1.6. They suggested that the C-S-H might exist in two different forms, which they called "surface" and "precipitated" hydrate. The precipitated hydrate was what had been observed by electron microscopy, and included both Type I and Type III Diamond varieties (30). The surface hydrate was formed from the surface regions of reacting C<sub>3</sub>S particles as a layer of approximately fixed thickness, which contracted as the C<sub>3</sub>S was consumed. Its mean C/S ratio was assumed to be below 1, and the actual value ranged from a maximum value of 3 at the C<sub>3</sub>S interface to a minimum well below 1 at the solution interface. Several assumptions are implicit in this hypothesis. First, variations in C/S with degree of hydration are due to changes in the relative amounts of different kinds of C-S-H, rather than to changes affecting the whole of the C-S-H. Second, there is a continuous conversion of surface into precipitated C-S-H. The concept thus differs from that of inner and outer hydrates in that, in the latter model, inner hydrate is never converted into outer or vice versa. The two concepts are not mutually exclusive, however, as the precipitated hydrate could be differentiated into inner and outer products.

A mechanism for portland cement hydration has been proposed (31-33) which also requires the formation of a protective layer around the alite grains. This layer, however, is considered to act as a semipermeable membrane, thereby allowing osmotic pressures to develop. Passage of Ca<sup>2+</sup> and OH<sup>-</sup> through the membrane leaves behind a silica-rich solution. C-S-H grows by a "silicate garden" process as the membrane ruptures and forces out the liquid beneath. These ideas are discussed more fully in the section on portland cement.

According to Taylor (1), the assumptions that some sort of protective layer causes the induction period and that nucleation of C-S-H or CH or both ends it need not conflict. Indeed, in his view, the combination is highly probable. Similarly, the delayed-nucleation theory and the hypothesis that an osmosis-like mechanism plays an important part in the hydration reaction are not necessarily contradictory. This conclusion is based partially on the recognition of the inherent difficulties in the concept (described earlier) of a membrane enclosing a silica-rich fluid through which Ca<sup>2+</sup> has to pass. It is almost certain that the silica would polymerize to form a gel, and it is difficult to visualize how calcium could migrate through such a gel to form C-S-H. Using an analogy of the behavior of rubber in benzene, Dent Glasser (34) noted that a gel can absorb solvent, develop an inhibition pressure, and swell without being enclosed in a semi-permeable membrane. She seems to be implying the existence of a polymeric gel, although the evidence shows

that polymerization occurs during later hydration. Thus, instead of a cement particle coated with a semi-permeable membrane that encloses a Si-rich liquid to which additional water flows by osmosis, we may be dealing with a semi-fluid gelatinous coating that draws water by inhibition. This concept may provide a bridge between the ideas of Fierens, Young, Skalny, and others on the one hand, and those of Jennings and Pratt -- and to some extent of Double, Birchall and others -- on the other hand. In Taylor's view (1), the ultimate driving force of the hydration reaction is twofold: attraction of protons to the basic oxide and silicate ions, and attraction of water molecules to all the ions. A calcium-depleted layer is produced, as suggested by Tadros *et al.* (22) and others, but this layer may be semi-fluid and based on a mobile, hydrogen-bonded network of highly protonated silicate ions and water molecules. If this layer actually imbibes water, as suggested by Dent Glasser (34), then a continuous hydration of the underlying C<sub>3</sub>S surface is feasible. Ca<sup>2+</sup> ions could diffuse outward through this layer, but would be held back on the surface by an excess of negative charge. This may explain the existence on the surface of a chemisorbed Ca-layer as reported by Tadros *et al.* (22).

#### The Post-Induction Periods

Until now we have discussed the experimental data and theories relative to the first few hours of hydration -- a period characterized by a relatively low rate of C<sub>3</sub>S-H interaction. However, the main property of cement -- namely, its structural integrity (strength, volume stability, and durability) -- is to a large degree the consequence of an accelerated C<sub>3</sub>S hydration during which a substantial amount of C-S-H forms a rigid network. Unfortunately, compared to the pre-induction period, the acceleration and diffusion-controlled stages of hydration are less fully explored. The reasons for this lack of knowledge are inadequate instrumentation and the extremely complex character of the structures formed, both on a micro- and a macro-scale. To illustrate our uncertainty about the post-induction mechanism, note the disagreement of various reported data on the composition of C-S-H as a function of time and temperature of hydration, the degree of hydration, composition of the liquid phase, etc. This issue has been discussed recently by Bentur and Berger (35). The "reactivity" of C<sub>3</sub>S is influenced by thermal history, particle size and distribution, polymorphism, form of minor components present, etc., and in turn, influences the post-induction period as well as earlier hydration. Although these issues may seem academic, they are actually the preconditions for full realization of cement potentials. This knowledge could enable prediction and better control of concrete properties on the basis of "microstructural engineering." More experimental evidence is thus needed to better explain this and the decelerating diffusion processes, e.g., the role of porosity and liquid phase composition.

Powers (36), Terrier and Moreau (37), and others have distinguished between "inner" and "outer" hydration products, formed in spaces previously occupied by anhydrous solid and water, respectively. It is not clear how these hydrates relate, if at all, to the types of hydrates recognized by Diamond (30) or to the "precipitated" hydrate discussed by Dent Glasser et al. (23). Stucke and Majumdar (38) have measured C/S ratios for both inner and outer hydrates, but the issue is far from resolved.

Taylor (1), based on previous work of Tadros et al. (22), Dent Glasser et al. (23), and others, proposed a possible mechanism for the post-induction period. It is shown, together with his ideas about the pre-induction period, in Fig. 4. As the  $C_3S$ -H reaction progresses, there is necessarily an interface that advances into the diminishing  $C_3S$  grain. Behind it follows a semi-solid, Si-rich (low C/S) layer, which, depending on its thickness, may dominate the composition of C-S-H as a whole. Outside this layer, some of the ions from the reacting  $C_3S$  form a zone of inner product with increasing C/S. Other ions pass through the inner product to augment the outer product. This hypothesis needs additional experimental proof, however.

Fig. 4 Mechanism of  $C_3S$  hydration proposed by Taylor (1).

#### 2.1.2 Hydration in the Presence of Admixtures

Since a special report on admixtures has not been prepared for this Congress, we will address the subject here. Because of space limitations, we will concentrate on more fundamental aspects of  $C_3S$ -admixture interactions and will continue the discussion in the section on cement. There is no single mechanism that will explain the way in which set-modifying admixtures affect the hydration of  $C_3S$ , primarily because the reaction rates and products of hydration are controlled by numerous simultaneous chemical and physical pro-

cesses. For example, the influence of any admixture may affect the length of the induction period, the time of maximum rate of heat evolution, or the area under the main heat peak (total heat evolution) (39). Any of these changes may cause acceleration or retardation. Furthermore, other properties have been used to evaluate set-modifying effects, such as strength development, non-evaporable water content, development of surface area, formation of hydrates, etc. — properties which are not necessarily related linearly.

#### Inorganic Electrolytes

It has been suggested in the past that the effect of an electrolyte, e.g.,  $CaCl_2$ , on the hydration process is sequential, i.e., it participates in only one reaction at a time. For example, DeKeyser and Tenoutasse (40), in their study of the ferrite phase, concluded that calcium monochloroaluminate-ferrite,  $C_3(A,F).CaCl_2.10H_2O$ , is not formed until all the available gypsum is consumed. On the other hand, Rozenberg and Kucheryaeva (41), in agreement with Ratnov and Rozenberg (42), concluded that simultaneous formation of basic salts from a complex hydration system is possible. Using  $CaCl_2$ ,  $Ca(NO_3)_2$ , and  $Ca(NO_2)_2$  with calcium hydroxide ( $C_3S$  reaction product) alone and with additions of  $C_3A$ , they calculated the reaction rates and yields for the various combinations and concluded that, when two or even three electrolytes are added to a system together, the reaction that has the higher rate constant will have the higher yield. Unfortunately, the authors do not discuss the effect of added salts on the mechanism of  $C_3S$ -H reaction.

Despite the long and extensive use of  $CaCl_2$  as a commercial accelerator, very little is known about the mechanism of its influence on  $C_3S$  hydration (43,44). Many investigators have compared the behavior of different metal chlorides (39, 45-48) and have attempted to correlate the effectiveness of the cations in accelerating  $C_3S$  hydration with their ionic radii and electronegativity. However, there is no general agreement on the proper order of rank for cations because, as Kantro's study shows (39), the relative accelerating power of cations depends on the salt concentration and the criterion used for acceleration.

The influence of various anions on the accelerating process has also been studied (39,47,48). Although these studies used different cations, and thus are not completely comparable, it is apparent that chloride ion is not necessarily the best anion for accelerating the hydration of  $C_3S$ . Kondo et al. (47,48) related the effect of the anion on the  $C_3S$  calorimeter curve to its ionic mobility (Fig. 5a) and found that sulfate, chromate, and thio-sulfate ranked ahead of the chloride ions for potassium salts. Kantro (39) observed similar anion rankings for calcium salts (Fig. 5b).

Although there is general agreement between the results of the two studies, there are some notable differences. For example, the calcium salts are generally better accelerators than the potassium salts, and the behavior of  $I^-$  and  $SCN^-$  is quite sensitive to the cation.

Fig. 5 Effect of inorganic anions on C<sub>3</sub>S heat evolution: (a) Potassium salts (ref. 47), (b) Calcium salts (ref. 39).

The effects of various other salts have also been studied (21,39,49-51). Most inorganic electrolytes behave as accelerators, with the exception of fluorides (47,48,21), phosphates (52), and those cations that precipitate insoluble hydroxides (39,47,48). It is clear that  $CaCl_2$  is not unique in this regard, but has the advantage of being a cheap and readily available material.

Young (53,54) has attempted to explain the influence of soluble salts by considering each stage of C<sub>3</sub>S separately and sequentially. The importance of the composition of the liquid phase, particularly with respect to CH supersaturation, is supported to some extent also by work of Teoreanu and Muntean (45). This would explain the higher accelerating effects of calcium salts compared to potassium salts. Kondo *et al.* (47,48) considered ion diffusion to be an important

property. A highly mobile anion, such as  $Cl^-$ , can penetrate the initial protective layer to the underlying C<sub>3</sub>S, forcing diffusion of other ionic species (e.g.,  $Ca^{2+}$ ) to maintain electro-neutrality, and thus accelerating hydration. The order of  $Cl^-$  diffusion coefficients was found to be  $D_{MgCl_2} > D_{CaCl_2} > D_{LiCl} > D_{KCl} > D_{NaCl}$ , and the values are greater than those of the cations. This order is also approximately that found for their accelerating effect on C<sub>3</sub>S hydration.

When cations precipitate insoluble hydroxides, retardation of C<sub>3</sub>S hydration is observed (39,47,48). This is attributed by Kondo *et al.* (47,48) to the formation of an impermeable layer of insoluble hydroxides or other insoluble calcium salts. Young (53,54) has suggested that the precipitation produces the retarding effect by keeping the contact solution from becoming supersaturated with respect to calcium hydroxide. However, neither theory explains why  $Na_2CO_3$  accelerates C<sub>3</sub>S hydration (21,51).

#### Organic Admixtures

Most organic admixtures retard the hydration of C<sub>3</sub>S — including those used as accelerators for cement, e.g., triethanolamine. Salts of lignosulfonates, which contain varying amounts of sugars and related compounds, are an important component of commercial retarding admixtures. Milestone (55) investigated the effects of such organics, using fractionated lignosulfonates, glucose, and sodium gluconate. At 0.1% concentration, fractions high in sugar at first retarded C<sub>3</sub>S hydration and then accelerated it. The same concentration of fractions high in lignosulfonate caused little delay, but a 0.5% concentration completely inhibited hydration of C<sub>3</sub>S. Adding 0.1% glucose delayed hydration for about 11 days, whereas the same amount of sodium gluconate caused complete inhibition. Milestone concluded that the retarding effect of lignosulfonate is due to the presence of sugar acid impurities, which are more effective than sugars alone because of their charge and stability, i.e., the readily ionized, negatively charged sugar acids adsorb on the positively charged surface of the C<sub>3</sub>S and retard hydration. Thus, as proposed by Tadros *et al.* (22,56), the delay in hydration is believed to be caused by poisoning of the CH nuclei. Total inhibition of hydration by sugar acids is perhaps caused by their adsorption on the C-S-H nucleation sites (55).

In a related study, Jawed *et al.* (57) found that the Na-lignosulfonate delayed or completely inhibited the growth of CH from a supersaturated solution (Fig. 6). At a lignosulfonate concentration of approximately 2.5 ppm, no effect on crystal growth was observed. At somewhat higher concentrations, well-defined induction periods were noticed followed by accelerated growth rate. At concentrations above 200 ppm, the growth, and probably also the nucleation, of CH was com-

pletely inhibited. In a C<sub>3</sub>S paste, higher supersaturation was required to overcome the poisoning effect of lignosulfonate. When crystal growth did occur, numerous small crystals formed rather than a few large ones. This may well explain the delayed acceleration observed by Milestone (55). (See also discussion in section on C<sub>3</sub>S-temperature effects.)

Fig. 6 Effect of lignosulfonate concentrations on growth of CH crystals from supersaturated solution (ref. 57).

### 2.1.3 Selected Issues

#### Hydration of C<sub>3</sub>S Polymorphs

It has been reported in the past that the various crystal forms of pure C<sub>3</sub>S have comparable reactivities with water. In the presence of impurities, minor differences in hydraulic activity are noted, but these are related to lattice and electronic defects rather than to the crystal form (58,59).

An attempt to better characterize the reactivity of the C<sub>3</sub>S polymorphs was reported by Harada *et al.* (60). Using synthetic C<sub>3</sub>S preparations at w/c of 0.3 and 0.4 (20°C) and quantitative X-ray diffraction analysis, the authors found the following order of reactivities at early stages of hydration: monoclinic < triclinic < rhombohedral. With time of hydration, the differences diminished, and, at 3 months, the degree of hydration of all three polymorphs reached approximately 70%. According to the authors, the morphologies of the C-S-H formed depended on which polymorph was hydrated:

C <sub>3</sub> S	C-S-H
rhombohedral	thin sheets
monoclinic	fibrous
triclinic	amorphous

The reactivity of C<sub>3</sub>S may depend on the particular oxide impurity used (61,62). Kausanskii and Timashev (63) believe that different defects affect reactivity to different extents. At low levels (<0.3%) of Al<sub>2</sub>O<sub>3</sub> in C<sub>3</sub>S, Al<sup>3+</sup> replaces Ca<sup>2+</sup> in the lattice, creating donor centers and releasing conductivity electrons. Above 0.3%, Al<sup>3+</sup> substitutes for Si<sup>4+</sup>, and creates acceptor centers or "holes." The presence of holes causes greater reactivity.

#### Effect of Temperature

C<sub>3</sub>S hydration is affected by temperature in the first three stages. The induction period shortens and the heat peak in Stage 3 becomes more intense. Later, when hydration becomes diffusion-controlled, temperature sensitivity decreases. Boyer (64) and Boyer and Berger (65) have found that the temperature of hydration affects the size of calcium hydroxide crystals. At 5°C, relatively large crystals are formed while, at 40°C, a much greater number of small crystals is formed. This change is even more marked when the temperature is raised just prior to the end of the induction period. A large number (~1000 times those formed at 5°C) of very small crystals is formed if the temperature is changed from 20° to 40°C, for example. This effect is believed to be due to the decrease of calcium hydroxide solubility with temperature. Raising the temperature causes the solution in contact to become highly supersaturated with respect to calcium hydroxide.

#### Seeding

Davis and Young (66) used afwillite to seed C<sub>3</sub>S hydration. Addition of afwillite accelerated the hydration of C<sub>3</sub>S, but strength development was not influenced to the same degree. Afwillite appeared to form both by conversion from C-S-H and directly from C<sub>3</sub>S. Seeding was most effective when the seed material was interground with the C<sub>3</sub>S rather than mixed by blending. Mchedlov-Petrosyan *et al.* (67) observed similar behavior when seeding C<sub>3</sub>S with prehydrated C<sub>3</sub>S. Stein and Stevels (68) have attributed the accelerating effect of amorphous silica to its influence on the nucleation of the "second" C-S-H.

#### Carbonation

C<sub>3</sub>S carbonation reactions have been pursued by a few authors, but most results are descriptive rather than mechanistic. According to Takagi *et al.* (69), hydrating C<sub>3</sub>S specimens prepared from triclinic, monoclinic, and rhombohedral polymorphs all produce calcite upon carbonation. Goodbrake *et al.* (70) developed a kinetic equation for the carbonation reaction of both C<sub>3</sub>S and β-C<sub>2</sub>S in the presence of water vapor:

$$[1 - (1 - \alpha)^{1/3}]^2 = K_T' t \quad (3)$$

where  $\alpha$  = degree of carbonation,  $K_T'$  = apparent rate constant, and  $t$  = time of reaction.  $K_T'$  depends on the actual rate constant,  $K$ , the

diffusion coefficient,  $D$ , and the average particle size,  $r_0$ :

$$K_T' = \frac{KD/r}{r_0^2} \quad (4)$$

The carbonation reaction is exothermic (-83 kcal/mol  $C_3S$ ) and follows a decreasing-volume, diffusion-controlled kinetic model. The activation energy was found to be 9.8 kcal/mol. The overall equation:

describes the carbonation process satisfactorily.

When liquid water comes in contact with the solid during carbonation ( $w/s = 0.10-0.20$ ), the course of the reaction changes, and C-S-H (believed to be similar to that formed in normal hydration) is formed and subsequently carbonated:

The overall reaction is the same as in Equation 5. A simple rate equation of the form

$$\frac{da}{dt} = k \log t \quad (8)$$

can be used to describe carbonation. The form is the same as is often used for hydration, but the rate constant is several orders of magnitude larger.

#### Mathematical Modeling of the Hydration Process

Mathematical modeling of cement hydration processes is the subject of another review; therefore, we will present only a brief discussion here.

Pommersheim and Clifton (71), using mainly experimental data of Kondo and co-workers (6,72) and de Jong et al. (4), developed a mathematical model for  $C_3S$  hydration by which the following output variables could be predicted as a function of time: degree of hydration and its rate, core and particle radii, amount of free and combined water, amount of CH and C-S-H formed, intergranular porosity, and the rate of the controlling process. For modeling purposes, the hydration was broken down into several processes: 1) diffusion of chemical reactants through ever-thickening spherical layers of precipitated porous hydrates to the interface between the  $C_3S$  core and the innermost hydrate layer, 2) dissolution of ions from  $C_3S$  and their hydration near this interface, 3) diffusion of soluble product ions out through deposited hydrate layers, and 4) precipitation of insoluble products (inner, middle, and outer C-S-H). The middle (barrier)

product layer forms at early stages of hydration; its later disappearance may mark the end of induction period and the beginning of the acceleration stage.

Tomosawa (73), in an attempt to relate the hydration process to practical engineering properties of concrete (e.g., strength development, heat liberation), developed a model that assumed an induction period at the early stages of  $C_3S$  hydration followed by a diffusion-controlled stage. Kinetic models for  $C_3S$  and  $\beta$ - $C_2S$  hydration were also proposed by Fujii and Kondo (12, 74).

#### 2.1.4 Proposed Mechanism of Hydration

The following concepts describe processes during the induction and acceleration periods of  $C_3S$  hydration:

- o C-S-H nucleation
- o CH nucleation
- o Osmotic pumping
- o Crystal defects.

Table I reviews the different theories on the three main stages of hydration.

An appropriate mechanism should be able to explain the effects of experimental variables on the hydration of  $C_3S$ . Table II lists the predictions of the various mechanisms for some of the variables discussed above. Based on the reported experimental data and on Taylor's ideas reconciling some of the conflicting views (1), we propose the following mechanism of  $C_3S$  hydration.

Stage 1. Initial hydrolysis with water causes protonation of  $O^{2-}$  to  $OH^-$ ,  $SiO_4^{4-}$  to  $H_nSiO_4^{(n-4)-}$ , and  $Ca^{2+}$  to  $Ca^{2+}(aq)$ . Hydrolysis occurs preferentially at active sites, and the number of such sites determines how rapidly this process occurs. As  $Ca^{2+}$  and  $OH^-$  preferentially leach into solution, a surface layer reaction product forms that can be best described as an assembly of silicate ions, such as  $H_3SiO_4^-$  and  $H_4Si_2O_7^{2-}$ , held together mainly by hydrogen bonds and a few calcium ions (Fig. 7). This layer is certainly amorphous and bears no resemblance to the original crystal structure. It may not be very rigid and might tend to imbibe water and swell (the imbibition pressure which causes swelling is similar to an osmotic pressure, but does not require a specific semi-permeable membrane). Charge balance is maintained by loss of  $Ca^{2+}$  into solution to compensate for  $H^+$  taken up from the water during hydrolysis. An electrical double layer sets up between

Table I  
COMPARISON OF MECHANISTIC CONCEPTS  
FOR  $C_3S$  HYDRATION

Initial Hydration (Stage 1)	(i) 1st hydrate ( $C_3SH_n$ ) (ii) Chemisorbed layer ( $C_{2-5}SH_n$ ) (iii) Semipermeable membrane C-S-H (iv) No specific retarding layer (v) Semi-liquid layer ( $C_{2-1}SH_n$ )	Congruent dissolution Incongruent dissolution Ca adsorbed on silica-rich hydrolyzed layer $Ca(OH)_2 + Si_2O_7^{6-}$ Change in solution composition Change in active sites
Induction Period (Stage 2)	(i) C-S-H Nucleation Control (ii) CH Nucleation Control (iii) Osmotic Pumping (iv) Crystal Defects	2nd hydrate $C_{1-1.5}SH_n$ (acicular) Acicular C-S-H also $C_{1.5-2.0}SH_n$ Osmotic pressures burst coating. C-S-H same composition as membrane Nucleation of C-S-H at active sites
Acceleration Period (Stage 3)	(i) Growth of C-S-H (ii) Growth of CH and C-S-H	Heat peak due to renewed hydration of $C_3S$ and formation of C-S-H. CH is a by-product Heat peak due to growth of CH which controls renewed hydration of $C_3S$

Table II  
EXPLANATION OF VARIABLES THAT AFFECT HYDRATION OF  $C_3S$   
IN TERMS OF PRINCIPAL HYDRATION MECHANISMS

Variable	C-S-H Nucleation	CH Nucleation	Osmotic Pumping	Crystal Defects
Temperature	Affects nucleation of 2nd hydrate	Affects initial rate of hydrolysis; thermal shocking may accelerate hydration	Affects initial dissolution of $C_3S$ and build-up of osmotic pressure	Affects rate at which reactive sites react. Quenching from kiln temperatures affects initial number of sites
Effect of adding $Ca(OH)_2$	Retards by inhibiting nucleation of second hydrate	Should shorten induction period, but crystals may be poisoned. Not always retarding	No predicted effect. Might assist in development of membrane and might influence development of osmotic pressure	No predicted effect
Effect of adding $CaCl_2$	Promotes nucleation of second hydrate	Shortens induction period by adding $Ca^{2+}$ and reaching supersaturation sooner	Not predicted	Not predicted, but may affect reactivity of active sites
Effect of adding a retarder	Not predicted	Lengthens induction period by inhibiting crystal growth. Higher supersaturation is required.	Not predicted	Active sites inhibited by adsorption of retarder molecules
Effect of adding amorphous $SiO_2$	Aids nucleation of second hydrate	Initial formation of C-S-H will occur which may prevent poisoning of CH	Not predicted but might aid membrane formation	Not-predicted

the relatively mobile  $\text{Ca}^{2+}$  and the immobile silicate surface layer, and is observed as chemisorption.

Fig. 7 Initial hydrolysis of  $\text{C}_3\text{S}$ .

Stage 2. The surface layer first formed in Stage 1 continues to develop, and  $\text{Ca}^{2+}$  and  $\text{OH}^-$  ions continue to pass into solution. But the process is slow because the ions must pass through the electrical double layer. The characteristics of the double layer will be affected by the concentration of  $\text{Ca}^{2+}$ , i.e., ions will move more readily through a diffuse double layer (solid line, Fig. 8) than through a condensed layer (dotted line, Fig. 8). Nuclei form from assembly of atoms in solution, but are not able to reach the critical size necessary for growth. The nuclei contain  $\text{Ca}^{2+}$ ,  $\text{OH}^-$ , and silicate ions, and will form either CH or C-S-H.

Fig. 8 Variation of double layer with ionic concentration in solution.

Stage 3. Ionic concentrations in solution become large enough for the nuclei to grow. Growth is first observed when the solution becomes supersaturated with respect to calcium hydroxide, and occurs close to the surface of the grain where ionic concentrations are highest (Fig. 9). Growth of C-S-H is confined to the surface because of the difficulties in transporting silica (surface mechanism). Mostly small particles form because of lack of silicate movement. Growth of CH may occur initially at the surface, but some crystals also form in the pores away from the grains. These grow more rapidly because of lack of space constraints, and eventually consume most of the smaller crystals near the surface. Growth of CH is controlled by the supersaturation of the liquid phase. Growth is first achieved at the end of Stage 2, but continues even during Stage 3.

Fig. 9 Nucleation and crystal growth at the end of the induction period.

Stages 4 and 5. Rapid initial growth of CH and C-S-H slows down as supersaturation decreases. Most initial growth takes place outside the original grain boundaries in the water-filled space. Later growth (see Fig. 10) takes place within the original grain boundaries (hence this C-S-H is often called the "inner product"). The interface and Si-rich layer move inward, and C-S-H precipitates predominately beneath the outer aciculae because these act as a barrier to ionic transport. However, some additional growth of aciculae will occur during the initial period of Stage 4. The morphology of the inner C-S-H will be different because of lack of space and changes in ionic concentrations (solutions are no longer highly supersaturated). The composition of inner C-S-H may also change because of changes in ionic mobility and space restrictions. Thus, inner and outer C-S-H may be quite different, or there

may be a structural and compositional gradient through the C-S-H layer.

Fig. 10 Formation of inner product C-S-H.

## 2.2 Dicalcium Silicate

Dicalcium silicate is one of the most important components of portland cement clinker, where it exists mostly as the metastable  $\beta$  polymorph, stabilized by the presence of impurities. Because the hydration rate of  $\beta$ -C<sub>2</sub>S is low compared to that of C<sub>3</sub>S (alite),  $\beta$ -C<sub>2</sub>S does not play an important role in the development of cement properties during the early stages of cement hydration. Consequently, only very limited research is focused on this clinker mineral. However, in view of its substantially lower temperature of formation compared to C<sub>3</sub>S, and the subsequent possibility of energy savings, more interest in the chemistry of C<sub>2</sub>S has been shown recently. It should also be noted that the hydration products of C<sub>2</sub>S play an important role in the development of the ultimate engineering properties of mortar and concrete. Hydration of C<sub>2</sub>S polymorphs has been recently reviewed (75,76).

### 2.2.1 Hydration of $\gamma$ -C<sub>2</sub>S

The  $\gamma$ -form is known to be the least reactive C<sub>2</sub>S polymorph at ambient temperature. Under normal conditions, it is not found in industrial clinkers. Danilov (77) explains the differences in the rates of hydration of clinker minerals in terms of the electronegativities and ionic/covalent character of Ca-O-X bonds, and states that the low reactivity of  $\gamma$ -C<sub>2</sub>S is caused by inadequate saturation of the liquid phase and subsequent low probability of formation of C-S-H nuclei. Others attribute the low reactivity of  $\gamma$ -C<sub>2</sub>S to the regular coordination of its calcium ions with oxygen atoms in the olivine-type (Mg<sub>2</sub>SiO<sub>4</sub>) orthorhombic structure, to the absence of holes of atomic dimensions, or to the differences in hydration mechanism between the  $\gamma$  and  $\beta$  forms. In the view of Sychev et al. (78), the limited hydration of  $\gamma$ -C<sub>2</sub>S proceeds by a "through solution" mechanism, whereas  $\beta$ -C<sub>2</sub>S reacts by a "topochemical" mechanism. Lea (79) questions some of these explanations for the

relative reactivity of C<sub>2</sub>S polymorphs. He argues that the absence of "holes" and a highly coordinated structure are much less important than the impurities used to stabilize the high-temperature polymorphs for the hydration studies. He uses the highly reactive C<sub>3</sub>S (six-coordinated Ca-ions) and very soluble NaCl (no "holes" in its structure) to prove his point. There is no accepted and experimentally proven explanation for the differences in the reactivity of the various polymorphs. Any future mechanistic research would have to consider all the above factors.

DTA and IR investigations by Bensted (80) of FeO-stabilized and pure  $\gamma$ -C<sub>2</sub>S have shown that the  $\gamma$ -form does hydrate to form C-S-H and calcium hydroxide, but that the rate and degree of hydration is much lower than for the other polymorphs, especially  $\beta$ -C<sub>2</sub>S. The C-S-H was similar to that formed by the hydration of  $\alpha$ ,  $\alpha'$ , and  $\beta$  modifications. At the end of five years, only approximately 20-25% of the material had hydrated. At elevated temperatures, especially in the presence of steam,  $\gamma$ -C<sub>2</sub>S is known to react rapidly to form various calcium silicate hydrates (81).  $\gamma$ -C<sub>2</sub>S also reacts rapidly with high concentrations of CO<sub>2</sub> (82), nearly as rapidly as  $\beta$ -C<sub>2</sub>S under the same conditions.

### 2.2.2 Hydration of $\beta$ -C<sub>2</sub>S

#### Effect of Solid Substitutions

Pritts and Daugherty (83) studied the effect of incorporation of small quantities of metal oxides (V<sup>5+</sup>, Cr<sup>6+</sup>, B<sup>3+</sup>, S<sup>6+</sup>, Na<sup>+</sup>, K<sup>+</sup>) on the rate of  $\beta$ -C<sub>2</sub>S hydration, and developed a model relating  $\beta$ -C<sub>2</sub>S to the charge/radius ratio of the stabilizing metal ion. As expected, they found the hydration of  $\beta$ -C<sub>2</sub>S to be temperature dependent and the activation energies of the acceleration stage of hydration to be 14 and 12 kcal/mol for the Cr<sub>2</sub>O<sub>3</sub>-doped and pure C<sub>2</sub>S, respectively. According to these authors, the data were consistent with a silicate polymerization rate-determining step for the acceleration stage of hydration. They concluded that, although it is possible to significantly alter the hydration rate of  $\beta$ -C<sub>2</sub>S by doping it with metal oxides, it still hydrates much more slowly than C<sub>3</sub>S and undoped  $\beta$ -C<sub>2</sub>S. Their data showed that, in all cases, both the calcium and silicon-substituted samples hydrated at lower rates that were inversely proportional to the charge/radius ratio. They concluded that partial replacement of C<sub>3</sub>S (alite) in industrial clinkers by activated  $\beta$ -C<sub>2</sub>S was not possible -- a view which is not universally accepted.

In a related study, Maycock and McCarty (84) explored the mechanism of  $\beta$ -C<sub>2</sub>S stabilization by metal oxides and discussed the subsequent reactivity of the doped product. Using a solid

state physics approach — interpreting the electrical conductance of the solids — they concluded that generation of point defects by adding impurities is not as important to the stabilization process as is the precipitation of impurity phases during the cooling process. The influence of lattice defects, generated by mechanical grinding and heating of  $\beta$ - $C_2S$  (and  $C_3S$ ), was studied by Maycock et al. (14) and Opoczky and Juhasz (85). Maycock et al. showed that lattice imperfections influenced both the pre-induction and the induction stages of hydration by enhancing the diffusion of ions within the solid particle. They argued that introduction of lattice defects in the unhydrated solid could not affect the solution processes or the diffusion through a "first hydrate" layer. Using thermoluminescence and quadrupole mass spectrometry, Fierens and Trilocq (86) have shown that the differences in the rate of hydration of  $\beta$  and  $\gamma$  modifications are not related to the very first stage of hydration (chemisorption of water on the anhydrous surface) because the sorption of water vapor is the same for both polymorphic forms.

#### Reaction Mechanisms

It is our opinion that the experimental evidence indicates substantial similarities between the hydration mechanisms of  $C_3S$  and  $\beta$ - $C_2S$ . The different hydration rates are believed to be a consequence of the differences in crystal structure between the two silicates. Therefore, the hydration of  $\beta$ - $C_2S$  and  $C_3S$  can be discussed in similar mechanistic terms. Major differences are the lack of high supersaturation with respect to CH and the low rate of heat evolution, which makes it difficult to study the reaction calorimetrically. The overall composition and morphology of C-S-H formed from  $C_2S$  and  $C_3S$  appear to be similar, but there are definite differences in microstructural details (87).

Tong and Young (88) have shown that, during hydration of  $\beta$ - $C_2S$ , the rate of release of ionic species is slow, with a consequent low degree of supersaturation and slow increase in the ionic product,  $K_{1p}[CH]$ . If, as is assumed, the degree of supersaturation is related to the nucleation of CH and C-S-H, then the small supersaturation observed for  $\beta$ - $C_2S$  will mean slow rates of hydration. It has been found (87) that larger CH crystals are formed in  $\beta$ - $C_2S$  than in  $C_3S$  pastes, as would be expected from a low degree of supersaturation. With small amounts of  $C_3S$  in the  $\beta$ - $C_2S$ , the crystallization of  $Ca(OH)_2$  and, thus, the  $\beta$ - $C_2S$  hydration proceed at a higher rate (89) because the faster hydrolysis rate of  $C_3S$  essentially restores the high degree of supersaturation needed for rapid formation and growth of nuclei.

The usefulness of liquid phase studies has also been demonstrated recently by Fujii and

Kondo (74). They consider the early hydration of  $\beta$ - $C_2S$  and  $C_3S$  to proceed in a similar manner. After initial congruent dissolution of the silicate, water molecules adsorb on the surface of the particles, and "CSH(I)" precipitates from solution, thereby causing a decrease in silicate ion concentration. Eventually, nuclei of calcium silicate hydrate, with a time-variable C/S, form and grow on the surface of the particles, while  $Ca^{2+}$  and  $OH^-$  diffuse into the solution and cause a supersaturation with respect to calcium hydroxide. At the maximum supersaturation (~80 hours after contact with  $H_2O$ ), the hydration of  $\beta$ - $C_2S$ , unlike that of  $C_3S$ , starts to accelerate; when the degree of hydration reaches approximately 20%, deceleration, followed by a renewed acceleration, is observed.

In saturated lime solution, the deceleration stage was found to be more pronounced, but no explanation for this phenomenon was given. Based on liquid phase and microscopic experimental data, and several assumptions (some of them, unfortunately, contradicted by experimental evidence, e.g., fixed C-S-H composition independent of time and temperature of hydration, and congruent dissolution of  $\beta$ - $C_2S$ ), the authors conclude that 1) the early  $\beta$ - $C_2S$  hydration may be a "propagative surface-nucleation-growth reaction," 2) the second acceleration stage is peculiar to  $\beta$ - $C_2S$ , and 3) in contrast to  $C_3S$ , the precipitation of CSH(I) at the very early stages of interaction with water does affect the hydration rate.

Recently,  $\beta$ - $C_2S$  hydration was studied (90) using ESCA and high-resolution SEM. As has been reported for  $C_3S$  (13), non-uniform etching of the surface was observed. Hydration products were observed on the surface at times as short as 15 seconds after contact with water (Fig. 11).

0.1  $\mu m$

### Influence of Admixtures and Special Treatments

Compared to the voluminous literature on the effect of admixtures on the hydration of tri-calcium silicate and cement, relatively few studies have been performed in recent years on the hydration of dicalcium silicate in the presence of admixtures.

Effect of Calcium Chloride. It is assumed that the effects of  $\text{CaCl}_2$  on the hydration of  $\beta\text{-C}_2\text{S}$  and  $\text{C}_3\text{S}$  are similar (43,44), although mechanistic interpretations are virtually nonexistent. It is generally agreed, however, that  $\text{CaCl}_2$  accelerates  $\beta\text{-C}_2\text{S}$  to a lesser degree than  $\text{C}_3\text{S}$ . According to Zharov and Demel (91), the dissolution of  $\beta\text{-C}_2\text{S}$  in the initial stages of hydration, both with and without  $\text{CaCl}_2$ , is incongruent. This result contradicts data given by others (11,74,84). The authors (91) found the 28-day strengths of  $\text{CaCl}_2$ -doped  $\text{C}_2\text{S}$  pastes to be 10-15 percent higher than those of chloride-free samples, whereas Young and Tong (87) did not observe significant differences in tensile strength. Klyusov *et al.* (92) studied the effect of  $\text{CaCl}_2$  and  $\text{NaCl}$  upon  $\beta\text{-C}_2\text{S}$  hydration at temperatures of 20°, 5°, 0° and -5°C. As expected, the rate of reaction with water at lower temperatures decreased, and  $\text{NaCl}$ , but not  $\text{CaCl}_2$ , decelerated hydration. Young and Tong believe that, as in the case of  $\text{C}_3\text{S}$ ,  $\text{CaCl}_2$  controls the composition of the solution.

Effect of Carbonation. Studies of the effect of  $\text{CO}_2$  on calcium silicate hydration, initiated in the early 1970's (93-95), have been continued. The most recent work published on carbonation of  $\beta\text{-C}_2\text{S}$  and  $\text{C}_3\text{S}$  was by Goodbrake *et al.* (70, 96). As was the case for  $\text{C}_3\text{S}$ , the  $\beta\text{-C}_2\text{S}$  reaction with  $\text{CO}_2$  and water followed a decreasing-volume, diffusion-controlled kinetic model. The activation energy of this exothermic reaction was found to be approximately 17 kcal/mol and the heat of formation -44 kcal/mol. The degree of carbonation increased with increasing reaction temperature, particle surface area, reaction time, relative humidity, and partial pressure of  $\text{CO}_2$ . The ultimate reaction products were identified as aragonite and silica gel. In the presence of water vapor, only very small amounts of C-S-H were found in the early stages of carbonation; but, when liquid water was present, considerable quantities of C-S-H were formed (96). It is believed that the initial reaction is:

followed by carbonation of the C-S-H:

The reaction is similar to Equations 6 and 7 for  $\text{C}_3\text{S}$ , and the composition of the initial C-S-H is probably similar to that formed in ordinary hydration. Calcite is now the predominate form of calcium carbonate.

Highly reactive  $\beta\text{-C}_2\text{S}$ . Roy and co-workers (97, 98), using the evaporative decomposition of solutions (EDS) technique, succeeded in preparing  $\beta\text{-C}_2\text{S}$  with a reactivity 10 times higher than that of a comparable, conventionally prepared  $\beta\text{-C}_2\text{S}$ . By pumping a fine mist of solution of  $\text{Ca}(\text{NO}_3)_2 \cdot \text{aq}$  and colloidal  $\text{SiO}_2$  into a long hot zone at a temperature of 750° to 1050°C, they formed  $\text{C}_2\text{S}$  by the reaction:

Similar experiments were done with  $\text{CaCl}_2$ . The preliminary data showed that the quality of the  $\text{C}_2\text{S}$  formed depended on the choice and concentration of the feed solution and on the temperature of its decomposition. Attempts to form  $\text{C}_3\text{S}$  at low temperature failed: a feed solution of C:S = 3:1 yielded  $\text{C}_3\text{S}$  only at temperatures above 1250°C.

Under hydrothermal conditions, the  $\beta\text{-C}_2\text{S}$  produced by EDS was found to be much more reactive than  $\beta\text{-C}_2\text{S}$  prepared by usual techniques (99). Reactive, finely divided  $\beta\text{-C}_2\text{S}$  has also been obtained (100) by calcining carbonated wolastonites at 700-900°C.

### 2.2.3 Hydration of $\alpha'$ - and $\alpha\text{-C}_2\text{S}$

As is the case with the  $\gamma$  and  $\beta$  polymorphs, the reactivity of the high-temperature  $\alpha'$  and  $\alpha$  forms depends on the impurities used to stabilize the structure. Although earlier studies reported the  $\alpha\text{-C}_2\text{S}$  to be non-reactive, Ono *et al.* (101) showed that doped  $\alpha'$  and  $\alpha$  forms could react with water.

According to Bensted (80,102-104),  $\alpha'$ - and  $\alpha\text{-C}_2\text{S}$  are less reactive than the  $\beta$  form but much more reactive than the  $\gamma\text{-C}_2\text{S}$ . It has been reported that the reactivity of the  $\text{C}_2\text{S}$  polymorphs can be correlated with the concentration of lattice defects (105); the density of pits in the etched surfaces was found to be  $\beta\text{-C}_2\text{S} > \alpha'\text{-C}_2\text{S} > \alpha\text{-C}_2\text{S}$ . This finding does not agree with those reported by Maycock and McCarty (84).

Jelenic *et al.* (106) found  $\text{B}_2\text{O}_3$ -doped  $\alpha'\text{-C}_2\text{S}$  more reactive than a comparable sample of  $\beta\text{-C}_2\text{S}$ : both the degree of hydration and the compressive strength were found to be higher in the  $\alpha'$  form. Using electron microscopy and diffraction techniques, the authors attributed the larger reactivity of  $\alpha'\text{-C}_2\text{S}$  to differences in crystal imperfections.

The reactivity of  $\alpha$ - and  $\alpha'\text{-C}_2\text{S}$  thus must be considered to be sensitive to specimen-specific conditions, such as its thermal history, and type and level of stabilizing oxides. It is possible that exsolution of impurities during the phase transformations at lower temperature could cause reactive grain boundary precipitates as well as crystal defects.

### 2.3 Tricalcium Aluminate

#### 2.3.1 Mechanisms of Hydration

A well-established theory is that the rate-controlling step of C<sub>3</sub>A hydration is diffusion through a layer of "hexagonal hydrates" (C<sub>4</sub>AH<sub>13</sub> and C<sub>2</sub>AH<sub>8</sub>), which forms rapidly at the surface of each grain (107). Since these hydrates convert rapidly to C<sub>3</sub>AH<sub>6</sub> — due to the large heat of hydration of C<sub>3</sub>A which raises the temperature of pastes to critical levels — this barrier does not persist, and the C<sub>3</sub>A rapidly hydrates completely, primarily to C<sub>3</sub>AH<sub>6</sub>.

Corstanje *et al.* (107) have deduced from studies of mixtures of C<sub>3</sub>S + C<sub>3</sub>A + C<sub>2</sub>SH<sub>2</sub> that the primary cause of C<sub>3</sub>A retardation is not the sulfate ion but the precipitation of amorphous Al(OH)<sub>3</sub> on the surface of the C<sub>3</sub>A grain. The formation of the hexagonal hydrates (C<sub>4</sub>AH<sub>13</sub>, C<sub>4</sub>ASH<sub>12</sub>, and their solid solutions) provides an "insulating layer" that isolates each grain from the bulk of the solution. This layer is not sufficient in itself to severely retard C<sub>3</sub>A hydration since water and ions can move through it. However, their flow is sufficiently slow to allow the solution beneath the layer, in contact with the surface, to maintain a different composition from the bulk. Thus, subsequent formation of C<sub>4</sub>AH<sub>13</sub> depletes the solution in contact with the C<sub>3</sub>A grain in Ca<sup>2+</sup>, thereby causing Al(OH)<sub>3</sub> to precipitate:

Although C<sub>4</sub>ASH<sub>12</sub> can act as an "insulating layer", its formation will not cause the precipitation of AH<sub>3</sub> since Ca<sup>2+</sup> ions are supplied by the gypsum present. Breakdown of the insulating layer, e.g., by conversion to C<sub>3</sub>AH<sub>6</sub>, will cause the AH<sub>3</sub> layer to be broken down by the high concentrations of Ca<sup>2+</sup> and OH<sup>-</sup> in the bulk solution, and C<sub>3</sub>A will continue to hydrate. In the absence of sulfate ions, this happens quite readily.

It can be seen from Fig. 12 that the conduction calorimetric curves can be quite complex and are significantly influenced by the different amounts of C<sub>3</sub>S and gypsum present. Evidence is presented for a sequence of unusual reactions that occur in the presence of these additional compounds:

The last reaction gives an endothermal effect (Fig. 12). This sequence apparently is most noticeable at intermediate gypsum additions for reasons that are not clear. If the insulating layer were not present, then the diffusion of ions into the surrounding solution would not allow concentrations sufficient for the precipitation of AH<sub>3</sub> when C<sub>4</sub>AH<sub>13</sub> first forms. Periodic breakdown of the insulating layer, e.g., by conversion to C<sub>3</sub>AH<sub>6</sub>, would allow the AH<sub>3</sub> retarding layer to be attacked by Ca<sup>2+</sup> and OH<sup>-</sup> in the bulk solution, and C<sub>3</sub>A would continue to hydrate.

Tadros *et al.* (108) suggested that retardation by the hexagonal hydrates does not play a significant role. They studied the kinetics and stoichiometry of C<sub>3</sub>A dissolution in water and HCl and found initial dissolution to be incongruent by both solution and surface analyses: more calcium and fewer aluminum ions were released into solution compared to the stoichiometry of C<sub>3</sub>A. In the experiments in which C<sub>3</sub>A was reacted with HCl solution, an induction period was observed, at the end of which the pH rose sharply (Fig. 13). The authors suggested that the primary retardation of the dissolution was caused by formation of an Al-rich layer, and that the induction period represented the process responsible for the removal of the Al-rich layer. The time required for these processes to occur was long in the presence of HCl but was short when C<sub>3</sub>A was reacted with neutral water. Hydrolysis of Al<sup>3+</sup> to form polynuclear complexes such as [Al<sub>8</sub>(OH)<sub>20</sub>]<sup>4+</sup> and Al(OH)<sub>4</sub><sup>-</sup> may represent such processes.

Both of these theories, while ultimately predicting the formation of some kind of aluminum hydroxide, approach the problem from quite different perspectives and must be considered to be speculative at this time. Surface analysis, high resolution SEM, thermal analysis, and solution chemistry will all have their part to play in unraveling the complexities of C<sub>3</sub>A hydration, particularly the early formation of precipitates. The initial formation of an amorphous gel, first observed by Breval (109) (see Fig. 14), is perhaps pertinent here. It can be considered to be either AH<sub>3</sub> or the precursor of C<sub>4</sub>AH<sub>13</sub> through reaction with Ca<sup>2+</sup> and OH<sup>-</sup> from solution. Knowing that crystalline hexagonal hydrates grow from the gel layer, we may not be have to invoke the special conditions of precipitation suggested by Corstanje *et al.* (107).

The exact role of the Al-rich layer in the overall hydration of C<sub>3</sub>A is not yet clear. Does it persist through the hydration process, or is it no longer capable of forming once C<sub>3</sub>AH<sub>6</sub> nucleates and grows? In pure water, the induction period will be quite short, as observed by Spierings and Stein (110), and the gel (or aluminum hydroxide) may be responsible for the later retardation of C<sub>3</sub>A. To further understand the consequences of initial hydrolysis and early formation of precipitates, we will need to investigate this part of the reaction in considerably greater detail, drawing on a wide range of solid state

(a)

analyses. These early reactions are of considerable importance in characterizing the retardation by sulfate ions and organic molecules.

### 2.3.2 Hydration Products

Breval (109) has exhaustively studied the sequence of product formation in  $C_3A$  hydration and has confirmed the overall findings of numerous early studies. She has, however, developed some new interesting details (see Fig. 15). Gel formation is apparently the precursor of the hexagonal hydrates, which grow first as thin, irregular flakes with poor X-ray diffraction patterns. With time, these flakes can grow to better crystallized, hexagonal forms, but this process competes with the transformation to  $C_3AH_6$  at normal ambient temperatures. Breval suggests that thin hexagonal plates, which are observed only at low hydration temperatures, may be formed from a secondary precipitation process rather than by growth from the gel. According to Breval's data,  $C_3AH_6$  forms at or below  $20^\circ C$ , somewhat lower than the generally accepted transformation temperature. This may well indicate that even when very small quantities of  $C_3A$  are hydrated in large quantities of water ( $\sim 2$  mg  $C_3A/100$  mg water), local temperature rise at the surface of grains may nucleate  $C_3AH_6$  in the gel layer. The fact that  $C_3AH_6$  has been reported in pastes hydrated as low as  $-5^\circ C$  (111), where its formation is excluded thermodynamically, lends credence to this view. Once nuclei have formed, it is likely that they can slowly grow at this low temperature to form large isolated crystals. The gel persists above  $60^\circ C$  as a transient phase, but then  $C_3AH_6$  forms directly from  $C_3A$  as an aggregate, or matrix, around the grain. Breval's data re-emphasize the importance of the heat of hydration in controlling the hydration products in small quantities of pastes or slurries ( $\sim 100$  mg  $C_3A/100-500$  mg  $H_2O$ ), since  $C_3AH_6$  is the major hydration product even at  $-5^\circ C$ . Simulating the hydration of  $C_3A$  under conditions that might approximate those of a cement paste would consequently present considerable difficulties.

Figure 15. Sequence of formation of  $C_3A$  hydration products (adapted from ref. 109).

### 2.3.3 Effect of Prehydration

Another topic of potential technological significance is the effect of prehydration of  $C_3A$  upon contact with water vapor. This phenomenon can have a profound influence on the subsequent performance of the cement because changing the course of  $C_3A$  hydration can affect the sulfate balance and the way admixtures interact with cement. Since no liquid water is involved, at least some of the  $C_3A$  can interact without sulfate ions being present, as was found by Breval (112,113). From this study, she concluded that, if the bound water ( $W_k$ ) is less than 3%, the hydration products formed do not interfere with subsequent hydration in water. If, however,  $W_k > 3\%$ , the hydration products profoundly influence the products during subsequent hydration, leading primarily to the formation of  $C_3AH_6$ .

Wittmann (114), using thermoluminescence to study the vapor hydration of  $C_3A$ , has reported that initially metastable hydration centers are created, which can be destroyed by subsequent heating or drying. With increasing relative humidity, these centers become stable. No other studies of this nature have been reported, although the influence of prehydration on the subsequent reaction with sulfates and other admixtures is clearly of interest. Studies of prehydration

could be quite valuable in helping to elucidate hydration mechanisms.

### 2.3.4 Effect of Admixtures

#### Alkalies

It is now well known that sodium can substitute readily in  $C_3A$ , thereby inducing different crystal modifications. There seems to be general agreement (110,115-117) that the reactivity of  $C_3A$  markedly decreases as the  $Na_2O$  content in the crystal increases. This has been attributed (116, 118) to the formation of a less reactive structure as  $Na^+$  ions fill the holes in the lattice. Spierings and Stein (110), on the other hand, believe that the lower reactivity is due to the effects of  $Na^+$  after it is released into solution. When  $Na_2O$  was incorporated into  $C_3A$ , the time of conversion to  $C_3AH_6$  during hydration, as observed by calorimetry, increased considerably, and the size of the heat peak was markedly reduced. With increasing  $Na_2O$  content, this effect was much less pronounced.

To further understand the reactions, Spierings and Stein (110) hydrated pure  $C_3A$  in various concentrations of  $NaOH$ . The calorimetric data were rather complex and suggested that both  $OH^-$  and  $Al(OH)_4^-$  were influencing the reaction, but the effects appeared to be independent of the cation. As the concentration of  $NaOH$  increased up to 0.1 M, the early reactivity of  $C_3A$  decreased markedly. On the basis of conductivity measurements, this result was attributed to the precipitation of a retarding, amorphous  $Ca(OH)_2$  precipitate, promoted by the highly alkaline conditions. The formation of  $Al(OH)_4^-$  would, in this case, tend

to prevent precipitation of  $\text{AH}_3$  and to favor the formation of  $\text{C}_2\text{AH}_8$  rather than  $\text{C}_4\text{AH}_{13}$ . The calorimeter peak corresponding to conversion to  $\text{C}_3\text{AH}_6$  became increasingly retarded and smaller as NaOH was added, suggesting that the hexagonal hydrates, or gel, were stabilized with respect to  $\text{C}_3\text{AH}_6$ . This peak occurred earlier at high concentrations of NaOH, and it also became sharper, although the area under the peak did not change very much. Spierings and Stein (110) attributed this result to the decreasing stability of the hexagonal hydrates, but their calorimetry data indicated that the overall hydration of  $\text{C}_3\text{A}$  decreased as the concentration of NaOH in solution increased.

### Sulfates

Tadros *et al.* (108), Skalny and Tadros (119), and Mehta (120) have recently questioned the role of ettringite in the retardation of  $\text{C}_3\text{A}$  by sulfate ions. In studies of the dissolution of  $\text{C}_3\text{A}$  in acid media, it was found (108,119) that the induction period, discussed above (Fig. 12), was significantly increased in the presence of sulfate ions. This was attributed to the adsorption of sulfate ions on the positively charged surfaces, and a Langmuir-type adsorption isotherm was found to apply. Increasing the concentration of sulfate ions resulted in a decrease in the positive surface charge, but charge reversal did not occur. At the concentrations used, no precipitation of ettringite was observed, although substantial retardations were found. Similar results were obtained with additions of  $\text{CaSO}_4$  or  $\text{Na}_2\text{SO}_4$ .

Fierens *et al.* (121) observed from thermoluminescence studies that the initial reactivity of  $\text{C}_3\text{A}$  did not influence its reaction with gypsum, in contrast to its behavior in pure water. This observation could be explained by a rapid adsorption of sulfate ions on active surface sites. For  $\text{C}_3\text{A}$  in cements, Locher *et al.* (122) found an induction period lasting several hours, which was independent of sulfate concentration (the clinkers contained some alkali sulfates) and the formation of ettringite and hexagonal hydrates (monosulfoaluminate?).

Collepardi *et al.* (123) have challenged these conclusions in a new study of the system  $\text{C}_3\text{A}-\text{CH}-\text{CSH}_2-\text{H}$ . They observed that retardation of  $\text{C}_3\text{A}$ , as determined by isothermal conduction calorimetry and by DTA, occurred only when ettringite was formed. Thus, when  $\text{Na}_2\text{SO}_4$  was added, there was little early retardation because ettringite did not form. The effect of the sulfates on later hydration is not clear from this study. Retardation was greatest when both  $\text{CSH}_2$  and CH were present, a fact attributed to the presence of small, colloidal-sized crystals of ettringite that form under such conditions (124,125). Mehta (124) suggests that this is a gel-like form of ettringite. It is noteworthy that, in such systems, a gel-like coating apparently precedes the growth of identifiable ettringite crystals (126) and appears remarkably

similar to that observed by Breval (109) in sulfate-free systems.

Corstanje and co-workers (107) took a slightly different point of view. At S/A molar ratios where ettringite can be detected, retardation was observed; but, at S/A ratios less than 0.10, when ettringite does not form,  $\text{CSH}_2$  tended to promote  $\text{C}_3\text{A}$  hydration. As discussed above, monosulfoaluminate can form an "insulating layer," but its formation does not promote  $\text{AH}_3$  precipitation to the same extent as  $\text{C}_4\text{AH}_{13}$  formation.

These various studies come to disparate conclusions; clearly, more work needs to be done to clarify the situation. As in the case of sulfate-free hydration, the evidence indicates that, after the initial hydrolysis, a gel forms which can cause retardation. In this case, the gel undoubtedly contains  $\text{SO}_4^{2-}$  ions, and the relative proportions of calcium, aluminum, and sulfate may well determine how readily the gel may recrystallize to other hydration products — ettringite, hexagonal hydrates, or  $\text{C}_3\text{AH}_6$ . Such a hypothesis is an extension of that suggested by results of studies on sulfate-free systems and considers ettringite formation to be the process following the initial retardation.

The apparent contradiction between the studies discussed here can be reconciled if it is remembered that the conditions of hydration were very different. Skalny and Tadros (119) studied suspensions, whereas Collepardi *et al.* (123) studied pastes. A brief induction period of about 15 sec was observed (126) in pastes and could well have occurred in Collepardi's systems also. Corstanje and his associates investigated  $\text{C}_3\text{A}$  hydration in the presence of  $\text{C}_3\text{S}$ , and Locher *et al.* studied  $\text{C}_3\text{A}$  in portland cement. It might be useful to consider three sequential retarding steps, any one of which may be the dominant mechanism for a given set of conditions:

- 1) Formation of a hydrolyzed double layer, which is important in dilute suspensions
- 2) Formation of an amorphous hydration product (gel), which may be most important in cement pastes
- 3) Formation of ettringite, which dominates retardation in pastes of  $\text{C}_3\text{A}$  and gypsum.

Recent studies (126,127) have confirmed earlier observations that monosulfoaluminate may form even when gypsum is still present. Evidently, the crucial factor is the reactivity of  $\text{C}_3\text{A}$  compared to the rate of release of sulfate ions from the gypsum crystals, i.e., the sulfate balance must be assessed from a kinetic viewpoint as well as from stoichiometric considerations.

### Chlorides

Although calcium oxychloride has not been recognized as a normal hydration product of

C<sub>3</sub>A in the presence of chlorides, its formation has been reported by Lepnev *et al.* (111) in pastes containing CaCl<sub>2</sub> — but not NaCl. However, Traetteberg and Grattan-Bellew (127) confirmed earlier conclusions that C<sub>3</sub>A·CaCl<sub>2</sub>·10H<sub>2</sub>O forms along with C<sub>4</sub>AH<sub>13</sub>, and that the formation of oxychloride is dubious, or, at best, occurs only under special conditions. C<sub>3</sub>A·CaCl<sub>2</sub>·10H<sub>2</sub>O has an X-ray diffraction pattern very similar to that of C<sub>4</sub>AH<sub>13</sub>, and a solid solution may exist between the two (127). The chloroaluminate hydrate may be mistakenly identified as α-C<sub>4</sub>AH<sub>13</sub>. Calcium chloride accelerates the formation of ettringite (127). With high proportions of chloride (16 wt. %), the chloroaluminate hydrate forms before ettringite converts to monosulfoaluminate. This finding agrees with previous results of Tenoutasse (128).

#### Other Inorganic Admixtures

Holten and Stein (129) studied the effects of finely divided quartz on the reactions between C<sub>3</sub>A and CSH<sub>2</sub> under conditions where ettringite was the stable phase. They found that the quartz significantly increased the rate of reaction of C<sub>3</sub>A and concluded that this was primarily due to the formation of ettringite on quartz particles, which prevented it from acting as an "insulating layer" of the type described earlier. This explanation ignores the possibility of any reaction between quartz and the solution, even though some chemical activity might be expected. A similar phenomenon might be expected in the case of natural pozzolanic silicas, but, in this case, the initial reaction of C<sub>3</sub>A was retarded compared to that with quartz (130). The effect of the pozzolans was to increase the conversion to C<sub>3</sub>AH<sub>6</sub> in gypsum-free systems, and to increase the rate of consumption of calcium hydroxide whether or not sulfate was present. It is even more likely in this case that the silica was chemically active in the system, and it is thus tempting to attribute the accelerated consumption of CH to the formation of calcium silicoaluminate hydrate, recently reported by Regourd *et al.* (131).

Tashiro and Oba (132) reported that oxides that retarded the hydration of C<sub>3</sub>A (e.g., Cu(OH)<sub>2</sub> and ZnO) stabilized the hexagonal hydrates with respect to C<sub>3</sub>AH<sub>6</sub>, while those that accelerated hydration (e.g., PbO) increased the rate of conversion. This result is analogous to the influence of organic admixtures (133). Both Cr<sub>2</sub>O<sub>3</sub> (132) and CaCrO<sub>4</sub> (134,135) also retard the hydration of C<sub>3</sub>A. The effect of CaCrO<sub>4</sub> is attributed to the initial formation of the chromate analog of ettringite, which later transforms to the hexagonal C<sub>3</sub>A·CaCrO<sub>4</sub>·nH<sub>2</sub>O. The X-ray diffraction pattern of this compound appears to be similar to that of C<sub>2</sub>AH<sub>8</sub>, and the peaks attributed by Tashiro and Oba to C<sub>2</sub>AH<sub>8</sub> may actually result from the presence of C<sub>3</sub>A·CaCrO<sub>4</sub>·nH<sub>2</sub>O or the cuprate and zincate analogs. Ti<sub>2</sub>CO<sub>3</sub> retarded the reaction of C<sub>3</sub>A with gypsum (136), and calcium carboaluminate hydrate was detected in the system.

#### Organic Admixtures

Ramachandran (137) reported that triethanolamine accelerated the hydration of C<sub>3</sub>A both with and without sulfate, increasing the amount of C<sub>3</sub>AH<sub>6</sub> or ettringite formed in the first few minutes. No changes in the nature of the hydration products were observed. Milestone (138) showed that sugar acids such as gluconic acid, which are formed as oxidation products of sugars, were very effective retarders of C<sub>3</sub>A hydration. Gluconic acid was about 10 times more effective than glucose, for example. The retarding power of commercial lignosulfonate admixtures was attributed (139) to the presence of small, but significant, quantities of sugar acids.

Milestone's study confirms that retardation is accompanied by the stabilization of the hexagonal hydrates due to organic molecules entering the crystal lattice. Since it has been shown that the hydrates are poorly crystalline in the presence of retarders, it could be argued that organic retarders impede the crystallization of the initial gel layer to the hexagonal hydrates and C<sub>3</sub>AH<sub>6</sub>. The effect will depend on both the concentration and the alkaline stability of the admixture. Compounds that retard the hydration of pure C<sub>3</sub>A also retard its reaction with calcium sulfate. This would be expected if the admixtures affect the initial gel layer, regardless of whether it contains sulfate ions. This would also explain why accelerators such as triethanolamine react the same way in both systems.

Normally, a retarder is added with the mixing water; but, when it is added after a few minutes of hydration, retardation increases (133). The degree of retardation is assumed to be controlled by the concentration of the admixture in solution which, in turn, is controlled by the degree to which the retarder is removed from solution by sorption on the solid materials. Sorption is greater when the retarder is added during the initial formation of the hydration products. In a recent study (126), a retarder, citric acid, was allowed to contact the solid surfaces of a C<sub>3</sub>A-CSH<sub>2</sub>-C mixture before water was added. The result was a longer induction period followed by increased reactivity and then prolonged retardation (Fig. 16). When the citric acid was allowed to come in contact with C<sub>3</sub>A only, early reactivity increased even more, but no subsequent retardation occurred. Clearly, the competition between citric acid and water at different solid surfaces is an important factor.

What causes some organic compounds to be accelerators and some retarders? It has previously been shown (133) that retarders are good chelating agents; yet, accelerators, such as triethanolamine or 8-hydroxyquinoline, are also excellent chelating agents. An accepted view is that chelation with the aluminate ion [Al(OH)<sub>4</sub><sup>-</sup>] may accelerate the initial hydrolysis of C<sub>3</sub>A by changing the chemical potential of species in solution and thereby preventing immediate precipitation of a gel. Evidence for the formation of aluminate complexes has been summarized elsewhere (133). Once precipi-

pitiation of a gel starts, removal of some of the admixture by adsorption in the gel or crystalline hydration products will allow further rapid precipitation, thereby causing flash set. The initial acceleration is usually followed by retardation of later reactions, as would be expected if the adsorbed admixture can interfere with recrystallization of the hydration products. As postulated by Skalny and Tadros (119) for sulfate retardation, the organic molecules in very strong retarders may adsorb on the Al-Ca double layer, which would inhibit even initial hydrolysis. Adsorption of this kind has been suggested by Jawed *et al.* (57) for lignosulfonate-alkali carbonate combinations in cement. The relative importance of adsorption on hydration products in any particular case will depend on the molecular structure and concentration of the admixture.

### 2.3.5 The Nature of the Retarding Layer

The recent results discussed above clearly require a reformulation of the previously accepted view of retardation. Although the formation of an Al-rich layer at the surface of each  $C_3A$  grain may occur initially, other evidence points to the formation of a second retarding layer by precipitation processes, which probably accounts for secondary, extended retardation. It may not be necessary to postulate the existence of precipitates of distinct chemical composition as suggested by Stein and co-workers. The retarding layer can be considered as a co-precipitate of aluminum and calcium hydroxides and sulfates, the exact composition of which depends on the surrounding solution. The degree of condensation of the alumina phase will also depend on the nature of the solution. From this amorphous precipitate — Breval's gel phase — can grow  $C_4AH_x$ ,  $C_2AH_8$ ,  $C_4ASH_{12}$ ,  $C_6AS_3H_{32}$ , or  $C_3AH_6$ , depending on the particular circumstances. However, the gel phase could be a hydrolyzed layer similar in principle to the protective layers suggested for  $C_3S$  hydration. Minor components or admixtures, such as alkalies, chlorides, organic molecules, etc., may also enter the gel and modify crystal growth by random substitution in the lattice of the hexagonal hydrates. This mechanism would have much in common with other cementitious systems, that of  $C_3S$  and  $C_2S$ , monocalcium aluminate, or magnesium oxychloride.

### 2.4 The Ferrite Phase

Recent studies (140-150) have confirmed previous conclusions that hydration of the ferrite phase (Fss) is very similar to that of  $C_3A$ , both in the presence and absence of sulfate. Reactivity increases with increasing A/F ratio (140,141), but Fss reacts more slowly than  $C_3A$  (141,142).

Figure 16. Hydration of  $C_3A$ - $CSH_2$ -C mixture with citric acid (CA) added at different times (adapted from ref. 126): (a) Rate of heat evolution in the first few minutes, (b) Rate of heat evolution over several hours.

#### 2.4.1 Hydration Studies

##### Hydration Without Sulfate

At low temperatures,  $C_4(A,F)H_{19}$ , usually detected as  $C_4(A,F)H_{13}$ , is the stable product; but, at about  $20^\circ C$ , it soon converts to  $C_3(A,F)H_6$ . Ramachandran and Beaudoin (150) considered the conversion of  $C_4(A,F)H_{19}$  to  $C_3(A,F)H_6$  to be slower than in  $C_3A$  hydration — possibly because  $C_3A$  pastes may reach very high temperatures due to the high heat of hydration. Thus, the conversion of the hexagonal hydrates to  $C_3AH_6$  cannot be

distinguished calorimetrically unless the reaction is retarded. In contrast, the conversion to  $C_3(A,F)H_6$  in  $C_4AF$  pastes can be readily separated (see Fig. 17) (67), and the process  $C_4AF$  in which  $C_3(A,F)H_6$  has already formed. At higher temperatures ( $>50^\circ C$ ), only  $C_3(A,F)H_6$  is formed. Although Bensted (142) claims that the hydration of the ferrite phase should be studied only in the presence of calcium hydroxide to simulate conditions in a portland cement paste, others (140,141) have shown that its presence has very little effect on the hydration kinetics and does not change the hydration products. Sanzhaasuren and Andreeva (148) found, however, that calcium hydroxide retarded the conversion of  $Ca_4(A,F)H_{13}$  to  $C_3(A,F)H_6$ .

Fig. 17 - Influence of seeding on hydration of  $C_4AF$  (ref. 67): (a) No seeding, (b) seeds mixed with  $C_4AF$ , (c) seeds ground with  $C_4AF$ .

Two unresolved questions concerning the hydration of the ferrite phase have been:

- 1) Is amorphous ferric hydroxide (or aluminum hydroxide) formed as required by stoichiometry?
- 2) What is the degree of iron substitution in the hydration products?

Rogers and Aldridge (143) provided direct evidence on these two points. Using the SEM, they observed finely divided particles that contained only iron and must therefore have been ferric hydroxide (or more likely, hydrated ferric oxide). This phase could not be detected by XRD and was therefore amorphous, as is usually assumed. Since no aluminum hydroxide was observed, the reactions must be (143):

These reactions are in general agreement with the degree of Fe-substitution found in the hexagonal hydrates and determined by variations in the d-spacings (Table III). Since there was a small

substitution of iron in all cases, a little Al was probably included in the  $FH_3$ . By contrast, Sanzhaasuren and Andreeva (148), using the same method, estimated 60% F in  $C_3(A,F)H_6$  at  $20^\circ C$  and 50% F at  $50^\circ C$ . Klyusov et al. (151) reported the presence of gibbsite in  $C_4AF$  pastes. It is not clear why different results were obtained for iron substitution in the hydration products.

Table III

DEGREE OF SUBSTITUTION OF Fe IN  $C_3(A,F)H_6$  (Ref. 143)

Temp. of Formation	$C_6A_2F$	$C_4AF$	$C_6AF_2$
$21^\circ C$	$2.5 \pm 1\%$	$6 \pm 3\%$	$30 \pm 3\%$
$50^\circ C$	$3.0 \pm 2\%$	—	$2 \pm 2\%$

Neither Rogers and Aldridge (143) nor Teoreanu et al. (146) found evidence for the formation of  $C_3FH_6$  in these systems, in contrast to the claims of Tamas and Vertes (144). They also found less Fe-substitution than assumed by Vertes and Ranogajec-Komor (145). The interpretations by Vertes and co-workers were based on Mossbauer measurements alone, but Rogers and Aldridge were not able to distinguish between any hydration products —  $C_4(A,F)H_{13}$ ,  $C_4FH_{13}$ ,  $C_3AH_6$ ,  $C_3FH_6$ , or  $FH_3$  — by Mossbauer measurements.  $C_4FH_{13}$  and  $C_3FH_6$  formed only in  $C_2F$  hydration (see below).  $C_3(A,F)H_6$  was unstable at high temperatures and will break down to  $C_3AH_6$ , hematite ( $\alpha-Fe_2O_3$ ), and lime; thus, decomposition was complete at  $150^\circ C$ . In contrast, Teoreanu et al. (146) did not observe  $Fe_2O_3$  above  $75^\circ C$ .

#### Hydration With Admixtures

**Sulfates.** When gypsum is present, the hydration sequence is the same as for  $C_3A$  (141,142,147,152); ettringite is first formed and later converts to monosulfoaluminate when the gypsum is exhausted. The calorimetric curve has the same features as observed for  $C_3A$  (142). However, early hydration of  $C_4AF$  is much more strongly retarded by gypsum than is  $C_3A$ , and, when calcium hydroxide is also present, early hydration practically ceases. It is not clear why this difference occurs; perhaps sulfate adsorption, as discussed for  $C_3A$  hydration, is very effective in first step retardation.

At high gypsum contents, Ramachandran and Beaudoin (152) observed conversion of ettringite to monosulfoaluminate before all the gypsum was exhausted. This may have been caused by local depletions due to the screening action of ettringite. The effect was more noticeable with high temperatures and low porosities.

**Hydration With Chlorides.** When hydrated with  $<3N$   $CaCl_2$  solution (151,153),  $C_4AF$  forms  $C_3(A,F) \cdot CaCl_2 \cdot 10H_2O$  as a major hydration product. Stukalova and Andreeva (153) considered this compound to contain only about 10% F at

concentrations of  $\text{CaCl}_2 > 4.5\text{N}$ . The chloride analog of ettringite forms, but not if  $\text{NaCl}$  is used instead of  $\text{CaCl}_2$  (151). Also,  $\text{C}_4(\text{A},\text{F})\text{H}_{19}$  does not form in the presence of chloride, and only  $\text{C}_4(\text{A},\text{F})\text{H}_{13}$  is observed. As in the case of the  $\text{C}_3\text{A}-\text{CSH}_2$  system,  $\text{CaCl}_2$  accelerates the formation of ettringite from  $\text{C}_4\text{AF}-\text{CSH}_2$  mixtures (154). After the sulfate is consumed,  $\text{C}_3(\text{A},\text{F})\cdot\text{CaCl}_2\cdot 10\text{H}_2\text{O}$  forms rather than monosulfaluminate. These results are in general agreement with earlier studies for  $\text{C}_3\text{A}$  pastes (140). The presence of chloride does not change the stoichiometry of ettringite. The Fe-substitution remains at about 35%.

#### 2.4.2 Hydration of Calcium Ferrites

Hydration of  $\text{C}_2\text{F}$  forms  $\text{C}_4\text{FH}_{13}$  (140,143), which has been shown to initially form as  $\text{C}_4\text{FH}_{19}$ , and amorphous  $\text{FH}_x$  (143). At  $38^\circ\text{C}$ ,  $\text{C}_4\text{FH}_{13}$  converts to  $\text{C}_3\text{FH}_6$  within 1 day, but the latter rapidly breaks down to  $\text{CH}$  and hematite. At  $80^\circ\text{C}$ ,  $\text{C}_3\text{FH}_6$  has never been observed, only its decomposition products. Teoreanu et al. (146) did not observe either  $\text{C}_4\text{FH}_{19}$  or  $\text{C}_3\text{FH}_6$  in their study of  $\text{C}_2\text{F}$  hydration. However, it has been pointed out (143) that these hydrates give the same Mossbauer spectra as  $\text{FH}_x$ , and that XRD is not sensitive unless a good monochromator is used to filter out iron fluorescence. Aldridge and Rogers also studied " $\text{C}_3\text{F}$ " and " $\text{C}_4\text{F}$ ," which are really intimate mixtures of  $\text{C}_2\text{F}$  and  $\text{C}$ . As expected, they behave similarly.  $\text{CF}$  also hydrates in the same way, but much more slowly.

#### 2.4.3 Competition with $\text{C}_3\text{A}$

Since their hydration is so similar,  $\text{C}_3\text{A}$  and the ferrite phase must compete for sulfate ions during the hydration of portland cement. This interaction has not been adequately studied, but Jawed et al. (141) added small quantities of  $\text{C}_3\text{A}$  to  $\text{C}_4\text{AF} + \text{gypsum}$  and found that conversion of ettringite occurred much sooner, depending on the amount of  $\text{C}_3\text{A}$ . The calorimetric curves showed what appeared to be a conversion peak for  $\text{C}_3\text{A}$  followed by one for  $\text{C}_4\text{AF}$ . These results indicate that  $\text{C}_3\text{A}$  competes more effectively for sulfate ions and suggest that local exhaustion of  $\text{SO}_4^{2-}$  may occur near the more reactive  $\text{C}_3\text{A}$  grain. When hemihydrate was used instead of gypsum, the conversion reactions were retarded. It was not clear why this happened, but the more soluble hemihydrate will release  $\text{SO}_4^{2-}$  at a greater rate, thereby allowing  $\text{C}_4\text{AF}$  to form more ettringite initially and so retard its hydration more effectively.

It must be remembered that impure phases are present in portland cement.  $\text{C}_3\text{A}$  may contain up to 10%  $\text{F}$  (corresponding to  $\text{C}_6\text{A}_8/3\text{F}_{1/3}$ ), while the ferrite phase contains  $\text{Si}$ ,  $\text{Mg}$ , and alkalis. The effect of these substitutions might be to lower the reactivity of  $\text{C}_3\text{A}$  (155) and increase the reactivity of the ferrite phase (156), thereby making competition easier.

### 3. HYDRATION OF PORTLAND CEMENTS

Portland cements are composed of clinker minerals and smaller amounts of minor components, e.g., alkali sulfates and  $\text{MgO}$ . In addition, a limited amount of calcium sulfate, usually in the form of gypsum, is added for set regulation. The main clinker minerals in cement are impure forms, containing small quantities of every element that is present in the raw materials.

#### 3.1 Hydration Mechanisms

Selected mechanistic studies performed on cement-water, rather than on pure clinker mineral-water system will be discussed in this section. Because the early development of  $\text{C}-\text{S}-\text{H}$  is primarily due to the hydration of alite, a direct correlation is generally made between the hydration of cements and alite. However, we do not know the precise influence of the  $\text{C}_3\text{A}$  and  $\text{C}_4\text{AF}$  phases on the hydration of the silicates. Neither do we know the exact effect of gypsum, alkalis,  $\text{MgO}$ , etc., on the above interrelationships.

##### 3.1.1 Mechanisms Suggested by Soviet Scientists

The basic cement hydration mechanisms are given special attention in the U.S.S.R. (157). The cement-water system is generally handled as a heterogeneous liquid-solid system with interacting components, in which the development of hardened cement paste properties is the result of condensation of disperse systems. General conclusions regarding the solidification of all cementitious systems are based on theoretical considerations.

Sychev (158) presents views very similar to those discussed earlier in the  $\text{C}_3\text{S}$  section. The low coordination of some surface atoms plays an important role. Thus, for example, the formation of the first hydrates on the surface of an alite particle may well initiate at these active centers. The first hydrate, formed on the surface and initiating the induction period, is believed to be an unstable, semi-permeable film of  $\text{C}_3\text{S}\cdot\text{H}_2\text{O}$ . For structural reasons, some of the  $\text{Ca}$  atoms, not coordinated with the silicate tetrahedra, react with water, thus enabling transfer of  $\text{Ca}^{2+}$  into the liquid phase. The  $\text{C}_3\text{S}\cdot\text{H}_2\text{O}$  membrane changes into a layer of hydrates with  $\text{C}/\text{S} < 3$ , which is more permeable, and the hydration reactions resume to form a cementitious phase with high surface area (acceleration period).

The formation of new phases is related to the surface protonation of calcium silicate particles (which produces an increase of  $\text{pH}$ ), ionization of silica tetrahedra, and formation of a double layer. These phenomena are considered important during the paste structure development. As the  $[\text{Ca}^{2+}]$  in the liquid increases, saturation level is reached, and adsorption of  $\text{Ca}^{2+}$  on the surface leads to formation of hydrates outside the originally formed primary hydrate ("outer product"). Water molecules diffuse through the hydrates to the anhydrous surface forming the

"inner product." The solidification of a cementitious paste is the result of condensation of the solid particles and formation of hydrogen and donor-acceptor bonds at the interparticle contacts. The adhesive and strength properties of the cementitious system are strongly dependent on the electrostatic properties of the cations and their ability to form covalent bonds. In hydrated portland cement, hydrosilicates with lower C/S should have increased strength.

According to Danilov (77), the initial step in the hydration is the transfer of a proton (from water) to the oxygen ions at the cement mineral surface (e.g.,  $C_2S$ ,  $C_3S$ ,  $C_3A$ ). The ions thus formed (e.g.,  $Ca^{2+}$ ) transfer into the solution where they react with water to reach an equilibrium distribution of complexes. These complexes adsorb on the surface, thus passivating it and initiating an induction period. The relative reactivity of the various clinker minerals is ascribed to the differences in the electro-negativity of the metal ions and the ability of the double oxide to protonate. This approach is used to explain the higher hydraulic activity of  $C_3S$  (characterized by the Ca-O-Ca bond) compared to that of  $\beta$ - $C_2S$ , as well as to explain the increased reactivity of  $Al_2O_3$ -substituted alite and the inhibited hydration rate of  $P_2O_5$ -substituted alite. The induction period ends when hydrate nuclei are formed and disrupt the adsorption equilibrium. The kinetics of the crystallization are determined by the location of the new nuclei formed (bulk liquid phase, surface of impurities, or adsorption film). Kapranov (159) and Polak (160) have presented quantitative treatment of the initial hydrolysis and formation of crystal nuclei. Usherov-Marshak and Urzenko (161) also conclude from thermodynamic considerations that nucleation controls cement hydration.

Vydrov (162) considers the hydration of cement to be a topochemical process characterized by the formation on the anhydrous surface of layers consisting of thermodynamically unstable hydrate. These layers can form because the rate of primary hydrate formation is greater than the rate of its concurrent dissolution. The induction period is thus caused by a decrease in the anhydrous surface-to-water interaction. The renewed reactivity (acceleration period) is ascribed by Vydrov to recrystallization of the primary hydrate layer into new hydrates or to its disruption by "internal mechanical stresses of a physico-chemical nature." The hydration process is described as topochemical also by Sorochkin *et al.* (163)

### 3.1.2 Osmotic Pressure Mechanisms

Double *et al.* (31), using high-voltage electron microscopy (HVEM), postulated an analogy with "silicate gardens" and developed the following mechanism. Within minutes after the initiation of hydration, a semi-permeable silicate hydrate envelope forms around the anhydrous silicate grains. The gelatinous envelope separates the anhydrous material from the bulk liquid, thus initiating the induction period.

Whereas calcium ions can diffuse through the membrane, the silicate ions, formed by dissolution of the anhydrous material beneath the membrane, cannot penetrate the membrane and, thus, increase the osmotic pressure. This mechanism, according to the authors, is evidenced by the sharp increase in the  $Ca^{2+}$  concentration but a low silicate concentration in the bulk liquid during the induction period of hydration. When the osmotic pressure is sufficient to rupture the membrane at weak points, the calcium-depleted hydrosilicate is squeezed into the bulk liquid where it recombines with the  $Ca^{2+}$  ions to precipitate tubular fibrils and, possibly, other morphologies. This event marks the initiation of the acceleration period. The mechanism is based mostly on microscopic evidence.

Decrease of the pressure within the membrane enables further dissolution of the cement grains with deposition of C-S-H material (of different morphology and, possibly, composition from that formed in the outer spaces) inside the original grain boundaries. The authors believe that the two different but simultaneous precipitation processes account for the difference in the morphology and composition of the "inner" and "outer" hydration products. However, the mechanism does not address the question of various morphologies as distinguished by Diamond (30). The formation of calcium hydroxide and aluminate hydrates proceeds by the conventional dissolution-nucleation-crystal growth mechanism. A similar mechanism, schematically shown in Fig. 18, was proposed by Birchall and co-workers (32). According to this model, the early hydration of the calcium silicates involves neither nucleation and growth of C-S-H nor a "through solution" mechanism.

Whereas Double *et al.* and Birchall *et al.* used diluted suspensions in a special environmental cell, Jennings and Pratt (27,33) were able to examine pastes of normal consistency in a differentially pumped specimen stage. Their HVEM data also showed the formation of a membrane which they considered permeable to water and Ca, but, in contrast to the above authors, they believed that the end of the induction period, indicated by the disruption of the membrane, was caused by  $Ca(OH)_2$  nucleation on its surface. Solutions rich in  $Ca^{2+}$  and silicate mixed, forming C-S-H of thin-foil morphology, which subsequently rolled up during drying to form acicular Type I C-S-H. Although neither of the above "protective membrane" mechanisms addresses explicitly the function of the aluminate, ferrite, and minor clinker phases in the overall cement hydration mechanism, Jennings and Pratt acknowledge the presence of minor components in the membrane, and suggest that they are responsible for the differences in hydration, as well as in the morphology of hydrates formed from pure  $C_3S$  and portland cements. In contrast to Double *et al.* (31), who reported the existence of hollow C-S-H needles formed by an osmotic mechanism, Jennings and Pratt found hollow acicular needles containing Ca, Si, Al, and S, implying ettringite composition. The situation is unclear, and much

more evidence is needed to explain the available data. Care must be taken in extrapolating observations made on suspensions at high w/s to pastes at normal w/s. High water-solids ratios extend the induction period of C<sub>3</sub>S and may change the mode of formation of C-S-H.

Fig. 18 - Mechanism of hydration proposed by Birchall *et al.* (32)

### 3.1.3 Hollow-Shell Hydration

Barnes *et al.* (164,165) have recently reported the occurrence of "hollow shell" hydration of cement particles. Although first observed at glass-cement interfaces (164), this feature is also found in the bulk of the paste and may occur also in pure silicates. The mode of hydration leading to the observed structure formation is not known, but it is an additional factor that must be ultimately explained in any description of hydration.

## 3.2 Selected Issues

### 3.2.1 Early Structure Formation

The practical implications of the early hydration reactions of cement are found in the setting behavior and early strength development. Specific examples of how these properties are affected by such factors as alkalies, crystal modifications, admixtures, etc., are discussed in

the next sections. Here we briefly review the more general aspects of the subject. The wealth of information available on cement hydration clearly indicates that alite hydration controls early strength development and probably normal setting behavior, although Gebauer (166) has suggested that highly reactive alite may contribute to abnormal setting behavior in certain cases. Adams (167) and Previte (168) have found good correlation between the end of the induction period and the initial set determined by standard ASTM tests; final set occurs about midway through the acceleration period. However, Locher *et al.* (122) believe that normal setting occurs upon the recrystallization of ettringite, rather than by the formation of new hydration products of C<sub>3</sub>S. Schramli (169), considering the effect of C<sub>3</sub>A on the setting of portland cement, points out that such an analysis is complicated by lack of uniformity in 1) methods of determining setting, 2) measurements of C<sub>3</sub>A content, 3) material on which experiments are conducted, i.e., paste, mortar, or concrete, and 4) the changes in cement composition that occur when C<sub>3</sub>A contents are changed.

Locher *et al.* (122) have concluded that the effects of gypsum on setting behavior are due not to changes in the rate of hydration of C<sub>3</sub>A, but to the way the hydration products form. With the correct amount of gypsum, small crystals of ettringite cover the surfaces of the grains and do not affect the rheology of the system. Setting will occur when the ettringite recrystallizes to form larger crystals which bridge the cement grains. If too much sulfate is present, large crystals of ettringite will form initially and cause premature stiffening. Recrystallization of gypsum or precipitation of syngenite will cause the same effect but generally more rapidly. If too little ettringite is present, large crystals of the hexagonal hydrates can form and bridge particles in the same way. In extreme cases, flash setting may occur. Thus, C<sub>3</sub>A causes "abnormal" setting behavior if the SO<sub>3</sub>-C<sub>3</sub>A balance is not correct. Either the reactivity of the sulfate or of the C<sub>3</sub>A (117) or the presence of admixtures (170-173) can affect this balance. In low-C<sub>3</sub>A, Type V cements, C<sub>4</sub>AF may play the same role as C<sub>3</sub>A. Frigione (174) has studied the false set caused by gypsum dehydrated in the grinding mills.

It must be remembered that the effects on setting and early hardening may be quite different because of the concomitant effects on C<sub>3</sub>S hydration (117, 172). The rate of early strength development is of course determined by the rate of C<sub>3</sub>S hydration in the acceleration period, but the processes occurring at this stage may also affect later strength development. For example, CaCl<sub>2</sub> influences the properties of C-S-H and the pore size distribution. Similarly, Bentur (175) has shown that the presence of sulfate ions can reduce the "intrinsic strength" of C-S-H, and thus affect the optimum gypsum content of a cement. Such influences on C-S-H may also change the diffusion coefficient of the C-S-H layer around the cement grains and, hence,

the rate of later hydration.

### 3.2.2 Interactions Between Hydrating Cement Compounds

The main cement compounds do not react in isolation, and interactions between them can be important. For example, it is known that  $C_3S$  hydration is retarded when  $C_3A$  is involved in uncontrolled initial reactions. This behavior is believed to be one of the factors affecting optimum gypsum content (176) and the low rate of  $C_3S$  hydration attributed to a high lime demand during the formation of hexagonal hydrates. However, Cottin (177,178) attributes retardation to the release of small amounts of soluble alumina when sufficient gypsum is present. A similar explanation is offered by Bobrov and Shikiryansky (179) to explain the adverse effect of  $C_4AF$  on  $C_3S$  hydration in the absence of sulfate. Conversely,  $C_3S$  will slow the rate of hydration of  $C_4AF$  by the liberation of large quantities of lime into the solution. The formation of calcium silicoaluminates (131) indicates interaction of  $C_3S$  and  $C_3A$  during the hydration.

Young and Tong (87) have shown that only small quantities of  $C_3S$  are necessary to control the concentration of  $Ca^{2+}$  in the contact solution. They argue that the faster nucleation of CH in the presence of  $C_3S$  should speed up the hydration of  $\beta$ - $C_2S$ , as has been observed earlier.

### 3.3 Factors Affecting Hydration Behavior

The reactivity of cement depends on parameters such as crystal size, solid state impurities, stabilization of polymorphs, presence of minor components, etc. The way these factors are affected by manufacturing processes is discussed in the review papers of Theme I of this conference. The mechanistic implications of some of these factors have already been addressed; other parameters, which are important in cement hydration, are discussed below.

#### 3.3.1 Effect of Minor Components

##### Alkalies

Jawed and Skalny (180) have written a comprehensive review on the effect of alkalies on the hydration and properties of cement. Although release of alkalies from the silicate phases may be slow, within a month or so, alkali concentrations in the pore fluid of pastes made with low-alkali cement may rise to about 0.2 M and may exceed 0.7 M in pastes of high-alkali cements. However, in many modern clinkers, a substantial fraction of the alkalies is present as sulfates. These pass into solution very rapidly, leading to a continuous rise in alkali concentration and complete dissolution of almost all the alkalies after about 28 days. The high alkali concentrations thus raise the pH of the solutions and lower the concentration of  $Ca^{2+}$  ions and the solubility of  $Ca(OH)_2$  accordingly. Alkalies must therefore influence the hydration processes and modify the setting and hardening of cement pastes.

Alkali sulfates accelerate the hydration of cement (117,181-186) and may lower their activation energy (181). They principally affect alite hydration, which agrees with results of studies on pure  $C_3S$  (175). Cottin (178) concludes that  $K_2SO_4$  accelerates alite hydration by preventing the alumina poisoning that occurs when  $C_3A$  is present without sulfate ions. However,  $K_2SO_4$  is known to accelerate  $C_3S$  hydration in the absence of  $C_3A$ . Collepardi et al. (187) have confirmed previous studies that sodium carbonate is an accelerator. Since  $CaCO_3$  was found in the system, they postulated that sodium sulfate forms according to the reaction:

Luginina et al. (188) reported that alkali silicates also increased the rate of cement hydration. From these various studies, it can be concluded that alkali salts increase the hydration rate by affecting alite hydration, presumably through their influence on  $Ca(OH)_2$  solubility. The anion might influence  $C_3A$  hydration and could lead to setting problems as discussed below.

Alkalies can promote flash setting of cements, and this phenomenon has been the subject of recent research. Richartz (189) and Sprung (190) found that rapid setting by potassium sulfate was due to the formation of syngenite:

Syngenite not only causes a plastic-type set, but the reduction of  $SO_4^{2-}$  in solution prevents satisfactory retardation of  $C_3A$  hydration. Regourd (117) also observed syngenite formation when  $C_3A$  hydration in a cement was accelerated by the presence of  $K_2SO_4$ . Rapid stiffening and lower early strength observed in certain cements have been attributed (191) to the presence of alkali carbonates in the clinker. Rapid setting with alkali carbonates (187,191) was also attributed to lowered  $Ca^{2+}$  concentrations, which hindered the formation of a retarding ettringite layer and thus accelerated  $C_3A$  hydration.

Although alkali sulfates present in clinkers will increase the rate of alite hydration, and hence early strength, strengths at 28 days or later generally decrease (192-194). This is in keeping with the general observation that more rapid early hydration results in lower ultimate strengths. Johansen (193) obtained good correlation between the amount of  $K_2SO_4$  in a clinker and 28-day strengths. Increasing the  $K_2SO_4$  content decreased 28-day strength but increased the amount of water combined after 3 minutes of hydration. Changes in optimum gypsum requirements (see discussion below) may have a bearing on this behavior (186,195).

##### Effect of $SO_3$ and $C_3A$

Hobbs (195) has recently reviewed the earlier literature concerning optimum gypsum content in cements. Although optimum content can be correlated

with the  $C_3A$  and alkali contents of the cement, Ost (196) used a standard multiple regression analysis to show that Lerch's original data (197) could be correlated primarily with cement fineness and secondarily with alkali content. Further, there was correlation with  $Fe_2O_3$  content rather than with  $C_3A$ . Hobbs (195) re-analyzed earlier data on  $SO_3$  concentrations that caused large expansions during moist curing up to 7 days and found a correlation with cement fineness or, less probably, with alkali content. From these studies, it can be concluded that fineness is the major parameter controlling optimum gypsum content, but, with the tendency for some modern clinkers to contain larger quantities of alkali sulfates, a new study of this subject could be of value. Smith and Matthews (198), for example, have shown that alkali sulfates in the clinker are more effective in controlling  $C_3A$  reactions than is added gypsum, although this contradicts the results of Collepardi *et al.* on pure  $C_3A$  (123).

When other parameters are equal, optimum gypsum content depends primarily on clinker sulfate levels. A reasonable correlation exists between 3-day heat evolution and total  $SO_3$  content.

#### Other Minor Components

Minor components can have three effects on the hydration of cement:

- 1) They can affect the reactivity of the cement minerals by influencing their defect structure (see discussion in earlier sections of  $C_3S$  and  $\beta$ - $C_2S$  hydration and References 60,199,200).
- 2) Their release into solution can accelerate the hydration of the silicates. Chromium (201,202), which exists primarily as  $K_2CrO_4$ , accelerates  $C_3S$  hydration. Phosphorus causes  $C_3S$  to be more reactive (200), but, in the presence of P-substituted  $C_3A$ ,  $C_3S$  hydration is retarded unless gypsum is also present. This can be explained by assuming that the rapid hydration of  $C_3A$  releases phosphate ions, which are known (52) to retard the  $C_3S$  hydration.
- 3) Minor components may change the relative amounts of each cement compound in a clinker. Thus,  $TiO_2$  (203) lowers the amount of  $C_3S$  formed and hence reduces early strength. Similarly,  $P_2O_5$  in raw materials is known to decrease alite in the clinker.

#### 3.3.2 Grinding and Prehydration

The effect of grinding on defect structures has already been discussed (14,85) and has been used to explain the effects of prolonged grinding (85). Grinding by jet milling (204) was observed to increase the hydration of the clinker compounds, particularly  $C_3S$ .

Prehydration of cement is the cause of "silo set" or "pack set" that can occur in storage

silos. This is most likely to occur if the cement is stored while still warm, and too much water has been carried over from the grinding process (189); but, in certain circumstances, gypsum may dehydrate in the silo to provide additional moisture. Under the near-adiabatic conditions of a silo, the warmth of the cement combined with heat of prehydration may push the temperatures above  $100^\circ C$ , causing partial or complete dehydration of the gypsum. A cement temperature of  $\sim 70^\circ C$  may be sufficient (205). Sprung (190) has shown that gypsum dehydration depends on 1) local temperature (temperature gradients in the silo result in greatest dehydration in the center), 2)  $C_3A$  content, and 3) alkali content of the  $C_3A$ . Dehydration is thus apparently aggravated by the desiccating action of hydrating  $C_3A$ . Water given off by the dehydrating gypsum can condense in cooler parts of the silo where prehydration without dehydration can occur.

There is general agreement that high-alkali, high- $C_3A$  cements are very sensitive to the effects of prehydration. It appears that alkali substitution in  $C_3A$  increases its initial reactivity towards water. If alkali contents are low or most of the alkali is in the form of sulfates, the effects of prehydration are low. This result is in apparent conflict with observations that alkali-substituted  $C_3A$  is less reactive. Most probably, if the crystal structure is not changed, substitution will enhance crystal imperfections.

Prehydration delays setting times because a coating of hydration products grows on the  $C_3A$  grains. Although ettringite is generally cited as a major hydration product, Theisen and Johansen (206) did not observe it in their studies. The relative humidity must be high ( $> 80\% \text{ rh}$ ) (113) to form the water films between grains that allow the transport of sulfate ions necessary for the rapid formation of ettringite. In addition, premature stiffening can sometimes occur due to the reduced reactivity of  $C_3A$  after prehydration: syngenite ( $KCS_2H$ ) can form when there is a high alkali sulfate content, or gypsum dehydration can be enhanced (189,190,207). Prehydration also reduces 1-day and 28-day strengths, particularly with high- $C_3A$  and high-alkali cements. Most cements will have normal setting and strength development if the loss on ignition at  $500^\circ C$  due to prehydration (corrected for gypsum and CH) is less than 0.35% (113). This can be done by keeping cements cool, mill humidities low, or using a grinding aid (207).

Storage of unground clinker can also cause problems with strength development. Cussino and Pinter (208) have attributed this to the influence of prehydration on the grinding of the clinker. Small clinker particles that are significantly prehydrated become easier to grind, thus producing a preponderance of fine material with low reactivity. The good, unhydrated clinker is more coarsely ground, and thus reacts more slowly than expected.

#### 3.3.3 Effect of Temperature on Hydration

### Sub-Zero Temperatures

The hydration of cement at temperatures below zero is of particular interest to Russian scientists because of their need to place concrete in severe climates. Cement and cement compounds will hydrate at  $-5^{\circ}\text{C}$  (92,151,209-211), but hydration essentially stops at  $-10^{\circ}\text{C}$  (151,211). Hydration is very slow at sub-zero temperatures, particularly in the case of  $\beta\text{-C}_2\text{S}$  (92,210), and accelerating admixtures, such as  $\text{CaCl}_2$  are used. Logodia *et al.* (210) believe that hydration can be initiated at temperatures as low as  $-15^{\circ}\text{C}$  by supercooled water: the heat of hydration then causes localized melting at the surface of the cement grain, which allows further hydration to proceed. The data in Table IV support this concept since most hydration takes place in the first 3 days when it is relatively rapid and temperature sensitive.  $\beta\text{-C}_2\text{S}$  does not hydrate appreciably because it is inherently less reactive and has a much lower heat of hydration than the other compounds. Hydration of cement at  $-20^{\circ}\text{C}$  is dependent on the length of time the fresh paste is held at ambient temperature before being frozen (211); the critical period appears to be 4-6 hours (Fig. 19), which is sufficient time for alite hydration to pass through the induction period.

Fig. 19 - Influence of prehydration (at ambient temperatures) on the hydration of cement at  $-20^{\circ}\text{C}$  (ref. 211).

Table IV

DEGREE OF HYDRATION IN FROZEN SUSPENSIONS AT $-15^{\circ}\text{C}$ (QXDA data) (from Ref. 210)		
Compound	Percent Hydrated	
	3 days	90 days
$\text{C}_3\text{S}$	44	53
$\beta\text{-C}_2\text{S}$	3	4
$\text{C}_3\text{A}$	71	86
$\text{C}_4\text{AF}$	64	79

The mechanism of hydration does not appear to be radically altered by lower temperatures. The induction period in  $\text{C}_3\text{S}$  hydration is lengthened, but subsequent hydration can be quite rapid (Table IV). The hydration products are generally the same as those observed at normal temperatures; C-S-H, however, has somewhat different properties when formed at low temperatures (209,212). Measurements on C-S-H formed at  $4^{\circ}\text{C}$  (77) suggest that the changes in properties result from slower aging processes.

### Above-Ambient Temperatures

$\text{C}_2\text{S}$  hydration is reported to be accelerated more than that of  $\text{C}_3\text{S}$  at higher temperatures (213). Hydration of  $\text{C}_3\text{S}$  is accelerated to a greater extent above  $60^{\circ}\text{C}$  than between  $20^{\circ}$  and  $60^{\circ}\text{C}$  (213-215). Since the solubility of silica increases more rapidly above  $60^{\circ}\text{C}$ , and the solubility of calcium hydroxide decreases approximately linearly in the range of  $30^{\circ}$ - $80^{\circ}\text{C}$ , the dissolution of silica may be a controlling factor. No changes in hydration mechanism have been reported in the temperature range up to  $90^{\circ}\text{C}$ . The induction period is shortened (214,215), and the second heat peak is sharper and more intense, indicating very rapid hydration at the end of the induction period (213-216). After the initial rapid hydration, the rate of  $\text{C}_3\text{S}$  hydration decelerates at elevated temperatures (214-216), the apparent result (214) of a dense C-S-H layer around the  $\text{C}_3\text{S}$  grains due to accelerated aging processes. Bentur *et al.* (212) have reported data on the properties of C-S-H at  $65^{\circ}\text{C}$  that support this view.

A long-standing question concerning the hydration of  $\text{C}_3\text{A}$  is the stability of ettringite at elevated temperatures. It has variously been reported unstable at many different temperatures ranging from  $40^{\circ}\text{C}$  to above  $100^{\circ}\text{C}$ . Recent studies have not clarified the situation. Barvinok *et al.* (217) found ettringite to be unstable in the range  $50$ - $70^{\circ}\text{C}$ , while Lach and Burev (213) observed ettringite up to  $90^{\circ}\text{C}$ , which is the limiting temperature of stability according to Moldovan and Butucescu (218).

### 3.3.4 Influence of Admixtures on Cement Hydration

Research programs assume, either tacitly or explicitly, that the effect of admixtures on cement hydration is due only to their influence on the hydration of  $\text{C}_3\text{S}$  and/or  $\text{C}_3\text{A}$ , and that  $\text{C}_2\text{S}$  and  $\text{C}_4\text{AF}$  can be ignored. The validity of this assumption has been justified by experience, since the precise action of a "set-modifying" admixture depends on how it affects the hydration of  $\text{C}_3\text{S}$  and  $\text{C}_3\text{A}$ . Under normal circumstances, it is the hydration of  $\text{C}_3\text{S}$  that affects setting, while  $\text{C}_3\text{A}$  is responsible for unusual setting behavior and changes in water requirements.

The classification of accelerators and retarders poses some problems of definition. An accelerator is generally described as a material that hastens the setting time and/or strength

development of portland cement. However, such a definition does not specify the exact nature of the measurement being used to develop the criteria, nor does it indicate the effects on the basic hydration processes. For the purposes of this review, we will classify accelerating admixtures into those that primarily accelerate the hydration of  $C_3S$  to achieve their effect and those that primarily accelerate  $C_3A$  hydration. The exact effect on cement will depend on the relative acceleration or retardation of each component (219). Such a classification is of more fundamental value than one based on inorganic/organic or setting/hardening distinctions, even though these have practical advantages.

#### Accelerating Admixtures

Since calcium chloride is the most widely used commercial accelerator, it has been extensively studied. A review article (43) and a book (44) summarize the influences of calcium chloride on hydration and properties of cement compounds and pastes.

Admixtures Accelerating  $C_3S$  Hydration. As discussed earlier, most inorganic electrolytes accelerate the hydration of  $C_3S$ , with soluble calcium salts being the most effective due to their greater effect on the crystallization of calcium hydroxide. It is clear from Kantro's extensive survey (39) that there is no single mechanism that can explain all observations. A salt may change the length of the induction period, the time of maximum heat output, or the area under the main heat peak (Fig. 20). Young (53,54,133) has attempted to analyze admixture interactions in terms of possible  $C_3S$  hydration mechanisms.

Fig. 20 - Effects of accelerating admixtures on cement hydration (solid line: normal hydration): (a) Shortened induction period, (b) faster rate of heat evolution in stage 3, (c) increased amount of heat evolution in stages 3 and 4.

The accelerators of  $C_3S$  hydration may affect also the hydration of  $C_3A$ . For example,  $CaSO_4 \cdot 2H_2O$  retards the hydration of  $C_3A$  more than  $Na_2SO_4$  (123), while calcium chloride

can accelerate the formation of ettringite in the presence of gypsum (127,128,220). It should be noted, however, that many salts can form complex hexagonal calcium aluminate hydrates of the type  $C_4AX_2H_n$  [ $C_3A \cdot CaX_2 \cdot nH_2O$ ]. Thus, if  $C_3A$  forms hexagonal hydrates in the early stages of hydration, then the possibility exists for complex formation with the admixture. In such instances, overall  $C_3A$  hydration would probably be retarded. Because of this retardation, there is no good correlation between temperature rise and cement setting times.

Admixtures Accelerating  $C_3A$  Hydration. Although most organic compounds retard the hydration of cement, some are considered to be accelerators. Triethanolamine (TEA) is a case in point and has been the focus of much interest since it is also extensively used commercially. Recent studies (172,221) have shown that the accelerating characteristics of TEA are due to its effect on  $C_3A$  hydration, since it retards  $C_3S$  hydration. In small quantities, TEA has little effect on the setting times of cement and strength development. Cements containing more than 0.1% TEA tend to flash set and show reduced strength after 3 days. This effect of TEA is similar to that of sugars (172), which also tend to cause flash setting in large quantities, but which are strong retarders of  $C_3S$  hydration.

It is thus questionable whether we should consider TEA (and similar molecules) an accelerating admixture because of its influence on  $C_3S$ ; yet, it is often included in an admixture formulation to offset the retarding action of a water-reducing component. This strategy presumably works because an increase in the rate of hydration of  $C_3A$  will allow the hydration products to absorb larger quantities of the retarding molecules (53,133). TEA can be used successfully since the concentration needed to achieve adequate acceleration of  $C_3A$  does not cause excessive retardation of  $C_3S$  and flash setting. This conclusion is supported by data summarized in Table V. Nevertheless, flash setting induced by TEA in the commercial admixture has been reported (172).

#### Retarding Admixtures

Studies on the hydration of pure cement compounds have shown that retardation of cement depends primarily on retardation of alite. As has been mentioned above, a retarder may retard or accelerate the hydration of  $C_3A$ . Again, the overall hydration of pure  $C_3A$  may be retarded while initial reactions may be accelerated, thus leading to the practical problems of premature set or excessive slump loss (171,172,173,222,223). Studies of such problems (170,172,222) have clearly demonstrated that, in many cases, an admixture can upset the aluminate-sulfate balance so that the cement behaves as if it were under-sulfated. Addition of sulfate to attain the optimum sulfate content for the cement-admixture combination can often alleviate the problem. The situation is somewhat complex since no two cements behave in the same way. The amount and reactivity of the  $C_3A$  are clearly important, as is temperature. Sometimes the potential for false set arising from dehydrated calcium sulfates

can be changed by the addition of an admixture. On the

TABLE V

EFFECT OF TRIETHANOLAMINE AND SUGAR ON CEMENT HYDRATION				
Admixture	Concentration (wt. %)	% Change in Setting Time		Ref.
		Initial	Final <sup>a</sup>	
Triethanol-amine	0.025	+ 13	+ 2	221
	0.05	+ 12	+ 1	221

	0.2	F.S.	c	172
	0.3	F.S.	c	172

NOTES: Negative sign indicates shorter setting time.

a) Changes > 200% indicate excessive retardation of C<sub>3</sub>S.

b) F.S. = flash setting indicating uncontrolled reactions of C<sub>3</sub>A.

c) Final set according to ASTM C-266 even though C<sub>3</sub>S has not yet completed the induction period.

other hand, although sugar-based admixtures are most commonly implicated in setting problems, the potential exists for most retarding admixtures to cause difficulties under the right circumstances. In view of the practical implications and scientific interest in the problem, the lack of basic studies is somewhat surprising.

If the mechanism of retarding action is to be elucidated, it is useful to know how different organic compounds affect the hydration of C<sub>3</sub>S. Taplin (224) reported such a survey for a commercial cement, and Milestone (225) has made a similar survey using conduction calorimetry. The two studies are in good qualitative agreement, but we must assume that the observations for cement reflect the combined influence of C<sub>3</sub>S and C<sub>3</sub>A hydration. It can be concluded that a molecule must have a strong chelating group if it is to be a good retarder. The best chelating unit is typified by the β-hydroxyl-carboxylate grouping (Fig. 21a), which forms a strong 6-membered ring with a metal ion. For example, tartaric acid, which contains the grouping, is a strong retarder, while succinic acid, which does not have the β-hydroxyl group, is not; maleic acid retards, but fumaric acid, which cannot chelate, does not; and, similarly, glyceric acid is retarding, but propionic acid is not. Groupings which form larger or smaller chelate rings have less retarding power (Fig. 21b). Electronic effects are also important as can be seen in comparing pyruvic and glyceric acids or different hydroxybenzoic acids (Fig. 21c). The retardation effect is related to the molecule's ability to chelate at more than one site, shown by the difference in retarding power between the dihydroxybenzoic acids (Fig. 21c) and also between ketoglutaric acid and gluconic acid

(Fig. 21d). More detailed comparison of retarders require studies of their effects on the hydration of pure C<sub>3</sub>S. Milestone (55), for example, has shown that 0.1 wt % gluconic acid has greater retarding power than glucose for pure C<sub>3</sub>S, although this is not true for all cements (225,226). Undoubtedly, the C<sub>3</sub>A content is an important factor in determining relative behavior.

(c) effect of substituents on retarding power

(d) effect of more than one chelating group

Fig. 21 - Effect of different molecular structures on retarding ability. Times represent the retardation of the main heat evolution peaks at 0.1 wt. % additions.

A few inorganic salts are known to retard  $C_3S$  hydration — water-soluble diphosphates and polyphosphates (52), and fluorides (21, 217, 219) are recent examples. However, fluorides apparently accelerate  $C_3A$  hydration (217).

#### Water-Reducing Admixtures

With the introduction of the new "super-plasticizing" admixtures, considerable interest has centered on the effects of these materials on cement performance. Unfortunately, few investigations have looked specifically at the influence of such admixtures on cement hydration, but it is clear from various observations (227) that interactions with the hydrating compounds must be important: 1) water reduction is most effective when the admixture is added after the mix water, 2)  $C_3S$  content and sulfate levels affect the degree to which superplasticizers increase workability, 3) subsequent slump loss is also affected by cement composition, and 4) excessive slump loss can be ameliorated by the concomitant use of a retarding admixture.

Little is known about the mechanism of action of high-range water reducers, although a vast amount of literature is available on their effects on the physical properties of mortars and concretes (227). They are believed to act by: 1) decreasing the surface tension of water, 2) charging the cement particles with equidirectional charges, or 3) producing a lubricating film at the particle surfaces. An interesting basic work, addressing the effects of surface-active chemicals on the viscosity of cement suspensions, has been published by Petri (228), but the effects on hydration are not discussed. Kondo and co-workers (229, 230) have studied the effects of various dispersing surfactants, including a "superplasticizer," on the hydration of cement. Quaternary ammonium chlorides, representing cationic surfactants, caused some acceleration due to the influence of the chloride ion. Polyvinyl alcohols, representing non-ionic species, showed only slight retardation. Sodium p-n-dodecylbenzene-sulfonate represented various sulfonate anionic surfactants; generally, alite was much more strongly retarded than cements, particularly at high concentrations when the admixture contained long-chain aliphatics, and some hydrophilic substituents were present in the hydrophobic component. However, studies (229) have indicated that adsorption of these compounds is relatively low, and that absorption into calcium aluminate hydrates is not as strong as that observed for other retarding molecules. It has been hypothesized that differences in adsorption behavior due to molecular structure determine the extent to which adsorbed layers of these admixtures will affect the access of water to the surface.

Suzuki *et al.* (231) also studied the interaction of surfactants with  $C_3S$  and came to similar conclusions. Non-ionics, such as polyethenes, have little effect on hydration, whereas anionics, such as sodium gluconate or laurate, have retarding properties. Sodium gluconate strongly retards the hydration of  $C_3S$  at concentrations  $>0.1\%$  and changes the surface charge to a positive value. affects surface charge less. These results are

explained in terms of different adsorption characteristics. Tarnarutsky (232) found that additions of high molecular weight fatty acids as hydrophilic admixtures tended to retard hydration of cement and of the individual cement compounds. The effect on cement hydration depended on the alite content. Sugi *et al.* (233) considered lignosulfonate and polyol water reducers to influence gypsum solubilities and hence to affect false-setting tendencies of a cement. However, more work is necessary to further refine their ideas.

"Superplasticizers" can be used to either improve workability or lower w/c ratios to achieve strength. Another approach to attaining low w/c, high-strength concretes has been to work with ground clinkers using conventional lignosulfonate admixtures along with an alkali carbonate. The combination of lignosulfonate and sodium carbonate produces greater dispersing power and retardation of both ground clinker and cement than does lignosulfonate alone (57, 234, 235): the presence of carbonate apparently maintains higher concentrations of lignosulfonate for longer periods (57, 234). The precipitation of  $CaCO_3$  decreases lignosulfonate in solution and causes the onset of  $C_3A$  hydration and eventually  $C_3S$  hydration. It has been hypothesized (57) that a negatively charged lignosulfonate carbonate complex forms, which can adsorb effectively on the cement grains to form negatively charged surfaces that repel each other. This adsorption strongly retards  $C_3A$  hydration even in the absence of sulfate, but does not prevent  $Ca^{2+}$  ions from passing slowly into solution. When  $Ca^{2+}$  concentration exceeds a normal level,  $CC$  precipitates, destroying the lignosulfonate complex.  $C_3A$  can now hydrate more normally, and lignosulfonate is gradually removed from solution either by precipitation as calcium lignosulfonate or by absorption into calcium aluminate hydrates. Removal of lignosulfonate from solution overcomes its poisoning effect on calcium hydroxide crystallization, and  $C_3S$  can proceed to hydrate normally.

#### 3.4 New Experimental Techniques

It is evident from the foregoing discussions concerning the mechanism of hydration of portland cements and its compounds that we are dealing with a complex system. It is therefore desirable to assess the potential of new experimental methods that might provide additional insight into the physico-chemical processes occurring. A number of papers that explore these possibilities will be reviewed in this section. We can divide these into four classes: new analytical methods, electrical measurements, spectroscopic investigations, and miscellaneous techniques. Theoretical interpretation of the data obtained by many of these methods is difficult because of the complex nature of pastes. Comparisons with established techniques would be helpful in many instances, but are not always available. From a practical point of view, a method may provide useful comparative data, for example on the effect of admixtures on setting behavior, even when complete theoretical interpretations are not possible.

### 3.4.1 Analytical Methods

The application of silicate polymerization analysis as an alternative means of assessing the degree of hydration in C<sub>3</sub>S pastes has been suggested (23). This idea is based on the assumption that no monosilicate occurs in C-S-H; it remains to be seen whether this holds true for cement paste.

The composition of the liquid phase is known to be an important consideration in the hydration process. In the calculation of ionic equilibria, activities should be used in preference to concentrations. Specific ion electrodes measure activities directly, and the calcium ion electrode has been used in the analysis of hydrating systems (25,236). Concentration-time profiles determined by this method agree well with those from conventional methods. pH changes with time can be measured using a glass electrode, but, once pH rises above 12, the method does not seem to be sensitive (25). This may be due to potential errors that can occur at high pH, and it has been suggested (237) that metallic electrodes can be used successfully. Other specific ion electrodes could be of use for investigating admixture interactions.

### 3.4.2 Electrical Methods

Measurements of electric conductivity of cement pastes have been used for many years in hydration studies. A number of other parameters based on electrical measurements have also been evaluated in recent years. Changes in the dielectric constant of a paste are observed (238,239) during hardening and can be used to follow the setting process. Dielectric changes have been correlated with other measurements during early hydration (238). Podkin and Rozenthal (240,241) and Rozenthal and Fedigin (242) have also measured both dielectric constant and electrical conductivity in the radiofrequency range (5-100 MHz). The dielectric constant at 5 MHz is very sensitive to the dipole orientations that lead to thixotropic behavior, and changes in its value are observed on redispersion of pastes during the first few hours. In contrast, the dielectric constant at 100 MHz is insensitive to such changes. Conductivity measurements correlate with hydration behavior rather than with physical changes within the paste. Reboul (243, 244) has determined complex electric permittivities of pastes from microwave resonance measurements (permittivity depends on free water content; it decreases with time and can be used to estimate setting). At 3 kHz and -20°C, permittivity is affected by water adsorbed on surfaces. It has been shown that adsorption of water on C<sub>3</sub>S or cement surfaces is complete in 10-15 minutes, even though no hydration products are observed within 30 minutes.

### 3.4.3 Spectroscopic Investigations

Nuclear magnetic resonance (NMR) has been used in the study of cement pastes, and Lahajnar *et al.* (245) have surveyed the various applicable

NMR methods. Proton relaxation data (either spin-lattice, T<sub>1</sub>, or spin-spin, T<sub>2</sub>) of adsorbed water, as distinct from crystalline water in a structural lattice, change with time and can be used to follow hydration (246-249). Pulsed NMR methods are better than spin-echo techniques for determining these parameters. Other NMR methods that can be used are line-shape measurements, proton-free induction decay, multiple pulse method, and <sup>27</sup>Al NMR studies. The intent of all these methods is to separate signals due to adsorbed water and crystalline H<sub>2</sub>O or OH<sup>-</sup>.

Blin and co-workers (246) studied the proton and deuteron relaxation times in hydrating C<sub>3</sub>S and cement pastes. They concluded that the H<sub>2</sub>O molecules were highly mobile in the adsorbed monolayer and exchanged rapidly with pore water in contact with the monolayer. They also showed that the relaxation times directly reflected the number of active surface sites and could be used to follow the hydration process. These studies (using T<sub>1</sub>) have been applied to probing the effect of admixtures on the hydration of cement. The results are encouraging: setting times and rate of hardening can be estimated. Unfortunately, correlations with other hydration studies do not appear to have been explored. Palkin *et al.* (249) used line-shape studies to follow hydration of cements and concluded that the formation of structured liquid layers preceded the development of microstructure.

Infrared (IR) spectroscopy has been used to study compounds of interest in cement chemistry, but line broadening and difficulties in quantitative measurements have precluded its use in detailed hydration studies. Bensted and Bansted and Varma (250,251) have drawn attention to the possible application of laser Raman spectroscopy and the complementary nature of the two techniques. It is likely that IR and Raman spectroscopic studies could be used more in hydration studies than has been the case, but experimental methods and approaches may have to be further developed to utilize their full potential.

### 3.4.4 Miscellaneous Techniques

Changes in ultrasonic pulse velocity measurements during setting and hardening have been studied on cement (252) and C<sub>3</sub>S (253) pastes. The pulse velocity rapidly changes from 1400-1500 m/s in the fluid state to over 3000 m/s in the first few hours after setting. Velocity then continues to increase more slowly to above 4000 m/s. The method has been shown (252) to correlate well with heat evolution and changes in voltage between electrodes embedded in the paste. The maximum rates of change in pulse velocity, voltage change, and heat evolution agree well with the final set as measured conventionally. The method is useful to distinguish between the influence of admixtures in hydration (252,253) and on microstructural development (253).

Taylor (254) has described a method of hydrating undisturbed specimens for subsequent SEM observations. Advantages claimed are high sensitivity to early hydration, detection of

both amorphous and crystalline phases, and a capability for following the hydration of individual phases in a mixture. However, the method entails the use of a very high w/c ratio. Other workers (13,126) have hydrated, premounted, and compacted specimens in a similar way to follow early hydration reactions of cement compounds.

Thermoluminescence studies are described in the discussions of reaction mechanisms, and Mossbauer spectroscopy has been used to study the hydration of the ferrite phase and cement. Shchurov *et al.* (255) have used low angle X-ray scattering (LAXRS) to study the hydration of  $C_3S$  and  $C_3A$ . They point out that LAXRS can detect volume heterogeneities in anhydrous cements with similar BET surface areas but different LAXRS surface areas. Slegers and co-workers (256) have studied radial electron density distributions (RED) of hydrating  $C_3S$ . Interpretation of the complex curves supports the idea that silicate polymerization occurs during hydration.

#### 4. CONCLUSIONS

Considerable progress has been made in our understanding of cement hydration since the last Congress. There is general agreement on the main features of hydration, although there is still considerable disagreement over details of interpretation. We have a sufficient body of knowledge to be used to advantage in the cement and concrete industries; however, technology transfer is the major limiting factor in our progress.

The large gaps remaining in our knowledge concern the cement-water interactions occurring in the first few hours of hydration. If precise control over the development of microstructure is to be achieved, the hydration process that directs it must be understood in more detail. Control of microstructure will lead ultimately to the greater realization of the potential of portland cement and, perhaps, to new uses of concrete not yet imagined. The developments of modern-day metallurgy and ceramics are good examples of the powerful effects of microstructural control on engineering properties.

To achieve these aims, we should try to answer the following practical questions in the indicated areas:

- 1) Controlling the reactivity of calcium silicates

How can we increase the reactivity of  $C_3S$  of  $C_2S$ ? How do we measure reactivity? Can two plants (or even laboratories) produce cements with exactly the same properties?

- 2) Cement-admixture interactions

Are there alternative materials to

gypsum for set regulation? Can we scientifically design admixtures? Can we better predict rheological behavior?

- 3) Control of microstructure formation

How do alkalies and minor components affect the course of hydration? How do interactions between clinker compounds affect the course of hydration and structure formation? How can we use external factors to direct the formation of microstructure?

We already have some partial answers to many of these questions. To make further progress, we must make greater use of techniques used in other disciplines, such as ESCA, NMR, Raman spectroscopy, etc., and develop research programs that will probe the fundamental behavior of the cement-water system.

## I. PRODUCTS FORMED AT ORDINARY TEMPERATURES

The reaction of portland cement with water in pastes at ordinary temperatures gives as the main products a nearly amorphous form of C-S-H,  $\text{Ca(OH)}_2$ , and smaller amounts of an AFm (hexagonal plate) phase or an Aft (ettringite-type) phase or both. We review here current knowledge and hypotheses of the compositions and structures of these phases in the forms in which they exist in cement pastes. We shall deal also with  $\text{C}_3\text{S}$  and  $\text{B-C}_2\text{S}$  pastes, but not with mechanisms of formation, morphology, microstructure or relations to properties.

## C-S-H COMPOSITION: INDIRECT OR DIFFERENCE METHODS

The Ca/Si ratio of the C-S-H in a  $\text{C}_3\text{S}$  or  $\text{B-C}_2\text{S}$  paste can be obtained by difference, using determinations of unreacted starting material and of  $\text{Ca(OH)}_2$  formed. Such methods give values usually between 1.5 and 2.0 for fully-reacted pastes, depending somewhat on water/cement ratio and other factors. For low degrees of reaction, results vary widely. Some workers have reported that the Ca/Si ratio passes through a minimum for  $\text{C}_2\text{S}$  but not  $\text{C}_3\text{S}$  pastes (1,2), but this is not universally agreed; for a discussion, see Odler and Dorr (3). The results at low degrees of reaction are very sensitive to small experimental errors, and different methods of determining the  $\text{Ca(OH)}_2$  tend to give different results; some or all of the published results may be wrong. However, it has also been suggested that the Ca/Si ratio in the early stages of reaction, and whether or not it passes through a minimum, may depend on the reactivity of the starting material (1,3,4).

## DIRECT OR ELECTRON-OPTICAL METHODS

Indirect methods give an average Ca/Si ratio for all the C-S-H in a sample and can thus eliminate sampling errors, but they have serious limitations. Their reliability at low degrees of reaction has already been mentioned. In addition, they cannot give information about possible differences in composition between different regions, such as "inner" and "outer" products, or between individual particles within a given region. They cannot safely be applied to cement pastes, because of uncertainties connected with subsidiary components and phases.

Direct or electron-optical methods can avoid these drawbacks. Electron probe microanalysis (EPMA) and scanning electron microscopes (SEM) fitted with X-ray detectors have been in use for some time. These methods allow ready correlation of composition with microstructure, but have limitations. The volume analyzed (about 2  $\mu\text{m}$  in each direction) is probably too large for the scale of heterogeneity of the material, and certainly too large for the study of between-particle variability. Corrections for absorption and other effects can be difficult, especially if rough surfaces are used. The identity of the sample analyzed, or its freedom from crystalline impurities, cannot be checked by a diffraction pattern. Some newer instruments overcome these limitations. In the analytical electron microscope (AEM), a transmission electron microscope is fitted with an X-ray detector; analyses can be obtained from regions a few hundreds of Å in each direction (5). The scanning transmission electron microscope (STEM) offers further possibilities (6), but these have thus far scarcely been exploited in the analysis of cement hydration products.

ELECTRON-OPTICAL ANALYSES OF  $\text{C}_3\text{S}$  PASTES

EPMA and SEM studies of the C-S-H in  $\text{C}_3\text{S}$  pastes (7-9) have mostly indicated Ca/Si ratios of 1.6 - 1.9, in general agreement with results of indirect methods for mature pastes. Some have distinguished between inner and outer products: Goto *et al.* (10) found 1.8-2.0 for the inner product of a mature paste, and 4-4.5 for the outer product; this latter value presumably relates to a mixture with  $\text{Ca(OH)}_2$ . Stucke and Majumdar (11), studying a 1-month old paste, obtained values of 1.9 and 1.6 for the inner and outer products respectively.

Using AEM, Gard *et al.* (12) found mean Ca/Si ratios of 1.5 - 1.7 for the C-S-H in  $\text{C}_3\text{S}$  pastes cured for 1 - 180 days. The means for two different  $\text{C}_3\text{S}$  preparations were 1.5 and 1.6, but no significant correlations with curing time, degree of reaction, or morphological type of C-S-H were found. All the samples showed significant compositional variation between particles; the range of Ca/Si ratio over the 161 particles analyzed was 1.21 - 1.96. For high degrees of reaction, the results agreed broadly with those obtained for the same samples by an indirect method, but for low degrees of reaction the latter gave lower Ca/Si ratios. Two possible explanations were suggested: either the indirect results were wrong, or the AEM results related to only a part of the C-S-H. The specimens were prepared for electron microscopy by grinding and redispersing, and this procedure could have enriched them in material easily detached from the cores of unreacted  $\text{C}_3\text{S}$ . This question will remain unanswered until a better method of specimen preparation, such as ion-thinning, has been developed.

## C-S-H COMPOSITION IN CEMENT PASTES

This could not be reliably determined before electron-optical methods were available, but some useful indications were nevertheless obtained. Kalousek (13) concluded from thermal analysis that the amounts of AFm and Aft phases were too small to account for all the sulfate ion present, and that some of it must enter the C-S-H. Copeland and coworkers, in studies summarized by Copeland and Kantro (14), concluded from indirect evidence that the C-S-H could accommodate  $\text{Al}^{3+}$ ,  $\text{Fe}^{3+}$  and  $\text{SO}_4^{2-}$  ions, in each case to the extent of about 1 ion per 6 Si, and that their presence in the C-S-H was associated with an increase in Ca/Si ratio. SEM studies have supported some of these conclusions: Diamond (15) found Ca/Si ratios of 2-3 and evidence of significant S substitution, while Stucke and Majumdar (16) reported a bimodal distribution of Ca/Si ratio with maxima at 1.90 and 2.15.

Lachowski *et al.* (17) analysed 365 particles of C-S-H,  $\text{Ca(OH)}_2$ , AFm phase and Aft phase from pastes of cements and clinkers using AEM. All the phases other than  $\text{Ca(OH)}_2$  showed significant compositional variation between different paste specimens and also between different particles within each specimen. Fig. 1 gives a general indication of this variability in a typical case. Nearly all the C-S-H particles analyzed contained significant amounts of Al, Fe and S, and smaller amounts of Mg. Many contained a little Na or K, and a few contained traces of Ti or Cl. For the pastes to which Fig. 1 refers, the mean atomic contents, expressed as ratios relative to 10(Ca + Mg), were:

Na	Mg	Al	Si	S	Cl	K	Ca	Ti	Fe
<0.1	<0.1	0.5	5.7	0.8	<0.1	0.1	10.0	<0.1	0.1

Fig. 1 - Atomic ratios in particles of hydration products in some cement pastes, determined using analytical electron microscopy (17). Open and full circles denote  $\text{Si}/10(\text{Ca} + \text{Mg})$  ratios below and above 1.5 respectively. Water/cement ratio = 0.7, curing times 1 - 28 days.

For 156 C-S-H particles from these and other pastes, the mean  $\text{Ca}/\text{Si}$  ratio was 2.0.

#### THE WATER CONTENT OF THE C-S-H IN PASTES

For the C-S-H of fully reacted and D-dried  $\text{C}_3\text{S}$  or cement pastes,  $\text{H}_2\text{O}/\text{Si}$  ratios are typically about 0.5 below  $\text{Ca}/\text{Si}$  ratios<sup>14</sup>; i.e.,  $\text{H}_2\text{O}/\text{Ca}$  is about 0.7. Heating to 150-200°C under dynamic (TG) conditions leaves a similar amount of water in the C-S-H, though the effect on the structure is not necessarily the same. In either case, the water retained presumably occurs partly as molecules and partly as OH groups bound in various ways, but the respective amounts are unknown. Opinions differ as to whether the  $\text{H}_2\text{O}/\text{Si}$  ratios of C-S-H in partly reacted pastes are higher or lower than in the case of fully reacted pastes, and for this and other reasons, the use of 'fixed water' as a measure of the degree of reaction is of uncertain validity.

The terms 'chemically' and 'physically' bound water have no intrinsic meaning, but it is legitimate to enquire about the mobility of water molecules lost under given conditions, the part they play in the structure, or the way in which the latter is affected by their loss. The results of Feldman and others indicate that substantial and partly irreversible changes begin to occur at water contents much above those produced by D-drying.

#### STRUCTURE OF THE C-S-H IN CEMENT AND CALCIUM SILICATE PASTES

Because the C-S-H formed in pastes cured at ordinary temperatures is almost amorphous, X-ray or other diffraction methods provide only slight structural

information and there have been no significant recent developments in this respect. Mather (18) and Diamond (19) have reported typical X-ray powder patterns, which show only a very weak, diffuse band at 2.6 - 3.1 Å and a somewhat sharper one at 1.8 Å. A 20-year old  $\text{C}_3\text{S}$  paste gave a closely similar pattern (20) and there appears to be no foundation for occasional suggestions that the crystallinity of the C-S-H increases significantly over a period of some decades.

Of other methods used to provide structural information, trimethylsilylation (TMS) has proved the most useful. This is a chemical method that provides information on the distribution of Si among different anionic species. It was first applied by Lentz (21), who showed that the monomeric anions ( $\text{SiO}_4$ ) initially present are replaced in the course of reaction by dimer ( $\text{Si}_2\text{O}_7$ ) and ultimately by polymer. Recent improvements in TMS procedures (22,23) have led to a more exact and detailed understanding of this process.

#### ANION-SIZE DISTRIBUTION IN $\text{C}_3\text{S}$ AND $\beta\text{-C}_2\text{S}$ PASTES

The silicate anions in  $\text{C}_3\text{S}$  and  $\beta\text{-C}_2\text{S}$  are monomeric, and recent TMS studies have shown that for calcium silicate pastes cured at room temperatures the amount of monomer corresponds to that of unreacted starting material found using QXRD (2,4,24,25). Little or no monomer is therefore present in the C-S-H. This does not hold, however, for  $\text{C}_3\text{S}$  pastes cured at 4°C. Bentur *et al.* (24) found that such pastes contained much more monomer than could be attributed to unreacted  $\text{C}_3\text{S}$ . They suggested that the C-S-H formed initially contained monomer, which was later converted into dimer and then into polymer; at room temperatures, the dimerization step was sufficiently rapid that the concentration of monomer was very low.

It is now widely agreed that the C-S-H of  $\text{C}_3\text{S}$  pastes cured at room temperature contains much dimer, a very little linear trimer ( $\text{Si}_3\text{O}_{10}$ ), virtually no cyclic trimer ( $\text{Si}_3\text{O}_9$ ) or cyclic tetramer ( $\text{Si}_4\text{O}_{12}$ ), and varying amounts of polymer (2,4,23-25). Unless otherwise stated, this latter term will be used here to include all silicate species larger than those listed above. Dent Glasser *et al.* (4) found that for degrees of reaction up to about 20% the Si in the C-S-H was present entirely as dimer, but that at later stages of reaction polymer was also present. The absolute amount of dimer increased throughout the period studied (about 15 months); a nearly fully-hydrated paste of this age contained about equal amounts of Si as dimer and as polymer. Comparison with electron-microscope evidence suggested that Type I C-S-H (nomenclature of Diamond, 19) contained only dimer and that Type III C-S-H contained either polymer, or a mixture of dimer and polymer. Mohan (20) later extended this study to a 20-year old  $\text{C}_3\text{S}$  paste provided by Dr. D.L. Kantro (Portland Cement Association); of the total Si, 2% was recovered as monomer, 36% as dimer and 47% as polymer (total yield, 85%).

#### ANION-SIZE DISTRIBUTION IN CEMENT PASTES

In the main, results obtained by TMS procedures have been similar to those for calcium silicate pastes. The most important difference is that for pastes hydrated at ordinary temperatures, the C-S-H contains an appreciable amount of monomer (26, 27). For three fully-hydrated cement pastes 1.8-6.3 years old, Lachowski (26) found 9-11% of the Si to be recoverable as monomer, 22-30% as dimer, and 44-51% as

polymer. Polymer here includes 1-2% as linear trimer, and the total yields were 80-88%. As with  $C_3S$  pastes, little or no cyclic trimer or cyclic tetramer has been found, but Sarkar and Roy (27) observed peaks in the GLC curves of the TMS derivatives which they attributed to linear tetramer ( $Si_4O_{13}$ ) and cyclic pentamer ( $Si_5O_{15}$ ). Berger *et al.* (2) found that, for cement pastes cured for short times, the proportion of the Si in the C-S-H present as polymer was less than for comparable  $C_3S$  or  $C_2S$  pastes. The higher proportions of monomer in cement pastes could be associated with partial replacement of Si by other elements (2,27,28). A little monomeric silicate could also occur in the AFm and Aft phases.

#### ANION-SIZE DISTRIBUTIONS WITHIN THE POLYMER FRACTION

These have so far been studied most effectively by gel-permeation chromatography (GPC) of the TMS derivatives (26,27); thin-layer chromatography also appears promising (29). It is also possible, from chemical analysis of the TMS derivatives, to determine the mean connectivity ( $\bar{Q}$ ) of the polymer fraction; this quantity is defined as the mean number of Si-O-Si linkages formed by each Si atom and is, for instance, 1.6 for linear pentamer, 2.0 for a ring or infinite chain, and 3.0 for the finite, three-dimensional ion  $Si_8O_{20}$ .

For fully-reacted cement pastes, both Sarkar and Roy (27) and Lachowski (26) found anion-size distributions within the polymer fraction peaking at a molecular weight of about 1100 for the TMS derivatives. Sarkar and Roy considered the main component of the polymer to be cyclic pentamer. They found no evidence of anionic species larger than this, but Lachowski's distributions (Fig. 2) for the three pastes mentioned in the previous section showed tails on the high molecular weight sides, with minor peaks or shoulders indicating significant contributions from anions with 6-9 Si. The number and weight means for the anion size corresponded to 8-9 Si and 14-17 Si atoms respectively, and the mean connectivities were 2.3. Later work using a different GPC instrument indicated the slightly higher modal molecular weight of 1300 (30).

Mohan (20) has applied Lachowski's methods to  $C_3S$  pastes ( $w/c = 0.45$  or  $0.47$ ). He obtained GPC curves which broadly resembled those in Fig. 2, and which gave the results shown in Table I. Some tentative interpretations are as follows. First, for the 7-day old paste, about a half of the Si in the polymer fraction is present in anions containing less than

Fig. 2 - Gel permeation chromatograms of poly-silicate derivatives from cement pastes aged 1.8 - 6.3 years (Lachowski, 26)

8 Si, possibly mainly linear pentamer; much of the rest is in anions with 8-9 Si. Second, during the next 3 months, there is little change in the fraction present in anions with less than 8 Si, but the fraction present in highly-polymerized anions ( $>10$  Si) increases at the expense of that present in anions with 8-9 Si. Third, changes continue over a period of years, during which time the fraction of the Si present in anions with less than 8 Si also decreases considerably; in the 20-year old paste, possibly half of the Si in the polymer fraction is present in highly-polymerized anions. The connectivity results are also of interest, and their significance is discussed later.

Ono *et al.* (25) have obtained somewhat higher molecular weights for the polymer TMS derivatives obtained from alite pastes with and without added  $Na_2O$ . They reported values of about 3000 for pastes 3-28

TABLE I

$C_3S$ Pastes : Anion-Size Distributions Within the Polymer Fraction (Mohan, 20).						
Curing Time	Molecular Weight of TMS Derivatives			No. of Si Atoms in the Anion		Mean Connectivity ( $\bar{Q}$ )
	Mode	Number Mean	Weight Mean	Number Mean	Weight Mean	
7 days	1300	1600	1900	7	8	1.8
14, 30, 42 "	1300	1600	2100	7	9	1.8-1.9
84 "	1300	1700	2400	7	10	1.8
180 "	1300	1800	2600	8	11	1.8
20 years	1300	2500	7000	11	33	2.1

days old, rising to nearly 4000 for the  $\text{Na}_2\text{O}$ -free paste at 91 days.

#### STRUCTURAL MODELS FOR C-S-H

Two assumptions about the structure of the C-S-H of cement and calcium silicate pastes are widely accepted: first, that it is a layer structure, and second, that when the silicate ions polymerize, they do so in a way that produces chains. Both assumptions derive, at least in part, from the suggestion made over 20 years ago by one of us (H.F.W.T.) that the structure resembles that of tobermorite. The view that there is any close relationship to tobermorite is now generally rejected, but the assumptions of a layer structure and of silicate chains remain, and it is timely to examine whether they are soundly based.

Four arguments for a layer structure may be considered, *viz*:

(i) *Diffraction*. The most obvious interpretation of the weak x-ray peaks or bands at 1.8 and about 3 Å is that they are  $hk$  reflections from layers similar to those in  $\text{Ca}(\text{OH})_2$ , but possessing only short-range order and distorted because many of their oxygen atoms are shared with silicate tetrahedra in a particular way. Very occasionally, particles have been found that give selected-area electron-diffraction patterns (31,32), and these patterns are also consistent with the above explanation (33).

(ii) *Surface-Area Studies*. Differing structural models have been advanced to account for the results of studies of specific surface areas and related properties, but nearly all share the common feature of a layer structure. It is not clear whether layer structures are the only ones that can explain the data, or whether they have been adopted because of the other arguments outlined here.

(iii) *Morphology*. Some, though not all electron-microscope studies suggest that Types I and II C-S-H, which predominate at early ages, are composed of either flakes or foils, in some cases either rolled into scrolls or joined to form honeycombs (31,32, 34-36). For Types III and IV C-S-H, which seem to predominate in mature pastes, the morphology gives little clue to the underlying structure, though the description of Type III C-S-H as "irregularly equant or flattened particles" (19) could possibly be considered as suggesting a layer structure.

(iv) *Analogy with Other Basic Salts*. Many, though by no means all basic salts are known to have layer structures, and analogy suggests that these could include the C-S-H of cement and calcium silicate pastes.

None of this evidence is conclusive, but taken as a whole it suggests that there is indeed a tendency towards formation of layers, which is possibly stronger in Types I and II than in Types III and IV C-S-H. The diffraction evidence shows that it is no more than a tendency. As Diamond (19) has emphasized, the structure possesses only short-range order, and the absence of any X-ray powder spacing in the 9-15 Å region shows that there is no close approximation to a set of regularly spaced layers. The structure must differ markedly from those of such crystalline or quasi-crystalline phases as tobermorite, jennite, C-S-H(I) or C-S-H(II), and the use of any of these as models is likely to be misleading.

The only significant argument for a chain-type anion appears to be the diffraction evidence; condensation

of the  $\text{SiO}_4$  tetrahedra into chains would distort the Ca-O sheets in a way that would produce the observed diffraction effects. However, some other patterns of condensation, including the mere formation of dimer, would probably have the same effect.

The TMS evidence gives no support to the hypothesis that polymerization produces chains, and affords some indications against. Sarkar and Roy's (27) view that the main constituent of the polymer fraction is cyclic pentamer has already been mentioned. The combination of relatively low mean molecular weight and relatively high connectivity found by Lachowski (26) and Mohan (20) does not support the view that the higher molecular-weight constituents of the polymer have chain structures. It suggests rather that they are rings or, perhaps more probably, compact and roughly equidimensional anionic species similar to, though not necessarily the same as those known to exist in silicate solutions (37).

These arguments suggest that most and perhaps all of the models that have been suggested indicate a higher degree of crystalline order than really exists. In Types I and II C-S-H, there may well be an approximation to continuous Ca-O layers, in which the oxygen atoms form parts of  $\text{Si}_2\text{O}_7$ , OH, and, for the C-S-H of cement pastes,  $\text{SO}_4$  and  $\text{Al}^-$  and Fe-containing groups. For Types III and IV C-S-H, such sub-crystalline order as exists could be confined to the neighborhood of small fragments of Ca-O layers, perhaps only some tens of Å large and only rarely parallel to each other (Fig. 3). The intervening spaces could be totally amorphous and any silicate ions in them might well be of compact types. It is by no means certain that Types III and IV C-S-H are particulate in nature, and Fig. 3 has been drawn in a manner intended to show this.

Fig. 3 - Suggested structure for Type III C-S-H (schematic; ref. 38)

A model of this type would appear compatible with some other data, such as the densities of 2.3-2.4 g  $\text{cm}^{-3}$  found for material equilibrated to 11% R.H. (39). Nitrogen specific surfaces of about 60  $\text{m}^2\text{g}^{-1}$  could reasonably apply to the C-S-H particles, and the much higher values of around 950  $\text{m}^2\text{g}^{-1}$  found using low-angle x-ray scattering (40) to the Ca-O sheet fragments and the anions directly associated with them.

#### CALCIUM HYDROXIDE IN CEMENT PASTES

Analytical electron microscope analyses of  $\text{Ca}(\text{OH})_2$  crystals from cement pastes showed that most contain a little Si, S and Fe and that a few contain a little Al; maximum contents of any of these elements relative to Ca were 0.02-0.03 (17). The relative

abundance of Fe compared with Al suggests that it may be present as  $Fe^{2+}$ , which could replace Ca. It is not clear whether the other elements are present in the  $Ca(OH)_2$  structure or in inclusions, although no indications of a second phase were observed.

# AFM PHASES

These are crystalline phases of hexagonal-plate morphology and are typified by monosulfate,  $[Ca_2Al(OH)_6]_2(SO_4)_3 \cdot 6H_2O$ . The basic crystal structure and other data are well established; several reviews exist (41-43). AFm phases have layer structures related to that of  $Ca(OH)_2$ ; every third Ca is replaced in an ordered way by a tripositive cation, which causes considerable distortion, and anions and  $H_2O$  molecules are intercalated between the layers. The general formula is  $Ca_2M(OH)_6 \cdot X_{aq}$ , where M is an octahedral cation (normally  $Al^{3+}$  or  $Fe^{3+}$ ), and X is the interlayer anion. Many anions can occupy these sites, including among others  $OH^-$ ,  $CO_3^{2-}$ ,  $SO_4^{2-}$ ,  $Cl^-$ ,  $Al(OH)_4^-$  (in  $C_2AH_8$ ),  $H_2AlSiO_5^-$  (in  $C_2ASH_8$ ) and a silicate ion of unknown constitution. Up to one interlayer anion can be accommodated per unit of  $[Ca_2Al(OH)_6]^+$ .

The AFm phase of cement pastes has often been regarded as monosulfate or as a mixture or solid solution of this phase with its hydroxide analog,  $C_4AH_x$ , but this view is an oversimplification. Regourd *et al.* (44) studied  $C_3S$ - $C_3A$ -gypsum pastes by SEM and EPMA. They found that both AFm and Aft phases can be formed which contain Si but no S. Lachowski *et al.* (17) studied the AFm phase in portland cement pastes with w/c 0.7, hydrated for 7 days at 25°C; they found the following atomic ratios:

Mg	Al	Si	S	K	Ca	Fe
0.01	1.06	0.11	0.15	0.02	1.99	0.03

These are mean ratios for 30 particles and are given relative to  $2(Ca + Mg)$ . Assuming the Fe to be in octahedral sites, and ignoring minor replacements, this gives the ionic constitution

$[Ca_2Al_{0.97}Fe_{0.03}(OH)_6](SO_4)_{0.15}Al_{0.79}Si_{0.11}O_4H_7$ . The constitution of the interlayer is not given in more detail because the forms in which the Al and Si occur are not known. Marked compositional variation between particles was observed (Fig 4a) and the AFm phase clearly has aspects of both a mixture and a solid solution. The mean composition corresponds to that of a mixture or solid solution of which the components are  $C_4AH_x$  (about 50 mole %), monosulfate ( $C_3A \cdot C_5H_8$ ; about 30 mole %) and a composite component with interlayer Al and Si (about 20 mole

%), all with some replacement of Al by Fe. With increase in time to 28 days (Fig. 4b), the proportion of this composite component increases, at the expense largely of  $C_4AH_x$ ; a major part of it is  $2[C_2AH_6]$ . Lachowski *et al.* also analyzed the AFm phase formed in pastes of finely-ground clinkers; as might be expected, the interlayer sites were occupied largely by  $OH^-$  and by Al- or Si-containing species, with relatively little sulfate.

# AFT PHASES

These are crystalline phases of hexagonal prism or needle morphology, and typified by ettringite,  $[Ca_3Al(OH)_6 \cdot 12H_2O]_2(SO_4)_3 \cdot 2H_2O$ . As with AFm phases, the basic structure and other data are well established; for reviews, see refs. 41-42. Aft phases have columnar structures, the material enclosed in the square brackets forming the columns and that outside them occupying the intervening channels. The Al can be replaced by  $Fe^{3+}$  or, in thaumasite,  $[Ca_3Si(OH)_6 \cdot 12H_2O](SO_4)(CO_3)$ , by Si. Various anions can occupy the channel sites, including  $SO_4^{2-}$ ,  $CO_3^{2-}$ ,  $Cl^-$ , a silicate ion of unknown constitution (45) and possibly  $OH^-$  (45). Under some conditions, solid solutions between ettringite and thaumasite can be made (46).

The Aft phase in cement pastes has usually been regarded as ettringite, but the work of Regourd *et al.* (44) suggests that it may contain Si. Lachowski *et al.* (17), in their AEM study, had difficulty in obtaining reliable analyses of Aft phase because of suspected loss of S and Ca in the beam; for a typical portland cement hydrated for 1-28 days, the mean atom ratios were Ca 4.74, K 0.09, Mg 0.03, Al 1.64, Fe 0.06, Si 0.30, S 1.60. These are means for 100 particles and are given relative to  $(Al + Fe + Si) = 2$ . The theoretical contents of Ca and S are 6 and 3 respectively; the deficiency in S is probably too large to be wholly attributable to loss in the beam and some of the channel-anion sites may be occupied by  $OH^-$  or  $CO_3^{2-}$ . The results confirm the presence of Si, and it was only possible to explain them rationally by assuming that this largely or wholly replaced Al.

# DISTRIBUTION OF SUBSIDIARY ELEMENTS IN CEMENT PASTES

The AEM studies of Lachowski *et al.* (17) give tentative indications of the distribution of the Al, Fe and S among the product phases. Comparison of the mean C-S-H composition with that of the cement suggests that about a third of the Al and by far the greater part of the S ends up in the C-S-H; the mean composition and probable amount of AFm phase are compatible with this. The data did not justify such calculations for the Fe, but suggested that this tends to enter C-S-H in preference to AFm and Aft phases.

Copeland *et al.* (47) obtained X-ray evidence of the formation of a hydrogarnet phase from a wide range of cements. It had  $a = 12.4 \text{ \AA}$ , and they concluded that it may have been silica-containing and of approximate composition  $C_6AFS_2H_8$ . Relatively few other workers seem to have detected hydrogarnet phases in normally cured portland cement pastes (18).

Seligmann and Greening (48) concluded from indirect evidence that the C-S-H formed at early ages should be high in  $SO_4$  and low in Al, and that it should lose  $SO_4$  and gain Al as reaction proceeded. There is probably no direct evidence for or against this view in the case of Al. Evidence for a decrease in  $SO_4$  content was found by Lachowski *et al.* (17).

Fig. 4 - Compositions of individual particles of AFm phases in pastes of a cement hydrated for (a) 7 days and (b) 28 days. The components are defined as  $C_4AS \cdot aq$ ,  $C_4A \cdot aq$  and  $C_4A(AS_2S_2) \cdot aq$ , with substitution of Fe for Al in each case (ref. 17).

## II. PHASES FORMED AT ELEVATED TEMPERATURES

## INTRODUCTION

The hydration products of portland cement,  $C_3S$  or  $B-C_2S$  in pastes at temperatures up to or somewhat above  $100^\circ C$  do not differ essentially from those formed at ordinary temperatures, though there are differences in morphology and microstructure. Odler and Skalný (49) studied  $C_3S$  hydration at  $25-100^\circ C$ ; the C-S-H Ca/Si ratio increased (from 1.88 to 2.04), while the  $H_2O/Si$  ratio for D-dried material decreased from 1.52 to 0.98. Bentur *et al.* (24) found more polysilicate in C-S-H formed at  $65^\circ C$  than in that formed at  $25^\circ C$ . The upper stability limit of ettringite has been studied, because of the importance of this phase for expansive cements; from static experiments, Roy *et al.* (50) placed the transition temperature for decomposition to monosulfate plus hemihydrate at  $105 \pm 5^\circ C$  at 690-1380 KPa. Satava and Veprek (51), using dynamic hydrothermal analysis, placed the onset of the DTA peak in liquid water at  $111^\circ C$ , in reasonable agreement; taken together, these studies define the maximum stability temperature at relatively low confining water pressures. Izoaki and Nakagawa (53) found that various inorganic salts failed to stabilize ettringite at  $180^\circ C$  under saturated vapor pressure. Monosulfate is reported stable up to  $190^\circ C$  (51), and in an Fe-substituted form has been obtained from  $C_4AF$  and Fe-Al-ettringite at  $190^\circ C$  (52).

The phases described in the remainder of this review are formed in autoclaved or hot-pressed materials, or hydrothermally, as in deep oil-well or geothermal cementing operations. They range from X-ray amorphous to highly crystalline phases. Because of their varying degree of crystallinity and sometimes also difficulties of isolation, many uncertainties remain about compositions and structures, especially in regard to products formed in autoclaved cement-based materials, which typically result from reactions lasting only a few hours. Nevertheless, there has been progress since the Moscow Congress review (42), in both synthetic and structural studies. Taylor and associates in Aberdeen have obtained new powder diffraction data from many of the phases for inclusion in the JCPDS file; these revisions have emphasized the use of calculated patterns whenever the structures are known, to permit recognition of impurity peaks, reliable indexing, checks on intensities, and unit-cell refinements. New combinations of analytical and structural tools have been applied to help elucidate relationships between initial phase compositions, reaction conditions, and structures and compositions of products; of particular interest is the development of a microscope for direct observation of autoclave processes (54). Some new mineral localities have been investigated that contain an abundance of hydrothermal calcium silicates and related minerals, of which the chief are the Hatrurim Formation in Israel and the Fuka locality in Japan, which have been studied by Gross (55) and by Henmi and associates in Okayama respectively.

Table II lists the phases that either have been found in cements hydrated at elevated temperatures, or which from other evidence could possibly be found in such materials, and summarizes new data. Fuller accounts of some of these recent studies follow.

## WOLLASTONITE GROUP

Xonotlite has assumed increasing importance from its

persistent formation in higher-temperature autoclaved materials and presumably in deep oil-well and geothermal cements. Kudoh and Takéuchi (56) determined the crystal structure of the Al polytype; it basically resembles the much more approximate structure found earlier by Mamedov and Belov. Kalousek *et al.* (57) studied 15 natural and synthetic xonotlites by X-ray diffraction, TG and AEM. An earlier suggestion (58) that xonotlites can be defective in Ca was confirmed; the deficiency is balanced by presence of SiOH groups, which partly or wholly explains observations that samples made at low temperatures contain more water than that indicated by the formula  $C_6S_6H$ . The results also showed that Al can enter the structure and that this affects the cell parameters. Tashiro and Kawaguchi (59) studied the effects of Ca/Si ratio and added  $Cr_2O_3$  on xonotlite synthesis. The formation temperature is increased either by departure from the 1:1 composition; or by adding  $Cr^{3+}$ . The formation temperatures at 0% and 10%  $Cr_2O_3$  were, respectively,  $210^\circ$  and  $450^\circ C$  at C/S 0.83,  $160^\circ$  and  $280^\circ C$  at C/S 1.0, and  $250^\circ$  and  $270^\circ C$  at C/S 1.2. The Cr appears to enter the C-S-H(I) structure and to interfere with formation of tobermorite.

A new polytype of wollastonite (7T) has been discovered (60). Foshagite has been proposed as a feasible constituent of geothermal cements; it appears to contribute favorably to the mechanical properties due to its fibrous habit (61,62). Hillebrandite can also occur under conditions relevant to geothermal cements (62).

## TOBERMORITE GROUP

**11 Å Tobermorite.** Considerable effort has been directed to both synthesis and properties of tobermorite phases. Many of the studies center on 11 Å tobermorite, which is a major component of many autoclaved building materials and is also formed in cementing deep oil wells. Mitsuda and Taylor (63) discussed 'normal' and 'anomalous' behavior in natural tobermorites (in normal tobermorite the basal spacing decreases to about 9.3 Å on heating at  $300^\circ C$  while in the anomalous variety it does not). Normal behavior is associated with defective silicate chains and Ca/Si ratios above the theoretical 5:6, while in the natural anomalous tobermorites studied, all of which contained Al and alkalis, the structure was defective in Ca and the Ca/(Si + Al) ratios were below 5:6. El-Hemaly *et al.* (64) reported on the synthesis of normal and anomalous tobermorites; they found reaction to pass through the sequence semi-crystalline C-S-H  $\rightarrow$  normal tobermorite  $\rightarrow$  anomalous tobermorite. Addition of  $Al^{3+}$  generally favored growth of normal tobermorite, while  $Al^{3+}$  plus alkali yielded anomalous or intermediate varieties.

**Other Crystalline Tobermorite Phases.** 14 Å tobermorite has been synthesized (64,65); Hara *et al.* (65) obtained it from prolonged reactions at  $60^\circ C$  under conditions similar to those used originally by Kalousek and Roy (66). The occurrence of 10 Å tobermorite as a natural mineral has been confirmed; Ca/Si ratios of 1.3-1.7 have been found (55,67). Tacharanite appears closely related to the tobermorite minerals; it contains essential Al and may be identical with the previously reported 12.6 Å tobermorite (55,68).

**Hydrothermally-Produced C-S-H and its Conversion into Tobermorite.** In autoclaved materials and cements hydrated under hydrothermal conditions, various forms of C-S-H can occur either as intermed-

iates in the formation of 11 Å tobermorite or as the final product. The designation "C-S-H" denotes any sub-crystalline or amorphous calcium silicate hydrate and includes a wide variety of phases, many of which probably differ markedly in structure both from the C-S-H of normally-cured cement pastes and from the tobermorite phases. The term 'C-S-H(I)' refers more specifically to forms of C-S-H with a relatively high degree of crystallinity and a composition and structure approaching those of the crystalline tobermorites. Sauman (69) explored the conditions of formation and character of the binding phases in autoclaved cement-silica materials; imperfectly developed 11 Å tobermorite and  $\text{CSH}_n$  (a form of C-S-H) were reported to be the major phases in compact silicate concretes, but cellular (aerated) concretes contained well-developed crystals of tobermorite; Mitsuda and Chan (70) showed this to be anomalous. Crennan *et al.* (71) and El-Hemaly *et al.* (72) also studied dense lime-quartz materials. They found the binder to be a poorly crystalline C-S-H, and TMS studies showed a gradual change from monomer and dimer to polysilicate as reaction proceeded and the binder Ca/Si ratio decreased. The binder  $\text{H}_2\text{O}/\text{Si}$  ratio was related to its Ca/Si ratio, very much as in the C-S-H of normally cured cement.

Several studies have been made on the transition from C-S-H into tobermorite, in reactions starting from various combinations of lime, colloidal silica and quartz (73-77). In the lime-quartz-water reaction, the reaction of the lime is controlled by the rate of dissolution and that of the quartz by diffusion through the coating of reaction products (76). The role of  $\text{Al}_2\text{O}_3$  in this reaction is complex; kaolinite can retard the reaction of the quartz, perhaps through the formation of dense, surface coatings (76, 77), but it can also accelerate the crystallization of tobermorite from C-S-H (74, etc.). Alkali accelerates reaction of quartz but retards conversion of C-S-H into tobermorite (78,79), which can take up K (80). Formation of C-S-H and tobermorite from mixtures of cement or  $\beta\text{-C}_2\text{S}$  with quartz has also been studied with reference to geothermal and other borehole applications (79,81-84). Reaction passes through successive formation of various types of C-S-H to tobermorite, and high strengths have been obtained both with C-S-H(I) and with tobermorite as the binder.

#### JENNITE GROUP

Jennite has not been synthesized, but Gard and Taylor (33) showed a possible relationship to the semi-crystalline, fibrous C-S-H(II), which can be made by aging dilute aqueous suspensions of  $\beta\text{-C}_2\text{S}$  or  $\text{C}_3\text{S}$ . They reported that W. Wieker had shown using paper chromatography and molybdate methods that C-S-H(II) contains di- and polysilicate anions. Three independent studies show that jennite does not contain any significant amount of Na, as previously supposed (55,85,86). Jennite and its dehydration product metajennite have layer structures, with the possible constitutional formulae given in Table II.

#### GYROLITE GROUP

Recent interest in phases of this group has arisen mainly because of their formation in potentially useful geothermal cements. Buckner *et al.*'s (87) observation that they form particularly readily from starting materials that include high-surface area silica has been confirmed in several recent studies (61,62,88-91); however, contrary to some previous

suggestions, they can also form from mixtures of cement or  $\beta\text{-C}_2\text{S}$  with quartz or fly-ash (61,90) and when once formed can persist in runs as long as 98 days at 350°C and 69 MPa. Concern over the suitability of truscottite as a phase in geothermal cements centers around its stability relative to the alternate assemblage containing xonotlite and quartz (89,90).

AEM and X-ray studies of natural and synthetic truscottites show that in absence of substitution, the formula is  $\text{Ca}_7(\text{Si}_{12}\text{O}_{29})(\text{OH})_{4.1}\text{H}_2\text{O}$  and that the phase can accommodate Al and K in absence of each other to the extents of about 0.7 Al or 0.25 K in the above formula (92). Substitution of Al causes a small increase in cell dimensions, which can approach those of reyerite. The latter phase is structurally very similar to truscottite, to which it appears to be related by ordered replacement of one Si in the above formula by Al and incorporation of alkali cations in otherwise vacant sites. The molecular water is zeolitically held and for any given temperature and humidity the water content of reyerite is probably at most only slightly higher than that of truscottite.

X-ray and electron-diffraction studies of Assarsson's Z-phase confirm that it is structurally related to gyrolite (93), in the formation of which it can be a precursor.

#### PHASES STRUCTURALLY RELATED TO $\gamma\text{-C}_2\text{S}$

This group includes kilchoanite,  $\text{C}_8\text{S}_8$ , calcio-chondrodite and the indefinite mixture or intergrowth of these phases known as  $\text{C}_2\text{SH}(\text{C})$  or  $\text{C}_2\text{S}$   $\gamma$ -hydrate. TMS studies confirm the presence of monomer and linear trimer in kilchoanite (27). Eilers and Nelson (94) have shown that kilchoanite can form from mixes of portland cement and quartz hydrated in heavy brines under simulated geothermal conditions, its formation being favored by use of finely ground cement with relatively coarse silica and concentrated brine. Calciochondrodite has been found in very strong, dense, hot-pressed cement pastes reacted for 30 min at 250°C, where its relatively high density is consistent with that of the microstructure (95). Jernejčič and Jelenič have confirmed that kilchoanite and  $\text{C}_8\text{S}_8$  ("P-phase") can be prepared from  $\gamma\text{-C}_2\text{S}$  and quartz at ~200°C (96).

#### OTHER CALCIUM SILICATE HYDRATE PHASES

"3.15 Å Phase". This phase, the name of which refers to the strongest powder reflection, was first described by Bezjak *et al.* (97), who determined the composition and the unit cell or pseudo cell, and studied the thermal decomposition behavior. It has also been obtained by Kalousek and Nelson (84). In both these cases the starting materials included  $\gamma\text{-C}_2\text{S}$ , but it has also been formed, together with truscottite, from mixes of  $\text{Ca}(\text{OH})_2$  and silicic acid (90). It forms typically at 250 - 300°C under hydrothermal conditions and, while possibly a purely metastable product, has been found to persist in runs of up to 28 days' duration.

$\alpha$ -Dicalcium Silicate Hydrate. This dense, orthorhombic phase forms in portland cement pastes that have been autoclaved without added silica, or in autoclaved lime-quartz pastes of suitable composition. Its presence in autoclaved building materials is normally, though not always associated with low mechanical strength, presumably caused by relatively high porosity. Chiocchio *et al.* (98) autoclaved

$\beta$ -C<sub>2</sub>S with small amounts of C<sub>3</sub>A and C<sub>3</sub>F, and showed that some Al and Fe can enter the  $\alpha$ -C<sub>2</sub>SH structure and that this generated resistance to sulfate attack.  $\alpha$ -C<sub>2</sub>SH can form as a first product on autoclaving  $\beta$ -C<sub>2</sub>S even in presence of quartz if the  $\beta$ -C<sub>2</sub>S is extremely finely divided (83). The crystal structure of the Ge analog has been determined (99); the constitution Ca<sub>2</sub>(HSiO<sub>4</sub>)(OH) found in Heller's original determination was thereby confirmed but some of the atomic positions were significantly in error.  $\alpha$ -C<sub>2</sub>SH has been found as a natural mineral (55).

**Other Phases.** New crystal structure determinations or refinements have been reported on suolunite (100), awillite (101), killalaite (102), and tricalcium silicate hydrate (103). Killalaite is identical with, or closely similar to the "Phase F" which has been found in autoclaved products. Tricalcium silicate hydrate has been found in hot-pressed cement pastes prepared at 250°C and 350 MPa (95). Dellaite has been found in reaction products of materials under investigation for high-temperature geothermal cements (61,62) but the cement compositions yielding it are probably not the most favored.

#### MISCELLANEOUS PHASES

Scawtite is a ubiquitous phase in hydrothermal calcium silicate reaction products obtained in the presence of minor concentrations of CO<sub>2</sub> up to about 350°C (61,84,90). Its formation in geothermal cementing seems to be impeded by Al (84,90) or alkalis (62). In moderate quantities it can apparently be a satisfactory binder. A new CO<sub>2</sub>-containing phase, fukalite, has been discovered (104). Pectolite, a fibrous phase, can form in large amounts in Na-bearing hydrothermal systems (62,78-80). It has been reported to coexist with truscottite, gyrolite, tobermorite, xonotlite and foshagite. Rustumite, contrary to earlier reports, contains essential Cl; its crystal structure has been determined (105).

Several calcium aluminate and aluminosilicate phases are readily formed in autoclaved materials or hydrothermally processed cements. Hydrogarnets and strätlingite (C<sub>2</sub>ASH<sub>8</sub>) have long been known; new thermal and structural data for the latter have been obtained (106). Both triclinic anorthite and its hexagonal polymorph have been found in geothermal cements (61,62,90,107). The hexagonal form can be a dominant phase, having cementing properties (61,62). A product called X-phase is now believed to be closely similar to hexagonal CAS<sub>2</sub> (61). Bicchulite (C<sub>2</sub>ASH) is another common product in high-temperature geothermal cements (61,62,90). Its crystal structure is related to that of sodalite but differs in symmetry (108). It is also related to that of C<sub>4</sub>A<sub>3</sub>H<sub>3</sub>, with which bicchulite probably forms solid solutions in which Al + H replaces Si; C<sub>4</sub>A<sub>3</sub>H<sub>3</sub> forms hydrothermally and also (95) in hot-pressed cements.

Contrary to some earlier reports that it cannot be made, the hydrogarnet end-member C<sub>3</sub>FH<sub>6</sub> has been obtained by hydration of ferrite phase at temperatures up to 80°C (109), but at 110°C only Ca(OH)<sub>2</sub> and hematite were obtained. Mössbauer spectra were found useful as an aid for characterization in this system. Hydrogarnet phases can be a major constituent of very strong pastes made either by hot-pressing (95,110), or by hydration, with or without autoclaving, of dense C<sub>4</sub>AF compacts (111). Both studies showed that strength depends not only on the structure and morphology of individual phases, but also on the density and microstructure of the material.

## 1. INTRODUCTION

Slags arising from metallurgical and similar industrial processes differ characteristically in their chemical compositions, their mineralogical and physical structure and, therefore, also in their typical properties and the possibilities of their utilization /1/ /2/ /3/ /4/ /5/. Some typical analyses of well-known types of slag are compared in TABLE I. It can be seen that even the two most important slags of iron and steel making, as there are blastfurnace slag and steel slag (LD slag in this special case), are basically different. On the other hand, blastfurnace slag can be rather similar to phosphorus slag.

The best known and quantitative most important slag is the blastfurnace slag. It arises besides the pig iron during the metallurgical treatment of iron ores and leaves the blastfurnace as a highly viscous rock melt of 1350 to 1550 °C. The specific quantity of slag which 30 years ago still amounted up to 1 t/t pig iron decreased more and more in the last years. Today slag quantities of about 0.3 t/t pig iron are sufficient for modern blastfurnaces. In 1974 the world production of pig iron was 513 Mt/year. This comes up to more than 250 Mt blastfurnace slag.

## 2. GENERAL CHARACTERIZATION OF BLASTFURNACE SLAGS

The molten blastfurnace slag is formed out of the gangue and the secondary constituents of the iron ores, the combustion residue of coke and the necessary additions as there are limestone or dolomite. Their chemical main components are CaO, SiO<sub>2</sub>, Al<sub>2</sub>O<sub>3</sub>, and MgO. At a given ore base a relative small range of the chemical composition has to be kept, because otherwise the blastfurnace operation would be disturbed or too much thermal energy would be necessary. F. SCHRÖDER reported in detail /6/ on the most useful composition of these slag melts, their liquid structures, and their liquidus

temperatures. Also V.I. SATARIN referred to it once more /7/ /8/.

This slag melt has a high content of thermal energy of about 1700 kJoule/kg (406 kcal/kg). If this energy is fully dissipated by slow cooling a stable crystalline CaO-MgO-Al<sub>2</sub>O<sub>3</sub>-silicatic rock product is formed with mechanical properties similar to basalt and being used for a long time as road construction material to a very large extent and also being suitable as concrete aggregate /1/ /2/ /3/ /4/.

The location of the blastfurnace slags within the quaternary system CaO-SiO<sub>2</sub>-Al<sub>2</sub>O<sub>3</sub>-MgO at the 10 % MgO level is shown in FIGURE 1.

FIG. 1 - Main Field of Chemical Compositions of Blastfurnace Slags with 10 wt-% MgO.

TAB. I - Characteristical Compositons of Metallurgical Slags in wt-%

	Non-Ferrous Slags				Ferrous Slags	
	Lead-Zinc Un. Kingdom	Nickel Canada	Copper South Africa	Phosphorus- furnace USA	Steel BOF (LD Slag) Germany	Iron Blast- furnace Europe
SiO <sub>2</sub>	18	29	34	41	13	34
CaO	20	4	9	44	47	41
MgO	1	2	4	1	1	7
Al <sub>2</sub> O <sub>3</sub>	6	1	6	9	1	13
FeO <sub>x</sub> + MnO <sub>x</sub>	38	53	44	1	31	1
CaO/SiO <sub>2</sub>	1.1	0.1	0.3	1.1	3.6	1.2

The most important minerals of blastfurnace slag which were found so far are given in TABLE II. The main part of the basic blastfurnace slags consists of melilite and merwinite. If the  $\text{CaO/SiO}_2$ -ratio becomes smaller than 1.0, pyroxene can occur increasingly. Contrary to some other slags and to Portland cement clinkers, blastfurnace slags never develop free oxides, such as free  $\text{FeO}$ , free  $\text{CaO}$  or free  $\text{MgO}$ . Also the lime rich clinker minerals  $3\text{CaO} \cdot \text{SiO}_2$  and  $3\text{CaO} \cdot \text{Al}_2\text{O}_3$  do not arise.

TAB. II - Mineral Compositions of Crystallized Blastfurnace Slags

Possible main components	
Melilite	solid solution of
Gehlenite	$2\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{SiO}_2$
and	and
Akermanite	$2\text{CaO} \cdot \text{MgO} \cdot 2\text{SiO}_2$
Merwinite +	$3\text{CaO} \cdot \text{MgO} \cdot 2\text{SiO}_2$
Diopside ++	$\text{CaO} \cdot \text{MgO} \cdot 2\text{SiO}_2$
and other Pyroxenes	
Possible minor components	
Dicalcium silicate +	$2\text{CaO} \cdot \text{SiO}_2$
( $\alpha, \alpha', \beta, \gamma$ )	
Monticellite +	$\text{CaO} \cdot \text{MgO} \cdot \text{SiO}_2$
Rankinite	$3\text{CaO} \cdot 2\text{SiO}_2$
Pseudo-Wollastonite	$\text{CaO} \cdot \text{SiO}_2$
Oldhamite	$\text{CaS}$
Seldom observed minor components	
Anorthite ++	$\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$
Forsterite	$2\text{MgO} \cdot \text{SiO}_2$
Enstatite ++	$\text{MgO} \cdot \text{SiO}_2$
Perovskite	$\text{CaO} \cdot \text{TiO}_2$
Spinnelle	$\text{MgO} \cdot \text{Al}_2\text{O}_3$
+ only in basic slags ++ only in acid slags	

Fully crystallized blastfurnace slags of the usual composition have either no or only very weak hydraulic or latent hydraulic properties. If, however, caused by quick cooling, this lowest energy level of the crystallized stage is not reached, then an unregular slag glass, richer in energy is formed (heat of crystallization about 200 Joule/g). This granulated blastfurnace slag is latent hydraulic. The lower energy level is obtained by forming solid hydration products under heat evolution when activated by lime and sulphate. These are

principally the same hydrates as we have in Portland cements /7/ /9/.

The yearly production of granulated blastfurnace slags in Western Europe amounts to approx. 22 Mt /2/. The tendency to use their hydraulic properties for cement, concrete, and road building material is increasing.

### 3. GRANULATED BLASTFURNACE SLAG

#### 3.1 Granulation

It was in 1953 when the granulation of the blastfurnace slag was started in order to produce a granular bulk material out of the slag melt which can easily be transported. In doing so a sand with a more or less high content of glassy constituents was formed. In 1962 EMIL LANGEN found out that this product showed certain hydraulic properties. Some time later it was proved that the glassy constituents of granulated blastfurnace slag, namely the super cooled slag melt, was the carrier of the latent hydraulic properties. Thereupon, the granulation processes were improved to obtain granulated blastfurnace slags with a high glass content for the production of slag cements. The glass content of modern cement slags amounts to 90 wt-% and more.

Since 1953 many granulation processes were tested and applicated /1/ /10/. It was the aim of all these processes to abstract as much heat as possible from a large quantity of molten slag in the shortest possible time. For that purpose in all cases the slag is broken into small droplets or grains up to a size of 3 or 5 mm which then are brought into contact with a lot of air or water as coolants. Processes running with compressed air have the advantage of a dry product. By this dry-granulation process, however, glass contents of only 60 to maximum 80 wt-% are obtained and, therefore, granulation is mainly done with water today.

In case of basic blastfurnace slags suitable for the cement production it is especially important to reach very quickly temperature ranges  $< 800^\circ\text{C}$  in order to keep the glassy state /6/. The glass already starts to recrystallize between 800 and  $900^\circ\text{C}$ , and merwinite is precipitated as the first phase /6/. High quantities of water or an increased water pressure are necessary for prevention. Mostly both methods are combined. Water quantities of up to  $10 \text{ m}^3/\text{t}$  of slag are reported for granulation in water channels. If granulation is carried out with spraying jets the water jets are under compressions up to 6 bar. In this case the water quantity could be reduced to  $3 \text{ m}^3/\text{t}$  of slag. The most modern German granulation plant is situated at a blastfurnace with a pig iron production of 9500 t/day. The capacity of this plant is to granulate 3000 t of  $1550^\circ\text{C}$  hot blastfurnace slag a day at a hydrostatic pressure of 2.2 bar and a water quantity of about  $10 \text{ m}^3/\text{t}$  of slag /11/. The glass content of the granulated slag reaches 95 to

100 wt-%.

After granulation the water content of slags can be undesirably high and can exceed 30 wt-%. The greatest portion of the water will, therefore, be removed by intermediate storage in gravel filter basins /11/ or in interposed water extraction tanks /12/. Another part is still lost during transport to further treatment. Subsequently the granulated blastfurnace slags still have water contents of 8 to 12 wt-% and can directly be grinded to slag cements in dryer-mills /11/ /12/. For grinding in usual cement mills or for producing supersulphated cements the slag is dried up to a residual moisture of wt-%.

A new granulation equipment named "Pelletizer" was developed in Canada and is operating in some other countries, too /10/ /13/ /14/. It is a half-dry granulation process by which the molten slag is pre-cooled with water and is flung into the air by a rotary drum (300 r.p.m.). As it is shown in FIGURE 2 different fractions result from this process. The large pellets up to 15 mm have a lower glass content and are suitable as lightweight aggregate. The smaller fractions up to 3 or 5 mm have a higher glass content and are reported to be suitable for the production of blastfurnace slag cements. The process seems to be advantageous because of the low water consumption of about 1 m<sup>3</sup>/t of slag and the small residual moisture of the pelletized material of about 10 wt-%.

FIG. 2 - Slag Pelletizer (System GALEX /14/)

Tests of CERILH showed an even lower water consumption by this thermomechanical granulation method. Even at a total dry thermomechanical treatment blastfurnace slags still had satisfying hydraulic properties /15/ /16/.

According to prevailing opinion a hydraulic active blastfurnace slag should have a high glass content, if possible > 90 wt-%. On the other hand, it seems that small amounts of crystalline material in the vitreous slag will not have very detrimental ef-

fects /15/. From other investigations it is even reported that crystal nuclei in the vitreous slag have an advantageous effect /7/ /8/ /17/.

### 3.2 The Structure of Vitreous Blastfurnace Slag

The network theory of ZACHARIASEN /18/ proved a suitable basis to describe the structure of the vitreous slag and some of its properties /5/ /19/. At this the glass consists of a more or less disturbed three-dimensional net of oxides of network forming elements. They are characterized by small ionic radii and by highest possible ionic valencies. They are surrounded by 4 oxygen atoms only (co-ordination number 4) in the form of a tetrahedron. The network is formed that way that distinct oxygen atoms belong to two tetrahedra at the same time. One typical network former is silicium. Within the vitreous blastfurnace slag it forms  $\text{SiO}_4^{4-}$  tetrahedra,  $\text{Si}_2\text{O}_7^{6-}$  groups, chains, and other polymerization products /20/.

The negative valencies of these anionic-groups become neutralized by the positive valencies of cations. They are called network modifiers. In general, they have larger ionic radii and higher co-ordination numbers than the network formers and are mostly situated in the cavities of the network. A typical network modifier within the vitreous blastfurnace slag is the  $\text{Ca}^{++}$ -ion with the co-ordination number 6.

The higher the part of network modifiers is the smaller the polymerization grade of the network-forming  $\text{SiO}_4$ -tetrahedra will be. That means that the glass has a smaller stability and a higher chemical reactivity. The state of bond of the other two main components of the blastfurnace slag, as there are aluminium and magnesium is said to play an important role. These two amphotere metals appear in silicates, both in fourfold co-ordination and in sixfold co-ordination /6/ /19/. Their bond within the vitreous slag as network former ( $\text{AlO}_5^{5-}$  and  $\text{MgO}_6^{6-}$ ) or as network modifier ( $\text{Al}^{+++}$  and  $\text{Mg}^{++}$ ) has been investigated with different results for a long time /6/ /7/ /19/ /20/.

Today it is proved that aluminium and magnesium can also arise in the vitreous slag both in fourfold co-ordination and in sixfold co-ordination at the same time /6/ /7/ /20/. In this case the ratio of  $\text{MeO}_6/\text{MeO}_4$  depends on the chemical composition and the thermal treatment (granulation) of the glass /7/ /20/.

The kind of bond of the  $\text{MgO}$  as a constituent of the three-dimensional glass network makes it understandable why no free  $\text{MgO}$  was found in granulated blastfurnace slags even not at  $\text{MgO}$ -contents of 10 to 20 wt-% /21/ /22/ /23/. In case of hydration of the vitreous slag the magnesium will be incorporated into the hydration products and even at high  $\text{MgO}$ -contents up to 20 wt-% no  $\text{Mg}(\text{OH})_2$  and no expansion phenomena were observed /7/ /8/ /20/ /24/ /25/ /26/ /27/ /28/ /29/.

The minor components of the blastfurnace slag, such as manganese, titanium and sulphur, are also constituents of the glass structure in the granulated slag. Sulphur is probably incorporated homogeneously as S in the places of oxygen into the network. The precipitation of sulphides starts first at contents of  $> 3.3$  wt-% /30/. Manganese was found in sixfold co-ordination in synthetic vitreous slags with MnO-contents up to 7.5 wt-% /19/. Titanium seems to exist in sixfold co-ordination at  $\text{TiO}_2$ -contents up to 4 wt-%. At  $> 4$  wt-%  $\text{TiO}_2$  it becomes a network former with fourfold co-ordination /20/.

The opinions on the influence of the glass structure on the hydraulic properties of the blastfurnace slag are not always uniform. This is due to different reasons. First of all it depends on the method by which the hydraulic properties are tested. The following properties of the slag can be measured: rate of solution, reactivity at alkaline and/or sulphatic activation, strengths of test cements after a few days or after months.

In case of different slags the reactivities mostly have another sequence than the strengths of the cements. Cements with low early strength often develop a higher final strength than early strength cements. Furthermore, besides the thermal pretreatment the glass structure is very strongly influenced by the chemical composition /7/ /20/ /31/. Therefore, the influence of the chemical composition on the hydraulic properties of the slag can mostly be recognized much clearer than the influence of the glass structure on the hydraulic properties /32/.

The strength forming constituents of the hydrated slag cement are the calcium silicate hydrate phases as it is with Portland cement. Consequently, pure  $\text{CaO-SiO}_2$ -glasses should reach the highest strengths. They would, however, react too slowly at normal temperature. It is therefore important that the network of  $\text{SiO}_4$ -tetrahedra within the blastfurnace slag is disordered by additional constituents, such as aluminium and magnesium. As a result, the glass is on a higher energy level, is less stable and has a higher reactivity.

For this case, the way in which these amphotere elements become effective by modifying the glass structure was estimated in different ways. They are reported to have a high effectiveness if they are present in sixfold co-ordination and thus in form of network modifiers they reduce the degree of polymerization of the  $\text{SiO}_4$ -tetrahedra /20/ /33/. Thus the reactivity of the glass is increased. It has, however, to be taken into account that not all network modifiers have this function. Manganese for example is present in sixfold co-ordination at contents up to 7.5 wt-% MnO /19/, but nevertheless it stabilizes the slag glass and reduces its hydraulic activity /34/. According to a different opinion aluminium in fourfold

co-ordination as a network former is of high effectiveness because the cations of the  $\text{AlO}_4$ -tetrahedra in the network are bound more weakly as for example by the  $\text{SiO}_4$ -tetrahedra and, therefore, they become dissolved more easily /35/.

The investigation of 15 Russian blastfurnace slags with same  $\text{Al}_2\text{O}_3$ -contents (5.3 to 6.1 wt-%) and comparable chemical compositions (4.4 to 6.3 wt-% MgO) showed that the highest effectiveness can be expected in case of a certain ratio of Al and Mg in sixfold co-ordination to Al and Mg in fourfold co-ordination /7/. The highest strengths were obtained at a

$$\frac{\text{MeO}_6}{\text{MeO}_4} - \text{ratio of } 0.35$$

There not always exists unanimity on the significance of the states of bond and co-ordination numbers in the glass structure of the blastfurnace slag and the measuring methods are partly quite complicated. On one point, however, all experts agree: the glass structure of the slag has to be disordered as strongly as possible to get a high hydraulic effectiveness.

There is also the opinion that the beginning of crystallization can result in a more disordered glass structure and in an increased reactivity of the slag /17/ /36/. In this connection, however, various investigation methods and effects have to be taken into consideration. The solubility of certain elements, such as Ca, Na, K, and S, increases with increasing amount of crystalline constituents in the granulated blastfurnace slag /36/. This, however, is no argument for better hydraulic properties of the glassy constituents.

If, however, the influence of the crystalline constituents on the strength of a blastfurnace slag cement is tested, their kind and distribution will certainly be of importance. If parts of the ground slag are present in form of totally crystallized grains, the strength will accordingly be lower. If, on the other hand, crystals of smaller size are tightly intergrown with the vitreous slag, they will most likely be of unessential influence on the strength. A higher strength could be expected if the crystalline constituents are homogeneously distributed in the vitreous slag as sub-microscopic crystal nuclei.

Finally it has to be considered that by crystalline influences the grindability of the slag will improve. Advantageous and detrimental effects have possibly to be discussed altogether in case there are mentioned good hydraulic properties of blastfurnace slags containing noticeable crystalline portions /7/ /15/ /37/ /38/.

An additional view is based upon the opinion that even without crystalline separations the vitreous slag will not have a homogeneous structure but consists of micro heterogeneous ranges (500 to 4000 Å) of different

glass phases /39/ /40/. The highest hydraulic effectiveness is expected if the different ranges are not too large and if there is an optimum phase separation /41/.

The investigation of the microstructure of the vitreous blastfurnace slag is very important from the scientific angle of view. It cannot be expected, however, that the hydraulic behaviour of glasses is mainly based on their structure /42/. Due to the fact that the test methods are rather complicated, they did not reach much importance for the valuation and the control of cement slags. It is more essential to control the glass content of the granulated blastfurnace slag by well-known microscopic or X-ray methods in a relatively simple way.

One testing method by which also structural properties of the blastfurnace slag can indirectly be evaluated, too, is the well-known investigation of their fluorescence in the ultra-violet radiation /6/ /7/ /43/. The reason for this fluorescence in the light pink and red range of the spectrum are defects in the glass structure which also increase the reactivity of the slag. This ultra-violet test is an approved method to control well-known blastfurnace slags. In case of more different slags a combination with the CaO/SiO<sub>2</sub>-ratio proved appropriate /43/. Ultra-violet tests with unknown slags should also consider the chemical analysis.

### 3.3 Influence of the Chemical Composition

In case of evaluating the hydraulic properties of the blastfurnace slag in practice besides the glass content the chemical composition is of great importance. It is a characteristic attribute, for it determines the basicity and the kind of reaction of the slags and also influences the structure of the vitreous slag.

In TABLE III analyses of blastfurnace slags from different areas of the world were summarized which are used as hydraulic active components of cements or concretes. It has to be considered that within the various ranges increasing MgO-contents generally coincide with decreasing CaO-contents. The ranges of CaO + MgO are, therefore, smaller than the ones of CaO. It can be seen that generally the ranges of SiO<sub>2</sub>, CaO + MgO and Al<sub>2</sub>O<sub>3</sub> are rather similar. The on an average high MgO-contents of the slags from South Africa and the very high Al<sub>2</sub>O<sub>3</sub>-contents of the slags from India are remarkable.

As chemical analyses can be carried out in rather a simple and quick way a lot of attempts were made to characterize the blastfurnace slags by chemical hydraulic-factors or -moduli. For the discussion of these factors and formulas the following abbreviations are used:

$$\text{SiO}_2 = S \quad \text{CaO} = C \quad \text{MgO} = M \quad \text{Al}_2\text{O}_3 = A$$

The basicity ratios  $p$  of the slag /1/, well-known from the blastfurnace practice, were the starting-point for most of the hydraulic

identification values.

$$P_1 = \frac{C}{S} \quad P_2 = \frac{C+M}{S} \quad P_3 = \frac{C+M}{S+A}$$

These basicity ratios- however, are not very suitable as hydraulic factors because the alumina is not taken into account in the proper way. Furthermore, the common name "acid slag" for  $p_1 < 1$  is no limiting value for hydraulic slags, if the lower CaO-contents are compensated by corresponding higher contents of MgO and Al<sub>2</sub>O<sub>3</sub>.

TAB. III - Ranges of Chemical Composition of Granulated Blastfurnace Slags in wt-%

Area	SiO <sub>2</sub>	CaO	MgO	Al <sub>2</sub> O <sub>3</sub>	Reference
USSR	30/40	30/50	14/2	5/17	(7)
USA and Canada	33/42	36/47	16/1	6/16	(2) (44) (45)
Australia	33/38	39/44	4/1	15/19	(2) (45)

Western Europe + Yugoslavia <sup>+</sup>	30/38	33/47	10/2	9/18	(2) (10) (45) (46)

Ranges of minor components generally less than 4 % TiO<sub>2</sub>, 2 % MnO, 3 % FeO, 2 % S, 2 % Na<sub>2</sub>O + K<sub>2</sub>O

<sup>+</sup>) average ranges of granulated BF-slugs from Yugoslavia, Italy, Spain, France, Belgium, Netherlands, United Kingdom, and Germany-West

The best-known hydraulic factors are listed in TABLE IV. The first group  $F_1$  to  $F_7$  consists of the main components of the blastfurnace slag only.  $F_1$  is also included because in a comprehensive comparison the ratios  $F_1$  to  $F_6$  showed the same statistical significance of insignificance, respectively.  $F_2$  and  $F_3$  anyhow contain nearly the same statement /1/.  $F_3$  is the best-known modulus which was incorporated into the regulations of various countries (e.f.  $F_3 \geq 1.0$  in Western Germany,  $F_3 \geq 1.4$  in Japan).  $F_7$  was developed for the 28-day strength of MgO rich slags with Al<sub>2</sub>O<sub>3</sub>-contents in the range of 10 to 35 wt-% and is not relevant for the usual blastfurnace slags.

In the factors  $F_8$  to  $F_{10}$  MnO and other minor components are taken into consideration, too.  $F_{10}$  was proposed for MnO-contents up to 14 wt-%. In the case of the moduli  $F_{11}$  and  $F_{12}$ ,

the hydraulicity of the slag is reduced by increasing  $Al_2O_3$ -contents.  $F_{11}$  was originally developed for the 28-day strengths. In the case of  $F_{12}$  it is especially stated that this modulus is valid for strengths after 28 days and more only, whereas  $F_3$  and  $F_4$  are more suitable for the 2-day strengths /10 /32/.

The applicability of the ratios  $F_3$ ,  $F_5$ ,  $F_6$ ,  $F_8$ , and  $F_{11}$  to 26 blastfurnace slag cements with 50 wt-% slag was statistically tested in a comprehensive program with 13 different granulated blastfurnace slags /53/. For the early strengths up to 3 days no correlations could be determined. In the case of the strengths after 7 and 28 days,  $F_3$  and  $F_8$  showed the best correlations. The coefficients of determination (square of the correlation coefficient  $r$  in %) were

$$r^2 = 35 \text{ to } 83 \, \%.$$

TAB. IV - Well-Known Hydraulic Factors for Granulated Blastfurnace Slag

$F_1 = 100 - S$ (1)	$F_2 = \frac{100 - S}{S}$ (1)	$F_3 = \frac{C + M + A}{S}$ (1)
$F_4 = \frac{C + M + A - 10}{S + 10}$ (47)	$F_5 = \frac{C + 1.4M + 0.6A}{S}$ (22)	
$F_6 = C + 0.5M + A - 2.0S$ (48)	$F_7 = \frac{6C + 3A}{7S + 4M}$ (49)	
$F_8 = \frac{C + 0.5M + A + CaS}{S + MnO}$ (1)	$F_9 = \frac{C + 0.5M + A}{S + FeO + (MnO)^2}$ (50)	
$F_{10} = \frac{C + M + A + BaO}{S + MnO}$ (51)		
$F_{11} = \frac{C + M + 0.3A}{S + 0.7A}$ (52)	$F_{12} = \frac{C + M}{S + 0.5A}$ (32)	

A similar experiment was made in the Forschungsinstitut Eisenhüttenschlacken during an extensive test series with 24 granulated blastfurnace slags (glass contents > 95 %) the chemical analyses of which covered the whole range of Western-European slags listed in Table III /46/. 192 blastfurnace slag cements were made (2 clinkers, 2 specific surfaces, 60 wt-% and 75 wt-% granulated slag) and strengths according to German Cement Standard DIN 1164 were measured from 2 up to 91 days. The linear correlations to a lot of hydraulic factors were tested on the basis of the compressive strengths after 2 and 28 days of the 96 blastfurnace slag cements with 75 wt-% granulated slag. The ratios  $F_1$ ,  $F_2$ ,  $F_3$ ,  $F_4$ ,  $F_6$ ,  $F_8$ , and  $F_9$  showed the best coefficients of determination  $r^2$ . They all were low and there was no significant difference between the 7 moduli. After 2 days  $r^2$  ranged from 51 to 61 % and after 28 days from 44 to 50 %. In this case the average results of the simple ratios  $F_1$  and  $F_2$  considering  $SiO_2$  only were not worse than the more complicated ones. This phenomenon was referred to by F. KEIL a long time ago already /4/.

By the calculation of coefficients for each of the chemical components on the basis of multiple regressions, the items  $F_3$  and  $F_6$  could be extended to hydraulic ratios with  $r^2$  from 60 to 75 %. A decisive improvement was obtained only after the basis of linear influences was neglected. The compressive strengths of 2, 7, 28, 56 and 91 days then resulted in the complicated empiric interpolation formula

$$D = a_0 + a_1 \cdot f(C+M) + a_2 \cdot f(A) + a_3 \cdot f(MnO) + a_4 \cdot f(Na_2O + 0.66 K_2O) + a_5 \cdot f(P_2O_5)$$

The individual terms " $f(X)$ " of this formula are non-linear functions of the chemical components. The coefficients "a" strongly depend on the type of clinker component especially at early strengths. All the coefficients of determination  $r^2$  were better than 90 %. After 2 days they amounted to 93 % and after 28 days to 94 %.

This formula practically represents only the mathematical description of the strength development of 192 blastfurnace slag cements (960 data).  $SiO_2$  does not appear in the formula, for it is implicated as a completion to 100 wt-%. Because of the high statistical significance the following results were safely proven:

a) An increase of the  $Al_2O_3$ -content above 13 wt-% increased the early strengths only. FIGURE 3 shows that the 91-day strengths were even lower at higher  $Al_2O_3$ -contents. This tendency is indicated in Table IV by the factors  $F_{11}$  and  $F_{12}$ .

b) MgO in the range up to 11 wt-% had quantitatively the same effectiveness as CaO had.

c) If the minor components MnO (up to 1.4 wt-%),  $P_2O_5$  (up to 0.2 wt-%), and alkali (up to 1.9 wt-%) were not considered,  $r^2$  decreased to a value of 80 to 85 %. In every case MnO had a negative effect. The influences of  $P_2O_5$  and alkali depended on the kind of the clinker used and on the testing age. After 28 days  $P_2O_5$  always proved positive. Partly the effect of the minor components was so strong that after 7 days already some blastfurnace slags with 11 wt-%  $Al_2O_3$  showed higher strengths than those with 15 wt-%  $Al_2O_3$ .

d) The statistical examination of  $TiO_2$  (up to 1 wt-%), FeO (up to 2 wt-%), and sulphur (up to 2 wt-%) did not prove any significant influence.

e) Besides the clinker-content and the fineness, the strength developments of the blastfurnace slag cements also considerably depended on the kind of clinker.

For the investigated range of the chemical compositions these results conform well to the general state of knowledge upon the hydraulic properties of granulated blastfurnace slag.

All experts agree that increasing  $SiO_2$ -contents generally have a negative effect and

FIG. 3 - Average Variation of Compressive Strengths of Blastfurnace Slag Cements with Increasing Al<sub>2</sub>O<sub>3</sub>-Content of the BF Slag. Cements with 75 wt-% slag and 3850 Blaine.

that CaO usually has a positive influence. With the exception of a few special cases also MgO is said to have a positive influence up to contents of 18 wt-% /20/ /53/, 15 wt-% /22/ /54/ and, for sure up to contents of 12 wt-% /46/ /55/. According to Russian authors the most suitable MgO-content depends on the Al<sub>2</sub>O<sub>3</sub>-content /56/. In the case of MgO-contents of 10 to 12 wt-% /55/ or 13 to 18 wt-% /20/ accordingly higher Al<sub>2</sub>O<sub>3</sub>-contents of 14 to 18 wt-% are recommended. For the hydraulic moduli (see Table IV) MgO is added to CaO by multiplying it with factors of 0.5 to 1.4. The most often used factor is 1.0 which was statistically confirmed for MgO-contents up to 11 wt-% /46/.

The two publications reporting on a strength-diminishing influence of MgO cannot be compared with the other literature. In the first publication blastfurnace slags with 25 to 28 wt-% Al<sub>2</sub>O<sub>3</sub> from India were investigated which apparently react in a different way /27/. In the second publication synthetic glasses of the system CaO-MgO-Al<sub>2</sub>O<sub>3</sub>-SiO<sub>2</sub> were activated with Ca(OH)<sub>2</sub>, only /49/. A comparison with the strengthening of slag cements is impossible because the important components sulphate and alkali are missing. In blastfurnace slag cements sulphate is added not only as a set-regulating component but is also used for the optimum activation of the slag /6/ /9/. Furthermore, pore solutions in hardening Portland cements and blastfurnace slag cements are no Ca(OH)<sub>2</sub>-solutions at all but highly concentrated alkali hydroxide solutions with Ca(OH)<sub>2</sub> as a precipitate /57/ /58/.

The interpretations of the influence of Al<sub>2</sub>O<sub>3</sub> are apparently contradictory because the influence depends on the testing age /32/ /46/ and on the Al<sub>2</sub>O<sub>3</sub>-range investigated /46/ /53/. The considerably positive influence up to contents of 18 to 21 wt-% /20/ /22/ /55/, also expressed in most of the hydraulic factors is evidently re-

stricted to the early strengths /32/ /46/. At testing ages of 28 days and more a diminishing of the effectiveness of Al<sub>2</sub>O<sub>3</sub> is reported /53/ and a negative influence begins if the Al<sub>2</sub>O<sub>3</sub>-contents will exceed a maximum of 13 to 14 wt-% /46/. According to other investigations contents of more than 11 wt-% already can cause a distinct decrease of the strengths after 7 and 28 days /32/. These results prove that the influence of Al<sub>2</sub>O<sub>3</sub> in a hydraulic formula cannot be described as a linear term.

MnO is commonly said to have a detrimental influence /1/ /7/ and according to this it appears as a strength diminishing term in all hydraulic moduli (see Table IV). Nevertheless, there is also a report on good hydraulic properties of blastfurnace slags containing up to 14 wt-% MnO /51/. In case of a special form of the glass structure /34/ or at higher Al<sub>2</sub>O<sub>3</sub>-contents /59/ no effect was found at all or even advantageous effects were observed at MnO-contents up to 6 wt-% /60/.

As reported TiO<sub>2</sub> distinctly diminishes the strength in case of contents of more than 4 wt-% /61/. The detrimental influence can be reduced by adding alkali to the slag melt /62/.

Finally it must be considered that the kind of the clinker component has a great influence on the strength development of blastfurnace slag cements /46/ /63/ /65/. Little is known of quantitative correlations so far. Generally, clinkers with high CaO-contents or high C<sub>3</sub>S-contents or with highest possible early strengths are preferred. While discussing the clinker components of blastfurnace slag cement the fact was often neglected that not only the clinker activates the slag but that vice versa the slag itself and its minor components can have great influence on the strength development of the clinker component.

Summarizing, it has to be taken into account that a hydrating blastfurnace slag cement is a complicated multi-material system. Therefore, it cannot be expected that the resulting strength development can be predetermined by aid of simple hydraulic factors. In the regulations of several countries these hydraulic moduli are referred to for a rough classification into different groups of blastfurnace slags and they have also proved suitable for the control of known slags within relatively small ranges. This applies especially to blastfurnace slags coming from one steel plant only. They, however, neither have the grade of generally valid functional correlations between hydraulicity and chemical composition nor are they suitable to quantitatively classify blastfurnace slags coming from different plants.

#### 4. CHARACTERISTIC PROPERTIES OF BLASTFURNACE SLAG CEMENTS

Blastfurnace slag cements with slag contents in the range of 36 to 80 wt-% (Western

Germany) or up to 95 wt-% (France) can be produced in the same strength classes (28 days) as Portland cements except those of the highest strength class getting more than 60 N/mm<sup>2</sup> after 28 days (ISO). Blastfurnace slag cements, however, have a somewhat different strength development than Portland cements. Having the same 28-day strength the 2-d strength of blastfurnace slag cements in general is lower, but the strength increase after 28 days is higher and more continuous than the one of Portland cements. FIGURE 4 shows the characteristic strength developments of a Portland cement and a blastfurnace slag cement containing 65 wt-% slag.

FIG. 4 - Average Strength Development of Cements Z 35.  
Reference point: 45.0 N/mm<sup>2</sup> after 28 days

For a long time these specialities are as well-known as the low hydration heat of blastfurnace slag cements and their higher resistance against various chemical attacks /6/ /7/, which only recently has been proved by new investigations /66/ /67/. Also the special qualification of blastfurnace slag cements for marine constructions was verified again by evaluating extensive long-time studies with mortar and concrete /68/ /69/, as well as by research works on seawater desalination equipments /70/.

Discussions on steel corrosion in connection with blastfurnace slag cements are not to be repeated here for they are mostly based on theoretical suppositions only. In practice any damages of this kind are not known, and in the meantime respective apprehensions have proved unfounded /6/ /71/ /72/ /73/. In Western Germany blastfurnace slag cement is used for all kind of prestressed concrete /67/. One of the most modern big engineering structures made entirely from blastfurnace slag cement (HOZ 35L and HOZ 45L) is the prestressed posttensioned concrete bridge over the river Rhine at Köln-Deutz. The bridge was built as unsupported cantilever construction with lightweight concrete /74/.

Three important characteristic properties of blastfurnace slag cements less known up to

now were investigated quantitatively only recently:

Blastfurnace slag reduces the reactivity of the cement with alkali reactive aggregates /75/ /76/ /77/ /78/. For the quantitative correlation between the effective alkali content  $A_{eff}$ , decisive for the alkali reaction, and the total alkali content  $A$  of the cement in dependence of its content of granulated blastfurnace slag  $H$  the formula

$$A_{eff} = A \cdot \left[ 1 - \left( \frac{H}{H_0} \right)^2 \right]$$

was proposed /79/.  $H_0$  is a constant, which means that in case of  $H \geq H_0$  no expansion phenomenon will occur. The examination of 40 Portland and blastfurnace slag cements executed by a working group of the Verein Deutscher Zementwerke e.V., confirmed this formula. Provided that Portland cements with  $\leq 0.60$  wt-% alkali (Na<sub>2</sub>O-equivalent) in practice do not cause any alkali damages (low alkali cements) - that means, in case of  $A_{eff} \leq 0.60$  wt-% - the permitted alkali content of low alkali cements resulted in /80/

$$A \leq \frac{0.60}{1 - 1.8 \cdot (H/100)^2}$$

The effect of blastfurnace slag in this formula is plotted in FIGURE 5. TABLE V shows the limiting values for NA-cements (low alkali cements) fixed in German regulations /81/.

FIG. 5 - Alkali Contents of NA-Cements.  
(Cements with  $\leq 0.60$  wt-% effective alkali)

One property being of importance for the corrosion protection of the reinforcement as well as for the prevention of alkali aggregate reactions, is the high resistance of concrete made from blastfurnace slag cement against the diffusion of chlorides /68/ /82/ /84/ /85/ and alkalies /84/ /86/. The diffusion resistance increases considerably with an increasing content of granulated blastfurnace slag /84/ /86/ /88/. At this

TAB. V - Cements with Low Effective Alkali		
	Total alkali in wt-% Na <sub>2</sub> O equivalent	Granulated blastfurnace slag in wt-%
Portland cement	≤ 0.60	-
Blast- furnace slag cement	≤ 1.10	≥ 50
	(≤ 2.00)	≥ 65

the composition of the cement has a distinctly stronger influence than even the w/c-ratio of the concrete has /87/ /88/. If blastfurnace slag cements containing > 70 % slag are used, concrete layers of more than 2 cm thickness become practically impermeable for NaCl /67/ /86/. The graph in FIGURE 6 shows the influence of the blastfurnace slag in the cement on the progress of Cl-diffusion in concrete bars 10 x 10 x 50 cm. The relative intensity of the influence is characteristic for blastfurnace slag /83/ /84/ /87/.

FIG. 6 - Chloride Diffusion into Concrete Bars.  
NaCl-solution: 3 mol/l - Test layer: 2/4cm  
The third typical property of concrete made from blastfurnace slag cement is the increasing impermeability with increasing content of blastfurnace slag /6/ /89/ /90/. Some special properties of blastfurnace slag cements are closely connected with

this higher density. In this case not the total pore volume, which highly depends on the w/c-ratio, is decisive, but the more advantageous pore-size distribution of the blastfurnace slag cements /87/ /91/. The hardened cement paste of Portland cements has a higher quantity of capillary pores (radius > 300 Å), whereas blastfurnace slag cements develop more gel pores. That means that in the paste of blastfurnace slag cements the average pore size is smaller /87/. The results of an extensive test series with 6 cements with graduated contents of blastfurnace slag and with different storage conditions of the test specimens could be evaluated statistically /91/. With increasing content of blastfurnace slag, the pores > 300 Å decreased continuously. With increasing slag content of 0 to 76 wt-% slag, the quantity of these pores expressed as volume-% of the hardened paste were reduced from 30.5 to 22.5 volume-% (after storage in water) or from 37.0 to 25.0 volume-% (after dry storage). That means a relative reduction of the capillary porosity of about 25 to 30 %.

#### 5. REVIEW ON THE UTILIZATION OF GRANULATED BLASTFURNACE SLAG

Besides Portland cement clinker, granulated blastfurnace slag is the only cement component which corresponding to its hydraulic effectiveness can be used as well as a secondary constituent of the cement as also a main constituent with more than 50 wt-% up to 80 wt-% (Germany) or even 95 wt-% (France). Such high slag contents should only be used, however, if these slag cements are produced in the cement plant from the definite single components in the same way as all the other cements, and if they are tested and controlled in the same way. In countries where suitable blastfurnace slags and sufficient experience with slag cements are available, blastfurnace slag cements are used in the same way as other cements and in certain cases they are favoured /6/ /7/ /68/ /69/ /81/. The tendency is increasing for there is no other cement component by which more energy and natural resources can be saved than it is with the granulated blastfurnace slag /3/ /53/ /92/. In case of a modern fabrication technique for the production of 1 t Portland cement about 1.5 t raw meal and 3.53 G Joule ( $840 \cdot 10^3$  kcal) energy are necessary. For the production of 1 t blastfurnace slag cement containing 65 wt-% slag which originally had a residual moisture of 15 wt-%, only 0.5 t raw meal and 1.67 G Joule ( $400 \cdot 10^3$  kcal) are necessary. In this calculation the drying of the slag was considered as well as the different demands of electrical energy which are necessary to grind either the raw meal and the clinker, or the slag /93/. Calculations with similar results are reported for North America where it is expected that the blastfurnace slag component of all cements will rise to about 30 wt-% within the next decade /92/.

It is nearly impossible to list up the total utilization of granulated blastfurnace slag quantitatively, for in many countries also Portland cements are allowed to contain slag (for instance in Germany  $\leq 5$  wt-%, in Austria  $\leq 15$  wt-%, in Yugoslavia  $> 15$  wt-%). In other countries (for instance South Africa and Great Britain) most of the granulated blastfurnace slag is mixed into the concrete at the building site. In France about 10 to 15 million t "Graves-Laitier" are used for road construction yearly /2/ /3/. This hydraulic hardening material contains 15 to 20 wt-% granulated blastfurnace slag and about 1 wt-%  $\text{Ca(OH)}_2$  as an activator /94/ /95/ /96/ /97/. In 1977 in France 3.0 million t granulated blastfurnace slag were used for road construction and 2.9 million t were used for cement production /3/. At last blastfurnace slags are used in multicomponent mixtures, too, which besides clinker and slag contain also natural or artificial pozzolanas. The production of super sulphated cement has been very much reduced.

For these reasons statistics about worldwide production data and applications of granulated blastfurnace slag often differ very much. Even data given for slag cements are not in good accordance. To allow at least a rough orientation for the cements, in TABLE VI data are summarized for those countries which produce more than 2 million t slag cement a year. Data for 1977 were asked for by personal correspondence /45/, whereas data for 1978 were taken from official statistics /98/. Table VI was completed with known data for 1971 /7/.

TAB. VI - BF-Slag Cement Production of Countries with Amounts of $> 2$ Mt/year			
Country	Slag cement production in Mt/year	Percentage of total production	Year
USSR	27.1	27	1971
	30.0		1973
France			1977
$> 35$ % slag	2.0	7	
$< 35$ % slag	10.0	35	
Germany-West			1978
$> 35$ % slag	5.4	16	
$\leq 35$ % slag	2.7	8	
Poland	5.2	40	1971
CSSR	4.3	54	1971
Japan	3.3	4	1977
India	3.3	17	1977
Roumania	3.0	36	1971
Italy	2.7	7	1977
Netherlands	2.2	55	1977
Belgium	2.2	32	1977

### **Mecanism and kinetics of slag Cement Hydration**

**M. DAIMON**  
**Tokyo Institute of Technology**  
**JAPAN**

## INTRODUCTION

Blastfurnace slags are the most useful latent hydraulic materials, because the amount produced is very large and its properties are very stable compared with other industrial byproducts.

Slag cements have been an important topic in the previous symposiums, and are reviewed at each time (1, 2). Many reviews concerning the utilization of slag (3-6) are written after the previous symposiums, showing the importance of slag utilization in every country. There are also several attempts to find new way (7-11) to utilize blastfurnace slags.

The present authors wish to take this opportunity to introduce results obtained in this field especially after the previous symposium in 1974. They will welcome comments on their own research work, as well as on this review paper.

## DETERMINATION OF THE DEGREE OF HYDRATION

Slag hydration should be determined by the similar methods to those used for cement hydration (12). There are two differences; (i) slags are in glassy state, and (ii) the hydration of slag is generally very slow.

The general problem in determining the cement hydration is the change in the compositions of the produced hydrates with the progress of the hydration. Therefore several kinds of experimental techniques must be used in order to get a full picture of cement hydration.

Quantitative Analysis of Slag

The degree of hydration is usually shown by the amount of residual reactant, in the usual hydration of cements, when produced hydrates change in their compositions with the progress of hydration. X-ray diffractometry can be used when reactants are crystalline. As slag used in cement are in glassy state, it is necessary to find a suitable method for the quantitative analysis of slag.

Kondo and Ohsawa (13) introduced an extraction technique; 0.5g sample is put into a beaker together with 2.5g of salicylic acid, 35cc of acetone and 15cc of methanol at room temperature for 1 hour. After 1 day, it is filtered and residue is washed with methanol, dried and heated at 850°C for 10 minutes. The original slag sample should be treated in the same way before hand, in order to correct the experimental results. Fig.1 is the typical results obtained by authors (14). Mironov, Kurbatova and Vysotskie (15) recommended this method.

At elevated temperature hydration products are well crystallized and dissolved into acid solution very slowly, and so extraction method is not available. Authors adopted X-ray quantitative analysis of melilite crystallized

by heating at 900°C for 5 min. (16). A density separation method (17) and an infrared spectroscopy (18) have been also proposed, but these techniques are only for the original mixes of slag cements or for the semi-quantitative analysis. The thermoluminescence measurement was also applied to study slag hydration (19)(20).

Non-evaporable water, free lime and free gypsum

The amount of the non-evaporable water (21) in cement paste increases with the curing time to give a similar results as the curve of the reduction of reactant slag. But two results do not coincide exactly, as the stoichiometry is not constant in the course of slag hydration. It must be noted that the sample should not be heated up to too high temperature in order to avoid a weight increase due to the oxidation.

Mikhail, Abo -El -Enein and Gabr (22) adopted the non-evaporable water value to evaluate the hydration degree of slag cements. The amount of combined water should be closely related to the strength of hardened body. Because hydrated cement is a typical porous material, and porosity is the main factor to determine the mechanical strength. Pore space which was originally occupied by water decreases with the formation of hydration products.

$\text{Ca}(\text{OH})_2$  and  $\text{CaSO}_4$  are the most typical activating component of slag hydration. It has been reported (23) that activators play role in slag hydration not only as glass attacking catalysts but also as reagents in hydrate formation reactions. Therefore it is very important to know the residual amount of  $\text{Ca}(\text{OH})_2$  and  $\text{CaSO}_4$ . There have been proposed many extraction methods for free lime (24,25), and Forén's method (13,26) for free gypsum.

Fig. 2 shows the reaction rate of gypsum in the same high sulphated slag cement as in Fig.1. Both graphs exhibit similar tendency, and suggest that the gypsum is not an exciter, but an important reactant in this system.

Fig. 1 - Percentage of reacted slag as a function of time in slag + 10wt.%  $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$  + various amount of  $\text{Ca}(\text{OH})_2$  (14)

Fig. 2 - Percentage of reacted  $\text{CaSO}_4$  as a function of time in slag + 10wt.%  $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$  + various amount of  $\text{Ca(OH)}_2$  (14)

### Calorimetry

The heat of solution, the adiabatic and the conduction calorimeters are frequently used for the calorimetric determination. Among those, the conduction calorimeter have been used for the measurement of the heat of hydration, as heat can be obtained continuously at almost constant curing temperature for a long period. Many investigators have made conduction calorimeters (12,27,28), in which determination is possible using small amounts of cement samples for the convenience of using synthesized samples. But larger amount of sample should be used in the case of slag hydration for slag hydrates slowly.

The results of conduction calorimetric measurements also show the parallel tendency with the degree of slag hydration obtained by extraction method, although they are not exactly identical (14). De Jong (29) studied slag hydration mainly with this method.

### LATENT HYDRAULIC PROPERTY OF SLAG

Certain activators such as sodium hydroxide, calcium hydroxide and gypsum have been known to accelerate the hydration of slag. The activation mechanism on the hydration of slag has not been adequately reported.

### Hydration of Slag

Kondo (12,30) studied the hydration of calcium aluminosilicate glass powders and found that glasses with composition of above 50%  $\text{CaO}$  and below 20%  $\text{SiO}_2$  content had hydraulic properties. In the suspension hydration of  $\text{C}_2\text{AS}$  glass, a low permeable coating which was approximately  $\text{ASH}_6$  in composition and  $0.2 \mu\text{m}$  in thickness was formed on their surfaces, and the liquid concentration was kept low as shown in Fig. 3. Fig. 4 showed that the suspension hydration of  $\text{C}_2\text{AS}$  glass was accelerated by the addition of  $\text{Ca(OH)}_2$ , because  $\text{SiO}_2$  and particularly  $\text{Al}_2\text{O}_3$  were apt to be liberated from above men-

tioned coating, and the solubility of hydrate decreases under this condition. These results were reconfirmed by the authors (31).

Such activating effect seems similar to the effect of  $\text{MgCl}_2$  in magnesia cement. Table 1 shows the  $\text{MgO}$  concentration in liquid phase, after mixing  $\text{MgO}$  and  $\text{MgCl}_2$  solution (32).  $\text{MgO}$  dissolves very rapidly into  $\text{MgCl}_2$  solution of higher concentration. Main difference between the hydration mechanisms of slag and magnesia cement might be that the former hydrates topo-chemically and the latter with through solution mechanism (30,31). Regourd (33) considered that the poorly crystallized hydrated layer around the slag grains could be called "pseudomorphic" layer.

Fig. 3 - Repeated extraction of  $\text{C}_2\text{AS}$  glass (5g of  $\text{C}_2\text{AS}$  per 100ml of water) (12,30)

Fig. 4 - Solubility of  $\text{C}_2\text{AS}$  glass with 2 moles of  $\text{Ca(OH)}_2$  (1g of solid per 100ml of water) (12,30)

Conc. of MgCl <sub>2</sub>	5min	1h	2h	3h	4h	5h	6h
10.72%	.059	.011	.007	.005	.003	.004	.005
20.22%	.078	.313	.487	.596	.622	.130	.086
29.49%	.155	.433	.632	.754	.835	.895	.905

#### Hydraulic Reactivity of slag

Reactivity of slag has been considered to be determined by the glass content (34) and chemical composition, which can be represented by a number called hydraulic moduli or basicity such as  $(\text{CaO} + \text{MgO} + \text{Al}_2\text{O}_3) / \text{SiO}_2$ .

When other conditions than chemical composition are in good control, certain trends can be shown in hydraulic activity and composition. Coal, Wolhuter, Jochens and Howat(35) reported the iso-strength plots of lime activated slag cement, in  $\text{SiO}_2$ - $\text{Al}_2\text{O}_3$ - $\text{MgO}$ - $\text{CaO}$  system. Teoreanu and Georgescu(36) also presented such iso-strength plots for slag cements, with 15% portland cement clinker and 2%  $\text{CaCl}_2$ . Miyairi and Takaki(37) concluded that  $\text{CaX}_2$  accelerate the hydration of portland cement. Taneja(38) discussed the role of  $\text{Al}_2\text{O}_3$ ,  $\text{MgO}$  and  $\text{MnO}$  contents in slag.

Taneja(39) observed, that the incorporated MgO up to 2.5% improved the hydraulic behaviour MgO in slag have been supposed to behave very differently from that in portland cement. Mascolo(40) suggested the formation of a solid solution between  $\text{C}_4\text{Aaq}$  and  $\text{M}_4\text{Aaq}$ , and explained the volume stability of slag portland cement with slags having very high MgO content. But, according to Casselouri and Parissakis(41), blastfurnace slag did not stabilize the volume unstability of high magnesia cement, while a certain fly ash had a stabilizing effect.

But it has recently been found that two values, i.e. hydraulic moduli and glass content can not describe the latent hydraulic property of slag. Akatsu, Ikeda and Sadatsune(42) studied on glass with the composition between  $\text{C}_2\text{AS}$  and  $\text{C}_2\text{MS}_2$ . The results could not be explained by basicity. Smolczyk(43) reported none of the well known formulas was able to give generally valid information of the hydraulic activities of 192 laboratory cements. Totani, Saito, Kageyama and Tanaka(44) studied using three different slags with similar glass content and chemical composition and found that the reactivities are very different each other. This is supposed to be one of the most important problem in this field which must be solved. Detailed studies should be performed on the structure of glass.

#### Activators for Slag Hydration

Fig. 5 is the changes in the amount of combined water of hydrated slag with various activators(45). In the case of  $\text{Ca}(\text{OH})_2$  (a), the curves showed that slag hydration was not largely dependent on  $\text{Ca}(\text{OH})_2$  content when it

was more than 5%. In the case of NaOH (b) and  $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$  (c), the combined water continuously increased with the amount of additives. When NaOH was used, the reaction proceeded to a considerable extent within one day and almost the same as those of 3 and 7 days. The curves for  $\text{Ca}(\text{OH})_2 + \text{CaSO}_4 \cdot 2\text{H}_2\text{O}$  (d), showed an optimum lime content, which was very low value.

It was found that the activators,  $\text{Ca}(\text{OH})_2$ ,  $\text{Ca}(\text{OH})_2 + \text{gypsum}$ , and NaOH remarkably promoted the hydration of slag (45).  $\text{Ca}(\text{OH})_2$  represents slag portland cement, and  $\text{Ca}(\text{OH})_2 + \text{gypsum}$  represents high sulphate slag cement. NaOH is a powerful activator, but this has not frequently been utilized until now. New techniques using such alkaline activators have recently been attempted (10,11).

Voinnovitch and Dron(23) proposed the stoichiometric formulas in the first approximation for the slag hydration as follows.

It can be seen that lime and gypsum are not simple "activators" but main reactants. But in the case of NaOH activation, NaOH seemed to play a role as a simple catalyst(23). Sersale, Aiello and Colella(10) recognized C-S-H and hydrogarnet as hydration products in this system. Regourd(46) gave more details on different activators.

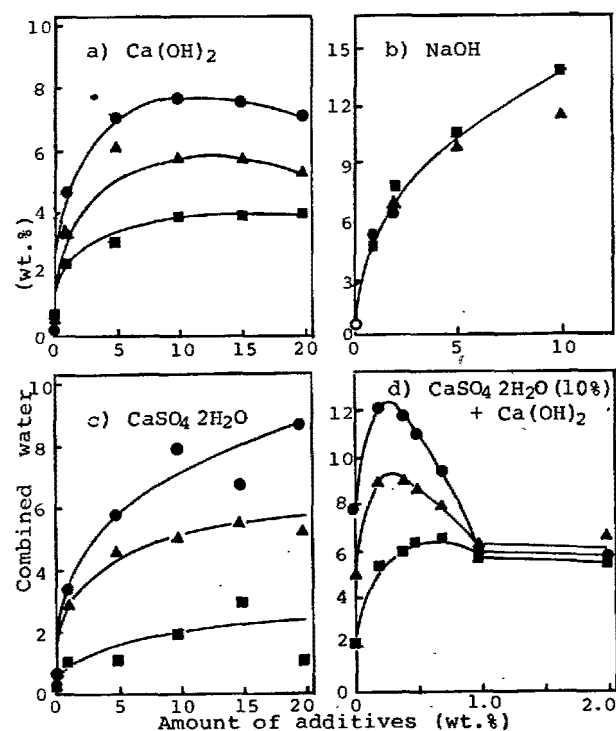

Fig. 5 - Amount of combined water during the hydration of granulated blastfurnace slag with various activators (■ 1d, ▲ 3d, ● 7d) (45)

## HYDRATION OF SLAG IN SLAG CEMENTS

Gypsum and lime are the most typical activators. Lime has activating effect by dissolving  $Al_2O_3$  and  $SiO_2$  from slag. Gypsum, on the other hand, does not have such effect, although it is an important reactant to form Aft phase. And so gypsum is always used with a certain alkaline activator. Accordingly, lime and gypsum + lime are the most typical activating system, and they are related to the most important slag cements, i.e. slag portland cement and super sulphated slag cement.

Slag Portland Cement

Slag portland cement is the most popular way to utilize granulated blastfurnace slag. Slag portland cements with higher slag contents are frequently used for mass concrete because of their low heat evolution. And those with lower slag content are generally used as a substitute of portland cement. Smolczyk(47) reported this cement was very suitable to be used with alkaline active aggregates. Slag have been permitted to be added in portland cement in several countries (1,2), and Japanese Industrial Standard has also permitted the addition of 5% slag or other latent hydraulic or pozzolanic materials.

For slag portland cements, activation of slag is accomplished by the  $Ca(OH)_2$  liberated during the hydration of portland cement. Therefore  $Ca(OH)_2$  has been generally used instead of portland cement in fundamental studies of kinetics and mechanisms of hydration, in order to simplify the experimental system.

Table 2 is the results obtained by Abo-El-Enein, Daimon, Ohsawa and Kondo(25). 20 wt%  $Ca(OH)_2$  was used as the activator. Slag hydration is not such a simple reaction as shown in formula(A). A high lime product with molar  $C/(S + A)$  ratio of 2.5 - 2.6 is formed during the early stage of the hydration process. Then the molar  $C/(S + A)$  ratio drops to a value around 1.6.

Table 2 shows, slag was hydrated at relatively high rate during the first 7 days, but thereafter the reaction extremely delayed. The calculated depth of the hydrated layer on the

Fig. 6 - Effect of  $Ca(OH)_2$  activator content on the compressive strength developed by blastfurnace slag (35)

slag grains was found to be as little as 0.3  $\mu m$  in the later stages. This coincided well with the previous results by Kondo and Ohsawa (13), and they concluded that the reaction rate became very slow when compact sheath had grown around the slag grains to a certain thickness.

Thus the slags have been supposed to hydrate very slowly, so that the strength developments of slag portland cements are smaller than usual portland cement. But there are two papers reporting that slags hydrate fast in some cases when they are activated by portland cement or  $Ca(OH)_2$ .

Coale, Wolhuter, Jochens and Howat(35) found slag hydrated, in the presence of very small amount of lime, rather rapidly especially at later periods. Fig. 6 is their results. Nagataki and Tanaka(48) observed the microstructure of hardened concrete with slag aggregates, and found very thick reacted layers around each aggregate grains.

Table 2. Hydration of the low porosity paste of blastfurnace slag and 20 wt.%  $Ca(OH)_2$  (25).

Hydration time (days)	1/4	1	3	7	28	90	180
Combined water (wt.%)	1.132	2.120	3.124	4.013	5.628	7.168	8.799
Combined slag (wt.%)	3.13	5.19	6.70	11.09	16.05	20.14	20.55
Combined lime ( $CaO$ ) (wt.%)	1.81	3.11	3.28	3.33	3.54	3.82	5.24
Ignited products (wt.%)	4.94	8.30	9.98	14.42	19.59	23.96	25.79
Reaction ratio of lime	0.114	0.195	0.206	0.209	0.222	0.240	0.329
Reaction ratio of slag	0.038	0.062	0.081	0.134	0.193	0.243	0.248
Depth of reacted layer ( $\mu m$ )	0.040	0.065	0.080	0.150	0.220	0.260	0.280
$CaO/(SiO_2 + Al_2O_3)$	2.507	2.563	2.295	1.825	1.630	1.553	1.714

Those two results were obtained in very different experimental conditions. The former occurred at very low ratio of activator to slag, and the latter at very high ratio of activator amount to slag surface. Further studies are desirable to clarify those phenomena.

### High Sulphated Slag Cement

High sulphated slag cement is not such a common cement, as slag portland cements, but has been used successfully for concrete in soil involving sulphate in Europe for a long time. As it contains 80 - 90% of slag, it should be the best way for the full utilization of latent hydraulic property of blast-furnace slags.

A small amount of lime or portland cement is commonly used in supersulphated slag cement, as an activator together with calcium sulphate. Van Haute(49) proposed to use a combination of aluminous cement +  $\text{Ca(OH)}_2$  +  $\text{K}_2\text{SO}_4$  as alkali agitator. Uchida, Nomi and Minegishi(50) obtained a good results by using haunye type clinker.

Fig. 7 shows the results of calorimetric study with different lime contents(51). It can be seen that the hydration processes are much influenced by the amount of lime. The curve of low lime content,  $<0.3\%$   $\text{Ca(OH)}_2$ , shows a small but sharp peak which corresponds to the main hydration in a short period of time (less than 9h) and after 3d, it approximates to that of 0%  $\text{Ca(OH)}_2$ . On the other hand, the curve of high lime content,  $>1.0\%$   $\text{Ca(OH)}_2$ , shows a broader peak and after 3d, drops below that of 0%  $\text{Ca(OH)}_2$ . The time for the appearance of the main hydration peak tends to be delayed with the amount of lime.

It is suggested from these results that, in the presence of lime, the early reaction rate is greatly accelerated. In the case of low lime content, the reaction is steadily accelerated throughout the test period (5d). This behaviour is sharply contrary to that of the high lime. From the results obtained, it can be estimated that the optimum lime content for activating supersulphated slag cement is very small (around 0.3%). Similar results have been reported by Tashiro and Urushima(52).

Fig. 8 shows the effect of lime content on the amount of reacted slag. This appears to support those from the calorimetric study. Fig. 9 is the result of free lime determination. It is seen that the consumption of  $\text{Ca(OH)}_2$  in the early stage is rapid especially in the case of 0.3%  $\text{Ca(OH)}_2$  addition, the  $\text{Ca(OH)}_2$  is almost consumed within the first 3h. After this, the concentration of free  $\text{Ca(OH)}_2$  gradually increases. The trends in free lime curves are generally similar for all the lime added samples. Moreover, free lime is detectable in the unadded sample (0%  $\text{Ca(OH)}_2$ ) after 1d and also shows a slightly increasing trend. This suggests that free lime can also be extracted from other hydrated phases in the system, as reported by Bentur

Fig. 7 - Conduction calorimetric curves of slag hydrated with 10 wt.%  $\text{CaSO}_4$  and various amount of  $\text{Ca(OH)}_2$  (51).

Fig. 8 - percentage of reacted slag as a function of time in slag + 10 wt.%  $\text{CaSO}_4$  + various amount of  $\text{Ca(OH)}_2$  (51).

Fig. 9 - Percentage of free lime as a function of time in slag + 10 wt.%  $\text{CaSO}_4$  + various amount of  $\text{Ca(OH)}_2$  (51).

and Berger(53).

The above mentioned results indicate the following mechanism. In the case of no  $\text{Ca}(\text{OH})_2$  addition, it may be considered that calcium silicate hydrate (C-S-H) is formed, and thereby  $\text{Al}_2\text{O}_3$  is liberated from the slag.  $\text{CaSO}_4$  slowly reacts with the liberated  $\text{Al}_2\text{O}_3$  to form Aft phase (54,55) and the reaction proceeds with a controlled rate throughout the process. With  $\text{Ca}(\text{OH})_2$  addition, the reaction in the early stage, in comparison with the former, is considerably rapid as seen in Fig. 1. This may be explained by that  $\text{Al}_2\text{O}_3$  is rapidly dissolved under high basic condition, and the Aft phase is formed by a violent and rapid reaction of  $\text{CaSO}_4$  and  $\text{Al}_2\text{O}_3$  released into the solution. As time goes by, reaction products increasingly coats the surface of unhydrated slag grains and results in the inhibiting hydration reaction of slag.

These discussion are coincided with the results by Tashiro and Urushima(52), Yang(56) and Midgley and Pettifer(57), they concluded that the hydration products in this system were C-S-H and ettringite, or Aft phase.

C.E.R.I.L.H.  
Paris, FRANCE**

## 1. INTRODUCTION

According to the principal report on slag Portland cement presented at the Moscow Congress in 1974, by SATARIN (1), two lines of research on cement hydration can be determined: in one case the reaction mechanisms between the slag and the water and the other the development process of the structure during the setting and hardening. The Paris Congress will continue these two themes of which the first is given to DAIMON.

This report highlights the work done on the microstructure of slag cements published since the Moscow Congress. These studies concerning the hydrate structures and their comportment was accomplished by varying a certain number of parameters such as the composition and the granularity of vitreous slag, the mode of activation (alkaline, sulfatic), the thermal treatments and the aggressive agents (sulfates, chlorides, sea water).

## 2. SLAG CEMENTS HYDRATION

## 2.1 Activated slag hydration

The thermodynamic study by DRON (2) of the quaternary system  $\text{CaO} - \text{SiO}_2 - \text{Al}_2\text{O}_3 - \text{H}_2\text{O}$  has shown that the hydrated phases that coexist with the aqueous phase in slag pastes are limited to three. The system of three compatible hydrates shows on the ternary diagram lime-silica-alumina a unique mode of subdivisions in triangular domains (fig. 1) but no matter which activator is used, the hydrated calcium silicate is always present.

Fig. 1 - Triangulation of the ternary diagram of slag hydration in presence or not of gypsum (ref. 2).

## 2.1.1 Alkaline Activation

Alkaline activation can be either soda or lime activation. Activated by soda, the slag gives C-S-H,  $\text{C}_4\text{AH}_{13}$  and  $\text{C}_2\text{ASH}_8$ . The  $\text{C}_4\text{AH}_{13}$  and  $\text{C}_2\text{ASH}_8$  are hexagonal plates which play the role of crystalline bridges between the slag grains. Electronprobe microanalysis reveals that the plates of  $\text{C}_4\text{AH}_{13}$  contain silicon (3). The C-S-H covers the slag grains but by the intermediary of the solution, it is found equally on the inert supports such as a metallic (4) or a glass (fig. 2) blade on which was placed a drop of slag-soda solution suspension. TERRIER (5) has found its  $\text{CaO}/\text{SiO}_2$  ratio to be weaker than that of the clinker C-S-H: it is around 1 according to the electronprobe microanalysis measurements by DRON *et al* (6).

The soda activation in the preceding examples was obtained with NaOH solutions. The soda can be replaced by sodium carbonate (7) or sodium silicate (8, 9).

In the lime activation the hydrated phases compatible with  $\text{Ca}(\text{OH})_2$  are C-S-H and  $\text{C}_4\text{AH}_{13}$ . The hydrated gehlenite  $\text{C}_2\text{ASH}_8$  does not show itself in the presence of calcium hydroxide. In slag-lime cements with a low porosity ( $w/c = 0.20$ ), ABO-EL-ENEIN *et al* (10) found a first hydrate rich in lime  $\frac{C}{S+A} = 2.5$  but at 180 days, this ratio was only 1.7.

## 2.1.2 Sulfate Activation

According to D'ANS and EICK (11), sulfate activation due to gypsum leads to the formation of C-S-H, ettringite  $\text{C}_3\text{A} \cdot 3\text{CaSO}_4 \cdot 32\text{H}_2\text{O}$  and aluminum hydroxide  $\text{Al}(\text{OH})_3$ .

The sulfate activation is slow during the evolution of pastes composed of slag (90 %) + gypsum (10 %),  $w/c$  ratio = 0.5, ground between 40 and 63  $\mu\text{m}$  and observed at 2, 7, 15 and 28 days. The ettringite is only detected after 15 days and X-ray diffraction lines of gypsum are still present at 28 days. At that time the slag grains are surrounded by a thick layer of C-S-H and ettringite needles (fig. 4). The adherence of the C-S-H to the smooth slag grains is not good: a part of the hydrate layer detaches from the anhydrous grain during the breaking of the sample by traction. The feeble adherence of C-S-H to the slag grain is an unfavorable factor in the case of slags coarsely ground. The same observation has been reported by SYRKIN *et al* (12).

Sulfate activation can be obtained with other sulfates than gypsum, for example hemihydrate, anhydrite and phosphogypsum. The sulphur present in the slag can also be an autoactivant.

## 2.1.3 Mixed Activation

In the presence of gypsum and lime or gypsum and soda, the alumina  $\text{Al}(\text{OH})_3$  is transformed into ettringite. The sodium is found in the form of sulfate  $\text{Na}_2\text{SO}_4$ .

The sample of slag paste containing 90 % slag + 10 % gypsum and mixed with a normal soda solution is covered with C-S-H fibers and ettringite from the second day at which time half the gypsum is already consumed. The sodium sulfate is detected on the X-ray diffraction diagram: the soda, therefore, has played an important activating role and has given a notable proportion of hydrates. According to the theoretic formulas of VOINOVITCH and DRON (8), the soda

activation uses five times more activant than the lime activation, but the quantity of hydrates formed is twice as great. The soda plays the simple role of a catalyzer while the lime and gypsum enter into the hydration reaction.

Ettringite ( $\Delta$ ), C-S-H (x)

## 2.2 Slag cements hydration

Two slag activants are present in cements : the gypsum and the lime liberated by the hydration of the clinker silicates.

In all samples of industrial slag cement, the Portland cement clinker is the first to hydrate. The C-S-H hydrated silicate due to the dissolution of the tricalcium silicate covers both the clinker and the slag grains. The portlandite  $Ca(OH)_2$  is present in layers of hexagonal plates (fig. 5). The ettringite is spread out in non dense needles in the C-S-H, but rather localized around the clinker grains (fig. 6).

In the 2, 7 and 28 days study of industrial slag cement pastes, w/c ratio 0.5, the beginning of the slag hydration was only observed at 28 days. It shows on the X-ray diffraction diagrams by a lessening of the  $Ca(OH)_2$  content in samples containing 20 and 50 % slag and by the disappearance of portlandite in cements with an 80 % slag content. Slag grains already covered by the clinker C-S-H are surrounded by a compact hydrated zone (fig. 7). Elementary analysis with the aid of X-ray energy dispersive analysis shows the difference in composition of Mg, Al and Si between the slag grain, its hydrate and the clinker C-S-H in a hydrated paste at six months : the slag hydrate is richer in  $MgO$  and  $Al_2O_3$  than that of the clinker. The slag C-S-H is poorly crystallized. According to the infrared absorption spectrometry studies of BENSTED (13), the silica tetrahedra of this C-S-H are only slightly polymerized.

Along with the lime activation, there is also a sulfate activation which first of all gives ettringite. The morphology of the ettringite needles depends upon the slag content. The needles are shorter and more fixed in the samples rich in slag and in 80 % slag cement, they seem to play the role of a binder (fig. 8). At later dates, when the gypsum is completely combined, the ettringite transforms into monosulfaluminate which forms solid solutions with tricalcium aluminate  $C_4AH_{13}$  (fig. 8).

According to DE JONG (14) and following the theory of D'ANS and EICK (11), sulfate is the principal slag activator. The alkaline reactions cause, in the beginning, the formation of acid hydrates surrounding the slag grains. These first hydrates can block the slag hydration. The sulfate ions dissolve the first hydrate and favorize the formation of a second hydrate of a rougher structure that does not oppose the penetration of water.

Hydrogarnets  $C_3ASH_4$  have been identified by TANEJA (15), SERSALE et al (16) and DASGUPTA (17) in cements with a low magnesium content. To the contrary, in the products with a high  $MgO$  content, the hydrated aluminates  $C_4AH_x$  transform into  $M_4AH_x$  (15, 18). The hydrotalcite  $Mg_6Al_2CO_3(OH)_{16}4H_2O$  has been found by KÜHLE and LUDWIG (19) in slag cement pastes containing up to 29 %  $MgO$ . KOERTH (20) has detected the vicatite  $C_3S_2H_3$  : it is a transformation of the awillite  $C_3SH_3$ . It can contain  $MnO$ ,  $ZnO$ ,  $FeS$ ,  $MnS$ ,  $CaS$  which in its crystalline lattice substitute for  $CaO$ .

HYDRATION OF A SLAG PORTLAND CEMENT

1. Hydration of Portland cement

Fig. 6 : C-S-H (x), Ettringite (Δ)

2. Slag hydration

Fig. 7 : Slag grain S, monosulfoaluminate (M), C-S-H (x).

Two layers of hydrate (1, 2) surround the slag grain.

The X-ray energy dispersive analysis shows that the "pseudomorphic" slag hydrate (1) is richer in  $Al_2O_3$  and MgO than that of clinker (2).

Fig. 8 : Binding ettringite (Δ) and monosulfoaluminate -  $C_4AH_{13}$  solid solution (o).

## 2.2.1 Influence of the glass structure

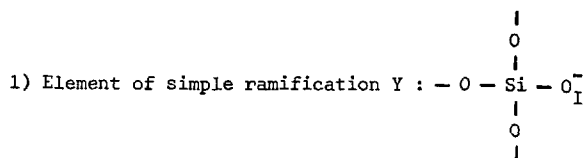

In his principal report at the Moscow Congress, SATARIN (1) discussed the relation between the hydraulic properties of slags and the structure of their glassy phase. Silica tetrahedra coexist in slag glass. These tetrahedra can present a certain degree of polymerization which, if too high, can lead to a lessening of the hydraulic activity. Aluminum ions are coordinated either tetrahedrally or octahedrally with the oxygen ions. The Al-O liaison in the tetrahedron  $(AlO_4)^{5-}$  is less covalent than the liaison Si-O in the tetrahedron  $(SiO_4)^{4-}$  and therefore is weaker. It is a fact that there must be an optimal rate of octahedral and tetrahedral coordination for a maximal hydraulic activity. The  $Si_2O_7^{6-}$  or  $SiAlO_7^{7-}$  complex seem to be a base structural unit of melilite glasses of high hydraulic activity.

The depolymerization of silica-oxide complexes has been studied by ROYAK et al (21) by electron paramagnetic resonance and infrared spectroscopy. The authors have concluded that the slag activity is in function to the degree of depolymerization of the oxide-silica complexes, the energy of the Me-O liaison of the depolymerizing cation and the coordination of this last factor which could differentiate between two slags with an identical chemical composition but with different hydraulic properties.

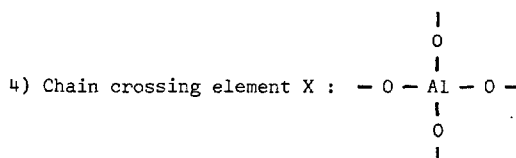

The highest mechanical resistances were obtained by SABATELLI et al (22) with slags which, during the devitrification study, recrystallized only in melilite. An increase in the MgO and CaO content diminishes the degree of polymerization of slags and increases the  $SiO_4^{4-}$  fraction (23) favorable to a diffusion of  $Mg^{2+}$  and  $Al^{3+}$  ions from the moment of the devitrification and the formation of melilite. In the same way, VAN LOO (24) has shown that the merwinite is unfavorable to the hydration of slag.

These ideas on the polymerization of the tetrahedra have just been precised by DRON (25, 26). The silicate glasses with an average basic oxide content, such as slags, can, like the glasses with a high oxide content studied by MASSON (27), be represented by statistical methods.

The silicate melts are formed of isolated linear elements (straight chains) or branched (internal or external ramifications) of which the numeric distribution form geometric series. It is the creative probability of the singly bonded oxygen atoms on the silicon and the other tetracoordinated structural elements (Al and Mg) which determine these structures. In the domain of average basicity, the silicon atoms at zero or four atoms of singly bonded oxygen are practically nonexistent. The Si atoms with one, two or three singly bonded oxygen atoms are distributed following a binomial law and constitute respectively the following elements :

Because of its more metallic character, aluminium would essentially be surrounded by four doubly bonded oxygen atoms and would constitute an element of double ramification designated by the symbol X.

This chain crossing element carries a negative charge  $(AlO_2)^-$ . The aluminium atoms surrounded by four doubly bonded oxygen atoms have the same tetrahedral configuration as that of monocalcium aluminate.

The magnesium atoms are tetrahedrally coordinated to the doubly bonded oxygen atoms as in the crystalline structure of akermanite  $C_2MS_2$ . The chain crossing element X carries two negative charges  $(MgO_2)^{2-}$ .

To the contrary, calcium only leads to ionic bonds. It is the oxygen atom brought by the CaO which, in forming bonds of the covalent type with the structural elements in the degree of their affinity, determines the reduction in the degree of chain branching. This idea identifies with that which has been called degree of depolymerization, an expression which is not precise since the monomers of the type  $(SiO_4)^{4-}$  and more surely those of  $(AlO_4)^{5-}$  do not exist in the domain of granulated blast furnace slags. The octahedral coordination does not exist for Al or Mg.

The hydration of the granulated slag leads to its dissolution in the aqueous phase and to the recombination of the liberated ions in this solution conforming to the schema of LE CHATELIER. In the initial phase, that is to say before the first C-S-H precipitations, it is the most basic structural elements of glass which pass preferentially into solution such as  $(SiO_3)_3^{3-}$  or  $\frac{1}{2}(Si_2O_7)^{6-}$  and  $(AlO_2)^-$ . This dissolution is hydrolytic and non hydroxylic. It explains the basic reaction of the slag. It is to be noted that one finds the same entities in the crystalline lattices of rankinite  $C_3S_2$  and monocalcium aluminate CA.

Following and especially in normal reaction (dissolution-precipitation of C-S-H) the dissolution becomes approximately congruent. The C-S-H C/S ratio is inferior to that of the slag, the solution therefore becomes richer in calcium and correlatively weakens in silicon to respect the product of solubility constant.

Further, the aluminium accumulates in the solution up to the beginning of the crystallization of the aluminates which is late in occurring (28).

The microstructure study of seven blast furnace cements containing the same Portland cement but slags of a different chemical composition has shown that there is a correlation between the amount of akermanite of the recrystallized slag and the degree of hydration of the granulated slag (29). The variation of the crystalline parameters of the recrystallized melilite has given akermanite contents varying from 20 to 55 % for seven slags. A coefficient of linear relation equal to 0.98 was found between the akermanite content and the rate of slag hydration. This was determined by chemical analysis using the dissolution method of KONDO and OHSAWA (30) : the richer the slag is in  $C_2MS_2$  the slower it is to hydrate.

Foreign ions Mn, Ti, P, in solid solution in the recrystallized melilite enlarged the X-ray diffraction reflections and thusly created substitution or addition disorders but they did not displace the angular position of the maximum of the characteristic reflections. The amorphous phase halo of the granulated slag is proof that a certain degree of local order already exists in the liquid and it was fixed by the quench. The long distance order, to the contrary, does not exist.

The influence of the quench on the hydraulic reactivity of slags has been studied by FIERENS *et al* (31, 32, 33) with the aid of electron thermoluminescence, exoemission and thermogravimetry. The products used were gehlenite, synthetic slags and industrial slags (32). The thermoluminescence is well adapted to the study of synthetic products. It proves that the quench influences the superficial excited centers and allows, by the lowering of its characteristic peaks, to study the degree of advancement of the hydration. The study of the lessening of the thermoluminescence peaks of gehlenite shows that the hydration is effectuated following a nucleation reaction auto-inhibited by the hydrate which progressively covers the grains. The deep hydration is produced following a process of diffusion shown by the thermogravimetry. The same mechanism can be applied to synthetic slags : there is a relation between the kinetic coefficient of diffusion and the cooling speed estimated by thermoluminescence. The quench is very important in the case of basic slags. For industrial slags, only the photostimulated exoemission results were used : for the same industrial slag, the number of exoemitted electrons varies in function with the quench and the long term hydration occurs according to a process of diffusion. The quench also influences the texture of the hydrated product and for a same degree of progress in the hydration reaction, the mechanical resistances are in function to the cooling process. The same techniques were used in the study of aged products which hydrate slower than the fresh. The hydration mechanism remains unchanged. A three year old gehlenite is not devitrificated but the loss of a part of its hydraulic power is probably due to a progressive deactivation of the excited centers of the surface.

### 2.2.2 Influence of the fineness

Slag cements finely ground hydrate quicker than ordinary cements and give more compact structures (1, 12, 34). The fineness of the clinker influences the first mechanical resistance while the fineness of the slag enters into the final resistance (1). However, the simultaneous grinding of the clinker and the slag

to a high degree of fineness gives a clinker very finely ground and a slag still too coarse. A separate grinding of the slag and the clinker will allow a much finer slag.

The hydration of a slag cement, Blaine specific surface equal to  $5720 \text{ cm}^2 \cdot \text{g}^{-1}$  composed of 85 % slag ground to  $6310 \text{ cm}^2 \cdot \text{g}^{-1}$ , 13 % Portland cement clinker ground to  $3500 \text{ cm}^2 \cdot \text{g}^{-1}$  and 2 %  $\text{CaSO}_4$  has been followed by X-ray diffraction (fig. 9) and scanning electron microscope. The samples studied were fragments of ISO mortar samples ( $4 \times 4 \times 16 \text{ cm}$ ) having served for the measure of mechanical resistance at 2, 7 and 28 days.

Fig. 9 : X-ray diffraction pattern of the anhydrous slag cement.

The slag cement was compared to the Portland cement that entered into its composition :

- from the second day, there is a greater quantity of ettringite in the mortar of the slag cement than in the mortar of the Portland cement (fig. 10). This ettringite was formed by the reaction of  $\text{CaSO}_4$  with both the  $\text{C}_3\text{A}$  of the clinker (on the order of 1.5 % in the slag cement) and the alumina of the slag. The C-S-H comes from the simultaneous hydration of the  $\text{C}_3\text{S}$  of the clinker and the slag. The proof of the early reactivity of the slag is illustrated by the diminution by 30 % in the intensity of the amorphous phase halo. Scanning electron microscope observations reveal that a large quantity of ettringite is spread throughout the sample in contact with the slag grains and in the pores.

- at seven days, the ettringite is partially transformed into sulfoaluminate  $\text{C}_3\text{A} \cdot \text{CaSO}_4 \cdot 12\text{H}_2\text{O}$  and hydrated aluminate  $\text{C}_4\text{AH}_{13}$  in Portland cement. On the slag cement X-ray diagram, one can observe the increase in the C-S-H reflections.  $\text{CaSO}_4$  and all the clinker phases have disappeared. Ettringite is still abundant and microscopic examination shows it to be crystallized in fine needles.

- between 7 and 28 days, the hydrates continue to develop. The size of the slag grains that have not yet reacted with water at 28 days is between 10 and 20  $\mu\text{m}$ .

The early hydration of the slag gives a compact material after short periods. In tests accelerated by

soda, the slags  $6310 \text{ cm}^2.\text{g}^{-1}$  are well separated from the slags  $3500 \text{ cm}^2.\text{g}^{-1}$  (Table I).

Fig. 10 : X-ray diffraction patterns of Portland cement (a) and slag cement (b) at 2 days.

Table I : Compressive resistance ( $R_C$ ) and flexure resistance ( $R_F$ ) for the same slag ground to two degrees of fineness. Test accelerated with soda.

Time of hydration	$6310 \text{ cm}^2.\text{g}^{-1}$		$3500 \text{ cm}^2.\text{g}^{-1}$	
	$R_C$ MPa	$R_F$ MPa	$R_C$ MPa	$R_F$ MPa
6 hours	23.7	5.7	8.5	2.2
24 hours	32.2	8.8	15.7	4.5

In the same conditions and for a specific surface of  $3500 \text{ cm}^2.\text{g}^{-1}$ , a reactive slag gives  $R_C = 7$  to  $8 \text{ MPa}$  at 6 hours and  $12.5$  to  $15 \text{ MPa}$  at 24 hours.

A finely ground slag cement presents a feeble bleeding, a good plasticity, an early but relatively minor heat liberation, a slight shrinkage (fig. 11) and an increased resistance to flexure as well at  $20^\circ\text{C}$  as at  $5^\circ\text{C}$  (fig. 12).

The crystallization of ettringite into fine needles can explain the minor shrinkage as well as the high traction resistance. The shrinkage, generally tied to the presence of fine grains, would be compensated by the crystallization of trisulfoaluminate with 32 molecules of water. This crystallization into fibers would be more favorable to the flexure resistance (35). Such a correlation between the flexure strength and the formation of fibrous ettringite has also been reported by SUGI *et al* (36).

Fig. 11 : Shrinkage of slag cement (A) finely ground, compared to those of OPC and slag cement (B) ground to  $3500 \text{ cm}^2.\text{g}^{-1}$ .

Fig. 12 : Flexure strength at  $5^\circ\text{C}$  of slag cement (A) compared to those of OPC and slag cement (B).

### 2.2.3 Influence of thermal treatments

The temperature is at the same time a thermodynamic and a kinetic factor : it modifies the values of the free enthalpy of the hydrate formation and accelerates the hydration reaction.

#### (i) Thermal treatment

Hydration reactions of cements are exothermic. At a given instant, the quantity of heat liberated can characterize the overall state of the advancement of the reactions. If the dormant period is excluded, that is to say if one considers the heat liberation from the beginning of the setting process, the calorimetric isotherms at 20, 40, 60 and 80 °C are affine. The heat production, therefore, acts like a system of separated variables, temperature and time. The affinity ratios follow the *ARRHENIUS* law (37). The energy value of activation  $E$  of the hydration reaction of cement can be easily determined from the calorimetric curves if one keeps in mind a certain lessening which increases in relation to temperature. The same affinity ratios have been found in the evolution of mechanical resistances of ISO mortars.

After about 4 hours at 20 °C, the calorimetric curve of a Portland cement presents an important thermal effect which characterizes the beginning of the setting and hardening process during the course of which precipitate hydrated silicates, portlandite and sulfoaluminates. The same cement hydrated at 60 °C gives an earlier and narrower signal. If we consider the heat liberation from the beginning of the set to the end of the thermal effect, we notice that to obtain the same degree of advancement  $\alpha$ , it takes ten times less time at 60 °C than at 20 °C and 26 times less time at 80 °C than at 20 °C. The energy activation value  $E$  determined from these three experiments is 46 kJ.mol<sup>-1</sup>. However, it must in all cases be precised that the calorimetric curves show a lessening in the total quantity of heat liberated at 60 °C and 80 °C. This diminution is 5 % at 60 °C and 10 % at 80 °C. According to X-ray diffraction measurements, this corresponds to a lesser rate of  $C_3S$  hydration (37).

The evolution of the compressive strengths of ISO mortar samples has been followed at the same temperatures. The resistances were measured up to 45 days at 20 °C in order to encompass the major part of their growth. At 60° and 80 °C the measurements were continued up to the point where the variations became very weak from one day to another, that is to say 10 days at 60 °C and 7 days at 80 °C. A study of the evolution of these resistances shows that the maximum values obtained at 60 °C and 80 °C are less than those obtained at 20 °C. The curves corresponding to the temperatures of 60 and 80 °C cross the curve traced at the ambient temperature. However, when one represents the variations of resistance in relative values giving a value to  $\alpha$  equal to 1 when the resistances no longer vary in a significant manner, one notices that the curves are affine. A coefficient must be utilized to compensate for the lessening in resistance from 20 % at 80 °C. It is observed that the affinity ratios are the same as in the case of the evolution of the heat of hydration.

In the same manner, the variation curves of the heat of hydration (fig. 13) and the resistance to compression (fig. 14) at 20, 60 and 80 °C of a clinker slag cement (CLK) containing 80 % slag permit the deduction of affinity ratios which are higher than those of OPC (12 instead of 10 at 20 °C, 34 instead of 26 at 80 °C) and a greater energy of activation (50 kJ.mol<sup>-1</sup>

instead of 46). Therefore, thermal treatment shows itself to be favorable to slag cements.

Fig. 13 : Heat liberation of a slag cement at 20 and 60 °C. The left curves, in relative coordinates, are affine.

Fig. 14 : Compressive strengths of a slag cement at 20, 60, 80 °C. The bottom curves, in relative coordinates, are affine.

However, all granulated slags do not react in the same manner during a thermal treatment. Three slags, A, B, C, were used in the composition of three blast furnace cements CHF (70 % slag) beginning with a Portland cement containing 62 %  $C_3S$  and 12 %  $C_3A$ . The table II of the resistances obtained after a treatment at 80 °C compared to resistances measured at 28 days at 20 °C show a prolonged thermal treatment is not favorable to cement A.

Table II : Compressive strengths of ISO mortars thermally treated.

CHF cement 70 % slag	ISO mortar compressive strengths (MPa)		
	28 days at 20 °C	7 h at 80 °C	14 h at 80 °C
A	54	21	22
B	46	26	30
C	39	22	27

If, after the treatment 7 h at 80 °C, the three cements are placed in water at 20 °C for 28 days, the resistance will be :

- Cement A : 27 MPa
- Cement B : 37 MPa
- Cement C : 36 MPa

Cement A only reaches half its resistance at 20 °C. X-ray diffraction analysis of the mortar samples show that there is a large quantity of monosulfoaluminates. Microscopic examination shows these monosulfoaluminates to be compactly grouped in the form of hexagonal plates (fig. 15). A very dense layer of C-S-H surrounds the slag grains and covers the grains of sand with a thick layer which ends up as foils (fig. 16). The rather brutal hydration of this cement over short periods at 80 °C, only progresses feebly after the thermal treatment is discontinued. To the contrary, with the two other cements, the hydration continues up till 28 days. The essential difference between the three slags concern their chemical composition and especially their content in alumina (Table III). The slag C-S-H contains less lime than the anhydrous grain. The differences in the chemical composition between the slag and its hydrate are more important for alumina and magnesia. With the same thermal treatment the C/S ratio of the Portland cement C-S-H is 1.4 at 20 °C and 1.7 at 80 °C.

The favorable role of thermal treatment on the setting and hardening of slag cements was equally noticed by KUREPA *et al* (38) : 70 % of the final projected resistance were reached after 12 hours of thermal treatment at 40 °C. According to MIRONOV (39), in 20 % slag cements a short treatment at 95 °C diminishes the difference in the resistance between Portland cement and slag cement. However, some precautions are always necessary concerning the composition of slag cement and the gypsum content. HATO *et al* (40) have thermally treated concretes prepared with cements containing 0 to 60 % slag for either 1 hour at 65 °C or 3 hours at 80 °C. If the gypsum is not consumed during the course of the thermal treatment, the ettringite formation which takes place at the end of the treatment results in unstable concretes.

Fig. 15 : Monosulfoaluminate in a slag cement after 7 hours at 80 °C.

Fig. 16 : C-S-H in a slag cement mortar after 7 hours at 80 °C.

Table III : The C/S, C/A, C/M ratios values in the anhydrous slag grain and in the C-S-H of the three blast furnace cements (70 % of slag) surrounding the slag grain.

Slag		CaO/SiO <sub>2</sub>	CaO/Al <sub>2</sub> O <sub>3</sub>	CaO/MgO
Anhydrous	A	1.4	5.6	6.9
	B	1.4	6.4	3.7
	C	1.3	6.6	3.8
20 °C (28 days)	A	1.0	4.6	3.2
	B	0.9	4.8	1.9
	C	1.3	4.8	1.4
80 °C (6 days)	A	1.0	5.4	3.5
	B	1.3	5.0	1.4
	C	1.1	4.4	1.5

(ii) Autoclavage

Autoclavage associates the elevation of the temperature to pressure. The work done since the Moscow Symposium concerns synthetic slag and industrial products.

With the aid of infrared absorption spectrometry, conductimetry, X-ray diffraction and differential thermal analysis, GOVOROV (41) has identified four types of synthetic glasses giving different hydrates in the case of finely ground slag pastes treated 2 days at 150, 200 and 250 °C in an atmosphere of saturated water vapor. The highest mechanical resistances were measured on samples with a composition approaching that of wollastonite or anorthite. The structure contains a limited number of silica tetrahedra and form during hydration essentially tobermorite or gyrolite. Higher alumina contents tend to reduce the resistance of slag pastes in particular for treatments at 150 to 200 °C, with the exception of glasses containing isolated silica tetrahedra which favorize the development of hydrogarnets. Xonotlite was found by BASH (42) in slag + loess mixes autoclaved above 250 °C. Its formation leads to an increase in mechanical resistances. The lessening of resistances observed at temperature superior to 200 °C can be tied to the presence of  $C_2SH$  and to a too violent crystal growth of the hydrates.

In a 95 % slag mix (ground to less than 100  $\mu m$ ) and 5 % gypsum, compacted to 200 MPa and autoclaved at 180 °C, MASSIDDA and SANNA (43) have tied the increase in the resistance to compression to the fact that the material is less porous. Plazolite was identified by X-ray diffraction, the crystals filled the spaces between the slag grains. In slag pastes + activator (lime, sodium carbonate) studied by SERSALE *et al* (7, 16), the hydrates formed in the course of a steam treatment at 205 °C are amorphous or slightly crystallized silicates and hydrogarnets. The resistances are tied to the microstructure of the materials : at 20 °C there are many spaces in the paste which are filled after autoclavage. Sodium carbonate is proven more efficient than calcium hydroxide. It gives a more compact material from which the possibility to produce molded products (100 MPa) and the hydrothermal treatment of slag. Molding pressure and fineness of the grind favorably influence the mechanical comportment of slag mixes +  $Ca(OH)_2$ , but high temperatures are not always favorable to mechanical resistances.

According to a study by KONDO *et al* (44), the initial stage of the hydrothermal reaction in the system slag + lime + water corresponds to the formation of C-S-H with a low lime content. The ulterior formation of crystallized C-S-H and hydrogarnet diminish the mechanical resistances. In the system slag + lime + quartz + water, a C-S-H rich in lime is the first to form, but after the free lime is completely consumed, this C-S-H weakens in calcium. The slag is very reactive but it inhibits the reactivity of the quartz especially in the initial phase of the reaction.

Tobermorite at 11 Å was identified by X-ray diffraction in cements with a high slag content that were treated for 5 hours with saturated water vapour at 1.3 MPa. KAMEL (45,46) found hillebrandite, tobermorite and xonotlite in samples only containing slag that were treated in the same manner as slag cements.

ABO-EL-ENEIM *et al* (47, 48, 49) have reported the following from their systematic study of autoclaved mixes slag + lime, slag + lime + sand, slag + clinker + sand. The hydrated phases obtained in the

different mixes are :

- Slag + lime : C-S-H + hydrogarnets  $C_3ASH_4$
- Slag + lime + sand optimum composition : first, the tobermorite poorly crystallized, then the tobermorite at 11 Å crystallized in plates. The acceleration of the slag hydration inhibits the reactivity of the quartz.
- Slag + clinker : C-S-H +  $C_3ASH_4$  +  $Ca(OH)_2$
- Slag + clinker + sand : semi-crystallized tobermorite, then tobermorite at 11 Å (fig. 17).

Fig. 17 : Tobermorite in an autoclaved mortar (ref.47)

The resistance of autoclaved slag + clinker + sand paste samples could be linked to the pore structure and their distribution in relation to the microstructure of the hydrates formed. Mesopores with a hydraulic radius (surface of the water molecule = 11.4 Å) between 18 and 23 Å of lamellar structure (36 - 46 Å) have more effect on the resistance to compression than micropores with a hydraulic radius between 3 and 4 Å or lamellar structure (7 Å). The number of mesopores diminishes up to the sixth hour of treatment (10 atmospheres saturated vapor pressure) and correspond to an increase in  $R_c$ . After 6 hours the number of mesopores increases to a maximum at 12 hours and simultaneously; the resistance diminishes.

MIYAIRI and MYOJIN (50) confirmed the previous results : the compressive strength is maximal after 6 hours of autoclavage at 180 °C in the case of Portland cements containing 60 % slag. The optimum alumina content of the cement must not be greater than 9 %.

According to NAKAHARA *et al* (51), a water vapour treatment at 75 °C is favorable to slag cements with a high gypsum content (10 % OPC, 65 % slag, 25 % gypsum) but an autoclavage at 90 °C causes an expansion and a cracking for mixes containing less than 50 % slag and more than 20 % gypsum.

The good resistance of autoclaved cements containing 8.5 % MgO from blast furnace slags has been tied by NIKIFOROV *et al* (52) to the very fine periclase crystallization. MASCOLO *et al* (18) have shown the crystallization of  $M_4AH_4$  which causes no expansion during autoclavage and the formation of  $5MgO \cdot Al_2O_3 \cdot SiO_2$ .

This review of the work on hydration of slag cements has revealed that these products give the same hydrates as Portland cement. They are slow to react with water but they can be activated chemically (alkaline or sulfate activation), mechanically (over grinding) and thermally. Slag cements to the contrary are

well known for their resistance to aggressive chemical agents.

### 3. BEHAVIOUR OF SLAG CEMENTS

All long term tests have shown the good performance of slag cements in aggressive environments such as sulfate water, sea water and pure water.

#### 3.1 Resistance to sulfate water

The attack on cements by sulfates like  $\text{MgSO}_4$  is double. The magnesium takes the place of the calcium of the cement hydrates such as  $\text{Ca}(\text{OH})_2$  and C-S-H and gives respectively  $\text{Mg}(\text{OH})_2$  and M-S-H without binding properties. The  $\text{SO}_4^{2-}$  ions react with the  $\text{Ca}^{2+}$  ions displaced by the  $\text{Mg}^{2+}$  ions and form a secondary gypsum  $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$  which reacts itself with the aluminates giving birth to an expansive ettringite.

This series of reactions can be observed in samples of synthetic mixes containing 50 %  $\text{C}_3\text{S}$  + 15 %  $\text{C}_2\text{A}$  + 5 % gypsum + 30 % quartz immersed in a solution of 5 %  $\text{MgSO}_4$ . From the first day, the samples showed a large swelling, they were destroyed at the end of 7 days. The hydrates formed, detected by X-ray diffraction and scanning electron microscope were  $\text{Mg}(\text{OH})_2$ ,  $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$  (high quantity of gypsum, much superior to the 5 % in the anhydrous mix),  $\text{C}_3\text{A} \cdot 3\text{CaSO}_4 \cdot 32\text{H}_2\text{O}$  (secondary ettringite) and C-M-S-H (fig. 18).

Fig. 18 : Secondary gypsum and cracked C-M-S-H

In a second series of samples, the 30 % quartz was replaced by 30 % granulated blast furnace slag. After seven days of immersion in sulfate water, the samples were still in good condition. The hydrates observed were a dense C-S-H (fig. 19), crystals of  $\text{Ca}(\text{OH})_2$  and monosulfoaluminate and some dispersed needles of ettringite of which the size was only about  $\mu\text{m}$  (fig. 20). The hydrated slag grain are surrounded by a layer of C-S-H. It is partially a lime activation : the quantity of  $\text{Ca}(\text{OH})_2$  is less after 7 days than after 1 day according to the X-ray diffraction diagram on which is detected neither  $\text{Mg}(\text{OH})_2$  or secondary  $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ . Here, the denseness of the material and the low lime content are both favorable to the sample resistance to sulfate attack.

According to SMOLCZYK (53), the good chemical resistance of 65 % slag cements remains even if the concrete is in contact with sulfate water after its preparation. KODAMA and KITAMURA (54) have also shown the good resistance of cements containing 60 % slag ground to a Blaine specific surface of  $4000 \text{ cm}^2 \cdot \text{g}^{-1}$ . A finer than normal slag granulatiry, on the order of

$5000 \text{ cm}^2 \cdot \text{g}^{-1}$ , however, increases its chemical resistance in decreasing its porosity (55).

Fig. 19 : Dense C-S-H in presence of slag.

Fig. 20 :  $\text{Ca}(\text{OH})_2$  (o) and finely crystallized ettringite (x) in presence of slag.

#### 3.2 Resistance to chloride waters

Mortar samples of slag and Portland cements were immersed in different solutions of  $\text{MgCl}_2$  by KOBAYASHI and OKABAYASHI (56). The penetration of the  $\text{Cl}^-$  ion in successive layers has been estimated by chemical analysis at :

- 20 mm after 4 weeks for OPC,
- 10 mm after 52 weeks for the cement containing 65 % slag,

both having been immersed in a solution containing 25 g of  $\text{MgCl}_2$  per liter.

Chloroaluminates  $\text{C}_3\text{A} \cdot \text{CaCl}_2 \cdot 10\text{H}_2\text{O}$  have been characterized by X-ray diffraction. VIRODOV et al (57) have detected hydrotalcite  $\text{Mg}_6\text{Al}_2(\text{OH})_6 \cdot \text{CO}_3 \cdot 4\text{H}_2\text{O}$  in the presence of  $\text{MgCl}_2$ .

#### 3.3 Resistance to sea water

When a Portland cement, totally immersed in sea water, shows a large swelling, it would be the same for slag cements containing less than 60 % slag. This result was obtained on ISO mortar samples ( $4 \times 4 \times 16 \text{ cm}$ ) conserved in the same conditions for one year (58).

OPC	1000 $\mu\text{m}/\text{m}$
OPC + 50 % slag	750
OPC + 30 % slag	690
CLK (80 % slag)	190

### III - 2/21

**Table IV** : Evolution, in function of percentage of slag, of the compressive resistances of 4 x 4 x 16 cm mortar samples immersed in sea water, compared to the compressive resistances of the same samples immersed in fresh water (59).

$\frac{R_c \text{ compression 6 months fresh water}}{R_c \text{ compression sea water}} \text{ in } \%$											
Portland cements			Slag Cement type A S < 30 %			Slag Cement type B 30 % < S < 60 %			Slag Cement type C S > 60 %		
6 months	1 year	3 years	6 months	1 year	3 years	6 months	1 year	3 years	6 months	1 year	3 years
* 73	57	x	66	51	33	68	86	118	99	124	191
** 64	33	x	59	41	x	63	63	52	95	140	193
*** 58	24	x	53	25	x	68	63	x	108	133	160

x : destruction of the sample, S : slag.

Potential composition of Portland cement (% in weight)

	C <sub>3</sub> S	C <sub>2</sub> S	C <sub>3</sub> A	C <sub>4</sub> AF
*	46	32	6	16
**	55	22	10	13
***	60	17	10	13

Further, the compressive resistance of samples of the same type compared by MIYAIRI *et al* (59) to their resistance at six months in fresh water (Table IV) showed that for a non marine cement, only the addition of more than 60 % slag will give an increase to resistance over a period of time.

The aggressive sea water salts are magnesium sulfate and magnesium chloride. The secondary products are therefore Mg(OH)<sub>2</sub>, M-S-H, CaSO<sub>4</sub>.2H<sub>2</sub>O and C<sub>3</sub>A. 3CaSO<sub>4</sub>.32H<sub>2</sub>O (60).

In sea water as in fresh water, the clinker hydrates first in slag cements. The chlorine and the sulfur coming from the dissociation of the chlorides and the sulfates dissolved in sea water diffuse in the sample forming chloroaluminates and sulfoaluminates.

The figure 21(a) shows the polished section of a pure paste slag cement sample examined by electronprobe microanalysis after three years of immersion in fresh water. A comparison with the same sample immersed three years in sea water [fig. 21(b)] reveals that the material is just as compact in the two cases and that in sea water there was neither the dissolution of CaO nor a diffusion of Mg<sup>2+</sup> ions. To the contrary, in the Portland cement which enters into the composition of the clinker slag cement (CLK), the Mg<sup>2+</sup> ions were able to progress and formed M-S-H around the clinker grains [fig. 21(c)].

The penetration of chlorine into the samples leads to the formation of chloroaluminate [fig. 21(b)]. However, it is limited in slag cement if compared to that of Portland cement [fig. 21(c)]. The reticulated C-S-H containing Cl<sup>-</sup> ions in their crystalline network were not observed in slag cements. Ettringite is finely crystallized and more disseminated in the clinker slag cement (CLK) than in the Portland cement where it is more localized around the C<sub>3</sub>A crystals where the alumina saturation is the strongest. Figure 21(c) also shows two zones superimposed around a grain of C<sub>3</sub>A, the interior zone is composed of chloroaluminate and is the first to form, the exterior is

composed of ettringite. Chloroaluminates are not stable in sea water. In decomposing, they permit a new crystallization of ettringite. Trisulfoaluminate can also be obtained at later dates by a delayed hydration of C<sub>3</sub>A crystals which are in the large clinker grains; this leads to a cracking of the C-S-H.

In clinker slag cement (CLK), all the alumina of the slag grains does not combine with the chlorides and the sulfates, it also enters into a solid solution in the C-S-H which remains compact (60).

The kinetics and the mode of crystallization of ettringite are different from those of Portland cement. Trisulfoaluminate appears by a relatively slow process of the passage into solution, its distribution is diffused (61). Its content is less because of the low percentage of Ca(OH)<sub>2</sub> which could give rise to a secondary gypsum.

Fully immersed, the samples are covered by a white film composed of brucite Mg(OH)<sub>2</sub> and CaCO<sub>3</sub> in the form of a calcite and aragonite mixture. MARCHESE and SERSALE (62) found more aragonite than calcite in Portland cements. To the contrary, in blast furnace cements, the calcite content is greater than the aragonite. The vaterite  $\mu$ CaCO<sub>3</sub>, which could come from the carbonation of the hydrated silicates in fresh water (63) is not observed in sea water.

In alternate immersion, the attack is both physical and chemical. The degradation of certain blast furnace (CHF) and clinker slag (CLK) cements that had insufficiently resisted to the conjugated action of sea water, waves, sand, wind, sun and freezing has been tied to the slow hydration speed of the slag grains. In this sense, T. IDEMITSU *et al* (64) have shown that the comportment of slag cements is very sensible to the initial conditions of conservation. Certain precautions are therefore necessary in a marine environment : surface protection, a longer hydration period than that for Portland cements before immersion in sea water, dense concretes or mortars with a heavy cement content (65). After having tested

Absorbed Electrons : S = slag, M = monosulfaluminate, C = chloroaluminate, E = ettringite, K = clinker.

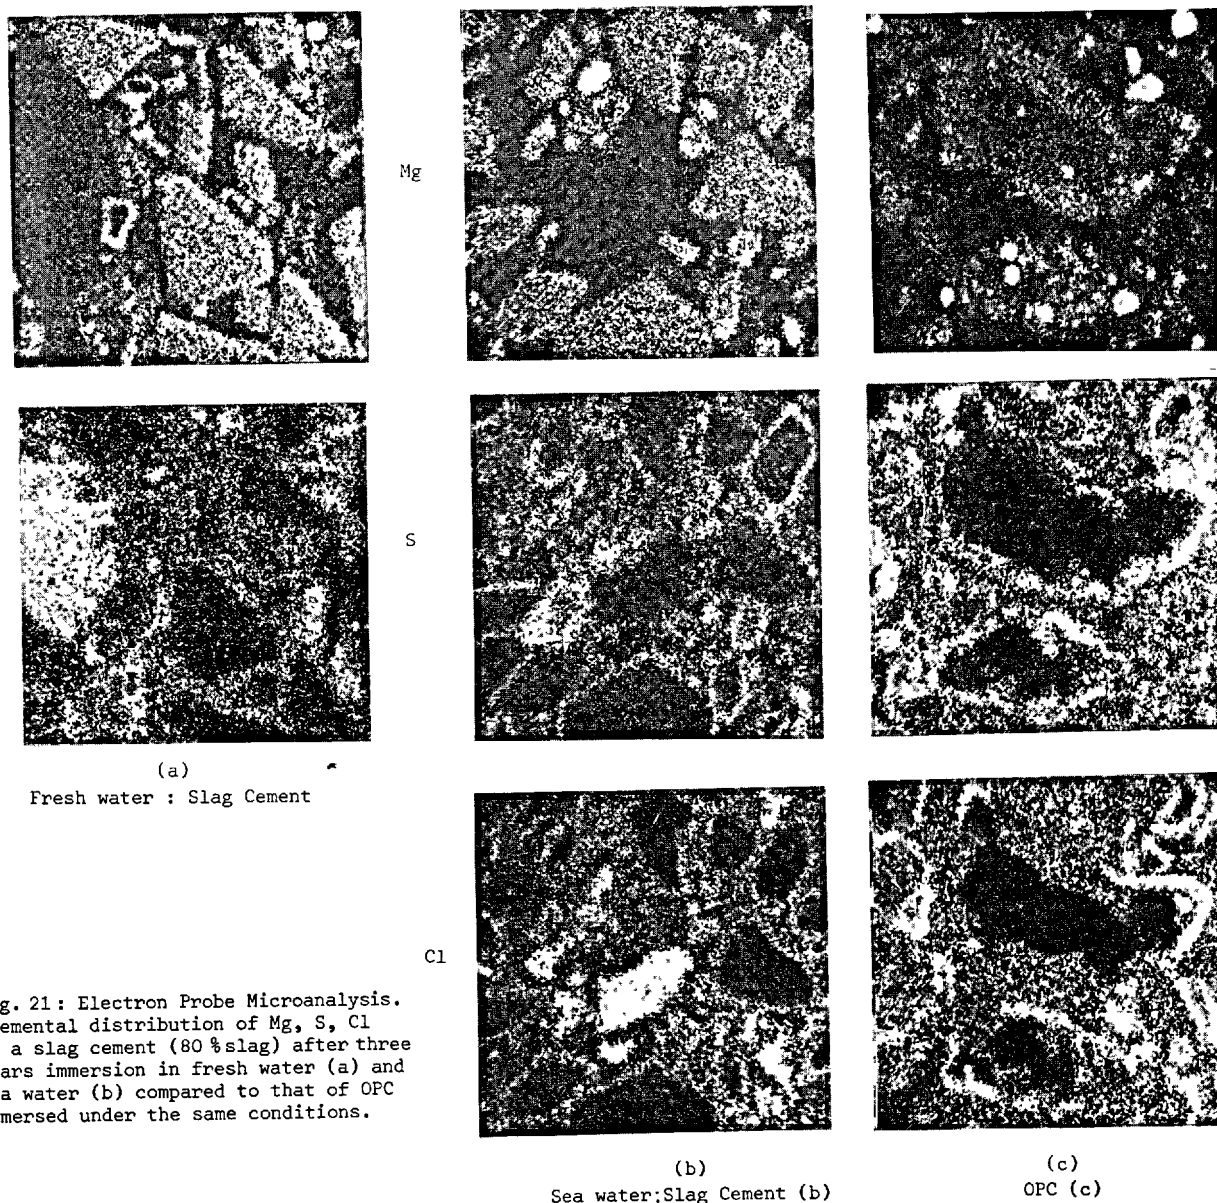

Fig. 21: Electron Probe Microanalysis. Elemental distribution of Mg, S, Cl in a slag cement (80 %slag) after three years immersion in fresh water (a) and sea water (b) compared to that of OPC immersed under the same conditions.

different types of cement for seven years, l'Electricité de France selected a blast furnace cement (CHF) for the construction of the Rance tidal power station started up in 1966. The total surface exposed to sea water is 90,000 m<sup>2</sup>. This work of civil engineering remains in excellent condition. Slag cements are also used in the form of injection grouts in marine environment (66).

### 3.4 Resistance to carbonation

The carbonation of slag cements which, in the case of reinforced concretes, leads to the depassivation of the steel reinforcing, is no greater than that of Portland cement if the concrete is compact and conserved in an atmosphere sufficiently humid (53). The results of SMOLCZYK (53) are confirmed by YODA et al (67), after seven years conservation in an atmosphere of 100 % relative humidity, the carbonation is zero in cylindrical samples 15 x 30 cm.

In carbonated cements, the steel rusts at the same speed in a slag cement containing sulfur and a cement without sulfur (53). Electrochemical measurements (pH, conductance, redox potential, corrosion potential, potentiometric curves) taken by LONGUET (68) on the aqueous interstitial phase of concretes have proven that the clinker slag cements (CLK) containing more than 80 % slag protect the steel reinforcing as well as Portland cements.

Slag cements have a good resistance to thermal carbonated waters. The CO<sub>2</sub> dissolved in the water can only penetrate very slowly because of the compactness of the material (69).

Short term carbonation does not sensibly modify the crystalline texture of the hydrates according to MURAT and NEGRO (70), the reaction with CO<sub>2</sub> would be a true pseudomorphosis. Carboaluminates were observed by FRIGIONE and SERSALE (71). Their quantity is in function to the gypsum content of the cement. In the case of a high gypsum content (> 4 %), the carboaluminates give way to ettringite.

### 3.5 Comportment at low temperatures

Slag cement is not as favorable as Portland cement in countries with long and rigorous winters because it hydrates slower at temperatures lower than 20 °C (72). However, it is possible to increase its resistance to freezing and its mechanical performance by accelerating its hydration with chemical activators such as sulfoaluminosilicate (73).

Portland cement accelerators admixtures are not always as good with slag cements : CaCl<sub>2</sub> is fixed in a greater quantity by the slag (74) but it increases the porosity (more "open structure") of the cement paste (75). The accelerating effect of CaCl<sub>2</sub> decreases from tricalcium silicate to dicalcium silicate (principal constituents of Portland cement) to rankinite C<sub>3</sub>S<sub>2</sub> and to wollastonite CS, silicates with a composition close to that of the slags (76).

The addition of air entrainers equally increases the porosity and diminishes the rate of hydration of the cement (77).

### 3.6 Resistance to the alkali-aggregate reaction

In concretes containing reactive siliceous aggregates, slag cements are preferable to Portland cements which are rich in alkalies. Tests conducted by SMOLCZYK (78) on 30 different types of cement mixed with ground Pyrex glass show that the expansion due to the alkali-silica reaction decreases in function to

the slag content. An addition of 70 % slag to a Portland cement can move the admitted limit of Na<sub>2</sub>O from 0.6 % to 2 % without risk of degradation to the concrete.

## 4. CONCLUSION. FUTURE RESEARCH

The hydrates of slag cements are the same as those of Portland cements : C-S-H, C<sub>3</sub>A.3CaSO<sub>4</sub>.31H<sub>2</sub>O, C<sub>3</sub>A. CaSO<sub>4</sub>.12H<sub>2</sub>O, C<sub>4</sub>AH<sub>13</sub>. The granulated slag reacts slower than the constituents of Portland cement but it can be activated. The activation can be chemical, mechanical (overground) or thermal. Whichever form of activation is used, hydrosilicate C-S-H is always present. It is not as well crystallized but denser than the fibrous C-S-H of Portland cement. The ettringite is present in fine binding needles more disseminated in the paste than the ettringite of Portland cement localized close to the C<sub>3</sub>A crystals. The alumina of the slag grains is also found in the C-S-H in solid solution.

In the hydration of slag cements, the alumina plays a role which has not yet been completely elucidated and which has already been signaled by SCHRÖDER (79) at the Tokyo Symposium in 1968. In certain cases, the increase in mechanical resistance from one slag to another has been tied to a higher alumina content. In other cases, alumina shows itself to be unfavorable to the development of these same resistances at the ambient temperature as well as during thermal treatment or autoclavage.

Two vitreous slags of identical chemical composition can present different hydraulic properties which leads to the difficulty of using one or the other of the hydraulicity modules proposed in the last few years (80). The difference in reactivity seems to be tied to the structure of the glass. Current studies on the polymerization of silica, alumina and magnesia tetrahedra by bridging oxygen atoms will permit a better understanding of the mechanism of slag hydration.

Cements with a high slag amount contain little or no Ca(OH)<sub>2</sub>, their C-S-H is compact and contains alumina in solid solution. These cements offer a strong resistance to chemical attack.

The medium and long term performance of slag cements are equal or greater to those of Portland cement and their short term performance can be improved.

The utilization of blast furnace slags, by-products of the metallurgical industry, enters in the framework of the savings energy and will be necessary developed in the near future. Europe and Japan have already acquired a large experience in their use.

Current studies involving other by-products are : slags from the steel industry or LD converted slags (81, 82, 83, 84), copper slags (85,86), electrothermophosphorous glasses (87), slags containing foreign elements such as Ti (88), Mn (89) and Ba (90). Certain of them, much less hydraulic than blast furnace slags, call for a greater activation the conditions of which are yet to be defined.

## Acknowledgements

The author would like to thank the members of the Microstructure Department of C.E.R.I.L.H. who were of great assistance in the preparation of this report and especially J. VOLANT who took charge of the bibliographic review.

I am equally very grateful to Prof. Dr. R. Sh. MIKHAIL for having provided the scanning electron microscope photos of autoclaved mortars and to Dr. R. DRON for having transmitted the results of his study on the structure and hydration of slag glasses before its publication.

## **THEME IV**

### **Structure of pozzolana and fly-ash and the hydration of pozzolanic and fly-ash cements**

## **SUB-THEME IV-1**

**Structure  
and characterisation  
of pozzolanas  
and of fly-ashes**

**R. SERSALE  
Napoli University  
ITALY**

This paper is a normal state-of art of a part of the reports submitted by Massazza (1) and by Kokubu and Yamada (2) at the 6th International Congress on Chemistry of Cement. Consequently it will not deal with the knowledge already acquired with certitude, but will be limited to giving an account of the subsequent addition to our knowledge, by defining, where possible, the practical results of the scientific and technological progress, whilst endeavouring to give specific emphasis to the problems which call for further research.

## 1. INTRODUCTION

Table I represents the classification of the principal materials having the property of fixing lime. This classification takes the origin into account.

TABLE I  
Classification of the principal lime-combining materials

Natural			Artificial	
Sialic material	Siliceous	Mixed type	Traditional	Non traditional
Unaltered Pozzolanas	Diagenetic Lithoid Clay tuffs (clay (zeolitic) minerals)		Fly ash Clays Shales Burnt diatomaceous earths	Plant ash

It can be observed that the natural materials can be divided into: sialic, siliceous and mixed-type products.

The former groups include materials rich in silica and alumina, such as: volcanic glass, zeolites and clay minerals, but the latter do not yield an appreciable hardening when they fix lime.

The latter groups are characterized by materials of organogeneous origin, extremely porous and crumbly, formed mostly by the siliceous remains of radiolarians and diatoms. As a group, these types of earths are very reactive to lime but, being formed by angular, porous and spindle-shaped skeletons, they need a considerable quantity of water when they are mixed with the cement and the resulting pastes and mortars present, consequently, a decrease in the resistance to atmospheric agents and an increase in drying shrinkage. Therefore they are not considered as materials of quality (3) even if sometimes they are used in the production of binders (4).

The reactivity of diatomites can be increased by thermal treatment at 500°-600°C (5)(6). The class of the mixed-origin materials, sialic and siliceous, includes Gaize (Ardennes and Mense) and Moler, a tertiary deposit of diatomaceous earth with a rather high clay content (Denmark). French gaizes, polluted by clay, can be used after the thermal treatment.

## 2. SIALIC MATERIALS

### 2.1 Unaltered materials

#### 2.1.1 Pozzolanas

This term must be reserved solely for essentially vitreous pyroclastic material easily zeolitizable. It is well known that one of the fundamental conditions for a rapid zeolitization is the structure of finely subdivided volcanic glass (7). Equally familiar is the fact that the zeolitization process of pozzolanas causes cementation of the incoherent material so that

(true) pozzolanas must be considered as the non-zeolitized equivalents of volcanic tuffs. In this connection it is interesting to note that not all pozzolanas zeolitize with the same ease. In fact the most easily zeolitizable pozzolanas are precisely those which have a more marked hydraulic activity (trachytic or leucitic pozzolanas (8)).

#### 2.1.2 Selection of pozzolanas

This can be done on the basis of the vitreous phase content, by the difference between the silica and lime content respectively, which is determined by the usual chemical methods. A limit value around 34% would reveal the absence of the vitreous phase (9). Colour of pozzolanas would only result from the degree of iron oxidation without implying reactivity. Therefore black pozzolanas are not inferior in quality to red pozzolanas (11).

#### 2.1.3 Composition of pozzolanas

It fluctuates between the following limits:  $\text{SiO}_2$ : 45-60%;  $\text{Al}_2\text{O}_3 + \text{Fe}_2\text{O}_3$ : 15-30%;  $\text{CaO} + \text{MgO} + \text{alkali}$  ~ 15%; loss on ignition up to 10%.

A true pozzolana is formed essentially of a small quantity of crystalline minerals (feldspar, leucite, augite etc.) plunged into an abundant vitreous mass, more or less altered by atmospheric agents, porous to such a point that it simulates a gel and with wide internal surface. Beside solubilizable silica, it contains significant quantities of solubilizable alumina.

#### 2.1.4 Origin of pozzolanas

They form (12)(13) as a result of volcanic, explosive-type eruptions, because of the violent projection of melted magma into the atmosphere, in the form of minute particles which bring about a phenomenon of tempering responsible for producing a vitreous state. They are made up of elements of different aspect and dimensions: pumice, scoria etc. which can be distinguished by grading.

On the contrary non-explosive eruptions produce volcanic ash, much less reactive with lime than pozzolanas even if identical in composition and grading, since the quick tempering process has not occurred. Indeed only once has Vesuvius produced pozzolanas, during the well-known eruption which destroyed Pompeii and Herculaneum in AD 79 and which Pliny the Younger described in his letter to Tacitus (14). Following this and failing explosive phenomena, it has only produced ash.

#### 2.1.5 Dosage of the vitreous phase of pozzolanas

The reactive fraction of pozzolanas is the vitreous one, since the partially altered minerals react to a lesser extent.

By X-ray diffraction it was found that the diffused band which can be attributed to glass is directly proportional to the vitreous phase content, therefore it could be determined after appropriate calibration of the instrument with an obsidian whose mineralogical composition is as close as possible to the sample to examine (15).

A vitreous state index, calculated on the basis of the width of the diffused band of diffractograms around  $d = 4-5 \text{ \AA}$  appeared to give good correlation with scanning electron microscope observations and with values of mechanical strength by making it possible

to classify pozzolanas according to reactivity (16).

#### 2.1.6 Detection of pozzolana texture

The observation under the optical microscope at low magnification (50 x) allows pozzolanas to be classified into scorias and pumice.

The scanning electron microscope cannot reveal the differentiation of the feldspar from the vitreous phase because of a transgranular break in the crystals, given the common conchoidal aspect of the elements (17).

#### 2.1.7 Internal structure of pozzolanas

The absorption infrared spectroscopy has been used to underline the variations in structure determined by a chemical attack or by a thermal treatment of pozzolanas (18). Although pozzolana spectra are difficult to interpret, since the high degree of vitreous state allows the recording of only slight differences, however the interferences between atomic vibrations and infrared rays seem to be the most appropriate means for studying components formed by amorphous and crystalline fractions and they give useful information on their reactivity.

### 2.2 Diagenetic materials

#### 2.2.1 Lithoid tuffs

The term tuff must be reserved to pyroclastic rocks which form because of diagenetic phenomena acting on the vitreous, incoherent fraction which has settled in different circumstances because of volcanic explosions (7).

Volcanic materials, mostly vitreous, accumulating in all the different sedimentary basins, represent in fact in most cases the cradle of zeolitization phenomena. Silicate glasses with their higher content in free energy are particularly sensitive to any sort of reaction especially in a wet medium and, by hydration, solubilization, hydrolysis, they can give rise to phenomena of zeolitization, feldsparization or transformation into clay which are responsible for the cementation of the original material.

Therefore we can only call tuffs the zeolitized equivalents of pozzolanas. The most compact compounds, therefore, show a lithoid aspect and have a compressive strength of about 100-300 kg/cm<sup>2</sup>; from early times this property determined their use in building. Once ground, these tuffs show an aptitude to combine with lime similar to that of non zeolitized equivalents (true pozzolanas) and sometimes an increased aptitude, since the zeolitic fraction is more easily attacked by lime than the pozzolana glass.

As for characteristics of quality, cements made with trass, for example, make very plastic, compact concretes which are impermeable to water and have low heat of hydration (19).

#### 2.2.1.1 Origin of tuffs

It seems logical to attribute the process which governed the genesis of the best known and best studied formations - such as the Rhine "trass", the Naples yellow tuff, the tawny tuff of the Alban Hills, the Grand Canary tuff etc., to the category of diagenetics, set up by the action of meteoric waters on volcanic glass.

The zeolitization mechanism has been interpreted in the light of the factors which encourage this process and also assumptions justifying the contemporary presence in some formations of zeolites and clay minerals have been proposed (7).

#### 2.2.2 Clays

Pyroclastites are also liable to transform into clays (20); as we have already emphasized, this process is sometimes combined with zeolitization, in turn determined by diagenetic phenomena. The development of volcanic glass in one or other direction is probably determined by a series of factors: chemical composition, microstructure, grading and permeability of sedimentary materials, the pH of the sedimentary medium, the type of ions present in the solution, the age of deposits, the pressure and temperature, the composition of pore waters.

Clays do not interest the cement industry as materials capable of reacting with lime. Indeed although the decomposition of clay minerals under the action of lime causes the neoformation of the same hydrated phases which can be observed from non clayified equivalents (pozzolanas and tuffs) and although the combining rate as well as the quantity of reacting lime generally have higher values (21), their use with clinker lowers mechanical strength. This confirms the fact that the quantity of lime reacting with the compounds having this property, is not enough to foresee the development of the mechanical strengths (22)(23). Their plasticity implies that clays are not adapted to be incorporated in cement (13).

The mechanism prevailing in the processing by lime at ambient temperature is a long alteration process of the crystalline lattice. This process affecting more directly the octahedric strata of the structure was revealed by means of infrared spectrometry.

In the field of neoformation compounds roentgenographic analysis carried out on materials originated by reaction at 39°C during 250 days of lime on kaolinite has allowed C-S-H hydrated calcium aluminates and hydro-garnets to be identified (25).

### 3. ARTIFICIAL MATERIALS

As shown in table I, these can be classified in two categories: traditional materials and those of more recent use. The first comprises in order: fly ash, burnt clays and shales.

#### 3.1 Fly ash

The term "artificial pozzolana", adopted to describe these important materials as well as those obtained by thermal treatment of clays and earths, in general must be dropped, because it only sets up confusion between categories of materials which have in common the aptitude of reacting with lime, but which present substantial differences in origin, formation and microstructure (13). This term went through a period of validity of course, since in the past there was a need to overcome the distrust of introducing on the market little known products, little known especially in their behaviour. Today it is no longer meaningful because fly ash proved to be not inferior to the best pozzolanas. Indeed they were successfully tested in several cases: as secondary components to cements (26)(27)(28)(29) added to mortars and concretes (30)(31) as raw materials (32)(33) in the precast industry and in road works (34)(35).

Consequently, the residues from combustion of pulverised coal in power stations must be called fly ashes. They represent an industrial-product of growing interest, especially if we take into account the fact that world production reaches about 180 million tonnes (36) with a rate of use of approximately 16-17%.

This production will probably increase since less liquid and gas fuels are being used in power stations. Power station boilers can be of two types with melted ash and dry ash. In the first case 85-99% of solid residue is collected in a state of fusion and quench-

ed rapidly in water. The unburnt carbon content is extremely low. In the second case, a fraction (10-15%) of solid waste settles at the bottom of the combustion chamber; it is removed mechanically and is made up of small size particles ( $30\mu$  - 30 mm cinders); the remains (85-90%) collects along the exhaust path, to be removed afterwards by the electrofilters (37). This is true ash, sold either in a dry state, or humidified (8-12%).

The vitreous state of the material is due to the combustion temperature and then to the quenching. Ash formed at temperatures from 1200-1400°C can be used in cements but higher quality ash is obtained only at 1500-1700°C (38).

About 45 million tonnes of fly ashes are produced per year in the U.S.A., with a yearly increase of 10%.

The cement industry uses about 10% of the annual production (3). France is in second position behind the U.S.A. amongst the countries which devote vast quantities of ash to their production of hydraulic binders. About 95% of production comes from coal ashes (39)(40) with a very low calcium content and a Blaine specific surface between 2500 and 4000  $\text{cm}^2/\text{g}$ . Out of 5 million tonnes produced in 1976, 2.5 were used in the building industry (41).

On a lesser scale France also produces ashes from lignite combustion (42) characterized by higher calcium content and specific surface (5000-8000  $\text{cm}^2/\text{g}$ ) called sulphocalcic ashes. It also produces ashes containing a high percentage of calcium ( $\sim 44\%$ ) called hydraulic ashes. Both are used in the hydraulic binder industry.

England produced 10 million tonnes of fly ash in 1971-72. About half of this production was used (43) mostly as filler and a small quantity in cement production.

### 3.1.1 Composition of fly ashes

Coal ash is basically composed of silica and alumina. The composition is approximately: 50%  $\text{SiO}_2$ , 30%  $\text{Al}_2\text{O}_3$ , 2%  $\text{CaO}$ , 5% alkalis, 7%  $\text{Fe}_2\text{O}_3$ . The unburnt matter ranges between 1 and 6%. These are therefore silico-aluminous products with a high degree of vitrification and few crystalline elements.

Electronic probe investigation reveals extensive variability in the particle composition, variability which has no influence on the overall chemical composition for ash produced by a single well-tuned power station burning coal from one mine.

Lignite or hydraulic ashes are richer in lime and their composition varies within the following limits (44)  $\text{SiO}_2$ : 23-50%;  $\text{Al}_2\text{O}_3$ : 8-14%;  $\text{Fe}_2\text{O}_3$ : 8-20%;  $\text{CaO}$ : 18-50%. Its hydraulic reaction increases in proportion to the lime content and from ashes richer in lime, the neoformation compounds are identical to those obtained from Portland cement, the reaction occurring with heat evaluation. The light colour of this ash is a proof of good quality.

As regards the most interesting ashes, the more important chemical characteristics taken into consideration by standards in different countries are those indicated below in the prescribed limits (45).

Loss on ignition, directly limited to the unburnt matter (1-6%) varies between 5 and 12%. The sulphate content which can cause volume instability of concretes falls between 2.5 and 5% as  $\text{SO}_3$ . This content, as well as that of the unburnt matter, is an element to be taken into consideration for ashes used in reinforced concretes (46). The percentage of main oxides ( $\text{SiO}_2 + \text{Al}_2\text{O}_3 + \text{Fe}_2\text{O}_3$ ) should not fall below 70%. The magnesia content can reach a maximum of 5%, since we have not yet checked with certainty if its methods used to

estimate volume stability of Portland cement are valid for fly ash cements. The alkali content, such as  $\text{Na}_2\text{O}$  should not exceed 1.5% for concretes made with reactive aggregates. The humidity content must lie between 1 and 3% since a higher content favours loss of reactivity.

The quantity of the unburnt material which varies with furnace design, regulation of combustion and the coal volatile matter content, should be kept as low as possible. Unburnt matter is generally found in the smallest fractions, is inert and although it causes no damage up to a maximum content of 12%, it can influence the colour of the concrete. Lean coals leave a higher rate of combustible material than the rich coal. It can be eliminated by sieving, by mechanical ventilation or by both methods combined. Black stains occur because the residual carbon contained in ash used in manufacturing cements may rise to the surface. These stains can be prevented from forming by adding a tensio-active agent (sodic alkyl naftalenesulphonate (47)) with absorption of organic molecules at the surface of carbonated fractions, lowering of the solid-water interface tension and consequently elimination of the spontaneous flotation phenomenon.

### 3.1.2 Physical properties of fly ash

Fineness is one of the principal parameters to define the aptitude of ash to be added to cement since it influences the rate of development of mechanical strength and the relative values to be attained. There is an optimal fineness above which the increase in strength becomes less significant because of the increase in the specific surface (48).

This fineness which can be determined by the Blaine method varies from country to country from 270  $\text{m}^2/\text{kg}$  to 425  $\text{m}^2/\text{kg}$ . Because of its porous nature the presence of combustible material distorts this determination since it gives higher specific surface values if the air permeability measurement methods are used. This is why the sieve procedure is preferable (45).

Laboratory tests carried out on fly ashes containing slightly reactive forms of  $\text{MgO}$  and  $\text{CaO}$  (49) have shown that grinding lasting 10-15 minutes under suitable conditions in a planet mill gives rise to chemical activation linked to a phenomenon of agglomeration and amorphization of the structure producing hydrates of higher mechanical strength.

The influence of the ground material fineness is underlined by research carried out on lignite fly ashes of Greek origin (50). Mechanical strength tests on mortars have shown that the ash can replace 20% of Portland cement if ungraded material is used. The quantity to add can reach 45% if only the  $< 45\mu$  fraction is used. It is preferable to grind ungraded material rather than to sieve. Optimal grinding time is about 10 minutes (51).

### 3.1.3 Structure of fly ash

The specific characteristics of each ash are revealed by scanning electron microscope investigation (52).

Ash is seen as a powder made up of fine spherical particles whose sizes vary from 0.5 to 200  $\mu$ . Shape and colour are variable. There are indeed small hollow or solid spheres, angular grains with bulges and hollows, open shells. The grain surface is generally smooth and glossy.

From the mineralogical point of view they consist mostly (53) of vitreous aluminosilicates with modest quantities of iron, sodium, potassium, calcium, magnesium, titanium. The other predominant phases are mullite, quartz, hematite and magnetite as well as combustible material. Traces of mullite in the residue after

er diluted chlorhydric acid attack seem to be a means to differentiate ash from pozzolana in cements (13).

### 3.2 Clays, shales, burnt diatomaceous earths

Heating clays, at temperatures corresponding to those of the thermal destruction of minerals which characterize them, brings about rupture in the lattice and consequently the formation of a mixture of amorphous silica and alumina in the stoichiometric proportions of the original minerals. Since the increase in structural disorder brings about an increase in the instability of the system, reactivity with lime and loss of plasticity become noticeable. Cement pastes with appropriate proportion can offer mechanical strengths of the same magnitude as those obtained using pozzolanas or fly ashes.

The use of burnt clays added to cement is not widespread owing to the energy needs and the eventual competition of fly ashes which have already undergone thermal treatment and require no further energy consumption, not even for grinding. From this point of view they prevail over pozzolanas.

Even spent oil shales (ashes) can be used to combine with lime (54). Ungraded material with density above 2 can be competitive if used in an area not exceeding a distance of approximately 30 km from the production or the collecting point; which explains how ternary blends of shales (85%) fly ashes (13-15%) and lime (1-2%) are used in road works.

Finally the main consequence of the thermal treatment on diatomaceous earths is the activation of clay minerals which makes them polluted.

### 3.3 Non traditional artificial materials

Amongst plant-based materials which can be used as a source of active silica, rice husk seems the most appropriate. Rice growing is extensive all over the world, particularly in developing countries (55). This use of husk appears very timely since a tonne of raw rice produces 200 kg of husk which, because of its low specific gravity, is very bulky. Without counting the calories which can be retrieved for energy purposes, burning rice at about 800°C will produce 20% of its weight as ash containing a high percentage (80-95%) of very reactive silica and 1-2% of potash. The remaining part is unburnt matter.

It was stated that by adding 50% of this ash to clinker, mechanical strengths higher than those of Portland cement are obtained even in the case of short curing (56) and the mortar gains resistance to attack by diluted acids, whether organic or inorganic.

Other reactive forms of silica are dusts trailed by fumes from ferrous alloy production furnaces; the Blaine fineness is about 20.000 cm<sup>2</sup>/g (57). Their use increases cement hardness and chemical resistance (58). Very interesting projects also concern the use of by-products and manufacturing wastes which lead to savings in natural raw products (59).

## 4. POZZOLANIC ACTIVITY

Pozzolanic activity - that is to say the phenomenon which determines the neo-formation of phases likely to show mechanical strength after hardening - occurs through the effect of the reaction of lime on compounds formed by the alkaline attack of acid silicates (60). The reaction produces hydrated phases similar to phases neoformed by clinker/granulated blastfurnace slag reaction (61) - hydrated calcium silicates and aluminates with excess lime - and is very advantageous from the industrial point of view when the basis material contains silica and alumina easily mobilized, which is typical of amorphous structures and particu-

larly acid glasses. This explains why pozzolanas, fly ashes and burnt clays are preferred as active additions.

In the case of zeolitic type crystalline structures, reactivity which is sometimes even higher than that of vitreous equivalents (12) is probably due to the more open porous structure, therefore more likely to be attacked. Indeed these pores allow chemical agents to penetrate, attacking their crystalline structure through destruction and freeing of silica, alumina and alkalis, the first two of which combine with lime.

In an alkaline medium, zeolitic minerals as well as glass are subjected to a hydrolysis process which brings silicate and aluminate ions into the solution. With Ca<sup>2+</sup> and Mg<sup>2+</sup> ions, very low solubility product phases form, such as silicates and aluminates. Their precipitation promotes the passage of other silicate and aluminate ions into the solution, so that the hydrolysis process can continue, differently from what would happen if the attacking agent were only water. With this last assumption the system tends to balance after a certain time.

A pozzolanic reaction mechanism was recently proposed with reference to the structure of feldspar (60). It is well-known that the KAlSi<sub>3</sub>O<sub>8</sub> orthoclase consists of three SiO<sub>2</sub> units and one AlO<sub>2</sub><sup>-</sup> unit, the aluminate ion charge being compensated by K<sup>+</sup>. These units are tetrahedrons.

Within the feldspar structure, a SiO<sub>2</sub> unit can be represented as in figure 1. Each of the four oxide O<sup>2-</sup> ion is linked to the central Si<sup>4+</sup>, as well as to others which are not on the figure but lie along the dotted line.

On the contrary the situation is quite different for a unit on the outside surface: instead of an oxide ion there is an hydroxile according to:

This allows the -2 charge to find compensation outside the external surface. The contact with a water solution also allows the other O<sup>2-</sup> ions to transform progressively into OH<sup>-</sup>. The tetrahedron is thus less and less bonded and at a given moment breaks away from the original position and passes in solution as H<sub>3</sub>SiO<sub>4</sub><sup>-</sup>. If this solution contains Ca<sup>2+</sup> ions, insoluble, hydrated calcium silicates are formed.

The glassy structure of a pyroclast is more predisposed to the replacement of  $O^{2-}$  ion by  $OH^-$  ions since less intense links allow progressive detaching of units from the tetrahedron.

These would not be topochemical-type reactions since the hydrated phases would occur through total desintegration of the glass silico-aluminous lattice (60). Very probably for stable crystalline structures such as in feldspars, the surface attack by the lime-saturated solution proceeds in an orderly way, layer by layer. With more labile crystalline structures of the zeolitic type, the attack starting here again on the external surface where the links are less intense, would penetrate more easily inside, because of the "open"-type structure, leading to grain gelification and swelling.

This assumption would be confirmed by the trend of curves showing lime combination by zeolitic minerals and powdered tuffs (62); these curves go up suddenly even after short attack times. The calcium/alkali exchange cannot totally explain this development. The lime solution attack is made easier by the subdivision of the solid and by its porosity (63) even though (as already pointed out) this is on the molecular level.

With short periods of curing, the specific surface plays a fundamental role on the reaction kinetics; with long periods of curing, the chemical composition predominates, that is to say the silica and alumina (vitreous and zeolitic phase components) determine the behaviour (64).

Research on kinetics and mechanism of reaction of pulverised zeolitic tuffs subjected to combining with lime in water solutions and at a temperature of  $65^\circ C$  (65) seems to prove that the attack by the lime-saturated solution brings about surface dissolution of the grains from the very beginning of the reaction, with rapid local formation of C-S-H gel. The dissolution of the original compound would continue at the interface C-S-H solid/grain surface in a favourable medium to reach levels of sursaturation. Then the development of gelatinous silicate toward forms of greater crystallinity would be regulated by a process of controlled diffusion.

Without forgetting that each pyroclast has specific characteristics and must be studied individually (66), with the aim at bringing light on the complex chemico-physical phenomena which cause pozzolanic activity, solids with simple structure and constitution have been used. The reaction of silica gel with lime has been studied (67) by determining its reactivity as a function of prior thermal treatment and the relative modifications in its structure. The temperature used and the contact time with the solution at first saturated with lime were obviously the determining factor for the activity of the solid. Research also checked that the silica gel selectively combines with potassium and in general the alkalis (68), so that its behaviour can simulate that of a pozzolana only when no alkali is present.

As shown in industrial practice, colloidal silica combines with lime (69) by increasing the strength of cement pastes after short curing, even if they call for a quantity of water which can only be reduced by incorporating the appropriate admixtures.

#### 4.1 Factors which influence "pozzolanic" activity

##### 4.1.1 Incoherent lithoid pyroclasts. Other natural products

Apart from the structure, the morphology and the chemical composition, it is the fineness of the ground ma-

terial which determines the reactivity of pyroclasts (11)(64). The quantity of lime added, without however disregarding its type (16), plays a fundamental role on the binder hardening kinetics, as well as the water content which intervenes in the composition of neoformed phases bringing about cohesion.

The development of mechanical strength can be mainly attributed to the low basicity hydrated calcium silicates (11) with high water content, whilst alumina - tes seem to play only a secondary role.

Thermal treatment would not appear to be a useful means of increasing pyroclast reactivity. In any case there is no convincing explanation for a possible increase in reactivity (70), but the treatment can be positive if the basic product is polluted with clay. This treatment is negative if it determines a lowering of specific surface (71) as probably happens for powdered volcanic tuffs or in an extreme case if it brings on crystallization of any kind.

With lithoid pyroclasts (tuffs), reactivity is also determined by the quantity and type of zeolitic mineral diffused in the matrix, by its amorphous fraction and pumice content (13) as well as by the more or less noticeable presence of stable crystalline phases.

In Italy vitreous pyroclasts (pozzolanas) found extensively in Campania and Latium are used for binder production more often than lithoids (tuffs) since the former require less costly grinding. In other countries the use of lithoid materials is investigated with interest and recently it is referred to in the case where the materials available for cement production have high alkali content (72) in order to prevent alkali/aggregate reaction.

Tuffs and ignimbrites comparable to the former, although their composition is different from the genetic point of view, have proved to be appropriate in pozzolanic cement production (73).

Fineness of grinding (74) and the particular nature of the basic component also determine the reactivity of some compact, effusive rocks (which are found amongst others in the Massif Central) made up of a myriad of microcrystals surrounded by amorphous glass. Their composition is similar to that of pozzolanas, even if their basicity is higher. Indeed blends of basalt, lime and water in cylindrical specimens have shown the same values of compressive strength as the best pozzolanas (75).

##### 4.1.2 Fly ash

The reactivity of ash varies with: the type and source of coal, the chemical and above all mineralogical composition, the vitreous phase quantity, the combustion temperature, grinding fineness as already emphasized and low unburnt carbon content. Fineness of grinding and carbon content again determine the mixing water demand (53). As in the case of pyroclasts, reactivity becomes high after a period of latency (76) even if the ash and the pyroclast are not inert even with the shortest curing periods (2)(77).

Mechanical strengths of mortars increase with fineness of grinding and the decrease in carbon content percentage (78).

It seems that the particles of ash most easily attacked by lime are those which are not entirely vitreous (79) containing inclusions of mullite and quartz. However the latter show low reactivity (78).

The grains of ash seem to be covered by a glassy film which shows down the action of the water but sets up the reactivity. The grinding process by breaking this film would accelerate the reaction with water (80).

Chemical analysis of ash determines the inert and reactive fraction percentages, as well as that of soluble silica (total silica minus the inert fraction percentage) and makes possible the classification of the material according to an activity factor resulting from the sum: soluble silica + alumina + lime + + magnesia + sulphuric anhydride.

Ash reactivity is favoured by temperature (81), by certain setting time accelerators ( $\text{Na}_2\text{SO}_4$ ,  $\text{Na}_2\text{CO}_3$ ,  $\text{NaOH}$  etc.) as well as by the use of slightly acidified or alkalinized water (36). Ash can just as well be actified by immersion in a concentrated solution of  $\text{Ca}(\text{OH})_2$  (82) at  $60^\circ\text{C}$ , followed by desiccation, which causes decomposition of the grain surface vitreous layer. The fixing activity of the lime increases, but there is no corresponding increase in mechanical strength, at least as regards mixtures with 20% ash.

According to research concluded on synthetic silico-aluminous ashes (83) aimed at determining the influence of fineness, crystalline structure and chemical composition on reactivity, the results show that the properties of combining with lime would be influenced by the vitreous phase contents much more than by fineness. The state of tension in the vitreous phase (68) would influence reactivity. The iron content would reduce it, the calcium increase it. The soluble components in  $\text{HCl}$  and  $\text{HF}$  would give an approximate evaluation of the reactive fraction in ashes. Moreover it seems that the pozzolana activity is put directly in correlation with the  $\text{Al}_2\text{O}_3$  content (85). The reactivity of ash in cement is shown by a surface "corrosion" of active particles (86) by lime released during hydration. Consequently the formation of bonds with the hydroxide yields mechanical strength because of the neoformation of calcium silicate insoluble in water and hydrated calcium aluminates. At first hydration is slower than in the case of pure Portland cement (87) and then becomes faster so that at the end the nature of hydration products are quite similar to those of Portland cement (88) even if the reciprocal ratios between the resulting new formed phases are different (53).

The time necessary to achieve the equilibrium condition depends on the quantity of ash and its activity as well as fineness and other factors; generally it is about three months. The reactions are identical to those of pure Portland cement in the initial period, ashes having high fineness and activity, or when the material is further ground if the quantity of ash falls under 25-30% (89).

Light has been brought on the hydraulic behaviour of ash with high lime content (90). Most of it is silico-aluminous and badly crystallized. First contact with water causes portlandite crystallization followed by considerable formation of ettringite due to high calcium sulphate content (91). The vitreous fraction releases silica and alumina slowly and without interruption, causing formation of C-S-H and hydrated gehlenite at the expense of a part of portlandite.

##### 5. EVALUATION OF POZZOLANIC ACTIVITY

Preparing a simple and quick test to estimate pozzolanic activity with certainty is still today a complex unsolved problem (92). Many research groups including CERILH, the Laboratoire des Ponts et Chaussées (French civil engineering laboratories) and the cement manufacturers are at present studying this question (93).

To determine the activity of a pyroclast or a fly ash, it can be tested on mortar or concrete (3) by continuing strength tests up to a year if necessary (94).

However it is possible to obtain useful information from simple compressive strength on pozzolana binder /lime (80% pozzolana + 20% slaked lime) specimens (95). These considerations result from a survey on recently completed chemical, physical and mechanical methods.

Tests were undertaken to correlate pozzolana activity and the soluble component content in acids or bases.

As regards pyroclasts, the soluble silica content - which can be related to the capacity of the material to combine lime rather than its mechanical strength potential properties - can in any case be considered proportional to the compressive strength only by a comparison between the products of same origin and nature. For curings up to 28 days a difference of 10% in the soluble silica content would have repercussions on the strengths determined on lime mortar following the ASTM Standard C 595 but not on blends with Portland cement (96).

The methods appropriate for correlating the lime reaction kinetics to the dissolution heat in a nitro-hydrofluoric mixture are apparently not suitable for fly-ash. Considering the fact that the mixture of 2 molar of nitric acid and 0.6 molar of hydrofluoric acid would be too aggressive (97), by hiding the differences in particle reactivity, a determination of pozzolana activity is proposed by means of measuring the electrical conductivity of a fly ash suspension in 0.1 molar hydrofluoric acid (non-ionic) following the increase in conductivity due to the new formation of hydrofluosilicic acid (ionic) proportional to the quantity of dissolved silica. Assuming that for ashes the silica dissolution follows a diffusive phenomenon, a pozzolana index in agreement with mechanical behaviour is obtained.

However objections have been raised (98), namely that, beside silica, other ash components are soluble in hydrofluoric acid and that consequently the electrical conductivity cannot be put directly in correlation with the active silica content of ashes.

There is also uncertainty as regards the methods of determining pozzolana activity on the basis of the quantity of combinable lime. This lime can be added as it is or as clinker. Having carried out tests to determine the quantity of lime consumed by pyroclasts or by fly ashes after 16 hours' boiling of a gram of the compound, with a gram of lime and 200 cm<sup>3</sup> of water, they need to be completed by chemical analysis of the solid and by a balance between the lime in solution and that still in solid state (99).

To obtain the kinetics curve of the process of lime combining by vitreous or lithoid pyroclasts and properly pulverised zeolitic minerals, a constant quantity of the material must be kept shaken in contact with the same quantities of distilled water, without  $\text{CO}_2$ , having different initial quantities of calcium oxide (62). With rapid sampling, at determined intervals of time, of a certain quantity of clear liquor above the bottom deposit and the following determination of alkali and lime concentration, it is possible to determine the moment from which the contact solution becomes unsaturated. By subtracting from the total quantity of lime the amount still present in the solution which is no longer saturated, as well as that removed by the successive liquor sampling, the operator finds the quantity of stably combined lime, taking into account the influence of alkalies. This process ensures to obtain a certain differentiation in the behaviour of the above-mentioned components towards time.

A possible objection to this method is that for su-

sponds it requires delays and therefore considerably deviates from the actual water/cement ratio condition.

To evaluate the activity of pozzolanas, the ISO pozzolanicity test was used improperly. It was conceived to verify whether a cement can be considered pozzolanic without requiring the knowledge of the base portland cement.

The validity of the test for pozzolanic cements has been recently confirmed (101).

On the contrary the test is less suitable for characterizing the activity of pozzolanas (53) since it undergoes the influence of many factors depending on the working modes (101)(100), the clinker composition (102)(103)(104)(105) and the difficulty, typical of the systems made up of hydraulic binders, of attaining complete equilibrium conditions (99)(100). By trials, the pozzolanicity test allows the determination of the minimum quantity of pozzolana or fly ash necessary to prepare a really pozzolanic cement (53).

Some useful indications concerning activity of fly ash have been obtained by analyzing the concentration of a lime-saturated solution at room temperature and at higher temperature (82).

As regards evaluating pozzolanic activity on the basis of the nature of hydration products, it is impossible to differentiate those of clinker from those of pozzolanas since the latter are quite identical to the former, except for calcium hydroxide.

Mechanical strength tests are still today the indispensable complement to chemical and physical methods. Of course it is impossible to differentiate the clinker fraction from that of the pozzolana fraction in their contribution to mechanical strength. It is nevertheless possible to determine at ordinary temperature the mechanical strength of mortar specimens prepared with blended cements and to compare the resulting values with those obtainable in standardized conditions with mortar specimens prepared with the same neat cement or with the equivalent quantities of effectively inert material (106).

The most meaningful mechanical tests seem to be those carried out on mortar of normal consistency, prepared with active materials and lime, although the results are affected by the amount of inert fraction and porosity. From one country to another in fly ash investigation there is a certain variability in the test terms as well as in the percentage to add to the binder.

Accelerating the setting and hardening process by curing the specimens in an atmosphere with vapour saturated at 100°C or in an autoclave cannot be considered a practical approach (100). It is possible to extend the Chapelle test to cements, by testing a pozzolanic cement and by comparing the quantity of remaining lime with that due to hydration of the corresponding quantity of binder without additions (99).

To intensify this phenomenon a gram of pure lime can be added and the mixture shaken magnetically.

It was shown that at the end of the test the quantity of lime measured is under one gram, that is to say that the pozzolana combines with more lime than that released by the clinker. However the quantity of combined lime will not increase in proportion to the quantity of active additions.

By considering that the rate of lime combining (as well as the contribution of fly ash to the development of mechanical strengths) is sensitive to temperature changes and, even if slow at low temperature, it increases more quickly than Portland cement, the introduction of a determination of the lime combining

aptitude of the same type as that proposed for pyroclasts (107) is looked favourably (45). It advocates a comparison between the compressive strength of a mortar hardened at 18°C and at 50°C. The increase in strength recorded on the specimen hardened at ordinary temperature, can be practically attributed to the additions. With this test it is possible to obtain in seven days a useful indication of the contribution which a particular ash added to the cement can give to the development of mechanical strengths with long curing times (53).

To assess the quality of ash it was proposed to take into account tests on concrete, bearing in mind that for an equal level of replacement of cement by fly ash, the water/cement ratio decreases and the compressive strength increases in relation to the mortar (80)(108). As regards certain ash where the  $SO_3$  content is below 1% (36) a good correlation coefficient has been noted between the quantity of combined lime after three hours and the compressive strength. If the  $SO_3$  content increases up to 2-3% there is no longer any possible relationship.

Investigations have even been carried out on the correlation existing between Blaine specific surface, Chapelle test, percentage of the quantity of material sieved at  $40\mu$  and compressive strength. The best correlation would be that between the percentage of material sieved at  $40\mu$  and the compressive strength in the case of ash treated with 10% lime or blends of sand, ash and lime.

Finally it was proposed (109) to express the hydraulic value of an ash by a factor (K) so as to determine the quantity of ash necessary to replace a certain quantity of cement. This factor depends on the curing temperature, as well as on the fly ash/cement ratio and the water/cement ratios of concretes with or without ashes having the same strength.

#### 6. NEW MATERIALS FORMED FOLLOWING THE REACTION OF PYROCLASTS AND FLY ASH WITH LIME

In a lime-pozzolana mortar, the quantity of lime is generally in excess, so because of the presence of hydroxide, there is no possibility that hydrated gehlenite forms and there are formations of calcium silicate and hydrated tetracalcic aluminate (13). The gehlenite can form from products such as calcined kaolin, following the consumption of the whole quantity of added lime and therefore to the detriment of the lime produced by the decomposition of aluminate.

For sulphaaluminate to form there must be sulphates, obviously present in fly ashes. With excess lime (60) two phases will develop: hydrated calcium silicate and ettringite. The monosulphate will occur only after total consumption of calcium sulphate during the formation of ettringite. It will form to the detriment of the latter.

According to the similitude between hydration products of Portland, slag, pozzolanic and fly ash cements, binding properties are attributed to new formation compounds. However morphology, microstructure, stoichiometry, quantity etc. which contribute, each differently, to the formation of bonds also contribute at different levels to make up the mechanical strength and the chemical stability of the conglomerate.

With roentgenographic analysis on lime-pozzolana pastes from Auvergne (10) prepared with 10 to 34% of lime and 8% water, it is possible to define, among the various crystalline phases, only the  $4CaO \cdot Al_2O_3 \cdot 11H_2O$ , probably carbonated. This analysis takes care of the fineness, since the vitreous fraction more finely ground, tends to concentrate in the finest part. The

hydrated calcium silicate was detected by scanning electron microscope and by microprobe it was possible to determine that the  $\text{CaO}/\text{SiO}_2$  ratio was below 1. The quantity of combined lime and the compressive strength increased till a year.

Investigation of pozzolanic cement hydration by the observation of the main infrared spectral bands allowed the identification of the hydrated calcium silicate of a type similar to that formed by the hydration of alite and belite of ordinary Portland cement. Research on some Roman and Flagean pozzolanas, mixed with different quantities of lime, wetted with water, formed and cured with steam at  $50-90^\circ\text{C}$  (112) has revealed that the reaction is influenced by the temperature and by the pozzolana treatment, by the quantity of added lime and that the amorphous calcium silicate similar to that neoformed at ordinary temperature, represents the main reaction product (113).

It has also been observed (114) that beside the well-known combinations between lime and pozzolana, it is possible to obtain other reactions between pozzolana and  $\text{C}_3\text{A}$  or its hydration products through a mechanism governed by the presence of gypsum.

It was also noticed (53) that the fly ash-lime product tends towards a C-S-H (I) with a lower  $\text{CaO}/\text{SiO}_2$  ratio than the final Portland cement hydration product which is of the C-S-H (II) type. The quantity of C-S-H gel in a hydrated fly ash cement is higher than that occurring with Portland cement, which causes a fall in the permeability of the conglomerate. This phenomenon together with the decrease in calcium hydroxide concentration explains the better resistance to the chemical attack, especially of sulphates. The gelatinous C-S-H increases in proportion with the ash content, whilst the portlandite phase decreases.

The hydrated pastes of ash-based cements are better predisposed to carbonation than those of Portland cement (89)(115) when ashes exceed 30%.

The reactions between fly ash and calcium oxide have also been studied in hydrothermal conditions (116). Blends with fly ash/lime weight ratio = 3:1, treated at  $175^\circ\text{C}$  have revealed, after 2-4 hours heating, the presence of C-S-H (I), of 11 Å tobermorite and of a hydrogarnet whose composition is close to  $\text{ASH}_4$ . After four hours' processing, the C-S-H (I) develops into 11 Å tobermorite.

As the ash  $\text{SiO}_2$  content increases, there is also an increase in the quantity of new formed 11 Å tobermorite and a decrease in hydrogarnet, whilst  $\text{Fe}_2\text{O}_3$  and  $\text{Al}_2\text{O}_3$  would have a contrary effect.

The alkalis making up the vitreous phase up to a content of about 3% would promote the formation of tobermorite. Beyond this value it would decrease.

As regards the link between the nature of phases and mechanical strength, tests carried out on pastes containing 15-30% lime, 65-85% ash and 0-5% gypsum, autoclaved between 140 and  $185^\circ\text{C}$  have shown (118) that the highest compressive strength values around 300-400  $\text{kg}/\text{cm}^2$  can be reached with a very low hydrogarnet content (<5%) and a considerably high gelatinous hydrated calcium silicate content, with partial isomorphous replacement of  $\text{Si}^{+4}$  by  $\text{Al}^{+3}$ .

#### 7. IDENTIFICATION OF PYROCLASTS AND FLY ASH IN CEMENT

To combine with lime, an addition must meet certain specific conditions, for example it must be acid, that is contain a high percentage of silica and alumina; it must have a high percentage of vitreous fraction and a high specific surface. By treating it with hydrochloric acid at 1:50, it will be possible to set aside the basic fraction (cement) and in this way determine the percentage of addition and, if need be,

its specific surface (99).

The presence of a band which can be determined by X rays, included between 2.5 Å and 5 Å (16) with a maximum at 3.5 Å, will characterize the vitreous phase and after preliminary calibration of the apparatus, will give indications on quantities. The determination of feldspar and pyroxene phases leads to the definition of vitreous pyroclasts. The presence of zeolites disseminated in the matrix which can only be revealed by using X rays (7)(12) allows the pyroclasts of lithoid origin to be determined; traces of mullite lead to recognize the acid fly ashes (119).

If the insoluble fraction in the acid exceeds the normal quantity, the pyroclast can be differentiated from siliceous additions by infrared spectroscopy provided that the spectra of the materials used are known. In the case of vitreous pyroclasts quantitative analysis uses infrared spectroscopy at the  $697\text{ cm}^{-1}$  band or titration with an alcohol solution of salicylic acid (120).

The direct determination of the quantity of siliceous addition in the cement can also be carried out on the basis of the different solubility of the components (clinker and additions) in sulpho-salicylic acid. The method could also be used when each component is not available separately (121).

It was also proposed a analysis method by X ray diffraction (122) which is appropriate for rapid detection of phases characterizing fly ashes and other materials of industrial interest.

#### 8. PRESENT DAY INTEREST FOR ACTIVE ADDITIONS

Beside the positive specific effects which fly ash and pozzolana determine on binders, the interest concerning their use and consequently the promotion of scientific and technological research in this field is obvious when reference is made, for example, to the energy aspect of binder production (123)(124). Ten tonnes of addition represent a saving of a tonne of fuel (76). In Italy pozzolana cement production has brought about a saving of half a million tonnes of fuel.

Adding more than a million tonnes of fly ash to cement has enabled the French cement industry to save 120,000 tonnes of fuel per year (125).

About 15 million tonnes of pozzolanic cement were produced in Italy in 1977, that is to say approximately 40% of the total cement production, by using at least 5 million tonnes of pozzolana.

#### 9. EFFECTS OF VITREOUS PYROCLASTS AND FLY ASHES ON CEMENT

Pyroclasts added to cement in optimal quantity make pastes more workable (126), reducing the heat of hydration (127), thermal expansion, increasing water proofing, resistance to sulphate attack, and lowering expansion due to the alkali reaction with aggregates (128), so cutting production costs.

Another point of interest concerns the influence on the freezing-thawing behaviour, especially as regards lime, pozzolana and aggregate mixtures used in road construction (129).

Unfavourable effects will be found if materials with a mediocre hydraulic value are used or if the ratios between the mix components are not appropriately chosen.

Adding pyroclasts also produces cements with a good capacity for stopping chlorides - which are a danger to steel reinforcement - by a mechanism setting up the formation of hydrated calcium chloro-aluminate and, subordinately, chloride compounds of hydrated calcium silicates (130). Different reactions are ob-

tained in the case of materials of another origin containing active silica but incapable of producing hydrated calcium aluminates owing to the reaction with lime.

In the same way adding fly ashes to clinker lowers the amount of water demand (131) compared with that needed for concretes prepared with Portland cement; it also reduces heat evolved (132), shrinkage-expansion and improves resistance to corrosion (133)(134) either from aggressive of pure waters, and also the freezing-thawing behaviour (135). This latter advantage is however considerably diminished if there is a quantity of carbon residue (136). All fly ashes can also lower mortar expansion owing to the alkali-aggregate reaction (137).

Adding ash is yet again beneficial as regards the reduction in expansion of cements containing 7-10% MgO (138)(139)(140). Further more there is an increase in sulphate resistance (141), it rises in proportion to the C<sub>3</sub>A content of Portland cement, reaches its maximum with 50% ash and falls beyond this content. The positive influence of ash is due on one hand to the reactivity of lime and the formation of stable compounds, and on the other to the reduction in water content with identical consistency and to the resulting increase in compactness of the concrete.

The presence of ash also brings about an increase in the rate of hydration of calcium silicates, as compared with the case of Portland cement (142). It also makes the mix more sensitive to hardening with steam curing, therefore the curing of relative cements can occur at higher temperatures (89).

Steam curing also improves concrete surface hardness. However this hardness is compromised when the quantity of ash added to the cement reaches 40% (143).

Finally if ash is added to aluminous cement (144), by lowering the CaO content, it modifies the CaO/Al<sub>2</sub>O<sub>3</sub> ratios.

When ashes rich in lime are added to cement, they further lower the heat of hydration as regards the silico-aluminous ashes. This decrease varies with the quantity added (145). The corresponding binders have slightly longer setting times and a small drop in mechanical strength compared with cement.

#### 10. CONCLUSIONS

The general trend of research completed since the Moscow International Congress suggests the following statements:

1. It is time to draft an orderly terminology of the range of materials used in the industry for their aptitude of combining lime. Therefore it seems timely to restrict the term of pozzolanas to vitreous pyroclasts and that of tuff only to pyroclasts changed into lithoids by a zeolitization. For other materials with equally high characteristics of quality, such as properly called fly ashes, the most apt term must be reserved to express their origin, composition and microstructure. The term "artificial pozzolana" must therefore be dropped, since up to now it was used to identify very different materials, setting up unnecessary confusion which still continues today.
2. The prospects for using the vast range of materials adapted to the cement industry through their property of combining with lime seem very promising. Amongst these materials particular emphasis is placed on fly ashes and pozzolanas as cement addition, not only for aspects linked with the shortage of fuel and the possible use of by-products, but essentially for the very positive effects these materials produce in the respective

binders. This implies that research in this field should be particularly fostered.

3. Modern analytical methods for identifying materials reactive with lime can give useful indications for their differentiation in homogeneous groups and for assessing the combining kinetics and the quantity of combinable lime. These indications are however insufficient to foresee the mechanical behaviour with certainty.
4. The most appropriate way to determine the reactivity with lime of industrially interesting materials is still the test on mortar or concrete obviously limited by long delays in obtaining results. Moreover useful information can be deduced on the basis of compressive strength tests carried out on pastes prepared with hydrated lime.
5. The rapid and quantitative determination of pozzolanic activity therefore remains a complex and unsolved problem, requiring the preparation of a test exempt of any uncertainty.
6. The quantity of combinable lime in active materials is not generally correlatable with the values of mechanical strength (146), even if the factors which govern this process have been identified sufficiently.
7. There are valid bases for assuming the mechanisms of attacks by lime on vitreous or lithoid pyroclasts and on related materials, but the subject deserves research to develop further experimental tests, whilst neoformation products have already been identified to a satisfactory degree.
8. The probable activation of the materials used in the industry as additions sets up problems worthy of further research.

**H. UCHIKAWA**

**Onoda Cement Co, JAPAN**

## IV - 2/2

### 1. POZZOLANIC REACTIVITY

"Pozzolana" is defined as natural or artificial solids involving constituents which react with  $\text{Ca}^{2+}$  or  $\text{Ca}(\text{OH})_2$  and form new binding compounds under the presence of water.

"Constituents", we say, means minerals, crystals, noncrystalline materials, glasses and "artificial" means chemical or physical treatment for natural materials. Fly ash is one of pozzolanas in this meaning.

"Pozzolanic reactivity" is defined as index of reaction degree at ordinary temperature between pozzolanas and  $\text{Ca}^{2+}$  or  $\text{Ca}(\text{OH})_2$  with water or between pozzolanas, water and material which produces  $\text{Ca}(\text{OH})_2$  under the presence of water.

As the definition of "pozzolana" says, the mere physical absorption is excluded from pozzolanic reaction because this term means the formation of binding compounds by the reaction. In general, the chemical reaction has absorption process as one of reaction processes and after that process forms new compounds, but we interpretate here such a physical absorption process as so-called induction period and evaluate the degree of pozzolanic reaction of this period as zero.

In the definition of "pozzolanic reactivity", properties of reaction products or aggregate system which involves raw materials and reaction products are not mentioned. The reason is that the properties of paste which involves reaction products are substantially independent from pozzolanic reactivity. For example, strength, which is one of the representative properties of paste, is strongly influenced by the kinds, shapes, sizes and distribution of hydration products and pores, has not so good correlation with the degree of reaction.

The base of pozzolanic reactivity can be defined so that the difference of free energy between source system and products system or magnitude of activation energy from source system to products system, in the reaction system of pozzolanas,  $\text{Ca}^{2+}$  (or  $\text{Ca}(\text{OH})_2$ ) and water, or pozzolanas, water and materials which form  $\text{Ca}(\text{OH})_2$  under the presence of water. The nature of pozzolanic reactivity is determined by the character of pozzolanas, that is, the composition and structure of pozzolanas.

In the many papers, the term of "pozzolanic activity" or "pozzolanicity" other than reactivity has been used. Some of them (1), (2) used the pozzolanic activity for the test results of strength of pozzolanic cements. ISO (3) uses the "pozzolanicity" for the test results of  $\text{Ca}(\text{OH})_2$  concentration in the liquid of cement suspension. The concept of these terms is not always authorized or standardized and gives us unnecessary confusion. In this paper, the authors use only the term of "pozzolanic reactivity", as defined at the first.

### 2. THE CHARACTER OF SEVERAL JAPANESE POZZOLANAS

#### 2.1 Progress in Analytical Method

In general, since ceramics is the mixtures of fine particles composed of single crystal, polycrystal and amorphous phase, for the methods of characterization, it is necessary not only to know chemical and mineral composition of micro area, the micro texture and surface state but also to gather wide range information from micro to macro, besides understanding conventional average chemical and mineral composition of the object. The recent development of analysing method for that purpose is remarkable and it is indispensable to take in and apply those new analysing method to the study of cement for the advance of cement chemistry. The detailed explanation in this field was recently done by Uchikawa (4).

##### 2.1.1 The classification of analysing method

The analysing methods mainly used at present is classified roughly as compositional separation method and compositional analysis, identification method. Compositional separation method is further divided into two groups, that is, chemical separation method which dissolves or leaves desired composition in the sample by the difference of pH or the complex formation constant using aqueous solution such as acid, alkali and complex formation agents, or nonaqueous solution, and physical separation method which utilizes the difference of specific gravity, surface property, magnetic susceptibility and electrical property.

For the compositional analysis and identification of substance, method is divided into two main classes, for macro character and for micro character. Average chemical composition is one of the main factors of macro character. Though the methods change with the property and the shape of the sample, the kind and the quantity of coexisting component and required precision, main component is determined mainly with chemical analysis such as gravimetric and volumetric analysis, fluorescent X-ray and emission spectrochemical analysis, for the analysis of trace component atomic absorption and spectroscopic analysis are widely used. As for new analysing methods, inductively coupled plasma method, radio activation analysis, anodic elution voltammetry are going to be in practice. For the average structure analysis and state analysis, there is powder X-ray diffraction which is used for analysis of solid solution (peak shift), crystallinity (peak profile), low crystalline materials (radial distribution function method) and long-range order crystal (small angle scattering method). UPS (ultraviolet rays) and XPS (soft X-rays excitation) are used for the methods to examine atomic bond state from the position, the shape and the intensity of spectrum of X-ray, electron beam, ultraviolet and

infrared absorption.

As the methods for the determination of micro character, the apparatus which can determine the variance of composition of micro area without separation procedures of the sample are going to be widely used. Electron Probe Microanalysis (EPMA) is the apparatus that can analyse elements qualitatively or quantitatively and estimates the state of electron of atom by measuring characteristic X-rays generated with mutual interaction between accelerated electron beam and material. Analytical electron microscope (AEM) is very useful tool for the analysis of micro area as it has high resolving power especially for thin sample which has less matrix effect. Scanning electron microscope (SEM) is effective for observation of micro surface structure with back scattered electron and secondary electron generated from the sample. Elemental analysis can be also made with the image of Auger electron, and cathode luminescence (7) of wave length 4500-10000Å can make elemental analysis and clarify the state of atomic bond. Ion microprobe mass analyser, which makes mass analysis of secondary ions generated by ion bombardment instead of electron beam, is utilized for surface analysis.

#### 2.1.2 The progress in several characteristic methods

The extension of measurement to ultra soft X-rays area, which have large amounts of information owing to the improvement and the development of apparatus and soft ware, and the application to microquantitative analysis are considered to be one of the remarkable progresses in the field of fluorescent X-ray analysis. In recent years synchrotron orbital radiation (8) comes to be used for excitation of X-rays which has higher intensity than conventional source of X-ray, high degree of parallel, polarized ray. Quantitative analysis and state analysis of 6C, 8O, 9F (9) can also be made by the progress of analysing crystal such as TAP and RAP, and organometallic thin film analysing element such as LMD (Lead Myristate Dicanoate). Semiconductor X-ray detector that Li is doped into Si or Ge and has high sensitivity is developed and is used for trace analysis as energy dispersive spectrometer.

Inductively coupled plasma spectroscope (ICP) also comes to be used for trace analysis of cement and related samples. It measures the intensity of emission generated by the excitation of elements of atomized sample heated at 7000°K by plasma and has higher sensitivity compared with conventional atomic absorption analysis (5), (6). Burman, Ponter and Bostron (10) used ICP for the analysis of Si, Al, Ti, Ca, Mg, Na, Fe, Mn, Cr, Ba, Zn, Cu in quartzite and Scott and Kokot (11) applied ICP to quantitative analysis of Cu, Zn, Ni, Co, Pb, Mg, Fe, Al in soil and obtained good result.

In laser micro emission spectrochemical

analysis, laser light is gathered at the analysing point and generated emission is recorded. It has characteristics that the component of extremely microquantities can be analysed since temperature of generated plasma is above 10000°K, that the effects of the shape of sample the state of chemical bond and formation process of plasma are small because the vaporization of sample is very rapid that the quantity of sample is less than 1 µg and it needs little time for analysis. Bensted (12) investigated the structural inhomogeneities of clinker mineral particles, characterization of clinker minerals, the identification of calcium sulfate and the detection of carbonation of cement hydrates by Raman spectroscopy using laser.

EPMA is most widely used for micro area analysis with electron beam, but the space resolution of obtained information is not so high because incident beam diffuses into thick sample. To overcome this problem AEM was developed recently. AEM is designed to analyse excited X-rays generated with transmitted electron through thin sample before it diffuses, and has practically space resolution of 100Å. Since X-rays are generated from extremely micro area of very thin sample and very weak, energy dispersive spectrometer with semiconductor detector is used instead of analysing element for wave dispersion which is applied in EPMA. The trace analysis of fine crystal can be made with this method and is utilized for identification of Mg, Si, Fe and so on in calcium aluminate sulfate hydrates, sizes of which are about 100 x 500 µm, existing in hardened cement paste (13) and for compositional analysis of each phases in rock minerals.

Though the resolving power of Transmission Electron Microscope (TEM) is dependent on the wave length of electron beam and spherical aberration, in recent years TEM of which resolving power is about 1.4Å (100KV) can be designed with the progress of high power magnetic field object lens. Lattice image can be observed sufficiently with that resolving power and many kinds of lattice images are explained with diffraction theory and imaging theory. The observation of SiO<sub>4</sub> chain arrangement of calcium silicate hydrate (13) and the direct observation of the lattice image of cordierite (14) provide effective data for the studies of lattice defects, dislocation, crystal growth and so on.

As for NMR, conventional method which uses continuous high frequency magnetic field, is modified to pulse Fourier transformation NMR with the introduction of computer and the means of Fourier transformation. Since the amounts of information in definite time is increased highly with that method, the observation of the nuclides which have low natural existence rate or have low sensitivity such as <sup>13</sup>C, <sup>15</sup>N becomes easy. In the field of cement chemistry, adsorbed water was analysed quantitatively by pulsed proton NMR and the

## IV - 2/4

information about hydration and structure of cement was obtained (15).

The precision of X-ray diffraction recently rises and the delicate difference of radial distribution of glass phase comes to be able to be discussed by means of computer and measurement technique of high precision. Yasui, Hasegawa and Imaoka (16) analysed radial distribution of  $K_2O-SiO_2$  using  $MoK\alpha$  X-ray monochromatized by graphite monochromator and balanced filter and showed that experimental curve well coincided with calculated radial distribution considering various conditions. That method is desired to apply to structural study of glass phase in pozzolana.

New information and epoch-making progress on the studies of cement chemistry are very largely due to development and establishment of new analysing methods. The authors expect that a lot of outcomes of studies which are obtained using those new apparatuses and methods will be presented on Paris Congress.

### 2.2 Characterization of Japanese Pozzolanas

#### 2.2.1 The geological consideration and microscopic observation of natural pozzolanas

##### (a) Beppu white clay (V)

Beppu white clay is collected at the district of Beppu hot spring, Oita prefecture. The rock, which constitutes the neighborhood of mineral deposit of Beppu white clay, is made of hornblended andesite. Silicate minerals in hornblended andesite decomposed to silica gel by the action of hot spring and formed opal. That opal stayed original position and formed irregular massive fairly-soft ore deposit.

Observing by microscope, Beppu white clay is constituted mainly of amorphous silica, and small quantities of quartz, cristobalite and opaque minerals.

##### (b) Higashi-Matsuyama tuff (G)

Higashi-Matsuyama tuff yields in the neighborhood of "Yoshimi Hyakketsu", Saitama prefecture. The lithofacies of that acidic tuff has no bedding and is homogeneous. The surface of outcrop is like white powder, the inner is tinged with blue-gray.

Higashi-Matsuyama tuff is constituted mainly of glass phase and small quantities of quartz, plagioclase, clay minerals and very small quantities of zeolite. Main composition of volcanic glass is  $SiO_2$  and  $Al_2O_3$ .  $Fe_2O_3$  and K are also contained.

##### (c) Furue shirasu (F)

"Shirasu" was formed by a large quantity of eruptions which fell down after Pleistocene (the secondary glacial age) from two caldera

volcanos, Aira and Ata, south part of Kyūshū. That eruptions have several rock faces which are pumice fall, pumice flow and welded tuff, and shirasu was formed from pumice fall.

In general, shirasu is constituted of volcanic ash, volcanic sand and pumiceous lapilli. As the mineral composition, shirasu is made up with glass phase mainly and has small quantities of quartz, feldspar and hypersthene.

With optical microscope, almost particles are made with glass phase and quartz and plagioclase are slightly observed.

##### (d) Tominaga Masa-soil (M)

"Masa" is a term of geology or engineering work. Masa-soil exists abundantly in Aichi and Gifu prefecture and is the sand of weathered granite and contains feldspar, quartz, mica, kaolinite limonite and so on.

In the six kinds of rocks which constitute that district granodiorite is closely connected with masa-soil. Granodiorite is in general constituted of coarse-grained and relatively homogeneous. The color of granodiorite is dark-green or black and it contains amphibole and biotite. Granodiorite is decomposed easily by the weathering action and forms masa-soil.

##### (e) Kanto loam (Hachiōji loam) (R)

"Kanto loam" layer exists widely in the diluvial upland of Kanto plain. Kanto loam is considered to be formed with falling ash by volcanic activity of Diluvial age.

Several terraces are observed in Kanto loam layer, Tachikawa Terrace, Musashino Terrace, Simo-Sueyoshi Terrace and Tama Terrace and the collected loam is corresponded to upper Musashino loam layer.

Musashino loam layer contains pyroxene and olivine as colored minerals, and hypersthene and magnetite are also contained. As noncolored minerals, much quantities of feldspar, small quantities of quartz are contained. Allophane and less than 20% of hydrated halloysite exist as clay minerals. Under optical microscope, quartz, plagioclase hypersthene and weathered olivine are main minerals, the rest are fine opaque minerals.

#### 2.2.2 Characterization of natural and artificial pozzolana

Characterization was made for five kinds of Japanese natural pozzolanas and one kind of artificial pozzolana of fly ash which used in the present study.

As the item of characterization, the means, which investigate the composition and the structure of pozzolanas itself directly, are adopted. That is, the structure was observed with optical microscope, SEM and

Table I Chemical composition of pozzolanas

TEM, the composition was determined with chemical analysis and powder X-ray diffraction. In addition to those examination, the physical tests, which are thermal analysis, IR analysis and measurement of cation exchange capacity (CEC), were made. Results are shown in Table I, II and Fig. 1.

### 3. HYDRATION REACTION BETWEEN LIME, CEMENT COMPOUND, PORTLAND CEMENT AND POZZOLANA

#### 3.1 Hydration in the system pozzolana-Ca(OH)<sub>2</sub>

##### 3.1.1 The process of hydration

The crystalline hydrates formed in the reaction between lime and pozzolana in the presence of water were summarized by Massazza (17) as hexagonal calcium aluminate hydrate (C<sub>4</sub>AH<sub>5</sub>), calcium carboaluminate hydrate (C<sub>3</sub>A·CaCO<sub>3</sub>·H<sub>12</sub>), calcium aluminate monosulfate hydrate (C<sub>3</sub>A·CaSO<sub>4</sub>·H<sub>12</sub>), calcium silicoaluminate hydrate which were identified by means of DTA, powder X-ray diffraction and electron diffraction analysis.

The kinds and compositions of produced hydrates are generally related to the character, that is, chemical composition, crystal structure of constituents of pozzolana, and the conditions of hydration. However, there

Table II Characters of pozzolanas

Pozzolana	Shape		Specific surface area (BET) ( $\text{m}^2/\text{g}$ )	Density ( $\text{g}/\text{cm}^3$ )	Mineralogical composition (%) Glass Phase line (XRD, OM)	Chemical composition	Size of grain (%)	Thermal properties		IR	CEC

Fig. 1 - Scanning electronmicrograph of pozzolanas

are no remarkable difference between hydrates formed in paste and those of suspension hydration at later age.

Ludwig and Schwiete (18) studied the hydration in the system  $\text{Ca}(\text{OH})_2$  and two kinds of trasses containing 50-70% of glass phase, feldspar, quartz analcite etc. in suspension and paste. They confirmed the formation of  $\text{C}_4\text{AH}_{13}$  and  $\text{C}_3\text{S}_2$  hydrate in the case without gypsum, and ettringite and monosulfate hydrate with gypsum.

Amicarelli, Sersale and Sabatelli (19) studied the suspension hydration of argillified pyroclasts in lime saturated solution. They found  $\text{C}_2\text{ASH}_8$ ,  $\text{C}_4\text{AH}_{13}$  and tobermorite-like calcium silicate hydrate in clayish pozzolana containing large amount of halloysite,  $\text{C}_2\text{ASH}_8$  and tobermorite in zeolitic pozzolana containing chabazite and  $\text{C}_3\text{A} \cdot \text{CaCO}_3 \cdot \text{H}_{12}$  and tobermorite in tuff containing leucite and halloysite at the age of 20 days. The amount of combined lime was 17% by weight of added lime. Hydrogarnet, or  $\text{C}_2\text{ASH}_8$  and hydrogarnet, were formed at the later stage of 70-150 days, when the combined lime was from 46 to 60%.

In the five years old paste initially containing 40% of lime and 60% of calcined pozzolana, Sabatelli, Sersale and Amicarelli (20) observed two typical different cases

consisting of C-S-H (I) and  $\text{C}_2\text{ASH}_8$ , and C-S-H (I),  $\text{C}_2\text{ASH}_8$ ,  $\text{C}_4\text{AH}_{13}$  and  $\text{C}_3\text{A} \cdot \text{CaCO}_3 \cdot \text{H}_{12}$ .

In the authors' study, the hydrates produced in the paste hydration of pozzolana- $\text{Ca}(\text{OH})_2$  in W/S=0.56-0.46 at 20°, 40° and 60°C using five kinds of Japanese natural pozzolanas and one kind of fly ash were classified into three cases according to pozzolanas, that is, (1) C-S-H only, (2) C-S-H,  $(\text{C}_3\text{A} \cdot \text{CaCO}_3 \cdot \text{H}_{12} - \text{C}_4\text{AH}_{13})_{ss}$  and hydrogarnet in later age, (3)  $\text{C}_2\text{ASH}_8$ , hydrogarnet, and a little amount of C-S-H. The first case was Beppu white clay consisting of opal. The second case was tuff containing volcanic glass and shirasu containing volcanic glass and plagioclase. The third case was Kanto loam containing much allophane. The formation of hydrogarnet in allophane rich pozzolana was accelerated in the increased amount of  $\text{Ca}(\text{OH})_2$  and in the rise of temperature.

The hydrates formed in the paste hydration in the system pozzolana- $\text{Ca}(\text{OH})_2$  are shown in Table III.

Regourd, Hornain and Mortureux (21) recognized silicoaluminates of  $\text{C}_3\text{A} \cdot \text{CS} \cdot \text{H}_{12}$  and  $\text{C}_3\text{A} \cdot 3\text{CS} \cdot \text{H}_{31}$  near  $\text{C}_3\text{A}$  grains in the hydrated paste of  $\text{C}_3\text{S}-\text{C}_3\text{A}$  and  $\text{C}_3\text{S}-\text{C}_3\text{A}-\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$  at 28 days by SEM with energy dispersive X-ray analysis (EDX). These hydrates might be produced in the pozzolana system.

Table IV CaO/SiO<sub>2</sub> ratio of formed C-S-H in the system pozzolana-Ca(OH)<sub>2</sub> estimated by FESEM with EDX

Accelerating voltage ; 20kV

Pozzolana	CH/P ratio	Curing Temp. (°C)	Age (M.)	Ca/Si molar ratio
Beppu white clay(V)	25/75	20	3	0.87-0.77
		40		0.85-0.80
		60		0.81-0.75
Higashi-Matsuyama tuff(G)	25/75	20	3	1.49-1.35
		40		1.75-1.60

The concentration of Ca<sup>2+</sup> in the liquid of the system pozzolana-Ca(OH)<sub>2</sub> is kept between 2 m mole/l and 9 m mole/l (22). The former corresponds to the value equilibrating to C-S-H and the latter corresponds to the value in the liquid equilibrating to Ca(OH)<sub>2</sub> coexisting with alkalies. The molar CaO/SiO<sub>2</sub> ratio is closely related to the concentration of Ca<sup>2+</sup> in the liquid. Some of the authors' results are shown in Table IV. In the case of Beppu white clay the CaO/SiO<sub>2</sub> ratio was about 0.8, because the added lime was consumed before 3 months and in the case of tuff the ratio was 1.4-1.7, coexisting with remained lime.

### 3.1.2 Kinetics of hydration in the system pozzolana-Ca(OH)<sub>2</sub>

Drzaj, Hocevar, Slokan and Zajc (23) studied kinetics and mechanism of reaction in the system zeolitic tuff-CaO-H<sub>2</sub>O at 65°C using the 1:1 mixture of CaO and three kinds of tuffs and one kind of heulandite hydrated in W/S=50/6 at 65°C. They determined the relative decrease of the minerals in reactants and the relative increase of the amounts of CSH(I), tobermorite, tetracalcium aluminate hydrate, nekoite, osumilite in products by powder X-ray diffraction referring the SEM observation. They described that the initial

reaction was the diffusive dissolution of zeolite and  $\text{Ca(OH)}_2$  as it agreed with Fick's first law, and that the reaction was diffusion-controlled topochemical reaction limited by the diffusion of  $\text{Ca}^{2+}$  and  $\text{OH}^-$  through the membrane of CSH(I) gel, which formed on the surface of zeolite grain in the processes of  $\text{zeolite} + \text{Ca(OH)}_2 \rightarrow \text{CSH(I)} + \text{tobermorite}$ , and the interface layer between zeolite and CSH(I) gel membrane. They also pointed out that CSH(I) formed in the early stage of reaction and that tobermorite formed as final product through heterogeneous nucleation on the solid (CSH(I))-liquid (solution) interface.

Kondo, Lee and Daimon (24) studied the hydrothermal reaction at  $181^\circ\text{C}$  in the system  $\text{quartz-Ca(OH)}_2\text{-H}_2\text{O}$ . They classified the reaction by the  $N$  in the modified Jander equation:  $(1-\sqrt[3]{1-\alpha})^N = kt$ . They explained that  $N = 1$  meant the surface reaction on the grain boundary and rate determining step was the dissolution and precipitation, and that  $N = 2$  was the diffusion, of which rate determining step was diffusion of material through the reacted layers. Dividing these into two parts they considered that  $N < 2$  implied the reaction of which reacted layer became less dense with age and  $N > 2$  implied the reaction of which reacted layer became denser with age. They speculated by the calculation of  $N$  that dense hydrated layer with high  $\text{CaO/SiO}_2$  was kept in the presence of  $\text{Ca(OH)}_2$  solid and less dense hydrated layer with low  $\text{CaO/SiO}_2$  was formed when solid  $\text{Ca(OH)}_2$  was completely consumed.

In the authors' study, the amounts of reacted  $\text{Ca(OH)}_2$  per unit weight of pozzolana in each pastes prepared under the condition described in 3.1.1 with varying the mixed amounts of  $\text{Ca(OH)}_2$  are shown in Fig. 2.

Fig. 2-Reacted  $\text{Ca(OH)}_2$  in the system pozzolana- $\text{Ca(OH)}_2$  estimated by X-ray diffraction analysis varying the mixing ratio and curing temperature

In all pastes regardless of the kind of pozzolana and curing temperature, the more  $\text{Ca(OH)}_2$  was mixed, the more the amount of reacted  $\text{Ca(OH)}_2$  became. That is, the rate of pozzolanic reaction is accelerated by mixing more  $\text{Ca(OH)}_2$ . And it was decreased with age in logarithmic relation.

Judging from the  $N$  calculated from modified Jander equation, the reaction in early stage is considered to be controlled by the dissolution of atom or atomic groups from the surface of  $\text{Ca(OH)}_2$  grain and the precipitation of hydrates on the surface of pozzolana grain as a rate determining step ( $N < 1$ ) and after a week,  $N$  attains above 2, it is also considered to be governed by the diffusion of atoms and atomic groups through denser layer of hydrates formed between pozzolana and  $\text{Ca(OH)}_2$  grain as a rate determining step.

On the other hand the degree of reaction of pozzolana was the order of Kanto loam, Beppu white clay and Furue shirasu as shown in Fig. 3.

Fig. 3-Degree of reaction of pozzolana in the system pozzolana- $\text{Ca(OH)}_2$

These data coincide with the rate of reaction estimated from the amounts of reacted  $\text{Ca(OH)}_2$ .

Raask and Bhaskar (25) thought that the rate of the dissolution of silica fraction in pulverized fuel ash was governed by the diffusion of silica through insoluble layers on the surface of grain and that this process could be adopted by the equation of diffusion-controlled dissolution for uniform spherical particles.

$$W_r/W_0 = 1 - 6/\pi^2 \sum_{n=1}^{\infty} 1/n^2 \cdot \exp(-D\pi^2 n^2 t/a^2) \\ = 1 - 6/\pi^2 \cdot \exp(-D\pi^2 t/a^2) \quad (1)$$

where  $a$  is the radius of particles,  $D$  is the diffusion coefficient,  $n$  is an integer,  $t$  is time,  $W_r$  is the amount of silica reacted at time  $t$ .  $W_0$  is the total silica. When  $d$  represents the density of grain and  $S$  represents

specific surface area, the equation becomes

$$W_r = W_0(1 - \beta e^{-\alpha t}), \quad \alpha = D\pi^2/a^2 = \pi^2 D d^2 S^2/9$$

$$\beta = 6/\pi^2 \quad (2)$$

Considering  $\log(1 - W_r/W_0) = \log \beta - \alpha t$ , the relation shown in Fig. 4 are obtained by plotting  $\log(1 - W_r/W_0)$  against age from the author's data.

Fig. 4-Logarithmic plott of  $(1 - W_r/W_0)$  against age

The slope of the curve was the largest in the Kanto loam which has the largest specific surface area and that of Beppu white clay and Furue shirasu followed in this order, which indicate the good fit to the equation of diffusion controlled dissolution. The value of  $\alpha$ , the slope of the curve, decreased with age. This implies the decrease of specific surface area of pozzolana which has far great contribution to  $\alpha$ . After very fine particles are completely consumed, the rate of reaction is governed by the diffusion coefficient, which has close relation to the nature of amorphous film on the surface of pozzolana grain attributed to its structural factor and by the character of precipitated hydrates layer outside the film.

### 3.1.3 The mechanism of the hydration in the system pozzolana- $\text{Ca}(\text{OH})_2$

The mechanism of the hydration in the system pozzolana- $\text{Ca}(\text{OH})_2$  has been studied mainly on suspension hydration and few researches on paste hydration were published.

Drzaj, Hocever, Slokan and Zajc (23) studied the suspension hydration on the system zeolitic tuff and  $\text{Ca}(\text{OH})_2$  at  $65^\circ\text{C}$  and reported that the hydration proceeded by the diffusive dissolution of zeolite and  $\text{Ca}(\text{OH})_2$  and by topochemical reaction of the precipitation of hydrates on the surface of zeolite from the experimental fact that CSH(I) precipitated on the surface of zeolite grains.

Diamond and Kinter (26) found that the adsorbed amount of  $\text{Ca}(\text{OH})_2$  molecules on the surface of clay grains is at most 3% by weight of mixture while the consumption of  $\text{Ca}(\text{OH})_2$  proceeds over 3% with age. From these results they thought that  $\text{Ca}(\text{OH})_2$  molecules are adsorbed on the surface of clay grains at first, then adsorbed  $\text{Ca}(\text{OH})_2$  molecules and clay grains dissolve into water precipitating hydrates near the clay grains.

It is well known that the concentration of  $\text{Ca}(\text{OH})_2$  in the liquid is lowered towards zero when allophane is dispersed in the  $\text{Ca}(\text{OH})_2$  solution.

Berrell and Gradwell (27) considered that cations are adsorbed on the surface of allophane as the adsorption equilibria followed BET equation.

Wada and Ataka (28) considered that cations were adsorbed on the surface of allophane as salt from the fact that CEC was related to the concentration of exchanged salt and pH value of the solution. On the other hand, Jimura (29) described that cation adsorption of allophane was an ion exchange phenomenon based on the dissociation of weak acidic group of the grain surface.

Greenberg (30) studied the reaction between silica and calcium hydroxide solution and concluded that the reaction could be divided into six elementary processes, that is, the adsorption of  $\text{Ca}(\text{OH})_2$  to silanol group of silica surface, the dissolution of silica, the reaction of  $\text{H}_4\text{SiO}_4 + \text{Ca}(\text{OH})_2 \rightarrow \text{C-S-H}$ , the formation of nuclei, the growth of nuclei and the precipitation of crystal. They also emphasized that the dissolution of silica was the rate determining step of overall reaction. And the rate of reaction was influenced by the surface area of silica and its free energy state but it was not influenced by the concentration of  $\text{Ca}(\text{OH})_2$  above 3.6 m mol/l.

Van Aardt and Visser (31) studied the reaction between feldspar and  $\text{Ca}(\text{OH})_2$  relating to the alkali-aggregate reaction of cement and described as follows:  $\text{Ca}(\text{OH})_2$  liberated by the hydration of cement precipitates on the surface of feldspar grains and dissolves alkalis in feldspar. The alkalis exist in the liquid phase as KOH and NaOH or from alkali silicates to precipitate on the surface of feldspar grains as gel. Alkali silicate film is destroyed by the repetition of expansion and shrinkage caused by the adsorption and the adsorption of water. The fragments of destroyed film of alkali silicates are flown into opening and crack of aggregate as viscous fluid and repeat the expansion and shrinkage.

Many pozzolanas contain fairly large amount of glass phase and a little amount of alkalis. It is easy to imagine that glass phase plays an important role and alkalis are related strongly to the reaction between pozzolana and  $\text{Ca}(\text{OH})_2$ .

Sanders and Hench (32) showed that, on contact with water, alkalis in the glass dissolved preferentially into water leaving the thin layer of silica gel. They also said that dissolution proceeded more actively in soda glass than in soda-lime glass, and that the inhibition of dissolution in soda-lime glass, was due to the formation of Ca and Si rich layer where  $\text{Na}^+$  was leached off.

El-Shamy (33) studied the reaction between potassium glass and water. He showed that the surface of glass was protonically attacked remarkably in the high alkaline solution of  $\text{pH} > 9$  and  $\text{SiOH}$  group dissociated to  $\text{SiO}^-$  and  $\text{H}^+$  making electric double layers between the surface of glass and the solution, and that the resulting negatively charged glass attracted alkali ions in the solution. He described that the diffusion of ions through the reacted surface layer was the rate determining step of the erosion reaction of glass by alkalis.

These previous researches are very suggestive in considering the mechanism of hydration in the system pozzolana- $\text{Ca}(\text{OH})_2$ .

In the hydration in the system pozzolana- $\text{Ca}(\text{OH})_2$ , C-S-H precipitated near the pozzolana grains and Ca-Al hydrate Ca-Al-Si hydrate etc. precipitated apart from pozzolana grains as shown in Fig. 5.

A. C-S-H B. Ca-Al hydrate

Fig. 5-Transmission electronmicrograph of the hydrates formed in the system pozzolana- $\text{Ca}(\text{OH})_2$

Ultra fine particles of  $\text{\AA}$ -order suggesting the dissociation of  $\text{SiO}_4$  from the pozzolana grains were recognized in high resolution transmission electron microscopic observation as shown in Fig. 6.

As shown in Fig. 2, regardless of the kind of pozzolana, the amount of hydrates formed by the reaction between pozzolana and  $\text{Ca}(\text{OH})_2$  was proportional to the added amount of  $\text{Ca}(\text{OH})_2$  even in the age when solid  $\text{Ca}(\text{OH})_2$  coexisted.

Clifton, Brown and Fronsdorff (34) reviewed the works for the reaction of fly ash with

A.  $\text{SiO}_4$  group product  
B. precipitated type I C-S-H  
C. pozzolana grain

Fig. 6- $\text{SiO}_4$  group released from pozzolana grain observed in high resolution transmission electronmicrograph

cement, as follows : the adsorption of calcium hydroxide on the surface of fly ash particles occurs initially, and forms a membrane over fly ash particle. Water gap exists between the membrane and fly ash particle. The pozzolanic reaction products are precipitated in the water gap and cover the fly ash particle to form a reaction rim.

Summarizing these experimental results and the previous works, the mechanism of the paste hydration in the system pozzolana- $\text{Ca}(\text{OH})_2$  is considered as follows :

After mixing with water the liquid is saturated with  $\text{Ca}(\text{OH})_2$  in the short time and pH of the liquid is kept above 12.7. Pozzolana grains are protonically attacked by water in high caustic solution dissociating the  $\text{SiOH}$  group on the surface of the grains to  $\text{SiO}_4^{4-}$  and  $\text{H}^+$  leaving negatively charged grains.  $\text{Ca}^{2+}$  is adsorbed on the surface of pozzolana grains by electrostatic force and alkalis in pozzolana dissolve into the liquid phase. The dissolving-out of alkalis and so on remains a thin amorphous Si, Al-rich layer on the surface of pozzolana grain.  $\text{SiO}_4^{4-}$  and  $\text{AlO}_2^-$  in the layer gradually begin to dissolve and combine with  $\text{Ca}^{2+}$  to increase the thickness of the layer. The expansion and destruction of the layer due to the osmotic pressure caused by the difference of concentration between outside and inside of the thin layer proceed following the mechanism

mentioned-later (31).

$\text{SiO}_4^{4-}$  is considered to diffuse more slowly than  $\text{AlO}_2^-$ , as the former has larger electric charge and has more oxygen atoms than latter. The concentration of  $\text{Ca}^{2+}$  enables Ca-Al hydrate to precipitate is generally higher than that of C-S-H. For these reason, Ca-Al hydrate precipitates at the place apart from pozzolana grains.

Pozzolana having large dissolving surface area, wide precipitating site of hydrates and high free energy state gives high rate of pozzolanic reaction.

### 3.2 Hydration in the System Pozzolana-Cement Compound

#### 3.2.1 Hydration in the system pozzolana- $\text{C}_3\text{S}$

Few papers are published on the hydration of the pozzolana cement compound.

Stein and Stevels (35) investigated the influence of amorphous silica on hydration of  $\text{C}_3\text{S}$  using  $\text{C}_3\text{S}$ , amorphous silica, quartz and portland cement. The conduction calorimetry on the hydration of  $\text{C}_3\text{S}$  and cement paste, TEM observation of pastes and suspension and the measurements of calcium and silicate ion concentration, electrical conductivity and pH in  $\text{C}_3\text{S}$  suspension brought them to the following conclusion. Amorphous silica accelerates the rate of hydration of alite in cement pastes and that of  $\text{C}_3\text{S}$ . By lowering calcium and hydroxyl ion concentration in the liquid phase for a few minutes after mixing with water silica converts the C-S-H film on the surface of  $\text{C}_3\text{S}$  or alite into less protective film composed of low Ca/Si ratio which accelerates the hydration of  $\text{C}_3\text{S}$  and cement paste. In portland cement pastes not only the hydration of alite but also the consumption of sulfate by the formation of ettringite are accelerated by the addition of amorphous silica. As calcium ion concentration is low, ettringite crystallizes generally apart from  $\text{C}_3\text{A}$  particles.

Lukas (36) investigated the rate of hydration of each clinker compound by X-ray diffraction and quantitative analysis of  $\text{Ca}(\text{OH})_2$  by DTA using the specimens prepared from 30% of fly ash and 70% of cement with W/S ratio of 0.4 from two kinds of cements and one kind of fly ash. Fly ash accelerates the early hydration of  $\text{C}_3\text{S}$  phase. But after three days it inhibits the hydration of  $\text{C}_3\text{S}$ . Though the rate of hydration of  $\text{C}_3\text{A}$  in cement is not so fast as that of pure  $\text{C}_3\text{A}$ , fly ash accelerates its hydration. Ettringite was not found by X-ray diffraction in early stage owing to its low content. But it increased from the first day to 14 days and then decreased. At the age of 14 days monosulfate hydrate was detected. The amount of  $\text{Ca}(\text{OH})_2$  is lower than that calculated from the stoichiometrical equation, so C-S-H has higher Ca/Si ratio than 1.5 shown in the stoichiometry. The decrease of  $\text{Ca}(\text{OH})_2$  in paste at the later age is attributed to the absorp-

tion by fly ash over than the amount of  $\text{Ca}(\text{OH})_2$  released by hydration.

Nelson and Young (37) investigated the additions of colloidal silicas and silicates on the hydrations of the Type I cement and  $\text{C}_3\text{S}$  pastes. The amount of added four kinds of colloidal silicas and silicates were based on percentage of the theoretical amount required to convert all the  $\text{Ca}(\text{OH})_2$  to C-S-H gel. Water was added to achieve given workability and water reducing agent was used when necessary.  $\text{C}_3\text{S}$  with colloidal silicas needed a higher W/S ratio than that without colloidal silicas to achieve given workability and its strength decreased with increase in W/S ratio. The decrease in  $\text{Ca}(\text{OH})_2$  content occurs in all cases especially in quite early age such as within one day. Amount of silica added to portland cement were 6.6% of cement by weight, which is 25% of theoretical amount required to complete the pozzolanic reaction with  $\text{Ca}(\text{OH})_2$  produced. The W/S ratio was adjusted 0.45 adding much water reducing agent. While one day strengths were improved by addition of colloidal silicas and silicates, later strengths were not affected by them. The reduction of  $\text{Ca}(\text{OH})_2$  in portland cement pastes by given amount of colloidal silicas and silicates is greater than in  $\text{C}_3\text{S}$  pastes which indicate the occurrence of other reaction than C-S-H formation.

Takemoto, Uchikawa, Ogawa and Yasui (38) studied the hydration of the 6:4 mixture of  $\text{C}_3\text{S}$  and pozzolana with 0.4 of water solid ratio. Five kinds of Japanese pozzolanas and one kind of Japanese fly ash were used in this experiment. From the conduction calorimetry at initial and early stage of hydration, estimation of the rate of hydration of clinker compound by X-ray diffraction, quantitative analysis of unreacted pozzolanas by salicylic acid-methanol extraction method and observations of broken surface of hardened paste by SEM, they concluded that the addition of pozzolana and fly ash to  $\text{C}_3\text{S}$  accelerated the initial hydration within an hour. This tendency is remarkable in Beppu white clay and Kanto loam which are mainly consisted of opal and allophane, respectively. Degree of hydration of  $\text{C}_3\text{S}$  after the induction period was increased by the addition of pozzolana. Pozzolanas consisting mainly of opal and allophane were more reactive with  $\text{C}_3\text{S}$  than that consisting mainly of volcanic glass and fly ash.  $\text{C}_3\text{AH}_6$  and  $\text{C}_4\text{AH}_{13}$  are found by DTA at the age of 28 days in case of the pozzolanas rich in allophane and aluminum-rich fly ash, respectively. But in the other pozzolanas no Ca-Al hydrate was found at 91 days. They also showed that there exists the void between the surface of pozzolana or fly ash and the layer of hydration products so that the hydrates tend to be stripped easily in the form of shell as shown in Fig. 7.

Summarizing above-mentioned previous works: Additions of pozzolanas accelerate the hydration of  $\text{C}_3\text{S}$ . Acceleration of hydration

T - C<sub>3</sub>S

after induction period by pozzolana is due to the stimulation of C<sub>3</sub>S dissolution by the adsorption of Ca<sup>2+</sup> in the liquid with pozzolana and due to the increase of surface by the addition of pozzolana which is preferable to the precipitation of C-S-H. C-S-H precipitated after induction period has higher Ca/Si ratio than 1.5, when sufficient amount of Ca(OH)<sub>2</sub> exists. C-S-H and Ca-Al hydrate etc. are generally formed by the pozzolan reaction between Ca(OH)<sub>2</sub> and pozzolana after one day and the physical properties, for example strength of paste, develops in later age. Aluminate hydrates are formed later and their period of formation depends on the characters of pozzolanas, that is, aluminum content and their solubility. Addition of pozzolanas also accelerates hydration of alite and C<sub>3</sub>A phase in cement.

### 3.2.2 Mechanism of the hydration in the system pozzolana-C<sub>3</sub>S

Studies on the mechanism of the hydration of C<sub>3</sub>S are actively performed recently.

Dent Glasser, Lachowski, Mohan and Taylor (39) reported informative work, and recent works on this field were reviewed by Skalny, Jawed and Taylor (40). They suggested that the reaction of hydration proceeded in the following cycle, that is release of calcium ion from the surfaces of C<sub>3</sub>S particles and formation of amorphous silica rich layer by protonic attack of water, swelling and opening of surface film by osmotic pressure, formation of inner hydrates by movement of calcium ions from outside to the inside of the film by passing through the opening, precipitation of Ca(OH)<sub>2</sub> on outside of the film. This view is accepted as a whole to be right.

Takemoto, Uchikawa, Ogawa and Yasui (38)

carried out the observation of the polished surface of hardened paste in the system pozzolana-C<sub>3</sub>S and the analysis of hydrates between C<sub>3</sub>S-C<sub>3</sub>S grains, C<sub>3</sub>S-pozzolana grain and pozzolana-pozzolana grains by FESEM with EDX. Considering the data obtained by FESEM with EDX and the results of analysis of liquid phases at initial and early stages and SEM observation of C-S-H precipitation on the surface of quartz grain in C<sub>3</sub>S-quartz and that in C<sub>3</sub>S-alkali treated quartz systems, they obtained the following results. C-S-H formed between C<sub>3</sub>S and pozzolana grain precipitated in spherical structure wrapping C<sub>3</sub>S grain which extended from C<sub>3</sub>S grain to pozzolana grain and showed zonal structure. Each zone had its own chemical composition. Stepwise decrease in Ca/Si ratio from C<sub>3</sub>S grain towards pozzolana grain was clearly observed.

Ca(OH)<sub>2</sub> crystals could be observed where Ca/Si ratio was abnormally high. The dissolution of alkali from pozzolana was higher in the system C<sub>3</sub>S-pozzolana than in the case of pozzolana alone. C-S-H precipitated on the surfaces of all C<sub>3</sub>S and quartz grains in the system C<sub>3</sub>S-quartz, while C-S-H did not seen occasionally on the surface of alkali treated quartz grain though it was observed on the surface of C<sub>3</sub>S without exception in the system C<sub>3</sub>S-alkali treated quartz.

Considering above mentioned results they proposed the following mechanism of the hydration in the system pozzolana-C<sub>3</sub>S.

As shown in Fig. 9, calcium ions dissolved from C<sub>3</sub>S run about freely in liquid are captured by collision to the negatively charged pozzolana grains and are adsorbed on the surfaces. C-S-H formed by hydration of C<sub>3</sub>S precipitates as the hydrates of high Ca/Si ratio on the surface of C<sub>3</sub>S grains and

Fig. 9 - Schematic explanation of the mechanism of hydration in the system pozzolana-C<sub>3</sub>S (38)

as the porous hydrates of low Ca/Si ratio on the surfaces of pozzolana grains. On contacting with water, surfaces of pozzolana grains are protonically attacked by  $H_3O^+$  formed by the dissociation of water. It brings gradual dissolution of  $Na^+$  and  $K^+$  etc., resulting in Si and Al rich amorphous layer on the surfaces. Dissolved  $Na^+$  and  $K^+$  accelerate the dissociation of water, intensify the protonic attack of water and accelerate the dissolution of  $SiO_4^{4-}$  and  $AlO_2^-$  which combine with  $Ca^{2+}$  and increase the thickness of layer. Due to the osmotic pressure generated by the difference of concentration of ions, such as alkalis,  $SiO_4^{4-}$ ,  $AlO_2^-$ , between inside and outside of layers, the layer swells gradually and the void between layer and pozzolana grain is formed. The void is filled with Si, Al,  $Na^+$  and  $K^+$  rich liquid. When osmotic pressure attains certain pressure, the film is broken and  $SiO_4^{4-}$  and  $AlO_2^-$  diffuse outside through the openings to meet  $Ca^{2+}$ . The condition of precipitation being satisfied, C-S-H and Ca-Al hydrate precipitate on the surface of outer hydrates of C<sub>3</sub>S. Solution near the outer surfaces of destroyed film becomes poorer in  $Na^+$  and  $K^+$  than inside and  $Ca^{2+}$  is apt to be adsorbed on the film resulting in the precipitation of C-S-H and Ca-Al hydrate. Considering the thickness of film and the distribution of Ca ion concentration, the amount of the precipitated C-S-H and Ca-Al hydrate is, however, very small compared with the amount of outer hydrates of C<sub>3</sub>S. Vacant space remains inside the film as the hydrate do not precipitate there because of high concentration of alkalis. The

hydration proceeds according to the repetition of above mentioned cycle. Accordingly vacant space always exists between the film and pozzolana grain.

When alkalis do not exist, destruction of amorphous Si, Al rich film enables  $Ca^{2+}$  to move into the inside of the film from the openings and to precipitate C-S-H and Ca-Al hydrate on the surface of pozzolana grain and filled the clearance. Therefore no clearance is observed between pozzolana grains and hydrates.

Pozzolana is a mixture composed of alkali containing minerals and glasses and those without alkali. In paste hydration, some places become rich in alkali and others are poor. Therefore, the hydrates produced in alkali rich region tend to be stripped off from pozzolana surface and the hydrates produced in alkali poor region attached closely to pozzolana grain. The glass such as in fly ash contains homogeneously much alkali, so the typical stripping off of the hydrates from pozzolana grain is often clearly observed.

### 3.2.3 Hydration in the system pozzolana-C<sub>3</sub>A

Few investigations have been made on hydration reaction in the system pozzolana-C<sub>3</sub>A.

Holten and Stein (41) examined the influence of quartz surface upon hydration in the system of  $C_3A-CaSO_4 \cdot 2H_2O-H_2O$  by measuring the heat of hydration by conduction calorimetry, the identification of formed phases by X-ray diffraction and the observation of hydrated specimen by SEM. They found that heat evolution peaks are divided into four stages. The first peak corresponds to the formation of ettringite, the second one to perfect consumption of  $CaSO_4 \cdot 2H_2O$ , the third to a part of formation of AFm and the fourth to the formation of monosulfate hydrate and 8.2Å carboaluminate coexisting with ettringite. Quartz prevents ettringite from precipitating on C<sub>3</sub>A surface by presenting the site of its precipitation and lowers the retardation by  $SO_4^{2-}$ . Surface of C<sub>3</sub>A particles is covered with layer having similar composition to  $Al(OH)_3$ , because  $Ca^{2+}$  on C<sub>3</sub>A surface is preferentially extracted by dissociated hydronium ion. The hydration in NaOH solution, disturbed surface layer having similar composition to that of  $Ca(OH)_2$  is formed on surface of C<sub>3</sub>A particles by the preferential extraction of aluminate ion by  $OH^-$ .

Collepari, Baldini, Paure and Corradi (42) examined the hydration in the system C<sub>3</sub>A,  $CaSO_4 \cdot 2H_2O$ ,  $Ca(OH)_2$  and volcanic and diatomaceous silica rich pozzolana at  $20 \pm 0.5^\circ C$  and W/S = 0.8 by carrying out the measurement of the heat evolution, DTA and SEM observation. They found that the heat evolution in the system of C<sub>3</sub>A hydration decreases with addition of pozzolana, especially in diatomaceous silica rich pozzolana. This effect is rather small when the rate of hydration of C<sub>3</sub>A is retarded by  $CaSO_4 \cdot 2H_2O$  and/or  $Ca(OH)_2$ .

They concluded that retardation of hydration of  $C_3A$  by pozzolana was caused by the absorption of pozzolana to surface of  $C_3A$  particles.  $Ca(OH)_2$  in  $C_3A$  paste decreases rapidly when pozzolana exists. This decrease can not be related to the lime-pozzolana reaction, which is much slower. They described that ettringite, lime and  $C_3A$  reacted to form hexagonal solid solution when gypsum existed and that hexagonal hydrates were easy to convert to  $C_3AH_6$  in the  $C_3A$  sample containing  $Ca(OH)_2$  and volcanic pozzolana. These facts show that reactions between pozzolana and  $C_3A$  or pozzolana and hydrates from  $C_3A$  proceed besides well known reaction between lime and pozzolana.

Uchikawa and Uchida (43) studied the hydration in the system  $C_3A-CaSO_4 \cdot 2H_2O-Ca(OH)_2$  containing 40% by weight of five kinds of Japanese pozzolanas or one kind of Japanese fly ash at  $20 \pm 1^\circ C$  and  $W/S=0.60$ . The identification and quantitative analysis of formed hydrates by DSC-TG under Ar atmosphere, conduction calorimetry in hydration, quantitative analysis of  $C_3A$  by X-ray diffraction, SEM observation and the measurement of cation exchange capacity of pozzolana brought them following results. In the absence of  $Ca(OH)_2$ , hydration of  $C_3A$ , formation of ettringite and conversion of ettringite to monosulfate hydrate were accelerated by the addition of pozzolana especially pozzolanas mainly composed of allophane, volcanic glass and opal. The acceleration was roughly proportional to the added amount of pozzolanas. The formation of ettringite and conversion of ettringite to monosulfate hydrate were retarded by the addition of  $Ca(OH)_2$ . Pozzolana containing much alkalis (Na, K) accelerated the formation of  $C_3AH_6$ . They deduced that the reaction of acceleration of hydration of  $C_3A$  by addition of pozzolana was adsorption of  $Ca^{2+}$  to the surface of pozzolana and that the acceleration of the dissolution of  $C_3A$  particles was due to less formation of ettringite film on  $C_3A$  grains caused by the precipitation of ettringite on the surface of pozzolana grains. As the hydration of  $C_3A$  is accelerated by the addition of pozzolana, so that the complete consumption of solid calcium sulfate is also accelerated, which make the ettringite convert to monosulfate hydrate. The reason why conversion to  $C_3AH_6$  was accelerated in pozzolana containing much alkalis is probably the decrease of the stability of hexagonal hydrate with increasing alkalis concentration as reported by Spierings and Stein (44).

Summing up above mentioned previous works, hydration of  $C_3A$  is accelerated by addition of pozzolana. The degree of acceleration is larger in pozzolana with larger specific surface area and higher CEC value. The reason for acceleration of the hydration of  $C_3A$  by pozzolana is adsorption of  $Ca^{2+}$  in liquid phase to the surface of pozzolana and acceleration of  $C_3A$  dissolution due to the precipitation of ettringite on the surface of pozzolana. Accelerated conversion to  $C_3AH_6$  under coexistence of pozzolana containing

much alkali is responsible for decreased stability of hexagonal hydrates under high alkali concentration. Decrease of  $Ca(OH)_2$  in initial and early stages of hydration may not be due to pozzolana reaction but another elementary process of reaction such as adsorption.

### 3.2.4 Mechanism of the hydration in the system pozzolana- $C_3A$

There are many studies on the hydration of  $C_3A$  and on the effect of  $Na_2O$  (44) (45) and  $SO_4^{2-}$  (46) (47). Summing up these reports, Skalny, Jawed and Taylor (40) presented the mechanism of the hydration of  $C_3A$  as follows:

On contact with water,  $C_3A$  dissolves incongruently leaving Al rich surface. Ca ions chemisorb on this surface producing positively charged particles. The formation of such a structure decreases the number of active dissolution sites and thus, the rate of  $C_3A$  dissolution decreases. Sulfate ion is adsorbed on the positively charged  $C_3A$  particles resulting in further reduction of dissolution sites. This blocking effect retards rate of hydration further more.

There are few reports, however, on the mechanism of hydration on the system containing pozzolana- $C_3A$ .

Uchikawa and Uchida (43) presented the following mechanism of the hydration on the system  $C_3A-CaSO_4 \cdot 2H_2O-Ca(OH)_2$ -pozzolana combining the idea of Skalny et al (40) on  $C_3A$  and the mechanism of the hydration of pozzolana as shown in Fig. 10.

On contact with water,  $C_3A$  is protonically attacked by  $H_3O^+$  formed by the dissociation of water releasing  $Ca^{2+}$  and leaving amorphous Al rich layer on  $C_3A$  grain surface. Amorphous layer is expanded by osmotic pressure and forms slight clearance between hydrated  $C_3A$  particle and itself. This clearance is filled with  $AlO_2^-$  rich solution. There exists  $Ca^{2+}$ ,  $SO_4^{2-}$  rich solution at the near outside of the layer brought by the coproceeding dissolution of calcium sulfate and calcium hydroxide.  $Ca^{2+}$  is adsorbed on the amorphous Al rich layer on the surface of  $C_3A$ . The grain charges positively and the active sites on the surface of  $C_3A$  decreases. Therefore, hydration of  $C_3A$  is stopped temporarily.  $SO_4^{2-}$  is adsorbed on the surface of positively charged grain and play a part of blocking against protonic attack of hydronium ion. Amorphous Al rich film is broken at the weakest point by osmotic pressure. From the openings  $Ca^{2+}$  and  $SO_4^{2-}$  introduced into inner side of film.  $AlO_2^-$  moves towards outer side of film and ettringite precipitates on both sides of film. On inner side of film, monosulfate hydrate often precipitates as  $SO_4^{2-}$  is apt to be in shortage. Monosulfate hydrate on the inner side is generally small in size because of the narrow precipitation space. Precipitated hydrates have high crystallinity, so it is easy for  $Ca^{2+}$ ,  $AlO_2^-$ ,  $SO_4^{2-}$  etc. to diffuse through the hydrate

Fig. 10 - Schematic explanation of the mechanism of hydration in the system pozzolana-C<sub>3</sub>A under the existence of Ca(OH)<sub>2</sub> and CaSO<sub>4</sub>·2H<sub>2</sub>O (43)

layer covering the C<sub>3</sub>A grain. The porous ettringite layer is broken by the expansion of itself to make the contact of water to C<sub>3</sub>A easy.

Hydration of C<sub>3</sub>A proceeds repeating above mentioned process as one cycle. When solid CaSO<sub>4</sub>·2H<sub>2</sub>O is consumed completely and concentration of SO<sub>4</sub><sup>2-</sup> lowers, monosulfate hydrate or solid solution of monosulfate hydrate and C<sub>4</sub>AH<sub>19</sub> precipitates on the outside of film. Void in the paste outside the grain is usually large, so hexagonal monosulfate hydrate or its solid solution precipitate as large crystal towards large void to build the well known card house structure.

Ettringite once formed converts to hexagonal hydrate, monosulfate hydrate or its solid solution. The time of conversion of hexagonal Ca-Al hydrate to cubic C<sub>3</sub>AH<sub>6</sub> depends upon the concentration of alkali ion. Negatively charged grains of pozzolana, on the other hand, adsorb Ca<sup>2+</sup> formed by the hydration of C<sub>3</sub>A, CaSO<sub>4</sub>·2H<sub>2</sub>O and Ca(OH)<sub>2</sub> on their surface. By the adsorption of Ca<sup>2+</sup> in liquid phase and by presenting the site of precipitation of ettringite, pozzolana accelerates the hydration of C<sub>3</sub>A.

General features of hydration of pozzolana are about the same as those of pozzolana-C<sub>3</sub>S system.

SiO<sub>4</sub><sup>2-</sup> and AlO<sub>2</sub><sup>-</sup> near at the outside of film

precipitate as ettringite, monosulfate hydrate, Ca-Al hydrate and C-S-H on the surface film of the outside of pozzolana grain or on the surface hydrate layer of C<sub>3</sub>A grain according to the concentration of Ca<sup>2+</sup> and SO<sub>4</sub><sup>2-</sup> in the liquid. As the rate of diffusion of SiO<sub>4</sub><sup>4-</sup> is slow and the concentration of Ca<sup>2+</sup> is rather high even at the neighbour of pozzolana grain. C-S-H is observed in the paste containing negatively charged acidic pozzolana with low alkali and high SiO<sub>2</sub>.

Concentration of SO<sub>4</sub><sup>2-</sup> in the liquid near the pozzolana grain is low, so the nearest hydrate to the pozzolana grain consists mainly of Ca-Al hydrate and towards outside, the solid solution of Ca-Al hydrate and monosulfate hydrate and monosulfate hydrate precipitate in this order. Ettringite, precipitated in the early stage of hydration, is not observed in the later stage.

### 3.3 Hydration in the System Pozzolana-Cement

There is no essential difference between the hydration in the system pozzolana-cement and that in the system pozzolana-Ca(OH)<sub>2</sub> and pozzolana-cement compounds. Here the authors' results are shown.

Pózzolanic cement, 4:6 mixture of five kinds of Japanese natural pozzolanas, one kind of fly ash and ordinary portland cement, was hydrated at 20°C with W/S=0.3.

Heat evolution curve by conduction calorimetry, degree of hydration of alite in the pozzolanic cement paste estimated by X-ray diffraction analysis and the degree of pozzolanic reaction with curing time are shown in Fig. 11, Fig. 12 and Fig. 13.

The degree of pozzolanic reaction was expressed in term of the difference between the amount of estimated Ca(OH)<sub>2</sub> which might be formed in the case when no pozzolanic reaction occurs and that formed actually in pozzolanic cement paste. The amount of former was determined by measuring the degree of hydration of alite in ordinary portland cement by X-ray diffraction using the predetermined relation between the degree of hydration of alite and the amount of Ca(OH)<sub>2</sub> formed in the ordinary portland cement paste hydrated in the same conditions as pozzolanic cement.

Fig. 11 - Heat evolution curve in hydration of pozzolanic cement

Fig. 12 - Degree of hydration of alite in pozzolanic cement

Fig. 13 - Degree of pozzolanic reaction expressed in term of the quantity of reacted  $\text{Ca}(\text{OH})_2$

The hydration of pozzolanic cement, especially the hydration of alite, was accelerated by the addition of pozzolana, except for the initial stage of Kanto loam and fly ash.

The pozzolanic reaction in general is considered to proceed the hydration of cement from the early stage. But it took 7 days for Beppu white clay mixed pozzolanic cement and Takehara fly ash mixed fly ash cement, and 28 days for Furue shirasu mixed pozzolanic cement, Higashi-Matsuyama tuff mixed pozzolanic cement and Tominaga masa-soil mixed pozzolanic cement to be able to recognize clearly the pozzolanic reaction by the amount of reacted  $\text{Ca}(\text{OH})_2$ . In Kanto loam mixed pozzolanic cement, the pozzolanic reaction seems to proceed even in the initial stage.

There were no difference in the kinds of produced hydrates among the kinds of pozzolanic cement within 180 days. In the early age ettringite, solid solution of monosulfate hydrate- $\text{C}_4\text{AH}_{13}$  and  $\text{Ca}(\text{OH})_2$  were produced. Ettringite disappeared at three days. C-S-H attained to the detectable amount by X-ray

diffraction at 28 days. In the Kanto loam mixed pozzolanic cement containing much amount of alumina,  $\text{C}_3\text{AH}_6$  were observed at  $40^\circ\text{C}$ . Gehlenite hydrate ( $\text{C}_2\text{ASH}_8$ ), which appeared in the system pozzolana- $\text{Ca}(\text{OH})_2$ , was not detected.

#### 4. STRENGTH OF POZZOLANIC CEMENT

##### 4.1 Microstructure of Pozzolanic Cement Paste

In the study for morphology, composition and structure of cement paste and particles which constitute cement paste, the analytical method, experimental means and interpretation of obtained results are significantly different with the sizes of the objects.

In this report, to avoid the complexity, Diamond's classification (48) is used with some modification, as follows:

- (1) the problem for texture level ( $\mu\text{m}$  order); remarking the texture of hardened paste
- (2) the problem for particle level ( $0.1 \mu\text{m}$  order); remarking gel structure with hydrates particles and unhydrated particles which constitute paste structure
- (3) the problem for atomic level (unit cell order); remarking atomic arrangement and crystal structure of hydration products which constitute hydrates particles

Texture level corresponds to the order of paste structure as texture. The composition can be analysed by EPMA, and the morphology can be observed by SEM as the macro structure. The objects of texture level are aggregate texture of C-S-H particles, aggregate texture of crystalline hydrates particles, that is,  $\text{Ca}(\text{OH})_2$ , ettringite, monosulfate hydrate, hydrogarnet, unhydrated particles and capillary space.

Particle level corresponds to gel structure, the composition can be analysed by AEM and the morphology can be observed by SEM or TEM as the micro structure. Type I to type IV C-S-H particles, polycrystalline particles like  $\text{Ca}(\text{OH})_2$ , ettringite, monosulfate hydrate, hydrogarnet and gel pore are the object of this level.

Atomic level structurally corresponds to crystal structure, which is observed by TEM as lattice image. We now have no tool to analyse the composition directly such micro area. The objects of this level are solid solution, lattice defect, atomic arrangement, strain of lattice and so on.

##### 4.1.1 Texture level

Cement gel and unhydrated particles make characteristic aggregation according to water material ratio, degree of hydration, morphology and size of hydrate, precipitation time and form characteristic paste structure.

Fig. 14 - Scanning electronmicrographs of the fracture surface of hardened pozzolanic cement paste

- |                              |                        |
|------------------------------|------------------------|
| A. ettringite                | F. calcium hydroxide   |
| B. type I C-S-H              | G. monosulfate hydrate |
| C. fly ash grain             | H. pozzolana grain     |
| D. cast-off shell of fly ash | I. pozzolana grain     |
| E. type III C-S-H            | J. capillary space     |

Ciach, Gillott, Swenson and Sereda (49), who studied hardened  $C_3S$  paste structure with electron microscopy, showed that fibrous grain, formed around  $C_3S$  particles, interlocked each other and made mesh structure of pseudo-hexagonal arrangement, and that amorphous C-S-H particles of high  $CaO/SiO_2$  particles filled the pores of mesh structure to form platy particles. This platy particles bound unhydrated particles each other or bound amorphous particles formed at the position of unhydrated particles.

Not only  $Ca(OH)_2$  but also C-S-H particles formed platy particles having high compressive strength. It was due to fibrous network in amorphous materials, and the reason of low tensile strength was that those platy grains didn't interconnect each other but merely overlapped.

Colleparidi, Marcialis, Massiddo and Sanna (50) studied the reaction between  $Ca(OH)_2$  and four kinds of Italian pozzolanas. Hardened pastes had textures consisting of low crystalline,

irregular shaped grains. The texture become closely with the higher  $CaO/SiO_2$  ratio and the pore size distribution was divided into two parts,  $1 \sim 0.2 \mu m$  and  $0.2 \sim 0.02 \mu m$  with the measurement of mercury penetration porosimeter of the pressure between 100 to 10,000 atom. The former was the pores in pozzolana, the latter was the pores in the particle texture formed with the reaction between  $CaO$  and pozzolana.

On the other hand it is known that  $Ca(OH)_2$  forms on the surface of fly ash like a film in the reaction process between fly ash and cement or  $Ca(OH)_2$ , Kokubu (51) showed that the  $0.5 \sim 1.0 \mu m$  water gap (capillary space) existed between unhydrated fly ash particle and hydrates with the observation of fracture surface of concrete cured for 3.5 years, and assumed that  $Ca^{2+}$  was supplied to fly ash surface through the gap.

In the early stage of pozzolana cement reaction, the hydrates texture mainly consists of type I and type III C-S-H particles,

needlelike crystal of ettringite, card house structure of monosulfate hydrates formed towards pores just like as in portland cement paste. With the curing time, type III C-S-H becomes predominant phase and the piled large  $\text{Ca}(\text{OH})_2$  crystal often penetrates the aggregate texture.

In the reaction between fly ash cement, even in the early stage, hexagonal  $\text{Ca}(\text{OH})_2$  crystals penetrate the hydrate texture can be seen. Type III C-S-H forms on the surface of fly ash, and card-house structure of monosulfate forms toward pores. The shape of  $\text{Ca}(\text{OH})_2$  crystal becomes irregular and makes piled crystal with the curing age.

There are very few studies for hardened paste, not only pozzolanic cement, fly ash cement but also portland cement in texture level though those play an important role on the properties of hardened paste. Those problems will become much more apparent by SEM and the new tools in near future.

#### 4.1.2 Particle level

When cement paste is considered in hydrated particles order, C-S-H is morphologically classified (48) type I (fibrous particle), type II (reticular network), type III (small equant grains) and type IV (inner product). Each particle is usually polycrystal.

Calcium hydroxide forms as hexagonal or irregular accumulating shape. Ettringite is columnar. Monosulfate hydrate is hexagonal plate and forms far apart from each other or makes card house structure. Calcium aluminate hydrates have the same morphology as monosulfate hydrate or can rarely be observed as a trapezohedron, those hydrates have high crystallinity in general and some are considered to be consisted of single crystals.

Recently the composition of particle level, that is  $0.1 \mu\text{m}$  ( $1,000\text{\AA}$ ) order, is frequently determined with the spread of AEM (13) (39). Diamond (52) showed, using SEM-EDX, that C-S-H of cement contained  $\text{SO}_3$ . Uchikawa, Uchida and Mihara (13) showed, using TEM-EDX, that in the case of ultra rapid hardening cement, C-S-H contained sulfur and aluminum and monosulfate hydrate and ettringite contained silicon.

Lukas (53) analysed, using EDX, composition of ettringite which showed the higher intensity of  $\text{SiK}\alpha$  in the hydration of fly ash cement than that in the case of ordinary portland cement. Though we do not have works on these matter for pozzolanic cement, similar invasion of the "third" ions to the hydrates could be occurred for pozzolanic cement.

TMS (trimethylsilylation) analysis (54) has given the better understanding of the structure of C-S-H in these days. Dent Glasser, Lachowski, Mohan and Taylor (39) suggested, in the hydration of  $\text{C}_3\text{S}$ , that C-S-H contained dimer and polymer and the latter increased with curing time using TMS analysis. The authors found by TMS analysis, in the hydra-

tion in the system pozzolana- $\text{C}_3\text{S}$ , that the paste containing the pozzolana of higher reactivity yielded more quantity of polymer at the same curing age.

#### 4.2 Pore Structure of Pozzolanic Cement Paste

##### 4.2.1 Total porosity, capillary space and gel pore space

Pozzolanic cement, mixture of five kinds of Japanese natural pozzolanas and one kind of fly ash with 40% of ordinary portland cement, was hydrated at  $20^\circ\text{C}$  with  $\text{W/S} = 0.3$ . Hardened paste was D-dried and total porosity, capillary space, gel pore space and compressive strength which changed according to the curing time was determined. The result was shown in Fig. 15.

Fig. 15-Change in total porosity, capillary space and gel pore space of pozzolanic cement paste with age

Total porosity was determined with the method by Yudenfreund, Older and Brunauer (55) and the volume of capillary space which was corresponded to the pores above  $75\text{\AA}$  radius was measured with mercury penetrating porosimeter. Gel pore space was calculated as the difference between total porosity and capillary space. Therefore, gel pore, mentioned here, contains pores above  $20\text{\AA}$  which is average distance of C-S-H particles.

Total porosity was increased according to the quantity of added pozzolana in the early and middle age. That phenomena is considered to be mainly according that the increase of added pozzolana causes less formation of hydrates. Though total porosity decreases with the curing time, it shows still higher value than that of portland cement at about 180 days.

The volume of capillary space decreased remarkably with the curing time and the degree of decrease has characteristic tendency with the kinds of pozzolanas. This means that hydration products are liable to precipitate

selectively on the surface of particles surrounding relatively large pores, and shows the process that larger pores are in turn filled with hydration products. Therefore the decrease of volume of capillary space is remarkable in the early age when reaction of cement hydration is active and large pores mainly exist. The decrease of volume of capillary space is small in pozzolanic cement made of Kanto loam or Tominaga masa-soil which has large amounts of soluble alumina. The reason for this is supposed that besides C-S-H, large crystals of calcium aluminate hydrates or/and gehlenite hydrates precipitate significantly and form porous structure of hydration products. Though fly ash has large amounts of soluble alumina, the volume of capillary space is similar to natural pozzolanas which have small amounts of soluble alumina, because pozzolanic reaction of fly ash is rapid and large amounts of hydration products are formed.

Gel pore increases with the curing time in the early stage, but turns to decrease between 91 days and 180 days. The fact shows that along with filling capillary space by hydration products formed in the early and middle age, fine gel pores are newly formed in the filled capillary space and gel pore space begins to decrease in the later age when the amounts of filling of gel pore with fine crystals, such as C-S-H, exceeds the volume of formed gel pore. Therefore, the ratio of the amounts of gel pore and total porosity, that is  $G/T$ , increases rapidly till 91 days, then decreases after that. The change of gel pore ratio accompanied by the curing time is similar in the following couples, that is, Beppu white clay mixed pozzolanic cement and Higashi-Matsuyama tuff mixed pozzolanic cement, Furue shirasu mixed pozzolanic cement and Takehara fly ash mixed fly ash cement, Tominaga masa-soil mixed pozzolanic cement and Kanto loam mixed pozzolanic cement.

#### 4.2.2 The shape of gel pore

Adsorption-desorption isotherms with  $N_2$  gas

Fig. 16 - Adsorption - desorption isotherms with  $N_2$  gas of hardened pozzolanic cement paste and hardened ordinary portland cement

of Beppu white clay mixed pozzolanic cement, Takehara fly ash mixed fly ash cement and ordinary portland cement paste are shown in Fig. 16.

In the pozzolanic cement, pronounced hysteresis of adsorption-desorption is observed with the curing time and the tendency that can easily adsorb but hardly desorb, is noticed. This result is considered to show that the proportion of fine pore or pore which has small opening to gel pore increases with the curing time and the order is in turn Beppu white clay mixed pozzolanic cement, Takehara fly ash mixed fly ash cement and ordinary portland cement.

Calculating the ratio of height and radius of pore using the data of specific surface area determined by BET method and adsorption isotherms and assuming the shape of pore as cylinder (56), in Beppu white clay mixed pozzolanic cement paste, the ratio is 4 at 3 days and 11 at 91 days, in Takehara fly ash mixed fly ash cement paste, the ratio is 4 at 3 days and 7 at 91 days and in portland cement paste, the ratio is 3 regardless of the curing time. That is, in the pozzolanic cement the shape of gel pore changes to be slender with the curing time.

#### 4.2.3 Pore size distribution

The data of pore size distribution above  $75\text{\AA}$  radius in pozzolanic cement by mercury penetrating method is shown in Fig. 17.

Pore size distribution and change of pore size distribution with time is divided into three groups. In Beppu white clay mixed pozzolanic cement and Higashi-Matsuyama tuff mixed pozzolanic cement, pore size distribution has peaks at  $125\text{-}375\text{\AA}$  and above  $1,870\text{\AA}$  at 3 days. Though the peak at  $125\text{-}375\text{\AA}$  decreases and shifts to small radius with the curing time, the amounts of decrease of the pores above  $1,870\text{\AA}$  is small and a significant amount of pores remains even at 180 days.

Tominaga masa-soil mixed pozzolanic cement and Kanto loam mixed pozzolanic cement paste have higher peak at  $125\text{-}375\text{\AA}$  at 3 days compared with above case and have a smaller amount of pores above  $1,875\text{\AA}$ . Though the peak shifts to small radius, the amounts of decrease of peak height is small. The considerable amounts of pore about  $100\text{\AA}$  exists even at 28 days.

In Furue shirasu mixed pozzolanic cement and Takehara fly ash mixed fly ash cement paste, pore size distribution is similar to that of Tominaga masa-soil mixed pozzolanic cement paste till 3 days, but after 7 days it changes like that of Beppu white clay mixed pozzolanic cement and Higashi-Matsuyama tuff mixed pozzolanic cement paste.

These pore size distributions of pozzolanic cement pastes are different from that of portland cement paste, therefore, it is supposed that the difference of the peak

Fig. 17 - Pore size distribution curve of hardened pozzolanic cement paste measured by mercury penetration

Fig. 18 - Gel pore size distribution curve of hardened pozzolanic cement measured by BET method using  $N_2$  gas

height of 125-375Å and above 1,875Å at 3 days is due to the amounts of produced hydrates and the pore size distribution of mixed pozzolana itself.

Pore size distribution of gel pore measured by  $N_2$  gas adsorption of BET method is shown in Fig. 18.

Though the quantity of gel pore is different with the kinds of pozzolanic cement, that is 0.195 cc/cc in Beppu white clay mixed pozzolanic cement paste, 0.201 cc/cc in Takehara fly ash mixed fly ash cement and 0.150 cc/cc in portland cement, in all the cases pore size distribution shifts to small radius with the curing time and the peak appears at about 10Å radius at 91 days.

#### 4.3 The Strength of Pozzolanic Cement Paste and the Character of Pozzolana

There are many studies which have tried to connect the strength of pozzolanic cement with the character of pozzolana.

Hanna and Afify (2) described that definite relation existed between 91 days mortar strength of pozzolanic cement and the ratio of the quantity of soluble  $SiO_2 + R_2O_3$  in pozzolanic cement paste to the quantity of  $SiO_2 + R_2O_3$  in the starting materials except for diatomaceous earth and granulated slag.

Battaglini and Shippa (57) stated that there existed correlation between the strength of pozzolanic cement and the change with time of specific surface area and the quantity of adsorbed CaO by pozzolana, that is,  $\Delta s/\Delta t$  and  $\Delta c/\Delta t$ , till 3 days and that  $\Delta s/\Delta t$  had higher correlation with the strength, and concluded that pozzolana, which was rich in amorphous silica and glassy silica, was desirable.

Jambor (58) stated that there existed the relation expressed in equation of tertiary order between compressive strength of pozzolana-lime mixture and the volume of hydration products except for burnt kaoline which formed different hydration products, and porous silica gel.

Chatterjee and Lahiri (59) showed that, though mortar strength of pozzolana- $\text{Ca(OH)}_2$  mixture had correlation with the specific surface area of the same pozzolana, the correlation was varied by the kind of pozzolana.

Thorne and Watt (60) showed that the strength of 2.5:1:2 mortar of fly ash,  $\text{CaO}$  and sand had correlation with the specific surface area of fly ash till 91 days, and after 91 days, with the content of  $\text{SiO}_2 + \text{Al}_2\text{O}_3$  in fly ash.

Joshi and Rosauer (61) reported that the strength of 2:1 paste of synthesized fly ash and  $\text{Ca(OH)}_2$  had correlation with the specific surface area of fly ash and that  $\text{CaO}$  in fly ash increased the strength but  $\text{Fe}_2\text{O}_3$  decreased the strength.

Spitanos, Voyatzakis and Melidis (62) stated that the mortar strength of fly ash cement mixed with 30% of classified fly ash had correlation with grain size of fly ash and the finer the grain size of fly ash, the higher the strength was.

Summing up the result of above mentioned previous studies, it is showed that the character of pozzolana such as chemical composition,  $\text{SiO}_2$ ,  $\text{Al}_2\text{O}_3$ ,  $\text{Fe}_2\text{O}_3$ , etc., in pozzolana, the quantity of amorphous silica and glassy silica, and specific surface area, and the factor which have relations with the character of pozzolana such as the amount of formed hydration products, the quantity of  $\text{CaO}$  absorption in paste and the increment of specific surface area of paste, have some correlation with the strength. Those correlations, however, are mere results obtained under restricted condition as there exist not a few exceptions and the result is restricted to the case of the same pozzolana.

The fact clearly shows how difficult to connect the character of pozzolana with the strength of pozzolanic cement unequivocally and universally is. Therefore in the present study, the relation between character of pozzolana and the strength of pozzolanic cement should be connected by mediating other properties which have better-defined relation with character of pozzolana such as pozzolanic reactivity or properties concerning with the pore of paste of which correlation with the strength have been clarified to some extent.

#### 4.4 The Strength and the Pore of Pozzolanic Cement Paste

It is well known that there exists fair linear correlation between the strength of the material and the porosity, and it is confirmed that the strength of cement paste also has a similar relation with the porosity (63).

Uchikawa and Tsukiyama (64) showed in the studies on the hydration of ultra rapid hardening cement that the slope of strength-porosity correlation curve changed by the size and shape of pores dependent on the size

and morphology of crystals of hydration products and stated that in the early stage the strength remarkably developed but decrease of the porosity was small with formation of the large amount of prismatic crystals of ettringite and in the later stage in spite of relatively small strength development, porosity decreased remarkably with the formation of C-S-H.

Crennan, El-Hemaly and Taylor (65) studied that the relation between porosity and coarse dense crystalline material using the strength as parameter and showed that the lower the porosity, the higher the strength of the same amount of coarse dense crystalline material, the porosity increased to a constant value and beyond that decreased with the increase of the amount of coarse dense crystalline material. Therefore, there exists the amount of coarse dense crystalline material which makes porosity maximum and that in general the strength is higher when the amount of coarse dense crystalline material large.

Uchikawa and Tsukiyama (66) analysed the relationship between the shape of pore and the degree of stress-concentration under the loading by finite element method and showed that the strength of cement paste was influenced by the shape of pore.

The relation between compressive strength of pozzolanic cement, made with Japanese natural pozzolanas and fly ash, and total porosity is shown in Fig. 19.

Fig. 19- Relation between total porosity and compressive strength of hardened pozzolanic cement paste

From the result of Fig. 19 and Fig. 15, it became clear that the strength of pozzolanic cement paste had good correlation with total porosity and it had particularly good correlation with capillary space in the early and middle age, and with gel pore space in the later age.

The value of developed strength, however, is different even if the value of porosity is the same. For example, in Beppu white clay mixed pozzolanic cement and Higashi-Matsuyama tuff mixed pozzolanic cement, though the change of porosities with curing time are nearly the same, the early strength of the

former is extensively higher and the latter attains to nearly same value at 180 days. In Furue shirasu mixed pozzolanic cement and Takehara fly ash mixed fly ash cement, though the change of porosities with curing time are approximately the same, the development of the strength of the former after 28 days is larger than the latter and the strength of the latter is higher till 91 days than the former.

The fact suggests that besides porosity, pore size distribution and the shape of pore have the effect on the strength.

As shown in Fig. 17 in the early age Higashi-Matsuyama tuff mixed pozzolanic cement has larger amounts of pores of which size is between  $0.2 \sim 0.02 \mu\text{m}$  but on the contrary Beppu white clay mixed pozzolanic cement has larger amounts of pores of that size in the later age, therefore it can be understood that pore size distribution and strength have close relation. In Furue shirasu mixed pozzolanic cement and Takehara fly ash mixed fly ash cement, the difference in the strength of the two is considered to have closer relation to the difference of pore shape than pore size distribution.

The strength of Tominaga masa-soil mixed pozzolanic cement is low and that of Kanto loam mixed pozzolanic cement is the lowest, that difference of strengths is too large to explain only with porosity, pore size distribution and the shape of pore.

That is, as other factors than above mentioned, it is supposed that the strength of nonporously coagulated hydration products participates.

Duckworth (67) showed that there existed following relation between the strength of a porous brittle polycrystalline body (S) and specimen porosity (P):

$$S = S_0 e^{-bp} \quad -(3)$$

where  $S_0$  is calculated strength of a brittle nonporous polycrystalline body and b is constant. The strength for pozzolanic cement and the data of total porosity is substituted in above equation and the value of calculated

strength of a brittle nonporous polycrystalline body ( $S_0$ ), that is, the case of total porosity is zero and the constant (b) is obtained as Table V.

Considering from the equation for the calculation of total porosity, zero total porosity means the case that there exists no water except for the combined crystalline water and the paste is constituted only with unhydrated cement particles, unreacted pozzolana particles and nonporously coagulated hydration products, and  $S_0$  means the strength of the aggregation of those particles. If the strength of unhydrated particles is supposed to be higher than the hydration product,  $S_0$  is considered to be the value which reflect the strength of nonporously coagulated hydration products. The fact, that the value of  $S_0$  is high in Higashi-Matsuyama tuff mixed pozzolanic cement, Beppu white clay mixed pozzolanic cement and Furue shirasu mixed pozzolanic cement, and low in Kanto loam mixed pozzolanic cement, Tominaga masa-soil mixed pozzolanic cement and fly ash cement, is considered to show that  $S_0$  is related to the S/A ratio of acid soluble part of pozzolana and the strength of nonporously coagulated C-S-H is relatively higher compared with that of nonporously coagulated Ca-Al hydrate. The reason why  $S_0$  of the high siliceous pozzolanic cements are higher than that of pure portland cement is the same as above mentioned.

Though the constant b is different with the kind of material, the kind of measured strength, the relation between the shape of pore and the direction of load and so on, for compressive strength, it is said that in the case of idealized cubic closest packing of sphere,  $b = 6$  and in the case of hexagonal closest packing,  $b = 9$  (68) and large b value means the increase of contact points of mutual particles, that is the increase of the contact surface. The b value was about 11 in most of natural pozzolana mixed cements and was lower value in fly ash cement. These differences in b value are not clear at present.

#### 4.5 The Evaluation of Pozzolana

It is considered that there exists following

Table V.  $S_0$  and b calculated from the strength and total porosity of paste using the equation (3).

Cement	W/S	$S_0$ (N/mm <sup>2</sup> )	b
Portland cement	0.30	421	7.0
Portland cement	0.40	657	7.6
F-PC	0.30	1088	10.6
G-PC	0.30	1421	11.9
R-PC	0.30	941	10.7
V-PC	0.30	1303	11.2
M-PC	0.30	304	6.3
T-PC	0.30	559	7.6

Table VI. Weighting constant (w) and correlation coefficient (r) in equation (4)

System	Curing temperature (°C)	Age (day)	$C = w_0 + w_1f_1 + w_2f_2 + w_3f_3 + w_4f_4$					r
			$w_0$	$w_1$	$w_2$	$w_3$	$w_4$	
Pozzolana- $\text{Ca}(\text{OH})_2$ (W/S=0.56, 0.46)	20	7	-0.62	0.159	0.268	0.601	0.070	0.99
		28	16.68	0.020	0.021	0.418	0.060	0.89
		91	21.5	0.064	0.100	0.589	0.106	0.98
	40	7	-7.41	0.267	0.225	0.845	0.226	0.99
		60	2.80	0.217	0.127	1.03	0.274	0.99
Pozzolana-Cement (W/S = 0.30)	20	91	-2.69	0.030	0.057	0.219	0.086	0.99
		180	-2.44	0.066	0.264	0.264	0.086	0.99

C : amount of  $\text{Ca}(\text{OH})_2$  reacted (g/100g pozzolana)

$f_1$  : amount of glass (wt%)

$f_2$  : amount of acid soluble part (wt%)

$f_3$  : S/A in acid soluble part

$f_4$  : specific surface area ( $\text{m}^2/\text{g}$ )

r : correlation coefficient

unequivocal proportional relationship between the characters, such as chemical composition, the kind and the quantity of glass, the kind and the quantity of mineral, specific surface area and so on, and pozzolanic reactivity represented by reacted  $\text{Ca}(\text{OH})_2$ .

$$C = \sum w_i f_i \quad (4)$$

where C is the quantity of reacted  $\text{Ca}(\text{OH})_2$ , f is the factor of character and w is weighting constant. Satisfactory linear relationship between the quantity of reacted  $\text{Ca}(\text{OH})_2$  and the character of pozzolana was obtained in the case mentioned 3.1. The weighting constant of each factor and correlation coefficient are shown in Table VI.

Since in the calculation not all the characters of pozzolana are used, the value of r is considered to approach to 1, when the new factors of characters obtained by advanced characterization are added to the calculation.

On the other hand the correlations between the quantity of reacted  $\text{Ca}(\text{OH})_2$  and the strength, are low in general as shown in Fig. 20 except for a few cases.

The correlations between pozzolanicity by ISO method for five kinds of Japanese pozzolanas and one kind of fly ash and the strength are also low in general as shown in Fig. 21 except for a few cases.

Therefore, to evaluate the quality of pozzolana by measuring the pozzolanic reactivity is not appropriate and it is considered that pozzolana should be evaluated with direct measurement of the most important properties in many pozzolanic properties and if the strength is assumed to be representative property, evaluation should be done by strength test itself although there are some inconveniences that it takes long time to obtain the result of evaluation (69).

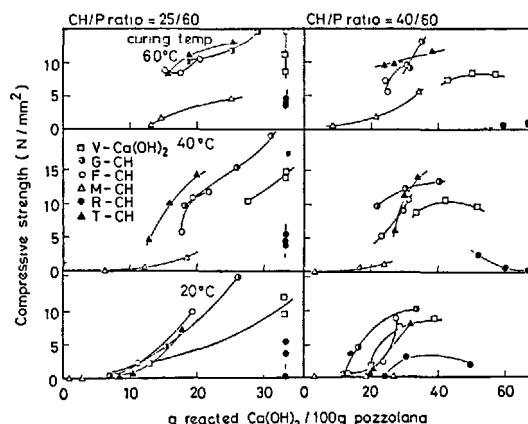

Fig. 20 - Relation between reacted  $\text{Ca}(\text{OH})_2$  and compressive strength of hardened paste in the system pozzolana- $\text{Ca}(\text{OH})_2$

Fig. 21 - Pozzolanicity test for pozzolanic cement (P/C = 20/80) by ISO

## 5. CONCLUSION

On the hydration of pozzolanic cement, following results were clarified referring the previous studies mainly after Moscow Congress and by the authors' investigation.

(1) Though the character of pozzolana has correlation with the quantity of reacted  $\text{Ca}(\text{OH})_2$ , that is, pozzolanic reactivity, the correlation between the character of pozzolana and strength of pozzolanic cement is low. The correlation between pozzolanic reactivity and the strength of pozzolanic cement paste is also low.

Therefore, the quality of natural or artificial pozzolana for pozzolanic cement should be evaluated by strength test, not by reactivity test.

(2) The new analytical methods and sample preparation techniques such as ESCA, AEM, ICP, TMS and ion thinning etc. are giving great progress to cement chemistry, but their application to pozzolanic cement are poor at present. They will bring us more extensive information of cement chemistry in near future.

(3) The decrease of  $\text{Ca}(\text{OH})_2$  in the early stage is not due to pozzolanic reaction but to other elemental processes such as adsorption. With the consideration of the kinetics of pozzolanic reaction from the both sides, the quantity of reacted  $\text{Ca}(\text{OH})_2$  and reacted pozzolana, it could be seen that pozzolanic reaction is diffusion-controlled dissolution reaction which rate determining step is the dissolution of unhydrates and the precipitation of hydration products in the early stage, and the diffusion of ions or ion radicals through amorphous surface layer of pozzolana and precipitated hydrates layer on the surface of pozzolana in later stage.

(4) Though the hydration products in pozzolana- $\text{Ca}(\text{OH})_2$  system are slightly different according to the kind of pozzolana, condition of hydration and so on. Those were either combination of C-S-H,  $\text{C}_3\text{A} \cdot \text{CaCO}_3 \cdot \text{H}_{12} - \text{C}_4\text{AH}_{13}$  solid solution,  $\text{C}_2\text{ASH}_8$  and hydrogarnet.

(5) In the hydration of pozzolana- $\text{C}_3\text{S}$  system, addition of pozzolanas accelerate the hydration of  $\text{C}_3\text{S}$ . Acceleration of hydration after induction period is due to the stimulation of  $\text{C}_3\text{S}$  dissolution by the adsorption of  $\text{Ca}^{2+}$  in the liquid with pozzolana and due to the increase of surface by the addition of pozzolana which is preferable to the precipitation of C-S-H. C-S-H precipitated after induction period has a higher Ca/Si ratio than 1.5, when sufficient amount of  $\text{Ca}(\text{OH})_2$  exists. C-S-H and Ca-Al hydrate are generally formed by the pozzolanic reaction between  $\text{Ca}(\text{OH})_2$  and pozzolana after one day but the physical properties, for example mechanical strength, develops in later age. Aluminate hydrates are generally formed later and their period of formation depends on the characters of pozzolanas, that is aluminum content and their solubility.

(6) In the hydration of pozzolana- $\text{C}_3\text{A}$  system under the existence of  $\text{Ca}(\text{OH})_2$  and  $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ , hydration of  $\text{C}_3\text{A}$  is accelerated by the addition of pozzolana. The degree of acceleration is larger in pozzolana with larger specific surface area and higher CEC value. The reason why hydration of  $\text{C}_3\text{A}$  is accelerated, is the stimulation of  $\text{C}_3\text{A}$  dissolution by the adsorption of  $\text{Ca}^{2+}$  in the liquid with pozzolana and the precipitation of ettringite on the surface of pozzolana grain. When pozzolana which contains much alkali are used,  $\text{C}_3\text{AH}_6$  are formed earlier, the reason is considered to be the decrease of the stability of hexagonal hydrates under the existence of alkalies.

(7) The hydration in the pozzolana- $\text{C}_3\text{S}$  system and pozzolana- $\text{C}_3\text{A}$  system under the existence of  $\text{Ca}(\text{OH})_2$  and  $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ , proceeds through the processes, that is, alkali dissolution from the surface of pozzolana grain, formation of negatively charged amorphous layer rich in Si, Al, collision of  $\text{Ca}^{2+}$  in the solution with pozzolana grain, swelling of the amorphous layer on the surface of pozzolana grain by osmotic pressure, destruction of film and so on. In the pozzolanic reaction, alkali in pozzolana plays an important role and has an influence on the state of precipitation of hydration products.

(8) Total porosity of pozzolanic cement paste is larger than that of portland cement paste in the early age. Capillary space decreases with the curing time, but gel pore space defined as below  $75\text{\AA}$  in radius increases till definite age, then turns to decrease. Pore size distribution shifts to small diameter with the curing time. Those change has the characteristics according to the kind of pozzolana. Though the shape of gel pore comes to be slender with curing age in pozzolanic cement paste and fly ash cement paste, there is almost no change with age in portland cement paste.

(9) The strength of pozzolanic cement paste has good correlation with total porosity in the same pozzolanic cement, especially with capillary space. When the kind of pozzolana is different, however, developed strength is different even if total porosity is the same. The strength is influenced by pore size distribution and the shape of pore besides total porosity. The factor which has influences on the strength besides above mentioned, is the strength of assumed nonporously coagulated hydrates and it was suggested that the strength of nonporously coagulated C-S-H is higher than that of nonporously coagulated Ca-Al hydrate.

### **Aluminous Cements A review of recent literature (1974 - 1979)**

**C. M. GEORGE  
Lafarge Fondu International  
Paris FRANCE**

## SUMMARY

World wide use of many different types of aluminous cement continues to increase and with it the interest in the chemistry of calcium aluminates. The type of cement most frequently encountered is still that made by fusion of natural bauxite and limestone and containing approximately 40 % alumina. Generally known as cement Fondu, this was the first to be produced industrially, the original patent dating from 1908, and is the main subject of this, and previous reviews. High alumina cements containing up to 80 % alumina, used almost exclusively for refractory applications (to approximately 1800°C) are made by both fusion and sintering processes, but the overall pattern of manufacture has not changed appreciably during the period in question (1974 - 1979). Publications concerning these special cements are mentioned only in-so-far as they contribute to general understanding of the chemistry of the alkaline-earth aluminates.

The principal hydraulic constituents of the aluminous cements,  $C_{12}A_7$ , CA,  $CA_2$  are generally, but not exclusively reported to melt incongruently: in particular the melting point of  $C_{12}A_7$  appears to be affected by oxygen partial pressure or water vapour. Iron oxide, in the lower purity cements, is soluble in all the calcium aluminates to a significant degree, and can replace up to 50 % of the alumina in gehlenite, which occurs in silica containing aluminate cements. Further studies of pleochroite now prove that it requires a fairly high ratio of ferrous to ferric ion for its formation as a stable phase. The iron oxide content of 40 % alumina cement is however greater than can be accommodated in the above manner, so that calcium aluminoferrites of the  $C_2A - C_2F$  solid solution series, and even free wustite, appear in the crystallised product.

The reactivity of the calcium aluminates with water increases with the C/A ratio, but the predominance of CA in aluminous cements makes this the most important hydraulic constituent. Pleochroite is largely inert in comparison, but the aluminoferrite solid solutions display significant reactivity. Gehlenite is inert, however stratlingite does appear as a hydration product of the lower purity cements, due to the interaction of mono-calcium aluminate hydrate and calcium silicate hydrate formed from the small quantities of  $\beta$ - $C_2S$  found in these cements.  $CAH_{10}$  is the principal hydrate formed from CA at temperature of 20°C or less,  $C_2AH_8$  predominates at temperatures around 30°C, and both 'convert' increasingly rapidly to  $C_3AH_6$  as temperatures are further increased. Stoichiometry is maintained by the formation of  $AH_3$  and free water. The free water released by conversion (or by carbonation) is taken up by further hydration of residual cement in mixes made at or below the critical water/cement ratio, so that changes in porosity are minimised. The hydration of  $C_4AF$  leads to the formation of  $C_4(A,F)H_{13}$  at room temperature, and to  $C_3(A,F)H_6$  later or at higher temperatures.

The  $Ca_2Al(OH)_6^+$  cationic layers in the  $C_4AH_n$  structure are separated by aqueous anionic interlayers in which many mono- and di-valent anions can be substituted from solution,  $Al(OH)_4^-$  being a special case which shows  $C_2AH_8$  as a solid solution product of  $C_4AH_{13}$ . Substitution of certain anions in the

$C_2AH_8$  interlayers confers a degree of stability to the structure, and reduces the rate at which conversion to  $C_3AH_6$  occurs.

Hydration of CA in the presence of carbonate leads to the formation of mono-carbo aluminate and a lower rate of conversion of the hexagonal aluminates to the cubic form. The ultimate products of carbonation are calcite and gibbsite. The reaction of atmospheric  $CO_2$  with hardened cement, and that of solutions of sulphates to produce ettringite and chlorides to produce mono-chloro aluminates, is a very slow surface phenomenon at low water/cement ratios, and does not adversely affect strength. Chemical attack is thus associated with permeable high water/cement ratio mixes which are in any case to be proscribed for reasons of strength alone.

It has been shown that precipitation of calcium aluminate hydrates from solutions in contact with CA or aluminous cement does not occur through heterogeneous nucleation by the anhydrous grains. Nevertheless, the nature of the hydrate which crystallises is influenced by the C/A ratio of the solution and, as hydration proceeds, apparently by the nature of the hydrate initially precipitated. Another new result is that the hydration of amorphous  $CAH_n$  ( $10 > n > 1.5$ ) does not lead to cementitious bonding although the hydrate formed,  $CAH_{10}$  is chemically the same as that produced from CA. Morphology is thus also a critical factor in strength development.

A high proportion of publications continues to deal with the effects of conversion on long term behaviour. Some authors appear to maintain support for the view that the initial extremely high strength of aluminous cements due to  $CAH_{10}$  can be exploited in permanent structures provided precautions are taken to prevent conversion, while others still regard conversion as an inevitable cause of vulnerability. Yet there is virtually universal recognition of the importance of temperature and water/cement ratio on the durability of aluminous cement concrete, although failure to distinguish between free and total water/cement ratio causes confusion in some cases. The most important publications relating long term strength and conversion however, clearly show that aluminous cements will convert relatively rapidly (a few months or years) under nearly all service conditions, so that the rapid hardening properties should be used only by designing to the converted strength of low water/cement ratio mixes. Much work on measuring conversion by derivatographic methods has appeared. Although this is a valuable technique under strict control, its wide adoption as a quick method of assessing concrete quality in the field is far from reliable. To use degree of conversion as function of age to infer water/cement ratio is to rely on an effect which is difficult to quantify even in the laboratory, and to ignore the overriding effect of temperature. Thus heating, deliberate or not, will cause rapid conversion whether a low or a high water/cement ratio has been employed.

Some alternative approaches to quality assessment are mentioned and data is given to show that the porosity of converted aluminous cement concrete is not greater than that of Portland cement concrete of the same water/cement ratio. In relating conversion to mechanical properties several recent publications provide further information on

the modulus of elasticity and creep of aluminous cement concrete.

## 1. COMPOSITION

### 1.1. Manufacture

Since the original French patent of 1908, a variety of methods have been reported for the manufacture of aluminous cements involving sintering, fusion under oxidizing conditions, reductive fusion in the Blast Furnace or by cupola, and melting in electric furnaces, (1). However, over the last 5 years, no major changes are apparent in the pattern or methods of manufacture of aluminous cements, although the increasing preoccupation with the use of waste products as raw materials is to be noted.

The literature concerning manufacture which has appeared since 1974, frequently in the form of patents, has been concerned mainly with the production of high alumina cements containing 70 % or more aluminium oxide, and it is not appropriate to discuss this extensively in the present paper: brief mention only will be made of some of the publications in this area.

Sintering is difficult to control when raw materials containing appreciable quantities of iron oxide are used. For this reason the preferred process is still fusion for the manufacture of the most widely encountered type of aluminous cement, the raw materials being red bauxite and limestone; hence the origin of the name ciment Fondu for this product. To the author's knowledge, and contrary to an earlier report, (2), fusion in electric furnaces has not been used for many years for the manufacture of this type of cement containing approximately 38 % CaO, 39 %  $Al_2O_3$ , 16 % iron oxide and 4 % silica.

A laboratory study of the use of ferrous sulphate as a mineraliser for the sintering of lime or limestone and alumina has been reported by TBOREANU and co-workers (3) and the same research institute has also described (4), the properties of sintered mixtures of alumina and combinations of magnesium, calcium and barium carbonates. The mixtures were chosen to give either 20 % or 50 % magnesia spinel in the fired material. From the study of the porosities of the clinkers produced it was found that compositions in the partial system BA-BA<sub>6</sub>-BC<sub>2</sub>Al<sub>4</sub> sintered without formation of a liquid phase and thus gave clinkers of higher refractoriness, although harder to grind to cement fineness.

DROZDZ and WOLEK, (5) have extended earlier studies of barium aluminate cements prepared by sintering. The principal mineralogical phase formed is BA which has considerable hydraulicity - a heat of hydration between 200 and 300 cal/g,  $\approx$  twice that of commercial aluminous cements, is reported. In preparing refractory concretes from such cements, if more than the minimum amount of gauging water needed to form barium aluminate hydrates is used, alumina hydrate and barium hydroxide are formed, or barium carbonate in the presence of atmospheric CO<sub>2</sub>. Contrary to calcium aluminates, the carbonation of barium aluminate cements does not improve strength. The rapid setting characteristics of barium aluminate can be retarded by citrates and borates, for example but apparently not by halide salts, phosphates or sugar. Despite its high refractoriness barium aluminate cement does

not appear to have yet achieved any industrial success.

KRAVCHENKO et al (6) have investigated the manufacture by sintering of high alumina cements (alumina contents, 70 to 80 %) using various metallurgical slags. The use of alumina rich slags containing only small quantities of silica minimises the amount of gehlenite, C<sub>2</sub>AS formed thus increasing the CA content of the final clinker and hence its cementitious behaviour.

KONDRASHENKO (7) discusses the preparation of a cement composed primarily of CA<sub>2</sub>. This is produced by melting, either as a slag during the production of ferro-titanium or ferro-chrome by aluminothermic reduction or by remelting of such slags in an electric furnace, with suitable additions of alumina and lime. The product contains 70 to 80 % alumina with CA<sub>2</sub> as the principal phase, and is thus intrinsically more refractory than cements based on CA. However its rate of hydration and hence bonding efficiency, is much less than that of the mono-calcium aluminate cements since the hydraulic activity of the calcium aluminates increases with the lime/alumina ratio.

Another publication, (8) also discusses the manufacture of aluminous cements from metallurgical slags produced in the smelting of aluminium. One of the difficulties normally associated with using such slags (60 - 90 %  $Al_2O_3$  content) is due to the presence of AlN or Al<sub>4</sub>C<sub>3</sub>, which evolve ammonia or hydrocarbon gases in contact with water. By sintering such slags with a complement of lime in the presence of manganese carbonate or oxide, these impurities are removed.

Alternatively the slags can be remelted in an electric furnace and ferro-manganese or ferro-silicon added together with the necessary lime. This study was not restricted to high purity cements, the range of compositions produced being CaO 20 - 35 %,  $Al_2O_3$  40 - 65 %, SiO<sub>2</sub> 2 - 10 %, together with small amounts of Fe<sub>2</sub>O<sub>3</sub>, MgO and other impurities. Setting times in the range 40 to 150 minutes are reported, with reasonable subsequent strength development.

### 1.2. Mineralogy

The calcium aluminates, C<sub>12</sub>A<sub>7</sub>, CA and CA<sub>2</sub> encountered in industrial aluminous cements as well as the calcium aluminoferrites, were reviewed by ROBSON (9) at the 1974 International Symposium on the Chemistry of Cements (Moscow). All the calcium aluminates can take up appreciable quantities of ferric oxide in solid solution, the remaining iron appearing as calcium aluminoferrites. Ferrous oxide can appear as wustite and may also be combined in pleochroite.

The aluminoferrites are solid solutions between the end members, C<sub>2</sub>A - C<sub>2</sub>F. The general formula C<sub>4</sub>AF is thus frequently given. However, in aluminous cements of the Fondu type, the composition is most often on the iron rich side of the solid solution range, represented by the formula, C<sub>10</sub>AF<sub>4</sub>, (9).

C<sub>12</sub>A<sub>7</sub> in dry conditions, CA and CA<sub>2</sub> are all reported to melt incongruently. C<sub>12</sub>A<sub>7</sub> however, takes up moisture at high temperatures and melts at 1390°C so that in air, for example, it appears to melt congruently. In a paper (10) which examines the

formation of CA from  $C_3A$  and  $\alpha-Al_2O_3$ ,  $C_{12}A_7$  is reported as an intermediate product :

The rate of formation of CA was accelerated in the presence of water vapour.

However, in another paper UDALOV, CHEMEKOVA and APPEN, (11) working on pure materials, state that water vapour does not affect the melting of calcium aluminates and that  $C_{12}A_7$  melts congruently in oxidising atmospheres.  $C_5A_3$ , which decomposes above  $820^{\circ}C$  to  $C_{12}A_7$  and CA under oxidising conditions, is stable under reducing conditions and also melts congruently. Congruent melting of CA and  $CA_2$  is also claimed.

PETZOLD and RIEDEL (12) discuss the phase compositions of aluminous cements made by reductive fusion of bauxite and limestone with coke, in electric arc furnaces. An optimum coke utilisation produced low iron (0.4 to 0.6 %) cement, without appreciable formation of calcium carbide, suitable for high temperature applications. Under the conditions used, the silica content of the raw materials appeared as  $\beta$ - $C_2S$  in the products, which on cooling transformed spontaneously to  $\gamma$ - $C_2S$  below 600°C, with disintegration due to the associated volume increase. The  $C_2S$  could be stabilised in the  $\beta$ -form by the addition of boric oxide or vanadium oxide. Many other materials are known to have the same effect. In relating the strength development of the cements to their mineralogy, these authors assimilate  $TiO_2$  with  $SiO_2$ . The best results are reported for compositions which when  $SiO_2 + TiO_2$  is considered as  $SiO_2$ , lie on the line CA- $C_2S$  of the C-A-S diagram. This is consistent with earlier observations where  $SiO_2$  is considered alone (13) for which the maximum utilisation of alumina to form CA is obtained for compositions close to the line CA -  $C_2S.C_2AS.CA$ .

GLASSER and SORRENTINO, (14), (15) have considerably extended the study of the phase diagram corresponding to aluminous cements of the Fondu type, ( $\approx 40\%$  alumina).

The lime-alumina-silica-iron oxide system of aluminous cements, under oxidising conditions ( $p_{O_2} = 0.2$  atmos - free air) has a ratio of ferrous oxide to total iron oxide which does not exceed 1.5. In this system, pleochroite is not formed on solidification. The same observation applies to the study of the subsolidus at these levels of oxidation. It follows, that since the pleochroite phase is occasionally encountered in practice, its existence as a stable phase requires the higher ferrous to ferric oxide ratios found in aluminous cements, (12). This is directly confirmed by a further publication, (16). At the same time these studies demonstrate that the  $SiO_2$  concentration at which large quantities of gehlenite are formed, is lower than in the lime-alumina-silica diagram alone. This is important in explaining the upper limit to the  $SiO_2$  level in these types of cement, beyond which a significant proportion of the alumina is used in forming  $C_2AS$  at the expense of  $CA$ , thus seriously reducing hydraulic activity.

In practice this limit is found at about 6 %  $\text{SiO}_2$ , whereas it would not be expected from the C-A-S diagram alone until the CA/C<sub>2</sub>AS boundary is reached

at  $\approx 10\%$ . Thus pleochroite formation has been, in the past, considered as the factor responsible. The recent studies show that in the presence of iron oxide, the CA/C<sub>2</sub>AS boundary moves to lower silica concentrations and indeed, to about the 6% level under practical conditions.

Several researchers have made further studies of pleochroite. A phase of composition  $22\text{CaO} \cdot 13\text{Al}_2\text{O}_3 \cdot 3\text{MgO} \cdot \text{SiO}_2$  found (17) in the  $\text{CaO}-\text{Al}_2\text{O}_3-\text{MgO}-\text{SiO}_2$  system is considered equivalent to pleochroite if  $\text{MgO}$  is replaced by  $\text{FeO}$  and some  $\text{Al}_2\text{O}_3$  by  $\text{Fe}_2\text{O}_3$ . Using electron microprobe analysis three possible compositions for synthetic pleochroite are proposed, (16) :  $22\text{CaO} \cdot 13\text{Al}_2\text{O}_3 \cdot 3\text{FeO} \cdot 4\text{SiO}_2$ ,  $23\text{CaO} \cdot 13\text{Al}_2\text{O}_3 \cdot 3\text{Fe} \cdot 3.5\text{SiO}_2$ ,  $23\text{CaO} \cdot 13(\text{Al}_2\text{O}_3 \cdot \text{Fe}_2\text{O}_3) \cdot 3\text{FeO} \cdot 4.5\text{SiO}_2$ .

Finally, from the analysis of this phase in industrial aluminous cement clinkers, a general formula is suggested, (18) of the type :  $(\text{Ca}, \text{Na}, \text{K}, \text{Fe}^{\text{II}})_A (\text{Fe}^{\text{III}}\text{Al})_B (\text{Al}_{20}\text{O}_7)_8 (\text{AlO}_4)_{6-x} (\text{SiTiO}_4)_x$ , where A and B take on various values to maintain ionic balance. Typical values are given as A = 28, and B = 13 but wide variations were observed : A = 31, B = 10 to A = 20, B = 17.

### 1.3. Siliceous aluminate cements

Some studies of aluminous cement compositions with high silica contents are reported by OHTA and AKIYAMA, (19). In general, cements containing 10 to 16 %  $\text{SiO}_2$  showed the presence of  $\text{C}_3\text{A}$ ,  $\text{C}_{12}\text{A}_7$  and  $\text{CA}$ . Those with more than 18 %  $\text{SiO}_2$  contained large quantities of  $\text{C}_2\text{S}$  and  $\text{C}_2\text{AS}$ , and exhibited much less hydraulic activity. All the compositions studied contained little or no iron oxide. The behaviour of mixtures of some of these cements with a  $\text{CA/CA}_2$  cement of composition 33 %  $\text{CaO}$ , 60 %  $\text{Al}_2\text{O}_3$ , 3 %  $\text{SiO}_2$  and 4 %  $\text{Fe}_2\text{O}_3$  is also described. The 1, 7 and 28 days strengths of the high silica cements alone were much lower than for the  $\text{CA/CA}_2$  cement, but when added (20 %) to the latter, strengths were higher than those of the  $\text{CA/CA}_2$  cement itself. The improvement was greatest with siliceous cements having the highest C/A ratio but it is to be noted that the addition of pure  $\text{SiO}_2$  was also beneficial :

Table I : Summary of results from reference (19)

R* = Ratio of 1 day strength of 80 : 20 mixtures of CA/CA <sub>2</sub> and siliceous cements to the 1 day strength of CA/CA <sub>2</sub> cement alone.						
R*	1	1.2	1.27	1.5	1.9	2.3
SiO <sub>2</sub> content of siliceous cement	20%	20%	16%	100%	16%	16%
C/A ratio of siliceous cement	1.35	1.85	1	-	1.3	1.33
Reported mineralogical compositions of siliceous cement	CA C <sub>2</sub> AS C <sub>2</sub> S	CA C <sub>12</sub> A <sub>7</sub> C <sub>2</sub> S	CA C <sub>2</sub> AS C <sub>2</sub> S	pure silica	CA C <sub>2</sub> AS C <sub>2</sub> S	CA C <sub>12</sub> A <sub>7</sub> C <sub>2</sub> S
R	0	0.64	0.56	0	0	1
R = Ratio of 1 day strength of siliceous cement to the 1 day strength of CA/CA <sub>2</sub> cement.						

Mixtures containing more than 20 % of the siliceous cements showed progressively poorer performances except in the case of the highest C/A ratios. The above results are somewhat difficult to explain except perhaps an increase in the strength at ages less than 1 day which occurred with the cement having a C/A ratio of 1.85 but not with that having a C/A ratio of 1.35 - accelerating effect of  $C_{12}A_7$  ?

ZAKHAROV (20) has described the preparation of an alumina-belite cement with a chemical composition intermediate between that of aluminous cement and ordinary Portland cement. The raw materials, limestone and alumina rich clays, with a small quantity of gypsum as a mineraliser, are sintered at a relatively low temperature and then quenched. By this means (arresting the reaction before equilibrium is reached) a clinker is produced containing principally  $\beta$ - $C_2S$  and CA and avoiding the formation of the inert phase,  $C_2AS$ .  $\beta$ - $C_2S$  contents of 60 % can be obtained but the CA content is quite low. Most of the iron oxide in the raw materials appears to be in solid solution in the silicate and aluminate phases, while the gypsum is combined in the form of  $C_4A_3S$ .

This cement is further examined in another publication (21) under the title 'Porsal' cement. The clinker produced, also on a laboratory scale, contained approximately 60 %  $\beta$ - $C_2S$ , 15 %  $C_4A_3S$ , 9 %  $C_{12}A_7$  and about 6 to 7 % CA. Sintering was at approximately 1300°C for 20 minutes after which the product was air quenched.

As may be expected from its mineralogical composition this type of cement displays hydration kinetics more typical of Portland than aluminous cements. Thus a standard mortar made with Porsal cement at a water/cement ratio just below 0.5 attained 14 MPa in compression after 3 days normal curing, and 26.5 MPa after 28 days. So although this material contains nearly 20 % alumina, considerably more than is encountered in Portland cement, its chemical and physical characteristics are not those of the aluminous cement class.

SORRENTINO, (22) describes the preparation of a  $\beta$ - $C_2S$  -  $C_{11}A_7$ .CaX cement by sintering at approximately 900°C in the presence of water vapour and mineralisers such as fluorides, chlorides or bromides. This approach differs from that of ZAKHAROV in that equilibrium is established during the heating process. The presence of substantial quantities of the  $C_{11}A_7$ .CaX phase leads to very rapid setting and considerable amounts of gypsum are added to provide workable properties. Early strength development intermediate between that of Portland and aluminous cements is reported, but the system appears somewhat difficult to control.

## 2. HYDRATION

The general chemistry of aluminous cements has been extensively reviewed in past publications ; eg. ROBSON, 1962 (1), LEA, 1970 (23), TALABER, 1974 (2), - and the papers on this subject which have appeared from 1974 onwards, while extending previous knowledge substantially confirm many of the views previously presented.

It should be remembered that aluminous cements of the most generally encountered type (Fondu type), although containing mono-calcium aluminate as the principle phase, do not contain more than 50 % of this compound. Thus in understanding the hydration and other characteristics of this type of material, it is important to take due account of the several other hydraulic constituents present :  $C_{12}A_7$ ,  $C_2S$ ,  $C_4AF$ . Recent studies have not ignored this fact, but more work, particularly on the iron containing phases, is undoubtedly desirable.

### 2.1. Calcium aluminates

BARRET and co-workers (24) (25), have investigated the processes occurring during the initial period of contact of calcium aluminates with water - i.e the period up to the time of initial set. Pure CA and an aluminous cement (Fondu) were studied.

In a first series of experiments curves of the Wells type are compared with the behaviour of filtrates (B curves) obtained after the first 5 to 10 minutes of contact (21°C with agitation) which leads to the maximum solution concentrations of lime and alumina. When the solids are placed in contact with distilled,  $CO_2$  free water, the W curves (heterogeneous system - excess solid present) and the B curves (homogeneous system - solids removed by filtering) for pure CA, both exhibit a dormant period which is characterised by stability in solution concentrations of lime and alumina. By contrast, using cement, while the B curve shows a dormant period the W curves do not. This suggests that pure CA grains present during the determination of the W curves are not providing nucleation surfaces for hydrate formation, whereas a nucleation mechanism may occur when cement is used instead of synthetic CA. However, when the cement is shaken with a saturated filtrate obtained from CA and water or cement and water, both W and B curves show a dormant period. The lack of a dormant period in the cement-pure water system cannot therefore be attributed to heterogeneous nucleation by the cement grains.

In a second series of experiments, aluminous cement is pretreated with water for various periods (up to half an hour) before being placed in contact with a saturated filtrate. The longer the period of pretreatment the shorter the subsequent dormant period observed in the Wells curve. It is also observed that the length of the dormant period for fresh aluminous cement (not previously treated with water) in contact with filtrates, decreases as the degree of undersaturation of the filtrate increases. This clearly points to the initial dissolution of the cement as the critical factor which triggers bulk hydrate precipitation.

These results represent an important step forward in the understanding of the behaviour of calcium aluminates on first contact with water.

Another publication (26) (27), relates the initial dissolution of calcium aluminates to the pH of the solution phase. The process is seen to be diffusion controlled both from the kinetics of concentration change and the acceleration induced by agitation. Like that of BARRET, this work also used high liquid/solid ratios but also mono-crystals as a means of slowing the process down to more readily measure-

ble rates. Both CA and  $C_{12}A_7$  were studied. The pH of 11.5 developed is attributed to hydrolysis of aluminate ions formed from the dissociation of dissolved calcium aluminate:

In agreement with this, the solution concentration of aluminate increases with pH and achieves the same values for the CA-water system as is found in the alumina gel-water system. Also, artificially increasing the pH of the solvent phase reduces the rate at which calcium aluminate dissolves.

The lime/alumina ratio in solution was 1.1 to 1.2 irrespective of the nature of the starting aluminate and these results agree well with the papers previously described, where pure CA and aluminous cement each gave values at saturation in the same range. However it may be noted that the initial C/A ratio of solutions in contact with Fondu type cement is slightly higher than that obtained with pure CA.

The dissolution of  $C_{12}A_7$  is extremely rapid, more so than that of CA or  $CA_2$  (indeed the rate of solution increases with the lime/alumina ratio of calcium aluminates). Thus, without prejudice to the mechanism of hydrate formation suggested by BARRET (24) (25), the shorter dormant period for aluminous cement (containing some  $C_{12}A_7$ ) compared with that of pure CA, in the B curves shown in his publications, may be due, at least in part to this effect. Consistent with the above idea, is the known acceleration of the setting time of calcium aluminate cements when  $C_{12}A_7$  is present, as reported anew by SMITH, (28).

Reference (26) also reports that  $C_2AH_3$  is the hydrate first precipitated when CA is put in contact with water at 25°C (or  $C_4AH_{13}$  if nucleation is slow compared to the rate of solution of the anhydrous material), thus the CA is never in equilibrium with its own solution.

BERGER and PUSHNYAKOVA (29) studied the solubility of  $C_3AH_6$  in solutions of alkali metal hydroxides. Solubility increased with the concentration of alkalis (and hence pH) with Li preceding Na, preceding K, in order of activity. The effect of adding calcium hydroxide was to reduce the solubility. Solution concentrations of dissolved  $C_3AH_6$  reached a maximum value and then fell to a quasi-equilibrium level in which the solution coexisted with a solid phase in which some  $C_4AH_{13}$  was apparent by DTA analysis, and in proportions which increased with the concentration of hydroxide employed.

COSTA, MASSAZZA and TESTOLIN (30) describe the hydration of  $C_{12}A_7$  and  $C_{11}A_7 \cdot CaF_2$ . Although this study was directed towards the behaviour of Portland cements, the results are of interest for aluminous cements which frequently contain small percentages of  $C_{12}A_7$ . Calorimetric and X-ray diffraction experiments showed a dissolution, nucleation and bulk precipitation process qualitatively similar to that reported by other workers for CA and for aluminous cements. At 20°C the initial hydrate formed was  $C_2AH_3$  from  $C_{12}A_7$  and  $C_3AH_6$  from the fluoro-aluminate. This correlated well with a higher lime/alumina ratio

developed initially in the solutions of the latter material. At later stages (3 days or more)  $C_3AH_6$  also formed from solutions in contact with  $C_{12}A_7$ . Small quantities of  $CAH_{10}$  were apparently formed, which could be explained on the basis of stoichiometric differences between the composition of the anhydrous starting materials (C/A = 1.7) and that of the hydration products (C/A = 2 or 3). However, the concomitant formation of alumina gel (undetected by X-ray diffraction) is an alternative mechanism.

## 2.2. Calcium aluminoferrite

Aluminous cements of the Fondu type contain appreciable quantities of calcium aluminoferrite. Although the contribution of these ferrites to the hydration of aluminous cement is generally eclipsed by that of the more active mono-calcium aluminate, they should not be regarded as an inert constituent.

A detailed study of the hydration of  $C_4AF$  is reported by RAMACHANDRAN and BEAUDOIN, (32). Neat pastes at water/cement ratios of 0.3 to 1.0, and pressed discs with water/cement ratios of 0.08 and 0.13 were studied by thermogravimetry and X-ray techniques to identify the products of hydration. The accompanying changes in porosity, micro-hardness, hydrate morphology, surface area and specimen dimensions were also measured over periods up to 45 days. Hydration temperatures were 23 and 80°C, and 216°C in an autoclave in some cases. Hydration was rapid, with  $C_4(A,F)H_{13}$  the initial reaction product, which predominated at the lower temperature. However at the higher temperature of 80°C,  $C_3AH_6$  was increasingly formed, and the cubic hydrate was also favoured by the very low water/cement ratios achieved in the pressed discs. Of course, as may be expected, the degree of hydration was lower than in the higher water/cement ratio pastes. The hexagonal hydrate  $C_4(A,F)H_{13}$ , reported from the DTA analyses was not detected by X-ray diffraction.

At 23°C the surface area of the hydrated specimens decreased markedly with water/cement ratio. At 80°C the pattern is less clear since although a predominance of cubic hydrate tends to reduce surface area, the greater degree of hydration has an opposite effect. Complementary scanning electron micrographs showed a more compact hydrate structure associated with the lower surface areas, and with the higher hydration temperatures. Such structures are considered typical of a strong cementitious material. Porosity decreased with decreasing water/cement ratio and increasing degree of hydration. A parallel increase in microhardness was observed and a correlation between porosity (p) and microhardness (h) was found of the form,  $\log h = k_1 - k_2p$ , where  $k_1$  and  $k_2$  are constants. The coefficient of correlation was 0.978. This compares well with the results of COTTIN & REIF (31) on aluminous cement and synthetic CA.

The overall conclusion is that the formation of  $C_3(A,F)H_6$  as the hydration product of  $C_4AF$ , in place of the hexagonal hydrate  $C_4(A,F)H_{13}$  of lower density, which appears to an important degree at lower temperatures and high water/cement ratios, need not be detrimental to the mechanical properties of cements containing  $C_4AF$  - Portland cement, and aluminous cement made from red bauxite. This paper thus provides valuable evidence in support of the contribution

of the ferrite phase to the strength development of aluminous cements. It can obviously contribute to the long term strength of this material at 'normal' service temperatures, and more so to massive aluminous cement structures which develop high internal temperatures during the initial cure, or concretes which are deliberately heat cured.

### 2.3. Calcium alumino-silicate

Another hydrate which may play a significant role in the later age strength of aluminous cement is  $C_2ASH_8$ , (33). Thus MIDGLEY describes the formation of stratlingite from the reaction between  $CAH_{10}$  and CSH.

$CAH_{10}$  is of course, a major product of the low temperature hydration of aluminous cement, while CSH is intrinsically available due to the presence of  $\beta$ - $C_2S$  as a minor constituent. The reaction of aluminium gel with CSH to form  $C_2ASH_8$  only occurs in the presence of CH, which is absent in hydrated aluminous cement. Although the formation of  $C_2ASH_8$  was demonstrated with experimental cements of an aluminous character formulated to encourage its presence, the contribution to strength could not be conclusively demonstrated.

The use of fly-ash as an addition to aluminous cement is advocated in another publication, (34). The authors suggest that  $C_2ASH_8$  and CSH are formed by such additions, and show that the solution concentrations in contact with such modified cements exhibits a lower than normal C/A ratio. The presence of these calcium silicate hydrates may enhance strength but the lower C/A ratio, by discouraging the formation of  $C_3AH_6$  in favour of the hexagonal hydrates of lower density is considered to be the main advantage of the fly-ash addition.

While it is undoubtedly true that the addition of a material which absorbs calcium ions will modify the pattern of the normally produced hydration products of aluminous cement, the use of fly-ash for this purpose is of doubtful value since its principal effect is as a diluent of otherwise more active hydraulic material. Also while the presence of fly-ash may hinder, it is unlikely to permanently prevent conversion. Moreover, fly-ash is an intrinsically variable material. So, although the addition of this material to aluminous cement may be of chemical interest, support for such a combination in practice is difficult to find.

A study of the hydration of Forsal cement (21) presents  $C_2ASH_8$  and  $C_4AH_{13}$  as the initial products formed. However, as mentioned in section 1.3., the chemical composition of this type of cement is more typical of Portland than aluminous cement, and more detailed consideration of this paper is not warranted in the present review.

### 2.4. Hydrate solid-solutions

The formation of complex hydrates from  $C_4AH_{13}$  and  $C_2AH_8$  has continued to attract research interest. The ionic constitution of these hydrates is :  $Ca_2Al(OH)_6^+$ ,  $OH^-$ ,  $3H_2O$ ,  $(C_4AH_{13})$ , and  $Ca_2Al(OH)_6^+$ ,  $Al(OH)_4^-$ ,  $3H_2O$ ,  $(C_2AH_8)$ . A solid solution between these two end members occurs when, for example,  $C_4AH_{13}$  absorbs aluminate ions from sodium aluminate

solution, (35). However, such solid solutions are only reasonably stable at low temperatures ( $0^\circ C$ ) and tend to decompose in alkaline solutions, to  $C_3AH_6$ .

The structure of these types of hydrates consists of cationic layers of  $Ca_2Al(OH)_6^+$ , separated by interlayers containing anions surrounded by water. The  $OH^-$  anion, or the aluminate anion can be substituted by a wide range of other mono or divalent anions, giving complex hydrates of the general formula :  $[Ca_2Al(OH)_6]^+ + [m/n X^{n-} \cdot (1 - m)Al(OH)_4^- \cdot mAl(OH)_3 \cdot aq.]^-$ . In this formula,  $n$  is the valency of the substituting anion  $X$ , and  $m$  is the degree of substitution.

KUZEL and SCHELLER, (36) show that  $\alpha$  and  $\beta$ -di-calcium aluminate hydrates are not polymorphs as previously proposed, but differ slightly in their water content :  $\alpha$ - $C_2AH_8$  and  $\beta$ - $C_2AH_{7.5}$ . The  $\alpha \leftrightarrow \beta$  transformation temperature lies near  $20^\circ C$  ( $18^\circ C$  at 36 % relative humidity,  $26^\circ C$  in nitrogen at more than 45 % relative humidity). The stacking of the  $Ca_2Al(OH)_6^+$  layers differs in the two forms.

DOSCH and KELLER, (35) have studied a wide range of anions, both inorganic and organic which can be introduced into  $C_4AH_{13}$  without modification of the cation layers, as shown by X-ray diffraction. The  $C_4AH_x$ - $C_2AH_8$  solid solution range is given as lying between  $m = 0.5$  and  $m = 0.7$ , in contrast to the range 0.66 to 1 previously reported.

The stabilization of  $C_2AH_8$  is also described by DOSCH and KOESTEL, (37). A number of anions, and particularly  $CrO_4^{2-}$  and  $SO_3^{2-}$  from the calcium salts are shown to form complex hydrates, stable in moist conditions up to  $70^\circ$  or  $80^\circ C$ , conditions under which  $C_2AH_8$  alone is very rapidly transformed into  $C_3AH_6$  and  $AH_3$ . This is suggested as a basis for preventing the conversion of aluminous cement. In support of this, the strengths of aluminous cement specimens, with and without the addition of these compounds ( $CaSO_3 \cdot 1/2H_2O$  and  $CaCrO_4$ ) are compared after 1, 7 and 28 days storage under water at  $30^\circ C$ . Specimens without the additives showed the highest strength at 7 days but the lowest at 28 days, compared to the stabilised product. A stabilising effect was thus evident, but longer term tests would be needed before any conclusion could be drawn about durability. From a practical point of view the quantities of 'stabilising' agent required (2.2 to 10.7 % by weight) are rather large.

HOUTEPEN and STEIN, (38) have studied the dehydration of  $C_2AH_8$  hydrates containing substituted mono-valent anions, by calorimetry and using a thermo-balance. The enthalpy of dehydration,  $\Delta H_{deh}$ , determined calorimetrically from the heats of solution of the hydrate and the dehydrated compound, were significantly lower than those calculated using the Clausius-Clapeyron equation, from the hydration and dehydration curves observed thermogravimetrically. This is explained by hysteresis in the hydration-dehydration curves associated with the change in the layer spacings of the crystals, necessary to accommodate the interlayer water. It is concluded that the heat of dehydration cannot be determined as isosteric heat of adsorption (i.e thermogravimetrically) because the dehydrated material is not an inert adsorbent.

BENSTED, (39) reports an investigation of calcium nitro-aluminate hydrate using infra-red spectroscopy, X-ray diffraction, DTA and chemical analysis. Calcium nitrate is shown to react with  $C_3A$  to form compounds of the general type:  $C_4[Al(OH)_6]_2 \cdot (NO_3)_2 \cdot 3H_2O$  or  $C_3A \cdot Ca(NO_3)_2 \cdot 9H_2O$ . Furthermore, the aluminium ion can be substituted by other trivalent cations, Cr, Mn or Fe. The nitro-aluminates thus resemble the chloro-aluminates and do not form higher substitution products, isomorphous with ettringite, at normal temperatures, probably for steric reasons.

The incorporation of chloride (from  $CaCl_2$ ) in various calcium aluminate hydrates, is reported by DARR and LUDWIG, (40).  $C_4AH_{13}$ ,  $C_4(A_{0.5}F_{0.5})H_{13}$ ,  $C_3A \cdot CaSO_4 \cdot 12H_2O$  and  $C_3A \cdot 3CaSO_4 \cdot 32H_2O$  were prepared by mixing appropriate proportions of  $C_3A$ ,  $C_4AF$ ,  $Ca(OH)_2$  and  $CaSO_4$  in water at a water/solids ratio of 2. Additions of  $CaCl_2$  were then made at 5°C, 20°C and 40°C. The highest  $CaCl_2$  addition was 1 mole/mole and  $C_4AH_{13}$  and  $C_3A \cdot CaSO_4 \cdot 12H_2O$  both proved capable of absorbing up to 0.9 moles of chloride. The mono-sulphate hydrate reached equilibrium later and took up slightly less than the tetra-calcium aluminate hydrate. Ettringite appears in increasing quantities when the mono-sulpho aluminate hydrate takes up  $CaCl_2$ . The iron substituted tetra-calcium aluminate hydrate absorbed only about half the quantity of chloride added. Up to 0.8 moles of  $CaCl_2$  were incorporated in ettringite at 5°C after 28 days. At 20°C, only 0.4 moles were absorbed after 100 days and 0.3 moles at 40°C, also after 100 days. In general, both the rate of incorporation of chloride in these hydrates and the total equilibrium quantity absorbed increases with the solution concentration of chloride added, but decreases as temperatures are raised.

## 2.5. Some effects of heat and pressure

BARRET and DUFOUR, (41) discuss the solubility of dehydrated mono-calcium aluminate hydrate. Dehydration under vacuum at temperatures up to 90°C removes water from the  $CAH_{10}$  structure progressively and the solubility in water of the dehydrated product increases from that of  $CAH_{10}$  to that of  $CA$ . When dehydration is carried out above 90°C (100 to 900°C), subsequent re-solution takes the form of a rapid increase in solution concentrations, to a maximum greater than that shown by  $CA$  itself, followed by abrupt precipitation and a decrease in concentrations to a normal and steady level. A few hours later, further precipitation occurs and solution concentrations fall to low values.

The dehydration products of  $CAH_{10}$  are amorphous until 900°C is reached, when X-ray diffraction and infra-red spectroscopy show the appearance of the  $CA$  structure. The re-solution is understood to take place through an initial hydroxylation of the solid surface and not through bulk solution of the dehydrated material. Since the precipitated hydrates formed by  $CA$  at room temperature are both  $CAH_{10}$  and  $C_2AH_8 + AH_3$  gel, while that of dehydrated, amorphous  $CAH_x$  is exclusively  $CAH_{10}$ , it is suggested that the 'amorphous' product still reflects the original hydrate structure and thus seeds the precipitation of  $CAH_{10}$ . High resolution electron microscopy and electron diffraction appears to confirm this conclusion. It is also observed that the precipitation of

$CAH_{10}$  from solutions formed by the dehydrated product does not lead to setting and hardening unless the original dehydration has been accomplished above 900°C - i.e., resulting in the formation of  $CA$ . Thus while precipitation of hydrate is a necessary condition for strength development it is not sufficient. This supports the view that hydrate morphology is also a critical factor for hydraulic bonding.

KUZEL, (42) suggested that the thermal dehydration of  $C_3AH_6$  occurs by the formation of  $C_{12}A_7$  and  $CH$ , and BALL, (43) provides confirmation with thermogravimetric and infra-red studies: for the reaction  $7C_3AH_6 + C_{12}A_7H + 9CH$  at 527°C the weight loss measured, 21.7 % agrees well with that calculated, 21.77 %.

Another study, (44) of the dehydration of  $C_3AH_6$  and  $\gamma-AH_3$  shows that gibbsite present in high alumina cement,  $CA$  or  $CA_2$  hydrated at 100°C (in which  $C_3AH_6$  is the other hydrate formed) loses its water without passing through the monohydrate (boehmite) stage, whereas in synthetic mixtures of separately prepared  $C_3AH_6$  and  $\gamma-AH_3$ , boehmite appears as a transition phase during dehydration. Further results on the dehydration of hydrated neat high alumina cements used in refractory formulations, are reported by WAGNER, (45).

Iron free high alumina cements containing less than about 0.2 %  $SiO_2$  are frequently employed as binders for cracking catalysts used in the manufacture of hydrogen by steam reforming of hydrocarbons, at temperatures approaching 1000°C, and the development of one such cement specifically for this purpose is reported, (46). Because of destruction of hydraulic bonding and the relatively slow rate of ceramic bond formation in this service temperature range, MILLS and HUGHES, (47) have studied the effects of curing such cements in steam and in carbon dioxide atmospheres: the effects of curing conditions on the intermediate temperature strength of aluminous cements is known to be important, (48), (49), (50). A cement consisting primarily of  $CA$ , cured at room temperature in air at 0.5 W/C is only partially hydrated in the first 2 days. Its 20°C strength, due to  $CAH_{10}$ , is good but its performance in steam at 850°C is indifferent. Curing in steam produces  $C_3AH_6$  and  $AH_3$  with complete hydration and its behaviour as a catalyst support binder is good. Curing in  $CO_2$  at normal temperatures produces  $CaCO_3$  and  $C_3AH_6$  with green strengths as high as those obtained from  $CAH_{10}$  at similar levels of hydration. Because of the high reactivity of the decomposition products, the performance at 850°C exceeds that obtained by steam curing with full hydration.

The effects of curing Fondu aluminous cement (approximately 40 %  $Al_2O_3$ ) and Secar, high alumina cement (approximately 70 %  $Al_2O_3$ ) under even more drastic conditions, is described by GOUDA and ROY, (51), who used a hot-pressing technique. Hot-pressing at 250°C for 1/2 hour at approximately 350 MPa produced  $C_3AH_6$ , and virtually all the gauging water was combined. At longer periods,  $C_4A_3H_3$  was also formed. No  $CH$  was detected with either cement even after 1 year. Hot-pressing at 150°C did not lead to the formation of  $C_4A_3H_3$ . Very high strengths and low porosities were obtained by this method with both cements, but it is noteworthy that the high alumina

cement gave less good strengths than the ordinary type, despite its greater calcium aluminate content. (The CA + CA<sub>2</sub> content of the Secar cement studied is approximately 50 % greater than that of Fondu cement). The water/cement ratios used were the same in both cases and much lower than the critical values (\*), and virtually all (approximately 99 %) of the water provided was combined. The possible conclusion that the morphology of the hydration products and hence their contribution to mechanical properties, is favorably affected by the non-aluminous contents of the lower purity cement remains to be proved.

FARRIS and MASARYK, (53) investigated the mineral products formed in dense massive refractory concretes made from high alumina cement. The initial hydrates normally found in 110°C dried concrete, C<sub>3</sub>AH<sub>6</sub> and γ-AH<sub>3</sub> were present, but progressively towards the centre of massive specimens, C<sub>4</sub>A<sub>3</sub>H<sub>3</sub> and AH (boehmite) were detected. These phases are known to form under pressure and it is concluded that conditions within the body of a large concrete specimen approach that of an autoclave. This is because the initial rapid heat evolution during hydration cannot be quickly dissipated. The effect is intensified at lower water/cement ratios. However, comparisons between small and large specimens revealed no influence of the different mineralogies on the strengths of the concretes.

### 3. CARBONATION

The equations for carbonation of calcium aluminate hydrates may be written :

In both cases, water is released and it may thus be expected that a decrease in strength with increase in porosity will result. This is not the case in practice, indeed, the reverse occurs and one explanation is that of further hydration of anhydrous cement by the water released. The overall effect would thus be :

In these circumstances the total weight of solid reaction products after carbonation is greater due to the incorporation of atmospheric CO<sub>2</sub>, and this would be expected to decrease porosity and increase strength : the increase in the volume of solids represented by the above reaction is about 10 %.

A study of the hydration of synthetic CA in the presence of silica or of CaCO<sub>3</sub> is reported, (54). DTA and X-ray diffraction were used to identify the reaction products at 5, 20 and 40°C. In the presence

of silica CAH<sub>10</sub> was formed at 5°C, and traces of C<sub>3</sub>AH<sub>6</sub> became detectable after 45 days. Alumina gel and gibbsite were present at all ages. At 20°C both CAH<sub>10</sub> and C<sub>2</sub>AH<sub>8</sub> were formed together with the alumina hydrates while some C<sub>3</sub>AH<sub>6</sub> was apparent earlier (28 days) than at 5°C. At 40°C, CAH<sub>10</sub> and alumina gel formed at ages less than 1 day were no longer apparent at later ages, while large quantities of C<sub>3</sub>AH<sub>6</sub> and gibbsite were observed. This pattern of behaviour is entirely consistent with the results of earlier investigations.

In the presence of CaCO<sub>3</sub>, CAH<sub>10</sub> was less in evidence at all temperatures but the appearance of C<sub>3</sub>AH<sub>6</sub> was also depressed in favour of the appearance of mono-carbo aluminate hydrate, C<sub>3</sub>A.CaCO<sub>3</sub>.11H<sub>2</sub>O. It is concluded that the rate of conversion is lower in the presence of CaCO<sub>3</sub> and that the formation of carbo-aluminate in place of C<sub>3</sub>AH<sub>6</sub> must reduce porosity and hence improve the strength of aluminous cement concrete.

Support for the above conclusion is given by RAASK, (55) who studied the absorption of CO<sub>2</sub> by hydrated aluminous cement paste with water/cement ratios of 0.38 to 1.0, at temperatures of 17°C and 37°C. From laboratory measurements of the rate of uptake of CO<sub>2</sub>, an equation was derived which predicted well the measured penetration of CO<sub>2</sub> into a 5 year old aluminous cement concrete beam assuming a service temperature of 22°C. However, beams which had been in service for 8 years at 37°C showed a much lower than predicted depth of CO<sub>2</sub> penetration. This is explained by lack of liquid water in the latter case, which virtually prevents the carbonation reaction. In a further series of tests at 0.38 total water/cement ratio carbonation was shown to decrease the degree of conversion and increase the strength of aluminous cement concrete treated in a CO<sub>2</sub> atmosphere at 52°C.

KUZEL and FISCHER, (56) have restudied the carbonation of tetra-calcium aluminate hydrates at various temperatures and relative humidities. No evidence of solid solutions was found in the system C<sub>4</sub>A.nH<sub>2</sub>O - C<sub>3</sub>A.CaCO<sub>3</sub>.nH<sub>2</sub>O. Starting from C<sub>4</sub>AH<sub>10</sub> or C<sub>4</sub>AH<sub>13</sub> crystals, carbonation leads only to a surface zone of half carbonate, C<sub>4</sub>A.1/2CO<sub>2</sub>.12H<sub>2</sub>O while the bulk of the crystals remain unaffected.

FIERENS et al, (57) have studied the formation of tricalcium aluminate mono-carbonate hydrate from mixtures of C<sub>3</sub>A and CaCO<sub>3</sub>, or C<sub>3</sub>AH<sub>6</sub> and CaCO<sub>3</sub>, in water at 25°C. The formula C<sub>3</sub>A.CaCO<sub>3</sub>.11H<sub>2</sub>O is given. This compound is known, (58) to form as the interface material between the cement paste phase and limestone aggregate in aluminous cement concretes, and may explain the higher strength of such concretes compared to those made using siliceous aggregates. The very rapid formation of the carbo-aluminate from C<sub>3</sub>A and CaCO<sub>3</sub>, together with the simultaneous presence of C<sub>4</sub>AH<sub>13</sub> is taken to imply the reaction scheme : C<sub>3</sub>A + H + C<sub>4</sub>AH<sub>10</sub> → C<sub>4</sub>AH<sub>13</sub> + CO<sub>2</sub> + C<sub>3</sub>A.CaCO<sub>3</sub>.11H<sub>2</sub>O. It is believed that the hydration of C<sub>3</sub>A in the presence of CaCO<sub>3</sub> does not lead to the formation of C<sub>3</sub>AH<sub>6</sub> as a precursor to the carbo-aluminate. FIERENS also demonstrates that the attack of CaCO<sub>3</sub> in the presence of C<sub>3</sub>A/H<sub>2</sub>O is greatest on those crystals faces with the highest density of CO<sub>3</sub><sup>=</sup> ions.

(\*) The critical water/cement ratio for an aluminous cement has been defined by ALEGRE (52) as that needed for complete hydration in the fully converted state.

An extensive study of carbonation of aluminous cement concrete was reported by VASQUEZ and co-workers (59) at the 1974 International Symposium on the Chemistry of Cement (Moscow), and published in 1975. Here again a reduction in the rate of conversion is observed in the presence of  $\text{CO}_2$ . Short periods (2 weeks) of carbonation at relatively low temperatures ( $20^\circ\text{C}$ ) appeared to show reversibility, wherein carbo-aluminate could be decomposed under vacuum to reform  $\text{C}_3\text{AH}_6$ . Longer periods of carbonation, and particularly higher temperatures, ( $43^\circ\text{C}$ ) produced a carbo-aluminate which was stable. Thermogravimetric analysis, X-ray diffraction and infra-red spectroscopy were used to identify reaction products and evidence is presented to show that  $\text{CO}_2$  substitutes step wise for 2, 4 and ultimately 6 molecules of water in the  $\text{C}_3\text{AH}_6$  hydrate in a manner analogous to the formation of hydraogarnets in the presence of silica. The final products of the reaction between  $\text{C}_3\text{AH}_6$  and  $\text{CO}_2$  are calcium carbonate and alumina hydrate.

As a general rule it may be stated that a carbonation of aluminous cement will only proceed at a significant rate in the presence of liquid water and when sufficient porosity exists to accommodate this water and allow penetration of  $\text{CO}_2$ . It thus follows that dense, low water/cement ratio material will show only very small depths of reaction even after many years. Recent studies, (60) of 25 aluminous cement concrete beams aged less than one year to up to 20 years showed exceptionally 60 mm penetration in the oldest beam, less than 5 mm in the youngest but 5 to 10 mm on average at ages up to 17 years. The water/cement ratios of these beams are not accurately known but are estimated to be generally 0.5 to 0.55 total, (61) which is relatively high.

RAUEN, (62) commenting on the failure of prestressing wires in some aluminous cement concrete of Bavarian origin (1962), reports depths of carbonation of several centimetres in 1 year old samples. Such a degree of attack is only conceivable in extremely porous, wet concrete made at very high water/cement ratios, but no information on this point is given. At the levels of attack reported by RAUEN the prestressing wires were inevitably in the carbonated zone and this may have contributed to one of the several forms of steel corrosion observed. By contrast, significant corrosion of prestressing wires was not observed in the very large number of concrete units of widely different ages, examined in the UK in recent years, (60), despite evidence of higher than recommended water/cement ratios. There is thus no evidence for depassivation of reinforcement due to carbonation in well made aluminous cement concrete.

Carbonation in the presence of alkalis (sodium and potassium hydroxides), in contrast to normal carbonation, can seriously weaken aluminous cement bonded materials. This has been known for a long time and the mechanism, usually referred to as alkaline hydrolysis, was explained by RENGADE, L'HOPITALIER and DURAND DE FONTMAGNE, (63) working in the Lafarge laboratories as early as 1935. The alkali is regenerated in the process so that relatively small quantities can sustain the reaction. The final reaction products,  $\text{CaCO}_3$  and  $\text{AH}_3$  are the same as when carbonation occurs in the absence of alkalis,

but the effect on strength is reversed. It is therefore highly probable that the two different mechanisms involved in the presence or in the absence of alkalis affect the morphology of the reaction products, but this remains to be proved.

From a practical point of view carbonation only reaches significant proportions when porosity or permeability is high, so that while alkaline hydrolysis was a problem in some early uses of aluminous cement concrete, it is very rarely encountered today, as NEVILLE, (64) points out. Now that the importance of maintaining a low water/cement ratio is recognised, aluminous cement concrete manufactured with a porosity high enough to engender alkaline hydrolysis must be considered unacceptable for long term applications whether alkalis are present or not.

#### 4. CONVERSION AND ITS EFFECTS

As in the past, so during the period covered by this report a high proportion of publications concerning aluminous cement discuss conversion and its effects on durability. Several papers (65), (66), (67) report the results of long term laboratory tests on aluminous cement concrete under various storage conditions, both artificial and natural. The effects observed are then explained in terms of conversion, wherein strength changes are related to changes in porosity of the cement paste phase. However, direct measurements of porosity are regrettably rare.

The overall consequence of recent publications is a substantial confirmation of previous knowledge.

Quantitative comparisons of the results of different workers is difficult due to different choices of experimental conditions: cement contents, mixing procedures, methods of compaction, curing and storage environments and water/cement ratio.

##### 4.1. Rate of conversion

MIDGLEY and MIDGLEY, (68) give a comprehensive account of conversion, bringing together a large amount of experimental data, some of which was reported prior to 1974. From laboratory tests on neat cement pastes, mortars and concretes a number of empirical relationships are developed relating conversion to both compositional factors (mineralogy and water/cement ratio) and environmental factors, (temperature, humidity, age). Rate of conversion is seen to be increased by temperature and humidity of curing and storage of specimens, as previously established. These authors also present evidence, (69) to show that, other factors constant, the rate of conversion increases with water/cement ratio. For concrete specimens stored under water at  $18^\circ\text{C}$  this appears to be the case with total water/cement ratios of 0.5 or more, at ages of 5 years and later. The effect is shown in figure 1. It is swamped by the effect of temperature when similar concretes are stored at  $38^\circ\text{C}$ .

  - + concrete after 8 1/2 years at 18°C
  - concrete after 8 1/2 years at 38°C
- Data from reference 66

Fig.1 - Water/cement ratio related to degree of conversion

The effect of conversion on the compressive strength of aluminous cement is then discussed and extensively illustrated. The results confirm that the minimum strength of aluminous cement increases with decreasing water/cement ratio, and also that the minimum strength is higher the slower the conversion takes place. Note that the rate of conversion is dependent on temperature, an increase in one being accompanied by an increase in the other. Consequently minimum strengths are higher when conversion takes place at lower temperatures. This is well known, (1).

A general expression,  $S = (k \log_e R + p) + q(w - m)$ , is given, where  $S$  is the minimum strength expressed as a percentage of the 1 day unconverted strength,  $w$  is the water/cement ratio (the water/cement ratio used would appear to be total water/cement ratio) and  $k$ ,  $p$ ,  $q$  and  $m$  are constants.  $R$  is the rate of conversion defined as:  
 $R = \log_e Dc / \{\log_e \text{age (years} \times 10^6)\}$ ,  $Dc$  being the degree of conversion, determined by DTA.

BRADBURY, CALLAWAY and DOUBLE, (70) have studied conversion in neat high alumina cement pastes of the 'Secar' type, containing  $CA$ ,  $CA_2$  and free alumina. Low, (0.2) and high, (0.6) water/cement ratios were used and curing temperatures of 18°C and 40°C. The hydrates produced were examined by DTA and electron microscopy. The initial formation of  $CAH_{10}$  and  $C_2AH_3$ , followed by conversion to  $C_3AH_6$  exhibited the normal pattern. There was qualitative evidence that conversion was less rapid at the lower water/cement ratio and the size of the  $C_3AH_6$  crystals was smaller than at the high water/cement ratio. An examination was also made of variations in the degree of conversion through a section of an aluminous cement concrete beam. Within the bulk of the concrete the degree of conversion was high (70 % typically) but near, or at the surfaces, values of 40 to 50 % occurred. This

accords well with the frequently observed 'skin' effect on aluminous cement concretes due to a lower rate of conversion as a result of drying, or to the superficial effects of carbonation.

The authors also remark that substantial variations in the water/cement ratio may occur from point to point in a concrete due to segregation effects before hardening commences, and that in aluminous cement concrete this can cause important differences in the degree of conversion and hence strength. The implication is, of course, that deleterious localised weakening will result and that the effect will be aggravated by errors in the control of water/cement ratio.

Two points may be made: (1), aluminous cement concretes should be designed on converted strength, (2), when the converted strength is taken as that resulting from rapid conversion (at 38°C) - severe in practice - this strength is not more sensitive to water/cement ratio than in the case of a corresponding Portland cement concrete, (66).

#### 4.2. Long term behaviour

TEYCHENNE, (66) reports the results up to 9 years of a major programme aimed at characterising the long term strength (in compression) of aluminous cement concrete. Concretes with total water/cement ratios ranging from 0.3 to 0.8 were stored under water at 18°C and also, after 24 hrs curing at 18°C, under water at 38°C (100°F). This latter temperature is considered a realistic maximum in practice for concrete in buildings in temperate climates. The cement used displayed converted strengths in the lower range of normally encountered values as was demonstrated by shorter term repeat tests on a number of other cements of the same origin. Its behaviour corresponded in fact, to the characteristic strength (95 % confidence) of the product tested. The data reported clearly reproduces the now well known sigmoidal strength development curve of aluminous cement concretes, although some doubt is left about the degree of strength increase beyond the minimum, due to the fact that the test age had not exceeded 8 1/2 to 9 years at the time of publication.

In view of this, and the importance of a real and significant increase in strength beyond the so-called minimum converted strength of aluminous cement concretes, the opportunity is taken to extend the results reported by TEYCHENNE, and also by GEORGE, (67) with the data shown in figure 2. The test programme represented by figure 2 was initiated in 1955, and in appreciating the value of the results today it is important to realise that 25 years ago, the relationship between the unconverted and converted properties of aluminous cement was considerably less well established and understood. Thus while it was evident that if porosity increased due to conversion this increase would not exceed that corresponding to complete conversion, the results shown in figure 2 and other long term tests which have now become available, are important: they establish with a degree of confidence never provided by accelerated tests, that there is a significant strength gain beyond the minimum converted value, and that this gain is considerable at lower water/cement ratios.

○ indicates minimum strength when the effects of conversion are complete

Fig. 2 - Concretes cured 24 hours in moist air at 18°C then stored outdoors (S. France)

#### 4.3. Conversion and curing

An interesting feature of the work reported by TEYCHENNE is the effect of different curing regimes on subsequent strength development. The experimental procedure was to cure concrete cubes under water either at 18°C or at a higher temperature (25, 35 or 50°C). The period at the higher temperature was varied from 3 hours to 24 hours and began immediately after placing the concrete, or after different periods (up to 21 hours) of curing at 18°C. It was found that the temperature of 25°C had relatively little effect, but the higher temperatures induced lower strengths at earlier ages, if imposed immediately after placing, than if delayed for 3 to 6 hours. Accompanying DTA estimates of the degree of conversion show a consistent pattern. Some examples are given in table II.

TEYCHENNE offers no explanation of this effect.

COTTIN and GEORGE, (71) studied the effect of steady and oscillating curing and storage temperatures on neat aluminous cement pastes. Seales pastes (to prevent carbonation) at a water/cement ratio of 0.4 were stored from time of gauging continuously at 30°C and 38°C. Other equivalent specimens were cured for 24 hours at 20°C, then for 24 hours at 30°C, at 20°C the following day, and so on. Finally the cyclic temperature test was repeated but with the initial 24 hours being at 30°C, followed by 20°C, etc. X-ray diffraction, DTA and infra-red spectroscopy were used to identify the hydrates formed and the proportion of cement reacted, while the percentage bound water was also measured. In parallel,

Table II : The effect of different curing regimes on degree of conversion and compressive strength of concrete

Data from reference (66)	Curing regime under water		T°C	Strength ratio (%) after 3 months, regime X/ regime Y		
	6 hours at T°C, then 18 hours at 18°C (regime X)	18 hours at 18°C then 6 hours at T°C (regime Y)		Total water/cement ratio		
				0.4	0.5	0.6
Degree of conversion  after 3 months	75	15	50	37	38	31
	40	10	35	95	49	36
	20	15	25	99	107	109

compressive strengths and penetration resistance of the specimens was recorded. At 38°C, C<sub>2</sub>AH<sub>8</sub> formed initially, was fully converted after 2 days and C<sub>3</sub>AH<sub>6</sub> and AH<sub>3</sub> were the principal phases. The CA and alumino-ferrite contents of the cement were rapidly reacted. At 30°C the same effects occurred more slowly with C<sub>2</sub>AH<sub>8</sub> finally disappearing after about 2 weeks. No CAH<sub>10</sub> was detected in either case.

The behaviour under cyclic curing depended on whether the first 24 hours curing took place at 20°C or at 30°C. In the latter case, the behaviour was qualitatively identical to that observed for continuous curing at 30°C. Despite subsequent 24 hour curing periods at 20°C, no CAH<sub>10</sub> was detected. By contrast when the initial curing was at 20°C, CAH<sub>10</sub> formed, and continued to form during later periods at 30°C, for up to 4 months. Beyond this age, with virtually complete hydration of the cement, the C<sub>3</sub>AH<sub>6</sub> and AH<sub>3</sub> contents continued to rise while the CAH<sub>10</sub> gradually converted. C<sub>2</sub>AH<sub>8</sub> formed only during the first 24 hours and disappeared after 2 days curing.

All this suggests that there is some sort of seeding or epitaxial effect whereby the form of the hydrate initially precipitated at the end of the dormant period, (initial set) or during the early stages of hydrate development, influences the further hydrate form, and hence both the measured degree of conversion and the associated mechanical properties. This hypothesis is also consistent with the effects mentioned above, observed by TEYCHENNE.

Another observation, (66) which appears to reflect the same phenomenon is that conversion is slower at a given temperature if the initial curing temperature is low. Thus concretes cured at 18°C for 24 hours and then stored at 38°C reach their minimum converted strength at a degree of conversion of 80 - 85 % after 3 months. Equivalent concretes cured and stored continuously at 38°C after placing, reach the same minimum strength after a few days. The inference is that the hexagonal hydrate, or CAH<sub>10</sub> at least, after a few hours ageing, is more resistant to conversion than at its time of formation. However, from a practical point of view the fact that the effect on strength is the same whether conversion is immediate or delayed, is the most important conclusion. This is another way of saying that the dominating factor for conversion is temperature; whether a concrete is subjected intermittently to an elevated temperature or continuously, immediately or later, the overall result will be the same.

This is one of the less widely known features of aluminous cement. It should not be confused with the fact that conversion occurs faster, and minimum strengths are lower and earlier, the higher the curing or storage temperature, (68), (72).

The long term tests reported by GEORGE, (67) involve a range of curing conditions (10 to 90°C), total water/cement ratios from 0.33 to 0.67 and 3 different storage conditions: - under water at 18°C, outdoors and in an outdoor hangar where specimens are protected from direct rain water. This last condition proves the most severe since not only did the concrete cubes experience climatic temperature variations from at least - 10°C to at least + 40°C,

but the effects of drying-out are not alleviated by liquid water. By contrast, storage under water at 18°C gave the highest and least variable strengths. The results over 10 years are in very good agreement with the 20 year test results reported for the first time in the present review and extend the work of TEYCHENNE to a wider range of storage conditions. They also show that if initial curing temperatures are sufficiently high to bring about a major degree of conversion the concrete increases in strength thereafter. It is suggested, (65), (72) that this offers a method of producing high strength concrete.

#### 4.4. Porosity

Although there is virtually universal agreement that porosity changes accompany conversion, relatively little experimental information (30), (60), (68) on this point has been published since 1974. The subject was very thoroughly studied earlier, (31) and it was demonstrated that the compressive strength of aluminous cement paste is related to porosity by an expression of the form:  $\log C = a - bP$ , where C is compressive strength and P is the percentage porosity.

Table III : Results from reference (31)

Curing temperature	Constants		Coefficient of correlation	Conditions
	a	b		
10°C	3.331	0.085	0.997	unconverted
70°C	3.714	0.105	0.976	converted

The porosity of concrete will depend on that of the aggregates used, voids due to entrained air or inadequate compaction, but primarily on that of the cement paste phase. Porosity will thus depend on cement content and water/cement ratio. Figure 3 shows results obtained, (73) through laboratory and field tests, on converted aluminous cement concretes. Some data on Portland cement concrete is included for comparison. Qualitatively, these results confirm earlier findings that conversion causes an increase in porosity and that this effect is greater the higher the water/cement ratio. However, from a quantitative point of view it is important to see that the fully converted porosity of aluminous cement concrete is not greater than, but if anything, less than that of a Portland cement concrete at the same water/cement ratio. Such a finding is clear indication that conversion does not automatically imply lack of durability. Water/cement ratio and temperature taken together are the decisive factors.

Fig. 3 - Porosity of cement paste as a function of water/cement ratio

## 5. ALUMINOUS CEMENT CONCRETE IN SERVICE

### 5.1. Mineralogical characterisation

Many publications have appeared describing methods of measuring the degree of conversion of aluminous cement. In most cases they have been developed as tools for assessing the quality of concretes made with this cement. Thermogravimetric and derivotographic techniques have received the most attention, and in particular the procedure reported by MIDGLEY, (74). It is clear from this work that the DTA method, and similar techniques such as differential scanning calorimetry DSC, semi-isothermal gravimetry and derivative thermo-gravimetry, DTG (75), offer a high degree of reproducibility, (0.5 %). Errors due to sampling are more significant and when interlaboratory differences are taken into account the overall result is to estimate the degree of conversion to within  $\pm 15$  % (at 95 % confidence limits). In other words, if a measurement of the degree of conversion of a sample of aluminous cement concrete by the method described by MIDGLEY yields a value of 50 % for example, there is apparently no more than one chance in 20 that the actual degree of conversion is less than 35 % or greater than 65 %.

Semi-isothermal thermogravimetry is a technique which appears to facilitate the identification of the hydrate phases as their water content is progressively driven off, (76). In this method, the instrument is switched from the dynamic mode (constant specimen heating rate) to the isothermal mode (specimen held at constant temperature) as each maximum in the DTG curve is reached. Continued weight loss is then recorded until the curve has again reached its base line. A return to the dynamic mode is then made, and so on. Results are given to

show that this provides a more accurate measure of the quantities of individual calcium aluminate hydrates present in an aluminous cement specimen, and a better separation.

REVAY and WAGNER, (77) use DTG to measure degree of conversion in conjunction with a modified sample treatment designed to overcome difficulties due to overlap in the dehydration temperatures of different hydrates. Their procedure involves measuring the TG and DTG curves for the sample in the as-received state, and again after autoclaving. The autoclave treatment crystallises the alumina hydrate to boehmite with a dehydration peak near 500°C, well removed from the others. During the same autoclave treatment, the hexagonal hydrates,  $CAH_{10}$  and  $C_2AH_8$  are converted to  $C_3AH_6$  and further AH. From a comparison of the results before and after autoclaving it is thus proposed to calculate the amounts of hexagonal hydrates which could exist in the material, and which may thus convert at some stage in the service life of the concrete.

STROBEL, (78) also points out the problem of peak identification using DTA due to overlap at dehydration temperatures below 200°C.

A number of points needs to be made about the use of the above techniques and the interpretation of the results obtained.

Semi-isothermal DTG appears to be the best method of overcoming assignment problems associated with overlap between different hydrates.

REVAY's studies aimed at assessing the ultimate porosity due to conversion which could arise in an aluminous cement concrete in service, and hence an estimate of its minimum converted strength. However the autoclave method gives a false picture since there is evidence, (68) that the minimum strength of aluminous cement concrete under most service conditions is passed before conversion is complete. Furthermore autoclaving changes the degree of hydration of the sample. Nevertheless REVAY's approach does not rely only on thermogravimetry: the cement content and as-received porosity in his samples is also measured. With this information some assessment of the quality of the concrete is indeed possible, as discussed later.

Most authors (74), (75), (76) calculate the degree of conversion from the formula:

$$Dc \% = \frac{100 \times AH_3 \text{ peak height}}{AH_3 \text{ peak height} + CAH_{10} \text{ peak height}}$$

Although strictly speaking, peak areas should be used, since Dc is expressed as a ratio better reproducibility between different laboratories was obtained using peak heights. The above formula is based on the equation:

$$3CAH_{10} + C_3AH_6 + 2AH_3 + 18 H$$

1 g                      0.378 g                      0.308 g

from which it can be seen that the weights of  $C_3AH_6$  and  $AH_3$  produced by the conversion of  $CAH_{10}$  are rather similar. As MIDGLEY points out, (68) such an approximation is not justified in laboratory studies. However it has been widely adopted in field studies of aluminous cement concrete.

It must be pointed out that the measurement of  $\text{AH}_3$  as an indicator of  $\text{C}_3\text{AH}_6$  ignores the fact that  $\text{AH}_3$  in aluminous cement can arise from sources other than the conversion of  $\text{CAH}_{10}$ . At temperatures of  $20^\circ\text{C}$  and above, the initial hydration of aluminous cement produces both  $\text{CAH}_{10}$  and  $\text{C}_2\text{AH}_8$ . The precipitation of  $\text{C}_2\text{AH}_8$  is accompanied by that of  $\text{AH}_3$ ;  $2\text{CA} + 11\text{H} \rightarrow \text{C}_2\text{AH}_8 + \text{AH}_3$ . (see for example references (65) and (79)). If any  $\text{CA}_2$  is present in the cement (rare in aluminous cement of the Fondu type) this will also produce  $\text{AH}_3$  during hydration. Finally the carbonation of calcium aluminate hydrates, results in the formation of  $\text{AH}_3$  as well:  $\text{C}_3\text{A} \cdot \text{CaCO}_3 \cdot 12\text{H} + 3\text{CO}_2 \rightarrow 4\text{CaCO}_3 + \text{AH}_3 + 9\text{H}$

Thus although techniques such as DTA, DSC and DTG give excellent reproducibility, the values of  $\text{Dc}$  obtained from  $\text{AH}_3$  are by no means an infallible measure of conversion.

The use of DTA to study the reaction of aluminous cement concrete with sulphates, chlorides and carbon dioxide is also recommended by MIDDLEY, (80). The reaction products, ettringite,  $\text{C}_3\text{A} \cdot \text{CaCl}_2 \cdot \text{nH}_2\text{O}$ ,  $\text{AH}_3$  and  $\text{CaCO}_3$  have characteristic endotherms which may be quantitatively determined by this technique. However, the peak temperature increases with the amount of material being estimated. Thus greater precision is obtained by calibration with synthetic mixtures of controlled increments of composition. Ettringite has a peak temperature at  $\approx 100^\circ\text{C}$  which can overlap with that of gypsum. However the above refinement enables the two compounds (product and reactant), to be distinguished. The peak temperature for  $\text{C}_3\text{A} \cdot \text{CaCl}_2 \cdot \text{nH}_2\text{O}$  is in the range  $150$  to  $170^\circ\text{C}$  approximately, depending on concentration. Attempts to distinguish between forms of  $\text{AH}_3$  produced as a result of carbonation in the presence or absence of alkalis, were unsuccessful.

This work was carried out in the context of disruptive chemical attack of highly porous aluminous cement concrete. While porosity (or permeability) is undoubtedly the dominant factor governing chemical attack (in any type of concrete), attention is drawn to the information on the porosity of converted aluminous cement concrete given in section 4.4. Conversion and vulnerability to chemical attack are not synonymous, and the fundamental importance of maintaining a low water/cement ratio in the manufacture of durable aluminous cement concrete cannot be over emphasised.

Thermogravimetric analysis has also been used by DAY and LEWIS, (81) to analyse the products of autoclaved refractory high alumina cements and concretes. Quantitative estimates of the phases present were made and mass balance calculations agreed well with the known chemical compositions of the starting materials: calibrations were carried out with pure samples of boehmite, gibbsite, portlandite and  $\text{C}_3\text{AH}_6$ . The results obtained also demonstrated the decomposition of  $\text{C}_3\text{AH}_6$  at approximately  $200$  to  $260^\circ\text{C}$ , to  $\text{C}_4\text{A}_3\text{H}_3$  and  $\text{CH}$ .  $\text{C}_4\text{A}_3\text{H}_3$  did not form directly from  $\text{CA}$ . By contrast, a commercial high alumina cement containing predominantly  $\text{CA}$  and free alumina produced  $\text{C}_4\text{A}_3\text{H}_3$  directly from the  $\text{CA}$  present. The reason for the difference in behaviour between laboratory and industrial materials is not known.

X-ray diffraction is an alternative method of determining the phase composition of set aluminous cement and is recommended by FLOWMAN and GYLLENSPETZ, (82). It has the advantage of more reliable identification of the various hydrates but is generally less quantitatively reproducible than thermogravimetric methods, (30). The use of both methods is generally more instructive than either one alone.

Infra-red spectroscopy has been usefully applied as a complementary technique.

LEJAWKA, (83) describes the use of quantitative X-ray diffraction to measure the  $\text{CA}$ ,  $\text{CA}_2$  and free  $\alpha$ -alumina content of aluminous cements, mainly of the purer type employed in refractory concretes. For cements containing less than 2 % of materials other than lime and alumina, an external calibration standard is considered satisfactory. Pure laboratory prepared samples of  $\text{CA}$ ,  $\text{CA}_2$  or  $\alpha\text{-Al}_2\text{O}_3$  are used as standards. For less pure cements an internal standard (quartz) is employed. In both cases the conditions of sample preparation are critical: grinding to crystal sizes less than  $5\mu$  is considered necessary.

## 5.2. The assessment of quality

The use of degree of conversion calculated from the DTA peak heights of  $\text{AH}_3$  and  $\text{CAH}_{10}$  has been made the basis of a method of assessing the quality of aluminous cement concrete and has been extensively applied, (60), (68), (84). This method, which it must be stressed is intended only as an initial rapid guide to quality and not a definitive assessment, is based on relating the degree of conversion to its age, from which the rate of conversion is then inferred.

Since laboratory studies had shown that the rate of conversion of aluminous cement concrete depends, in part, on water/cement ratio (see section 4.1.) a classification was made of concrete based on rate of conversion. This classification recognises three broad classes of concrete - those with minimum strengths greater than the 1 day strength, those with minimum strengths less than half the 1 day strength and an intermediate class. The limits are approximately

Table IV : Relative converted minimum strength and rate of conversion

S, minimum converted strength as a fraction of 24 hours $20^\circ\text{C}$ strength	$\text{S} > 1$	$0.5 < \text{S} < 1$	$\text{S} < 0.5$
Rate of conversion, $\text{R}^*$	$\text{R} < 0.24$	$0.24 < \text{R} < 0.27$	$\text{R} > 0.27$
Approximate degree of conversion % and age (years)	from 30 % at 1 year to 50 % at 20 years	intermediate	from 50 % at 1 year to 75 % at 20 years

\*  $\text{R}$  as defined in section 4.1.

In assessing the quality of aluminous cement concrete it is suggested that concrete having a value of R of 0.24 or less is good, while values of R in the intermediate range give cause for suspicion. Concretes with values of R above 0.27 are classified as 'highly converted' and this is assumed to generally imply poor quality, because it results from a high water/cement ratio.

The dependence of rate of conversion on water/cement ratio is not very pronounced and, as shown in figure 1., the trend is only really noticeable at high water/cement ratios. However the most serious criticism of this classification is that it takes no account of the dominant effect of temperature on rate of conversion. The relative importance of temperature compared to water/cement ratio can be judged from the fact that a change in curing temperature from 20 to 30°C can cause a bigger increase in this rate than that predicted at constant temperature, for a change in water/cement ratio of 0.27 to 0.6. Consequently a low water/cement ratio concrete which has been subjected to heat either during curing or at an early age will show a degree of conversion which would be considered on the above basis to imply a high water/cement ratio. The conclusions drawn as a result about the quality of the concrete would be quite wrong.

Another feature of the above method is the procedure used in sampling the concrete. This procedure involves drilling the concrete with masonry drills to give a powder specimen, (74). The well-known 'skin' effect on aluminous cement concretes, in which, due to dry surface conditions the degree of conversion is normally lower than in the bulk of the concrete, is allowed for by discarding the material produced during the drilling of the first 4 to 5 mm. Only the material extracted below this level is used for analysis, and results are presented to show that by this procedure a representative sample of the concrete is obtained. The results of two different drilling methods are described - rotary and rotary-percussion and compared with those obtained by crushing the concretes and taking internal samples.

These different drilling methods do not appear to give equivalent data. Admitting that each individual estimate of the degree of conversion is subject to an error of at least 5 %, one way legitimately analyse differences of 5 % or more observed between the degree of conversion of drilled and crushed samples. The results analysed in this way are shown in figure 4. - the dotted line is purely conjectural.

It is quite evident that the estimated degree of conversion is higher for drilled samples than crushed samples, and the difference is more pronounced the less the total degree of conversion. The most immediately obvious explanation is that the heat of drilling causes conversion and such an effect will evidently be greatest in those specimens which are initially the least converted. The determination of degree of conversion as a function of age must therefore be considered as a very imperfect preliminary measurement and not in itself a reliable guide to the quality of aluminous cement concrete. But in taking high rates of conversion to imply high water/

cement ratios it correctly recognises the overriding importance of water/cement ratio.

The above method is put forward because no reliable direct method of assessing the water/cement ratio of a hardened aluminous cement concrete has yet been published. At this point therefore the opportunity is taken to report some previously unpublished attempts to make such an estimate. The test procedure involves measuring several related properties of a concrete sample : porosity (by water impregnation under vacuum), cement content (by chemical analysis) and density, which is a property determined incidentally during the measurement of porosity. Also needed is a knowledge of the chemical composition of the aluminous cement employed and the amount of porosity in the sample due to air entrained while mixing the concrete, or resulting from inadequate compaction. Manufacturer's records normally provide a reliable estimate of the cement composition. The degree of air entrainment or lack of compaction cannot be established directly, and this is the only weakness of the method. However the degree of uncertainty which this imparts to the overall result is not necessarily serious.

Fig. 4 - Influence of sampling method (drilling or crushing) on the apparent degree of conversion of concrete

The general formula for calculating the total water/cement ratio is :  
 $W/C = (P - A + L \cdot d) 10/C$  where P is the porosity (% by volume), A is the estimated entrained air (% by volume), L is the loss on heating under nitrogen at 550°C (% by weight), d is the density of the concrete (kg/litre) and C is the cement content, (kg/m<sup>3</sup>).

Table V : Comparison of measured and actual water/cement ratios of hardened aluminous cement concrete

Concrete	Total water/cement ratio		Measured	% Air entrained
	Actual	Measured	Actual	
Partially converted	0.33	0.33	1.00	1.8
Fully converted		0.37	1.12	
Partially converted	0.4	0.38	0.95	2.1
Fully converted		0.455	1.14	
Partially converted	0.5	0.465	0.93	3.1
Fully converted		0.575	1.15	
Partially converted	0.67	0.67	1.00	6.0
Fully converted		0.70	1.04	

Table V shows the results of a series of experiments based on the above procedure on concretes prepared at known water/cement ratios, and for which the air entrained in the freshly placed concrete was also measured. For an unknown concrete it would be prudent to use a value of 2% for the air entrained (see also reference (85)) and table V shows that the method provides quite a reasonable estimate. Any systematic errors tend to give an overestimate of the water/cement ratio.

A disadvantage of this method, and that of REVAY (77), (86), is that a relatively large specimen of concrete is needed for analysis, which in many cases in practice must imply the destruction of the unit under investigation. Also several experimental procedures must be carried out in order to arrive at the final answer. A more simple, non destructive, though less rigorous approach, consists of estimating only the cement content of the concrete. This can be done with considerable accuracy by classical chemical analysis, as the following results show :

Table VI : Comparison of known cement contents with cement contents of hardened concrete estimated by chemical analysis

Cement content kg/m <sup>3</sup>		Average Measured Actual	Total water/cement ratio
Measured	Actual		
651, 640, 647	616	1.05	0.33
469, 495, 517	491	1.01	0.40
375, 345, 378	402	0.92	0.50
303, 310, 309	302	1.02	0.67

It is well established that the workability of concrete in general, for a given cement content, is very sensitive to water/cement ratio. Since in practice, workability is probably the most consistently controlled parameter in precast concrete manufacture, it follows that variation in water/cement ratio will closely mirror variations in cement content. Figure 5 constructed from data in the publication by TEYCHENNE, (66) is illustrative :

Fig. 5 - Aluminous cement concrete : slump (mm) and mix proportions

In view of this a simple estimate by chemical analysis of the cement content of an aluminous cement concrete, might provide quite a useful guide to water/cement ratio, and hence quality.

Acoustic emission as a non destructive technique for assessing concrete quality has been applied to aluminous cement based materials, (87), (88). Tests on beams during proof loading showed a correlation between acoustic activity, load and deflection. Laboratory prepared cubes cured at 20°C and at 40°C were monitored in compression. Acoustic emission increased with load but total levels of emission were lower for the samples cured at the higher temperature. These samples, due to conversion, also showed lower crushing strengths.

The acoustic emission of neat aluminous cement pastes at water/cement ratios of 0.35 and 0.65 was recorded during curing at 60°C. There was very little activity from the lower water/cement ratio sample indicating that conversion under these conditions does not cause acoustic emission. At the higher water/cement ratio, acoustic emission increased to a maximum after about 25-30 hours at 60°C (preceded by 24 hours curing at 17°C) and then decreased to reach negligible levels after about 40 hours. This activity is thus most probably associated with microcracking during conversion of the higher water/cement ratio, intrinsically weaker, specimen.

Recent mention has also been made of the assessment of aluminous cement concrete quality by measuring ultra-sonic pulse velocity, (65), (67), (89). It provides a broad non-destructive guide to

the quality of concrete in service but is only really reliable in cases where the many factors, water content, aggregate content, reinforcement, porosity, etc. affecting velocity can be individually allowed for through calibration tests on equivalent laboratory concretes of known composition. The USPV method is thus not adapted to comparisons between different concretes, or to the absolute determination of mechanical properties, but is certainly a useful tool for monitoring changes with age of a given specimen.

It is suggested that methods such as acoustic emission, pulse velocity, velocity of sound or gamma-ray absorption for example, could well find wider application in laboratory studies aimed at following the changes in properties of aluminous cement during hydration and aging. By such techniques the most important stages in property development might be more precisely identified and thus provide a means of choosing the most appropriate moments to carry out destructive tests, such as cube crushing. In this way better data might be acquired, from fewer specimens.

### 5.3. Modulus of elasticity and creep

The relationships between such mechanical properties of concretes as creep, modulus of elasticity and compressive or flexural strength change relatively little with the chemistry of the cement. The largest differences between Portland cement and aluminous cement concretes are found at early ages and are a consequence of the rapid hardening character of aluminous cements, (1).

Recent work, (66) on the modulus of elasticity of aluminous cement concrete confirms that it increases with compressive strength : values at the higher end of the range normally encountered with Portland cement concretes are reported. Results obtained for aluminous cement concrete with total water/cement ratios in the range 0.35 to 0.6 fall on the same curve, with higher values in the unconverted state (storage at 18°C) and lower values in the converted state, (storage at 38°C). Furthermore, it has been shown, (90) that the relationship between static and dynamic modulus is not affected by conversion, and is the same, for practical purposes, for Portland cement concretes and aluminous cement concretes.

The modulus of elasticity of aluminous cement-granite concretes, and an ultra-fine Portland cement-granite concrete were measured in accordance with British Standard 1881 (1970), by SWAMY, IBRAHIM and ANAND, (91) who give the equations :  $E = 4.87 \sqrt{C}$  (aluminous cement),  $E = 4.07 \sqrt{C}$  (Portland cement), where E is the static modulus and C is the cube crushing strength.

NEVILLE, (64) quoting the work of CUSENS and JACKSON, (92) in a review of aluminous cements, states that the elastic modulus in the unconverted state is slightly higher than that of Portland cement concretes of the same strength, and at the lower end of Portland cement values in the converted state.

SWAMY and co-workers, (91) have also compared the shrinkage and creep of Portland cement and alu-

minous cement concretes. The initial shrinkage and creep in the aluminous cement-granite concrete (first 24 hours), associated with the development of compressive strengths approaching 100 MPa, is necessarily high. The longer term characteristics however, are equivalent for the different types of cement. The specific creep of the aluminous cement concretes measured over a period when compressive strengths dropped from 109 MPa at 120 days age to 77 MPa at 390 days age due to conversion, was in the range 40 to 60  $\times 10^{-6}$  m/m per MPa, compared to a range of 50 to 80 for Portland cement concretes. Since the long term deformation characteristics are normal it is suggested that heat curing of aluminous cement concretes may be used. This produces concrete in the fully converted condition with early strength development and no possible subsequent strength changes due to conversion. Allowance should be made in design of prestressed units for the enhanced initial creep.

In another paper, SWAMY and ANAND, (93) report shear strain and some loss of prestress in the end zones of aluminous cement concrete beams. It is suggested that this is a consequence of conversion. If loss of strength due to conversion is large, and no shear reinforcement is provided, the effect could be serious if the concrete has been specified in terms of its unconverted characteristics.

It is pointed out here, as elsewhere in the present review, that the design of structural aluminous cement concrete should be based on the converted properties, which can be predicted and controlled through water/cement ratio.

### 5.4. Water/cement ratio

Water/cement ratio can be defined as total water content (that absorbed in the aggregates at the time of mixing plus the gauging water) divided by cement content, or free water content (that not taken up by the aggregates) divided by cement content. It follows that free water/cement ratio is equal to total water/cement ratio only in a neat paste, and becomes progressively less than total water/cement ratio as sand and aggregate is added. For concretes in practice the difference can be quite substantial :

Table VII : Relationship between free and total water/cement ratio of concrete

Ratio of cement to aggregate	R, Ratio of free to total water/cement ratio	Coefficient of variation % of R	Range of water/cement ratios used
1 : 3	0.852	1.6	0.30 - 0.40
1 : 4.5	0.820	3.7	0.35 - 0.50
1 : 6	0.810	2.4	0.45 - 0.60
1 : 7.5	0.819	2.1	0.59 - 0.80

Data from reference (66).

Failure to distinguish between free and total water/cement ratio can thus lead to significant errors. For example, in a report (94) on the quali-

ty of samples of an aluminous cement concrete which failed in service, it is stated that failure may have been due to the use of a free water/cement ratio greater than the value of 0.4 aimed at in practice, when the Code of Practice, (95) governing the manufacture of such concretes clearly specified a maximum total water/cement ratio not exceeding 0.4. Thus if the concrete in question had a free water/cement ratio greater than 0.4 it would have had a total water/cement ratio of 0.5 or more.

The difference between average and characteristic strength (mean - 1.67 standard deviations) has been mentioned elsewhere in this review, (section 4.2.) and like the difference between free and total water/cement ratio, must not be forgotten when comparing experimental results. These points are well illustrated by figures 6A and 6B.

Data from 3 different sources presented in 2 different ways

- a. Reference (95) ×  
average strength, total W/C
- b. Reference (96) ⊙  
average strength, free W/C
- c. Reference (97) ●  
characteristic strength, total W/C

corrected to total W/C
- c. Reference (97) ●  
corrected to average strength

Fig. 6 - Influence of water/cement ratio on compressive strength of aluminous cement concrete converted at 38°C

NEVILLE, (98) comparing curves a, b and c presented in the manner shown in figure 6A, concludes that there is a considerable lack of agreement between different workers, which implies that the converted strength of aluminous cement is unpredictable and may be lower than is generally reported. On the contrary, when the confusion between total and free water/cement ratio and between average and characteristic strength is eliminated, the converted strength is seen, figure 6B, to be highly reproducible and clearly fixed by water/cement ratio.

In concluding this section it is appropriate to provide an indication of the reproducibility obtained in the manufacture of aluminous cement. The example given is of a 40 %  $Al_2O_3$  cement of the 'Fondu' type manufactured in compliance with the British Standard, 915. Spot checks made on 39 different production batches gave the following results :

Table VIII : Compressive strength (MPa) of 100 mm Fondu cement concrete cubes made from 39 different production batches of cement

	24 hours curing at 18°C			Fast conversion by curing for 5 days at 38°C		
Total water/ cement ratio	0.35	0.40	0.50	0.35	0.40	0.50
Mean strength	74.8	66.8	59.4	51.0	40.5	25.6
Standard deviation	5.2	5.2	6.4	5.3	4.4	3.3

### 5.5. Recent recommendations

In 1974, the collapse of an aluminous cement concrete beam in the roof of a swimming pool led to very extensive investigations of many structures in Britain. The conclusions reached as a result are given in several reports (60), (61), (94) published by the government Building Research Establishment and the Department of the Environment. It is apparent from these investigations that service temperature in the UK can frequently exceed 30°C and may at times exceed 35°C so that conversion occurs more rapidly than was earlier believed. Consequently the previous practice of designing on unconverted strengths, assuming that in service conversion will be so slow that it will have a negligible effect on strength, must be revised. It is also apparent that much structural concrete had been made with total water/cement ratios in excess of the maximum of 0.4 prescribed (95).

It is because of these two conclusions that the recommendation was made (61) to assume a minimum compressive strength for aluminous cement structural units of 21 MPa when appraising buildings made with this material. It must be strongly emphasised that this figure applies to concretes for which the water/cement ratio is unknown but assumed to be above 0.4 total, and which have been converted relatively rapidly in service. The value of 21 MPa is consistent with a total water/cement ratio of 0.5 to 0.55, (95). By contrast, regular long term monitoring of structural aluminous cement concretes made at total water/cement ratios of 0.4 or below has demonstrated the excellent durability in practice that laboratory tests predict, (67), with a minimum converted strength of at least 40 MPa in compression.

The failure of structural concrete during service must always be the subject of serious investigations which should lead to more clear and reliable prescriptions for its future use. In the United Kingdom it was considered that the guidance given in the 1972 Code of Practice, (99) was inadequate for the manufacture of durable aluminous cement concrete and reference to this material was withdrawn from that Code in 1975 while the Building Research Establishment investigations were being carried out, and has not been reintroduced up to the present time. It seems clear that future recommendations must limit the water/cement ratio to 0.4 total as required by the earlier code (CP 116, 1965 - reference (95)) and not 0.4 free. Furthermore a minimum not a maximum cement content of 400 kg/m<sup>3</sup> is preferable to ensure adequate workability. Finally design should be on the basis of converted not unconverted strengths.

The Ministerial circular of 1970, (100) governing the structural use of aluminous cement concrete in France, was also reexamined after 1974 and this led, in 1979 to a new official circular, (101). The 1979 French circular fully confirmed the view reached in 1970, that aluminous cement concrete manufactured at low water/cement ratios (0.4 total or less) is a durable structural material. It also takes advantage of work since 1970, including the UK findings, to extend the scope of the prescriptions to be followed in using this material and to require manufacturers of this type of cement to

guarantee certain fundamental characteristics as well as to provide a complementary guide to its properties and applications. Such guarantees and guidance now exist for the aluminous cement known as ciment Fondu Lafarge, (103).

### ACKNOWLEDGEMENTS

The author is indebted to the many researchers whose publications it has been his privilege to review.

At the same time, apologies are extended to all whose work, due to the limitations of time and space, has been omitted or given but scant or inadequate coverage.

## **SUB-THEME V - 2**

### **Expansive Cements**

**W. KURDOWSKI**

**Research Center of the Industry  
of Binding Materials  
Krakow, Poland**

## INTRODUCTION

Commercial production of expansive cements was undertaken over 30 years ago /1/. In the last decade it had been expanded substantially in three countries: United States, Japan and Soviet Union /2-4/. In the United States about 300 000 tons per year of shrinkage-compensating cement is produced, in Japan - 50 000 tons of expansive additive, corresponding to 500 000 tons of the cement /3/. In the USSR 63 000 tons of self-stressing expansive cement only was produced in 1977 /5/, to say nothing of other types of these cements.

The development of expansive cements production is connected with an important progress in structural engineering, as well as with the necessity to eliminate the well-known shortcoming of Portland cement, consisting in the formation of cracks in the concrete, due to natural drying shrinkage.

Shrinkage-compensating cements are used wherever a prevention of the shrinkage cracking, as well as of the changes in initial dimensions of concrete units is required, namely for the manufacturing of structural concrete units, airfields, runways, pavements, water tanks, slabs of skating rinks, underground garages, warehouses, parkings, railroads etc.

The second field of expansive cements employment comprises the production of self-stressing concretes, in which the preliminary compressive stresses are obtained as result of so-called chemical stressing. This cement serves for fabrication of structural elements requiring a low optimum prestress, such as pipes, wall panels, thin slabs for floors and roofs, shells and folded plates, water tanks, pavements, sport objects etc. Recently the possibility of utilization of expansion potential of these cements to generate the jacking forces in concrete constructions was mentioned /6/.

Both the types of expansive cement differ in the magnitude of expansion potential. The level of compressive strengths developed is in the range of 25 to 100 psi /2 to 7 kg/cm<sup>2</sup>/ for shrinkage-compensating cements and up to 1000 psi /about 70 kg/cm<sup>2</sup>/ for self-stressing cements.

Generally it can be said, that the shrinkage compensating cements are the most commonly used and their technology is almost entirely acquired. The best experience in self-stressing cements manufacturing falls to the Soviet Union /4/.

An excellent review of theoretical foundations of expansive cement technology, properties of these cements as well as fields of application of expansive concretes was presented by Mehta at the Sixth Congress on the Chemistry of Cement in Moscow in 1974 /2/ and actualized recently /3/. Ever since not any new hypotheses concerning the theoretical basis of manufacturing these cements, especially the expansion mechanism, have been appeared.

However, the industrial practice has been developed considerably and the position of expansive cements in structural engineering is being now well established /7/. This allowed to collect detailed material on the properties of expansive concretes in various conditions and environments.

Also the growth of interest in other, than ettringite, expansive additives appeared, in particular in free CaO, which has found already a practical application in Japan /8/.

In this paper a review of recent opinions on the physical-chemical relations, governing the properties of expansive cements, as well as of suppositions tending to explain the mechanism of expansion is given.

Purely technological questions of expansive cements manufacturing as well as the problems related to expansive concretes and their miscellaneous applications were reduced to a minimum. However a list of any attainable bibliography in this subject is annexed.

## TYPES OF EXPANSIVE CEMENTS

As mentioned before, the most of all developed expansive cements are these in which the expansion phenomenon is originated by the reaction of ettringite formation. Their technologies differ only in utilized raw materials, which introduce the aluminium compounds, calcium sulphate and calcium oxide.

The most widely applied technology is that developed by Klein in the United States. This cement, so-called Type K, is based on  $C_4A_3S$  as alumina-bearing compound. It is usually produced by intergrinding ordinary Portland cement clinker, an expansive clinker containing  $C_4A_3S$  and gypsum /or a mixture of gypsum and anhydrite/. Besides  $C_4A_3S$  the expansive clinker generally contains alite, belite,  $C_2AF$ , anhydrite and some free lime. Its manufacturing is developed also in Japan /3/, and now in the Soviet Union the works go on to start in its production /9/.

The K-Type cement can be manufactured by two means. Expansive additive is sintered separately in the form of calcium sulphoaluminate clinker, which is then interground with Portland cement clinker and gypsum. One can also obtain - in a single process - a Portland-like expansive clinker with suitable tetracalcium sulphoaluminate content, by addition of calcium sulphate to raw materials, serving to ordinary Portland cement clinker manufacturing.

The grinding of this clinker with addition of gypsum and/or anhydrite gives the expansive cement. As yet a technology consisting in the separate preparation of the expansive clinker prevails. This method is applied in two variants: in the United States the components of expansive cements are ground jointly, giving a commercial product - expansive cement, while in Japan other way is choosed: an adequately ground expansive

additive rather than expansive cement is produced and marketed. This additive is added to concrete at the time of mixing, in amounts necessary to produce either a shrinkage-compensating or a self-stressing concrete.

The second type of expansive cements is obtained by addition of aluminous cement to Portland cement. This is so-called M-Type cement and its production has been developed particularly in the Soviet Union, owing to Mikhailov's works. In this technology the aluminous cement or aluminous slag as alumina-bearing component is utilized; in this latter case lime addition is applied /4/.

The first of these cements, SCT cement, is composed of Portland cement, calcium aluminate cement and gypsum in the ratio of 66:20:14 respectively; the second, SCN cement - of Portland cement, calcium aluminate cement, gypsum and lime in the ratio of 67:22:9:2.

The SCT cement concrete is exposed to hydrothermal curing and then to water curing at normal temperature. According to Mikhailov, during the heating stage of the curing process calcium monosulphoaluminate hydrate is formed, and then - during normal curing - it is transformed into ettringite, that is responsible for expansion. This technology is being applied in precast units plants.

The SCN cement contains an aluminous slag and lime. It hydrates in natural conditions and the formation of ettringite in the paste is retarded in early ages due to the presence of lime.

In elaborated by Mikhailov and produced in the USSR since 1948 so-called WEC cement, the high-alumina cement occurs as predominant component /4/. This cement is a mixture of high-alumina cement, gypsum and calcium aluminate hydrate  $C_4AH_{13}$  in the ratio such as 65:22:13 respectively. Calcium aluminate hydrate is obtained by hydration of a mixture of high-alumina cement and lime at 100°C. The annual production of this cement is about 15 000 tons.

Elaborated by Budnikov and Kravchenko and produced in the USSR expansive cement, unique in the world, being a mixture of aluminous slag and gypsum in the ratio of 70:30 respectively, can be included also to this group /4/.

All the expansive cements produced in the USSR are ordered in three grades: 20, 40 and 60, as the expansive potential generated in these cements is about 20, 40 and 60 kg/cm<sup>2</sup> /280, 570 and 860 psi/, respectively. The cement n° 20 is a shrinkage-compensating one and the two other are self-stressing cements.

The third type of expansive cement is S-Type cement, manufactured from Portland cement clinker with increased  $C_3A$  content. This technology finds limited applications, first of all by reason of the difficulties in the getting under control the steadiness

of ettringite formation rate from tricalcium aluminate. This means the difficulties with controlling expansion. Ettringite is formed very rapidly from  $C_3A$  phase in early hydration age and then the reaction becomes to be slowed down to very low rate at later age. In this connection even after 7 days the unreacted aluminate content is still appreciable.

At early age the  $C_4A_3\bar{S}$  phase hydrates more rapidly than  $C_3A$  and the rate of this reaction remains relatively high till the depletion of this compound. Fig. 1 shows the curves of ettringite formation from different anhydrous aluminate phases, plotted by Mehta /10/. After 1 day of  $C_4A_3\bar{S}$  hydra-

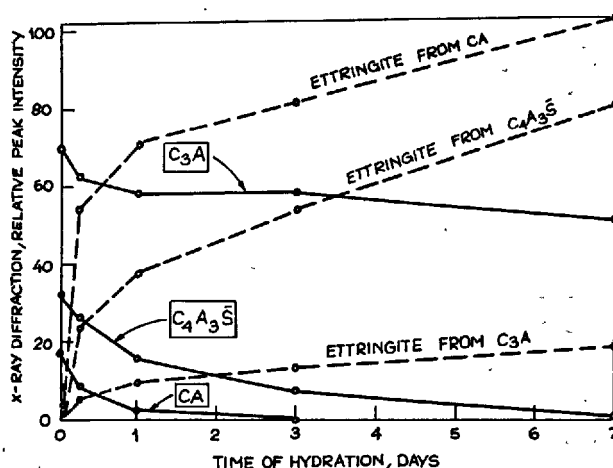

Fig. 1 - Relative rates of ettringite formation and depletion of  $CA$ ,  $C_4A_3\bar{S}$ , or  $C_3A$  in pastes containing both gypsum and lime /Mehta/

tion the rate of reaction is still appreciable, which results in complete transformation of this phase into ettringite within 7 days. Examination of the curves given in this figure allows also to account for the advantage of M-Type cement over S-Type one: in aluminous cement the aluminium occurs mainly in calcium monoaluminate phase and this phase transforms into ettringite at considerably earlier ages than 7 days.

The separate group is made by expansive cements with addition of activated alunite. Studies in this field are conducted by Bulgarian as well as Georgian investigators. Alunite containing raw materials utilized for this purpose are activated at 600° to 800°C, and then interground with Portland cement clinker and gypsum. Alunite gives - as a product of reaction with other constituents - the ettringite phase. This cement is manufactured in Bulgaria and USSR /11-14, 9/.

In the USSR a technology of expansive cement had been elaborated in which the by-

product from aluminium sulphate manufacturing process is utilized as alumina-bearing component /15-18/.

Further, entirely separate type of expansive cement encloses a group of cements, made in Japan, with calcium oxide as expansive component. Kawano et al. /8/ developed an expansive additive that contains predominantly uncombined calcium oxide; the additive can be obtained by sintering a mixture of limestone, clay and anhydrite. The principal phases of the additive are alite /about 38%/, free lime /about 44-47%/, and  $\text{CaSO}_4$  /about 6-10%/. This additive is interground with the Portland cement clinker. The  $\text{CaO}$  phase occurs in great part as inclusions of 10-30  $\mu\text{m}$  large crystals in developed up to 100-900  $\mu\text{m}$  alite grains, thus undergoing hydration more slowly, gradually as the alite itself hydrates, which ensures controlled expansive properties of the cement. Recently a new expansive additive is developed, which contains large alite crystals and small /5-20  $\mu\text{m}$ / free  $\text{CaO}$  crystals dispersed in an amorphous calcium sulphate matrix /3/. The composition of a mixture with 40-70% of alite, 20-30% free lime and 10-20%  $\text{CaSO}_4$  gives good expansion characteristic.

Pollitt and Brown in Great Britain /19/ and Allen et al. in the United States /20/ developed expansive cements based on similar principle as the first of the cements mentioned above, proposed by Kawano. English investigators believe the most preferred range of free  $\text{CaO}$  content to be 3-12%. According to Allen more than about 2% of free  $\text{CaO}$  in an ordinary Portland cement could lead to undesirably delayed hydration, when the free  $\text{CaO}$  is enclosed by less reactive compound, such as  $\text{C}_2\text{S}$ .

A method of producing  $\text{CaO}$  and  $\text{MgO}$  containing expansive cements was given by Collepar-di /21/. Also Daugherty et al. /22/ patented a process for preparing expansive cement with addition of free  $\text{CaO}$  and/or  $\text{MgO}$ . Expansive clinker containing 2-7%  $\text{MgO}$  and 1-70%  $\text{CaO}$  as well as  $\text{C}_2\text{S}$  is interground with Portland cement clinker. Utilization of  $\text{MgO}$  powder as expansive additive was also the matter of studies of Komendant et al. /3/.

#### MECHANISM OF EXPANSION

In the Portland cement technology a destructive phenomenon of volume change, resulting in failure of the concrete, has been well known for a long time. The three reactions cause this volume change: the formation of ettringite, portlandite and brucite. This phenomenon influences negatively the properties of mortars and concretes, if the process of formation of these phases occurs after the hardening of the cement paste is over. At that time high stresses appear in the material, exceeding often its strength, which results in disruption of the concrete.

Numerous studies allowed to state, that the factors influencing this unfavourable volume change are not only the content of harmful components, but also their grain-size distribution and repartition in the material. For example Gille /23/ as early as in 1952 stated that periclase in the form of crystalline grains not greater than about 5  $\mu\text{m}$  in size, do not gives unfavourable volume change even by its content of 4-6% of cement. Similar observations concern free calcium oxide /24/. Most of the studies on the expansion phenomenon dealt with ettringite formation, as that was the first, consciously utilized expansive reaction. The first hypothesis on the mechanism of expansion was suggested in 1929 by Lafuma /25/. He theorized, that possible mechanism of expansion consists in solid state hydration of tricalcium aluminate to ettringite in saturated solution of calcium hydroxide, thus in topochemical reaction, whereas ettringite formation by through-solution reaction do not causes expansion. This hypothesis provoked large discussions and finally had been rejected in result of works carried out by Mehta, who demonstrated, basing on scanning electron microscopy, that the ettringite is formed, as a rule, by through-solution crystallization /26/.

The next attempt to elucidate the expansion phenomenon resulted in hypothesis in which essential role was attributed to osmotic pressure /27/. It has been stated /28-29/ that electrically charged colloidal particles show the ability to swelling, due to osmotic "suction" of water by charged surface.

As follows from the work of Moore and Taylor /30/, the crystals of ettringite have a negative surface charge and according to Mehta /26/ a colloidal nature of this phase in solutions saturated with lime is quite sure. Thus the experimental results are not out of accord with the osmotic hypothesis of expansion.

The most comprehensively supported by experimental evidence is Mehta's hypothesis, developed in early seventies /31/. This author is of opinion, that negatively charged colloidal ettringite grains with high specific surface attract the polar molecules of water, which surround the crystals of this phase and cause interparticle - perhaps double-layer type - repulsion. This results in overall expansion of the system.

In order to confirm this hypothesis experimentally, Mehta realized a complete hydration of the mixture  $\text{C}_3\text{A} \cdot 3\text{S} + 8\text{CS} + 6\text{C} + 96\text{H}$  with formation of ettringite in conditions preventing moisture loss or carbonation of the sample. Ettringite sample obtained was then exposed to water; volume changes after various curing ages were determined. The curve, given in Fig. 2, shows quite a large expansion of the sample, which is accompanied by no difference in the X-ray diffraction pattern /32/. This mechanism is res-

Fig. 2 - Uniaxial expansion of ettringite on moist curing /Mehta/

possible also, according to Mehta, for expansion of other colloidal hydrates, as  $\text{Ca}/\text{OH}/_2$ ,  $\text{Hg}/\text{OH}/_2$  and alkali silicates. A further increase in the length of  $\text{CaO}$  samples after the hydration is completed, stated by Ramachandran et al. /33/, is the case for this opinion.

Independently of Mehta's hypothesis, many authors continue to consider, that the expansion can be caused by local transformation of anhydrous phases into hydrates /34-36/. Electrolyte solution migrates through capillary pores to the grain of anhydrous phase surrounded with hydrates, entailing an expansive reaction in situ. The hydrate, formed in situ, has substantially greater volume as porous anhydrous phase and this generates stresses, leading to volume change of the sample. This hypothesis is in a way a recurrence to the known Lafuma's conception. Experimental data supporting this hypothesis are rather scarce. One can here mention the scanning pictures of compact ettringite phases, forming the envelopes on  $\text{C}_2\text{A}$  grains /36/. Japan investigators suggested the formation of  $\text{C}_2\text{ASH}_2$  on  $\text{C}_2\text{A}_3\text{S}$  grains /37/. This hypothesis is not contradictory to the increase in porosity of pastes in the range of pore sizes from 0.2 to 0.8  $\mu\text{m}$ , typical of ettringite formation. These pores appear in the mortar as early as after 1 day of hardening, exist up to 7 days and finally disappear between 7-th and 28-th day of hardening /Fig. 3/. In non-expansive cement pastes no maximum is observed in this range of pore size distribution /36/. Generally speaking, expansive mortars are always more porous than Portland cement mortars /36/. Well-known fact of high ability of portlandite and ettringite to crystallization, two most easily detectable crystalline phases of the paste, is not out of accordance with this hypothesis.

Important experimental data supporting the hypothesis of expansion as result of the formation of hydrates in place of anhyd-

Fig. 3 - Pore size distribution of /1/ expansive and /2/ non-expansive cements /Gaspar/

rous compounds, thus in too small volume, has been presented by Cottin /38/.

Fig. 4 shows, according to this author, calculated as well as determined experimentally expansion of a mixt of aluminous

Fig. 4 - Expansion of a mixt of high-alumina cement with gypsum /Cottin/

cement with gypsum, hydrating with insufficient /30%/ water addition. Theoretical

expansion was calculated basing on the known phase composition of the hydration product.

Similar expansion characteristics were observed by Cottin for the samples exposed to water after a long period of preliminary moist storage /Fig. 5/.

Fig. 5 - Expansion characteristics of the samples exposed to water directly or after 160 hours of preliminary moist storage /Cottin/

Also Isogai's work /39/ seems to confirm this hypothesis. This author advances an opinion, that the calcium trisulphoaluminate hydrate is formed mainly by topochemical reaction in case of water curing, but chiefly formed by through-solution reaction in case of air curing.

The study of concrete corrosion processes, carried out by Regourd /40/ indicated, that the appearance of cracks was in relation to the formation of compact masses of amorphous ettringite, not detectable by X-ray diffraction, but also was accompanied with the formation of large crystals of this phase /Fig. 6/. This seems to

/a/

/b/

Fig. 6. - Different forms of ettringite in destroyed concrete. a - amorphous, b - crystalline /Regourd/

show, that rather the amount of ettringite formed than the size of crystals determines the expansion level.

Finally, the most recent investigations by Collepari et al. /41/ concerning the  $C_3A$  hydration proved, that an outside source of water is not indispensable for occurrence of expansive process; though in the sealed system it occurs less intensively. Collepari relates this fact with transformation of the liquid water, present in capillary pores, into a low density configuration with water molecules, adsorbed on ettringite crystals. Nevertheless these observations do not refute the hypothesis of the conversion in situ of  $C_3A$  grains, coated by a low-permeable ettringite layer, into hydrated calcium sulphoaluminate.

Bentur and Ish-Shalom /42/, examining the mixtures of  $C_3A_3S$ ,  $CSH_2$  and  $CH$ , proposed a model of this process, based on the growth of a porous ettringite layer around the  $C_3A_3S$  grains. This growth causes expansion of the sample as a result of spherically overgrowing ettringite layers pushing against each other.

As follows from this review, it is necessary to obtain further experimental data, in order to elucidate completely and explain conclusively the mechanism of expansion phenomenon.

#### SOME FACTORS INFLUENCING EXPANSION

##### Free lime

All the authors agree in the matter of fact, that the free lime content influences favourably the expansion process. This finds its expression in the compositions of industrial expansive cements. It has been found /37/, that the lime retards hydration of  $C_3A_3S$  and  $C_3A$ , and accelerates hydration of  $CA$  /43/. The role of lime will therefore consist in a reduction of the amount of ettringite formed at early age, and first of all within 5 hours of hydration. In this connection the phases, giving ettringite, are not consumed in the period of plastic state of the paste, in which its formation is not followed by expansion. Lime addition gives beneficial expansion characteristics, with higher level of volume change not only at early ages, but till the end of the process /Fig. 7/. The curves of the content of some components in liquid phase of the paste confirm also such a course of the process /Fig. 8/. In a free lime containing cement the lime concentration of liquid phase is substantially higher; the concentration of  $SO_4$  ions is higher too. This indicates the retardation of the process of ettringite formation, which becomes accelerated after 5 hours, simultaneously with the start of alite hydration. In a cement with very low content of free  $CaO$  the process of ettringite formation runs continuously since the moment of cement mixing with water.

According to Mehta's results and hypothesis,

lime content in the solution promotes the formation of fine-crystalline ettringite /26/.

Fig. 7 - Effect of lime addition on expansion characteristic

Fig. 8 - CaO concentration in liquid phase of expansive cement pastes without and with free CaO

#### Portland cement

Not many data are available on this subject. It seems to be evident that an increase in the amount of  $C_3A$  and alkalis in Portland cement clinker is unfavourable. The effect of alkalis can be easily explained by reduction in  $Ca^{++}$  ions content of the liquid phase in the paste and - as its consequence - acceleration of ettringite formation.

Higher  $C_3A$  content will make difficult the control of expansion, as in this case the latter appears to be extended in time.

Similar informations with respect to M-Type cements gives Gaspar /36/. He calls attention to the advantageous effect of  $CO_2$ , which promotes the expansion; on the other hand the ability to clinkerization of the raw materials as well as the high fineness of Portland cement are unfavourable /Fig. 9/.

Fig. 9 - Effect of fineness on expansion for M-Type cements /Gaspar/

#### Expansive components

Tetracalcium sulphoaluminate is the only known ternary compound in the system  $CaO-Al_2O_3-SO_3$  /44/. It forms easily at temperatures as low as  $1300^\circ C$  and shows good stability up to melting temperature,  $1600^\circ C$ .

In the mixtures rich in lime it reacts with  $CaO$  with formation of  $C_4A$  and anhydrite /2/. In this connection an excess of the latter in industrial mixes is favourable.

The  $C_4A$  is formed by sintering in rotary kilns, at temperatures not exceeding  $1300^\circ C$ . As raw materials limestone, various alumina-bearing materials and gypsum are utilized. A large number of informations on the manufacturing of the clinker containing calcium sulphoaluminate was given at the Symposium in Tokyo /45, 46/. The K-Type clinker contains, apart from phases typical of Portland cement,  $C_4A$  and small amounts of free lime and anhydrite. Expansive clinkers manufactured in the United States contain 3-50% of  $C_4A$ , depending on the degree of purity of used raw materials.

The computing procedure of mineral composition of K-Type clinker has been given by Mehta /2/. Adams and Larkin have elaborated a chemical method for determining the  $C_4A$  content of cement and clinker of K-Type. It consists in a combination of two separation procedures, a maleic acid-methanol leach and an ammonium chloride-water leach /45/. Occasionally, in the expansive clinkers burnt at low temperatures, the calcium silicosulphate  $C_2S/CS$  has been detected, which at temperature about  $1300^\circ C$  is known to decompose to belite and anhydrite /46/.

Substantial amount of this compound reduces the expansion potential of the cement.

Japanese expansive components for cement contain 15-20%  $C_4A_3S$ , 45-50%  $CS$  and 20-30%  $CaO$ . Belite is present as minor phase in these products /2/.

In the USSR expansive clinker differs in composition from known expansive clinkers produced in the United States and in Japan; it contains also a few percent of  $C_{12}A_7$  and a higher amount of  $C_2S$  /9/.

As regards the expansion process, the content of free lime is - as was stated above - advantageous, however the  $/C_2S/2CS$  phase should not to be present.

The specific surface of this component should be high; this can be obtained easily even by intergrinding of this clinker with Portland cement clinker, due to a good grindability of the former.

In the case of M-Type cement, as expansive additive either ordinary aluminous cement or refractory high-alumina cement - as SE-CAR - can be utilized /36/. The latter is more advantageous since as little as 1.5% of this additive gives a sensible expansion /36/. High fineness of aluminous cement has a beneficial effect, as is evident from Fig. 9.

#### EXPANSIVE CONCRETES

Many years of the practice in utilization of expansive concretes allowed to collect a comprehensive experimental material as well as to examine carefully their properties. These acquisitions had been presented at the Klein Symposium in Hollywood in 1972. Also Mehta /2, 3/ discussed widely the properties of these concretes, and ACI Committee 223 proposed recommended practice for the use of shrinkage-compensating concretes /7/.

Limiting oneself to essential problems only one should state, that shrinkage-compensating concretes are designed similarly to ordinary concretes with Portland cement and that, in general, their properties are in most respects close to those of Portland cement concretes.

Attention however should be called to the fact, that the type of aggregate utilized has sensible effect upon expansion /46/.

Recently Polivka and Mehta /47/ have emphasized the advantage of shrinkage-compensating cement, which is capable to give a concrete with very low drying shrinkage, even from high-absorption aggregates.

A higher water requirement of the shrinkage-compensating concretes makes additional problem; in the case of these concretes a water-cement ratio higher by 0.05 is employed /2/.

These concretes exhibit also somewhat greater slump loss, especially at elevated temperatures, than that of corresponding Port-

land cement concretes. It can be eliminated in practice by designing a concrete mix with increased initial slump or by addition of retarding agents. Mehta ascertained very good action of 0.05% citric acid /2/ and Collepardi et al. of other hydroxy acids and polyalcohols /48/. Nevertheless these concretes should be protected against drying in early stages of the hardening, as the drying shrinkage influences very unfavourably the expansion level and can cause shrinkage cracks.

For behaviour of expansive mortars and concretes in various conditions, especially during thermal curing as well as during drying, a great importance of the stability of ettringite has been emphasized. As reported by Mehta, no changes in X-ray diffraction pattern of a synthetic ettringite specimen have been observed when heating under dry conditions up to  $65^\circ C$  /51/. On the other hand, under moist conditions the ettringite phase is unaffected even when exposed to  $93^\circ C$  for 1 hour. Similar results were obtained by Satava and Veprek /52/. They found, that in the atmosphere saturated with water vapour the ettringite decomposes at  $111^\circ C$ , with formation of  $C_4ASH_{12}$  and  $CS_{0.5}$ .

Ludwig /53/ and four years later Skoblinkskaya and Krasilnikov /54/ examined desorption isotherms and corresponding X-ray diffraction patterns of ettringite samples. Ludwig reported, that the crystalline structure of ettringite shows no detectable changes in XRD pattern up to 12% relative humidity. At this humidity ettringite loses about 10 molecules of water. Also Berman and Newman stated that X-ray diffraction pattern of the specimen of ettringite after the removal of 9  $H_2O$  remains unchanged /55/. On the other hand Mehta and Klein observed no significant differences in the X-ray diffraction pattern of ettringite, which loses as many as 15 molecules of water /3/.

A detailed analysis of desorption isotherm of ettringite based on its crystalline structure, determined by Moore and Taylor /30/ has been carried out by Skoblinkskaya and Krasilnikov /54/. They found, that two of 32 molecules of water do not enter into the structure of ettringite; these molecules withdraw over a wide range of vapour pressures, which is characteristic of water in the lattice defects as well as of adsorbed water. Thus the structure of ettringite contains 30 molecules of water. In the first step of dehydration ettringite loses 12 molecules of water.

X-ray examination gives no changes in the structure and the microscopic observations indicate the presence of two hydrates: 30  $H_2O$  hydrate and 18  $H_2O$  hydrate. The 12 water molecules removed are probably these molecules from calcium polyhedra, which make additional vertices of the trigonal prisms.

In the second step of dehydration, ettringite loses further 12 molecules of  $H_2O$ .

That will be, at first, the third molecule of water from the main vertex of the trigonal prism, whereupon the last molecule of water leaves the Ca polyhedron, and  $n$  falls to 6. As early as the amount of water molecules decreases to 16, the 18  $H_2O$  hydrate ceases to exist and regular crystalline structure appears to disintegrate.

The third, last step of the dehydration is concerned with the most strongly bound 12 hydroxyl groups.

As is evident from all these investigations, the structure of ettringite is stable, and the curing of concrete under hydrotothermal conditions, even at temperatures exceeding 90°C, will cause not any decomposition of this phase. On the other hand, high-pressure steam curing will produce a decomposition of ettringite. Under these conditions calcium monosulphoaluminate hydrate can be stable, as it decomposes in saturated vapour atmosphere at temperatures exceeding 190°C /52/.

Resistance of expansive concretes to sulphate solutions depends on the type of expansive cement; only K-Type cement shows good resistance /2, 56/. Durability of these concretes is very high, as has been discovered by Polivka et al. /57/.

Self-stressing concretes should be designed with extreme care, basing on laboratory tests. The effect of the type and amount of steel reinforcement should be taken into account.

Polivka /58/ pointed out, that for successful application of self-stressing concrete triaxial restraints of its expansion are needed, except such elements as slabs, in which biaxial restraints are sufficient, if the concrete is kept at relatively low prestress level.

#### CONCLUSIONS

The position of expansive cements and concretes produced with these cements has been evidently fortified. At the same time a substantial progress is made in the understanding of the chemistry of these cements. It is to be expected, that in near future new factory produced types of these cements will appear, especially these with MgO as expansive component.

New prospects for application of the K-Type clinkers or very similar ones have been pointed out by Mehta /59/. They repose on the possibility of manufacturing of clinkers with modified compound composition at temperature substantially lower as Portland clinkers, but which would be similar in performance to Portland cement.

#### Acknowledgement

I gratefully acknowledge the assistance of the many research-workers who have communicated their results to me and have been

helpful in more complete presentation of the problem of expansive cement in this paper, and especially to Prof. Mehta, Prof. Mather, Prof. Calleja, Dr Cottin and Dr Skalny.

**INTRODUCTION.** Mankind today is facing two global problems - apart from others - whose successful solution is going to affect not only the economic affluence of the peoples in the modern world but the health and well-being of future generations as well. They are the necessity to protect the environment against pollution and that of conserving energy.

The cement industry is one of the most material- and energy-consuming branches, and its contribution to the solution of these two problems can be very considerable. According to forecasts made by some scientists, the world production of cement by 1985 will reach 1 billion tons (1) which will require more than 1.5 billion tons of raw materials and some 200 million tons of fuel.

The chemical, metallurgical, coal and other industries yield hundreds of tons of technogenic by-products and waste materials which are not sufficiently utilized as yet. Many of these materials may be successfully used as raw materials and active mineral admixtures in cement industry (2). The utilization of by-products is one of the main means of saving energy in cement industry (3,4).

Blast-furnace granulated slags have been extensively used in the Soviet Union for a long time. Their yearly consumption in cement industry is from 28 to 30 million tons. Calculations show that out of all possible ways of utilizing blast-furnace slags their use in cement industry is, from the economic point of view, the most profitable one. The valuable experience accumulated in this field in the USSR was summarized in a paper presented by V.I. Satarin at the Sixth International Congress on Cement Chemistry in Moscow (5).

Fuel ashes and slags are used more and more in the production of Portland cement. Extensive research and experimental work is carried out to utilize of other kinds of technogenic by-products produced by a number of industries (chemical gypsum, electrothermophosphorous slags, non-ferrous metallurgy slags, etc.).

#### I. UTILIZATION OF TECHNOGENIC INDUSTRIAL BY-PRODUCTS CONTAINING $2\text{CaO} \cdot \text{SiO}_2$ IN CEMENT PRODUCTION

The present paper deals with the experience of utilizing technogenic by-products, mainly dicalcium silicates formed during the production of alumina, in cement industry.

In contrast to foreign countries, the main trend in alumina industry in the USSR is more extensive use of highly siliceous kinds of alumina-containing raw materials,

like siliceous bauxites, nephelines, aluminates and some other minerals. Nephelinic ores are of special practical interest in this respect.

The nephelinic ores which are found in unlimited quantities in the USSR are poorer in alumina and richer in silica than bauxites and differ from the latter in that they have a higher alkali content (10 to 20 percent  $\text{R}_2\text{O}$ ). Such a composition makes them, according to Soviet researchers, a valuable raw material complex for the production of alumina, soda and cement.

In the USSR, following research by Soviet scientists (I.L. Talmud, O.N. Zakhar-zhevski, V.P. Pochivalov, N.I. Vlodavets, V.A. Krochevski, F.N. Stokov and others (6)), for the first time in world practice, an all-round and practically waste-free processing of nephelinic ores and concentrates into alumina, soda and potash using the so-called sintering method has been realized. It is done on an industrial scale, at three enterprises. The by-product of this process is a nephelinic slurry containing up to 50 percent water and 80 to 90 percent of  $\beta$ - $\text{C}_2\text{S}$  in the solid component.

The possibility of producing binders using the solid component of nephelinic slurry was first studied by V.A. Kind, N.I. Voronin and P.I. Bozhenov as early as 1932-1935. Their purpose was to produce a non-calculated binder which they called "nephelinic cement" and which consisted of 80 percent of dried slurry and 20 percent of lime, with an admixture of gypsum. But because this cement was found to quickly lose its activity during storage and transportation, it was not accepted industrially. The authors also pointed to the possibility of utilizing this reject material as raw material in the production of Portland cement.

This work was continued by S.D. Makashev (7) and in the postwar years by L.S. Kogan (8), S.M. Royak and others. They discovered some specific physico-chemical properties of the belite product, which considerably differ from those of the traditional raw materials in current use in cement production and which to use this product both in the production of Portland cement clinker at considerably lower energy consumption levels and as a hydraulically active component in cements which, according to the authors, closely resembled common Portland cement.

Though investigations in the field of comprehensive processing of nephelinic ores into alumina, soda and potash, with the belite by-product being utilized in the production of cement, were completed on the whole, in the USSR, in 1938-1940 (8,9), the industrial realization of the resultant technology had to be put off because of the World War II and was carried into effect in 1948 in Volkhov, near Leningrad.

Apart from nepheline, Soviet scientists in 1939-1941 investigated other raw materials suitable for the production of alumina and cement.

For example, I.S. Idlejev, B.I. Kogan, A.F. Dumskaya, S.D. Makashev and others studied the ash of the Moscow brown coals for possible use as a new alumina raw material. The ash, when processed by the alkaline method, yields, besides alumina, the so-called "ash slurry" whose solid part contains as much as 70 to 75 percent of  $\beta$ -C<sub>2</sub>S. S.D. Makashev (1939-1940) found that this technogenic by-product, just like nephelinic slurry, made a very effective raw material for producing clinker and a good component of Portland cement (7).

The same author obtained similar results for technogenic belite materials (slurries) formed during alumina extraction using the same method of extraction from new alumina raw materials like kaolin, mica slate, colliery dump rock etc. which were investigated at V.A.M.I. and G.I.P.Kh. It should also be remembered that the "Svobodny Sokol" plant in Lipetsk produced in 1938-1940 - 225 thousand tons of aluminate-silicate cement. The basic component of this cement was  $\gamma$ -C<sub>2</sub>S obtained by slow cooling of blast-furnace slags having a high percentage of alumina. The cement required no grinding due to the autopulverization effect during inversion ( $\beta$ -C<sub>2</sub>S  $\rightarrow$   $\gamma$ -C<sub>2</sub>S) and was of 250 to 400 grade.

Following the method and technology worked out by Ch. De Sey assisted by K. Dickerhoff, alumina was industrially produced from TPS ash at a cement factory in Rüdersdorf. The TPS was using brown coal, and the "black" slurry formed in the process and consisting for the most part of  $\gamma$ -C<sub>2</sub>S was utilized in cement production as a raw mix component (10).

So, the beginning of the industrial utilization of technogenic C<sub>2</sub>S in cement production dates back to the '30ies and '40ies.

The alumina industry in the USSR uses nephelinic ores from various deposits.

According to N.V. Belov (11), the crystal cell of nepheline has the following formula:

The chemical principle of extracting alumina from nepheline is based on formation of soluble alkali aluminates,  $\text{Na}_2\text{O} \cdot \text{Al}_2\text{O}_3$  and  $\text{K}_2\text{O} \cdot \text{Al}_2\text{O}_3$ , and on conversion of silica into the insoluble compound  $2\text{CaO} \cdot \text{SiO}_2$  in the course of reaction:

Here the following optimum ratios must be maintained in the alumina charge between the basis oxides (6):

I. STRUCTURE AND PROPERTIES OF DICALCIUM SILICATE IN TECHNOGENIC BY-PRODUCTS OF ALUMINA INDUSTRY. It is now accepted that C<sub>2</sub>S exists in five polymorphic forms:  $\alpha$ ,  $\alpha'$ ,  $\alpha''$ ,  $\beta$  and  $\gamma$ , with different stability intervals at heating and cooling.

Transition of modifications is accompanied by complete reconstruction of the crystal lattice (12) or an insignificant structure shift (13), which affects enthalpy and conversion rate (14).

The structure of crystal lattices of all the polymorphic forms of calcium orthosilicate has been studied fairly well. The  $\alpha$ -form features hexagonal (or, according to some reports, trigonal) symmetry, while the  $\alpha'$ ,  $\alpha''$  and  $\gamma$ -C<sub>2</sub>S forms are orthorhombic and the  $\beta$ -form is monoclinic. The structure of all the modifications is made up of independent SiO<sub>4</sub> tetrahedrons linked together by calcium atoms whose coordination changes from 6 to 10 during transition from the  $\gamma$ - to the  $\alpha$ -form. Hydraulic activity of dicalcium silicate modifications varies.  $\gamma$ -C<sub>2</sub>S is considered hydraulically inactive, although it is reported (15,16) that it shows binding properties in the presence of alkalis and in aluminosilicate cements. Aluminosilicate slags with compositions within the crystallization field of dicalcium silicate in the  $\text{C}_{12}\text{A}_7$ -C<sub>2</sub>S-CA elementary triangle of the CaO-SiO<sub>2</sub>-Al<sub>2</sub>O<sub>3</sub> system were industrially produced in a blast furnace.

When cooled gradually, the slags disintegrated into powder due to the transformation of  $\beta$ -C<sub>2</sub>S into the hydraulically active  $\gamma$ -form.

The strength of cement solution at 28 days reached 250-400 kgs/cm<sup>2</sup>. This was a fast-hardening cement with daily strength of 100-150 kg/cm<sup>2</sup>. Until then it was thought that only  $\beta$ -C<sub>2</sub>S was hydraulically active. At present activity has been found to exist in high-temperature forms of dicalcium silicate as well. Properties were found to depend on the composition and quantities of admixtures used for stabilization.

Stabilization of C<sub>2</sub>S modifications is due to isomorphism in cationic and anionic parts of the structure (16, 17). Isomorphic substitutions of Ca and Si lead to disarrangement of the structure which is accompanied by changes in lattice symmetry and results in corresponding changes in the physical, chemical and technical properties of C<sub>2</sub>S solid solutions. An important factor in the formation of C<sub>2</sub>S properties is the ability to form solid solutions with a great number of oxides. The C<sub>2</sub>S lattice may comprise ions of Al, Fe, K, Na, Ti, Cr, B, P, oxides or their combinations (12-14, 18, 19). Dissolution of CaO or SiO<sub>2</sub> in C<sub>2</sub>S lattice is also possible leading to deviation from the stoichiometric composition of C<sub>2</sub>S. In the case of CaO  $\beta$ -C<sub>2</sub>S is stabilized,

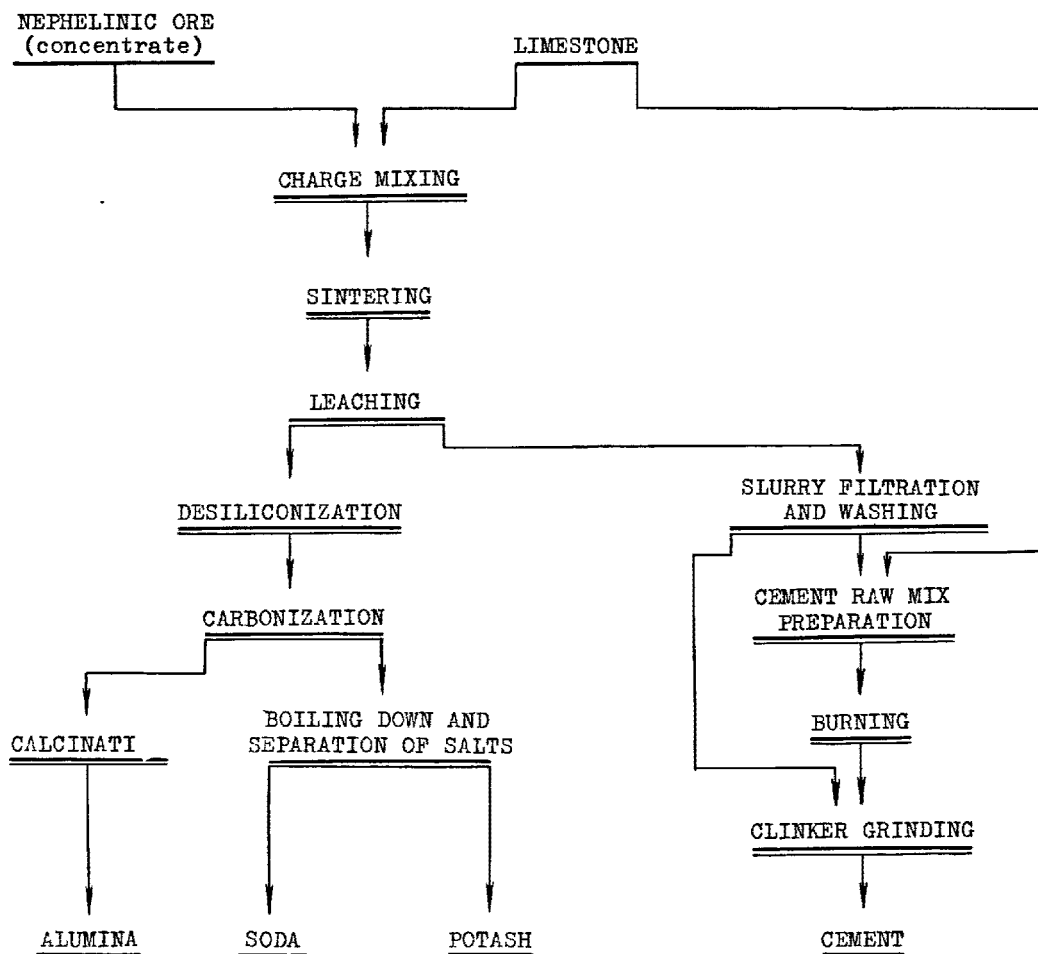

Fig. 1. Basic diagram of integrated processing of nepheline.

in the case of  $\text{SiO}_2$ , the  $\beta \rightarrow \gamma$  inversion is made easier.

In technogenic products of apatite or phosphorite, processing undecomposed residues of basic rocks are always present.

$\text{P}_2\text{O}_5$  present in these products, depending on quantity, may cause stabilization of  $\alpha$ ,  $\alpha'$  or  $\beta$ -forms of  $\text{C}_2\text{S}$  (18, 19). Although the presence of the  $\alpha$  and  $\alpha'$  modifications together with  $\beta$ - $\text{C}_2\text{S}$  does not reduce hydraulic activity of nephelinic slurries, it can lessen considerably their reactivity in burning.

Of particular importance to the structure of calcium orthosilicate in technogenic products are solid solutions with  $\text{Al}_2\text{O}_3$  and  $\text{Fe}_2\text{O}_3$  (red slurries) which facilitate the  $\beta \rightarrow \gamma$  inversion (15).  $\text{K}_2\text{O}$  at slow cooling was shown (20) to stabilize the  $\beta$ -form, while quick quenching resulted in the formation of an  $\alpha'$ - and  $\beta$ - $\text{C}_2\text{S}$  mixture.

According to reports (21), solubility in  $\text{C}_2\text{S}$  drops in the series  $\text{Fe}_2\text{O}_3 > \text{MgO} > \text{TiO}_2$  and is, respectively, 1.8%, 0.75 - 1.5% and 0.75%. These admixtures facilitate the  $\beta \rightarrow \gamma$  inversion progressively in the same order. Solubility of  $\text{Na}_2\text{O}$  in  $\text{C}_2\text{S}$  does not exceed 0.6% but, unlike the above mentioned oxides, alkali stabilizes  $\beta$ - $\text{C}_2\text{S}$ .

It was shown (22) that  $\text{Na}_2\text{O}$  may be included in the  $\text{C}_2\text{S}$  lattice in considerable quantities (up to 5% or more) if alkali is introduced as a carbonate or sulphate. The alkali-stabilized  $\beta$ -form, however, possesses reduced hydraulic activity in comparison to the  $\alpha$ - and  $\alpha'$ -modifications. Higher hydraulic activity in  $\alpha$ - and  $\alpha'$ -forms of  $\text{C}_2\text{S}$  and the possibility of their stabilization by chemical admixtures was reported by other authors as well.

It follows then that in alkali-containing technogenic products it is the  $\beta$ -form that is stabilized, whereas alkali-free

sinters contain mainly the  $\gamma$ -form of  $C_2S$ . On the other hand, alkalis should be removed as completely as possible because of the adverse effect they have on the quality of cement. It should be pointed out that in the presence of small quantities of fluorine not even sodium aluminate can stabilize the  $\beta$ -form, and inversion becomes very intensive. (23)

Kh.N. Nurmagambetov, S.A. Tscherban and V.A. Belousova studied phase composition of orthosilicate on sinters and slurries from alumina factories by infra-red spectrography and X-ray structure analysis (24). Fig. 2 which is based on their findings gives the infra-red spectra of  $\beta$ - and  $\gamma$ - $C_2S$ , as well as those of some nephelinic and bauxite sinters. According to the results obtained, in nephelinic sinters and slurries  $C_2S$  is present mainly in its  $\beta$ -form, whereas in bauxite sinters and slurries the  $C_2S$  form was not found to correspond to any of the known modifications. The authors ascribe this phenomenon to large quantities of ferric oxide dissolved in the  $C_2S$  lattice. But a more natural supposition is that the bauxite sinters studied by the authors were heterophase and contained, apart from  $C_2S$ , admixtures of aluminoferritic nature. An indirect confirmation of this, as the same study points out, is chemisorption of  $Al_2O_3$  by low-modulus solution whereas  $\beta$ - $C_2S$  from nephelinic sinter practically did not absorb a  $Al_2O_3$ . Formation in nephelinic slurry of practically only the  $\beta$ -form is also reported in (25), but in the same study it is also noted that  $\beta$ - $C_2S$  absorbs alumina from solution with formation of hydrogarnets.

According to other data, nephelinic sinters and slurries contain, apart from the  $\beta$ -form, also  $\alpha$ - and  $\alpha'$ -modifications of  $C_2S$  (26).

According to some reports, the presence of a particular form or forms of  $C_2S$  in slurries depends on the quantity of admixtures (see Table I).

Phase composition of slurries in this paper (26) was studied using X-ray, thermographic, crystalloptical, IR-spectrum and chemical methods.

The  $\alpha$ -form of  $C_2S$  in slurries resulting from the processing of highly siliceous bauxites was identified on the basis of X-ray data and by the presence of a broad absorption band in the 800- to 1000  $cm^{-1}$  region of the IR spectrum. When heated up to 800°C,  $\alpha$ - $C_2S$ -containing slurry samples showed an intensive  $\alpha \rightarrow \beta$  conversion. This process was accompanied either by separation of the admixtures and their localization around  $C_2S$  grains or by formation of a new phase of the mellite type. Stabilization of the  $\alpha$ -form of  $C_2S$  by alkalis was also reported in (27); the  $\alpha$ - $C_2S$  content of clinker was found to be closely connected with the quantity of insoluble alkalis.

It should be stressed in summarizing the above reports, that the crystallochemical structure of  $C_2S$  in the technogenic belite products of nephelinic slurries depends on the quantity of admixtures and the degree of leaching and of alkali aluminates extraction, i.e. on the physico-chemical and technological particulars of alumina production. On the other hand, the latter determines the hydration activity of the technogenic belite product in cement and its reactivity in cement raw mixes, i.e. exactly those properties which are of primary importance to the chemistry, technology and technical properties of cement. Consequently, an optimum technology for the all-round processing of nephelines can result only from combining the interests of both alumina and cement industries.

**2. REACTIVITY OF CEMENT RAW MIXES BASED ON TECHNOGENIC PRODUCTS CONTAINING DICALCIUM SILICATE.** The above discussion concerned the composition and properties of the solid substance of nephelinic slurries, mainly from the point of view of hydration activity generation which makes them suitable for cement production.

Of considerable interest is also utilization of this belite product as an ingredient of raw mixes used to produce cement clinker. One of the first reports concerning prospects of such an utilization was contained in the Makashev paper (7).

The same paper also discussed the main technological aspects of using nephelinic slurries as raw material to produce Portland cement clinker by the wet method.

As a raw material for clinker production, nephelinic slurry formed as a coarse suspension containing 40% of water, has the following technologically important features:

- all the silica and most of the calcium oxide in the solid substance of the slurry are present in the form of belite;
- a higher silicate modulus in comparison to the commonly used clays;
- a fairly considerable percentage of residual alkalis,  $Na_2O$  and  $K_2O$ .

The first factor is responsible for higher reactivity of the slurry, a lower level of carbonate raw material consumption and, consequently, an increased output capacity of kilns and a reduced heat consumption required for burning. In contrast, the two other features make the utilization of nephelinic slurries as raw material somewhat difficult.

Table 2 gives typical chemical compositions of the solid substance of industrial nephelinic slurries used by the cement industry (28).

The Achinsk slurry has a very high  $Al_2O_3$  and alkali content which points to worse conditions of sodium aluminate extraction from the sinter.

TABLE I										
Chemical composition and modification of technogenic $C_2S$ in slurries										
Slurry	Oxides in slurries, %									Cristal structure $C_2S$
	$SiO_2$	$Al_2O_3$	$Fe_2O_3$	$CaO$	$MgO$	$SO_3$	$TiO_2$	$Na_2O$	$K_2O$	
After processing:										
clays	22.38	4.0	1.08	54.65	1.64	0.21	0.17	0.33	0.11	$\gamma$
nephelins	28.79	2.48	2.89	54.67	2.55	0.93	0.33	0.93	1.16	$\beta$
highly siliceous bauxites	25.90	3.41	9.05	48.03	1.29	0.57	2.33	2.13	0.50	$\alpha$

Fig. 2a. Infrared spectra of the  $\beta$  and  $\gamma$ -modifications of dicalcium silicate.

Fig. 2. IR spectra of  $\beta$  and  $\gamma$ - $C_2S$  and sinters of nephelins and bauxites.

All of the solid substance of slurries is mainly composed by  $\beta$ - $C_2S$  crystals. The  $C_2S$  grains in all the slurries do not differ greatly in size (up to 12-18  $\mu m$ ).

Fig. 2b. Infrared spectra of the solid substance of slurries after the leaching of sinters: 1-nephelinitic sinter; 2-bauxitic sinter.

Judging by X-ray photographs,  $C_2S$  in the Achinsk slurry has the most defective structure of all.

In the course of heating, recrystallization of  $C_2S$  grains is observed, starting at about  $900-1000^\circ C$  and rapidly proceeding at  $1100^\circ C$ . Belite grains grow to up to  $35-50 \mu m$ . The belite product of the Achinsk slurry shows simultaneous disintegration of solid solutions and isolation, at grain boundaries, of ferric oxide which forms the aluminoferritic phase. According to P.I. Bozhenov (29), admixtures in  $C_2S$  crystals are originally adsorbed along the boundaries of mosaic blocks, in intercrystallite zones, where their concentration is much higher than in the crystal volume. At a change of temperature, disintegration of solid solutions may occur in these zones even before the solubility limit is reached in the crystal volume. When the cooling regime is changed, the admixture may be either isolated forming a new phase or "dissolved" in the crystal volume. Clinker properties thus become controllable. It should be noted that the presence of amorphized intercrystallite films in clinker phases, and their influence on clinker properties was confirmed by electronic microscopic investigations carried out by U.I. Papiashvili (30).

Recrystallization of  $C_2S$  grains on heating and decomposition of solid solutions somewhat reduces the reactivity of raw mixes based on nephelinic slurry. That is why the heating should be carried out as quickly as possible. Because of a higher silicate modulus, bicomponent mixes of nephelinic slurry and limestone are inferior, as far as reactivity is concerned, to mixes containing clay or marl and fluxes. That is why a tetra-component raw mix is in common use consisting of nephelinic slurry, limestone, and aluminous and ferriferous correction admixtures. This results in an unwanted reduction of slurry consumption per ton of clinker in comparison to bicomponent mixes (31).

Use of  $0.4 - 0.5\%$   $CaF_2$  admixture as a mineralizer allows to carry out successfully the burning of a bicomponent raw mix having a silicate modulus of 4.5. This increases the nephelinic slurry percentage in raw mix from 38-40 to 50%, while that of limestone is reduced from 55-57 to 50%.

Total raw material consumption is reduced by about 10 percent by mass (32).

Of particular importance to the reactivity of a raw mix and the quality of clinker obtained is the percentage of alkali oxides present, especially that of  $Na_2O$ , whose sublimation during burning does not take place as easily as in the case of  $K_2O$ . That is why the Achinsk slurry, as far as reactivity goes, is very inferior to the other two.

According to some authors, the unavoidable recrystallization of belite in the preparatory zones of rotary kilns results in such a substantial drop of reactivity in raw mixes based on nephelinic slurries that it affects the quality of clinker (33). Alite which is formed in such clinkers shows poorly defined crystallization and a defective structure with crystal sizes of 20 to

$30 \mu m$ , while the hydration activity of clinker is about 15 percent lower than when clay is used. However, the cause of the inferior microstructure and reduced activity of clinker is not the reduced reactivity of the raw mix but rather the adverse effect of  $Na_2O$  on the alite structure.

Fig. 3 gives changes in  $CO_2$  and  $CaO$  content in roast material along the length of the 175-meter kiln of the Achinsk factory (34). As can be seen, the amount of  $CaO$  does not exceed 5 percent in any part of the kiln, whereas in the case of the usual charge, it reaches 15 to 18 percent at the end of the decarbonization zone. Assimilation of lime by the belite product of nephelinic slurry takes place parallel to decomposition of  $CaCO_3$ .

Fig. 3. Change in content of (1)  $CO_2$  and (2) free  $CaO$  in roast material along the length of the kiln.

A high  $Na_2O$  concentration in the charge of the Achinsk factory is responsible for the formation of large quantities of spurrite  $2(C_2S) \cdot CaCO_3$  in the roast material. At the 135th meter of the kiln it accounts for 46.7 percent of the roast material mass. Decomposition of spurrite takes place at a temperature above  $940^\circ C$  according to the reaction:

The newly-formed belite and  $CaO$  *in statu nascenti* have adequate reactivity so that the formation of spurrite is, from this point of view, even useful. But at the same time intensive clinker dust generation

TABLE II

Composition of solid substance of nephelinic slurries which are utilized in the USSR cement industry, in percentages, and its modulus									
Slurry	SiO <sub>2</sub>	Al <sub>2</sub> O <sub>3</sub>	Fe <sub>2</sub> O <sub>3</sub>	CaO	MgO	Na <sub>2</sub> O	K <sub>2</sub> O	Silicate modulus	Alumina modulus
Pikalevo slurry	28.8	2.5	2.9	54.7	2.5	1.2	0.9	5.36	0.85
Volkhov slurry	28.4	2.8	2.6	55.2	1.7	1.1	0.8	5.17	1.06
Achinsk slurry	27.3	4.6	3.4	52.2	1.2	0.7	1.4	3.42	1.33

is observed which makes it much more difficult for the kilns to function. At other factories which use nephelinic slurries of a lower general percentage of alkali and especially lower Na<sub>2</sub>O content, the operation of kilns presents no snares caused by the dusting effect.

At higher content of water-soluble alkalis, rheological properties of raw slurry deteriorate as well when the wet method is used.

Table III gives average data (1973) on the mineralogy and strength (activity) of clinker at factories which use nephelinic slurry as a main component of raw mixes.

These data show that all these clinkers have high elite percentages.

The Achinsk clinker is inferior to the other ones in quality despite a higher C<sub>3</sub>A percentage, because of a higher alkali content both in nephelinic slurry and clinker. The Volkhov clinker is in the most active category and is superior in quality to most of the clinkers produced from traditional raw materials.

At all the above factories the output capacity of rotary kilns is at least 30 percent higher and the specific fuel consumption is 20 to 25 percent lower than for kilns of the same type used for the processing of traditional raw materials.

Earlier we discussed some of the investigation results and the main lines of practical utilization in cement industry of technogenic belite products which are formed during the all-round processing of nephelines into alumina, soda and potash.

In future, other technogenic belite products with similar physico-chemical properties can be obtained from the all-round processing of other alkaline aluminosilicate mineral rocks. Large deposits of such minerals are found in Siberia and the Far East, and in particular in the area through which the Baikal-Amur railway line is being built.

Similar belite by-products may also be obtained in alumina production using the alkaline charge sintering method, with soda added, from such materials as fuel ashes,

kaolins, clay and mica dump slate and other materials containing sufficient amounts of alumina.

But, in utilizing TPS ashes and kaolins, clays and clay slate and other alumina-containing materials, a non-alkaline method of processing may be preferable, like that proposed by the Polish academician E. Grzymek.

The non-alkaline method of processing such materials for alumina which yields  $\gamma$ -C<sub>2</sub>S powder, with  $\gamma$ -product grain sizes of about 10 to 20  $\mu$ m, to be used as a component of cement raw mixes, was discussed by E. Grzymek in detail at the 6th International Congress on Cement Chemistry in Moscow (35). One of its major advantages is the absence of alkali admixtures in its  $\gamma$ -product, and is the corresponding difficulties in clinker burning. It should be said, however, that ensuring a steady and complete pulverization of alkali-free alumina sinters, when the original raw material is of unstable composition, is not a simple matter.

Original raw materials almost always contain P<sup>5+</sup>, B<sup>3+</sup>, Mn<sup>4+</sup>, Cr<sup>6+</sup>, V<sup>5+</sup> and some other ions in various combinations which, though present in relatively small quantities, can have a stabilizing effect on C<sub>2</sub>S and thus obstruct the full polymorphic conversion on  $\beta \rightarrow \gamma$ -C<sub>2</sub>S. This can be prevented, according to E. Grzymek, if the sinter is burned in a reducing atmosphere.

Slower dispersion rates of alumina sinters may also be caused by melts of a certain composition, which facilitate formation of finely crystalline C<sub>2</sub>S where the formation of  $\gamma$ -C<sub>2</sub>S nucleus is somewhat hindered, by rapid cooling of the sinter as well as by other factors.

From 1954, experimental industrial production of alumina and cement utilizing fuel ashes has been in progress in the Polish People's Republic. Taking into account the experience accumulated over the years in this field, a factory is being built there with an output capacity of about 100 thousand tons of alumina and 1270 thousand tons of cement. A similar factory is being built in the Hungarian People's Republic in co-

TABLE III

Mineralogy and strength of clinker						
Factories (large pro- duction units, plants)	Composition of clinker, mass percentages					Compression strength at 28 days, MPa

operation with the PPR.

Following reports on the possibility of utilizing a number of new alumina-containing non-bauxitic raw materials, Soviet scientists have been engaged in extensive research of the technogenic  $\gamma$ -product for its possible use in raw mixes in cement clinker production.

For instance, researchers at V.A.M.I., Leningrad ascertained the basic possibility of utilizing, as an alumina raw material, the mineral part of coals and enclosing rocks from the Ekibastus coal field in the Kazakh SSR.

Around this unique coal field, a number of large TPStations have been planned and partly built which, apart from alumina-containing dump rock with as much as 35 percent of  $Al_2O_3$ , yield ashes and slags containing up to 25-32 percent of  $Al_2O_3$  and 62-68 percent of  $SiO_2$ . The overall output of these materials from 3.3 million tons a year is to reach 30 million tons by 1990.

The self-pulverizing aluminocalcium sinter (dispersion degree of up to 95-99%) produced from the above materials by the non-alkaline sintering method, subjected to leaching, yields a  $\gamma$ -product containing as much as 60 - 65 percent of  $\gamma$ -C<sub>2</sub>S (36, 37).

Research at Giprotsement (38) showed this material to be a highly reactive component of raw mixes for obtaining a highly active clinker, analogous in this respect to the  $\gamma$ -product which is formed during the extraction of alumina from the previously studied kaolin from the Angren deposit.

It should be noted however that, notwithstanding its positive properties discussed here, the  $\gamma$ -product produced by the above method, is lacking in, or, according to some reports, has a very weak hydration activity. This prevents its use as an active component of Portland cement, until methods of activation are found.

3. BUILDING AND TECHNICAL PROPERTIES OF PORTLAND CEMENTS WITH ADMIXTURES OF TECHNOGENIC DICALCIUM SILICATE. Before turning to the discussion of the existing data concerning properties of cements which, apart from clinker, contain various quantities of technogenic dicalcium silicates as an ac-

tive component, the term used to describe these cements should be discussed since it is not generally recognized yet.

The term used at present by some authors (39-41) "nephelinic cement". It was used previously to designate a binder produced by grinding together a mixture of dried nephelinic slurry, lime and gypsum.

Apart from this, a cement based on the mixture of Portland cement clinker and technogenic belite product can be produced, according to the above discussion, by the method of alkaline sintering not only from nephelinic raw materials, but also from other kinds of alumina-containing materials, like highly siliceous bauxites, fuel ashes, clay and clay slate, kaolin. To avoid introducing new names to designate the latter kinds of cement which are quite similar, as far as composition and properties are concerned, to the ones produced by processing of nepheline, cement which is composed of clinker and technogenic belite product in excess of 20 percent is called "belite Portland cement", shortened to BPC, throughout the discussion that follows. Portland cements with lower percentages of technogenic belite and clinker which is produced by burning a raw mix with nephelinic slurry in it require no special designation.

These cements are produced in the USSR at the factories in Volkhov and Achinsk, where technogenic belite product is used as an active mineral admixture in the production of Grade 400 and 500 Portland cements (with admixtures) and of the GOST 10178-76 fast-hardening Portland cement. The high-quality clinker from the Volkhov factory allows to produce mostly cements of enhanced strength. Building and technical properties of BPC with over 20 percent of technogenic belite were studied in detail at Giprotsement and L.I.S.I., Leningrad, under the guidance of P.I. Bozhenov (39-40).

Fig. 4. shows how the quantity of belite product in nephelinic slurry affects the strength of cement produced at the Pikalevo factory (42).

At initial hardening stages, BPC with a higher belite percentage is found to be somewhat inferior in strength to cement wit-

Fig. 4. The influence of nephelinic-slurry belite product and calcium silicate on BPC strength ( $R_{comp}$ ).

hout admixtures, but at one to three months (and even at 7 days in the case of cement from the Volkhov factory) BPC having 40 to 45 percent of nephelinic slurry catches up with the strength values of control samples of Portland cement without admixtures and even surpasses them at later hardening stages.

At greater percentages (60-80%) of belite product, BPC reaches the strength of cement without admixtures at six months. But high alkali content (as in some of the cements from the Achinsk factory) keeps the strength values down (below 20 MPa) at all hardening stages. However, cements with up to 80 percent of belite, after wet-heat treatment, and especially after autoclave treatment, allow to obtain articles of superior strength (39, 43).

Despite the different physico-mechanical conditions under which  $\beta$ - $C_2S$  is formed in belite products and Portland cement clinkers, these belites are so similar that their hydration processes are very much simi-

ke both in kinetics and in the phase composition of new formations.

BPC strength values in Fig. 4 are shown to depend not only on belite product content, but also on the quantity of  $C_2S$  and the overall  $C_2S$  content in cement, including belite contained both in clinker and in belite product (42).

It follows that starting at three to seven days, technogenic belite takes an active part in cement stone strength formation.

As the overall  $C_2S$  content grows and the  $C_2S$  quantity is accordingly reduced, cement hardening rate slows down, but at later hydration stages strength values grow, e.g. at six months to one year, the maximum strength is observed in cements containing 20 to 30 percent of alite and 50 to 60 percent of belite.

It should be mentioned, however, that water-consumption rates in BPC, estimated on the basis of water content in normal consistency paste, are increased by 3 to 4 percent in the presence of 40 to 60 percent of belite product. But, according to P.I. Bozhenov, this has no effect on the water-consumption rates in the case of BPC-based concretes.

A special problem, as far as BPC is concerned, is a considerable reduction of setting time at higher belite product content. Already at 30 to 40 percent the setting time drops to the lowest level of 45 minutes allowed by GOST 10178-76. At 45 to 60 percent, setting starts 20 or 30 minutes after mixing.

An additional washing of slurry to remove the residual alkali aluminates permits to maintain the standard setting times in BPC containing 50 to 60 percent of belite product, but even in this case the beginning and the end of setting are observed much earlier than in control samples.

Fig. 5 shows the effect of water-soluble alkalis present in nephelinic slurry on the content of oxides, in particular of  $Al_2O_3$ , in the liquid phase during the hydration of slurry (44).

These data show that in the initial stages, water-soluble alkalis cause a sharp increase in the extraction of aluminate ions from the slurry and in their transition to the liquid phase, which results in the reduction of setting time. At the same time, the hydration of  $\beta$ - $C_2S$  grains is considerably accelerated.

In order to avoid producing cements with non-standard setting times the industry still gives preference to the production of cements with up to 15 percent of belite product. General characteristics of industrial cements are given in Table 4.

All the cements are characterized by high bending strength which is 10 to 20 percent higher than in control Portland cements.

TABLE IV

Cement characteristics								
Factory	Grade	Setting time, hours, minutes		Normal consistency, %	Strength, R comp, MPa			
		Start	Finish		3d.	7d.	28d.	1 day (steaming)*
Achinsk factory	400	2 <sup>02</sup>	3 <sup>10</sup>	27.04	28.8	38.4	45	32.7
Volkhov factory	500	2 <sup>50</sup>	3 <sup>40</sup>	25.88	28.7	38.7	51.4	39.7

\* As per schedule: 2+3+6+2hrs (preliminary curing + temperature rise + warming up at 85°C + cooling).

Fig. 5. The influence of water-soluble alkali content in the liquid phase during the hydration of belite product on  $\text{Al}_2\text{O}_3$  content: 1-0.21%, 2-0.5%, 3-1.0% and 4-2.0% of  $\text{R}_2\text{O}$  (for  $\text{Na}_2\text{O}$ ).

Cements having higher belite-product contents (30 to 60 percent) were produced at the Volkhov factory. At contents up to 30 percent cements were of Grade 400 to 500; at 40 percent, Grades 300 to 400 were obtained, and at 50 to 60 percent, cements were of Grade 300 (45).

Standard setting times were observed only in cements containing up to 30 percent of belite product. But the somewhat accelerated setting did not prevent the experimental cements from being successfully used by Leningrad factories producing prefabricated reinforced-concrete articles. High-quality articles were also produced from lightweight aggregate concrete. Despite some increase in the specific consumption of cement, economy in clinker used to produce concrete, if we consider the reduction of its content in

cement, was 30 to 50 kg/cu.m.

Among other properties of BPC as a building and technical material a reduced heat-evolution during hydration, a lower water-separation rate, a sufficiently high corrosion and frost resistance and an ability to provide an increased water-tightness of concretes should be noted (40).

Concretes based on this type of cement are now intensively studied in particular their creep.

It should be noted that there is considerable progress in the technology of leaching of alumina sinters at Soviet alumina factories where nepheline is used. These improvements allow to raise the degree of alumina and alkali extraction and, what is of major importance to cement chemistry, to reduce accordingly the alkali content in the belite product.

A very interesting paper is presented at this congress (NIITsement) by Akunov, Dmitriyev, Makashev et al. concerning the possibility of increasing the strength of BPC by the method of jet pulverization instead of by grinding in traditional ball mills (46).

The authors also obtained positive results in applying this method to increase the strength of Portland cement containing 30 percent of  $\gamma$ -product.

At present nephelinic slurries are being used in cement industry mainly to produce clinker and to a lesser extent as an active mineral admixture for cements.

4. SPECIAL CEMENTS BASED ON TECHNOGENIC DICALCIUM SILICATE (BELITE PRODUCT). A low  $\text{C}_2\text{A}$  content in clinkers produced on the basis of nephelinic slurry, as well as high corrosion-resistance in cements with an admixture of technogenic belite product have drawn attention to the problem of using them to produce a sulphate-resistant cement.

To this end, the sulphate-resistance of the common Pikalevo clinker and that of an experimental highly siliceous clinker having a silicate modulus of 5.3 were studied. The latter was obtained by burning a bicomponent raw mix which was composed of nephelinic slurry and limestone (47). The common clinker and the highly siliceous clinker con-

tained, respectively, 4 and 2 percent of  $C_3A$ .

Cements based on these clinkers proved to be sulphate-resistant according to USSR standards, although the expected advantage of the experimental composition was not confirmed.

Practical application of clinkers based on belite slurry raw materials, and of belite product as an active component of sulphate resistant cements is difficult because of the high alkali content.

In order to overcome the adverse alkali effect, it is proposed to add small quantities of phosphorites to nepheline-containing raw mixes (0.8 to 1.5 percent of  $P_2O_5$  in the mix) (48).

In control clinker, formation of  $C_8A_3$  and  $KC_2S_{12}$  alkali-containing phases was observed, with considerable presence of free lime. In phosphorous clinker,  $C_8A_3$  or  $KC_2S_{12}$  phases were not observed, but the presence of the  $Na_4P_2O_7$  and  $Mg_2(PO_4)_2$  was noted. The aluminate phase, along with  $C_3A$ , contained  $C_{12}A_7$ , while the aluminoferritic phase showed a shift towards  $C_6A_2F$  formation.

This controlled phase modification caused clinker strengths to increase by 4 to 13 MPa (28-day samples), while corrosion resistance which was tested in a 5-percent  $Na_2SO_4$  solution and in sea water, was considerably improved. Longer setting times were also observed.

This method of overcoming the adverse alkali effect, although has not yet found practical application, is undoubtedly interesting.

The speedily developing production of oil and gas brought to the foreground the necessity of increasing the production of oil-well cements.

Oil and gas extraction from deep strata seems to be generally favoured throughout the world. This entails drilling or deep and superdeep wells in which temperature reaches hundreds of degrees and pressure is up to a thousand atmospheres. Common oil-well cements, including those used in hot wells, cannot be used under such conditions because they thicken easily and lose their mobility before plugging is completed and because of their low resistance in the extreme conditions of super-deep wells.

The Soviet practice is to use for such purposes cements based on blast-furnace granulated slags.

Investigations which have been carried out in the USSR show that oil-well cements with all the required technical properties may be obtained using technogenic belite products.

Several oil-well cement compositions for super-deep wells, their basic component being the technogenic belite by-product of

alumina production from nepheline, were proposed by S.M. Koyak and A.M. Dmitriyev (49).

The belite-siliceous oil-well cement (BSC) was prepared from a mix containing technogenic belite product and quartz sand at ratios from 70:30 to 30:70, which was ground to a specific surface of 2 to 4 thous.sq. cm/g.

It was found that at temperatures from 150 to 300°C and pressures from 500 to 700 atm. this cement hardened well without activizers such as Portland cement or gypsum. Setting times of BSC depend on the temperature of the medium. At temperature elevation from 105 to 200°C, the onset of setting was accelerated from 4 hrs 15 min to 1.5 hrs, which is within permissible limits. Additional retardation of the onset of setting (1.5 to 2 times) and an increased flow of oil-well mortars can be effected by adding up to 3 percent of bentonitic clay.

The strength of oil-well mortars was increased when the quartz sand content of BSC was raised to 30 percent. BSC prepared from a 70:30 mix of belite product and quartz sand reached its maximum strength of 45 to 50 MPa at 200°C. As the temperature and pressure were increased further, its strength decreased though it remained sufficiently high, up to 15-17 MPa at 300°C and 700 atm. A prolonged curing of hardened samples at this temperature did not cause any strength reduction.

Another BSC composition, along with belite product and quartz sand, includes acid blast-furnace slags. By changing the composition of cement, a product is obtained which can satisfy consumers both in terms of strength and in terms of setting time.

The composition of the new formations resulting from a prolonged steaming of BSC in an autoclave was studied by the method of X-ray structural thermography. The findings showed that both of the two basic components - belite product and quartz sand - take part in the processes of hydration and stone structure formation. Basic hydration products are low-base calcium hydrosilicates of the tobermorite type with minimum basicity of 0.8 (50). There are also unreacted  $\beta$ - $C_2S$  grains and some quartz. No free lime was found in cement stone.

#### CONCLUSIONS

The present paper summarizes mostly research data and experience industrial utilization of technogenic dicalcium silicate (belite products) which have been so far accumulated in the USSR.

Unfortunately, at the time this paper was prepared, rather few sources were known in which similar work done in other countries was discussed. That is why the present review is not as complete as it could have been.

It is to be hoped, however, that in the course of the 7th International Congress on Chemistry of Cement, in discussing corresponding papers, this shortcoming will be overcome.

This hope seems to be well-founded, if one is to take into consideration the continually expanded production of aluminium, that "20th-century metal", from new kinds of alumina-containing raw materials and the insufficient resources of low-siliceous bauxites which still remain the basic source of alumina for aluminium production.

Extensive research by Soviet scientists and the practical experience of all-round utilisation of nephelines and in the future of similar alkaline aluminosiliceous minerals in producing Portland cements in addition to alumina and alkali carbonates, will make it possible:

- to considerably extend the raw material base for the alumina, chemical and cement industries;
- to obtain, during the processing of nepheline into alumina and alkali carbonates, a technogenic belite by-product composed mainly of dicalcium silicate in the form of  $\beta$ -phase, which, on the strength of its physical and chemical properties, is the most effective material for the production of cement clinker and Portland cement;
- using the technogenic belite product, to realize a more economical, in terms of fuel, energy and raw materials, production of cement in relation to the traditional production based on carbonate and clay rocks;
- using the belite product, to develop an efficient production of (a) general-purpose cements of varying activity, including highly alitic and siliceous cements, and (b) special-purpose cements, such as sulphate-resistant cements, low-thermic cements, hydrotechnical and oil-well cements, where this technogenic material can be used as an active component both in cement raw mixes and in Portland cement.

Possibilities exist for extensive use of  $\gamma$ -products which are formed during the processing of alumina-containing materials by the non-alkaline method as a component in raw mixes.

On the strength of these research findings the USSR, for the first time in world practice acquired, apart from an industrially integrated, large-scale processing of nephelines by the alkaline sintering method into alumina, soda and potash, another large-scale and highly efficient production of cement from the technogenic belite by-products of the above-mentioned processing of nephelines.

According to the existing economic estimates, the combined nepheline-based production of alumina, soda products and cements allows to reduce specific investments by 20 to 25 percent and raw-material consumption by 25 to 30 percent, as compared to having a separate production of alumina and bauxites, of calcinated soda from salt solutions (sodium chloride) and limestone, and a separate production of cement based on traditional raw mate-

rials - carbonate and clayey rocks.

At the same time, an integrated and practically waste-free processing of nepheline and similar, alkaline and non-alkaline, aluminosiliceous rocks for alumina, cement and other products, stands for the maximum utilization of natural resources and is therefore, from the point of view of ecology, a more effective production process than the two separate processes of obtaining these products which result in the accumulation of many tons of unused waste (red slurry) from bauxite-based production of alumina, and of distillation slurries resulting from the production of soda out of limestone and rock salt.

#### ACKNOWLEDGEMENT

The author is grateful to Z.B. Entin and S.D. Mekashev for assistance in preparation of this paper.

## 1. FORMATION OF CEMENTITIOUS BONDS

### 1.1 INTRODUCTION

A binder is defined in the Handbook of Adhesives (1) as "a component of an adhesive composition that is primarily responsible for the adhesive forces which hold two bodies together." In cements the property that enables a binder to act in this capacity is also responsible for the formation of a cohesive structure and, because it is usually a multi-component system, it is not obvious which component is the binder. Of course, it may be that the same component, or combination of components, may serve both as the structure (grain or micro unit) and the binder (intergranular material).

In cement research, the strength and modulus of the unit or system, rather than its bond strength, has special significance. This is understandable because the cementitious binders based on portland cement consist of submicroscopic, colloidal-like particles, produced from supersaturated solutions, and which form a porous, interconnected network. The structure formation is a very complex process and it is difficult to define the grain, micro-unit or particle and the product at the boundary. Where these are crystalline and single component as in gypsum, the interparticle bond may resemble the grain boundary in ceramic materials. Because of this complexity, it is useful to maintain the concept of intraparticle and interparticle bonds.

It is the porous nature coupled with the indefinable stress concentration regime of the cementitious binders that undoubtedly presents the greatest difficulty in defining and measuring the nature of the bond. The measured value of strength cannot be reduced to a value of bond strength without a measure of bond area, a parameter difficult to measure. Many of the mechanical properties correlate with porosity and this, along with other data, enables comparison of results obtained by various workers.

Because hydration products are colloidal in size when first formed, models of other colloidal systems or gels (xerogel) have often been used to describe the nature of the structure of hydrated cement, especially to explain the nature of the bonds. Whether such models represent the structure of hydrated cement depends on whether their physical and mechanical behaviour is similar with respect to all the available experimental evidence. In such complex systems one cannot accept evidence of similarity on the basis of one type of measurement. The authors have strived to provide a body of experimental evidence for a variety of similar and dissimilar cementitious systems, including compacted porous materials, showing physical

and mechanical similarities and differences, to provide a basis for an evaluation of the structures of these different systems.

This paper will attempt to assess the available information with these criteria in mind. Mention will also be made of those parts of the knowledge system in this area which are as yet unknown.

### 1.2 BINDING SYSTEMS - NATURE OF BONDS

It is useful to use the term "binders" as it emphasizes the importance of the nature of bonds in a cementitious material. The question as to what kinds of bonds exist in cement paste has been discussed for a long time but little progress has been made because the greatest emphasis for practical applications has always been on strength and because the problem of measuring bond strength is very difficult.

Rehbinder et al (2) formulated theories for hardening of binders and stated that crystallization contacts are associated with the process of crystal coalescence, which is controlled by a given level of supersaturation. They suggested that there is a balance between the supersaturation level in the surrounding medium and the mechanical effort to maintain the crystals in a certain fixed position relative to each other. Thus internal strain is related to the pressure associated with the constrained crystal growth in a supersaturated solution. Strength increase is observed under conditions conducive to reduce internal strain. Presence of strain in hydrating systems is possible since all such reactions result in a molar volume increase. A study by Gillott and Sereda (3) showed that  $\text{Ca(OH)}_2$  crystals undergo considerable strain during the hydration process. Evidence of this was found in X-ray diffraction transmission Laue photographs of  $\text{Ca(OH)}_2$  crystals.

Sychev (4) has dealt with the structure formation as a synthesis of a solid body through condensation of a disperse system. He tried to link the binding property of the hydrating system with products having polar groups, and also to verify that the first step of hardening is associated with the "constrained state" when particles are brought together so close that long-range forces can begin to act and the polar groups in the surfaces can serve as a crystallization contact of valency nature.

This theory suggests that bonds are based on the superficial chemical "stitching-up" by water molecules and thus saturate the ionic fields of the surfaces brought close together. According to Sychev, this bond can be strong only when there is a low concentration of water at the contact faces; this is possible during the active hydration

(reaction) stages due to the withdrawal of water to the reacting material.

Ubelhack and Wittman (5) concluded that thin films of water occupy the interparticle bond area. These water films exhibit a high degree of ordering due to surface force interaction, creating the so-called disjoining pressure. The work of these authors, based on measurements of Mossbauer spectrum on samples of "xerogel of hydrated cement doped with calcium ferrite hydrates," is difficult to assess because they do not characterize the samples adequately to enable comparison with work of other researchers.

Wittman et al (6) obtained from Mossbauer measurement values of the coupling constant for samples of hydrated cement hydrogel. These values were found to decrease from  $2 \times 10^5$  dyn/cm at 0% relative humidity (RH),  $1.4 \times 10^5$  dyn/cm at 55% RH, to  $0.8 \times 10^5$  dyn/cm at 100% RH, which is consistent with the idea that water enters the system (including the interlayer spaces) and separates surfaces. That the modulus increases to a highest value at 100% RH, as observed by Wittman (7), can be explained, based on the fact that the water enters interlayer spaces where it reinforces the system by its interaction with the two layers. However, Wittman and Setzer (8) consider that the strength originates partly in chemical bonding which is not influenced by moisture. They estimate that about 50% of the total bond strength can be attributed to van der Waals' interactions, but give no explanation for this. Their explanation of the increased modulus in the high relative humidity region is based on a two-component system, with water constituting one of the components.

These theories do not appear to have considered the theory of bond formation that involves consolidation of a dispersed system to form solid-to-solid contacts followed by polymerization of SiOH groups of the silicic acid. Collepari (9) proposed the formation of Si-O-Si bonds by the interaction of SiOH + HO-Si. This conclusion is based on a study of pore sizes and surface area ( $N_2$  adsorption) and the changes with time, temperature and admixtures. For example, Collepari attributes the decrease in porosity and surface area to the formation of solid-solid contacts.

Various ideas regarding the structure formation and its bonds admit the possibility of both the chemical and physical nature of bonds and does not make any clear-cut distinction between the nature of the intraparticle bonds and interparticle (intergranular) bonds.

Sereda et al (10) studied the effect of different levels of relative humidity on the elastic modulus and also applied the cold compaction technique of breaking and making bonds. This study showed that Young's modulus increased as the dry cement paste was exposed to progressively higher levels of relative humidity beyond about 50%, as was also reported by Wittman (7). This was unexpected because it does not fit the description presented by most previous authors of the nature of this system, namely, that the structure was formed from "gel"-sized particles coalescing but maintaining layers of water at points of contact (although some chemical bonds were postulated because of the limited swelling). Such a system should show a decreasing modulus as water is adsorbed unless it is assumed that this water is interlayer water and has characteristics different than that of sorbed water. Sorbed water causes a decrease in modulus in the case

of hydrogen bonded systems, such as acetate silk or cellulose.

A comparison of the behaviour of cement paste at different levels of relative humidity with that of a high surface area material such as porous glass demonstrates that, although the porous glass has a surface area of  $175 \text{ m}^2/\text{g}$  and pore radius of 20Å (similar to cement "gel"), its modulus does not change over the entire range of relative humidities from 0 to 100% despite an expansion of 0.25% (11).

From these considerations, it must be concluded that water adsorbed in cement paste does not behave simply as surface adsorbed water, as in the case of porous glass, nor does it attenuate the bonds, as in the case of cellulose, but that most probably water enters the intraparticle bond area where it acts to reinforce the bonds. This conclusion was the basis for a model for the hydrated cement paste system presented by Feldman and Sereda (12). This model accounts for the highest modulus at 100% RH due to maximum influence of water on intraparticle bonds and no influence on the interparticle bond or contacts. Strength from interparticle bonds is highest at the dry state and suffers a moderate decrease when approximately a monolayer of water is introduced due to the crack propagation process that is characteristic of bodies with "fused" contacts.

The technique of cold compaction and recompaction of hydrated products has been used to provide evidence regarding the nature of bonds and structure that can be produced in this way and enable comparison of the bonds resulting from the structure formation during the hydration reactions (13).

In the case of the cement paste material, the modulus and microhardness give the same values for a significant range of porosities whether the material samples are compacted, recompacted or cast-in-situ. This can be explained by considering that the micro-units or particles made up of a system of interlayer C-S-H sheets with their complement of interlayer water were the same in each case because none was dried below a condition of 30% RH. The compaction process produced interparticle bonds similar in nature to those produced by the hydration process; this might lead to the conclusion that these bonds represent contacts of random nature between solid surfaces. Recent work by Marchese (14) presents evidence, using the scanning electron microscope, of fracture surfaces that present strong adhesion between C-S-H gel and  $\text{Ca(OH)}_2$  masses in alite paste, confirming the above idea.

Using the compaction technique, Feldman (15) has studied the contribution of interlayer water on bond formation as measured by Young's modulus. Two series of compacted samples in the porosity range of 10 to 60% were made: Series B made from bottle hydrated cement dried to 30% RH, and Series A from the same material dried to d-dried condition. Figure 1.1 gives the sequence of wetting and drying to which the two series of compacted samples, prepared at 11% porosity, were exposed. The values for Young's modulus at each condition are given.

Series B, hydrated cement compacted with interlayer water intact, and Series A, compacted with interlayer water removed (d-dried) both give high values of modulus. However, when series B samples are dried the modulus decreases by about one half. No change occurs to the modulus of series A samples on wetting but they, too, suffer a loss in modulus when dried again.

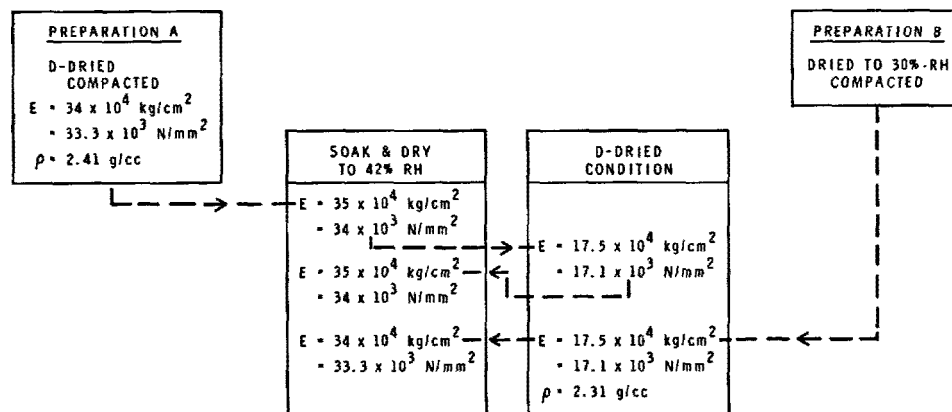

Fig. 1.1 - Sequence of conditioning and testing (15)

The role of interlayer water in this sequence of measurements is that of contributing to the bonding, perhaps by coordinating with calcium ions which are present between the sheets. It is also evident that compaction of the d-dried material can bring the layers close together and so increase the surface-to-surface interaction. The result of this is that the value of modulus is about the same as obtained for the system with interlayer water. The higher density product of 2.41 g/cc obtained when compacting d-dried hydrated cement (Fig. 1.2), confirms the explanation given above.

Fig. 1.2 - Density vs compaction pressure for bottle hydrated cement.

### 1.3 BOND STRENGTH AND MATERIAL STRENGTH

From the practical point of view, bond strength as such may not have any significance. It is the material strength, which is the value obtained in tests, that can be used in all design calculations.

If it were possible to obtain by measurement the total interparticle contact area, it would be easy to relate the material strength to bond strength. Although this

is impossible as yet, some indirect measurements such as change in surface area have been made by Collepardi (9).

When strength of a material is related to the total porosity, one obtains a characteristic that is probably related to bond strength and contact area. Where modulus, hardness or strength is determined for samples at any one porosity, the results do not characterize that property and cannot be used to compare such a material as a binder with any other material. This is a feature of porous materials that does not apply to non-porous materials, and must not be overlooked. Much information in the current literature has not considered this and is, therefore, of limited use.

When considering contact (bond) area, it must be remembered that size of particles plays a very important role. For example, when a model of uniform diameter particles is considered in a hexagonal, close-packed arrangement, the surface area per unit mass (assuming a density of 2.4 g/cm<sup>3</sup>) is related to particle diameter (Fig. 1.3). It is obvious that, for the same porosity, as the particle diameter decreases

Fig. 1.3 - Relation of diameter of spheres to their surface area in a hexagonal close-packed system

and surface area increases, the area of effective contact (where surfaces are within the field of force of long-range forces) increases. This is the situation with cement gel which is first produced as sub-microscopic particles of various shapes and includes silicate sheets with a surface area of over 700 m<sup>2</sup>/g (Winslow and Diamond (16)). This fact and the presence of stress generated by the hydrating reaction (as discussed in 1.2), provides the conditions for the formation of a structure that has considerable contact area between particles.

Most binders can be characterized by a relationship of the mechanical properties to porosity. This relationship may represent the bond strength or nature of the bond. In this regard the microhardness appears particularly useful because it seems to give the characteristic behaviour that is observed with flexure strength when the material is tested at different levels of relative humidity. Microhardness measurement must involve, wholly or in part, the progressive breaking of bonds between particles as well as fracturing of particles as the pyramid indenter penetrates the porous material. The work by Sereda (17) has shown that even different preparations of gypsum representing different morphologies of the crystals when compacted could be characterized by the hardness-to-porosity relationship, as shown in Fig. 1.4.

Using microhardness techniques, Beaudoin (18) characterized various binding cements by a hardness-to-porosity relationship (Fig. 1.5). From this relationship it can be seen that magnesium oxychloride provides the strongest structure, with normal portland cement ranking second, and magnesium oxysulfate cement ranking the lowest.

Fig. 1.4 - Microhardness vs porosity for compacts of different samples of gypsum (17)

Fig. 1.5 - Microhardness vs porosity for several inorganic cementitious systems (18)

Bache (19) developed a model for the strength of a brittle material built up of particles joined at points of contact. In this model, the particles are large in relation to contact area. In the derivation of the equation to represent strength, the assumption is made that the mechanical properties of the contact area are the same as that of the particle. This is essentially the assumption made in dealing with polycrystalline ceramic materials. The relation between strength and the volume concentration of cement in mortars made from silica "fines" and cement as obtained by Bache, agreed well with his theoretical equation.

Attempts have been made to predict the strength of cement paste by analysing various parameters of this system. Polak (20) derived a series of equations where the strength of the hardened system is a function of 12 parameters forming 4 dimensionless complexes. In this analysis the structure is defined by chemical and mineralogical composition, system geometry and force bonds derived from the structure of the material and the structure of its porous space. He suggests that 14 experiments are required to determine the parameters for use in the mathematical analysis but it is not clear what these experiments are. Grudemo (21) stated that, "The theoretical treatment of the strength vs structure relationship of such a system containing several solid phases in a non-random arrangement, and pores of various types in unknown proportions, is certainly very complex, if not impossible." However, he subsequently derived equations to relate properties with porosity. In this analysis (22) he does not include the influence of stress concentrations, or variation in stress intensity factors due to differences in pore shape or due to the heterogeneous distribution of matter in the solid phase including internal microstructural arrangements.

Lawrence et al (23) studied physical properties of hydrated tricalcium and  $\beta$ -dicalcium silicate pastes where the microstructures were altered by the use of

admixtures and by temperature variations during hydration. Thus tensile strength was compared for a range of microstructures and was found to be uninfluenced by large changes in outer C-S-H morphology induced by admixtures. They concluded that strength development in C3S pastes appears to depend primarily on the total capillary porosity and that changes in microstructure have little influence on strength. Although this result agrees with those of others--that porosity is an important parameter in determining strength--their conclusion appears to be in conflict with work where unique strength vs porosity curves were obtained for different preparations representing different morphologies (as discussed in Section 2). Perhaps the result of Lawrence et al (23) is fortuitous due to the fact that only one W/C ratio was used in the preparation of the samples.

#### 1.4 MICROSTRUCTURE AND BONDS

Since the emergence of the scanning electron microscope, a large number of micrographs have been published which show a range of morphologies of hydrated cement products. Diamond (24) summarized the information and proposed a classification based on 4 types of morphologies. It should be recognized, however, that it would be useful if an estimate were provided of the amounts of the different products characterized by a type of morphology in the microstructures, as stressed by Grattan-Bellew et al (25). In examining a system so lacking in distinct features as hydrated C-S-H, there is a tendency to concentrate on certain morphological features that may not represent the whole subject.

Most of the evidence from microstructural examination can be used to compare or characterize the particular samples under study but fails to indicate, even semi-quantitatively, when a given material is strong or weak, stable or unstable. When microscopic examination is used as evidence for structure formation, there is a tendency to use the information obtained at the beginning of the hydration process (at the time when the morphologies of the different products are distinct). Thus it is assumed that the microstructure and the process responsible for it are the same at the beginning and at the end. All evidence points to the conclusion that this assumption is invalid and that the nature of the first product formed and the process causing it to form is more than likely very different from the final product and process. For example, work by Double and Hellawell (26) concluded that, at the start, the hydration process is driven by osmotic pressure occurring in fibrils which are tubular. This may not be a property that is relevant to the mature structure.

#### 1.5 COMPACTION - STRUCTURE FORMATION

As an aid to a better understanding of the behaviour and properties of porous materials, the authors have used cold compaction of various powders for the past 15 years to produce porous bodies as "models" from various materials, ranging from sodium chloride, gypsum, sulfur, to a variety of cementitious binders. In the numerous experimental studies where this technique was used to prepare samples, the purpose was to provide a series of rigid, porous samples of varying porosity, thus enabling this parameter to be tested in relation to other properties such as sorption, dimensional change, modulus, hardness, and response to changing environmental conditions of various materials available as powders.

Compacted samples of calcium carbonate, silica gel, and molecular sieves were used successfully by Sereda and Feldman (27) and compacted samples of hydrated portland cement, by Feldman (28) to show the relation between sorption of water and dimensional change and to confirm the Bangham relation where simple adsorption occurs.

Compacted samples have been used effectively to study volume changes associated with hydration reactions of such materials as MgO (29) where it was shown that the expansion of the compact is related to the concentration of MgO in lime. Similarly, the expansion of gypsum plaster on hydration was determined by means of compacts (30) where it was shown that expansion was related to initial porosity and temperature as shown in Fig. 1.6.

Fig. 1.6 - Expansion of pottery plaster as a function of porosity and temperature (30)

The compaction technique was also used to study the nature of bonds in portland cement system and gypsum system, as discussed in the previous section (13,31).

To show the significance of microhardness measurement in characterizing different binders, Sereda (17) used compacted samples where it was possible to distinguish between different preparations of gypsum (see Fig. 1.4).

Hot pressing of unhydrated cement followed by hydration was shown by Roy et al (32) to be a successful technique to produce samples of hydrated cement of very low porosity and very high strength.

It can be concluded that compaction technique can be a useful tool to study porous materials, especially the hydrated cementitious systems.

## 2. POROSITY AND PORE-SIZE DISTRIBUTION IN ORDINARY PORTLAND CEMENT PASTE

This section of the paper will deal with some of the more important techniques used to measure porosity and pore-size distribution, which have helped determine the structure of hydrated portland cement. Pore structure is one of the most important parameters controlling the properties of porous materials. Many procedures to determine the pore structure of a solid have involved mercury porosimetry and nitrogen or water-vapour adsorption isotherms. Calculations based on these have been relatively successful for materials with pore structures that remain stable on removal or addition of water.

Measurements for unstable materials such as hydrated portland cement, however, have been difficult to interpret. Water used as a medium always gives a higher porosity for hydrated portland cement than that obtained by other media, e.g., nitrogen, methanol and helium (1,2). In order to measure many of the properties of hydrated portland cement, it must be dried; this presents a major problem since decomposition of some of the hydrates will occur. One may expect changes in porosity, surface area and other physical properties (3-10). Also, on exposing the material to water, rehydration of the decomposed hydrates may occur (11).

In recent years, several advances have been made in the application of two techniques that have been widely used on a variety of materials for measuring porosity and pore-size distribution. These are the capillary condensation method, which uses several different adsorbates (mainly nitrogen and water on cement paste), and mercury porosimetry. These will be presented and discussed.

However, since the Moscow Symposium, two new techniques have been applied to the hydrated portland system. These are:

- (i) the quasi-elastic or inelastic neutron-scattering method (12);
- (ii) the helium inflow and helium pycnometric technique (13).

With the first technique, the fractions of free and bound water can be determined to quite a good approximation. Previously, nuclear magnetic resonance had been used on these types of hydrated silicates to distinguish between protons having different induction decay times caused by different types of bonding (14,15), but the relative amounts of differently bonded protons for samples containing appreciable fractions of free water, as occurs in a saturated cement paste, were not measured.

With the second technique, changes to the structure can be followed as water is removed from the system or as water re-enters the system. This is important because much work has been done with the aim of relating porosity determined by water with that determined by other techniques. The difference has been termed "missing porosity" or "gel pores." The helium flow technique has detected this missing porosity, which is, in fact, the interlayer space normally occupied by approximately one layer of water when the material is in the wet condition. On drying and removal of the interlayer water, this space

partially collapses. The effort and controversy related to the study of the "missing porosity" and its importance relating to mechanical properties has justified its inclusion in a discussion on porosity.

### 2.1 INELASTIC NEUTRON-SCATTERING METHOD

Neutron inelastic scattering is sensitive to the mobility of atomic nuclei, especially those of hydrogen, which has an exceptionally large neutron-scattering cross-section. A bound molecule undergoes vibration with some particular frequency, characteristic of the particular mode, and gives rise to an inelastic scattering distribution of neutron energies, which reflects the density of vibrational states, together with elastic peaks reflecting the time-averaged position of the molecule. In contrast, a mobile molecule has no particular time-averaged position and so gives rise to no strictly elastic peak in the spectrum, but rather a quasi-elastic distribution that reflects the Doppler shifts in frequency caused by the molecular motions.

In the context of a water phase in a cement, Harris, Windsor and Lawrence (12) considered it plausible to postulate a multi-component structure, each component obeying Fick's law individually (16), having a distribution of diffusion constants. In the analysis of water in vermiculite clays, workers fitted their results to a single diffusion constant (17).

The cement paste spectra correspond quite accurately to those of two-component systems with free components given by the pure-water spectrum and bound components by a resolution function. There is no evidence from the shape of the quasi-elastic frequency distribution that any more complicated model than a two-component system with free and bound water states should be used.

Table 2.1 (based on ref. 12) contains a summary of experimental measurements by neutron scattering and conventional methods, on four saturated cement pastes approximately 2 years old. The weight losses incurred by drying at 100°C and by evacuation at room temperature are consistently greater than the amount of free water calculated from neutron scattering measurements on the saturated pastes (Rows 2 and 3 respectively). This can be explained if one concludes that some combined water has been removed during drying.

The volume fraction of free water calculated from the neutron scattering estimate of free water is approximately equal to the calculated (18) capillary water content (Rows 5 and 8). Other data (19) show that this capillary volume is approximately equal to the total volume available to liquid nitrogen in pre-dried pastes. As previously mentioned, the free water volume by drying at 100°C is much more than that determined by neutron scattering (Rows 7 and 5 respectively).

These results are very significant because they agree with nitrogen adsorption data, suggesting that nitrogen adsorption gives realistic values and that evaporable water is partly combined. They also suggest that the neutron-scattering technique can be used to elucidate the structure of saturated cement pastes because it avoids the uncertainties associated with drying.

The results from this work are illustrated in Fig. 2.1 (12), which shows the volume fractions of

TABLE 2.I - Estimation of free and combined water by neutron scattering and conventional methods (based on ref. 12)

Row	Properties - saturated pastes	w/c = 0.66	w/c̄ = 0.33	Compact	Compact
1	Ignition loss, weight fraction at 1000°C	0.4371	0.2880	0.2032	0.1209
2	Drying loss, weight fraction at 100°C	0.3006	0.1565	0.0933	0.0597
3	Free water by weight by neutron scattering	0.223	0.081	0.045	0.019
4	Cement volume	0.305	0.465	0.595	0.726
5	Free water volume by neutron scattering	0.394	0.172	0.109	0.052
6	Combined water volume by neutron scattering	0.301	0.363	0.296	0.222
7	Free water volume by loss on drying at 100°C	0.531	0.334	0.228	0.161
8	Capillary water volume, from weight loss on drying	0.379	0.135	0.063	0.064

cement, combined water and free water determined from (a) neutron scattering data, and (b) from traditional concepts using the usual drying techniques. The over-estimate of the porosity by the conventional techniques is obvious in this illustration.

## 2.2 HELIUM FLOW AND HELIUM PYCNOMETRIC TECHNIQUE

This technique involves the normal pycnometric measurement of the solid volume of a body during which the helium surrounding the body is compressed to 2 atm. Immediately after this period (a total of 2 min from the time helium is first admitted to the sample) the rate at which helium penetrates the body under an absolute pressure of 2 atm is measured for a period of 40 h (13). In other techniques such as sorption, weight or volume changes are measured as a function of partial pressure of sorbate, which does not take into account removal or replacement of, in this case, water from or to the molecular structure. The helium flow technique is capable of following these changes and has been used to study hydrated C<sub>3</sub>S and portland cement as well as some relatively well-defined systems (20).

The study of the C-S-H gel found in hydrated portland cement by the helium flow technique has revealed that much of what was formerly thought to be adsorbed water is associated with the solid as interlayer water. The removal or replacement of the interlayer water results in changes to the solid volume, density and porosity, which can be measured. Ageing effects that occur during wetting and drying treatments can also be detected.

The volume of interlayer space and the change in volume due to water removal or re-entry can be readily monitored by a combination of solid-volume and helium-inflow-change measurements. These measurements, together with those of other properties such as surface area, can determine hydraulic radius or average surface-to-surface separation and shape of the interlayer spaces.

Several of the pertinent experimental observations and types of calculations made through this technique are described in the following three sections.

### 2.2.1 Density and Porosity Measurements

Several types of density measurements can be made on hydrated portland cement (2). The most obvious density is that where most hydrates have been left intact. This can be partially obtained by measuring the solid volume of specimens conditioned at 11% RH, using the helium pycnometer. However, a constant procedure has to be adopted where the time-to-helium exposure is limited because of the problem of helium

Fig. 2.1 - The volume fractions occupied by cement, combined water and free water in saturated cement pastes (12). (a) Composition from neutron scattering; (b) Composition from drying loss

flowing into vacated interlayer spaces. The value for this density at different water contents drying from 11% RH is shown in Fig. 2.2 (2).

Once density has been measured, porosity can be calculated from the apparent volume. Porosity was calculated for d-dried hydrated portland cement from the data in Fig. 2.2 (2) and compared with that obtained with methanol and with water. The results, shown in Fig. 2.3 (2) for several water/cement ratio pastes, indicate that the porosities obtained with helium and methanol are very similar over the whole range. When water is used, porosity is about 8% more at a water/cement ratio of 0.4. This corresponds approximately to the value estimated by scanning isotherms (21) for the quantity of interlayer or hydrated water. When water is used to measure porosity or density of hydrated portland cement dried only to 11% RH, the values are similar to those obtained with both helium and methanol (2). This shows that most of the interlayer water is retained in the solid at this condition.

Density may also be calculated by including as pore space the volume of interlayer space that is free of water and in an uncollapsed state (22). In order to calculate this volume, the total volume of helium inflow at 40 h is subtracted from the solid volume measured by the helium pycnometer. The results

Fig. 2.2 - Relationship between density and weight loss for cement pastes with w/c ratios of 0.4, 0.6, 0.8 and 1.0 (2)

Fig. 2.3 - Relationship between porosity and w/c ratio for portland cement pastes (2)

Fig. 2.4 - Relationship between density (corrected for helium inflow) and weight loss for cement pastes with w/c ratios of 0.4, 0.6, 0.8 and 1.0 (2)

plotted in Fig. 2.4 (2) show that density increases with weight loss up to 5 to 6% after which it decreases. The maximum density occurs because collapsing sheets retard the inflow of helium into the interlayer space and in the 40 h of measurement complete filling of the volume does not occur. The low final density at the dry state is a result of the layers only partially collapsing which prevents helium from fully entering the space.

### 2.2.2 Collapse of Layered Structure on Drying

Figure 2.5 (2) shows typical helium flow curves with time for a hydrated portland cement dried from the initial 11% RH condition to a final condition obtained by heating at 140°C under vacuum for 6 h. Weight losses are recorded from the 11% condition.

Individual rate curves are functions of the volume of vacated interlayer space remaining and the size of the entrances. When the size of the entrances are large, rate of flow will be rapid but because collapse occurs initially from the entrances, the rate will decrease even though more vacated space may exist. This is illustrated by the crossing over of the rate curves in Fig. 2.5 (2).

The effect of the withdrawal of water may be more clearly observed in Fig. 2.6 (23). The total inflow after all moisture is withdrawn is less than that at the initial 11% condition, mainly because there is an abrupt reduction in inflow over a very low weight-loss range. This is due to partial collapse of the interlayer spaces.

Solid volume and total interlayer space vacated by water on drying. - Removal of interlayer water leads to a change in "solid volume" ( $\Delta V$ ) and to a change in total helium inflow,  $\Delta D$ . Because part of the vacated interlayer space has collapsed, resulting in a change in solid volume, an assessment of the space occupied by the water molecules can

only be made by combining these parameters. Thus, a parameter  $\Delta V - \Delta D$  is obtained where, owing to increased weight loss, the decrease in volume is a negative  $\Delta V$ , and increased inflow,  $\Delta D$ , is regarded as positive. This then accounts for the space vacated by the water if helium enters all the space in 40 h.

Figure 2.7 (23) shows a plot of  $\Delta V - \Delta D$  and  $\Delta V$  against weight loss, for 10 different samples. The  $\Delta V - \Delta D$  plot is linear up to 5.5% weight loss of slope 0.7886 mL/g, which is the space occupied by 1 g of water; the inverse is 1.27 g/mL ( $\pm 0.08$  g/mL), which is the density of the water.

Between 6 and 11% weight loss, there is very little change in  $\Delta V - \Delta D$  even though there is an increase in rate of change of  $\Delta V$ . The departure from linearity of the plot in Fig. 2.7 (23) is due to the reduction in helium inflow because of a restriction in helium inflow because of a restriction in the entrances of the interlayer spaces and their partial collapse.

### 2.2.3 Reopening of Layered Structure

When strongly dried hydrated portland cement is exposed to water vapour, water molecules re-enter between the sheets (6,11); as the material is exposed to higher humidities, more water molecules re-enter the structure. This re-entry can be investigated by exposing material to various humidities before measuring helium inflow at 11% RH; helium inflow increases with re-entry and as the interlayer space becomes filled, helium inflow decreases. Evidence of re-penetration of water molecules has also been obtained from low-angle X-ray scattering measurements (24).

The penetration of the layered structure by water molecules leads to a variation of solid volume and density. Drying and wetting cycles result in a significant increase in solid volume, an example of ageing of the structure.

Measurement of total space occupied by re-penetrating water. - The  $\Delta V - \Delta D$  vs weight change plot for re-exposure to water vapour is presented in Fig. 2.8 (6). It records an increase in  $\Delta V - \Delta D$  of only 1.75 mL/g for weight gain of up to 6.0%, on exposure up to 42% RH. The helium is not fully measuring the volume of the water that has entered structure. Beyond 6.0% a good linear correlation is obtained, resulting in a density calculation of 1.20 g/mL for the interlayer water.

The weight gain up to 42% RH would imply an impossibly high density for the water, and it is obvious that the water molecules are mainly entering the interlayer structure

Fig. 2.6 - Helium flow at 50 min and 40 h, plotted as a function of weight loss for 0.6 w/c ratio cement paste (23)

Fig. 2.5 - Helium flow into 0.8 w/c ratio cement paste at different water contents as a function of time (2)

Fig. 2.7 - Plot of  $\Delta V - \Delta D$  and  $\Delta V$  as a function of weight loss for 10 different pastes (23)

that had partially collapsed on drying. This also indicates that the monolayer of adsorbed water on the open surface is a relatively minor part of the 6.0% sorbed up to this stage.

Beyond this point, the water is completely held in interlayer positions because all these measurements are made at 11% RH, and a monolayer on the exterior surface is complete at 11% RH. The linear plot in this region indicates that helium fully enters the interlayer space (after exposure to 42% RH and up) and measures the volume of the inter-layer water and the remaining space.

Hydraulic radius and surface area of capillary porosity. - When d-dried hydrated portland cement paste is exposed to water vapour, the water molecules enter the pores, adsorb on the solid that is bounding the pores, and some molecules penetrate the layered structure within the solid. The solid particles swell, not only because of the interlayer penetration, but also because of the physical interaction of water on the surface of the solid. This is called Bangham swelling and is due to a decrease in surface tension forces that compress the solid. This swelling should be transmitted through the porous body and is referred to as  $\Delta l/l$ , which is the measured linear expansion of the porous body. If  $\Delta l/l$  is small,  $3 \Delta l/l$  is the volumetric expansion. If there is no change in porosity

or packing during changing conditions, then  $3 \Delta l/l$  is equal to the fractional volume change of the solid phase of the body.

A measurement of the solid volume by helium pycnometry would include the adsorbed water, as well as the solid in the expanded state. By measuring the solid volume at the dry state and at 11% RH, where the adsorbed water is approximately equal to a monolayer, one would obtain the volume of a monolayer of adsorbed water plus the increase of the solid. This is referred to as  $\Delta V/v$ .

The difference of the volume changes would then be equal to the volume of the adsorbed water as a fraction of the total volume of the solid. This may be written as follows:

$$\Delta V/v - 3 \Delta l/l = v/v$$

where " $v$ " is the volume of adsorbed water and " $V$ " the volume of the solid (25).

The measurement of both these volume changes assumes that during the change of condition from 0 to 11% RH, no ageing occurs. Previous work (7) has shown this to be the case.

Because " $v$ " is the volume of the monolayer of adsorbed water on the surface bounding the porosity, the surface area can be readily calculated. The hydraulic radius of a pore system is computed by dividing the total pore volume of the system by its surface area; thus the hydraulic radius can also be readily calculated, as shown in Table 2.II for hydrated portland cement paste of  $w/c = 0.4, 0.6$  and  $0.8$ .

Results were obtained for 10 different samples of hydrated portland cement and  $C_3S$  of various water/cement ratios. The surface areas of these samples were also determined by nitrogen adsorption, using the same drying technique. These quantities are plotted in Fig. 2.9 (based on unpublished work by one of the authors.) Although a deviation occurs at

Fig. 2.8 - Plot  $\Delta V - \Delta D$  as a function of weight change for 4 different pastes on rewetting (6)

TABLE 2.II - Surface area and hydraulic radius of hydrated portland cement by helium pycnometry

Water/cement ratio	Surface area, $\text{m}^2/\text{g}$	Hydraulic radius, $\text{\AA}$
0.4	35.0	39.4
0.6	49.0	64.2
0.8	44.0	107.0

Fig. 2.9 - Surface area by nitrogen adsorption and by helium pycnometry (Feldman, in process)

the lower surface areas, the agreement justifies the assumptions and confirms the general validity of the equation. The concept that the instantaneous helium pore volume is the same as the pore volume determined by nitrogen, and that the remaining pore volume is that of the partially collapsed interlayer space is sound. This confirms the validity of the inelastic neutron scattering experiments already discussed (2).

**Hydraulic radius of the interlayer space.** - As mentioned previously, the hydraulic radius of a pore system is computed by dividing the total pore volume of the pore system by its surface area. Until recently, this calculation could not be made without assuming a particular structure for the C-S-H gel, but the low-angle scattering data of Winslow and Diamond (24) has provided this value. In addition, as discussed earlier, the interlayer space is re-opened by exposure to 42% RH; at this condition, helium can fully enter the internal space within 40 h of flow time. The volume of the interlayer space can thus be measured on the partially-open or fully-open state depending on the relative humidity of exposure, using helium to measure the remaining volume.

The results from measurements on a hydrated cement paste cured at a water/cement ratio of 0.6, using the helium-volume-change method reported here, give a value of 1.35% of water for the monolayer on the external surface which gives a surface of 49  $\text{m}^2/\text{g}$ . After exposure to 100% RH, 10.8% water was

retained at 11% RH (11). This leaves 9.45% in the interlayer structure. A space of 2.4 mL unoccupied by water was also measured in the structure by helium inflow. Using 1.20 g/mL as the density of the water, referred to earlier, results in a volume of 10.28 mL as the internal space. The surface area for the internal space is 670  $\text{m}^2/\text{g}$ , determined by Winslow and Diamond (24), resulting in  $670 - 49 = 621 \text{ m}^2/\text{g}$  for the interlayer surface, and a hydraulic radius of 1.65  $\text{\AA}$  (0.165 nm).

Assuming that the pores are bounded by two parallel plates, the average separation between the plates is 3.3  $\text{\AA}$  (0.33 nm) (twice the hydraulic radius). This model is consistent with the internal system composed of layers separated by, on the average, one water molecule. The impact of this calculation may be enhanced by another simple calculation. If 9.45% of water is held as a single layer between two sheets, it will cover twice the normal area per molecule, i.e.,  $10.8 \times 2 \text{ \AA}^2$  (0.216  $\text{nm}^2$ ). This results in a surface area of 687.2  $\text{m}^2/\text{g}$  compared to 621  $\text{m}^2/\text{g}$  given by low angle X-ray scattering. This, however, assumes that all the water is held as a single layer, while in fact there may be "kinks" in the alignment of the sheets, leaving room for more than one layer of water. On the other hand, a coverage of 10.8  $\text{\AA}^2$  (0.108  $\text{nm}^2$ ) per molecule may be too high.

The hydraulic radius can be calculated for the sample when exposed only to 42% RH and where 5.15% water and 2 mL of space exist between the sheets. One obtains an average hydraulic radius of 1.0  $\text{\AA}$  (0.1 nm), obviously a result of a partially collapsed state.

Calculations of this type have also been obtained from data of Brunauer, Odler and Yudenfreund (26), and Mikhail and Abo-El-Enein (27). In these cases, the internal volume was obtained by measuring the difference between the total water and the total nitrogen porosity; the surface areas were determined by the difference between the surface areas given by Winslow and Diamond (24) and the surface area determined by nitrogen adsorption.

The results calculated from the data of Brunauer, Odler and Yudenfreund (26) are shown in Table 2.III; an average of 1.23  $\text{\AA}$  (0.123 nm) was obtained for the four pastes at water/cement ratios between 0.35 and 0.57.

In Table 2.IV, the data of Mikhail and Abo-El-Enein (27), corrected for degree of hydration, give an average value of 2.51  $\text{\AA}$  (0.251 nm) when the first value at 18.50% hydration is excluded. These data were obtained for pastes cured at a water/cement

TABLE 2.III - Surface areas, porosities and hydraulic radii of portland cement paste

Water/cement ratio	$S_{N_2}$ , $\text{m}^2/\text{g}$	$S_T - S_{N_2}$ , $\text{m}^2/\text{g}$	$V_{H_2O} - V_{N_2}$ , mL/g	$\frac{V_{H_2O} - V_{N_2}}{S_T - S_{N_2}}$ ( $\text{\AA}$ )	
0.35	56.7	580-56.7	0.0516	0.99	} avg = 1.23

VI	74.1	0.168	668	2.51	
VII	78.1	0.166	671	2.48	avg = 2.51

ratio of 0.2. This value is much higher than that obtained from the other data (Table 2.III) but is consistent with other results for low water/cement ratio pastes. Very low surface areas (27) and relatively low densities (28) are obtained for these pastes, and it must be concluded that there are many kinked regions in the stacking of the sheets and trapped space, due to lack of space during hydration. This is illustrated in Fig. 2.10, a further modification of a modification by Daimon et al (29) of a model by Feldman and Sereda.

### 2.3 MERCURY POROSIMETRY

The mercury porosimetry method enables the widest range of pore-size distribution to be measured. The upper diameter limit can be as high as 1000  $\mu m$ ; the lower limit can be as small as 30 Å (3 nm), depending on the pressure available and the contact angle used in the calculation.

A review of the porosimetry technique was published by Orr (30). More recently, Liabastre and Orr (31) assessed the structure of a graded series of controlled pore glasses and Nucleopore membranes, both of which have pores with right-cylinder characteristics, using both electron microscopy and mercury penetration. The data showed good comparison if a

Fig. 2.10 - Modification of Feldman and Sereda model (29)

simple pressure correction was applied. It was suggested that pores are compressed to an hour-glass shape, thereby exhibiting an effectively smaller diameter until mercury actually enters them. Upon the entrance of mercury, the pores expand because of the equalisation of hydrostatic pressure, and return to nearly their original volume. The partial closing and reduction in diameter accounts for the apparent entry of mercury into pores smaller than they actually are, and the subsequent return to shape explains correct volume measurements.

A survey of the method as applied to cement systems and some results for cement pastes at different water/cement ratios was made by Winslow and Diamond (32). It was observed that the pore volume left unintruded by mercury at 15 000 psi (102 MPa) was significantly less than the 28% by volume that should represent gel pores.

Diamond and Dolch (33) again addressed themselves to the problem of whether there is a separate class of "gel pores" in the range of tens of Ångströms. They showed that for a mature paste (318 days old) the pore volume, intruded below about 60 Å (6 nm) in diameter, is not only less than that predicted by a log normal plot, which suggests that all the pores intruded belong to a single pore-size distribution, but is almost negligible in absolute terms. The plot of cumulative percentage of pore volume intruded vs pore diameter is given in Fig. 2.11 (33) for this sample. The total pore volume in this sample was measured as 0.306  $cm^3/g$ . The volume intruded between pressures corresponding to pore diameters of 77 Å (7.7 nm) and 25 Å (2.5 nm) is only 0.011  $cm^3/g$ .

In their study of capillary porosity, Auskern and Horn (34) showed that the addition of a small amount of water does not affect the porosity measured by mercury, contrary to the findings of Winslow and Diamond (32). The porosity by mercury intrusion of an oven-dried sample up to 50 000 psi (340 MPa) was 0.108 cc/g; the oven-dried sample exposed to 5% RH had a porosity of 0.115 cc/g. This type of result was also observed by Beaudoin (35). As a result, Auskern and Horn (34) used 117 deg as the contact

Fig. 2.11 - Cumulative mercury pore-size distribution for 0.6 w/c paste 318 days old (33)

angle for all their work. They also found limited penetration below about 80 Å (8 nm) and concluded that the "missing porosity" relative to the porosity as determined by water adsorption must be smaller than 35 Å (3.5 nm). They found that the porosity measured by carbon tetrachloride saturation is close to, but a bit larger than, the porosity measured by mercury penetration. Beaudoin (35) measured total porosity by mercury porosimetry up to 60 000 psi (408 MPa) pressure and found that mercury porosimetry and helium pycnometric methods could be used interchangeably to measure porosity if the water/cement ratio was equal to or greater than 0.40. These results are shown in Fig. 2.12 (after ref. 35). Included in this Figure are results for other materials, including porous glass in which mercury was able to penetrate only 69% of the pore space. Average pore diameter of this material was measured by other techniques (36) to be between 50 and 60 Å (5 and 6 nm).

Fig. 2.12 - Mercury porosity vs helium porosity for hydrated portland cement paste (after ref. 35)

It is apparent that the results from the mercury intrusion method agree with those of other techniques described previously, and especially with the helium inflow measurements. The results showed that the porosity was made up of a pore structure into which helium could rapidly enter, and of interlayer spaces of hydraulic radius less than 1 Å (0.1 nm) when the paste is oven dried.

In a study of capillary porosity during hydration of  $C_3S$  and the effect of admixtures, Young (37) found that, on measuring the mercury intrusion, the pastes showed a threshold diameter that decreased with hydration; the results are shown in Fig. 2.13. This was in agreement with the finding of Winslow and Diamond (32). It was suggested by Young that the large intrusion immediately below the threshold diameter results from filling of the void spaces between C-S-H gel needles, and the filling of larger pores accessible only through intergrowth of needles.

Fig. 2.13 - Intrusion curves for a series of hydrating  $C_3S$  pastes ( $w/c = 0.4$ ) (37)

Diamond (38) investigated the evolution of pore structure of cement paste at two temperatures and two water/cement ratios, 0.4 and 0.6. Results for  $w/c = 0.6$  in Fig. 2.14 (38) show that there is a slight difference in the character of the product formed slowly at low temperatures as compared to that formed rapidly at higher temperatures; this shows up in the pore structure. After about one year of hydration, the pore volume of the paste cured at 40°C is higher than that cured at 6°C because of greater volume of pores smaller than 500 Å (50 nm).

Fig. 2.14 - Cumulative pore-size distributions of 0.6  $w/c$  cement pastes hydrated at 6°C and at 40°C (38)

#### 2.4 PORE-SIZE DISTRIBUTION BY NITROGEN ADSORPTION AND CAPILLARY CONDENSATION METHODS AND COMPARISON WITH MERCURY POROSIMETRY

Studies have been made (39-41) of pore structure as determined by water vapour adsorption. It has been shown in the previous sections that porosity determined by water is quite different from that determined by other fluids, largely because of the interaction of water molecules with the solid and their penetration into partially collapsed interlayer spaces. Several authors (42,43) have now confirmed, however, "that the high degree of specificity of water adsorption does not allow water vapour to be used as an alternative to nitrogen for determination of surface area and pore size distribution." It should, therefore, be exploited only to "provide information concerning the chemistry of the solid surface rather than its surface area and texture." This section will thus deal primarily with nitrogen adsorption.

The common method in use is that of "capillary condensation." The pore-size distribution data is obtained by applying the Kelvin or similar equation to either the adsorption or desorption isotherm. A number of different assumptions as to pore shape and thickness of the adsorbed film at each stage have been used (44-50), leading to some variation in calculation methods. However, in contrast to the wide range of sizes that can be determined by mercury porosimetry, capillary condensation methods are limited essentially to pores of diameters between a few tens to several hundreds of Ångströms. The lower limit associated with capillary condensation methods depends on the particular isotherms, but it is generally accepted that the Kelvin equation tends to break down for micropores. Kadlec and Dubinin (51) presented data suggesting that the Kelvin equation does not apply for pore diameters as small as 35 to 40 Å (3.5 to 4 nm). They concluded that this equation is inapplicable at relative vapour pressures slightly higher than those at which the adsorption-desorption hysteresis loop closes, and appears to be a characteristic of the adsorbate. The limiting diameters range from 20 to 35 Å (2 to 3.5 nm) for various adsorbates.

Recently Winslow (52) reported results that showed satisfactory agreement between mercury porosimetry and nitrogen adsorption for porous alumina in the pore range 500 to 40 Å (50 to 4 nm).

In a comprehensive study of a variety of pastes of portland cement and C<sub>3</sub>S, Bodor et al (53) found a maximum for the pore-size distribution at around 12 Å (1.2 nm) hydraulic radius, i.e., 48 Å (4.8 nm) diameter with the assumption of cylindrical pores. In a review, Diamond (54) observes that most plots in the literature display strong maxima between 30 and 50 Å (3 and 5 nm). Bodor states that no micropores are measured in hydrated portland cement by this technique nor by the "t-method." However, Diamond (54) observed that the cumulative volume determined by mercury intrusion was not too different from that by capillary condensation for pores 100 to 400 Å (10 to 40 nm) in diameter; below 100 Å (10 nm) this is not the case. The capillary condensation data by some workers show steep slopes and considerable pore volume below 100 Å (10 nm) and particularly below 50 Å (5 nm). This fact led Diamond (54) to suggest that large amounts of the C-S-H were encapsulated by calcium hydroxide and unintrudable by at least mercury, but the work of Auskern and

Horn (34) and the helium pycnometric work dispels this idea and, in any event, the pore-size distribution by mercury intrusion should still be reasonably representative of the whole of the distribution. Diamond (54) used radius of gyration results obtained by Winslow (52) in his low-angle X-ray scattering work, and calculated mean diameters, assuming various models. He obtained a mean diameter of approximately 300 Å (30 nm) assuming a cylinder of equal length and diameter. Mikhail, Turk and Brunauer (55) later refuted this work on the basis that the calculated surface area was too low. They used both radius of gyration and hydraulic radius to calculate the dimensions of an average cylindrical pore and obtained a diameter of 47.2 Å (4.72 nm) and a length of 466 Å (46.6 nm). These authors, however, had obtained their hydraulic radius by water adsorption which, as stated previously, is not valid.

Most recent work by Daimon et al (29) presented results on leached and unleached C<sub>3</sub>S. Accordingly, the pore volume of an unextracted Ca(OH)<sub>2</sub> sample should be multiplied by 1.43 to compare it with the extracted paste. In fact, it was found that the pore volume determined by nitrogen adsorption was 1.39 times the values of the unextracted pastes, suggesting that Ca(OH)<sub>2</sub> does not engulf any appreciable volume of C-S-H. Work by Feldman and Ramachandran (56) with the helium flow technique lead to the same conclusion.

The pore-size distributions obtained by Daimon et al (29) are presented in Fig. 2.15 and Table 2.V. In this table, columns are given for the calculation of pore distribution using both the adsorption and desorption isotherm, and for parallel plate (S<sub>pp</sub>, V<sub>pp</sub>) or cylindrical pores (S<sub>cp</sub>, V<sub>cp</sub>). Best fit is given by the adsorption curve, and both models give a reasonable fit although the cylindrical model is better for the extracted paste. This is determined by comparing calculated values with S<sub>BET</sub> and V<sub>p</sub> in the upper part of Table 2.V (29). The hydraulic radius gives the pore diameter down to about 60 Å (6 nm), assuming a cylindrical model.

Results by Collepardi (57) are shown in Fig. 2.16. Pore-size distribution by nitrogen capillary condensation shows that room temperature cured C<sub>3</sub>S

Fig. 2.15 - Pore-size distribution derived from adsorption isotherms (adsorption branches of N isotherms were used for calculation) (after ref. 29)

TABLE 2.V - N <sub>2</sub> adsorption data (29)				
Parameter	Unextracted C <sub>3</sub> S paste		Extracted C <sub>3</sub> S paste	
V <sub>m</sub> (cm <sup>3</sup> /g)	4.177		8.135	
S <sub>BET</sub> (m <sup>2</sup> /g)	18.17		26.69	
S <sub>t</sub> (m <sup>2</sup> /g)	17.5		25.5	
V <sub>p</sub> (ml/g)	0.1342		0.1862	
	Adsorption	Desorption	Adsorption	Desorption
S <sub>pp</sub> (m <sup>2</sup> /g)	18.09	33.43	24.32	43.78
S <sub>vp</sub> (m <sup>2</sup> /g)	21.09	42.00	28.53	48.37
V <sub>pp</sub> (ml/g)	0.1340	0.1412	0.1832	0.1942
V <sub>ep</sub> (ml/g)	0.1358	0.1453	0.1851	0.1994

paste has a maximum at about 20 Å (2 nm) pore radius, although the average value appears to be much higher. It is also shown that by hydrating at different temperatures the reduction in pore volume is due almost exclusively to the decrease in volume of the smaller pores down to about 60 Å (6 nm) radius. These results show general agreement with mercury intrusion, although nitrogen capillary condensation techniques indicate, in some cases, greater volumes in small pores. This difference may be explained, however, by the fact that "t"-curves are important in the calculation of the small pore distribution and measuring the appropriate "t"-curve is difficult for hydrated portland cement. In addition, the validity of their application for small pores is debatable.

### 3. PHYSICAL FACTORS CONTROLLING STRUCTURE AND STRENGTH DEVELOPMENT

Strength, modulus of elasticity, and permeability are important properties that determine the relative applicability of hydrated cement products. When portland cement paste is hydrated at room temperature and to a high degree of hydration, there is a fairly consistent relation between its mechanical properties and its porosity. If these data are extended to very low porosity, however, it is obvious that porosity by itself does not fully define the system (1-3).

Autoclaved cement pastes and pastes mixed with quartz and other sources of silica have been studied extensively by several investigators (4-12) and the sequence of reactions and nature of the products are reasonably well understood. It has generally been concluded that low strengths are associated with the formation of  $\alpha$ -C<sub>2</sub>S hydrate or hydrogarnets at medium to high porosities and that high strengths are associated with the formation of 11 Å tobermorite together with poorly crystallized CSH(I) and CSH(II). The high strength compounds are formed when a sufficient quantity of ground quartz or equivalent material is added to the cement. On the basis of their work on a variety of materials Feldman and Beaudoin (10), Crennan et al (7) and Taylor (13) concluded that there exists an optimum ratio of crystalline to poorly crystallized products for a high strength product; others considered that porosity alone could account for strength differences (14).

These approaches made it apparent, however, that several significant factors should also be considered in studying the mechanical properties of hydrated cements. Accordingly, a porosity study should include the following:

- (i) The relation of pore structure to bonding between crystallites and bonding within crystallites.
- (ii) The effect of pore size or shape and total porosity on mechanical properties.
- (iii) The effect of the nature of the solid; its mineralogical and chemical composition, its crystal size and density on the relation between porosity and mechanical properties.

These factors were discussed by Polak (15) in his study of the kinetics of structure formation of cements and by Jambor (5) in his study of porosity. Significant findings in these areas will be discussed later.

#### 3.1 MODULUS, STRENGTH AND BONDING

One of the first studies to indicate the type of bonding in hydrated portland cement is the compaction work of Sereda et al (16) and Soroka and Sereda (17). This showed that by merely compacting hydrated powder, bodies of strength and rigidity equal to hardened paste at this same porosity could be made; in addition it was shown that the bodies formed did not decrease in hardness or strength significantly when wetted from 15 to 100% RH. In fact, the modulus of elasticity increased significantly above 50% RH due to interlayer rehydration.

Further work by Feldman (18) showed that by compacting bottle hydrated powder in a d-dried state with dehydrated interlayer spaces, a body could be obtained with Young's modulus of a magnitude equal to that with interlayer water present. This was shown to be due to the sheets being forced closer together. Normally, without interlayer water, Young's modulus is

low. A higher Young's modulus indicates that either some new solid bonds have been established or simply that the proximity of surfaces, which results in increased van der Waals' forces (as suggested by Wittman (19)) is contributing. The fact that the water compensates exactly for any decrease in Young's modulus when the layers move apart emphasizes the bridging role of the water. It probably participates in bonding, perhaps by coordinating with calcium ions between the sheets.

It seems possible that the type of bonds that appear to form between sheets within a layered system might form between individual particles of C-S-H by compaction, or between different particles of C-S-H, originating from separate nuclei during hydration. The concept of cement paste as a continuous mass around pores, when the paste is reasonably mature rather than particles joined by special bonds may be a more useful concept with regard to models. Thus, the area of contact may be the critical factor in determining mechanical properties, and this is related to pore size and shape.

These concepts explain the particular ability of hydrating portland cement in filling space without large expansive strains. The very low surface areas observed by Mikhail and Abo-El-Enein (20) for pastes with low water-cement ratios and Hedin's views about pore filling (21) illustrate this point. Other bonds due to silica polymerization will form subsequently (22,23). Bentur et al (24) also observed increased silica polymerization with specimens under load.

The strength of a brittle material as opposed to Young's modulus is controlled by critical flaws according to Lawrence et al (25). These may occur mainly at regions of inhomogeneity, such as at the interface of C-S-H gel and calcium hydroxide crystals. Care should thus be taken in relating measured strength of such a body in terms of strength of a specific bond.

#### 3.2 EFFECT OF PORE SIZE, SHAPE AND POROSITY ON MECHANICAL PROPERTIES

The need to understand and improve strength and rigidity of portland cement and other concretes has led to the study of the influence of porosity on its mechanical properties. Correlation of porosity with mechanical properties has led to three types of equations, mainly semi-empirical. These are:

$$\sigma = \sigma_0(1-p)^A \quad (3.1)$$

derived by Balshin (26);

$$\sigma = \sigma_0 e^{-Bp} \quad (3.2)$$

derived by Ryskewitch (27). In these equations  $\sigma_0$  is strength at zero porosity and  $p$  is the porosity. In the equation

$$\sigma = D \ln \frac{P_{CR}}{P} \quad (3.3)$$

which was derived by Schiller (28),  $P_{CR}$  is zero strength porosity.  $A$ ,  $B$ ,  $C$  and  $D$  are constants.

Equations (3.1 and 3.2) were also used to relate Young's modulus to porosity. Schiller (28) showed that Eqs. (3.2 and 3.3) deviated only slightly at the two extremes of porosity: Eq. (3.2) is accurate at low porosities and Eq. (3.3) at high porosities.

Roy et al (1) and Roy and Gouda (2,29) used an equation similar to (3.3) to correlate data from specimens made to very low porosities and with high strengths by 'hot' and other forms of pressing.

These results are presented in Fig. 3.1.

Data from Yudenfreund et al (3) and Verbeck and Helmuth (14) are included in the figure. The results of Verbeck and Helmuth refer to capillary porosity and do not fit into the main curve. The rest of the data, plotted as porosity determined by water adsorption, is linear over a wide range of porosities.

Fagerlund (30) correlated data for paste using Eq. (3.1), but with different constants for each paste with a different degree of curing. In this case,  $\sigma_0$  was around 500 N/mm<sup>2</sup> and the constant A about 3.

Danyushevsky and Djabarov (31) studied the total porosity, pore-size distribution and phase composition versus strength of hardened paste from oil well cements, C<sub>3</sub>S,  $\beta$ -C<sub>2</sub>S and mixtures of these with silica flour, diatomite earth and bentonite. The pastes, which were made at several water-cement ratios, were hydrated at room temperature and autoclaved. It was found that with these cements at a CaO/SiO<sub>2</sub> ratio of 2, a large crystalline structure of low strength was formed after autoclaving. With the CaO/SiO<sub>2</sub> ratio down to 0.8, however, material with smaller pores and of high strength and low permeability was formed. The products were tobermorite, xonotlite or CSH(B). The spread of pore-size distribution found in this work is shown in Fig. 3.2. Data were correlated according to Eq. (3.1) by plotting data as a function of capillary porosity.  $\sigma_0$  was found to vary between 1.5 to  $3.0 \times 10^2$  N/mm<sup>2</sup>. These authors concluded that optimal strength at fairly high porosities was found with medium size crystals, such as xonotlite.

Dyczek and Petri (4) prepared specimens of tobermorite, xonotlite and CSH(I), and correlated data with an equation analogous to Eq. (3.2)

$$E = E_0 e^{-Bp} \quad (3.4)$$

where E is Young's modulus and E<sub>0</sub> is Young's modulus at zero porosity. They found E<sub>0</sub>'s to be 5.01, 0.097, and  $0.762 \times 10^5$  (N/mm<sup>2</sup>) respectively and discussed the results in terms of the very low value for xonotlite. The value for tobermorite seems excessively high. Porosities were measured by water adsorption and the values are not realistic because tobermorite loses and regains large amounts of structural water on drying and wetting.

Jambor (5), recognizing the importance of pore size as well as the type of product and total porosity, prepared a variety of materials using Ca(OH)<sub>2</sub>, several siliceous materials, C<sub>3</sub>S, and C<sub>3</sub>A. He measured pore-size distribution, pore volume and compressive strength. The five types of products formed and a plot of compressive strength vs volume fraction of each solid is shown in Fig. 3.3. It was found that pastes containing the same type of hydration products had similar pore-size distributions.

Pore-size distributions are tabulated in Table 3.I with the approximate pore radius range as determined by the mercury porosimeter. Figure 3.3 also shows that there can be a considerable spread in compressive strength for the variety of materials at the same solid volume fraction or, in other words, at the same porosity. Jambor concluded that these

Fig. 3.1 - Relation of compressive strength and log porosity cement pastes (29)

Fig. 3.2 - Pore-size distributions curves hydrated at various temperatures (31)

differences were primarily due to the average pore size within each characteristic composition; the smaller the pore size, the higher the compressive strength, at a given porosity. This is illustrated in Fig. 3.4.

Feldman and Beaudoin (10,32) measured and correlated strength and modulus data for several systems over a wide range of porosities. They measured compressive strength and Young's modulus of paste hydrated at room temperature, autoclaved cement paste with and without additions of fly ash and also included data of other workers (1,3). Measurements of porosity were obtained either from a helium pycnometer or from

a capillary porosity calculation. Correlation was based on Eq. (3.2). Plots for strength data are shown in Fig. 3.5.

There are essentially three curves. Curve AB, representing all the pastes cured at room temperature, covers porosities from 1.4 to 41.5% and terminates at about 230 N/mm<sup>2</sup> at zero porosity. The second line, CD, represents the best fit for most of the autoclaved preparations exclusive of those made with fly ash. This line intersects AB at 27% porosity (w/c ratio: 0.45). At porosities above 27%, the room temperature pastes, when compared at the same porosity, are stronger than those made by autoclaving. This confirms Jambor's view that porosity is not the only factor that controls strength, but it may be related to the pore-size distribution. In addition, it may also be related to the type of bonding within the bulk material or between crystallites. This type of behaviour was also shown in the work of Beaudoin and Ramachandran (33), in which they compared the

mechanical properties of several cements including magnesium oxychloride, gypsum and portland cement (see Fig. 1.5).

On the third curve, CD, points representing cement containing sulfur and those of hot-pressed data of Roy et al (1) are represented. At zero porosity a strength of over 800 N/mm<sup>2</sup> would be obtained for this series.

### 3.3 - EFFECT OF MINERALOGY AND SPECIFIC VOLUME ON THE RELATION BETWEEN POROSITY AND MECHANICAL PROPERTIES

Beaudoin and Feldman (10,11) prepared a variety of silicates by mixing different amounts of ground silica and normal type I cement and autoclaved each mixture at several water-cement ratios. Mechanical properties including microhardness, which approximately represents strength (34), were measured as a function of porosity. These results are plotted in Fig. 3.6 according to Eq. (3.2),  $\sigma = \sigma_0 e^{-Bp}$ ; a family of mechanical property-porosity lines results. The  $\sigma_0$  values and the B constant (the slope for each set of preparations) are presented in Table 3.II. The data of Danyushevsky and Djabaro (31) fall into the range of these data. As the silica content is varied, the slope B of the line changes.

In Fig. 3.7 are shown the range of specific volumes obtained in this series of preparations. Results show that mixtures with low silica content contain a predominance of well crystallized, high density  $\alpha$ -C<sub>2</sub>S when hydrated, while those with 20 to 40% silica contain predominantly CSH(I) and CSH(II) and tobermorite. The mixtures with 50 and 65% silica contain an excess of silica with tobermorite, CSH(I) and CSH(II).

The changes in slope and density support the view that an optimum amount of poorly crystallized hydrosilicate and well crystallized dense material provides maximum values of strength and modulus of

\*\* correlation coefficient

elasticity at a specified porosity. At high porosity, it is very evident that not only porosity but also the bonding of individual crystallites plays a role in controlling the strengths.

It is apparent that disorganized, poorly crystallized material tends to form a higher contact area of bonds, resulting in smaller pores. As porosity decreases, better bonding will develop between high density, well crystallized and poorly crystallized material and consequently higher strengths will result; the potential strength of the high density and high strength material is manifested. This explains how very high strength can be obtained by

hot-pressing, because a small but adequate quantity of poorly crystallized material at these low porosities provides the bonding for the high density clinker material. Work by Ramachandran and Feldman (35) with C<sub>3</sub>A and CA systems has shown that at low porosities, high strength could be obtained from the C<sub>3</sub>AH<sub>6</sub> product because increased area of contact forms between crystallites than is possible at higher porosities. Work with fly ashes of a variety of compositions has confirmed these concepts (12).

Taylor (13) and later Crennan et al (7), in a discussion of these ideas, suggested that the distribution of crystallinity in CSH formed in autoclaving can have a major effect on strength.

Increase in C-S-H crystallinity can either raise or lower strength, depending on the amount of unreacted quartz. This concept is presented in Fig. 3.8. Lines P to T present results obtained for 5 different quartz particle sizes by Crennan et al (7). The diagram illustrates that the effect of particle size may outweigh that of porosity. Alexanderson (36) also observed maxima in strength with crystallinity of calcium silicate hydrates.

### 3.4 - PORE REDUCTION BY IMPREGNATION AND ITS EFFECT ON MECHANICAL PROPERTIES

The effect of porosity on modulus of elasticity can be described by Eq. (3.4). This equation has a theoretical base for its derivation (37,38) but contains several assumptions. The constant  $B$  depends on pore geometry and orientation of the pores with respect to stress. As explained in the last section,  $B$  varies with different preparations. Equation (3.4) predicts that filling of the pores, even with a foreign material, would lead to greatly improved mechanical properties.

The technique of impregnation has been performed on many materials such as cement paste, concrete (39 to 42) and porous ceramic tile (43) with methyl methacrylate, epoxy resins (44), and sulfur (45 to 47). Mechanical properties have been found to increase by several hundred percent and large improvements in water impermeability and resistance to corrosion have also been achieved.

Several workers have applied mixing rule equations to the concrete impregnation system to explain results (42,46,48,49). However, a high degree of impregnation has not been achieved owing to the size of the specimens, and thus bodies approximating non-porous, uniformly impregnated specimens were not obtained. The main conclusions were that the elastic modulus and compressive strength of the impregnated cement paste or concrete are functions of the residual porosity after impregnation and that the increase of fracture energy of impregnated cement is due entirely to the polymer itself and is independent of the initial strength of the porous body.

Hasselman et al (50) and Hasselman and Pentry (51) noted that large increases in elastic moduli are surprising in the light of present theories of elastic behaviour of composites with fibrous, cylindrical or spherical inclusions. They concluded that the pore geometry must deviate considerably from these models and they theoretically analyzed flat or elliptic inclusions. Expressions were derived relating the effect of a

second phase on elastic behaviour to the stress concentrations in the matrix phase, e.g., for porous ceramic bodies having flat pore geometry major changes in elastic moduli resulting from polymer impregnation can be explained even when the elastic modulus of the impregnant is considerably less than that of the matrix.

Simplified equations used were:

$$E_c = E_{01} [1 + \{\alpha V_s / (1 + \gamma V_s)\}] \quad (3.5)$$

$$H_c = H_{01} [1 + \{\alpha V_s / (1 + \gamma V_s)\}] \quad (3.6)$$

where  $V_s$  is the volume fraction of the impregnant,  $\alpha$  and  $\gamma$  are terms incorporating stress concentration factors,  $E_c$  and  $H_c$  are the Young's modulus and microhardness respectively of the composite, and  $E_{01}$  and  $H_{01}$  are these properties at zero porosity.

When the stress concentration term reduces to one, Eq. (3.5) reduces to

$$E_c = 1 / \left( \frac{V_1}{E_{01}} + \frac{V_2}{E_{02}} \right) \quad (3.7)$$

where subscript 1 refers to the matrix phase and subscript 2 to the impregnant phase. This equation is the same as that derived from Reuss' model.

Portland cement paste and autoclaved cement-silica mixes from which mechanical property vs porosity data have been obtained (Table 3.II and Fig. 3.9), were impregnated with either sulfur or methyl methacrylate (41,45). Specimens were discs of 3.2 cm diameter and 1.3 mm thick to facilitate complete and homogeneous impregnation. The residual pore volume of the specimens, measured by helium pycnometry, was, in most cases, lower than 3% of the volume of the sample.

Young's modulus and microhardness were plotted as a function of the volume fraction of sulfur. Linear regression of the results for Young's modulus are shown in Fig. 3.9. Each composition has a distinct

Fig. 3.9 - Young's modulus of composite vs volume fraction of sulfur for preparations with different initial silica contents (45)

curve; for each curve a theoretical curve was plotted. Best fit for Young's modulus was with the stress concentration term  $\beta+1$ , thus in effect using Reuss' model equation (Eq. 3.7). Values of  $E_0$  were obtained from Table 3.II; they in turn had been obtained by extrapolating data according to Eq. (3.4). Curves for the specimens containing the high proportion of weakly bonded  $\alpha$ -C<sub>2</sub>SH have the greatest value for Young's modulus at a given sulfur content.

Equation (3.7) provides an independent method for calculating  $E_0$  for the various matrices. All the terms in this equation are measurable. If these values are substituted using the experimentally determined point with the lowest sulfur content,  $E_0$  can be calculated for each composition (52). This is shown in Fig. 3.10; the values differ by an average of 13.5% from those determined by Eq. (3.2). These results support the view that Eq. (3.4) is a valid expression to predict the effect of porosity on Young's modulus.

Microhardness data, however, could not be correlated with a Reuss-type equation. Unlike modulus of elasticity, microhardness measurements involve failure processes; if stress concentration factors are not included the agreement of Eq. (3.6) is very poor. However, despite the use of stress concentration terms, there is greater deviation between theory and experiment for microhardness than there is for modulus.

The results from these impregnation experiments provide some data for understanding the role of pores in these cement systems. The fact that Eq. (3.7) does not contain any stress concentration term suggests that impregnation is effective in modifying local stress concentrations so that they do not significantly affect the calculation of the elastic modulus of the composite. This of course was not true for microhardness, which involves failure processes and much higher stress levels than were used for Young's modulus determinations. Nevertheless, significant improvements were attained in microhardness through impregnation. The ratio of microhardness, before and after impregnation,  $H_C/H_U$ , is plotted in Fig. 3.11.

Improvements were greater by a factor of 5 for the specimen autoclaved with 5% silica, while predictions from Eq. (3.6) and an equation of the type

$H_U = H_0 e^{-B_H P}$  amounts to a factor of 4.25 at the same volume fraction of sulfur. Improvements for room temperature paste are about a factor of 3. This confirms that the shape of pores and the area of bonding are important in the strength formation of these systems. The systems containing  $\alpha$ -C<sub>2</sub>S were the weakest at intermediate porosities and had the lowest Young's modulus despite the high strength crystals (Fig. 3.6). However, after impregnation, they had the highest mechanical properties because impregnation provided the bond. Before impregnation, at these porosities, the bond between crystallites was very weak compared with pastes cured at room temperature and specimens autoclaved with 20 to 50% silica.

Much work has been done with methyl methacrylate as the impregnant (40,53) and impregnation has been performed with mixtures of polymers, e.g., n-butyl acrylate to methyl methacrylate (54) to give more ductility to the impregnant and thus to the composite. Thus, potential material properties can be tailored to particular structural service requirements as shown in Fig. 3.12. However, there is still much that is not known with regard to the state of the polymer in the pore, since the actual polymerization takes place

Fig. 3.10 -  $E_0$  calculated from mixture law vs  $E_0$  determined by extrapolation of log  $E$  vs porosity (52)

Fig. 3.11 - Ratios  $H_C/H_U$  (microhardness of impregnated sample to that of unimpregnated sample) vs volume fraction of sulfur of composite. (A - Experimental; B - Theoretical) (45)

in this confined space and it is unlikely that it will be the same as the polymer found under normal conditions. Little is known about the role of adhesion of the polymer to the matrix surface and about the durability of the composite. In an attempt to answer some of the questions the cement-silica systems were impregnated with methyl methacrylate (41). A calculation of  $E_0$  for the polymer from

Fig. 3.12 - Compressive stress-strain curves (54)

Eq. (3.6) results in values varying from 6.3 to  $11.8 \times 10^3$  MPa ( $\text{N/mm}^2$ ). This is two to three times the value of the polymer formed in the bulk phase. The paste samples hydrated at room temperature covered a wide range of porosities and the 0.7 and 1.1 water/cement ratios contained a high proportion of large pores. The calculated values for  $E_{02}$  for

the water/cement ratios of 0.25, 0.45, 0.7 and 1.1 were 11.84, 11.54, 7.52 and  $6.33 \times 10^3$   $\text{N/mm}^2$  respectively. Young's modulus of the bulk polymer is largely determined by van der Waals' forces between entangled long chains. However, when these long chains are formed in pores that have diameters of the same size as the length of the chains they may bond on both sides of a pore or crack. As a result, the properties of the polymer as it affects the composite may depend on the covalent bonds within a chain resulting in a higher composite modulus. As pores increase in size, the mean Young's modulus will decrease. Manson (in Ref. 53) has reported changes in the glass transition temperature of about 50 C deg for the polymethyl methacrylate in the pores. This may be due to the effects just discussed.

The values of Young's modulus for the polymer composite are similar to those for sulfur with regard to relative improvement for the various compositions but, quantitatively, the improvement ratios for the sulfur composites are higher. This is probably a result of the higher  $E_0$  for sulfur. These results, however, are reversed in the case of the microhardness measurements, suggesting that the polymer has a much greater facility for bonding with the surface of the matrix and is more effective in modifying regions of stress concentration in the composite. This factor is more important for improved microhardness than for improved modulus.

#### 4. INFLUENCE OF ADMIXTURES ON THE STRUCTURE AND STRENGTH DEVELOPMENT

In the previous sections the nature and significance of bonds, porosity and other structural aspects of portland cement pastes have been discussed. Introduction of admixtures to the hydrating cement influences to different extents, changes in setting, strength, morphology, porosity, density, surface area, volume, etc. In this section such changes are discussed with particular reference to more recent contributions. It must be recognized that variations in results reported in the literature for apparently similar systems are not unexpected, especially where commercial admixtures are used. In the presence of admixtures, the structure of the hydrating cement or cement mineral depends on the type and amount of admixture, chemical and mineralogical composition of cement, surface area, reactivity, w/c ratio, period of hydration, temperature and humidity.

##### 4.1 STRENGTH

##### 4.1.1 Cement Minerals

A direct study of the influence of admixtures on the hydration and structuration of cement, although a useful approach from the practical point of view is not easy to interpret because the admixture may act in a complex way to affect the hydration of the individual phases and their hydration products. Hence, much attention has been directed to a study of the role of admixtures on the strength development in individual cement minerals.

Addition of  $\text{CaCl}_2$  to portland cement results in a significant reduction in setting times and acceleration of strength development. Because of its ready availability, low cost and predictable performance characteristics and application over several decades,  $\text{CaCl}_2$  is more widely studied than other accelerators (1). Compared with many other complex admixtures,  $\text{CaCl}_2$  is relatively simple in terms of its chemical and physical nature. However, there is not only much controversy regarding the actual mechanism of its action but also a persistent disagreement on its effects on concrete (2).

The reactivity of cement minerals  $\text{C}_3\text{S}$  and  $\text{C}_2\text{S}$  to  $\text{H}_2\text{O}$  may be enhanced by increasing their fineness. In an examination of the strength development in  $\text{C}_3\text{S}$  and  $\text{C}_2\text{S}$  ground to different fineness values, Balazs and Boros (3) found that increased dosages of  $\text{CaCl}_2$  and fineness resulted in higher strengths (Fig. 4.1). In the presence of citric acid, the strengths decreased with increased dosages. However, as the fineness increased the strengths were enhanced. The main factors promoting strength development at increased fineness values are the initial compactness of the structure and higher reactivity.

It is generally recommended that the dosage of  $\text{CaCl}_2$  in concrete should not exceed 1.5% by weight of portland cement. This does not necessarily mean that strengths are lowered at higher dosages in cement pastes or in silicate phases. It has been observed by Traetteberg and Ramachandran (4) that in the system  $\text{C}_3\text{S}-\text{CaCl}_2-\text{H}_2\text{O}$ , at a w/s ratio = 0.5, addition of 2%  $\text{CaCl}_2$  gives better strength than that obtained by 5%  $\text{CaCl}_2$ . However, at a w/s = 0.3, addition of 5%  $\text{CaCl}_2$  yields even higher strengths than those obtained by 2%  $\text{CaCl}_2$  at a w/s = 0.5 (Table 4.1) (4). This indicates that in a more compacted system proximity of the particles would promote better bonding

on the surfaces and therefore higher than normal amounts of  $\text{CaCl}_2$  can be tolerated for achieving strengths.

TABLE 4.1 - Microhardness for  $\text{C}_3\text{S}$  pastes containing different amounts of  $\text{CaCl}_2$  (4)

Hydration time, days	Microhardness ( $\text{N/mm}^2$ )

15	186	92	311	353

Modulus of elasticity of a cementitious system can be obtained by the ultrasonic pulse velocity technique. In a study of  $\text{C}_3\text{S}$  hydrated with calcium salts of thiocyanate, propionate, maleate, perchlorate and chloride, Lawrence et al (5) found that the velocities were higher with pastes containing admixtures. The velocity-time behaviour could partly be explained by the higher degree of hydration. Results with  $\text{CaCl}_2$  were anomalous; compared to other admixtures, it gave lower velocities and lower porosity at equal degrees of hydration. Since the velocity depends on the density of the product and the number of contact points,

Fig. 4.1 - Effect of  $\text{CaCl}_2$  on cube strength of  $\text{C}_3\text{S}$  and  $\beta\text{-C}_2\text{S}$  pastes (3)

it is possible that in the presence of  $\text{CaCl}_2$  the higher density product that is formed reduces the contact points. Hence the applicability of the ultrasonic technique for the cementitious systems containing admixtures should be re-examined especially since the structure of the hydrate product is changed.

The silicate structure changes occurring in the hydrated cements was followed by Lentz (6) using the trimethylsilylation reaction. He found that with time of hydration the orthosilicate content gradually decreased, giving rise to disilicate and polysilicate structures. As an extension of this idea, polymerization of silicates in pastes containing  $\text{C}_3\text{S}$  or  $\text{C}_2\text{S}$  and admixtures  $\text{CaCl}_2$ , citric acid and thionyl chloride was examined by Tamas et al (7). The hydrated products were found to contain mainly the dimeric  $\text{Si}_2\text{O}_7^{6-}$  ions with small amounts of trimeric chains and tetrameric rings. In both  $\text{C}_3\text{S}$  and  $\beta\text{-C}_2\text{S}$ , the ratio of the mono-silicate/disilicate peak heights were lower for pastes containing  $\text{CaCl}_2$  (Fig. 4.2) (7) indicating the increase in the disilicate formation with the progress of hydration. As it is known that there is an increase in strength in the pastes containing  $\text{CaCl}_2$ , it is possible that strengths tend to be higher in pastes containing larger amounts of polymerized silicates. The citric acid admixture which is a retarder shows less polymerization effect at very early ages. More work should be done before it can be stated that polymerization is directly related to strength development.

A comparison of the strengths developed in pastes containing different types of admixtures are usually compared at equal times of hydration. This method

does not provide information on the intrinsic property of the product. The intrinsic property can be studied by comparing the strengths at equal degrees of hydration. In an investigation of tensile strengths developed by  $\beta\text{C}_2\text{S}$  containing  $\text{CaCl}_2$ ,  $\text{NaF}$ ,  $\text{NaHCO}_3$ ,  $\text{NaH}_2\text{PO}_4$  and  $\text{NaCl}$ , comparison at 60% hydration showed different values (8). This would indicate that the nature of the products formed in the presence of these admixtures is different.

Admixtures also influence the strengths developed in  $\text{C}_4\text{AF}$  and  $\text{C}_3\text{A}$  pastes. In suspensions containing  $\text{CaCl}_2$  concentrations of more than 3N, early strength of  $\text{C}_4\text{AF}$  can increase with the formation of a high chloride complex (9). Similar observations have been reported in the  $\text{C}_3\text{A}-\text{CaCl}_2-\text{H}_2\text{O}$  system containing 16%  $\text{CaCl}_2$  (10). These results would indicate that depending on the conditions of hydration and the materials, a much higher than normal amount of  $\text{CaCl}_2$  prescribed in cement can be used without detrimental effects to strengths.

#### 4.1.2 Cement Pastes

The relative importance of factors influencing strength in a cement paste containing  $\text{CaCl}_2$  is not completely resolved. Although it is recognized that  $\text{CaCl}_2$  yields high early strengths, there is no agreement on its influence on long-term strength development; the values may increase, decrease or remain the same as that of the reference cement paste. It is not even clear what the optimum dosage of  $\text{CaCl}_2$  is for achieving the maximum strength. For example, contrary to general belief, Wolhutter and Morris (11) have found that the maximum strength at 28 days is achieved with 4 to 6% anhydrous calcium chloride. This indicates the existence of many factors that influence the strength development in concretes. As described already, comparison of the properties at equal degrees of hydration forms a good basis to study the intrinsic property of pastes hydrated in the presence of different amounts of admixtures. This approach was adopted by Ramachandran and Feldman (12) for an examination of strength development in portland cement pastes hydrated in the presence of 0, 1, 2 and 3½%  $\text{CaCl}_2$ . Figure 4.3 (12) shows that at any one degree of hydration the sample with 3½%  $\text{CaCl}_2$  has the lowest strength; at lower degrees of hydration the sample containing 0%  $\text{CaCl}_2$  is the strongest, although with the progress of hydration samples containing 1 to 2%  $\text{CaCl}_2$  form stronger bodies than all others. Porosity, density and bonding are factors that affect these results. It is thus evident that addition of  $\text{CaCl}_2$  not only changes the rate of hydration but also the intrinsic nature of the hydration products.

The Soviet literature contains references to the use of many complex admixtures (13,14). For example, by using nitrites and nitrates in combination with  $\text{CaCl}_2$  higher strengths are reported at below-freezing temperatures. Mchedlov-Petrosyan et al (15) found that among the combinations used, a mixture of 1.1%  $\text{CaCl}_2$  and 1.2%  $\text{Ni}(\text{NO}_3)_2$  developed maximum strength. The higher strengths were attributed to a more complete hydration, low basic C-S-H formation and complex formation of the salt with the hydrating cement. Strengths are not a linear function of the degree of hydration and caution should be exercised when comparison is made of pastes containing complex admixtures. For example at 50% hydration of cement, the strengths developed with the  $\text{Ca}(\text{NO}_3)_2-\text{CaCl}_2$  combination and the reference cement were, respectively, 160 to 230  $\text{kg/cm}^2$  (15.69 to 22.56  $\text{N/mm}^2$ ) and 100  $\text{kg/cm}^2$  (9.8  $\text{N/mm}^2$ ) (16).

Fig. 4.2 - Peak height ratios in chromatograms of silylated reaction product of  $\text{C}_3\text{S}$  and  $\text{C}_2\text{S}$  pastes, with and without admixtures, as a function of hydration time (7)

Fig. 4.3 - Strength vs non-evaporable water relationship for cement paste containing calcium chloride ( $w/c = 0.4$ ) (12)

A number of organic and inorganic compounds, such as aluminates, sulfates, formates, thiosulfates, carbonates and amines, have been suggested as alternatives to the  $\text{CaCl}_2$  accelerator. None of them has been found to be as efficient and economical as  $\text{CaCl}_2$ . Using chlorides of Ca, Ba, Mg and Fe, Ranga Rao (17) found that 1.6%  $\text{BaCl}_2$  gives 1-day strength equivalent to that obtained with 2%  $\text{CaCl}_2$ . However, the 28-day strength with  $\text{BaCl}_2$  was lower than that obtained with  $\text{CaCl}_2$ . It was also found that  $\text{BaCl}_2$  is not as efficient an accelerator as  $\text{CaCl}_2$  at 10 to 15°C. It is likely that the differences in the solubility of  $\text{BaCl}_2$  and  $\text{CaCl}_2$  play a role in the mechanism of acceleration and strength development.

Triethanolamine is a constituent in certain admixture formulations in concrete and its addition is thought to reduce the excessive retarding action of a water-reducing admixture. Consequently, it is assumed that when used alone it should act as an accelerator. It may act as an accelerator for  $\text{C}_3\text{A}$ ,  $\text{C}_3\text{A} + \text{gypsum}$  hydration (18) and as a retarder for the hydration of  $\text{C}_3\text{S}$  (19). When added to portland cement, triethanolamine decreases its strength at all ages and also alters the setting characteristics (20). Fig. 4.4 (20) shows the strength development in cement pastes containing 0, 0.1, 0.25, 0.35, 0.5 and 1% triethanolamine. Strength decreases as the amount of triethanolamine is increased. Complex factors that may be involved for low strengths are: formation of C-S-H with higher C/S ratio, retardation of  $\text{C}_3\text{S}$  hydration, rapid initial setting followed by large heat development and a more porous structure. Sodium carbonate is also found to be an accelerator for the setting of cement. Strengths (1 to 28 days), however, seem to decrease by the addition of 2%  $\text{Na}_2\text{CO}_3$  (21). In addition, there is an increase in the water requirement caused by the quick initial hydration of  $\text{C}_3\text{S}$  and  $\text{C}_3\text{A}$  components and the precipitation of  $\text{CaCO}_3$ . The slow strengths are attributed mainly to decreased rate of subsequent hydration.

Water reducers, such as lignosulfonates, hydroxycarboxylic acids and, more recently, superplasticizers have been used widely in concrete practice either to achieve higher water reductions while maintaining the same workability or to obtain higher workability at the same  $w/c$  ratio. Use of

superplasticizers permits production of flowing concrete without any loss in strength. They can also be used to reduce water requirements by about 30% for the development of high strengths. Using 1 to 4% of a sulfonated melamine formaldehyde-based admixture, strength increases of the order of 50% over the control concrete have been obtained at the same slump value (Fig. 4.5) (22). There is still controversy as to whether the ultimate strength achieved, using a low  $w/c$  ratio (at nominal consistency) in the presence of a water reducer, is equal to or higher than the reference cement paste or concrete made at the same  $w/c$  ratio but at low workability (23-25). There is also some disagreement as to the relative strength values of cement pastes made with or without water reducers made at the same normal  $w/c$  ratio but with different workability characteristics. Generally the mix containing the water reducer yields higher strengths. The cement paste containing the water

Fig. 4.4 - Compressive strengths of cement pastes containing triethanolamine (20)

Fig. 4.5 - The variation in strength development of constant initial slump concrete with a superplasticizer (22)

reducer will have higher workability and will be better compacted, resulting in a better bonding of the hydrated products. Collepardi and Massida (26) have observed that a reduction in porosity occurs in such pastes containing the water reducer. In these pastes a higher degree of hydration has also been observed. It is thought that the water layer surrounding the cement particles in the presence of water reducers provides a source of efficient hydration (27).

Renewed interest has recently been shown in preparing cement pastes at a very low w/c ratio. This is achieved by using a high surface area clinker (6000 to 7000 cm<sup>2</sup>/g) and a mixture of lignosulfonate with a carbonate or bicarbonate of K or Na. By this method a w/c ratio of 0.20 to 0.25 is possible and strengths of the order of 19 000 lb/sq in. (131 N/mm<sup>2</sup>) have been obtained (28-31). Typically at a w/c = 0.22, the strengths at 15 h, 24 h and 3 days are, respectively, 2000, 9500 and 12 500 lb/sq in. (13.8, 65.5 and 86.2 N/mm<sup>2</sup>). Strength gain follows the kinetics of hydration, unlike what was observed in the hydration of portland cement containing gypsum. It has also been reported that addition of the Na<sub>2</sub>CO<sub>3</sub> + Na-lignosulfonate combination to clinker or clinker + gypsum at the same w/c ratio results in 1-day strength being higher and 28-day strength lower for gypsum-containing clinkers (30). The mechanism responsible for these effects is not immediately apparent.

Roy and co-workers (32) have been able to obtain strengths as high as 95 000 lb/sq in. (655.0 N/mm<sup>2</sup>) in cement pastes by using the technique of hot-pressing. The resultant reaction products formed using this technique are different from those obtained in normal hydration reactions. Also a substantial portion of the cement remains unhydrated. In an investigation of the effect of various admixtures, viz., triethanolamine, CaCl<sub>2</sub>, citric acid, sulfonated naphthalene condensate and a polymer resin on hot pressed type I and type III cements, CaCl<sub>2</sub> was found to give higher strengths (33,34). Generally strengths increased as the hydration progressed. Citric acid did not improve early strengths and triethanolamine gave very low strengths. The effect of admixture seems to be to change the rate of hydration and form a product that bonds the high density matrix of varying porosity. The presence of CaCl<sub>2</sub> seems to result in the inhibition of crystalline products (34) and a change in the nature of the polymerization of the silicates.

#### 4.2 PORE STRUCTURE

Total porosity and pore-size distribution are important parameters that provide information on the possible strength and durability characteristics of cementitious materials. A plot of strength vs porosity plotted on a linear scale or as a semi-log plot shows the dependence of strength on porosity. Although such a relationship appears to exist over a range of porosity values, its use for prediction purposes is limited because the relation is different for different materials prepared in different ways. Some work has been carried out to determine the effect of admixtures on the pore structure of hydrating cement and cement minerals. Porosity and pore size distribution data for apparently similar materials may show significant differences depending on what methods are adopted for their determination.

##### 4.2.1 Cement Minerals

A considerable amount of work has been done on the influence of CaCl<sub>2</sub> on the porosity and pore-size characteristics of C<sub>3</sub>S paste. Working on C<sub>3</sub>S

containing 1% CaCl<sub>2</sub>, Berger et al (35) found that at equal degrees of hydration the porosity of the paste containing CaCl<sub>2</sub> was lower than that of the reference paste. A plot of gel space ratio vs compressive strength indicated a linear relationship for pastes with or without CaCl<sub>2</sub> hydrated to different degrees. It was assumed that the specific volume of the pastes was not changed by the addition of CaCl<sub>2</sub>. Recent work of Ramachandran and Feldman (12) on cement pastes has shown, however, that CaCl<sub>2</sub> influences the specific volume of the pastes. Since these workers (12) used Hg porosimetry with a maximum intrusion pressure of 30 000 lb/sq in. (206.9 N/mm<sup>2</sup>), only pores of diameter >0.0065 μm could be registered. However, it is known that pastes containing CaCl<sub>2</sub> can have a substantial portion of total porosity in pores of diameter below 0.0065 μm (36-38). Collepardi (39) found that in C<sub>3</sub>S hydrated with 2% CaCl<sub>2</sub> at 1 day, at a w/c = 0.5, the hydrated product had most of the pores in the range of 10 to 50 Å radius. Skalny and co-workers (40) using N<sub>2</sub> isotherms also concluded that C<sub>3</sub>S hydrated in the presence of CaCl<sub>2</sub> for 28 days has a lower hydraulic radius (31.8 Å) than that of the reference paste (53.3 Å).

Figure 4.6 (41) shows the total porosity and effective pore diameter relationship obtained for C<sub>3</sub>S hydrated to different times in the presence of 1% CaCl<sub>2</sub>. As hydration progresses, porosity decreases because the hydration products fill the pores, and at 30 days the product contains mainly pores of smaller diameter.

Fig. 4.6 - Intrusion curves of a series of C<sub>3</sub>S pastes hydrated with calcium chloride (41)

In a study of the effect of 2 to 5% CaCl<sub>2</sub> on the properties of C<sub>3</sub>S hydrated at w/s ratios of 0.3 and 0.5, Traetteberg and Ramachandran (4) found that an approximate linear relationship exists between porosity and logarithm of microhardness (Fig. 4.7). Lack of perfect linearity may be attributed to differences in pore-size distribution, composition and morphology.

Some work has been carried out on porosity and pore-size distribution characteristics of C<sub>3</sub>S pastes hydrated in the presence of non-chloride admixtures such as calcium lignosulfonate, Na<sub>2</sub>CO<sub>3</sub>, polymers and calcium salts of maleate, perchlorate, propionate and thiocyanate. According to Collepardi (39,42), in C<sub>3</sub>S pastes hydrated to 1 day the porosity and pore-size distribution data for the reference paste and that containing calcium lignosulfonate are almost the same. However, in the presence of Na<sub>2</sub>CO<sub>3</sub> the total porosity decreases from 0.091 to 0.06 cm<sup>3</sup>/g, and the volume of pores in the range 10 to 50 Å is lower than that of

Fig. 4.7 - Microhardness vs porosity relationship for C3S paste; w/s = 0.5 ( $\Delta$ ), w/s = 0.3 (o) (4)

the reference. The lower porosity was attributed to the precipitation of  $\text{CaCO}_3$  on the pore entrances due to the reaction between  $\text{Na}_2\text{CO}_3$  and  $\text{Ca(OH)}_2$ . No data were collected for these systems to assess how the porosity and pore-size effects determine strength. Although the pore structure is similar for the reference paste and that treated with calcium lignosulfonate, the intrinsic structure may have been different if the results had been obtained at the same degree of hydration.

Young and co-workers (5,41) have measured the porosity and pore-size distribution values of C3S pastes hydrated with various calcium salts. Using mercury porosimetry, pore diameter only above  $0.0065 \mu\text{m}$  could be determined. At a constant degree of hydration the intruded volume, as well as the pore-size distribution, varied from one sample to the other. The differences were ascribed to variations in gel porosity, isolated large pores, air-entrainment, etc., assuming that they should have the same porosity. As already discussed, there is no reason to assume that the paste containing an admixture should have the same porosity as the reference material at the same degree of hydration.

#### 4.2.2 Cement Pastes

In an investigation on the effect of different amounts of  $\text{CaCl}_2$  (0, 1, 2 and 3½%) on the properties of cement pastes, Ramachandran and Feldman (12) found that the product shows a decrease in porosity as hydration progresses (Fig. 4.8). Helium pycnometry was used to determine the absolute density of discs of the pastes, and the porosity was computed from absolute and apparent densities. When cement is mixed with water it sets into a rigid body. Water in the pores slowly reacts with the unhydrated particles forming the hydrated products; these products fill the spaces originally occupied by the water molecules as well as spaces originally held by the unhydrated particles. Because the density of the hydrated cement is lower than that of the unhydrated cement a decrease in porosity results during hydration. The decrease is steep during the first 24 h, and at the same time

Fig. 4.8 - Porosity of cement pastes containing different amounts of calcium chloride (w/c = 0.4) (12)

there is a rapid rate of hydration. After 28 days most samples show a 50% decrease in porosity.

In Fig. 4.9 (12) the porosity of cement pastes is expressed as a function of the non-evaporable water content. Porosity decreases as the degree of hydration increases. The main factor causing this decrease is the filling of pores by the low density hydrated cement. A plot of absolute density vs

Fig. 4.9 - Porosity vs non-evaporable water relationship; (a) w/c = 0.25, (b) w/c = 0.4 (12)

porosity shows a linear relation (Fig. 4.10) (12). The relatively higher porosity values for pastes with a w/c = 0.4 are due to the higher initial amounts of water. A completely hydrated cement formed at w/c = 0.4 has an absolute density of  $2.19 \text{ g/cm}^3$  (43). An extrapolation of the line representing the sample made at a w/c = 0.4 to a density of  $2.19 \text{ g/cm}^3$  corresponds to a porosity of 22.5%. This is the minimum porosity that can be attained with a cement paste prepared at a w/c = 0.4 (made with or without admixtures). At the same degree of hydration for samples made at a w/c ratio of 0.4, porosity decreases as follows: Cement + 3½%  $\text{CaCl}_2$  > Cement + 2%  $\text{CaCl}_2$  > Cement + 1%  $\text{CaCl}_2$  > Cement + 0%  $\text{CaCl}_2$ . Collepardi et al (44) compared the porosity of cement hydrated for 7 days with and without  $\text{CaCl}_2$  and found that the total porosity was higher in the paste containing  $\text{CaCl}_2$ . The differences in the porosity obtained at the same degree of hydration indicate that the types of hydration products formed in pastes containing different

Fig. 4.10 - The influence of absolute density on the porosity of cement pastes hydrated with calcium chloride (12)

amounts of  $\text{CaCl}_2$  are intrinsically different in nature. It can also be concluded that in this system the differences in porosity are mainly due to the variation in the absolute densities of the hydration products.

Although a substantial amount of work has been carried out on the effect of superplasticizers on the physico-mechanical characteristics of concrete, only meagre information is available on their effect on cement pastes. Collepari (26) compared the porosity and pore-size distribution characteristics of cement pastes (with or without a superplasticizer) made at the same w/c ratios of 0.30, 0.35 and 0.44. The study covered only pore diameters in the range 0.01 to 1  $\mu\text{m}$ . Porosity values were lower in samples containing the admixture and this was partly due to a higher degree of hydration (Fig. 4.11) (26). The results do not

Fig. 4-11 - Cumulative pore volume in function of pore diameter or pressure of intruded mercury. The cement pastes were hydrated for 3 days with the following w/c ratios:

- 1 - w/c = 0.44; 2 - w/c = 0.35;
- 3 - w/c = 0.30; 4 - w/c = 0.44;
- 5 - w/c = 0.35; 6 - w/c = 0.30.
- 1-2-3 without Rheomac;
- 4-5-6 with Rheomac (26)

permit an evaluation of the intrinsic nature of the paste because pore volume was not determined for pore sizes below 0.01  $\mu\text{m}$ . In another study, however, Collepari et al (23) investigated the pore volume vs pore radius (down to 10 $\text{\AA}$ ) relationship for cement hydrated with calcium lignosulfonate. In the pore radius range 10 to 70 $\text{\AA}$ , both the reference specimen and that containing lignosulfonate showed a similar relationship. The lignosulfonate-treated sample showed a larger volume of pores of radius >70 $\text{\AA}$  than the reference paste. Similar trends were obtained in  $\text{C}_3\text{S}$  pastes containing lignosulfonate. The higher shrinkage rate observed in pastes containing lignosulfonate was explained by the presence of larger amounts of pores from which water can escape more rapidly.

Sodium carbonate can be used as an accelerator of setting. Addition of this admixture to cement changes the intrinsic nature of the hydrated product. Total porosity and pore-size distribution values of hydrated cement containing  $\text{Na}_2\text{CO}_3$  are not the same as that of the reference paste. In the presence of  $\text{Na}_2\text{CO}_3$  smaller pores ( $r = 10$  to  $100\text{\AA}$ ) are decreased and larger pores ( $r > 150\text{\AA}$ ) are increased slightly (21). The reduction in small pores may be due to the precipitation of  $\text{CaCO}_3$ . A decrease in total porosity of cement pastes from 19.2 to 8.1% was observed by Butt and Kolbasov (45) when  $\text{NaNO}_2$  was used as an admixture. The decrease in porosity was attended by an increase in compressive strength.

Uchikawa and Tsukiyama (46) compared the porosity of two regulated set cements A and B containing citric acid and  $\text{CaSO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$ , respectively. When strength was compared at different times, cement A containing citric acid appeared stronger than B containing  $\text{CaSO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$ . However, a comparison of strength at equal porosity values showed that cement B mix was stronger than cement A mix. This implies that the internal structure of mix B was different from that of mix A.

#### 4.3 SURFACE AREA

Surface area studies of a hydrated cement may yield information on the reactivity, strength, shrinkage and volume changes of the paste. The unhydrated portland cement has a Blaine surface area of about 3000 to 4000  $\text{cm}^2/\text{g}$ . In a set cement (saturated condition) the values, determined by the small-angle X-ray scattering technique (47), are as high as 600  $\text{m}^2/\text{g}$ . This figure is even higher if computed for the C-S-H portion of hydrate. The specific surface area determined by  $\text{H}_2\text{O}$  vapour yields a value of about 250  $\text{m}^2/\text{g}$  and that by  $\text{N}_2$  decreases to 50% of this value or less. The large surface area indicates that the individual particles comprising the hydrated cement are of colloidal dimensions. It is generally observed that the surface area of a cement paste determined by  $\text{H}_2\text{O}$  vapour gives a reasonably constant value independent of the method of preparation or history. Surface area determined by  $\text{N}_2$  gives values that differ for different preparations and accounts for changes occurring as a result of sample history and ageing processes. Addition of admixtures influences significantly the  $\text{N}_2$  surface area of pastes; in this section these effects will be discussed.

##### 4.3.1 Tricalcium Silicate

The  $\text{N}_2$  surface area of hydrated  $\text{C}_3\text{S}$  or  $\text{C}_2\text{S}$  is increased in the presence of  $\text{CaCl}_2$  (37,39,40,48-52). The extent of this increase differs, depending on factors such as particle size and purity of the silicate, w/s ratio, amount of  $\text{CaCl}_2$  added, extent of hydration, temperature

of hydration and drying conditions. If water is used as the adsorbate, surface area values are found to be much higher than  $N_2$  values. The  $H_2O$  surface areas of  $C_3S$  pastes containing calcium chloride are not much different from those hydrated without it.

Figure 4.12 shows the  $N_2$  surface area values as a function of the time of hydration for  $C_3S$  (51). In the presence of  $CaCl_2$  in the first day, the surface area is about  $220 \text{ m}^2/\text{g}$ , which decreases to a value of about  $80 \text{ m}^2/\text{g}$  in 3 months. This value is still about three times that determined for  $C_3S + 0\% \text{ CaCl}_2$ . Nitrogen area for  $C_3S + 5\% \text{ CaCl}_2$  is even higher than that for  $C_3S$  containing  $2\% \text{ CaCl}_2$  (53,54). Though surface area decreases as the temperature of hydration is increased, at any temperature, samples containing  $CaCl_2$  show higher surface areas than those without it (54). In Fig. 4.12,  $C_3S$  samples show a decrease in surface area as hydration progresses, and this is due to the "ageing" effect involving formation of physical and/or chemical interlayer bonds.

Surface area (by  $H_2O$  vapour) of hydrated  $C_3S$  carried out at a hydration degree of 64% shows a value of  $324 \text{ m}^2/\text{g}$  for  $C_3S + 0\% \text{ CaCl}_2$  and a value of  $261 \text{ m}^2/\text{g}$  for  $C_3S + 2\% \text{ CaCl}_2$  (40). The lower surface area is explained by the formation of C-S-H of higher c/s ratio and increased average thickness of the gel unit (55). A higher c/s ratio in the gel need not necessarily mean that it would have a lower surface area. For example, the gel with  $5\% \text{ CaCl}_2$  has a surface area of about  $15 \text{ m}^2/\text{g}$  larger than that formed with  $2\% \text{ CaCl}_2$ , though the c/s ratio of the gel at  $5\% \text{ CaCl}_2$  is higher.

Shrinkage of a  $C_3S$  paste is increased in the presence of  $CaCl_2$ . If the measurements are carried out at a particular time, the values may reflect the extent to which the hydration has progressed. Hence, Berger et al (35) compared the shrinkage of the  $C_3S$  paste and  $C_3S$  paste +  $1\% \text{ CaCl}_2$  at constant degrees of hydration. At any degree of hydration the paste containing  $CaCl_2$  showed a higher shrinkage. Though the higher shrinkage values have been thought to be due to an increase in the finer pore size range, it can be considered that a higher surface area promotes greater shrinkage.

The non-chloride admixtures may also influence the surface area of the  $C_3S$  pastes. At 1 day of hydration the specific surface areas of the hydrated portion of the reference  $C_3S$  paste, and that containing  $CaCl_2$ ,  $Na_2CO_3$  and calcium lignosulfonate, are, respectively, 45, 198, 26 and  $47 \text{ m}^2/\text{g}$  (39). Since  $C_3S$  is hydrated to different extents at 1 day, the results do not mean that the values will be similar if compared on this basis at all levels of hydration. Addition of triethanolamine (TEA) results in an increase in the surface area of  $C_3S$  paste. At 28 days of hydration  $N_2$  surface areas of  $C_3S + 0\% \text{ TEA}$ ,  $C_3S + 0.1\% \text{ TEA}$  and  $C_3S + 1\% \text{ TEA}$  are, respectively, 24.8, 30.9 and  $44.6 \text{ m}^2/\text{g}$  (19). It may be envisaged that the chemisorption of TEA on freshly formed C-S-H inhibits the orderly growth of plates in a tubular form and thus promotes the formation of a higher surface area product. Triethanolamine also increases the amount of non-crystalline  $Ca(OH)_2$ , and this factor may partly account for the increased area.

#### 4.3.2 Cement Pastes

The addition of  $CaCl_2$  increases the surface area of hydrated  $C_3S$  and hence it follows that a similar effect should also operate in portland cement paste. In the presence of  $CaCl_2$ , the surface area values of portland cement, pozzolanic cement and blast furnace cement increase from initial values of 43.2, 45.4 and

Fig. 4.12 - Surface area of a  $C_3S$  paste containing calcium chloride (51)

$45 \text{ m}^2/\text{g}$  to 76.3, 61.0 and  $198 \text{ m}^2/\text{g}$ , respectively (44). Calcium chloride is more effective in increasing the surface area of  $C_3S$  paste than that of portland cement paste. Part of the explanation is that  $CaCl_2$  increases only marginally the surface area of the  $\beta C_2S$  component of cement. The small increase in surface area of the pozzolanic cement is due to the negligible influence of  $CaCl_2$  on the lime-pozzolana reaction. The activation of the slag by  $CaCl_2$  may explain its significant influence on this system.

The surface area of various cement pastes, determined at a particular degree of hydration, was reported by Ramachandran and Feldman (12). At a particular degree of hydration the surface area generally increases as the amount of  $CaCl_2$  is increased (Table 4.II) (12). Chemisorption of  $Cl^-$  ions on the

TABLE 4.II - Specific surface areas of cement pastes containing  $CaCl_2$  at a particular non-evaporable water content (12)

1	20.3	24.3
2	37.9	28.7
$3\frac{1}{2}$	37.3	32.2

hydrating surfaces may be responsible for this effect (53). The significant differences in the surface area values for the same degree of hydration suggest the existence of differences in the intrinsic properties of samples. At higher degrees of hydration, any decrease in surface area of pastes

Fig. 4.13 - Shrinkage vs surface area for several admixtures (56)

containing 2 and 3½ CaCl<sub>2</sub> may be due to ageing. The shrinkage of a cement paste containing CaCl<sub>2</sub> depends on its surface area and the degree of hydration (44). If the degree of hydration is constant, the shrinkage values should depend on surface area. In Table 4.11 (12), the surface areas of pastes containing CaCl<sub>2</sub> are larger than those containing no CaCl<sub>2</sub>, indicating that shrinkage values should be higher in pastes containing CaCl<sub>2</sub>. This has been verified for the system C<sub>3</sub>S-CaCl<sub>2</sub>-H<sub>2</sub>O (35).

The significance of surface area on shrinkage in cements hydrated with calcium lignosulfonate, hydroxycarboxylic acid and triethanolamine has been investigated by Feldman and Swenson (56). A plot of shrinkage (drying from 100 to 50% RH) vs surface area (N<sub>2</sub>) for various samples showed that samples producing higher shrinkages had significantly higher surface areas (Fig. 4.13) (56). It appears that shrinkage is associated more with the degree of dispersion of the pastes than with the chemical composition or morphology.

As stated earlier, CaCl<sub>2</sub> at normal dosages increases the surface area substantially. At normal dosages calcium lignosulfonate increases only marginally the surface area of cement paste. Collepardi et al (23) found that with calcium lignosulfonate the areas increased from 43-48 to 48-53 m<sup>2</sup>/g. This increase was partly attributable to a higher degree of hydration in the presence of calcium lignosulfonate. Under similar conditions, addition of Na<sub>2</sub>CO<sub>3</sub> decreased the surface area of cement paste from 43-48 to 22.7 - 26.0 m<sup>2</sup>/g because of the blocking of pores by precipitated CaCO<sub>3</sub>. The shrinkage values were also lower in these pastes.

#### 4.4 MICROSTRUCTURE

The microunits formed in the cement paste are too small to be amenable to investigation by the optical microscope and consequently the electron microscope capable of very high resolution has received recognition for the examination of the microstructure of cementitious materials. Radczewski et al (57) were probably the first to apply this technique for investigating cementitious systems and since then several refinements to the technique have been made,

resulting in the publication of innumerable micrographs. It is beginning to be recognized that comparison of results by different workers has an inherent limitation because of the small number of micrographs usually published and the correspondingly small area represented by these micrographs, which may indicate a non-representative view of the structure. What may be selected by one researcher as the representative structure may differ from that selected by another. Even the description of apparently similar features becomes subjective (58). Consequently, speculations on the origin of strength and other properties, when based on these observations, have limited validity, especially since many properties of cement paste are influenced at a much lower microlevel than can be observed by the electron microscope.

In spite of human and instrumental limitations, electron microscopic techniques have provided useful information on morphological features and an estimate of the elements contained in the microunits of various products. Depending on the starting materials and conditions of hydration, addition of admixtures to cements and cement minerals modifies to different extents the microstructure of the hydration products.

##### 4.4.1 Tricalcium Silicate

The tricalcium silicate phase, constituting the major component in portland cement, greatly influences its strength characteristics and hence has received greater attention than other phases. A number of investigators have studied the effect of different concentrations of CaCl<sub>2</sub> on the morphological characteristics of hydrated calcium silicate. There has, however, been a variance in the actual description of the morphology (1). According to Odler and Skalny (55), hydrated C<sub>3</sub>S normally forms spicules or sheets rolled into cigar-shaped fibres 0.25 to 1.0 µm long and in the presence of CaCl<sub>2</sub> a spherulitic morphology is facilitated. Kurczyk and Schwiete (59) reported that needle-like products change to spherulites in the presence of CaCl<sub>2</sub>. Young (41) found that the morphology of hydrated C<sub>3</sub>S + 0% CaCl<sub>2</sub> was needle-like whereas that of hydrated C<sub>3</sub>S + 2% CaCl<sub>2</sub> was lace-like in structure. In contrast to the above, Murakami and

Tanaka (1) found the existence of a fibrous cross-linked structure in  $C_3S$  pastes treated with  $CaCl_2$ .

Using transmission electron microscopy, Ramachandran (53) found that  $C_3S$  hydrated at a w/s ratio = 0.5 showed needle-like morphology, whereas that hydrated in the presence of 1% or 4%  $CaCl_2$  exhibited a platy or crumpled foil-like morphology (Fig. 4.14). Collepardi and Marchese (51) and Berger et al (60) came to similar conclusions. These changes in morphology may have resulted from the chemisorption of  $Cl^-$  ions on the C-S-H surface and introduction of these ions into the C-S-H lattice.

The morphological features become less distinct when the hydrated products are formed in a confined space, as for example, when the pastes are prepared at low w/s ratios. This is because the particles are so close to each other that there is not enough space for crystals to grow into larger dimensions. In Fig. 4.15 (12) are shown the micrographs of  $C_3S$  hydrated at a w/s ratio of 0.3 and obtained with 0, 2 and 5%  $CaCl_2$ . A dense structure for pastes with 2 and 5%  $CaCl_2$  is evident and this feature may be responsible for a 50 to 150% increase in microhardness values over the paste containing no  $CaCl_2$ . It may, however, be argued that a lower porosity and better contact or bonding of the particles are factors causing strength increases. Bendor and Perez (61) have ascribed the higher strengths in  $C_3S$  pastes with  $CaCl_2$  to the honeycomb nature of the paste as opposed to the sponge-like feature in the reference  $C_3S$  paste. Berger et al (35, 41) compared the microstructure of  $C_3S$  hydrated with and without  $CaCl_2$  at the same degree of hydration and concluded that differences in external morphology indicated the differences in pore-size distribution. Porosity and pore-size distributions are recognized as important parameters affecting the strength development. However, in this work (35), it is not easy to assess pore sizes below 0.1  $\mu m$  from the morphological features. Lawrence et al (5), on the other hand, have concluded that the outer morphology observed by SEM is not as important as the contact points closest to the unhydrated grains (which cannot be resolved by SEM) in assessing the mechanical properties of the  $C_3S$  paste. It is important, therefore, to recognize that morphology, porosity, density and chemical composition are mutually dependent factors that determine strength characteristics.

Addition of  $CaCl_2$  modifies the morphology of autoclaved  $C_3S$ . Fibrous crystals and rectangular block-shaped crystals normally present are not found with  $CaCl_2$ . In the presence of  $CaCl_2$ ,  $C_3SH_{1.5}$  and  $\alpha$ - $C_2SH$  are not formed (62).

Changes in the  $C_3S$  paste microstructure occurring in the presence of admixtures containing Ca are well documented but their relevance to strength development is still largely unknown. Young and co-workers (5,63) studied the effect of various anions containing  $Ca^{++}$  as the common cation. The anions included perchlorate, thiocyanate, propionate, maleate and chloride. There was a change in the C-S-H morphology from an acicular to a lacey and honeycomb structure in the presence of some admixtures. Other changes such as the number of CH crystals per square millimetre, their relative sizes and crystal axis ratios, also occurred (Table 4.III) (63). The relevance of these changes to strength development is not completely clear and the results suggest that capillary porosity is the dominant factor controlling the tensile strength. The importance of the role of anions in modifying the morphology of  $\beta C_2S$  pastes has also been examined using sodium salts of fluoride, bicarbonate, chloride and orthophosphate (8).

Berger and McGregor (64) have made an extensive study of the microstructure of  $C_3S$  paste, with particular reference to the CH component. The pastes that

$C_3S+0\% CaCl_2$      $C_3S+1\% CaCl_2$      $C_3S+4\% CaCl_2$

resulted by using 62 admixtures could be divided into four groups, based on the c/a axis ratios. The morphology was found to be dependent more on the type of anion than on the type of cation. There is need to investigate how these differences influence the engineering properties. It has often been reported that in  $\text{C}_3\text{S}$  pastes containing various admixtures, the hexagonal phase typical of CH may or may not be present. According to Bendor and Perez (61), in pastes containing  $\text{CdI}_2$  the hexagonal CH phase formed, whereas it was absent in the presence of  $\text{CaCl}_2$  and  $\text{CrCl}_3$ . The mechanism responsible for these differences is not clear. In some instances the CH crystals may be obscured by the C-S-H gel.

#### 4.4.2 Cement Pastes

Addition of  $\text{CaCl}_2$  to the hydrating cement affects the microstructural features of the paste. Without the admixture, the paste may consist of clusters of sheets mixed with fibres, the fibres being much more abundant than in  $\text{C}_3\text{S}$  pastes. With the addition of 2%  $\text{CaCl}_2$  the fibrous particles may be completely absent (23).

Ramachandran and Feldman (12) compared the microstructural features of cements containing 0, 1, 2, and 3½%  $\text{CaCl}_2$ , all hydrated to the same degree. At lower degrees of hydration (corresponding to a constant non-evaporable water content of 8.2%) pastes

containing 0%  $\text{CaCl}_2$  showed well-defined needles representing C-S-H and ettringite formation. Columnar particles of CH, identified by energy-dispersive X-ray analysis, were also present. At 1%  $\text{CaCl}_2$  addition, however, thin plates of C-S-H appeared. At 2%  $\text{CaCl}_2$  the structure became more consolidated and contained plates and small particles. A sponge-like mass was evident at 3½%  $\text{CaCl}_2$  addition. Specific area, density, porosity and strength differences existing between samples could not be explained on the basis of microstructure. Some of these may depend on microstructural features that are not easily resolved by the SEM. Also some of the features may be obscured by the deposition of a gel-like hydration product. Micrographs, however, showed that there were some morphological differences, especially at lower degrees of hydration. In hot pressed cements containing admixtures such as  $\text{CaCl}_2$ , triethanolamine and citric acid, Sarkar and Roy (34) found differences in strength development but the microstructural investigation yielded no useful information to explain the strength variations.

Cement pastes containing a normal water-reducing agent, as well as a superplasticizer, and formed at w/c ratios in the range 0.30 to 0.50 may not show any morphological changes with reference to the cement paste containing no admixture (23,65,66). This would imply that the differences observed in creep and shrinkage with calcium lignosulfonate cannot be explained by the microstructural examination using the SEM technique (66).

A study of the low porosity portland cement paste (containing no gypsum) prepared at w/c ratios of 0.22 to 0.24 with Na-lignosulfonate and Na-bicarbonate admixture has shown that the admixtures modify the microstructure (67). In place of fibrous and reticular network-type structure, normally found in a cement paste, the admixture-treated paste appeared as thin sheets in the first few hours and than as small equant grains. The presence of the admixtures promoted a more massive type of structure, implying improvement in mechanical properties. Odler et al (68) used a mixture of lignosulfonate and carbonate with clinker and portland cement and found no distinct differences in morphological characteristics of pastes (with or without admixtures) though there were differences in the composition of the hydrated products.

It is generally difficult to study the microstructure of pastes formed at very low w/s ratios. Further difficulty is experienced when the pastes are formed using the hot-pressing technique. Because of high pressure, high temperature and low amounts of water, the structure becomes dense and nearly 70% of portland cement remains unhydrated. Using the hot-pressing technique, Oyefesboi and Roy (33) made compacts of cement in the presence of various admixtures. Although substantial differences in strengths were observed, SEM showed no obvious differences.

## **SUB-THEME VI-2**

### **Properties of hardened cement paste**

**F.H. WITTMAN  
Delft University  
NETHERLAND**

## 1. INTRODUCTION

The state of the art of knowledge on structure and properties of hardened cement paste has been compiled by Copeland /1/, Kondo /2/ and Taylor /3/ for the 6th International Congress on the Chemistry of Cement held in Moscow in 1974. In this contribution it will be tried to point out some new developments and major achievements of the last six years.

It is not the aim of this report to provide a comprehensive literature survey of all papers published on properties of hardened cement paste. This task is being done by the contributors to the annual "Cements Research Progress" which is published by the Cements Division of the American Ceramic Society and therefore this literature is easily accessible to everybody.

Instead of summing up all contributions on different properties it is tried to concentrate on the work done on the characteristic behaviour which is directly related to engineering applications. Special emphasis is placed on the interaction of hardened cement paste with water, because all properties are influenced by a change of water content.

The real structure of hydration products forming the xerogel of hardened cement paste is still not yet understood well enough. Therefore all relations between macroscopically observed behaviour and processes in the microstructure remain tentative and should not be overestimated.

Until now most contributions have concentrated on physical and chemical properties of C-S-H gel. It will be shown that mechanics of solids has to be taken into consideration to avoid erroneous conclusions derived from simple test data. The writer feels that this is one of the most important new aspects of materials science of hardened cement paste.

Another comparatively young branch concentrates on probabilistic aspects. This may mean the formulation of a statistically representative characterisation of the complex microstructure but it may also mean a probabilistic description of materials properties. In this context computer simulation methods will play an important role.

Further development in this field will largely depend on a closer contact and a better mutual exchange of ideas between the different disciplines involved.

## 2. STRUCTURE OF HARDENED CEMENT PASTE

### 2.1. General Remarks

One of the general aims of materials science is to relate relevant properties with the corresponding materials structure. In this way much success has been achieved in metallurgy. Experimentally observed behaviour could not only be explained satisfactorily by means of elementary processes but some properties could be ameliorated in a systematic way. In concrete technology comparatively little improvement has been reached by fundamental approach.

This fact may partly be attributed to lack of knowledge on the structure of hardened cement paste. Although more than 30 years ago Powers and his co-workers started with serious investigations into the microstructure of hardened cement paste /4/, we are

still far from fully understanding the system which is built up when cement is being mixed with water. Some recent trends of research on the microstructure will be briefly summarized in this section. It may be hoped that compilation of all results eventually may provide a solid basis for a materials science approach to study the most widely spread building material, concrete.

The structure of hardened cement paste can be subdivided into three major components: solid phase, pores and water.

The solid phase essentially consists of hydration products and remaining unhydrated clinker particles. A considerable amount of a given volume is occupied by pores with varying pore size distribution. Under normal conditions the pores are partly filled with water. The interaction of the solid phase with the surrounding adsorbed or capillary condensed water has a significant influence on all properties of hardened cement paste. Therefore water is considered to be a separate component. In contrast air and water vapour within the pore system are being neglected. The three essential components just mentioned will be treated consecutively.

### 2.2. The Solid Skeleton : xerogel

The solid phase of hardened cement paste consists of crystalline and smaller amorphous particles, with respect to X-ray spectrometry. The structure and composition of hydration products will be dealt with elsewhere in this volume /5/. In this context we shall concentrate on the solid skeleton which is built up by hydration products thus forming a xerogel.

Sorption measurements once meant a real break through /4/. The importance of the information which has been gathered by means of sorption techniques can hardly be overestimated. Yet there remain serious limitations. It was early recognized that the hydration products are not stable with respect to drying and subsequent rewetting /6/. That means, the system which is being studied changes during the measurements. The high internal surface is reduced as the adsorbed water films are removed. In this way the total energy of the system is lowered. In addition to this effect some hydrate compounds loose some of their hydrate or interlayer water as the vapour pressure is reduced. Only after several drying-wetting cycles the system stabilizes /7/. This hygral instability of hydration products is one of the reasons that sorption measurements have often been disputed and interpreted in different diverging ways.

By introducing simplifying assumptions a model for the structure of hardened cement paste has been developed 8, 9/. This model (Munich Model) is essentially based on sorption measurements but additional information has been drawn a series of different approaches such as direct measurements of van der Waals forces at low distances, thermodynamic calculations and experiments to determine creep, shrinkage and strength as function of relative humidity.

With the help of this model the behaviour of hardened cement paste under different hydal conditions can be predicted quantitatively. In fact based on this model the time dependent deformation of concrete has been calculated and this method is now being applied to the design of real structures /10/.

The Munich Model suggests that the influence of water content on the properties of hardened cement paste can be explained by means of two different phenomena, the surface energy of the colloidal particles and the disjoining pressure. In the region below 50 % relative humidity all properties are predominantly influenced by the surface energy of the gel particles. The surface energy changes due to sorption as the hygral equilibrium is changed. At higher relative humidities gel particles are separated by thin water films due to the action of spreading pressure of water. In the high humidity region therefore the xerogel, that means the structure of the solid phases, is mechanically less stable than in the dry state.

This model describing the interaction of the xerogel of hardened cement paste with water and the consequences for the mechanical behaviour has proved to be successful in predicting quantitatively properties of concrete. The heterogeneity of elements within the actual xerogel is replaced by a statistical average. The model does not take into consideration properties such as morphology of individual gel particles. By means of Scanning Electron Microscopes some information on this aspect can be gained. A huge number of papers describe observations with this technique. The benefit to further development of our knowledge, however, may sometimes be questioned. It must also be kept in mind that usual preparation techniques may alter the microstructure.

Diamond classifies four morphological distinct varieties of C-S-H gel /11/. At the early ages fibrous particles are observed. Following a suggestion of Berger et al. /12/ Diamond calls these acicular particles Type I = fibrous particles. A second type of morphology is characterized by Type II = reticular network. Rather common in hardened cement paste are irregularly equant or flattened particles. C-S-H particles of this form are designated by Diamond as Type III = equant grain. Finally there exists a phase which is normally maintained to an outer shell of other hydration products. This type is possibly filling the space which was originally occupied by C<sub>3</sub>S. This type of morphology therefore is called Type IV = inner product.

The huge variety of different morphological details all present in hardened cement paste is not completely covered of course by these four types. There are many more details to be observed which may or may not be important for the properties of the system. Furthermore one has to realize that a fractured surface does not necessarily represent a three-dimensional microstructure.

As scanning electron microscopes are further developed more information may be expected. Puchner has shown that visual inspection can be inaccurate and rather misleading /13/. He used conventional scanning electron microscopy in combination with scanning transmission electron microscopy.

Just one additional peculiarity of the solid skeleton shall be mentioned here. It is well-known that most particles within the xerogel are not well defined chemical or mineralogical compounds. The calcium/silica ratio for example may vary and many impurities have been detected /14/. As a result the actual composition varies locally and intergrowth takes place. In some cases the growth of fibrous particles (type I) is oriented in a fairly regular way by intermeshing

platelike material. In fig. 1 an example of this type of structure is shown /15/.

Considering the huge morphological variety in hardened cement paste it seems impossible to relate mechanical or non-mechanical properties directly with these structural details. It will probably turn out that the only way to approach this problem is to find appropriate statistical average representations. Computerized image analysing techniques may provide valuable information for a quantitative characterization of different microstructures.

As mentioned above X-ray spectroscopy gives only little information on the structure of elements in the xerogel of hardened cement paste. Based on earlier work by Lentz /16/ Tamas et al. /17/ used trimethylsilylation to determine the degree of polymerization of Si in hydration products.

This method proved to be most successful and is now being applied by several groups of researchers. In a comparatively short time basically new information on the structure of C-S-H has been compiled /18 - 22/. Now it seems that the structure of hydration products markedly differs from quasi-crystalline calcium silicate hydrates such as tobermorite or jennite as has been earlier believed. There is no reason to believe that there is a layered structure.

It is not yet quite clear what the presence of dimer, linear or cyclic trimer, tetramer, and pentamer really implies for the properties of the xerogel. In any way the fruitless discussion on postulated structural details used in simplifying models will come to an end. The quantitative determination of polymerization by means of trimethyl silylation provides a rational basis for a better understanding of gel properties. At this moment it cannot be differentiated whether polymerization exists within a gel unit or also across boundaries.

The mechanical properties depend on both the strength of the gel particles and their mutual coupling. Possibly further polymerization studies may lead to a better understanding of the link between structure and mechanical properties.

Since 1974 another method has been applied to study colloidal properties of the xerogel in hardened cement paste and that is Mößbauer spectroscopy. Usually the stiffness of a lattice immediately surrounding a Mößbauer isotope is determined by recoilfree resonance. It can be shown that in colloidal substances the recoilfree resonance is also influenced by the mutual coupling of gel particles /23 - 26/.

If the Mößbauer spectrum is measured as function of temperature the coupling force can be determined. It is of special interest to study the influence of porosity and adsorbed water layers on the mutual coupling within a xerogel. So far no other method can provide similar data.

Übelhack /24/ has clearly pointed out that the porosity dependence of the elastic modulus of hardened cement paste is essentially caused by the interaction between colloidal particles. This result has to be taken into consideration if one tries to explain Young's modulus of xerogels as function of porosity and of structures having different gel particles.

Fig. 1 : Micrograph taken with a Jeol ISM 35 with a magnification of 20.000x. The hardened cement paste was prepared using blast furnace slag cement. The orienting effect results in fairly regular fabric. (taken from Réf. /15/).

In concentrated suspensions the resonance lines of the MöBbauer spectrum are broadened by Brownian motion of the colloidal particles. As the Brownian motion of the gel particles gets obstructed the resonance lines become narrower. This effect was used to study the mobility of hydration products in water /27/. It was found that mechanical agitation destroys the gel structure in the suspension. After a few days, however, the metastable structure is rebuilt. This can be attributed to be ordering effect of thin water layers between the colloidal particles.

It is obvious that by means of MöBbauer spectroscopy the compiling of particles in a xerogel as well as in a suspension can be determined. If one combines this new and non-destructive method with polymerisation studies it might be possible to develop a conclusive description of the structure of hardened cement paste. Furthermore it might be advisable to incorporate more of those techniques common in classical studies of colloids (see for example /28/) into the investigations on C-S-H.

### 2.3. Pore System

In the previous section it was tried to point out some recent developments of investigations into the solid skeleton of the porous material. In some respect a complementary branch of research is porology. The aim of porology is to characterize a porous system by indications such as total porosity, pore size distribution, and pore geometry. Related values are hydraulic radius and internal surface.

There is not one universal method to study porous systems but different techniques are being used in different ranges of pore size. Until an average pore radius of 20 nm sorption methods are widely used. As the hydration products are not stable with respect to drastic changes of vapour pressure results of water sorption

measurements necessarily involve some uncertainty. But this is true for all other techniques. Pore size distributions calculated from water sorption measurements possibly do not differ far from reality and can be interpreted for instance in terms of degree of hydration /29/. Winslow and Diamond /30, 31/, however, found values for the internal surface by small angle X-ray scattering far in excess of those determined by water sorption. At this moment the meaning of this discrepancy is not clear.

Pores with a diameter between 10 nm and 10  $\mu$ m can be observed by mercury intrusion techniques. Here again an inherent inaccuracy must be mentioned. The method assumes cylindrical pores with a constant taper. It is obvious that this condition is never fulfilled. As a consequence a characteristic pore size distribution is measured instead of the real one. The results can, however, be used for comparison of similar systems and to study different influences on the pore system. Kayyali et al. /32/ as well as Rostasy et al. /33, 34/ have used mercury intrusion method to determine the influence of temperature on the porous structure. Beaudoin has compared results of mercury intrusion method with those of helium pycnometry /35/. He also discusses his findings critically.

Even larger pores can be observed with optical methods. Computerized image analyzing techniques have become popular /36/. Artificial sphere-shaped pores caused by air entraining agents can be detected in this way. The preparation technique, however, remains difficult.

As most mechanical properties such as strength and Young's modulus are directly related to the pore system of a material several attempts have been made to investigate the pore structure of modified cement pastes. The influence of superplasticizers on the structure has been studied by Wittmann /29/. Diamond

and Gome-Toledo studied the microstructure of low porosity Portland cement paste /37/. Using a somewhat more finely ground clinker instead of gypsum, lignosulfonate and alkali-carbonate or bicarbonate is added to regulate setting behaviour. They found that the microstructure of low porosity cement paste is quite different from what is known about ordinary cement pastes. Mikhail et al. studied the influence of fibre reinforcement on the microstructure /38/. The total porosity and the specific surface area have been determined and discussed in comparison with mechanical properties.

#### 2.4. Water in Hardened Cement Paste

All properties of concrete are severely influenced by the interaction of the porous hardened cement paste with water. The interaction of gel particles with adsorbed water molecules, however, is not yet satisfactorily understood even in much simpler systems. Therefore there still exist widely differing views on this subject.

By means of luminescence experiments it has been shown recently that the first adsorbed layers interact energetically with the surface of the xerogel. Monolayers also interact with clinker but no hydration does take place and the sorption process is reversible /39/. Only at much higher vapour pressures irreversible interactions can be observed.

A comprehensive report on the interaction of water with concrete has been published by Setzer /40/. He concentrates especially on thermodynamic aspects and develops a modified method to calculate pore size distribution from sorption measurements. Furthermore Setzer discusses mechanical properties of hardened cement paste on the basis of the Munich Model /8, 9/ as function of water content.

Lahajnar et al. /41/ have applied pulse NMR techniques for the study of water in hydrating cement. Their results clearly show that there are several modifications of differently bound water which essentially verifies earlier measurements /42/. The problem with NMR techniques, however, remains the comparatively poor resolution. In general these findings can be used in combination with other methods of investigation.

Winslow /43/ tried to apply the photoacoustic effect to study properties of water in hardened cement paste. With this method the thermal expansion of a thin gas layer surrounding a specimen is measured. This small pressure pulse is caused by a chopped incident light beam. From the presented results one can conclude that the photoacoustic effect is linearly increased as the water content decreases until D-drying state is reached. Further removal of water (heating) leads again to a linear increase of photoacoustic effect but with a higher slope. At this moment it is not yet quite clear what actually affects the photoacoustic signal. Probably it is mainly the absorption coefficient of the drying material. Anyhow the observed behaviour can at least qualitatively be explained on this basis and especially the further increase of the signal as hydration products are thermally decomposed is then a consequence of the changed optical properties /7, 44/.

With the major aim to study frost action and ice formation in hardened cement paste several authors determined phase transitions of water held in the pore system /45 - 48/. A typical example of measurements of the transition temperatures is shown in Fig. 2. Stockhausen et al. /48/ summarized these findings and they concluded that four different modifications of adsorbed and capillary condensed water can be distinguished.

Fig. 2 : Results of DTA. Hardened cement paste equilibrated with different relative humidities have been tested. (Taken from Réf. /48/).

In capillaries with a radius bigger than 100 nm normal bulk water is observed. These big pores are only filled if the sample is in direct contact with water.

Water condensated in capillaries with a radius bigger than 10 nm has a reduced chemical potential because of the interaction with the solid surfaces. As a consequence the freezing point of this second modification is shifted towards lower temperatures. This type of water is taken up by capillary condensation at high vapour pressures :  $90\% \leq RH \leq 100\%$ .

In still smaller capillaries the condensated water is structured. The corresponding capillary radius may range between 3 and 10 nm. These pores are filled by condensation between 60 % and 90 % RH. The third modification undergoes a phase transition at a temperature around  $-43^\circ\text{C}$ .

Finally there is a fourth modification and that is water adsorbed in layers not thicker than 2,5 monolayers. This type of water does not freeze until a temperature of at least  $-160^\circ\text{C}$ . The adsorbed films are firmly held on the surface but water molecules are very mobile within the layer. Therefore sometimes this fourth modification is called a two-dimensional van der Waals gas /9/. The comparatively high mobility along the surface has also been found by Vignes-Adler /49/.

This subdivision of adsorbed and capillary condensated water in hardened cement paste into four categories is based on experiments at temperatures below  $0^\circ\text{C}$ . It seems reasonable to assume that these conclusions hold true also at room temperatures.

### 3. MECHANICAL PROPERTIES

#### 3.1. General Remarks

The study of details of the microstructure of hardened cement paste is fascinating. Advanced modern measuring techniques can be and are applied. Next to the methods mentioned above results of techniques such as Raman spectroscopy /50/, ESCA /51/ and high resolution electron microscopy /52/ are described in the literature. The aim of all these studies, however, is to provide gradually a solid basis for a better understanding of properties of concrete. By means of computerized structural design complicated load histories and multi-axial states of stress can be taken into consideration in a realistic way. But the advantage of these methods can only be fully utilized if the corresponding materials data are available. In this respect fundamental research on concrete properties has recently gained a great deal of importance.

We have just pointed out that the structure of hardened cement paste is a complicated colloidal system and that many details are still not really understood. The chemical and mineralogical complexity of the xerogel in hardened cement paste necessarily leads to a certain smearing effect. The discovery of a close relation between structural details and macroscopic properties is thereby hampered. This may be one of the reasons that some authors prepare pastes with pure cement clinker compounds. Strength development and drying shrinkage have been measured by Lawrence et al. /53/ and by Mehta et al. /54/ using tricalcium and  $\beta$ -dicalcium silicate pastes. Young and Tong /55/ investigated the microstructure and strength development of  $\beta$ -dicalcium silicate pastes with

and without admixtures.

Certainly pure clinker pastes are generally easier to be described quantitatively but it may be questioned whether all results are characteristic for the material in which we are actually interested.

#### 3.2. Load Induced Deformation

First of all we will deal with deformation of hardened cement paste under sealed conditions. If it were possible to model the complex structure of hardened cement paste realistically, by means of an enormous computer study the stress distribution within the solid skeleton could be evaluated. On principle the total, that means the instantaneous and the time dependent deformation, could then be calculated. Considering the actual microstructure it becomes quite clear that there is no hope that this aim will ever be achieved. This one may choose between a phenomenological and a statistical approach.

Several authors tried to relate what they call measured Young's modulus with properties of the microstructure. In the dry state hardened cement paste approximately reacts like a linear elastic material. But even then bending tests of small samples will lead to erroneous results because of crack formation in the surface zone. At higher relative humidities hardened cement paste reacts like a linear visco-elastic material with relaxation times in the order of magnitude of seconds. Therefore a quasi-static measurement cannot provide all the necessary information to characterize the material. This has been clearly pointed out by Sellevold /56/. Instead of simple Young's modulus the complex form, that is storage and loss modulus, have to be used to describe materials behaviour. The internal friction which is given by the loss modulus is most probably caused by water redistribution within the solid skeleton.

In Fig. 3 the deformation modulus as measured at samples with a water/cement ratio of 0,4 is plotted

Fig. 3 : Influence of water content of hardened cement paste in equilibrium with different relative humidities on Young's modulus. Results of two test series are being shown. (Taken from Ref. /9/).

as function of relative humidity /8/. Dashed lines indicate the expected behaviour if only adsorbed water would interact with the xerogel. This behaviour is predicted by the Munich Model /8, 9/. The observed increase at higher relative humidities is caused by the above mentioned transition within the microstructure. The existence of internal friction and relaxation times in the order of magnitude of a test duration is an excellent example to point out how careful one has to be if one tries to correlate results of simple mechanical tests with microprocesses or properties of microstructure.

In many materials creep mechanism can be described in a statistical way by means of rate theory. This approach has been applied to hardened cement paste by several authors. Klug and Wittmann determined the activation energy and the activation volume of creep of hardened cement paste /57/.

The activation energy of the creep process has been experimentally determined by Straub /58/. He found a value of 4,45 kcal/Mol in the temperature range of -70°C to +20°C. Furthermore the activation volume has been evaluated from measurements of creep strain under compressive and tensile stress /59/. The activation volume depends on water/cement ratio and on age of loading. As can be anticipated the activation volume decreases as the microstructure becomes denser.

With the help of rate theory creep of hardened cement paste under sealed condition can be described satisfactorily. The influence of water content on creep in equilibrium can also be taken into consideration. Under practical conditions, however, creep is most often accompanied by drying shrinkage. This case will be dealt with in the following section.

### 3.3. Drying Shrinkage and Creep

As matured hardened cement paste is dried a volume change called drying shrinkage is observed. Here we shall not discuss chemical shrinkage or capillary shrinkage of fresh concrete /60, 61/.

Many authors have tried to correlate the macroscopically observed shrinkage with structural processes in the hydration products (see for example /62/). These attempts necessarily involve a great deal of ambiguity because as has been discussed above the structure itself is not well enough understood.

Young et al. /63/ came to the conclusion that shrinkage is caused by two different mechanisms and these are capillary drying and gel drying. Their subdivision is based on the measured length change plotted as function of weight loss. There is, however, no data point which would clearly indicate two regions of different mechanisms. But more important, the curve of length change as function of weight loss does not represent equilibrium points. The inner core of a sample may still be saturated while the outer shell is already dried to equilibrium with the ambient water vapour pressure. The moisture gradient is essentially dependent on the diffusion coefficient and on geometry. That means the total deformation measured cannot be linked directly to the shrinkage mechanisms involved. The only materials property which can well be related with properties and processes of the microstructure is unrestrained shrinkage. This value has to be determined by extrapolation of measured data to zero thickness. Probably the extensive studies by Young et al. /63/ on the micro-

structure using among other methods mercury intrusion porosimetry, nitrogen adsorption, and determination of polysilicate content may be reinterpreted taking real shrinkage data as a basis for discussion.

By evaluating equilibrium shrinkage strain values at different relative humidities Wittmann /8, 9/ suggested on the basis of the Munich Model that hygral length change at low vapour pressure ( $RH < 50\%$ ) is caused by a change of surface energy of the xerogel. At higher water content ( $RH > 50\%$ ) the surface energy is not influenced drastically by drying or rewetting. It is assumed that in this region spreading pressure of water between gel particles causes additional length change. At very high humidities near saturation the action of capillary action can be observed.

It is well known that the xerogel of hardened cement paste is thermodynamically instable. The high potential energy which is stored in the large surface area tends to reach a minimum. Thus most changes around the xerogel will lead to a coarsening of the microstructure. Drying and change of temperature are two possibilities to influence the metastable state of the xerogel.

There is a long lasting discussion in the literature whether or not mechanical loading has a similar influence. Several authors suggested triggering processes caused by an external stress. Recently Gamble and Illston /64/ raised this argument again. Parrott /65, 66/ explained his experimental findings by introducing transient thermal creep. He found some analogy between polysilicate formation and transient thermal creep as defined by Illston and Sanders /67/. By means of an extensive experimental investigation Mindess et al. /68 - 71/ observed changes in the microstructures of pure calcium silicate pastes as function of drying and loading. They subdivide the structure of calcium silicate paste into four groups. According to this classification the "C-S-H component" consists of C-S-H particles and the micropores ( $d < 2,6$  nm), the "Pore Component" includes all mesopores and macropores ( $d > 2,6$  nm). Besides of these two components they have characterized "Calcium Hydroxide" and "Unhydrated Silicate Residue" as two crystalline components. They conclude that irreversible strains are caused by changes in the "Pore Component" and the "C-S-H Component". Under load microshearing between C-S-H particles is believed to occur.

In this study /68 - 71/ very valuable data on the influence of drying and loading on the microstructure have been gathered. If, however, all the data available are condensed in a simple model, questionable assumptions on the microstructure have to be made. The actual meaning of all the data on changes in microstructure will probably only become clear when more quantitative details on the xerogel are at our disposal.

So far we have neglected one aspect which cannot be separated from considerations on shrinkage and that is crack formation. It is well-known that tensile strength of hardened cement paste is comparatively low. Stresses caused by the contraction of the drying outer shell rapidly overcome tensile strength. As mentioned above shrinkage strain of a tested specimen is not directly caused by shrinkage mechanisms but by the stress distribution which is given by the moisture gradient.

It can be shown that the stress distribution and as a consequence the measured shrinkage strain are severely influenced by crack formation. By means of a computer study shrinkage strain has been calculated /10, 72/. The approach is also mentioned in /73/. In Fig. 4 the obtained shrinkage strain, taking crack formation into consideration, is plotted by a solid line. Dashed lines represent calculated shrinkage strain as an external load of 2 and 10 N/mm<sup>2</sup> is applied respectively.

Fig. 4 : Calculated shrinkage strain as function of time. A solid line indicates the behaviour of an unloaded specimen. If crack formation is prevented by an external load of 2 and 10 N/mm<sup>2</sup> respectively dashed lines are obtained. (Taken from Ref. /10/).

An external load of 10 N/mm<sup>2</sup> prevents crack formation in the outer shell of a specimen. As can be seen from Fig. 4 the shrinkage strain under load at a certain duration of drying (50 days) is nearly doubled. The time when the external load has a maximum influence is dependent on geometry and on water permeability. It should be mentioned that creep deformation is not taken into consideration in Fig. 4. The only reason why shrinkage is increased if measured under load is thus the prevention of microcracking.

At this moment it cannot be decided whether this purely mechanical effect accounts for all the transient drying creep. In any case the deformation which might be caused by triggered processes within the microstructure is much less than usually assumed and possibly it is zero.

### 3.4. Crack Formation and Failure

Strength of concrete is undoubtedly related to crack formation and failure of hardened cement paste. Therefore a huge number of papers on this subject has been published and the already existing number increases with a considerable rate. Excluding purely phenomenological papers, the main attempts can be differentiated into four methodological different approaches. These are (1) microstructural investigations, (2) application of stochastic theories, (3) mathematical crack theory, and (4) application of fracture mechanics. Of course there are studies which incorporate more than

one of the above mentioned concepts. Grudemo /74 - 76/ studied the microstructure of Portland cement paste and pastes prepared with pure compounds by means of several classical methods of investigation such as mercury intrusion porosimetry and sorption weight change. He related his findings to results of tensile, compression and circular plate loading tests. In supplementary test series microhardness of hydrating samples has been measured. Grudemo pays special attention to statistical aspects of microstructures and he applies Weibull's distribution function. Summarizing his results Grudemo /76/ sketches possible crack path elements through the microstructure.

Higgins and Bailey /77, 78/ used a special optical microscopy technique taking advantage of diffuse illumination. By means of this method it is possible to detect stable crack growth in stressed samples of hardened cement paste. Higgins and Bailey did not find a zone microcracks in front of a crack tip as they expected. According to their observation the crack follows smaller microcracks in a line ahead of it.

In a homogenous material under tensile stress a crack propagates catastrophically once the stress has reached a critical value. In a composite material cracks may be arrested and thus failure take place in a less brittle way. It has been mentioned above that the complex structure of hardened cement paste can never be described analytically in a realistic way. Therefore a statistical representation seems to be a reasonable approximating approach. Several authors tried to describe failure of cement bonded materials as a statistical series of independent steps /79 - 82/.

Mihashi et al. /80, 81/ developed a stochastic theory for fracture of hardened cement paste and concrete. A specimen is subdivided into  $n$  units and each unit contains one crack. The orientation and the crack length may be distributed at random. The external stress field is markedly disturbed by the structural defects. As a consequence really acting stresses in a given unit are also randomly distributed within the solid skeleton. On these two basic assumptions a stochastic theory is developed.

The formulae obtained by Mihashi et al. /80, 81/ describe failure of hardened cement paste as function of various loading histories such as sustained load, high rate of loading, and cyclic loading. The variance of strength of porous materials is also taken into consideration. Experimental investigations essentially verify this extremely interesting approach /81, 82/.

In Fig. 5 results from experiments to study the lifetime of hardened cement paste under high sustained load are shown. The age at loading of the specimens varies between 1 day and 90 days. With a solid line the theoretical prediction of Mihashi's approach is shown. It seems that with this concept the influence of porosity and pore size distribution on strength and variability of hardened cement paste can be formulated quantitatively for the first time.

Wittmann and Zaitsev /83, 84/ have applied crack theory to describe the behaviour of hardened cement paste under load. Crack length in a porous matrix is studied as function of load. It is assumed that failure can be related to a critical total crack length. That means that the structure desintegrates under compressive load if the sum of all microcracks reaches a critical value. Under high sustained load

cracks propagate and the lifetime of a given sample is dependent on the time necessary to reach critical crack length in the microstructure by stable crack growth. For reasons of comparison in Fig. 5 the lifetime of hardened cement paste calculated on this basis is shown by dashed lines.

mined  $K_{IC}$  of hardened cement pastes, aggregates and the interface.

$J_{IC}$  and  $K_{IC}$  are measured by Mindess et al. /90/ at cement pastes, plain concrete and eight different steel and glass fibre reinforced concretes. They

**Fig. 5 :** Lifetime of hardened cement paste under high sustained load. The solid line is calculated by means of the stochastic approach of Mihashi et al. /80, 90/. Dashed lines are obtained by formulae given by Zaitsev et al. /83/.

Failure of hardened cement paste is comparatively brittle. Therefore the application of fracture mechanics seems to be justified. Fracture mechanics parameters have been determined by various authors /85 - 87/. Hillemeier /88, 89/ concentrated his investigations on the interface between cement paste and aggregate. Using a wedge loaded CT-specimen he deter-

conclude that the values of  $K_{IC}$  for concrete is not meaningful whereas  $J_{IC}$  can be used to characterize failure process of all cement bonded materials. Solz and Baron /91/ stated at the end of a thorough literature study that  $K_{IC}$  has to be measured at large concrete specimens. As a consequence they started experiments with specimens having a height of two meters.

They suggest that  $K_{IC}$  should not be considered to be a fixed value but rather a function of crack length.

Finally another approach to describe failure of concrete should be mentioned and that is endochronic theory. Bazant et al. /92/ have applied this very elegant method probably for the first time in this field.

#### 4. OTHER PROPERTIES

The term "other properties" is very wide and therefore a selection has to be made. Again major trends shall be outlined.

Schulte et al. /93/ investigated the electrical conductance of hardened cement paste as function of moisture content. Dry cement paste is a typical semiconductor. The change of electrical conductance by adsorbed and capillary condensed water can be explained in terms of the interaction of water with a xerogel.

In colloidal suspensions usually a Zeta-potential can be observed. Wittmann et al. /94/ have shown that movement of the diffuse double layer in the xerogel can be achieved by mechanical deformation. In fact on opposite sides of a bended bar a mechanically induced streaming potential can be measured.

Puchner et al. /95, 96/ measured luminescence at clinker components as well as at hydrated pastes. It can be concluded that surface luminescence is observed. Therefore the measured intensity is dependent on the amount of adsorbed molecules.

Due to aggressive industrial atmosphere and the increased use of concrete under severe climatic conditions such as in marine technology the durability of hardened cement paste gains importance rapidly. Marchese /97/ has studied chemical resistance of different hardened pastes. Durability of hardened cement paste as well as of reinforced concrete depends essentially on the permeability of the pore structure. Some preliminary results of a comprehensive study are to be found in /98/. Chen et al. /99/ have measured the diffusion of methane through concrete.

Measurements of the complex permittivity of hydraulic cement pastes can be performed with two different aims. First of all the dielectric behaviour of hardened cement paste and concrete has to be known for special applications. Besides the determination of materials properties dielectric measurements can also be evaluated analytically. The interaction of adsorbed molecules with the surface of the xerogel can be studied /100 - 102/. The range of frequencies used has been extended in the meantime until the microwave region /103/. This method can also be used as a fast and nondestructive way to determine the degree of hydration of hydraulic binders.

Internal friction of hardened cement past is dependent on moisture content. In /56/ low frequency internal friction has been related to short-time creep of hardened cement paste. There are reasons to suggest that low frequency internal friction is caused by water movement and that the mechano-electrical effect described in /94/ as well as the above mentioned increase of Young's modulus at high relative humidities can be attributed to the same physical phenomenon. The effect of drying and resaturation on internal

friction has been investigated by Sellevold and Rødjy /104/.

Microhardness of hydrating pastes with or without additions can be used to characterize the gradual development of mechanical properties. In /105/ Traetteberg et al. tried to relate microhardness with special features of the microstructure.

Finally the position anihilation as measured in hardened cement paste shall be mentioned /106, 107/. At a first glance this method seems to be rather exotic. There is, however, a possibility that by means of this approach new and valuable information on the microstructure can be provided.

Institute of Civil Engineering  
Kharkov, U.S.S.R.**

Modern methods of applied mathematics in combination with computer techniques open up possibilities for elucidating the general regularities of strength synthesis in cements with various physico-chemical characteristics. Solution of such problems will make it possible to forecast the physico-chemical properties of cement by calculation, to estimate the efficiency of the existing methods of production, to indicate the paths for further improvement of manufacturing processes and, in the final run, to establish more precisely the nature of manifestation of the binding properties of mineral materials.

At present, however, it is difficult to forecast the effect of the application of mathematical methods to cement manufacture. It is therefore natural that the problems of mathematical models of variation of cement paste properties in time are discussed for the first time as a separate topic at the 7th International Congress on the Chemistry of Cement.

The discrepancy between the possibilities of mathematical methods and practical results is due to the lack of rigorous systematization of the determining characteristics of the composition and structure of initial binders and hydration products, to the absence of definitions and methods of calculation of the kinetic characteristics of strength development in time with account taken of the hardening conditions, and also to the relative nature of estimation of parameters of the disperse structure of the cement paste and mortar. The application of mathematical methods in such circumstances is often reduced to description of the results within the framework of investigations carried out, supporting, as a rule, those scientific conceptions which were used to plan the given experiment. The number of factors that are taken into account in such experiments is limited, and the generalization of the results is qualitative; that is why there is the same gap between the science and practice of cement manufacture and application.

In this connection, in studying the variation of cement paste properties using mathematical methods, we shall consider successively the strength characteristics of clinker and clinker-based cement on the basis of plant data for a 11-year period, with emphasis on the features which are of methodological nature and allow one to treat unambiguously the results of investigations of the increase of strength of clinker and cement.

The duration of the time series of clinker strength is determined by the constancy of standard methods of determination of its physico-mechanical characteristics and chemical composition. Daily sampling was carried from the hot end of the furnace and was followed by averaging and testing. For monthly samplings, using the methods of mathematical statistics with a reliability level of  $P = 0.95$  with a two-sided restric-

tion, the upper and lower confidence limits were set up and the average monthly values ( $X_1$ ) and empirical dispersions calculated. The correspondence of the average monthly characteristics of clinker to the total set for the 11-year period was estimated by the Student criterion, and the homogeneity of empirical dispersions (spreads) was evaluated by the Bartlett criterion. The thus obtained characteristics of the strength of clinker are treated as individual values of the dynamic time series for the time period concerned. Analogous determinations of the successive values of the dynamic series have been carried out for the 3-day strength and mineral composition of clinker.

Graphs of the time series of compressive strength at an age of 28 days the activity of clinker ( $R_{28}$ , in MPa) and 3 days ( $R_3$ , MPa) and also of the content of  $C_3S$ ,  $C_2S$ ,  $C_3A$ , and  $C_4AF$ , are given in Fig. 1.

The solid lines represent the initial values, and the dashed lines, the trend and seasonal fluctuations.

In order to analyze the dependence of the activity of clinker on the factors indicated, the modified method of spectral analysis of random processes with subsequent correlation of the dynamic series was used (1-3).

At the first step, the mathematical expectation of the initial time series, the empirical dispersion ( $S^2$ ) are determined and with the aid of the Durbin-Watson criterion (the DW criterion) the necessity of picking out a trend of development of the phenomenon is estimated. In contrast to the accepted linear approximation of a trend, in all cases we made use of a trigonometric polynomial of fourth order, and its coefficients were determined with the aid of the Bessel formulas for the best (in the sense of the method of least squares) approximation. The amplitude characteristics of the trend ( $X_{t1}$ ) and the dispersion introduced by the trend ( $S_t^2$ ) are determined from the polynomial. The difference between  $X_1$  and  $X_{t1}$  is the starting quantity for determining seasonal variations ( $X_{s1}$ ), which is also evaluated by the DW criterion, and then the dispersion introduced by a seasonal variation ( $S_s^2$ ) is calculated. After the amplitude of seasonal fluctuations is subtracted, the dynamic series is expanded, with the aid of the Bessel formulas, into a Fourier series for  $K = N/4$  harmonics, which provides a good approximation for practical purposes. In this particular case, the amplitude characteristics of Fourier series ( $X_{h1}$ ) and the corresponding value of dispersion ( $S_h^2$ ) are calculated at  $K = 33$ . After  $X_{h1}$  is subtracted the values of the residual terms of the series are determined, which do not exceed in absolute magnitude the values of the procedural error in determination of the respective characteristics. The residual dispersion ( $S_{res}^2$ ), which is not taken into account by the trend, the seasonal fluctuations and the  $K$  harmonics of the Fourier series is determined for the residual terms. Thus, the

Fig. 1. Time series of the physico-chemical characteristics of clinker: 1a—the initial dynamics series and the trend of clinker activity; 1b—seasonal fluctuations of clinker activity; 2a—the original dynamic series and the trend of 3-day strength; 2b—seasonal fluctuations of 3-day strength; 3, 4, 5, and 6—the time series and trend of the content of  $C_3S$ ,  $C_2S$ ,  $C_3A$ , and  $C_4AF$  in clinker, respectively

TABLE 1						
Factor	Mean values	Empirical dispersions (above the line are given the absolute value, below the line, %)				
		$S^2$	$S_t^2$	$S_s^2$	$S_h^2$	$S_{res}^2$
$R_{28}$ , MPa	48.10	$\frac{5.593}{100}$	$\frac{2.244}{40.1}$	$\frac{1.083}{19.4}$	$\frac{1.846}{33.0}$	$\frac{0.420}{7.5}$
$R_3$ , MPa	35.58	$\frac{4.118}{100}$	$\frac{1.380}{33.5}$	$\frac{0.741}{18.0}$	$\frac{1.594}{38.7}$	$\frac{0.403}{9.8}$
$C_3S$ , %	56.93	$\frac{7.453}{100}$	$\frac{4.471}{60.0}$	$\frac{0.425}{5.7}$	$\frac{1.667}{22.4}$	$\frac{0.886}{11.9}$
$C_2S$ , %	15.79	$\frac{7.152}{100}$	$\frac{4.917}{68.8}$	$\frac{0.231}{3.2}$	$\frac{1.497}{20.9}$	$\frac{0.505}{7.1}$
$C_3A$ , %	8.03	$\frac{0.406}{100}$	$\frac{0.121}{29.8}$	$\frac{0.036}{9.0}$	$\frac{0.163}{40.3}$	$\frac{0.085}{20.9}$
$C_4AF$ , %	12.06	$\frac{0.189}{100}$	$\frac{0.053}{28.2}$	$\frac{0.006}{3.2}$	$\frac{0.075}{39.7}$	$\frac{0.055}{28.9}$

spectrum of the initial time series is distributed among the constituent dispersions in the form:

$$S^2 = S_t^2 + S_s^2 + S_h^2 + S_{res}^2 \quad (1)$$

The distribution of the values of empirical dispersions for the characteristics presented in Fig. 1 are tabulated in Table I.

Emphasis should be placed on the presence of significant seasonal fluctuations for the activity of clinker, which are +1.71 MPa for winter months and -1.81 MPa for summer months; for the 3-day strength the respective figures are +1.4 and -1.58 MPa, in relation to the trend of the time series.

At the second stage, cross-spectrum analysis is performed, which allows one to determine the coherence between the harmonic components of the clinker activity and the factors being investigated and to calculate the intensification factor and the overall correlation using Parzen weights. Considering that almost 60 per cent of the dispersion value of clinker activity is determined by the trend and seasonal fluctuations, we give the corresponding values of the correlation together with characteristics of mineral composition (see Table II).

TABLE II		
Factor	Trend	Seasonal fluctuations
$C_3S$	0.4836	0.7934
$C_2S$	-0.4341	-0.8166
$C_3A$	0.4198	-0.3518
$C_4AF$	-0.2914	0.3361

Let us note the significant correlation only for the seasonal fluctuations of the clinker activity and the content of  $C_3S$  and  $C_2S$ . The use of this correlation for construction a mathematical dependence will not, however, be of practical value since, according to Table I, the dispersion values per seasonal fluctuations of  $C_3S$  and  $C_2S$  are only 5.7 and 3.2 per cent of the total values of the corresponding dispersions. An almost analogous picture is characteristic of the 3-day strength of clinker.

Hence, for the entire time period being analysed it is impossible to establish a significant correlation in a linear approximation between the activity of clinker and its mineral composition and, therefore, one cannot control the activity of clinker, taking into account only on the chemical and mineralogical characteristics.

Let us now consider the possibility of constructing a mathematical model for the strength of cement, using as an example rapid-hardening Portland blast-furnace cement M 400, depending on the amount of clinker (C, per cent), slag (Sl, per cent), gypsum (G, per cent), and on the specific surface area (S, cm<sup>2</sup>/g), which is determined by the air-permeability method according to State standard GOST 310-60. "Cements. Methods of Physical and Mechanical Testing".

The content of clinker, slag, gypsum in cement and the magnitude of specific surface area are the determining factors for cement strength. A requisite condition is the constancy of clinker activity. Otherwise, the activity of clinker must be known in advance and incorporated into the mathematical model for calculating cement strength. In other words, in the case considered it is impossible to find an ade-

quate mathematical dependence of cement strength for the entire time series of the clinker activity of clinker which was used to prepare rapid-hardening Portland blast-furnace cement (BTShPTS-400). If the period of time is limited to constant clinker activity, it is practically always possible to determine the dependence of cement strength on its determining factors in the form of an adequate linear equation of regression. Thus, to plot of the strength of cement versus its composition and the specific surface area, we chose the last quarter of 1975 and the first quarter of 1976 (this time period is indicated in Fig. 1 by an arrow).

During this six-month period all the characteristics of the cement under study have a normal distribution with the parameters given in Table III.

The composition of cement is given in Fig. 2 as a ternary C-Sl-G diagram. The shown range of cement composition is restricted by the respective values of confidence limits which were calculated for  $P=0.95$  and two-sided restriction.

Fig. 2. Phase diagrams and strength increase of rapid-hardening Portland blast-furnace cement M 400.

Using the known methods (4), we find regression equations for the 3-day and 28-day strength:

$$R_3 = -350.0 + 3.8862.C + 3.2650.Sl + 4.3608.G + 0.002036.S \quad (2)$$

$$R_{28} = -1102.9 + 11.6881.C + 10.8713.Sl + 12.5853.G + 0.002971.S \quad (3)$$

which are adequate, have a significant coefficient of multiple correlation and take into account the condition

$$C + Sl + G = 100 \text{ per cent} \quad (4)$$

By constructing iso-strength and reflection lines for the 3-day and 28-day strength, we may "relate" to the composition diagram the time dependence of the strength characteristics of BTShPTS-400. The effect of specific surface area on  $R_3$  and  $R_{28}$  is pictured graphically with a 267 cm²/g step. Such a diagram allows one to easily trace the variation of cement strength in time as a function of its composition for different specific surface.

Arrows in Fig. 2 illustrate the possibility of graphical determination the increase of cement strength, using a sample having a composition designated by the point A: C = 55.2 per cent, Sl = 34.0%, G = 5.30% at S = 3147 cm²/g. The calculated values at age of 3 and 28 days are 23.0 and 47.7 MPa. The actual values of cement strength determined by the method described by USSR (GOST 310-60) State Standard at the age of 3, 7 and 28 days are 24.5, 34.2, and 47.1 MPa, respectively, which are designated in Fig. 2 by the points 1, 2, and 3.

Hence, at constant clinker activity, it is always possible to determine the dependence of cement strength on its composition and specific surface at a given moment by hardening. However, to determine strength variation in a continuous time scale a characteristic which takes into account the increase of cement strength should be introduced.

Investigations show that specific features of strength increase of various clinkers and types of cement are described by expression:

$$R_t = R_3 + A_s \cdot \log t / 3 \quad (5)$$

where  $R_t$  is the compressive strength of cement at the age of  $t > 3$  days, MPa;  $R_3$  is the compressive strength at the age of  $t = 3$  days, MPa;  $A_s$  is a coefficient which characterizes the increase of cement strength at the later stages of hardening;  $t$  is the time from the moment of mixing the cement paste with water, days.

From formula (5) the characteristic of the increase of the strength of cement at the later stages of hardening is calculated

$$A_s = \frac{R_t - R_3}{\log t / 3} \quad (6)$$

TABLE III

Statistical characteristic	Factors, dimensions				
	$R_{28}$ , MPa	$R_3$ , MPa	Sl, %	G, %	S, cm <sup>2</sup> /g
Mean values	47.65	22.95	40.41	4.55	3612
Lower limit	43.50	19.40	35.60	4.53	3170
Upper limit	51.77	26.49	44.80	5.30	3970
Empirical dispersion	4.69	3.16	5.85	0.21	43298
Coefficient of variation	4.55	7.74	5.98	10.20	5.76

For our sample of cement we obtain  $A_s = 23.29$ , therefore the 7-day strength is:

$$R_7 = 24.5 + 23.29 \cdot \log 7/3 = 33.1 \text{ MPa}$$

By substituting formulas (2) and (3) into formula (6), we may determine the dependence of the intensity of strength increase of the cement on the composition and specific surface area:

For our example we obtain

$$A_s = -776.18 + 8.0424 \cdot G + 7.8407 \cdot Sl + 8.4779 \cdot G + 0.0009643 \cdot S \quad (7)$$

If the strength of cement is expressed in relative units  $R_t/R_{28}$ , the dependence of the intensity of strength increase on its determining factors will be fractional-linear by virtue of the relation:

$$A_s = \frac{1 - R_3/R_{28}}{\log 28/3} \quad (8)$$

It should be noted that if the absolute and relative values of intensity of strength increase is determined by composition and specific surface area then the hardening temperature has only relative effect on the magnitude of  $A_s$ . Studies of various types of cements showed that the relative effect of hardening temperature in the range 0-40°C is characterized by dependence:

$$K_t = 0.58 + 0.021 \bar{t} \quad (9)$$

where  $K_t$  is the coefficient of the relative effect of hardening temperature on the intensity of strength increase;  $\bar{t}$  is the weight-average hardening temperature in a logarithmic time scale determined by formula

$$\bar{t} = \frac{\sum_{i=1}^n t_i \cdot \log \frac{\tau_{i+1}}{\tau_i}}{\sum_{i=1}^n \log \frac{\tau_{i+1}}{\tau_i}} \quad (10)$$

where  $\tau_i$  and  $\tau_{i+1}$  are the periods of variation of hardening temperature of standard samples under moist conditions, days;  $t_i$  is the hardening temperature in the time interval from  $\tau_{i+1}$  to  $\tau_i$ , °C.

Therefore, the strength of cement at the age of  $\tau \geq 3$  can be determined by the formula:

$$R_\tau = R_3 + K_t \cdot A_s \cdot \log \tau / 3 \quad (11)$$

where  $R_3$  and  $A_s$  depend on the composition of cement and the specific surface area, and the relative effect of temperature on the increase of the strength is given by formula (9).

The intensity of increase of the strength of cement at the later stages of hardening can be determined more precisely from experimental data by the method of least squares.

Of considerable theoretical and practical interest is the problem of the applicability of relation (11) in the range of at  $\tau < 3$  days. Here it becomes necessary to solve the problem of the determination of the kinetic characteristics of cement strength increase at the early stages of hardening. The early period of hardening is here the time commensurable with the periods of the beginning ( $\tau_{\text{beg}}$ , days) and the end ( $\tau_{\text{end}}$ , days) of cement setting. Special investigations have shown that the strength of 4 x 4 x 16 cm samples from cement mortar of 1:3 composition using normal sand produced in accordance with the USSR State Standard (GOST 340.4-76) "Cements". "Methods of Determination of the compressive strength and modulus of rupture" is  $R_{\text{beg}} = 0.2 \pm 0.03$  MPa at the beginning of setting and  $R_{\text{end}} = 0.42 \pm 0.02$  MPa at the end of setting. The zero hardening time is the time when the cement mortar is mixed with water. The characteristics indicated make it possible to estimate the increase of cement strength, from the beginning of setting of the cement paste.

It has been found that at the initial periods of hardening the best approximation of experimental data on the increase of strength at the early period of hardening is provided by equation of the type:

$$R_{\tau} = R_1 (1 - e^{-B\tau^{A_{in}}}) \quad (12)$$

where  $R_{\tau}$  is the strength of the cement mortar at  $\tau > \tau_{\text{beg}}$ , MPa;  $R_1$  is the one-day strength used for normalization in determination of coefficients  $A_{in}$  and  $B$ , MPa;  $A_{in}$  and  $B$  is the coefficient characterizing the kinetics of the increase of cement strength at the initial stages of hardening.

After linearization

$$\log \ln \frac{R_1}{R_1 - R_{\tau}} = \log B + A_{in} \cdot \log \tau \quad (13)$$

coefficients  $A_{in}$  and  $B$  are determined by least squares method.

Knowing coefficients  $A_{in}$  and  $B$ , one can find the time of the most intensive strengthening of the original (primary) structure of the hardening cement:

$$\tau_m = \left( \frac{A_{in} - 1}{A_{in} \cdot B} \right)^{\frac{1}{A_{in}}}, \text{ (days)} \quad (14)$$

Thus, the kinetic equation (12) for strength increase during the initial periods of hardening ( $R_I$ ) reflects the process of formation of the primary structure, and Equation (5) written in the general form

$$R_{\tau} = B_s + A_s \cdot \log \frac{\tau}{\tau_0} \quad (15)$$

describes the strengthening of the primary structure in subsequent periods of hardening ( $R_{II}$ ).

To make these equations consistent in time one must determine the time ( $\tau_0$ ) when the irreversible process of strengthening of the primary structure begins.

This may be solved taking into account the additive nature of actual compressive strength which includes strength due to formation of primary structure (adhesion forces, forces of weak chemical interaction) and strength due to further strengthening of primary structure (concretion of hydration products).

Knowing that

$$R_{\tau} = R_I + R_{II} \quad (16)$$

with  $R_I$  being the advanced strength, we can determine  $\tau_0$  from formula

$$\tau_0 = 1 / \text{EXP} \left( \frac{B_s}{M \cdot A_s} \right) \quad (17)$$

Thus, the overall equation for the kinetics of increase of cement strength in time takes the form:

$$R_{\tau} = R_1 \cdot [1 + \text{EXP}(-B \cdot \tau^{A_{in}})] + K_t \cdot A_s \cdot \log \frac{\tau}{\tau_0} \quad (18)$$

where the second term is taken into account only for  $\tau > \tau_0$ .

If we take into account that the intensity of strength increase at the later stages of hardening ( $A_s$ ) depends, as has been shown above, on the composition and specific surface of cement, then, knowing the setting times and, hence,  $R_{\text{peg}}$  and  $R_{\text{end}}$ , and also the one-day strength, we can calculate the strength of cement at any moment of time by means of Equation (18). It should be noted that Equation (18) may also be used for describing strength increase of clinker.

The procedure described here for the calculation of the strength in time is illustrated on the example of the clinker studied and rapid-hardening Portland blast-furnace cement M 400 prepared on from this clinker.

The periods of the beginning and end of clinker setting are 0.059 and 0.121 day respectively. The results of testing of clinker strength in time are listed in Table IV and are indicated by dots in Fig. 3. Performing linearization according to formula (13), we can determine, using the method of least squares, the coefficients  $A_{in} = 2.1656$  and  $B = 2.1053$  for ratio correlation  $r = 0.9842$ .

From Equation (14) we find the period when the primary structure is strengthened most strongly:

$$\tau_m = 0.5327 \text{ day}$$

The kinetic equation for the initial period of strength increase has the form:

$$R_{\tau} = 24.6 \cdot (1 - e^{-2.1053 \cdot \tau^{2.1656}}) \quad (19)$$

The values of strength calculated by means of this equation are given in Table IV (column 3) and in Fig. 3 ( $R_{K1}$ ). By subtracting the values in Equation (19) from the initial values of strength and employing the method of least squares, the parameters of Equation (15) which describes strength increase in the subsequent hardening periods and is valid at correlation ratio  $r = 0.9974$

$$R_{\tau} = 3.6417 + 14.8516 \cdot \log \tau$$

Equation (17) is used to calculate the beginning of strengthening of the primary structure:

$$\tau_0 = 0.5685 \text{ day}$$

TABLE IV				
Time of hardening $\tau$ , days	Actual strength, $R_{\tau}$ , MPa	Strength due to formation of primary structure, MPa, to equation (19)	Strength due to strengthening of structure, MPa, to equation (20)	Total strength according to equation (18)
0.058	0.20	0.112	0	0.112
0.121	0.42	0.529	0	0.529
0.250	1.29	2.443	0	2.443
0.330	3.51	4.273	0	4.273
0.500	8.78	9.213	0	9.213
0.667	14.90	14.354	1.029	15.384
0.833	20.30	18.638	2.463	21.101
1.000	24.60	21.604	3.642	25.245
3.000	36.10	24.600	10.728	35.328
7.000	41.10	24.600	16.193	40.793
28.000	49.30	24.600	25.134	49.734

Fig. 3. The kinetics of strength increase of clinker and quick-hardening Portland blast-furnace cement M 400.

Using the determined value of  $\tau_0$ , the equation of strength increase in the subsequent periods may be written as:

$$R_{\tau} = 14.8516 \cdot \log \frac{\tau}{0.5685} \quad (20)$$

The calculated values of strength are presented in Table IV (column 4) and in Fig. 3 ( $R_{cl2}$  for  $\tau > 0.5685$ ).

The differential values of these strength characteristics are given in the form of a histogram in Fig. 3.2.

The overall kinetic equation of strength increase for clinker is

$$R_{\tau} = 24.6 \cdot (1 - e^{-2.1053 \cdot \tau^{2.1656}}) + 14.8516 \cdot \log \frac{\tau}{0.5685} \quad (21)$$

where the second term is used when  $\tau > 0.5685$  day.

The values of strength calculated from equation (21) for clinker are presented in Table IV (column 5) and in Fig. 3 by a solid line. It should be noted that the root-mean-square deviation (the adequacy dispersion) is 0.62 MPa.

For the rapid-hardening Portland blast-furnace cement we can obtain, in an analogous manner, the following kinetic equation for strength increase:

$$R_{\tau} = 24.5 \cdot (1 - e^{-1.4264 \cdot \tau^{1.8456}}) + 23.1383 \cdot \log \frac{\tau}{0.7641} \quad (22)$$

where the second term is used when  $T > 0.7641$  day.

The adequacy dispersion for this equation is only 0.361 MPa. The general form of strength increase of the cement with composition represented by the point A in Fig. 2, is shown in Fig. 3 by a dashed line. The differential values of the strength characteristics of the cement are given in Fig. 3.3.

It should be noted that the intensity of cement strength increase at the later stages of hardening, as calculated by the procedure described here and by means of Equation (7), as a function of the amount of slag, gypsum and clinker as well as the specific surface area, practically coincide.

Analysis of kinetic equations of strength increase of clinker (21) and cement (22) shows the intensity characteristics of strength increase differ considerably at the initial and later periods of hardening, while 28-day strengths values differ only slightly and are 49.30 and 47.1 MPa respectively.

Hence, the kinetic equation of strength increase (18) makes it possible to employ calculations for determination of strength characteristics of hardening cements, discarding tedious and crude methods of rapid (accelerated) determination of activity.

In conclusion we would like to stress that the necessity of developing methods of calculation of cement strength was repeatedly noted at the VI International congress on the Chemistry of Cement (5).

# INTRODUCTION

For a very long time, the idea prevailed that a top-grade concrete from a mechanical point of view resulted, for the main part, of the filling, at maximum compactness, of the volume to cast with fragments of rocks embedded in a matrix, both phases having mechanical strengths as high as possible. Obviously, it was taken for granted from the outset that the bond was supposed to be established between these two compounds. Nevertheless, the adherence seemingly satisfying at work and the rocks not being able to be extracted far away from the place of use -which always makes a limited choice- the main research effort bore quite naturally on the matrix, not however on its binding ability, but on its embedding and filling ability.

However consider a concrete element subjected to a traction. Suppose, for simplicity's sake, that the grains of rocks and matrix possess identical deformability, that the element has a constant cross-section and sufficient length. Then, should there be adherence between the aggregates and the matrix, the strain and stress fields are uniform, except for the end sections. All around the aggregates, the stress shifts from traction to shear. Suppose that the bond between the two phases breaks down without either the aggregate or matrix being damaged. Then, the matrix alone bears the total stress ; it, however, only occupies a small fraction in any section of the element and the system behaves as if the aggregates were voids. They are almost completely useless, following the breakdown of the bonds.

In traditional concrete, the matrix is more deformable than the aggregates. The consequence thereof, as shown by DANTU [1] is a concentration of isostatics towards and inside these latter. The bond breaking then takes place at an earlier stage than in the theoretical example mentioned above.-

Suppose, on the other hand, that the breakdown starts in the matrix. The aggregates, less deformable, slow down the crack propagation provides the strength of the bond is sufficient ; however, the propagation will increase if the bond is weak.

Yet, the failure surfaces of concretes in traction follow the contour of aggregates (MASO [2] DHIR and SANGHA [3]). Some research carried out earlier, shows that if the bond does not exist or is very weak, its failure does not bring about that of the whole. The resistance depends only on the matrix, it is the first type of failure. If the bond is beyond a given value, its breakdown brings about the collapse of the whole because the matrix alone is unable to support the total loading. It represents the second type of failure (fig. 1). For equal composition, the strength in traction following the second type is higher than the one following the first type. Therefore, the bond plays a major role in the crack propagation process and the failure of the concrete. The concrete strength in traction is higher, all other things being equal, when the bond strength is higher.

These two types of breakdown are found also in compression but the aggregates continue to contribute to the strength, even beyond the rupture of the bonds. Furthermore, this process occurs for much higher loads than in traction. Indeed, the bonds stressed directly in traction are only stressed indirectly in compression, due to the differences in strength between the

matrix and the aggregates. These phenomena account to a great extent for the strength in compression being much higher than that in traction.

If engineers had not invented reinforced concrete and pre-stressed concrete to supply the weakness of concrete in traction, it is likely that researchers would have taken an interest in the bond between the matrix and the aggregates earlier, even if, as it will be seen further on, the study thereof proves more difficult.

Therefore, those physico-chemists who took an interest in the cement-aggregate bond were few, more because of lack of motivation than tools. But it is likely that research in this field will develop, for the benefits to be expected by the engineer are seen more and more clearly nowadays. In effect, the mechanics of composites, non-existent until recently, allows the analysis of the influence of bonds between phases on the mechanical properties of the concrete. Moreover, a greater and greater number of research investigations are being undertaken in the world on the internal mechanisms of crack propagation and failure of concrete. The necessity of analyzing the phenomena with fine resolution in order to understand and model them better, will lead inevitably to a greater number of researchers having an interest in the structure of bond.

We will not discuss the adherence, i. e. the mechanical aspect of the problem. The purpose of our paper is mainly to present the current state of knowledge on the structure and the formation of the bond. The mechanical aspects and the alteration under the action of corrosive agents will only be briefly discussed, to show to the physicists and chemists, how interesting is the physico-chemical study of the hydrated set cement-granulate bond for the mechanicians as well as engineers.

It is with regard to the techniques used that we present the chief attainments of scientific research in that field among the works of which we have knowledge. In effect, the results available, if they enable us to form an idea of the mechanisms of bond formation, are still very incomplete and their interpretation very dependent on these techniques.

#### I - THE BOND WITH NON-POROUS MATERIALS THE TRANSITIONAL RING

##### I.1 - Determination of the bond closeness by the impregnation method and observation by optical microscopy

This technique used by FARRAN [4] consists in taking

a sample of mortar and planing a flat face. The sample is then dried in an oven, set in a vacuum to remove the water and the entrained air and, then, impregnated with a coloured resin (Canada balm diluted in benzene, coloured with fuschine, red, or violet of gentian). Thin sections parallel to the plane face are cut and observed in optical microscopy.

FARRAN has studied, by this way, the closeness of bonds between artificial, blast-furnace, supersulphated and aluminous cements, on the one hand, and defined minerals issued from recent crushing of calcite, dolomite, quartz, silice, orthoclase, muscovite, biotite and anhydrite, on the other.

With a water-cement ratio  $W/C = 0,42$  and a one month curing period in water at  $15^{\circ}\text{C}$ , he noticed the lack of any coloured edge around the grains of calcite and dolomite, for all cements concerned. Edge developments of increasing size in the following order were observed : quartz, silice, orthoclase, mica and anhydrite.

Rings are thinner with aluminous cements than with artificial or blast-furnace cements. When anhydrite is used, the ring is thinner with supersulphated cement. We give in table I the chemical composition of the cements used by all the authors quoted in this paper.

TABLE I - Chemical composition (per cent) of the different cements

(1) non indicated

(2) chemical analyses for the cement phase (cement 65 %, slag 35 %)

The rings were, with the aid of a microscope, found to have values around the maximum of 100,000 and 1,000,000. These experiments have been repeated with the following results: the rings are found again except for the grains of cementized aggregate, which are surrounded by an intermediate ring. The micaceous minerals enter an almost total lack of bond with the hydrated set-cement in contact with them.

This technique can be criticized for the oven-drying followed by the vacuum treatment which certainly produces an important microcracking of samples before impregnation. Nonetheless we can say that when no coloured ring is observed, the bond will be very tight. When a coloured ring is observed one cannot be certain that there existed a defect of the bond in the non-treated sample, but we can, however, conclude that the bond, if it did exist, was more fragile than in the case of calcite or dolomite. It had to have been broken by the initial treatment.

A more recent technique will be described now which enabled us to specify partly these results.

Fig. 2 : Calcite mortar cured for 4 weeks  
G = calcite grain ; W/C = 0,48

By means of this method, PERRIN et al. [5] studied the bond between grains of quartz or calcite and Portland cement, in which W/C and the hardening time were made to vary. In most cases a first layer of hydrated finely crystallized compounds was observed, tightly clinging to the aggregate surface. Subsequently, a zone containing dark blotches tends to spread outwards, followed then by the matrix of hydrated set-cement. The dark blotches are due to grains clinging to the set-cement by the biode film, then trapped by the metallic film. These grains undissolved by acetone continue to cling to the metallic film. Their thickness is sufficient that the electrons emitted by the microscope are unable to pass through.

It appears, therefore, that the aggregates are surrounded by a particular matrix, varying in structure, composition and cohesion, between the surface of the aggregate and the matrix of hydrated set-cement, which we will call transitional ring.

For given material and cement, its thickness increases with the W/C ratio and decreases with the hardening time until about seven weeks after the mixing under

normal curing conditions.

For an identical W/C and identical time of curing, its thickness depends on the mineralogical nature of the aggregate : it is thinner with calcite than quartz (fig. 3). The loss of cohesion, allowing the film of biode to trap fragments of paste, is due to the machining of the plane surface of the mortar by abrasion.

The spreading and the number of particles removed (i. e. of the zone containing black blotches) are therefore quite representative of the set-cement in part of the transitional ring.

We give as an example, in figure 2, a micrograph of a calcite and portland cement mortar.

Fig. 3 : Calcite and quartz mortars cured for 4 weeks  
 curve a : variation in thickness of the transitional ring  
 (a<sub>1</sub> : calcite mortars ; a<sub>2</sub> : quartz mortars)  
 curve b : variation of half-distance between aggregates  
 (mortars have been mixed with W = constant = 0,314)

In figure 4, we can observe that for the lowest W/C, the area of low cohesion disappears. It will be noticed however that cohesion still exists for normal W/C. The coloured edge observed by FARRAN certainly corresponds to the area of lowest cohesion of the ring, cracked by thermic treatment, vacuum action and mechanical action of preparation of the polished section.

Fig. 4 : Calcite mortar cured for 4 weeks  
 G : calcite grain ;  $\gamma = 0,55$

In the case of calcite or quartz in association with Portland cement, it is not the interface proper. On the contrary, it is perhaps very likely the case with micaceous minerals.

PERRIN et al. were unable to determine the nature of fragments lifted by the biode. Their research ought to be extended to include other aggregates and different cements.

We pointed out that at the interface of calcite and quartz, a finely crystallized layer tightly clinging to the aggregate could be observed. The double replica technique neither allows them to be identified nor permits their observation on a higher resolution scale. However, this is possible, to some extent, using the method mentioned hereafter.

### I.3 - Study of the part of the transitional ring in close proximity of the aggregates by direct observation in T. E. M.

It is necessary to obtain sections of mortar thin enough to be crossed by the electrons in a T. E. M. OLLIVIER et al. [6] achieved this by ionic etching.

A first thin section of mortar, a few hundredth millimeters in thickness is obtained after the technique traditionally used for the preparation of samples intended to be observed in optical microscopy.

Fragments of this section including hydrated set-cement - aggregate bonds are subjected to the bombardment by a twin argon - ions beam (fig. 5). We can thus remove successive monoatomic layers on both faces of the sample. The intensity of beams being maximum in the center, we get samples the thickness of which varies from the center to the edges between 0 and about 1 000 Å.

The samples thus prepared are then observed by T. E. M. The resolution herein is in the range of 20 Å for normal use. This technique has only been used so far for mortars associating grains of quartz or calcite to Portland cement or to C<sub>3</sub>S. With normal W/C ratios, hardening times and modes of curing, there is no loss of cohesion of grains which would destroy the samples and would make the observation impossible.

The micrography of figure 6 gives, as an example, a picture of the first layer of a bond of hydrated set Portland cement with a grain of calcite.

Fig. 5 : Diagram of the ionic etching apparatus

The chief results provided by these studies are summarized below :

- no gap can be observed between the aggregates and the hydrated set-cement. If one does exist, its thickness is less than ten Å, which implies quite high attractive forces of the Van der Waals type, and excludes any gap at the interface.

- no crystal of portlandite can be observed in the immediate vicinity of calcite or quartz.

There can always be found, between the aggregate and the first portlandite crystals a thin film of tiny crystals causing a blurred ring around 3 Å by electron diffraction. This can be accounted for by the fact that the species observed are very tiny and do not present a sufficient number of crystalline networks to provide a distinct diagram in electron diffraction.

These two statements reinforce an hypothesis, already formulated by FARRAN in the case of calcite associated to Portland cement and to aluminous cement, about the formation of compounds by combination of ions emanating from the aggregates and of ions coming from the dissolution of anhydrous constituents of cements. We will consider this hypothesis again later.

The diminutive thickness of the first layer of the transitional ring, the smallness of formed species, the combined action of vacuum and heat in the etching apparatus, and in the microscope limit the possibilities of this method of study because it does not allow, except in a few well defined cases, the establishment of the diagnosis of the constituents found in the first layer at the interface.

However, other means have brought complementary views, X-ray diffractometry and scanning microscopy which we will examine in turn.

#### 1.4 - Study of bond by X-ray diffractometry and optical microscopy

Composite samples are fabricated according to the diagram of figure 7.

Fig. 6 : Calcite (c)-set cement (p.c.) interface in a mortar cured for 6 months  
 $\gamma = 0,45$

Fig. 7 : Preparation of mixed samples

The face of the adjoining part in contact with the set-cement or the mortar was previously polished so as to facilitate the forthcoming splitting of the two parts of the sample. The latter is kept under specified conditions, until the desired hardening time is reached. The two half-samples are then separated. The rupture occurs, either at the very interface or in the immediate vicinity, in the set-cement or in the adjoining part. In the two former cases, one can observe both faces (adjoining part side and hydrated set-cement side) by means of metallographic optical microscope and, by determination of refractive indices, identify the well crystallized compounds. A layer several  $\mu$  in thickness can also be obtained by scraping, on either side of the interface, and analysing it by X-ray diffractometry (powder diagram). This technique was used by FARRAN [4] to determine the components laid in contact with samples of glass, calcite, quartz, orthoclase and stainless steel during the hydration of cements mentioned in I.1. All the samples were kept in water at 15°C.

With aluminous cement and associated materials other than calcite, the contact film is constituted after a fortnight, of a non-identified gel and bicalcium aluminate,  $C_2AH_8$ .

With ageing, the gel progressively disappears, to give way to a finely crystallized mat of hydrated monocalcium aluminate  $C_4AH_{13}$  ( $x \sim 8$ ) which constitutes the main part of the film observed at the interface. The non-identified gel would be constituted almost exclusively of alumina and lime in an equimolecular ratio and water.

With calcite the previous formation of hydrated monocalcium aluminate is observed, which disappears progressively to give way to a solid solution of hydrated tetracalcium aluminate and calcium carbo-aluminate, also observed by FIERENS [7]. Corrosion patterns are also noticed on the surface of calcite, which clearly confirm the partial dissolving of this mineral in contact with aluminous cement.

With artificial cement, one is still led to distinguish between calcite and other associated minerals. With the latter, FARRAN observed that the interfacial film was either constituted of portlandite alone or of portlandite associated with a non-identified gel. He did not observe any visible evolution beyond a fortnight's hardening.

With calcite, FARRAN was unable to observe the interfacial film and by way of consequence, unable to identify the components because the rupture always took place in calcite. He assumed that, in this case again, the bond was insured for the most part of portlandite crystals. In order to justify the top-grade quality of the adherence between calcite and Portland cement, he formulated the hypothesis of epitaxial arrangements between calcite and Portland cement. We can observe in effect, on the one hand, that within 10. % the hexagonal base of portlandite crystals by association of three diamond-shaped faces of calcite rhombohedron can be obtained and, on the other hand, that calcite is etched, which results in bringing to light cleavage planes crystallographically blank. The conditions necessary to the forming of epitaxial coupling, according to ROYER [8], are thus reunited.

With blast-furnace cement, FARRAN does not point out the differences in behaviour between calcite and the other associated materials studied. The interface film is constituted of portlandite, ettringite in abundance, hydrated calcium aluminates and non-identified gel.

With supersulphated cement, FARRAN noticed at the interface of all associated materials a very thick tangle of ettringite crystals and a non-identified gel.

At the time, this research was carried out (1950-1955) and with the means at his disposal, FARRAN was unable to recognize the C. S. H. Besides, he could not establish whether the identified compounds were effectively in direct contact with the associated material, or at a certain distance, albeit very short, from the latter.

The principle of the identification method used by FARRAN, the results of which we have just presented, was employed again by BARNES, DIAMOND and DOLCH, replacing the optical microscope and X-ray diffractograms on powder by the scanning microscope and the E. D. X. A.

#### I.5 - Study of the bond by scanning microscopy and E. D. X. A.

BARNES, DIAMOND and DOLCH [9] studied the bond of glass with various cements. The optical microscopy is replaced by the scanning microscopy and the resolution thus increases from a few microns to a hundred Å. Furthermore, the analysis by X-ray diffractometry is no longer global on the over-all layer gathered by scraping but is local owing to E. D. X. A.

BARNES, DIAMOND and DOLCH brought to light the existence in close vicinity of the glass, of a twin layer which they called duplex film constituted of portlandite crystals the axes of which are perpendicular to the aggregate and layers of C. S. H. Beyond this film about one micron thick, they observed a highly porous zone bearing portlandite crystals the axes of which run parallel to the glass aggregate, well-formed and rather large in size, leaving between them large spaces partially filled afterwards with heaps of secondary portlandite crystals with their axes perpendicular to the glass-surface, smaller in size, and of C. S. H. Moreover, this zone contains a large quantity of HADLEY's grains [10]. The latter, as mentioned earlier are constituted by a C. S. H. shell about one micron thick, the inside of which is either empty or partially filled with a remainder of anhydrous cement grains or, sometimes, of hydrated compounds.

These authors do not mention the presence of ettringite. However, they mention lime-sulphate ratios ranging from 13 to 22 according to the sites.

BARNES, DIAMOND and DOLCH repeated these studies with siliceous sand mortars (OTTAWA - ILLINOIS). They find the same results again, but the preciseness of the contact area being smaller they were unable to bring to notice possible interactions at the aggregate-cement interface.

The schematic representation of the bond of figure 8, can be given from the observations of BARNES, DIAMOND and DOLCH.

Fig. 8 : Schematic representation of the bond according to BARNES, DIAMOND and DOLCH.

The phenomena of preferential orientation of portlandite by the glass-surface associated to the set-cement or by the aggregates is worthy of investigating.

#### I.6 - Study of the orientation of portlandite crystals by X-rays diffractometry

Utilizing again the technique used by FARRAN consisting of separating and splitting mixed cylindrical samples, GRANDET and OLLIVIER [11] followed the evolution of the intensity of the two beams at 4,90 Å and at 2,628 Å of portlandite as a function of the distance to the interface. Both half-cylinders obtained after separation are placed directly on the goniometer of the diffractometer and the ratio :

$$I = \frac{I(001)/I(101)}{0,74}$$

$I(001)$  = intensity of the beam at 4,90 Å of the 001 planes of portlandite

$I(101)$  = intensity of the beam at 2,628 Å of the 101 planes of portlandite

for layers about 1 micron apart, the surfaces successively analyzed being brought to light by minute scraping. Figure 9 gives the evolution of ratio  $I$ , characteristic of the degree of orientation for a given cement and different adjoining part.

The degree of orientation varies linearly with the distance to the interface. The distance at which the adjoining part has no longer an influence on the orientation of portlandite is important and independent of its nature.

(\*) The ratio  $\frac{I(001)}{I(101)}$  equals 0,74, when there is no preferential orientation.

Fig. 9 : Variation of the degree of orientation of portlandite as function of distance to the interface and for different types of aggregates

0 : Mosset marble (FRANCE) x : quartz  
+ : Calacata marble (ITALY) • : polyethylene

On the contrary, the slope of straight lines changes with the latter. It appears that the degree of orientation is smaller when the reactivity of the adjoining part is higher which would tend to reinforce the hypotheses of formation of solid solutions between the set-cement and the aggregates.

Lastly, the discontinuity of orientation of portlandite indicated by BARNES, DIAMOND and DOLCH is not observed here. There is disagreement on this point between the observations of these authors and those of GRANDET and OLLIVIER.

#### I.7 - Hypotheses concerning the formation mechanisms of the transitional ring

When the mixing takes place, the aggregates become coated by a film of water several microns thick, in which grains of anhydrous cement can be found only in very limited numbers, if at all. The concentration in anhydrous cement, null in the vicinity of aggregates, progressively increases afterwards with the distance to the latter.

When the anhydrous components are dissolved, the most mobile ions are the first to diffuse in the water-film. With the Portland cements, for example, the order of diffusion is as follows : sodium and potassium ions, sulphate ions, aluminium ions probably issued from an earlier dissolution of C3A before fixation of sulphate ions on their surface, followed by calcium ions. Silicon ions remain at first fixed by the anhydrous grains of the cement and spread only later on in the water film surrounding the aggregates.

If the latter are insoluble, these phenomena can be expressed as indicated on the theoretical diagram of figure 10-a. On the contrary, if they are partially soluble, a maximum concentration of ions issued from the aggregates is obtained at the surface of the latter ; this concentration decreases quickly with distance. It is represented in the theoretical diagram of figure 10-b.

Fig. 10 : Schematic representation of concentration of ions liberated by the cement and by the aggregates for a given time (1 curve type 1 or type 2 resembling those given for each ion)

a : case where aggregates are non-soluble

b : case where aggregates dissolve partially

In the water surrounding the aggregate the first nuclei to form are those of the hydrated components corresponding to the most mobile ions ; ettringite and portlandite in the case of Portland cement.

Development of crystals is not hindered, and they reach considerable size, larger than in the body of the set where supersaturation is much higher and space more limited. They form a looser network the pores of which are progressively saturated with less mobile ions, such as silicon and aluminum ions for Portland cements. A second generation of crystals then develops in the voids left by those of the first generation. Taking again the example of Portland cements, we find C. S. H., and again ettringite and portlandite in crystals of smaller size.

One can think, as a consequence of the experiments of OLLIVIER et al., that first generation crystals do not develop in continuous layer in direct contact with the aggregates.

Furthermore, the latter always being partially soluble, the space left between the first generation crystals and the aggregates progressively fills with a very tight crystallite network formed by the ions issued from the anhydrous cement and those coming from the aggregates which are able to combine.

HADLEY'S grains observed by BARNES, DIAMOND and DOLCH, could have arisen from the hydration of the first, not very dense, layer of anhydrous grains of cement.

From GRANDET and OLLIVIER'S experiments one can deduce that the thickness of the water film surrounding the aggregates at the time of mixing depends little or not at all on the nature of the latter. On the contrary, it would play a non negligible part in the orientation of the first generation crystals and, as a consequence, of those of the second generation.

Therefore, the hydration process, when the transitional ring is formed, would occur according to LE CHATELIER'S theory, and not, as in the body of the matrix, by formation of a crystallized coagulated network.

It is therefore important to stress the probable existence of an area of minimal concentration (figures 10-a and 10-b). It is in that part of the ring that the largest crystals and the highest porosity will be found. It must correspond to the coloured edges observed by FARRAN, to the zone of reduced cohesion pointed out by PERRIN and to that of maximum porosity beyond the duplex film shown by BARNES, DIAMOND and DOLCH.

Lastly, the partial dissolution of the aggregates increases the roughness of surfaces, which favours the mechanical clinging of hydration products, increases the interface, which increases the effect of bond forces of a physical type, can cause a formation of chemical type bonds by a combination of ions issued both from aggregates and cement.

#### I.8 - Relationships between the transitional ring and the properties of concrete - Perspectives

A material is all the less resistant to mechanical actions as it is more porous ; therefore, the transitional ring is more porous than the matrix of the hydrated set-cement.

Crack initiation and its propagation is easier in large size crystals than in the arrays of crystals of small dimension tightly entangled; therefore, the transitional ring contains crystals larger than those found in the body of the hydrated set-cement and in greater quantities.

Moreover, these crystals show a preferential orientation, an aspect favourable to the propagation of cracks.

For these three above stated reasons, the transitional ring is the weakest part of the granular cohesive material which constitutes hardened concrete.

In traditional concretes, the aggregates are less deformable than the matrix of hydrated cement. Under the action of external forces, there is always a concentration of stresses in the aggregates and, as a result, in the transitional ring.

The latter, therefore, happens to be both the most highly stressed part, and the weakest region of the concrete. It is then in the transitional ring that the first irreversibilities will occur, by packing, resulting from microruptures and the closing of pores, if it is compressed, by cracking when subjected to tractions or shears. The cracking, once initiated, then propagates from ring to ring. The observation of concrete fracture surfaces confirms this. In most cases, these follow the contour of aggregates.

Numerous authors think, however, that the shrinkage cracks or microcracks the set-cement. It is to be pointed out that the experiments seemingly confirming this fact, normally lead one to submit the concrete to treatments which amplify the phenomenon to a great extent. However, it appears that the cracks resulting from shrinkage initiate at the aggregates and cause as a consequence ruptures of the transitional rings. If the concrete is effectively fissured initially by the shrinkage, it is then the roots of the fissures which are subjected to the highest stress. The transitional ring would then no longer play a part in the first irreversibilities under the action of the external forces (beginning of crack propagation).

But its role would remain unchanged after the beginning of propagation for fissures would develop throughout the transitional rings.

On the other hand, the action of corrosive chemical agents depends not only of the nature of the elements in contact but also on the exposed surface. Yet, the transitional rings, through higher porosity, and if they are effectively connected by a network of capillaries or of microfissures resulting from shrinkage or from the action of external forces, constitute a preferential way for attack by aggressive agents since they offer a considerable amount of internal exposed surface.

In the case of Portland cements, furthermore, the elevated concentration of portlandite in the transitional ring is an extra factor of alteration.

The objective of research directed towards a better understanding of the composition and structure of the transitional ring is therefore obvious. It is important then to broaden the research efforts to include various types of cements and aggregates. It would

also be necessary to shed light on the influence of curing temperatures, admixtures, slags and pozzolanas. Finally, processes aimed at decreasing the ring porosity, at diminishing the size of crystals developing thereon and at preventing their preferential orientations would probably have very favourable consequences on the behaviour of concrete under mechanical, physical or chemical actions.

## II - THE BOND WITH POROUS MATERIALS

Two cases are to be examined. In the first, one of the faces of the porous material is in contact with the cement, while the other is in contact with the atmosphere. In the second case, the porous materials are completely embedded in the set-cement.

### II.1 - Case of porous materials with only one face in contact with cement

Studies by GRANDET et al. [12] have been undertaken on this topic using bricks and a Portland cement. They made up composite cylindrical samples associating a cylinder of brick to a cylinder of set-cement or mortar. The samples of brick were chosen so as to cover a domain of capillary patterns as wide as possible.

Furthermore, for each sort of brick, they varied the initial water content from 0 to 100 %. The samples were stored until testing in atmospheres saturated with water, devoid of CO<sub>2</sub> at the beginning.

After separating the brick from the set-cement, the two exposed faces were analyzed by X-ray diffractometry. They were subjected to successive scrapings, each time removing a layer a tenth of millimeter thick. The new surfaces so obtained were in turn analyzed by diffraction. These researchers were thus able to draw diagrams presenting the variations of concentration in crystallized components as a function of the distance to the interface.

With initially dry brick, one can observe that the percentage of ettringite, maximum at the interface, decreases towards the body of the set-cement or of the mortar. The portlandite concentration follows an inverse law of variation (fig. 11). The phenomenon is all the more obvious as the internal specific surface of the brick is higher. The analysis of X-ray diffractograms reveals the existence of a low hydrated area in the vicinity of the interface.

As the initial water content of the brick increases, the suction decreases and a diffusion of the ions from the water phase of the set-cement to that of the brick takes place. This results in an increase in the maximum concentration of ettringite at the interface, the diffusion effect augmenting that of suction. The portlandite concentration increases but still offers, even for the brick initially saturated with water, a value lower than one that would be in contact with a porous material.

Moreover, it can be observed that the delay of hydration in the vicinity of the interface also decreases when the initial water content of the brick increases.

Lastly, no noticeable preferential orientation of portlandite crystals in the vicinity of the brick is observed.

Fig. 11 : Variation in concentrations of ettringite and portlandite in contact with a porous material as function of distance to the interface

a : brick initially dry  
b : brick initially saturated with water  
c : glass (given for comparison)

$$KE = \frac{IE}{IC_3A} \quad KH = \frac{IP}{IC_3S}$$

IE = intensity of the beam at 9,73 Å of ettringite  
IC<sub>3</sub>A = intensity of the beam at 2,70 Å of C<sub>3</sub>A  
IP = intensity of the beam at 4,90 Å of portlandite  
IC<sub>3</sub>S = intensity of the twin beam at 2,764-2,739 Å of C<sub>3</sub>S

The mechanism of bond formation would be as follows. With the initially non-saturated brick, the set-cement water is drawn by the brick, and this all the more as the level of initial impregnation of the latter is lower and its internal specific surface higher. This occurs fairly quickly, upon casting, therefore prior to the beginning of the cement setting. The consequences of this suction phenomenon are, on the one hand, a diminution of the porosity of the set-cement or of the mortar, until the force of water retention by the set-cement balances that of suction by the brick, and on the other hand, the lack of a water film of considerable thickness in the vicinity of the interface.

We thus have important variations in water content between the brick and the body of the set-cement. For an initial W/C = 0,26, the W/C at the interface can be reduced to values from 0,14 to 0,11 with initially dry bricks.

Fig. 12 : Diffractogram relative to set-cement in association with brick initially dry

a) at 10 mm from the interface  
b) at the interface

In the course of time, the water may migrate from the body of the set-cement to the brick thus allowing a progressive but very slow hydration of still anhydrous silicates.

The phenomenon is less pronounced as the initial water content of the brick is higher and its pores larger in size.

The hygrometry of the environment in contact with the side of the brick facing the set-cement or mortar plays an important role due to the evaporation resulting thereof.

When the composite sample is exposed to atmospheric carbon dioxide previous to total hydration of the set-cement, carbonation of ettringite and portlandite from the interface liberates water in significant quantities, thus resulting in an acceleration of hydration of the less hydrated zone.

The very uneven surface of the porous material, owing to the large number of capillaries opening onto it, would prevent any preferential orientation. The clinging is of an essentially mechanical type, through formation of ettringite crystals at the opening of the pores of the brick.

## II.2 - Case of porous materials completely embedded in the set-cement

Whenever the porous material is completely embedded in the set-cement, as is the case with porous lightweight concretes, identical phenomena occur, excepting the evaporation of water in the atmosphere. They are therefore much less strong due to their having limited absorption capacities of water by the aggregates. Moreover, this absorption reverses after a few hours, the aggregates yielding back all or part of the water absorbed from the set-cement. No delay in hydration by lack of water in the vicinity of the aggregates can be observed.

Attempts made to observe a transitional ring by the techniques previously cited were all unsuccessful. This can be mostly accounted for, by the very intricate geometry, on the surface, of the porous aggregates. Methods of study adapted to this case then remain to be elaborated upon and put to work.

It is also to be noted that with some light aggregates, the migration into the set-cement, by the diffusion of ions issuing from the partial dissolution of aggregates can have noxious effects on hydration. This is the case with pumice aggregates and Portland cement. VAQUIER et al. [13] noticed that under wet curing, setting did not occur. They ascribed this phenomenon to the freeing, by pumice, of  $\text{SO}_4 \text{Na}_2$  which considerably lowers the pH of the solution (to about 10) thus preventing setting to take place.

It should be pointed out, last of all, that, as against aggregates used in traditional concretes, porous aggregates are, except for new concretes, generally more deformable than the matrix. Under the action of external forces, isostatics move away from the aggregates and those, as well as their bond to the hydrated set-cement, are less stressed than the latter. There is no longer any risk of rupture at the interface. On the contrary, any crack occurring in the matrix is attracted by the aggregates.

## III - CONCLUSIONS

At the time of mixing, the non-porous aggregate becomes surrounded by a water-film several microns thick, and hydration occurs mainly in accordance with the mechanisms described by LE CHATELIER. Around these aggregates, a transitional ring appears, different in its composition and its structure from that of the body of the set-cement - more porous and lower in cohesion. The mineralogical nature of the aggregates is of major importance.

In contact with porous materials not completely embedded, the suction of the set-cement water by these materials plays an essential part in the formation of the bond.

Around the completely embedded porous materials (case of lightweight concretes) no zone of composition different from that of the body of the set-cement can be observed.

Numerous studies remain to be done, in order to clarify, among others, the natures of the components formed immediately in contact with non-porous aggregates, the influence of temperature, of admixtures, of slags and of pozzolanic materials. One can hope, by diminishing the porosity of the transitional ring, the size and the orientation of the crystals which develop thereon, to improve significantly the mechanical properties of concretes and their resistance to corrosive agents.

### **Durability**

**J. CALLEJA**

**IETCC**

**Madrid, SPAIN**

## 1. - GENERAL INTRODUCTION

Even when it is intended to apply the term DURABILITY referred only to CEMENT as component, it would be erroneous to mislead CONCRETE as compound, and so much so when durability of any component of concrete and concrete itself may be affected by any other component of it (sulfate-bearing aggregates, reactive silica, reactive silica, reactive silicate or reactive carbonate-bearing aggregates and alkali-bearing cements) ( 1 ). Moreover, the main and even the only finality of cements are cement derivatives, i.e., concrete in its different modalities.

Mechanical strength of concrete is not -not always should be- the only or the main factor to be considered. On the contrary, durability should be always a factor to be taken in due account as it greatly and some times decisively influences and determines the strength of concrete and the general behaviour and performance of it in each moment, at shorter or longer terms ( 2 ).

Concrete durability and the reverse concrete deterioration respond to very complex phenomena according to the very many causes and to their several possible combinations acting simultaneously or successively ( 3 ).

Anyway, durability, as referred to cement or to concrete, is a term which needs to be clearly and precisely defined. Several arbitrary and conventional definitions of it are possible and some of them have already been expressed.

Durability may be defined in a most general way as the capability of material to maintain its good behaviour and performance in safety conditions and in the foreseen service circumstances during the foreseen service time ( 4 ).

In a more specific manner, durability may be defined as the resistance of cement and concrete to either internal (intrinsic) or external (extrinsic) physical, physico-chemical or chemical actions ( 5 ) ( 6 ).

Whatever may be its definition, durability is a so broad matter that needs to be limited if it is to be treated within given disponibilities of time and/or space. So, as far as the purpose of this paper is concerned, durability is conventionally defined as the resistance of cement and cement derivatives -pastes, mortars and concretes- against external actions merely chemical in nature, acting only chemically on hydrated cement paste. Nevertheless, durability even defined as resistance to chemical attack, to so limitate in some way the broad general problem of it, is by far complex ( 3 ).

Consequently, the (in origin) physical actions on cement or concrete such as the freezing of absorbed or adsorbed water; the causes and effects of damages due to reinforcement corrosion -though chemical or electrochemical in nature and external or internal in origin-; the disruptive actions and effects owing to

volume changes of internal -though chemical- origin (free lime and periclase expansive hydration), or external -though physical- origin (expansion, shrinkage, swelling due to rapid and big changes of temperature and/or humidity), are deliberately discarded in principle and as much as possible, as considered not directly belonging to the content of the bare chemistry of cement, which is the main -the only- matter of this 7th Congress. Alkali-aggregate reaction could fit in the group of internal chemical actions, but very specific in character. Protection and protective materials and treatments are also obviously excluded.

Nevertheless, chemical, physico-chemical and physical -even mechanical- internal and/or external actions are so narrowly and indissolubly linked together, at least in practice, that not always is either possible or convenient to separate from one another and to take into consideration only some of them, neglecting the rest. On the other hand, most of work done and papers written on durability of cement and concret seem to show in average an eclectic position in this aspect. Unfortunately, according to the reality, neither "pure" actions (whatever their nature) take place, nor single unitary effects are observed in practice, but exceptionally. This reality implies an enormous complexity of durability problems and a huge difficulty to study and solve them, at least as far as the finding of general solutions is concerned. This has been -and perhaps still is- the aim of a certain number of research workers on durability, even as it has been defined above. And the question arises: is it possible to reach such a purpose?. Before attempting to give an answer let us try to evaluate the progress attained up to date, taking as a reference the ratio of definite knowledge gained and practical -technical- problems solved, to the time devoted, the persons involved and the papers written and published, in the general research work done on cement durability. Probably it could be said about it something similar to what has been opportunely said as referred to shrinkage ( 7 ): many hundreds -perhaps much more than a thousand- of significant papers dealing with durability have been published in the last fifty years, and some basic knowledge has been gained with them; but the real and practical durability of today's concretes is not very different from that of the concretes in the thirties. At least it is not better to the extent which would be expected, considering the effort done. But possibly the same thing to one or another extent could be also said as referred to expansion, swelling, reinforcement corrosion, alkali-aggregate reaction, high-alumina cement conversion and alkaline hydrolysis and so many chief problems within a more extended field of durability.

What does it mean?. First of all and simply that a high proportion of the total effort has been vain or but scarcely profitable. And why?. The answer cannot be so simple, but a certain number of reasonable causes could be mentioned: a) repetition of tasks

owing to lack of communication and coordination; b) discordant or even contradictory results -at least apparently- as attributed to the same of very similar experimental conditions, when in reality very different, but anyway very frequently not (or not sufficiently) specified; c) difficulty or impossibility to compare results obtained in conditions to be considered as different enough to permit an acceptable comparison; d) conclusions hardly admissible or even erroneous as a consequence of an incorrect or undue evaluation and/or comparison of results; e) conclusions drawn through unadvised criterions of simplification, extrapolation, generalization or exaggeration applied to what is complex, specific, particular or normal; f) a certain "orientation" of the experimental work from the very beginning of it in order to reach with a given (higher) probability some expected results. This latter possibility is obviously unconceivable and inadmissible in a pure scientific and technical work, but it is not so much so in some other type of applied "research", the results of which being -obviously- also published, when interests other than those concerning pure and true knowledge are involved.

Present knowledge slowly accumulated along the time on durability is nonetheless very valuable and literature is extremely copious even as referred only to chemical attack on cement by whatever aggressive medium. Periodically and recently compilations and summaries of the copious references found in the general abstracts have been made in a very conscious and efficient manner ( 1 ). But even if it is intended in such compilations to deal with durability as referred only or mainly to cement, it is impossible to neglect concrete, as mentioned above, as otherwise the survey would be limited and unrealistic. On the other hand, selective criteria must be applied, as the number of references collected is really very high ( 1 ) ( 8 ) ( 9 ) ( 10 ). This is the reason why, as pointed out, it is intended in this paper to deal only with the main and more common chemical aspects on durability.

Despite the superabundant literature on the item, many dark and dubious aspects still remain without an adequate answer, so that a satisfactory and complete doctrine summarizing the fundamental matter is far from being reached ( 3 ). Nevertheless, interest in concrete corrosion themes is permanent. In recent times research lines and directions have been exposed and proposed ( 11 ); attempts have been made to solve the difficult problem of describing the complex corrosion process on concrete ( 12 ); methods for quantitative analysis of such processes have also been described ( 13 ); and criteria for evaluating either the aggressivity of the environment or the concrete resistance to it, have been dealt with too ( 14 ).

When trying to evaluate consciously the relative influence of all kind of factors (physical, mechanical or chemical in nature) affecting the chemical attack on concrete and the corresponding chemical resistance of the material, a sort of disorientation arises from considerations found in the extense biblio-

graphy existing on the subject. The reason in the author's opinion may be the very different importance quantitatively given to such factors, depending on the various points of view based on several distinct mentalities or professionalities of the authors. So, authors in which an engineering formation predominates, "automatically" or "instinctively" tend to focus the problems from mechanical or physical standpoints rather than from chemical bases. And so, one tends to pay greater attention to density, homogeneity, compacity, porosity, permeability, etc., in connection with penetrability, diffusion, capillary suction and capillary raise, osmotic pressure, etc., referred to pore size distribution -maximum, medium and minimum pore size-, evolution of porosity, intercommunication and accessibility of the pore system, etc. All the main parameters of concrete and concrete materials such as cement content, cement fineness, water/cement ratio, aggregate grading, etc., are considered as factors determining the foregoing characteristics and properties of the concrete itself, as it is really the case.

On the other hand, authors possessing a more basically scientific -perhaps chemical- formation will naturally tend to emphasize the importance of factors of chemical nature, such as composition of cements, reactivity of aggregates, etc., in connection with potential and actual reactions in any of the materials or between them, or even of them with external and/or internal aggressive substances. So, one tends to consider all these factors at least as important coadjuvants of the characteristics, properties and performance of concrete, as is really the case too.

But in any case -in both cases- the effects such as losses in weight and/or in strength either by leaching of soluble products or by formation of non-hydraulic compounds with softening of the resistant structure; or by expansion (crystallization and crystal-growth pressure cracking) causing disruption; or by reinforcement (electro) chemical corrosion, etc., must be equitatively considered at the light of all the possible causes and influencing factors.

Dealing with chemical attack on concrete very many authors begin, very many others finish -or both- invoking the compactness of the material as the first and by far the main condition to resist. This is really so to such extent that it is superfluous to afford particular references. Thus, the nature of the cement as far as its intrinsic resistance is concerned, is considered in many cases as secondary or not operative, except in cases of leaner mixes, so that a high compacity obtained through a high cement content permits for instance to use with similar results cements either of high or low content in  $C_3A$  (in sea-water attack), whereas lower cement contents impose the use of specifically resistant cements. Moreover, when differences in behaviour not easy -or not possible- to be explained are detected, variations in compacity are generally invoked as a valid explanation ( 15 ) ( 16 ).

A clear example of conscious eclecticism to be applied in this sense has still been exposed (17) when considering that kinetics of gas and water penetration in concrete, depending on its structure as determined by porosity and penetrability of aggregates and paste, in turn determining absorption, capillary rise and diffusion in the material, is decisive for durability. So that the knowledge of true coefficients of permeability, either correctly calculated or determined in laboratory tests carried out duly in real conditions, is absolutely necessary (17). But absorption tests, permeability tests and capillary rise tests must be designed on scientific bases in such a way that they do permit to describe the actual behaviour of a porous system as far as water penetration in concrete is concerned (18) (19). On the other hand, it must be added that not only physical factors as homogeneity, porosity, permeability, absorptivity, capillarity, etc., with their respective features and implications are important for durability; cement composition in anhydrous state, degree of hydration of cement paste, bond strength between paste and aggregates, and several others, are also factors affecting decisively concrete durability, which so becomes a very important but most complex and difficult problem (20), either in real practice or in the field of more basic laboratory research work.

On the basis of the foregoing considerations the task of this paper will mainly be centered on the more outstanding specific aspects of the chemical attack on cement and concrete, and on the chemical resistance of concrete to external aggressivity of them on it.

## 2. - TYPES OF CHEMICAL ATTACK ON CONCRETE

First of all it must be said that chemical attack on concrete needs water or at least humidity to proceed, and so the very many different aggressive media are mainly liquid (aqueous solutions): soil-waters, surface-waters, sea-waters, waste (industrial)-water, etc., containing acids, sulfides, sulfates, chlorides and in general salts of sodium, potassium, calcium, magnesium, ammonium, etc., in each case, and even organic compounds.

Much has been written on mechanisms of attack on concrete. Two main types of such mechanisms have been simply proposed for interaction between hardened cement paste and aggressive media in contact with it (2): dissolution (leaching, lixiviation) of water soluble products formed first on surface and consecutively in mass as the attack progresses inwards (21), and expansion. Dissolution may be caused in acid or soft waters and/or by ion-exchanging salt solutions. In turn, it causes a loosening and softening of the structure of the cement paste. Expansion may take place when sparingly soluble products are formed and crystallization pressure due to crystal growth of salts acts causing structural disruption. This is the case of sulfates, ettringite and/or thaumasite formed successively (2) (21).

The possibility and the intensity of chemical attack depend, on the one hand, on solubilities, concentrations and dissociation constants of aggressive media; on the other hand, on the same parameters corresponding to the reaction products, all referred to ordinary, "normal" or stagnant conditions. Extraordinary or "abnormal" conditions such as higher temperatures, freezing, water pressure or renewal of aggressive agents, as well as mechanical actions, may accelerate and intensify the chemical attack (2).

So, in such conditions the concentration or proportion of an aggressive substance in an aggressive medium is not the only parameter determining the rate, intensity and effects of any specific attack. This depends also on other factors as those mentioned, so that a given concentration may behave as innocuous or as highly aggressive (3). This is one reason of the uncertainty (and therefore of the lack of agreement) concerning the establishment of general limits of concentration for safety. It also explains the -to a great extent- probabilistic character of the chemical attack. On the other hand, not always the action of an aggressive substance is proportional to its concentration. Moreover, changes in it may affect even qualitatively the process involved in the attack. This is, among many others, a possible cause of failure of the accelerated methods of testing based on high concentrations of aggressive media (3).

Many types of chemical attack on concrete may be considered according to the specificity of the aggressive agent and its chemical nature. From this latter point of view, either inorganic and organic types of aggression may be foreseen, or acid, basic and saline attacks can be considered. Schematically this is very simple, but the reality is much more complex, as various simultaneous or consecutive chemical actions may take place in an aggressive process.

From equilibrium solubility studies in the system C-S-H it has been shown that  $\text{Ca}(\text{OH})_2$  is the least stable component of the hydrated cement paste, its solubility depending on the pH-value. Pore liquid in the paste as far as its  $\text{Ca}^{2+}$  and  $\text{OH}^-$  ionic concentrations are concerned, is in equilibrium with  $\text{Ca}(\text{OH})_2$ , provided this is present and in contact with the liquid phase. Otherwise, equilibrium establishes between liquid phase and  $\text{C}_x\text{S}_y\text{H}_z$ , the more complex solubility of the latter depending on the x/y ratio (22).

Parameters governing a pure acid attack are the acid strength and the concentration, i.e., the pH-value (22) (23). So, acid attack on cement acts on bases and basic salts formed in hydrated paste and causes deterioration provided that soluble salts are formed in it and leaching of them take place. In the case of organic acids it seems to be so to such extent that the order of aggressivity more or less coincides with the order of solubility of salt formed (23). But acid attack proceeds in a different way if less soluble salts are formed, which in turn can react with other

hydrated components of the paste -this is the case of sulfuric acid attack forming gypsum ( 24 )-.

The great influence of the pH-value is the reason why it is to be expected that acid waters of low pH ( $\leq 4.5$ ) attack very strongly concretes, whatever their cement may be, but more particularly if it is a portland cement. To such extent it is so, that as far as mineral acid attack on cement is concerned it has been roughly stated that none of the cements used resists the action of waters with pH-values lower than 4 ( 25 ) and even lower than 5 ( 23 ); that ordinary portland cements may resist without heavy damages waters with pH-values higher than 6, and that high-alumina cements may resist waters with pH-values between 4 and 6 without any special protection ( 25 ).

But not only the pH-value as such is to be considered in the attack of cement by acids; the rate of their diffusion and/or replenishment from the surrounding environment (for instance, soil), particularly if hydrostatic pressures are operative, must be taken into account. Possibilities of removal of the more or less soluble reaction products must also be considered in practice ( 26 ). This is another of the innumerable cases in which factors other than those closely related to the chemical attack itself influence its kinetics and determine the rate and the extent of the damage, the chemical parameters of the aggressive process being constant.

Sulfuric acid attack from bacteriological origin is a typical one acting on the surface of sewer concrete pipes, producing softening by loss of adherence between aggregate and cement paste. Destruction of concrete is caused by complex reactions of acid with hydrated lime and other basic hydrated compounds of cement to form sulfates (mainly of calcium), amorphous silica and calcium sulfoaluminates (ettringite). Sulfuric acid is produced by a bacteriological oxidation -at normal temperatures- of hydrogen sulfide, which in turn is formed by a bacteriological reduction of sulfates ( 24 ). Oxidation of hydrogen sulfide needs an almost neutral pH which can be reached through carbonation (weathering) of the fresh hydrated cement paste. Deterioration due to this type of acid attack is produced in two steps: first, formation of gypsum; second, formation of ettringite. So, portland cements low in  $C_3A$  are, at least in theory, more resistant to this type of aggression. In fact, it has been stated that there is little difference in behaviour and performance of ASTM cements of type I and type II. This seems to indicate that disruption caused by crystallization of gypsum formed in the first step may have a decisive importance ( 24 ).

Basic attack on concrete takes place when caustic bases such as sodium hydroxide penetrates the cement paste and undergoes a carbonation, or when alkali carbonates directly penetrate, particularly if penetration continues and wetting and drying alternations take place. In the case of sodium hydroxide and/or sodium carbonate penetration, hydrated sodium carbonates may be formed and damage may be

produced by crystalization and crystal growth pressure ( 27 ).

Saline attack produced by salts other than chlorides and sulfates may take place and produce effects depending on the chemical nature of the salt involved and on its interaction with hydrated cement compounds. For instance, ammonium carbonate, fluoride and oxalate form fairly insoluble products with cement paste and consequently they are not harmful to it ( 27 ).

Destructive effects may be produced by nitrates through the formation and crystallization of calcium nitroaluminates in the pores of the cement paste. The corrosive action depends on the nature and concentration of the nitrate involved, on the time of contact and on the nature of the cement. In this respect, pastes made with blast-furnace slag cements with slag contents higher than 70 % have shown higher relative resistances to nitrate attack. Portland cement pastes are relatively less resistant ( 28 ).

A special type of attack with internal origin in concrete is that produced by sulfuric acid and/or sulfates formed by oxidation of sulfides -generally iron sulfides (pyrite and marcasite  $FeS_2$  and pyrrhotite  $Fe_{x-1}S_x$ - contained in some aggregates or -calcium sulfide- present in slag aggregate or in blast-furnace slag cements. Oxidation may take place prior to the use of the material or once it has been incorporated to concrete ( 29 ).

Saline attacks more common are those involving chlorides and/or sulfates (sea-water). They are specifically treated. Nevertheless, mention must be made here on the influence of cations and anions, as saline components, in general attack, as well as in some specific type of attack as for instance that of sulfates.

In this latter respect three types of cations may be considered: those forming soluble hydroxides; those forming sparingly soluble hydroxides; and those forming volatile or neutral compounds.

The former -alkali cations- form gypsum (expansive or not by crystal growth pressure, depending on the initial sulfate concentration). In addition, they increase the  $OH^-$ -ion concentration lowering that of  $Ca(OH)_2$  in solution and facilitating an accommodative expansion process. On the other hand, at the same time the increase of  $OH^-$ -ion concentration facilitates the attack of other cement constituents and reduces the strength of the paste ( 30 ).

Cations forming low solubility hydroxides (earth-alkali cations as  $Mg^{2+}$ ) form expansive gypsum and hydroxide gels, some of them potentially expansive and some others potentially protective by coating; specially in the case of compact pastes rich in cement.

The third group of cations ( $NH_4^+$ ) neither favour accommodative processes nor protect by coating. They may cause a strong attack not only through expansion, but also by solubilization of cement components ( 30 ).

But, if it is true and well known that cation greatly influences the action and the corresponding effect of sulfate attack on cement, the reciprocal seems to be also true: anion influences the action and effects of cations, particularly those of  $Mg^{2+}$ . In the case of attack by  $MgCl_2$  the formation of the FRIEDEL's salt retards the corrosion of cement, so that portland cements with no  $C_3A$  are more affected than ordinary portland cements. Whereas in the case of attack by concentrated  $MgSO_4$  solutions ordinary portland cements, independently of their  $C_3A$  content, may be stable, due to a rapid formation of gypsum and gel products which difficult and retard the penetration of  $Mg^{2+}$  and  $SO_4^{2-}$  ions (31).

As far as organic matter attack on cement is concerned, it could be made the following general consideration: if chemical attack on cement and concrete is a very difficult theme, it is much more so when the aggressive medium is organic matter, as most commonly this matter is a complex mixture almost never sufficiently well defined as far as its composition is concerned. So, empiricism dominates the studies and research work on chemical resistance of concrete against aggressive matters of organic nature, much more than when dealing with inorganic attack. An example of the complexity inherent to the organic attack on concrete, even when the aggressive product can be precisely identified with a well defined chemical compound, is offered by the deterioration caused by urea, or better, by its hydrolytic products in alkaline solutions. The damaging effects are attributed to dissolution (even through the hygroscopicity of the urea), penetration, crystallization and disruption, i.e., to a series of phenomena physical in nature. But really, the exact nature of the chemical attack of urea in concrete is unknown (32). It seems not to be exaggerated to think that much more difficulties and consequently much more lack of knowledge exist when organic aggressives are more complex and their composition is variable and not well defined. Nevertheless, these are the cases actually present in practice.

On the other hand, it is difficult to find a method of general and uniform application to assess the attack caused on concrete by organic compounds or matters. Only on the basis of wide laboratory and industrial empirical experience has been possible an attempt to group organic aggressives into three classes: a) compounds causing reversible deterioration; b) water-soluble and non dissociable products forming calcium compounds; and c) water-soluble and well-dissociable compounds (33). This classification has been introduced in some national standards (for instance, in the new Hungarian Standards).

Some regularity seems to exist in the case of attack caused by organic acids, in the sense that the order of their aggressivity more or less agrees with the order of solubility of their salts formed in the attack (23). Phenols in aqueous solutions affect concrete as weak acids, so that water containing more than 1000 mg/l of phenols should be considered aggressive (34).

Carboxylic acids, alcohols, esters, etc., may attack cement paste depending on their ability to penetrate rapidly into the concrete, and on their more or less intensive acid properties. Dichlorobutene, for instance, has a pronounced acidic behaviour, so that it fully attacks the  $Ca(OH)_2$ , leaching it in the form of  $CaCl_2$  (which in turn causes reinforcement corrosion) (1). This might unduly induce to simplify, in the way of attributing the main capacity of attack by organic compounds to their acidic properties and to their possibility to form soluble calcium salts, particularly  $CaCl_2$  (in the case of chlorinated compounds).

### 3. - CARBONATION

Carbonation covers all the actions carried out and effects caused by carbon dioxide on cement and concrete. Carbonation may be spontaneous -that achieved by normal atmospheric  $CO_2$ - or forced -that artificially created by "pure" or "concentrated"  $CO_2$  even under pressure. Carbonation may act on anhydrous or hydrated cements, neutralizing their basic calcium compounds.

As far as hydrated cement pastes are concerned, it is obvious that the compound more susceptible to carbonation is calcium hydroxide. But it is also well known that other hydrated compounds -every hydrated compound (35) - can be affected to some extent by carbonation, being decomposed to form finally calcium carbonates and hydrated silica, alumina and ferric oxide, as ultimate products of a total carbonation (36) (37) (38) (39). For instance, total carbonation of tobermorite gels according to the schema

has been suggested that proceeds by steps:

A proof that compounds other than  $Ca(OH)_2$  may undergo simultaneous carbonation is that the decrease in non-evaporable water of cement after carbonation is lower than corresponding increase in carbon dioxide, taking into account that there is a correspondence mol-to-mol in the fixation of  $CO_2$  and the liberation of  $H_2O$  when  $Ca(OH)_2$  carbonates (42) (43). So, carbonation affects to hydrated and even unhydrated compounds, for instance  $C_3S$ , tending to form calcite with the hydrated products of  $C_3S$ , and vaterite with unhydrated  $C_3S$  (44). Alkalies and aluminates carbonate very fast and fast, respectively (35).

Different opinions have been exposed as to the "selective" action of carbonation on hydrated phases of calcium silicates and on cement pastes, as well as in connection with the products formed in it according to the degree of hydration of the starting products. It has been stated that CSH is attacked and decomposed by carbonation, whereas hydrogarnets are much

more resistant to it ( 1 ). XRD and IR data show that vaterite is formed in greater amount than aragonite when the degree of hydration of  $C_3S$  previous to carbonation is higher ( 45 ) ( 46 ). Carbonate phases have been detected by IR in carbonated CSH gel together with amorphous silica, the hydrated calcium silicate tending to disappear by further carbonation, whereas portlandite is still present, as XRD reveals. This seems to indicate that carbonation acts on hydrated calcium silicates rather than on portlandite, according to

Probably this is not the usual case ( 47 ) ( 48 ) ( 49 ) ( 50 ).

Other opinions consider that carbonation of cements affects preferentially silicates and aluminates, all the forms of calcium carbonate being formed in it, as well as ettringite ( 51 ). But on the other hand, other results conclude that ettringite is transformed into calcite under the action of carbonic water ( 45 ).

It has been assumed that calcium ions in hydrated products other than  $Ca(CH)_2$  may be in two forms: one relatively susceptible, and the other non-susceptible to carbonation. The former reacts topochemically with  $CO_2$ , but remaining attached to the gel structure. So, only a small part of the hydrated compounds other than CH may undergo a slow carbonation ( 36 ) ( 48 ) ( 52 ). This is a chemical reason why the situation of full carbonation is practically never reached in concrete; another (physical, mechanical) reason is that many factors hinder the carbonation progress.

Not always concrete carbonation has been related to free CH and, consequently to different types of cements involved. Carbonation penetration in blast-furnace slag cements and even in portland cement is determined by permeability of concrete, so that a high content of CH - as in the case of portland cements - cannot always protect concrete from carbonation, as has been stated ( 53 ).

As to the form in which silica liberated by carbonation appears, amorphous silica insoluble in hydrochloric acid has been suggested ( 38 ) and confirmed ( 54 ) ( 55 ), the ratio of soluble to insoluble residue of cement paste in hydrochloric acid decreasing with the intensity and degree of carbonation ( 40 ).

Calcium carbonate may appear as mixtures of vaterite, calcite and/or aragonite ( 35 ) in different proportions according to variable conditions. Hydrated alumina, firstly amorphous, is transformed afterwards into bayerite and finally into gibbsite ( 56 ). Gypsum may also appear together with aragonite, as result of carbonation of calcium sulfoaluminates ( 35 ).

Carbonation of concrete depends on many internal and external factors such as relative humidity, temperature and pressure, concrete porosity and permeability, depending on water/cement ratio, cement content, nature and fineness and secondary components of the cements ( 15 ) ( 35 ) ( 37 ) ( 53 ) ( 56 ) ( 57 ) ( 58 ) ( 59 ),

as well as on hydration conditions, age, strength and moisture content of the concrete. For instance, carbonation of normal or of hydrothermically hardened concrete is different, due to the different nature and composition of the calcium silicate hydrates in each case, and to the corresponding different structure of the paste ( 37 ) ( 40 ).

As far as carbonation of calcium silicate hydrates and its effects are concerned, the composition and the structure of the hydrated silicates are, as mentioned, particularly important. At first sight one could think that the higher the basicity of the hydrated silicates, the faster and deeper the effects of carbonation. Nevertheless, carbonation of less basic (tobermoritic) calcium silicate hydrates, in spite of their high density, is much faster than that of the more basic and less dense ones, as for instance those formed in hydrothermal treatments of cements ( 60 ) as mentioned ( 40 ). The explanation given is based on the high specific surface and the laminar structure of the less basic hydrates, together with the different nature of carbonation products, mainly  $CaCO_3$ , which depends in turn of the carbonation conditions; low concentration of  $CO_2$  and slow carbonation give large calcite crystals with better structure, whereas at much higher concentrations of  $CO_2$  small crystals equal in size are formed, which give place to a worse structure. This affects the strength as well as the degree of crystallization of the calcium silicate hydrates undergoing carbonation. In the case of tobermorite, the less crystallized product forms loose calcite crystals, whereas the more crystallized one forms large solid and strongly linked crystals ( 60 ).

Moreover, there is a great difference in initial carbonation of cements with lower early strength and high "afterhardening", on the one hand, and that of cements with higher early strength and lower afterhardening, on the other hand ( 53 ). This difference tends to disappear with the age of the concrete. In any case, taking into account the influences of permeability, cement content, strength development, etc., on carbonation, it has been stated that it is safer to make concretes with sufficiently high contents of normal or even slow-hardening cement, than concretes with lower contents of high-early strength cements, provided that concretes in both cases have similar initial strengths ( 53 ).

Compaction is also decisive for carbonation, as, depending on it, a retardation of 20 to 25 times in reaching a given depth may be observed. Assuming theoretically that the amount of  $CO_2$  penetrating to the depth  $x$  at a given time  $t$  is inversely proportional to  $x$ , i.e., that the time  $t$  required to carbonate (neutralize) the concrete at the depth  $x$  is  $t = k \cdot x^2$  (the constant  $k$  depending on concrete characteristics and mainly on compaction), it has been found for a concrete with  $w/c = 0,60$  poorly compacted that:  $t$  (years) =  $7.2 \cdot x^2$  (cm), whereas for the same concrete thoroughly compacted  $k = 167$ . So,  $167/7.2 =$  about 23 ( 36 ). In practice it has been observed that carbonation may be retarded by full compaction of dry-consistent concretes, as carbonation proceeds along voids, and easier and faster in concretes.

of higher w/c ratios and lower cement contents.

As to the influence of the moisture content, soaked concrete or periodically rain moistened concrete is more resistant to carbonation than concrete stored in normal conditions, as far as relative humidity is concerned (61). An optimum moisture content in concrete is necessary for carbonation (35).

As far as ambiental circumstances are concerned, relative humidity is equally decisive, as carbonation advances at very high rates for RH values between 50 and 75 % (being much slower for RH 75-100 % or 0-45 %). The reason is that another optimum humidity is necessary (35): values higher than optimum fill the cement pores with water and CO<sub>2</sub> must first dissolve and then diffuse to penetrate, which is much slower; values lower than optimum retard the process, probably because at such lower values water has not the liquid characteristics corresponding to ordinary water for dissolving either Ca(OH)<sub>2</sub> or CO<sub>2</sub> (36), according to old ideas (52) (62).

As far as carbonation kinetics is concerned, several empirical equations have been proposed, in function of carbonation speed (depth of carbonation -cm, mm-) or of carbonation intensity (amount of CO<sub>2</sub> fixed -grams- versus time -from days to years-), w/c ratio, compressive strength and some experimental constants depending on cements, degree of neutralization, induction period, etc. Speed of carbonation of concrete depends on the nature of the cement and on the porosity of its paste -indirectly on the cement fineness, the cement content and the w/c ratio- as intrinsic factors of concrete. Also, as mentioned, on the relative humidity as extrinsic factor (57) (59).

A summary of much of the mentioned equations, as well as an enumeration of the methods and devices used to determine the depth of carbonation has been recently exposed (40). Among such methods and devices can be mentioned those consisting on coloured indicators (63), radioactive tracer elements and neutronic radiography (64), porosity measurements (65) (66) and diffusion techniques (67), all of them summarily described as well (40).

One of the last equations proposed for carbonation kinetics, very similar to others previously suggested has been  $x = a \cdot t^{1/2} + b$  (35) (37) (53), in which  $x$  (cm) is the depth of carbonation,  $t$  (years) the time and  $a$  and  $b$  coefficients variable with a great number of factors and parameters. Other equations relate the amount of CO<sub>2</sub> fixed to the square root of CO<sub>2</sub> concentration (45).

The depth of carbonation of a fully compacted and normal cured concrete is largely determined by temperature (45) and by the w/c ratio in an almost linear relationship (61), through other opinion is that optimum w/c ratios -low in general- favour maximum carbonation (45). Depth is also determined by the type of cement: other things equal, carbonation penetrates deeper in concretes made with blast-furnace slag cements and pozzolanic cements (and so much so the higher their contents of pozzolan or slag) than in port-

land cement concretes. The reason seems to be the different proportion of "carbonatable" products in portland cements and in cements other than portland (61) -lower content of Ca(OH)<sub>2</sub> in the latter-. These relationships are qualitatively valid either for spontaneous outdoor or indoor carbonation, or for accelerated carbonation in chamber. In general, blended cements containing slags, pozzolans or fly-ashes carbonate faster than portland cements, and ordinary portland cements quicker than high-early strength portland cements. In fact, in blast-furnace slag cement concretes or in pozzolan cement concretes depths of carbonation have been observed one and half to twice than those corresponding to similar portland cement concretes (36).

Studies on artificial carbonation of hydrated as well as anhydrous portland cements submitted to later hydration have been recently carried out. In the case of hydrated cements ettringite, portlandite, vaterite, calcite, anhydrous C<sub>3</sub>A and (in short term hydration) gypsum are present. The non-carbonated phases are in proportion lower than in the case of not carbonated cements. As far as ettringite is concerned, it has been suggested that a decomposition process such as:

could take place (49) (50). If CO<sub>2</sub> acts on the same cement paste cured in humid conditions during much longer period, portlandite and ettringite are present in lower proportions, whereas calcite and vaterite show a considerable increase. Moreover, monosulfoaluminate present in not carbonated paste cured in the same conditions disappears. This has been attributed to a decomposition by CO<sub>2</sub> similar to that suggested for ettringite (49).

In the case of carbonation of anhydrous cement previous to its hydration, anhydrous C<sub>3</sub>A, ettringite, carboaluminates, portlandite and calcite have been found in pastes cured during short periods; in addition, vaterite and monosulfoaluminate are also present but anhydrous C<sub>3</sub>A is absent in pastes cured during longer periods. Carbonated phases are more abundant in this latter case. On the other hand, carboaluminates have not been detected in pastes of the same portland cement previously submitted to a longer and more intensive carbonation. It has been also suggested that water liberated in carbonation (from Ca(OH)<sub>2</sub> mol-to-mol with respect to CO<sub>2</sub> fixed) according to:

aids to the hydration. Nevertheless, carbonation of anhydrous cement seems to slow the hydration in bulk. This is patent in the lowering of tensile strength of the corresponding pastes of carbonated anhydrous cements (48) (49) (50).

Carbonation mechanisms in clinker minerals -pure compounds- seem to lead to products of different nature and texture, depending on conditions and parti-

cularly on humidity. Early carbonation of  $C_3S$ -solid solutions gives granular products which further on turn into calcite, except in low humidity conditions. At early carbonation whisker products are formed in the case of  $\alpha$ - $C_2S$  and angular plates are developed in the case of  $\beta$ - $C_2S$ , which grow to form stick structures in the case of  $\beta$ - $C_2S$ . All these formations correspond to the simultaneous formation of aragonite accompanied by vaterite (68).

Carbonation affects in one or another sense to several properties of cements themselves and of concretes, depending on particular conditions and on the fact that it may act spontaneously or in a forced and controlled manner, either on anhydrous or on hydrated products with different degrees of hydration (40) (48).

Carbonation of hydrated cement may be beneficial in some cases (69). So, it may enhance strengths - which is known since long time ago and has been more and more confirmed (38) (40) (70) (71) (72) (73) (74) (75); it may also improve the durability in different aggressive media (75) (76) (77) (78) (79) (80). In fact, either spontaneous or previously induced carbonation of concrete may protect it to some extent against acid attack in a similar way - and by similar reasons - as does the use of limestone aggregates in concrete (23). Benefits may extend to resist aggressive sulfate waters, mainly if the attack is produced in conditions of total immersion, for in alternative immersion a cracking may be produced depending on the  $C_3A$  content of the cement. This is attributed to differential shrinkage due in turn to differences in deformation moduli of external carbonated and internal non-carbonated zones of specimens (59) (81). Improvements in sulfate resistance may also be obtained by superficial carbonation of sufficiently consolidated concrete (27) (77).

In alkali sulfate attack on concrete leaching of lime may take place to some extent, which increases alkalinity:

if carbonation does not take place:

But more intensive carbonation could form thaumasite and plazolite, specially at much longer terms (82).

As far as shrinkage is concerned, and old knowledge confirmed along the time indicates that carbonation seems to increase it, depending on previous curing conditions and drying treatments of concrete, and also on the conditions of the carbonation itself (75) (83) (84) (85). Carbonation is worse when acting on fresh, not yet sufficiently consolidated concrete, as softening of its surface takes place (27).

Artificial (provoked) carbonation of anhydrous portland cements impairs them causing increases in their water demand for pastes of normal consistency and

in the time of setting (more for final than for initial set); it also causes decreases in specific surface, compressive strengths (specially at shorter terms) and heat of hydration (48). The action depends on relative humidity (being stronger at RH of 60-70 % than of 30-40 %). It manifests chemically in the formation of calcium carbonates, carboaluminates and carbo-silicates (51).

At higher RH values more ettringite and calcium carbonates and less carboaluminates are formed. It has been suggested that this is probably due in part to the process (51):

As "aeration" is intended the atmospheric action (spontaneous or not) on anhydrous cements through  $CO_2$  and  $H_2O$ .  $CO_2$  content in the air may vary in a range from 1 to 10, between values of 0.01 to 0.1 per cent in volume (0.03 in average) (35). Air moisture expressed as relative humidity may vary between very broad limits from low RH % to RH 100 %. Both  $CO_2$  and  $H_2O$  in air may act conjointly on anhydrous cements, so that their components may undergo either a partial hydration or (and) a carbonation depending on the chemical nature and fineness of cements. Studies based on IR spectroscopy on anhydrous portland cements submitted to humid atmosphere have revealed that hydration and carbonation may perhaps be interpreted as follows:

Terms "rapid" and "slow" are relative. Processes (II) and (III) are respectively controlled (other things equal) by diffusion of moisture through hydrated products and by protection afforded by calcium carbonate covering particles and closing their pores. Process (III) could explain the tendency of C and CH to disappear by aeration of cements, though it could be also explained (in the case of a strong humidification of cement) by a process such as:

as alternations observed in IR-bands corresponding to water and gypsum coincide with the formation of ettringite. On the other hand, strong aeration seems to affect to the ferritic phase, lowering its A/F ratio to form ettringite (48).

Carbonation may affect to high-alumina cements during and after their hydration in such a way that in  $C_3AH_6$ , 2, 4 or 6 water molecules may be gradually replaced by 1, 2 or 3 molecules of  $CO_2$  to form successively " $CO_2$ -hydrogarnets" such as  $C_3ACH_4$  and  $C_3AC_2H_2$ , and finally  $CaCO_3$  in a matrix of  $Al(OH)_3$  (86) (87).

## 4. - CARBONIC WATER ATTACK

Almost pure waters -natural acid waters, but not highly carbonic mineral waters- from mountains and snow melting may be aggressive, not only by their pH-value, but mainly by their contents of "total", "excess" and particularly "aggressive" dissolved carbon dioxide, and by their "temporary" -calcium bicarbonate in solution- and "permanent" hardness.

All "pure" waters contain a certain amount of "total" dissolved  $\text{CO}_2$ , depending on ambiental conditions. A part of it is "fixed" as calcium bicarbonate; another part is "free". In turn, a part of this latter -"equilibrant"  $\text{CO}_2$ - maintains calcium bicarbonate in solution, according to the equilibrium:

Free carbon dioxide in the form of carbonic acid, in excess over the amount needed to maintain the equilibrium -i.e., the difference between "total free"  $\text{CO}_2$  and "equilibrant"  $\text{CO}_2$ : "excess"  $\text{CO}_2$ - may attack and dissolve calcium carbonate, if the solution is not saturated with calcium bicarbonate, shifting the equilibrium to the right. But this attack progresses only up to reach saturation in calcium bicarbonate, so that only a part of the "excess"  $\text{CO}_2$  (the so-called "aggressive"  $\text{CO}_2$ ) acts more or less depending on the lower or higher initial concentration of  $\text{Ca}(\text{HCO}_3)_2$ . The "remainder" dissolved  $\text{CO}_2$ , if any, does not act in this way. Conversely, if "total free"  $\text{CO}_2$  in solution is less than the corresponding "equilibrant"  $\text{CO}_2$  -as is the case in "incrustant" (non-aggressive) waters-, the equilibrium shifts to the left and calcium carbonate precipitates. Consequently, the equilibrium determines in each moment the aggressivity of a carbonic water and hence the possible extent of its attack on calcium carbonate.

Excess  $\text{CO}_2$  of aggressive waters may attack  $\text{Ca}(\text{OH})_2$  from cements, but calcium carbonate formed precipitates in the pores of the paste. This is a way to compact concrete and, consequently, carbonation by carbonic waters may have a beneficial effect for concrete, provided that no leaching of calcium bicarbonate occurs and attack stops by a compaction effect near to the surface of the concrete (23) (27).

Anyway, all the "excess"  $\text{CO}_2$  can be considered as aggressive for concrete and a considerable leaching of lime is the outstanding result of an intense and continuous carbonic acid attack through aggressive carbonic water. (88).

A schematic exposition of all the preceeding relationships has been developed (23), which slightly modified could be presented as follows:

$$\text{Total } \text{CO}_2 = \text{fixed } \text{CO}_2 + (\text{total}) \text{ free } \text{CO}_2 \quad (\text{I})$$

$$(\text{total}) \text{ free } \text{CO}_2 (\text{I}) = \text{equilibrant } \text{CO}_2 \quad (\text{II}) +$$

$$+ \text{excess } \text{CO}_2 \quad (\text{III})$$

$$\text{excess } \text{CO}_2 (\text{III}) = \text{aggressive } \text{CO}_2 + \text{remainder } \text{CO}_2.$$

Considering excess  $\text{CO}_2$  as aggressive for cement, classification of carbonic waters as far as attack to concrete is concerned, may be as follows (23):

$$\begin{array}{lll} \text{when } \text{I} > \text{II} & \text{III} > 0 & (\text{aggressive water}) \\ \text{I} = \text{II} & \text{III} = 0 & (\text{equilibrated water}) \\ \text{I} < \text{II} & \text{III} < 0 & (\text{incrustant water}) \end{array}$$

It follows that for a given total  $\text{CO}_2$ , the higher the calcium content in water (hardness) the lower its aggressivity. This is specified in standards and recommendations in terms of "nul", "very weak" (or negligible), "weak", "strong" and "very strong" aggressivity, according to the content of aggressive (in this case "excess")  $\text{CO}_2$  -mg/l.- It could be added that a sure and serious attack is to be expected when aggressive (excess)  $\text{CO}_2$  concentration is higher than 60 mg/l (23).

So, natural water aggressivity depends conjointly on pH, on lime in solution and on aggressive (excess)  $\text{CO}_2$  content in it. The aggressivity may be lower at lower pH-values if the initial concentration of calcium bicarbonate in water is higher; conversely, it may be higher at higher pH-values if the initial concentration of calcium bicarbonate is lower. In sum, lower pH waters (if highly mineralized: with much dissolved CaO) may be less aggressive than waters of higher pH (if less or not mineralized) (25) (27).

Other dissolved salts may modify quantitatively the relationships so far exposed, as calcium salts increase and alkali salts decrease the dissolved carbon dioxide required to maintain equilibrium, so that for given equilibrium conditions the aggressive  $\text{CO}_2$  and the corresponding attack is lower in calcium solutions -for instance, in the presence of gypsum in solution-, and higher in sodium or potassium salts solutions (27).

Furthermore, other factors which may modify the extent (intensity) and the speed of the attack are the renewal of aggressive  $\text{CO}_2$  of waters containing it and the percolation of carbonic waters through concrete (25). In practice, and other things being equal, attack on concrete and concrete resistance to carbonic aggressive waters depend conjointly on the thickness of the concrete member attacked and on the time of action of the aggressive water (89). Thickness and time could be considered as conjugated parameters as far as effects and importance of the damages caused by carbonic waters are concerned.

Carbonic compounds present in water may influence other types of aggressivity on cement. For instance, sulfate attack depends on sulfate concentration and also on the pH of the aggressive media, so that when both -and even the  $\text{HCO}_3^-$ -ion concentration- change, it is difficult to explain the aggressive action on the basis of only one unitary process of attack. In the case of a sulfate-bicarbonate combined action, corrosion products such as ettringite, gypsum and calcium carbonate (calcite) are formed in three main different zones from the not yet attacked surface of cement paste outwards, as follows: a first inner zone where sulfate action begins, in which the amounts

of ettringite and gypsum increase, and portlandite decreases outwards to a minimum; a second zone in which ettringite and gypsum have reached their maximum concentration and the amount of portlandite increases to some extent; a third zone in which  $\text{Ca}(\text{OH})_2$  decreases to a practically null value, gypsum and ettringite also decrease, and the amount of  $\text{CaCO}_3$  increases to a high value (90). From thermodynamic considerations to explain the formation of ettringite and that of gypsum it has been concluded that both may take place together, predominating the latter when cement is richer in  $\text{C}_3\text{A}$ . The rate of penetration of the attack and the absolute and relative thickness of the zones depend on the rate of diffusion of  $\text{SO}_4^{2-}$ -ions, which in turn depends on the chemical nature of the cement paste (90).

Similar thermodynamic considerations and calculations have also permitted to determine the (relative) stability of hydrated cement minerals and corrosion products in terms of their solubilities in aggressive media, depending on the composition (anions, cations, pH) of their saturated solutions. So, further experimental results have confirmed the theoretical provisions as to the formation of calcite and gypsum in the surface attack of cement paste by simultaneously carbonic and sulfate waters (91).

#### 5. - ALKALI-CARBONATE REACTION

This type of reaction involving alkalis of cement affects to some carbonate rock aggregates, as for instance very fine grained dolomitic limestones containing clay, which are reactive and expansive. The problems in this field seems to be to differentiate by suitable methods expansive and non-expansive, among reactive rocks (27) (92).

In the expansive reaction considered as a "dedolomitization" (93) according to the schema:

dolomite alkali brucite calcite alkali carbonate

brucite is formed to which expansion and corresponding effects are attributed, through processes based on inhibition of water and creation of osmotic pressure by semipermeable membrane actions. Contribution to it is afforded by the weakening of bonds between rhombic crystals of dolomite. In all these processes the clay accompanying dolomite is thought to be involved (94).

Other point of view consider that transformation of dolomite into calcite and brucite according to:

has expansive effects if magnesium hydroxide crystallizes forming brucite instead of remaining in gel form acting as a binder (1).

A reflexion of the writer at this point is that, as in the case of alkali-silica reaction, alkali-carbonate reaction seems to take place with injurious character preferably if the concrete is easily -continuously or periodically- submitted to wet conditions. It should

be thought if the true main mechanism of expansion might be ascribed first of all to osmotic pressure phenomena, in which clays may act as semipermeable membranes, or to which they may cooperate by contributing to the formation of such membranes -for instance, affording ions necessary to give them a semipermeable character-. This point of view could aid perhaps to solve the problem of differentiating expanding and non-expanding reactive dolomites, in function of their content of clays and of the nature of the clays (92).

#### 6. - ALKALI-AGGREGATE REACTION

Alkali-silica reactions as concrete unsoundness causing internal autodestruction is different from that caused by an external chemical attack (9) and similar to that caused by expansive free-lime or free magnesia -periclase- in cements. It is not intended to deal here in detail with alkali-aggregate (alkali-silica, alkali-silicate (95) and/or alkali-carbonate) reactions and much less so when so many technical papers and excellent compilations, reviews and summaries of very interesting papers have been issued along the time (8) (96) (97) (98) (99) (100) (101) (102) (103) (104) (105).

Among them two have been recently issued. The one is a bibliographic compilation of 569 references of papers published from 1923 up to 1975, classified according to dates of publication, countries affected, test methods, laboratory investigations, performance of structures and case studies, cracking and pop-outs, pozzolans, aggregate performance, cement types, preventive measures, remedial action, bibliographic reviews and comprehensive papers and general articles (104). The other is a CEMBUREAU confidential "state of the art" report on alkali-aggregate reactivity in concrete, of about hundred pages, containing three appendixes dealing with glossary of terms, rock names and silica forms involved in reaction, references on aggregate classification and description, additional references -to (104)- on alkali-silica reactivity and figures, maps, graphics and photographs (105). Technical papers not only dealing with the current prospects on the possible future trends in alkali-aggregate reactions and expansions, mainly as far as their mechanisms are concerned, have been published by some of the main personalities specialized in the theme (106) (107) (108).

Nevertheless, some considerations will be made on the outstanding chemical mechanisms, as the not well known but extensively described alkali-silica reaction presents many peculiar aspects not easy to explain and not yet fully or satisfactorily explained.

Two types of alkali-aggregate reactions have been traditionally considered: alkali-carbonate (dealt with elsewhere in this paper) and alkali-silica reaction. As far as the possibility of a third type, that of alkali-silicate reaction, it seems to be ascribed to some phyllosilicates, and when attributed to some

"argillaceous dolomitic limestones" is not to be either confused or mixed with the alkali-carbonate (second type) of alkali-aggregate attack (109) (110). Each of them are possible, whether isolately or jointly. Alkali-silicate seems to proceed much more slowly and with but very little or negligible gel formation. But this is also possible in specific cases of alkali-silica reaction which may take place simultaneously. Nevertheless, the mechanisms and kinetics of controverted alkali-silicate reactions are far from being known and explained (109). Calcium hydroxide attack on clays and feldspars, in which tetra calcium aluminate hydrates, alkali silicates, hydrogarnets and free alkalis are formed depending on the type of feldspars involved, has been suggested as possibly related to cement (alkali)-aggregate reaction (111).

Some principal factors have been mentioned as governing the expansive alkali-silica reaction: crystallinity and (induced) changes in crystallinity of active parts of aggregates (112); "opaline" nature, amount and particle or grain size of reactive materials; amount and alkali content of cements; and water availability. As to the nature of the reactive materials, those containing glassy amorphous (hydrated), cryptocrystalline and microcrystalline forms of silica, or crystalline silica with lattice defects able to absorb water (21) are the more active. Studies on specific reactivity of rocks and minerals have revealed that, depending on materials, the degree of strain, the microstructure, the crystallite size, the degree of disorder in the structure, the amorphous character, the hydrated condition and the acidic nature of natural volcanic glasses, the alkali cation - sodium or potassium - of syntetic glasses and the microporous channel system of materials, are factors influencing the reactivity. The combination of some of the more decisive factors among those mentioned may explain the higher susceptibility of certain materials such as opal, as well as their expansive and damaging actions, even when in very low proportions in aggregates (98). In fact, it has been found that silicious aggregates showing a high IR absorption corresponding to OH bands, probably are alkali reactive. This seems to be in agreement with the hydrated character of the amorphous reactive silica, as in the case of opal (1) (113).

On the other hand, it has been stated that expansion is not always proportional either to the alkali content of cements or to the cement content of concretes - both determining mainly the total content of alkalis in concrete - (27) (114) (115). So, the heating-cooling and the wetting-drying exposure in accelerated testing of cement-aggregate combinations show a lack of close correlation between expansion measured and alkali content of cements. This means that although alkali-silica reaction may contribute to produce expansion during the testing, the incompatibility of the cement and the aggregate in combinations tested is independent - or not only dependent - on the expansive alkali-aggregate reaction, as very large expansions may be observed in specimens containing cement of very low alkali content,

whereas reaction rims may not appear on potentially alkali reactive aggregate particles (29).

The limits of alkalis (equivalent  $\text{Na}_2\text{O}$  contents) in cements causing sensible expansions recently seem to tend to be enhanced - about 20 % from 0,9 to 1,1 - (21). This might lead to consider if a similar criterion should be applied to the specification limits in cement standards, as far as the present limits - in general 0,6 % - are concerned, affecting to the so-called low-alkali cements. Such a consideration would be consequent with the spare of energy and lowering of fuel consumption in cement manufacture recommended by the International Energy Agency.

As far as the nature, amount and particle size of reactive material in aggregate are concerned, it has been claimed that there is no clear quantitative relationship between them and expansion caused: expansion is sometimes greater for lower amounts and medium-size particles than for higher amounts and smaller or greater particle sizes. Moreover, increases of reactive materials in concrete may sometimes cause decreases in expansion (1). All this - and sometimes the reverse - depends in turn on the degree of reactivity of the material itself (27) (114) (115), i.e., on the nature of the rocky material or artificial product, for instance, pyrex glass (1). Some standard test methods show that highly reactive aggregates may produce a smaller expansion than do considerable less reactive aggregates. This seems to depend on the content of reactive constituents and on their proportion as compared with that corresponding to the most unfavourable ratio of available alkalis to reactive silica. Nevertheless, it is not advisable to use highly reactive aggregates with high alkali cements, even though they may show a small expansion in a given standard test, whatever may be it (29).

Other different points of view consider that there seems to be an amount - concentration - and a range of particle sizes for which expansion is maximum. Mention is usually made since many years ago to "pessimism condition" of an active aggregate: maximum expansion for each size range, depending on the proportion of susceptible material in it; or for a given proportion, variable with size range - and depending on total content of susceptible material in total aggregate - (116). So, pessimism condition appears easier and with higher values of expansion: i) for higher proportions of reactive aggregate, the coarser it is; ii) for lower proportions of it, the higher its reactivity and/or the higher its density (the lower its porosity), as dense pore-free structures of reactive aggregates favour expansion; iii) for different (decreasing) proportions of reactive aggregate, depending on cement nature (portland, blast-furnace slag cements with increasing slag proportions); iv) for different (increasing) total alkali contents in cement, depending also on the cement nature; v) the higher the cement content in concrete (116).

The external manifestations, i.e., the appearance of the expanded specimens is different depending on the size of the expansive aggregate particles: exudation over them appears as an uniformly distributed fine white powder when expansive aggregate is fine, whereas

the exudation is transparent and presents a spot-pattern distribution when the aggregate is medium to coarse; the coarser the particles, the larger the spots. Generation and size of cracks also depend on the grain size ( 1 ) (117).

Not only the appearance and aspect, but also the composition of the alkali-silica gels -as well as that of the rims- formed in alkali-opal reaction and deposited in cracks, may be very significant to interpretate the expansion mechanism, in function of the distance of gels to the reaction sites. Exudations of specimens containing opal show calcium, potassium and silicon, whereas those of specimens free of opal only show both cations ( 118 ). So, opal is transformed into a calcium silicate hydrate of low basicity, but the calcium content of the gels formed and accumulated in cracks is lower in the zones of gels close to reaction sites, whereas it increases greatly in the zones more distant from the sites ( 119 ).

Nevertheless, despite the generally accepted opinion that critical reactive aggregate particle size ranges -variable with the nature of the material ( 1 )- are necessary for the expansive action, modern results show that fineness of aggregate -size particle under a given value even lower than 50 microns down to 30-20 microns- is not a guarantee that an active (opaline) material will be innocuous, though customarily it is thought that innocuity refers to expansion, not to alkali-aggregate reaction.

As to the lack of a general direct relationship between the extent and rate of the chemical alkali-silica reaction and the expansion -not always involved in it-, one of the difficulties has been the problem (not well solved) of measuring the extent and rate of the reaction, for the measurement of the expansion is solved. A proposal has been made to determine the extent of reaction based on determinations (and corrections) of total alkali content in pore liquid of reacting mortars and in that of blank mortars. Differences between the latter and the former values referred to the corresponding ages, expressed as percentages of the total alkali provided by the cement and plotted against time give the trend of the alkali consumption in reaction. Further hypothesis on stoichiometry (average value of  $(K_2O + Na_2O)/SiO_2$  mol ratio of 0,25) of the alkali-silica product formed permits to calculate the active silica consumed at each age by reaction in some given experimental conditions (120). Among the several factors influencing the method, one of them, that of the possible "reciclation" of alkalies displaced by calcium after reaction with silica -to form a more stable calcium-alkali silicate (that of a semi permeable membrane? -see later-) needs further consideration, as it may cause an underestimation of the extent of the alkali-silica reaction (120).

On the other hand, large expansion is not always accompanied by severe local cracking ( 10 ) ( 118 ). Differences to be attributed to grain size, as far as expansion is concerned, are more related to the rates and relative amounts of expansion than to the character of it. So, there seems not to be a limiting

size of aggregate over 20-30 microns below which expansion will not take place, though expansion due to the finer particles is sudden and complete in short periods, whereas that of larger particles is slower and more gradual and delayed. In the author's opinion the influence of the grain size is one of the many dark points in the alkali-aggregate problem, and this seems not to be consistent with the use of very finely ground expansive aggregate rocks and other materials -pozzolans, fly-ashes and slags- added to cement to avoid the effects of alkali-silica expansive reaction ( 27 ).

Another very important factor determining alkali-silica expansive reaction is the initial moisture content of the aggregate and the availability of water to be absorbed and fixed -in the presence of alkalinity ( $OH^-$ )- causing expansion ( 1 ). In any case it seems that permanent or almost permanent wet conditions are necessary for expansive reaction (21). The extent to which the presence of water is determinant for the reaction -other necessary conditions for it being fulfilled; highly reactive particles in proportions, sizes and amounts favourable for expansion, and high contents of high-alkali cement in concrete- has been emphasized by the fact that inhibition of drying in concrete samples shows that the moisture content of massive concrete is sufficient -but also necessary- to cause deleterious alkali-aggregate reaction (121).

An important paper has been attributed to the  $OH^-$ -ions in the mechanism of the reaction, as it has been claimed that they may attack silicious aggregates more intensively after the early reactions of hydration, when the depletion of sulfate-ions permits a higher  $OH^-$  concentration due to the higher solubility strength and dissociation of the alkali hydroxides formed with alkali cations ( 97 ). This is the mechanism by which alkalies forming sulfates -according to the writer in "saline" form- may pass to act as alkalies in "caustic" form. In fact, the expansive reaction seems to be conditioned by the pH of the liquid phase, determined in turn by the type and amount of dissolved alkali ions ( 21 ). But  $OH^-$ -ion concentration seems to be the main governing factor, rather than alkali cations, which can influence the physical nature of the products formed and the rate of the expansive reaction and cracking. In fact, the experience seems to indicate that it is only in concretes with high hydroxyl-ion concentration where attack on reactive aggregates can be expected. Such high concentrations are easier and earlier reached with high-alkali cements, as are those favoured by new manufacturing technologies developed even prior to fuel shortage ( 97 ).

All these complex and seemingly contradictory facts, as well as the stresses and "map cracking" resulting from reaction between some silicas and alkalies have been more or less convincingly but logically and generally interpreted (27) ( 122 ), as several mechanisms have been proposed to explain reaction and even expansion due to it ( 95 ) ( 97 ) (110). Among them, some assume that reactive silicious material may form with alkali and  $Ca(OH)_2$  wether

a solid non-expansive complex calcium-alkali-silica compound, or a solid complex alkali-silica compound able to expand by water imbibition. The formation (and the order of formation) of the one or the other of both complex compounds seem to depend on the relative concentrations of alkalies and calcium hydroxide, and on the surface of the reactive material: in low alkali concentrations the non-expansive compound forms first and the process may continue without expansion, if the amount of reactive material is either negligible or higher than a critical value, which depends on the alkali available and on the fineness of the active material. In high alkali-ion concentrations the expansive product first formed is a more or less fluid alkali silicate gel, whose imbibition and osmotic swelling may develop pressure depending on the proportion of reactive silica and available alkalies (29). The expansion may be stopped only when the active material presents a surface for reaction great enough (very many reactive particles and/or sufficiently fine) to substitute the expansive reaction by the non-expansive one (27).

The swelling of susceptible aggregates to alkali hydroxide solutions or that of gelly alkali silicates by water imbibition (123) have also been invoked, more or less in connection with the lack of space to accommodate alkali silicate reaction products of greater volume than that of the original reactive particle (95) (124). The osmotic pressure created in dilution of concentrated alkali-silicate solutions formed in reaction, by passing water through a silicate semipermeable membrane -see later- has been also proposed and sustained (95) (124).

The higher expansion produced in specimens containing mainly sodium rather than potassium (1) has been explained on the basis of a much greater increase of volume in the case of hydrated sodium silicate formation. In a similar manner, the lower expansions observed when lithium or barium salts are present have been explained in terms of the lower solubilities of the respective silicates formed (99).

In the writer's opinion -see later- a complementary -more detailed- explanation could be perhaps that a true semipermeable membrane of a complex silicate (of calcium and other cation) giving place to a "true" osmotic cell is more easily and effectively formed when the cation is mainly sodium. Then, the osmotic pressure action of the "true" cell is maximum, as well as the corresponding expansive and disruptive effects (125) (126).

Suggestive explanations of expansive alkali-silica reaction have been given and recently actualized considering the nature of the reaction products formed in rims and cracks of reaction zones (96) (126): hydrated silica gels, alkali silicates of sodium and/or potassium, and complex alkali-calcium silicates. Not all of them are considered as producers of expansion, for sodium and potassium silicates, when in vitreous condition or in solution are stable. On the other hand, it has been invoked that when  $\text{SiO}_2$  reacts with alkali hydroxides the volume of the alkali silicates formed is smaller

than that of the original reacting products. So, no expansion should be expected based on the formation of pure alkali silicates. Moreover, silica gels are also stable, so that expansions from that alkali-silica reaction should be based mainly on physico-chemical schemas other than hydration or imbibition of alkali silicates or silica gels, such as the following:

(here M is either  $\text{Na}_2\text{O}$  or  $\text{K}_2\text{O}$  and  $x = 3$  in general)

A point of view widely shared among many authors considers that expansion is primarily a consequence of the formation and widening of cracks due to mechanical pressure exerted by reaction products (127). But this seems not to be in accordance with experimental results showing expansions with no significant crack formation (118).

Osmotic pressure effect has been also suggested many years ago and supported by many authors since then, as causing expansion (128) (129). For it is necessary the existence (the formation) of a semipermeable membrane through which diffusion of ions and molecules may take place, so creating a high differential pressure between both sides of it. It has been suggested that the membrane may consist in complex alkali-calcium silicates of variable and not well defined composition or stoichiometry -polysilicic complexes with metallic ions, oxides and hydroxides adsorbed- (96) (126), formed according to the schema (126).

probably in two steps. In the first one the disperse alkali in solution acts on a localized alkali silicate

In the second one the disperse calcium hydroxide in solution may act on the alkali silicate first formed to give by partial cation exchange the localized complex compound previously mentioned, with liberation of alkali, ready for further action:

This schema is consistent with a point of view concerning the role of calcium. It states that in solutions highly concentrated in alkali ions and hydroxyl ions from moderately high-alkali cements the calcium ion concentration drops in a few days to a very low value corresponding to saturation of  $\text{Ca}(\text{OH})_2$ . Afterwards it drops again to vanishingly small levels in a few months. It implies a possible isolation of portlandite from the pore solution, probably caused by a low-lime calcium silicate. This induces to think that calcium

should not significantly participate in the initial reaction product of alkalis with susceptible aggregates. Instead of it, it seems that sols first produced, flowing through open cracks (130) (131) (132) (133). In their way outwards take from portlandite crystals calcium, which they finally fix, simultaneously losing a part or their content in alkalis which diffuse all around (130). In fact, complex compounds of the type CKNSH in the form of amorphous "expansive" gels are produced in the alkali-silica reaction (134).

On the other hand, the possible decisive influence of abundant calcium ion has been previously recognized and since widely accepted ( 97 ) through a somewhat different interpretation: that of the "safe" reaction products corresponding to limited -swelling gels rich in calcium and "unsafe" reaction products corresponding to osmotically active gels richer in alkali cations ( 122 ) potassium and sodium (but not lithium -another dark point in alkali-aggregate reaction- ( 135).

It is well known that semipermeable membranes consisting in insoluble amorphous gelly masses of polysilicic anions with adsorbed metallic ions, oxides and hydroxides showing undefined compositions ( 96 ) ( 126 ) may be formed when polyvalent metal (Fe, Ni, Co, Mn, Ca, etc.) salts are put in contact with solutions of alkali silicates ( 96 ), according to a schema more or less like this:

Other important factors conditioning the semipermeable and ion-interchanging character of the membrane able to create osmotic pressure are temperature, time of contact, and more particularly the proportion of its components. Membranes rich in highly and rapidly reactive silica are impermeable. To lower concentration of alkalis correspond higher concentrations of CH in the liquid phase and consequently highly calcic impermeable membranes. Therefore, there seems to exist a relatively narrow range of proportions and compositions most favourable to the semipermeability and hence to the creation of osmotic pressure. This range, depending on the composition and concentration of reactants in the liquid phase, corresponds to a sort of new notion of the concept of "pessimism" advanced long time ago ( 136 ) to express the highest probability of destructive expansion.

The statement that early cracking precludes the formation -or the permanence- of "true" osmotic cells should be taken in the sense of "classical" osmotic cells formed by an intact and "real" semipermeable membrane. Otherwise, it is possible to imagine the formation and the permanence of "virtual" osmotic membranes from gel structures, in such a way that solute ions electrically or chemically attracted by the gel framework are hindered to move freely, according to decreasing concentration gradients; consequently, the solvent -water molecules- moves in opposite di-

rection so generating osmotic pressure in confined zones, even in the absence of "intact" membranes ( 100 ). In the author's opinion this could be an acute eclectic interpretation linking swelling of gels by water absorption and true cells acting by osmotic pressure.

Finally, other things related to concrete characteristics being equal, an important last condition is necessary for osmotic pressure expansion to proceed: the presence of water -liquid water- to be diffused by endosmosis through the semipermeable membrane. This implies a "permanent" contact of concrete with water; otherwise, even if the remainder favourable circumstances for "pessimism" condition are given, expansion by alkali-silica reaction does not take place ( 96 ) ( 126 )

This vision of the alkali-silica expansive reaction mechanism enables interpretations of factors otherwise difficult to explain: the action of inhibitors such as pozzolans or other finely ground and highly active silicious materials -even the reactive aggregate itself- in shifting the membrane composition from its "pessimism" condition, and dispersing the intensive local actions changing them by much numerous and much weaker diffuse actions; smaller expansions observed with higher alkali cements and conversely; absent or much lower expansion when external water is not sufficiently available, etc. ( 96 ) ( 126 ).

According to the foregoing, some questions arise to the author's consideration. One first is the possible influence of the form in which alkalis are present in cements ( 97 ) -"neutral saline" form (as sulfates) and "basic saline" form (combined with calcium silicates and aluminates)- on the composition of membranes, and therefore on the possibility of expansion. A complete bibliographic compilation on alkali compounds in clinker, as well as on crystalline modifications of clinker phases by alkalis has been recently published (137). In the same way, a similar compilation on the influence of alkalis on the morphology and structure of hydration products, as well as on other aspects affecting stability and durability of cement pastes has been recently issued too (138).

If the influence of the form in which alkalis are present exists -and it is considered to be so ( 97 )- another second question to be considered is whether the total content of alkalis in cements or the partial content of them in one or another of the mentioned forms are mainly responsible for expansive reaction. If one of the two mentioned partial contents is more determinant of the expansion than the other -and if the value of the ratio  $\text{K}_2\text{O}/\text{Na}_2\text{O}$  is also decisive-, a third question arises concerning the justification of limiting to 0.6 % in cement standards the total alkali content (as equivalent  $\text{Na}_2\text{O}$ ) of the so-called low-alkali portland cements considered as more safe, as far as alkali-silica expansive reaction is concerned. In fact, it has been still claimed that the effect of the alkali content of a given cement

should be at least partially a function of the state of combination of the sodium and potassium in the cement, as well as of their total content. Most of the soluble portion of alkalis occurs as sulfates, either in the form of apthitalites  $NK_4S_5$  to  $NK_5S_6$  or calcium langbeinite  $KC_2S_3$ , or in the form of carbonates, equivalent to hydroxides. Insoluble -less rapidly soluble- portion of alkalis is combined in silicate  $(K,N)C_2S_{12}$  and aluminate -ferrite-  $(K,N)C_8A_3$  phases and the respective solid solutions, their speed of solution depending on their rates of hydration (97).

Moreover, alkalis may come not only from cement -clinker- but also from added materials (pozzolans, slags, fly-ashes), weathered aggregate constituents, concrete admixtures, sea-water or deicing salts, so that variable limits specified in standards for cements seem to be of less value than the effective amount of alkali present in a given volume of concrete -kg of eq.  $Na_2O/m^3$ - in order to assess the extent of alkali-aggregate reaction. In fact, for given "pessimum" conditions not always cements of higher alkali content give maximum expansion. Nevertheless, expansion is higher in general the higher the cement content in concrete. On the other hand, concretes with medium to low contents of high-alkali cements may not always show deleterious alkali-aggregate reaction according to actual results in practice (116) (139). Furthermore, some other laboratory tests have shown that their results either correspond to those observed in practice or -if not- they are placed on the safety side (140).

Laboratories are making progress in the development of more rational guidelines governing specifications limiting the alkali content of cements. Attempts are being made to specify the total amount of alkalis per cubic meter of concrete, rather than to fix limitations to the total alkali content of cements (141). All this is duly justified because it has been claimed that high alkali content in cement -even together with a highly reactive aggregate- does not necessarily produce relative great expansion and damage, but even may reduce them. Despite that the rate of silica reaction is increased, when increments in alkali content in cement are higher than an arbitrary and variable value they do not increase expansion, but reduce it. Then, large amounts of alkali react rapidly to form gelly reaction products with a  $Na_2O/SiO_2$  ratio high enough to be fluid -or even to pass quickly from gel to sol state by water adsorption-. The sol formed or the fluid gel, if not fully confined, penetrate and accommodate in pores and free spaces around reacting particles, neither exerting mechanical pressure nor producing damage (131) (132). This may make difficult to consider, at least in general, that the factor governing the kinetics of expansion is either the formation of alkali-silica compounds or their swelling (118).

All these aspects among others have been recently exposed (126). It seems that they claims for attention on further research in order to proof if the present limitation of total alkali content in cement standards is operative and justified or not, as compared with the influence of other various factors involved

in the expansive alkali-silica reaction. If not, there is no reason to maintain limitations affecting adversely the fuel consumption, particularly in most of the present more economical cement manufacturing processes (126). In any case, according to the preceding considerations, it seems to be clear that in the case of a possible and probable expansion to be fear by the use of susceptible silicious aggregates, portland cements, either low in alkalis or not, are not the most adequate to make concrete free of damages by expansion. Anyway, blast-furnace slag cements -and pozzolanic cements- seem to be more idoneus, partially because they permit a higher total alkali content in clinker, as established in most of the standards (142).

As final considerations it is worth wile to expose some of the more recent observations and conclusions concerning alkali-aggregate reactions. Among them (108): i) that the increase in reports of reactions during last years in several countries is important; ii) that more parameters and a variety of climatic conditions wider than that so far considered seems to be involved in reaction; iii) that very quick and very delayed reactions have been reported, not corresponding to long term field performance or to laboratory test behaviours of specimens; iv) that these facts, as well as many other factors question the reliability of the testing methods and criteria to detect, to evaluate, to foresee and to prevent damages from alkali-aggregate reaction. This could be precised as follows: i) low-alkali portland cements may cause deterioration -the opposite could also be invoked-, so that the limit of 0,6 % equivalent  $Na_2O$  does not constitute a guarantee, and so less so as the alkali content of pozzolanic materials, slags and certain rocks -an overlooked factor- seems to be potentially operative; ii) aggregates earlier considered safe must be reconsidered, as they may react and cause expansion and even deterioration, depending on their mineralogy and chemical (soluble) constituents other than  $SiO_2$  -another overlooked factor out of control-; iii) the mechanical simplicity of tests based on expansion of mortar or concrete bars does not correspond to the physicochemical complexity of the reaction and expansion kinetics, in which many internal and external factors and parameters not (duly) taken into account or out of control do in fact influence (108).

A critic and objective panoramic exposition of alkali-silica problem recently presented (107) states that the more extensive and deeper the partial knowledge about it, the more complex and difficult seems to be its solution. Questions not yet solved, among others, are: i) how and why disperse alkali-silica gels formed on discrete active particles of aggregates create locally accumulated expansions, as expansive imbibition of gels would exige integration of local efforts to produce fracture; ii) the true influence of the "pessimum" proportion (amount and granulometry) of reactive aggregates and the ratio of inactive to expansive aggregate giving maximum expansion, as well as the dependence of pessimum proportion on many other

different and variable factors; iii) the difficulty to establish a classification of different aggregates in types according to their alkali susceptibility (which does not permit to generalize testing methods, criteria for evaluation and preventive measures); iv) the preventive effect of pozzolans and the influence of their nature, as well as that of their alkali content, which makes it difficult to classify pozzolanic materials according to their more or less beneficial action. The paradoxical conclusion to be drawn from the dark points preceedingly exposed is that the broad knowledge obtained up to date only serves to recognize the enormous complexity and difficulty of the problem, but it hardly aids either to foresee better the alkali-silica expansion or to prevent it. A secondary conclusion in which the writer agrees is that much systematic and cooperative basic and applied research is needed, as well as a better application of the knowledge still gained and to be gained in the future on the chemistry of silicates (107).

Many aspects of cement research, some of them dealing with durability, are or seem to be in conflict with some of the main present guidelines in cement development. This is particularly the case of alkali-aggregate reaction as far as fuel consumption and profit of certain raw materials and by-products in cement manufacture are concerned (7). On the other hand, in the field of durability as well as in many other fields, most of research work runs around the same themes, using the same methods, applying the same ideas and arriving repeatedly almost always to the same partial and not decisive conclusions. As mentioned somewhere (7), as far as shrinkage is concerned, our present knowledge on durability either in general or in whatever specific aspect of it such as alkali-aggregate reaction in particular, it is by no means proportional to the effort made and to the number of papers published since the beginning of the century. In fact, up to the present time the problem of alkali reactivity has been studied during more than thirty years. No clear conclusions have been reached on the mechanisms of reactions, expansions and deteriorations, neither in the more common case of alkali-silica reaction nor in the more complex one of alkali-silicate reaction. Reasons for it may be the many variables involved and their simultaneous interactions creating feed-back problems which must be necessarily taken into account to establish test methods and criteria to evaluate test results (95). These also depend on many other factors involved in active materials to be tested, even other things being equal (143) (144).

This is perhaps, among many others, a case in which a work of synthese on the basis of a wide interdisciplinary cooperative research, in addition to an almost exclusive basic research would be of profit to go onwards. Probably such a synthese would serve to fix directions and guidelines according to which further research should be orientated (7).

## 7. - ATTACK BY CHLORIDES AND DE-ICING SALTS ON CONCRETE

It has been examined and described the actions (mainly physical) and the effects of chlorides -CaCl<sub>2</sub> and NaCl- used as ice-removing salts on concretes. Studies on de-icing salts and concrete resistance to them have been recently carried out and published (145). The characteristics of the concrete void and cement paste pore systems, the presence of admixtures (particularly air-entraining agents) and the nature of the tests (based either on immersion or in surface application) have influence on the effects caused by the crystallization pressure created on ice formation. Several papers on this matter have been reviewed recently (1).

As far as the influence of the void structure of concretes is concerned, it seems that a sufficient (minimum) amount of micro-air voids in concretes is needed to impart them an adequate de-icing salts resistance, provided that the void distribution and the maximum distance between voids are also adequate (21).

Two different mechanisms have been proposed to explain the attack of concrete by saturated calcium chloride solutions, depending on its low or high w/c ratio, and without taking into consideration freezing and thawing cycles. In the case of low w/c ratio large weight losses and degradations are observed, which cause loss in strength without expansion. This has been attributed to leaching. In the case of high w/c ratio weight gains and large expansions are produced, and degradations and loss in strength are observed due to crystallization. Nevertheless, more complicated seems to be the explanation in the case of (practical) intermediate w/c values (146).

On the other hand, two factors must be taken into account to explain the successive actions of de-icing salts -CaCl<sub>2</sub>, NaCl- in concrete, according to more recent points of view. The one, physical in nature, consist in a change (lowering) of the evaporable water content of the specimens, caused by an osmotic pressure action between the strongly concentrated salt solutions and the specimens in contact with them. This lowering of evaporable water firstly causes an increase of strength.

The other factor, chemical in nature, consists in a real attack which brings about a leaching and the corresponding losses in weight and decreases of strength. This leaching is caused by calcium chloride solutions, due to their low pH, which may produce the formation of soluble compounds with the cement paste. This is not -or this is much less- the case of strong NaCl solutions, and this may explain why these do not show the trend to reduce concrete strength, at least to the same extent as CaCl<sub>2</sub> solutions do it (147).

Of course, both mechanisms are independent of some others based on hydraulic pressure, which may be superimposed when freezing-thawing actions take

place simultaneously. The author calls attention on the importance given to the osmotic pressure actions also in other fields such as that of alkali-silica expansive reaction (96) (126).

From the chemical point of view, in the attack of portland cement by solutions of  $\text{CaCl}_2$  of various concentrations and at different temperatures, monochloroaluminate hydrate  $\text{C}_3\text{A} \cdot \text{CaCl}_2 \cdot \text{H}_x$  ( $x=10$ ) is always formed. And in addition to leaching of CH the formation of other complex salts containing both CH and  $\text{CaCl}_2$  -and even calcium carbonate  $\text{CC}$ - may be formed, depending on time, temperature and concentration of the  $\text{CaCl}_2$  solution. Thus, it could be inferred that the attack on cement by calcium chloride used as de-icing salt is caused by crystallization and crystal growth pressure of the mentioned complex salts formed. This action is facilitated by an increase of porosity due to the simultaneous leaching of CH (146) (148).

The attack of  $\text{CaCl}_2$  to concrete seems to depend greatly on temperature, as a rapid deterioration is produced at  $5^\circ\text{C}$ , which is neither observed at  $20^\circ\text{C}$  nor at  $40^\circ\text{C}$ . The explanation given for it is that an expansive product stable at low temperature is formed at  $5^\circ\text{C}$ , causing disruption (9) (149).

An interesting viewpoint concening de-icing salt attack is that attributing destructive effects not so much to chemical as to physical causes involving alterations in the frost mechanism through opposite actions conducting to an intensified freezing and to a stronger thermal shock, which produces serious contractions and the corresponding scaling (150).

In fact, independently of the chemical actions which de-icing salts may produce in hydrated cement pastes, the stronger damage observed in frost action when salts are dissolved in the freezing water has been physically explained by the lowering of the vapour pressure and the freezing point of the solvent. This makes, on the one hand, that the degree of water saturation of a porous body (cement paste) corresponding to equilibrium at a given relative humidity is higher when the porous body is impregnated with a salt solution than when it is imbibed with pure water. On the other hand, at lower temperatures the viscosity of the solution may be very high and pure solvent may crystallize, so that flow of pure liquid is hindered and the frost resistance thus impaired (151).

Anyway, though much research work has been done even in recent time (152) (153), and much practical experience has been gained, damages caused by freezing of water and crystallization of de-icing salts have been not yet fully explained, and it is admitted that all of the several factors involved must be taken into consideration (154). This point of view is supported even at present. In the author's opinion, this is one more of the innumerable cases of durability in which factors, actions and effects purely chemical or purely physical in nature cannot be separated from one another, as they are linked together in an indissoluble manner, acting either simultaneously

or successively. The importance attributed to the one or to the other of both factors will depend on conditions and circumstances, and on the evaluation made of them in each particular case by each individual author.

Reaction of ions from different salts penetrating a cement paste depends on the permeability of the paste to the diffusion of the ions involved ( ). Attack of chlorides proceeds by ionic penetration of  $\text{Cl}^-$  in ordinary concrete. It has been stated that this penetration seems to follow the FICK's diffusion law, and that it is independent of the chloride concentration, and hence of the concrete penetrability to the salt solution as a whole, or even to pure water. Diffusion seems to be to some extent independent -or not only dependent- of the porosity of the material. Moreover, it seems to depend more on the nature of the cement paste. An explanation given for it has been the "primary adsorption" of  $\text{Ca}^{2+}$ -ions (and the "secondary adsorption" of  $\text{Cl}^-$ -ions) by materials added to cement, or by combination products of them with the hydrolitic lime produced in hydration. This explanation may be valid in the case of pozzolanic cements (156).

If no gradient of electrical potential is established in the cement paste, diffusion and adsorption of both  $\text{Ca}^{2+}$  and  $\text{Cl}^-$ -ions (one of the former to two of the latter) must be simultaneous.

It has been stated that chloride penetration is greater in concretes with low  $\text{C}_3\text{A}$  cements, though the decrease in strength caused by sea-water attack, for instance, is greater with increasing  $\text{C}_3\text{A}$  content of the cement (1), for other factors are involved.

It has been quite recently stated that for ordinary portland cements the time is determinant for the  $\text{Cl}^-$ -ion penetration, even through high quality concrete; that w/c ratio influences the  $\text{Cl}^-$ -ion penetration to concrete surface layer and for short duration of concrete contact with chlorides; and that the type of cement has a major influence in deeper penetration and for longer durations of contact. Furthermore, in portland cements penetrations of  $\text{Cl}^-$ -ions have been observed being from 2 to 5 times greater than those observed in blended cements. Moreover,  $\text{Cl}^-$ -ionic diffusion depends not only on the permeability and binding capacity of the  $\text{Cl}^-$ -ions, but also on the ion-exchange capacity of the system, i.e., of the cement paste (157).

Apparent diffusion coefficients of  $\text{Cl}^-$ -anion and various cations from different salts (Li, Na, K, Ca, Mg) and salt mixtures (Li+Na+K) experimentally determined through hardened plates of portland cement paste have shown, in the case of the cations, to increase in the order:

$$D_{\text{Li}^+} < D_{\text{Na}^+} < D_{\text{K}^+} \text{ in approximate ratios of}$$

1 : 1.5 : 2 This order is nearly the reverse to that of the radii of solvated -hydrated- ions (155) (158). On the other hand, other things being equal, in the case of chlorides the diffusion and penetrability

lity of  $\text{Cl}^-$ -anion is greater when linked to divalent cations than when combined with monovalent cations, the order being:

Moreover, the diffusion of  $\text{Cl}^-$ -anion is much greater than that of the cations.

despite almost equal mobilities of  $\text{Cl}^-$  and  $\text{K}^+$ -ions; this is invoked as a proof of the electropositive character of the hardened cement paste considered as a semipermeable membrane (155) (158) (159).

These differences in ionic diffusion explain that in contact with  $\text{CaCl}_2$  or  $\text{MgCl}_2$ ,  $\text{Ca}(\text{OH})_2$  and  $\text{Mg}(\text{OH})_2$  -and even  $\text{LiOH}$ ,  $\text{NaOH}$  and  $\text{KOH}$  in contact with the respective chlorides- are formed on the surface of the cement paste by a mechanism of exchange between penetrating  $\text{Cl}^-$ -ions and  $\text{OH}^-$ -ions present in the paste, the latter reacting either with  $\text{Ca}^{2+}$  or  $\text{Mg}^{2+}$ -ions of lower mobility in solution. This exchange may be considered as mutual diffusion (counter-diffusion) of  $\text{Cl}^-$  and  $\text{OH}^-$ -ions (155) (158).

$\text{OH}^-$ -ions come out as a result of the deeper and rapid penetration of  $\text{Cl}^-$ -ions which interchange with  $\text{OH}^-$  in the bulk of the paste. Once in the external part of this,  $\text{OH}^-$ -ions compensate the alkali or earth-alkali cations previously left in excess by the more diffusive  $\text{Cl}^-$ -ions (155).

So, if it is accepted that the diffusion coefficients of alkali and earth-alkali cations decrease in the order:

it must be accepted that the destructive effect of  $\text{Cl}^-$ -ion decreases in the order:

according to the valency and the radii of hydrated cations (155).

Deep penetration by diffusion of  $\text{Cl}^-$ -ions into the paste from a solution of a divalent-cation chloride accelerates the dissolution of  $\text{Ca}(\text{OH})_2$ , which explains the acceleration effect on setting and hardening (hydration) of the cement paste caused by  $\text{CaCl}_2$  solutions.

Furthermore, the diffusion rate of  $\text{Cl}^-$ -ions is 10 to 100 times faster than that of  $\text{SO}_4^{2-}$ -ions. Nevertheless, sulfate attack caused by  $\text{Na}_2\text{SO}_4$  solutions is much greater than chloride attack produced by  $\text{NaCl}$  solutions on cement, as calcium sulfoaluminate hydrate is less soluble than calcium chloroaluminate hydrate (159).

During hydration of portland cement in the presence of chlorides it has been claimed that ettringite is always first formed, until all the gypsum has been consumed. Only then monochloroaluminate is formed. On the other hand, in the case of tricalcium aluminate and tetracalcium aluminate hydration in the presence

of chlorides, sulfates may act on monochloroaluminate previously formed to transform it into ettringite, with new formation of chloride. So, ettringite seems to be a more stable phase (159 bis).

Monochloroaluminate first formed and crystallized in chloride attack to concrete, due to the more rapid diffusion of  $\text{Cl}^-$ -ions, is unstable in the presence of  $\text{SO}_4^{2-}$ -ions, so that afterwards it is transformed into expansive ettringite. This occurs in sea-water attack and this is also a reason why the use of sea-water as mixing water is not recommended for cement rich in  $\text{C}_3\text{A}$ , since chloroaluminates first formed are transformed later on into ettringite. Moreover,  $\text{Cl}^-$ -ions also enter to form a reticular and porous solid solution in an initially fibrous CSH of the hydrated cement paste (15) (58) (59).

In attack on surface of either alite pastes or portland cement pastes by  $\text{NaCl}$  solutions and sea-water, different forms of calcium carbonate such as calcite, aragonite and vaterite have been detected as products of carbonation. The preferential formation of either of these forms depends on experimental or natural conditions (160).

Among salts other than sulfates and sodium and calcium chlorides, comporting conditions and properties to be aggressive to cement paste -such as water solubility, a corresponding base weaker than  $\text{Ca}(\text{OH})_2$  and an anion forming water-soluble calcium compounds-, magnesium chloride and ammonium chloride should be mentioned. Both react with  $\text{Ca}(\text{OH})_2$  to form calcium chloride and insoluble magnesium hydroxide (brucite) and volatil ammonia, respectively. In the latter case ammonia evolution rapidly deteriorates the cement paste (23).

Different expanding products are formed on portland cements with low (less than 1 %) or high (about 12 %) contents of  $\text{C}_3\text{A}$  as well as on blast-furnace slag cements (with about 75 % of slag) when attacked by 3M  $\text{MgCl}_2$  and  $\text{CaCl}_2$  solutions and by saturated  $\text{NaCl}$  solutions (161). Magnesium and calcium chlorides attack strongly to portland cement mortars, the expanding reaction products being  $\text{MgO} \cdot \text{Mg}(\text{OH})\text{Cl} \cdot 5\text{H}_2\text{O}$  and  $\text{CaO} \cdot \text{CaCl}_2 \cdot 2\text{H}_2\text{O}$ , respectively. Both are formed from free  $\text{CH}$ , causing a total loss of alkalinity. Astonishingly this affects more to denser than to less denser concretes. Slag cements do not form expanding oxichlorides and consequently they do not suffer deterioration. This may be one of the several explanations of the better performance of slag cements in sea-water attack and so much so the higher the slag content of the cement (162).

Sodium chloride, as stated (146) (148), forms  $3\text{CaO}(\text{Al}, \text{Fe})_2\text{O}_3 \cdot \text{CaCl}_2 \cdot 10\text{H}_2\text{O}$  with either portland or slag cements and the alkalinity of the paste is not lowered (147) (161).

As far as magnesium chloride attack on different cements is more particularly concerned, it has been pointed out that  $\text{Mg}^{2+}$ -ions form  $\text{Mg}(\text{OH})_2$  on the surface of the concrete (specimens). The amount of brucite formed -as well as penetration of  $\text{Cl}^-$ -ions to

form chloroaluminate are higher in portland and fly-ash cements than in slag cements. Consequently, the strength of the former decreases considerably, whereas that of the latter shows very little change. All this seems to be in accordance with the exchange of Ca by Mg in  $\text{Ca}(\text{OH})_2$ , causing leaching of calcium, which leads to an increase of porosity and pore volume in specimens. This may aid to explain the more remarkable loss in strength in the case of magnesium chloride attack on portland cement mortars and concretes (163).

But, on the other hand, magnesium hydroxide formed may protect the cement paste -by coating its surface- from further attack, provided that  $\text{MgCl}_2$  concentration is not very high, so that crystallization of brucite may disrupt the structure of the paste (23). This is one of the many examples of compounds formed in aggressive reactions which may either cause damage or afford protection, depending on different conditions and circumstances. And this is also one of the several reasons by which durability problems are, at least apparently, so complicated, and their actions and effects so different and even so contradictory.

In opposition to what has been generally accepted (at least in the case of sea-water attack), i.e., that the presence of chlorides reduces the sulfatic action, the contrary effect has been postulated in the case of attack in the severe conditions in hot arid internal areas, where soil contains chlorides and sulfates, for climatic factors seem to influence decisively the nature and extent of the attack. Anyway, opinions on favourable, unfavourable or indifferent influence of chlorides on sulfate attack are very diverse, as shows the bibliography on this item, particularly in the last twenty years. Arguments based on variations of solubility of gypsum (in general sulfate compounds) in chloride solutions, and on their influence in inhibiting the formation of ettringite seem not to be valid in arid regions. On the contrary, the growth of ettringite crystals in the presence of chloroaluminate has been invoked, as well as the stability of the latter in the presence of an excess of the former. These facts could explain the higher expansion and damage of cement pastes, sometimes observed, caused by mixtures of chlorides and sulfates (164).

It has been proposed a schema to explain all these facts. It consists in the formation of  $\text{CaCl}_2$  and  $\text{NaOH}$  by reaction between  $\text{Ca}(\text{OH})_2$  and  $\text{NaCl}$ . Calcium chloride forms chloroaluminate and simultaneously ettringite is formed which in the presence of it experiments a crystal growth. If there is an excess of  $\text{NaCl}$ , more  $\text{CaCl}_2$  may be formed which, if not reacting with  $\text{C}_3\text{A}$ , may be leached, so increasing concrete porosity and permeability (164). As previously mentioned, the action of chlorides is reinforced by the much faster and deeper penetration of  $\text{Cl}^-$ -ions into the cement paste and by their greater adsorption in it, as compared with those of  $\text{SO}_4^{2-}$ -ions (59).

Summarizing, in the author's opinion it could be assumed that penetration of  $\text{Cl}^-$ -ions take place more

or less always (partially depending on the nature of the cement -portland, fly-ash cements pozzolan cements, slag cements- in all the cases). But serious deteriorations occur only when the chloride containing compounds formed are highly expansive in nature. The extent of the deterioration caused by them may be greater in some denser concretes, probably due to a more intensive and efficient effect of the expansive pressure created. On the other hand, it seems to be evident that conditions for chloride actions in sea-water attack and in dry and hot arid regions in connection with a simultaneous sulfate attack are not the same. The mechanisms of attack as well as the resulting damages of it are also probably different. So, no contradiction seems to exist necessarily between both types of aggressivity, not comparable to one another.

## 8. - SULFATE ATTACK

Taking into account the chemical nature of the hydration products of the cements, it is easy to foresee the types of aggressivity to which they can be subjected (165). The more or less basic character of them implies the possibility of an acid attack at pH below a certain variable value. On the other hand, a base exchange may take place between  $\text{Ca}(\text{OH})_2$  and salts of cations giving weaker and/or less soluble hydroxides and anions forming soluble calcium salts, as for instance magnesium salts. And finally more complex attack is possible by interaction of hydrated aluminates and ferrites with sulfates (23). It has been estimated that about 75 % of publications on concrete corrosion deal with sulfate attack (23).

All the knowledge accumulated on sulfate attack to cement has been mainly centered in the chemical reaction of  $\text{C}_3\text{A}$  with external sulfates, by complex mechanisms even not yet quite clear due to confusing or contradictory results leading to different, opposite or erroneous conclusions. Something similar could be said as far as the limits of  $\text{C}_3\text{A}$  in cement are concerned, to guarantee an immunity or an admissible degree of attack (166).

Nevertheless, chemical reactions and processes involved in sulfate attack to cements, as well as their effects, on concretes, depend basically on the nature of all three: sulfates, cements and concretes; on salts concentration, external conditions and time. Cations linked to sulfate anion, mixtures of different sulfates (and their relative proportions), the presence or absence of chlorides and the more or less abundant  $\text{C}_3\text{A}$  in anhydrous cement and of CH in hydrated paste may determine various isolated or conjoint -simultaneous or successive- types of attack. This may be significant for sulfate concentrations starting from limits widely and diversely established by different authors -in general about 1000 ppm- (167). Anyway, a strong attack is always to be expected when concentration of  $\text{SO}_4^{2-}$ -ions is higher than 3000 ppm (23).

The effects of mixtures of sulfates are sometimes unexpected. They cannot be foreseen, as they are not additive; on the contrary, they are in some way "subtractive", for additions of  $\overline{NS}$  to  $\overline{MS}$  or conversely reduce the attack of each of the two salts acting alone (166) (168).

Most abundant sulfates in soils are those of calcium (gypsum, selenite), magnesium (epsomite), sodium-calcium (glauberite) and sodium (thenardite), which have very different solubilities. Soluble alkali and earth-alkali sulfates produce different effects on cement paste, as they act in different ways. Sodium sulfate react mainly with hydrated aluminates to form ettringite, whereas magnesium sulfate also reacts with hydrated silicates to form gypsum, brucite and silica gel (27). Ettringite formed in stronger attack (169), being instable in the presence of  $\overline{MS}$ , the attack of this produces even more gypsum, so that damages caused by  $\overline{MS}$  are in general greater than those produced by other sulfates -apparent on real exceptions have been duly explained (27)-. Calcium sulfate as such, due to its lower solubility affects to cement to a lesser extent than other more soluble sulfates.

Sulfuric acid and other sulfates may be formed in soils by oxidation in acidic media of iron sulfides such as pyrite, pyrrhotite, marcasite (29) (170). Sulfates may reach concrete in different ways and to different extents by several mechanisms conditioning the rate of attack, such as penetration, osmotic pressure, capillary rise, etc., depending mainly on concrete porosity and permeability, in turn related to the quality of construction materials and technologies (170).

The diffusibility of  $\text{SO}_4^{2-}$ -ions through hydrated cement pastes, as compared with that of cations ( $\text{Li}^+$ ,  $\text{Na}^+$ ,  $\text{K}^+$ ), is smaller towards pure water and greater towards saturated lime solution. This indicates, as stated elsewhere in this paper, that hardened cement paste behaves as a semipermeable electropositive membrane facilitating diffusion of anions (155) (158) (159), depending on their nature. So, the rate of diffusion of  $\text{SO}_4^{2-}$ -ions is 10 to 100 times lower than that of  $\text{Cl}^-$ -ions; in spite of it, chloride attack is always much weaker than sulfate attack, due to the different nature and solubility of the main products formed in each case (higher solubility for calcium chloroaluminate than for sulfoaluminate) (159). So, internal physical parameters of concrete, such as density, compacity, porosity, permeability, capillarity, etc., depending on factors other than (but in addition to) the chemical nature of the cements, complicate the problem of sulfate attack -and those of durability in general- to such an extent that it is very often difficult to establish clear and even logical relationships between chemical composition of cements and its influence on their chemical resistance (171). This is also valid as far as results of methods to study and to test durability are concerned.

Pore size distribution and amount of capillary pores over a given size (2500 Å) after a sulfate ( $\overline{MS}$ ) attack

varies very much depending on the nature of the (pure portland or blended) cement. In the case of blended cement the amount and nature of admixtures have also an influence, so that cements suffering more severe attack present more and larger pores than do better resisting cements (169). This may condition the further course of the attack on either of the two types of cements.

All these factors influence greatly the sulfate attack because in it two different processes are involved. One being of chemical nature is very rapid, whereas the other, physical in nature -ionic diffusion as mentioned- is much slower and governs the rate of reaction. This is a reason why the physical state of the mortar of concrete is decisive in determining the effects of sulfate attack and the resistance to it (172) (173). This also makes that the time before attack being very important (174), may be very variable and even very long, but once the attack starts, the destructive process runs very fast (2) (172) (175). Both processes may explain that the most important factor in the attack by sulfates is, in given circumstances, a combination -the product, as far as regression coefficient is concerned- of the (high)  $\text{C}_3\text{A}$  content in cement and the (high) w/c ratio in the paste (172).

Even external physical factors such as temperature are important in sulfate attack on cement, though this is not always taken into due consideration. Temperature may condition the type and the nature of hydrated aluminates and also those of sulfoaluminates formed in the attack of cements by sulfates. In addition, changes of these compounds once formed may be caused by changes in temperature, as they are stable phases in different equilibria which may be shifted in one or another direction depending on temperature variations (171) (176). This might explain the different (better) behaviour (but not immunity) of thermically treated cement products in sulfate attack. These different behaviours are not always sufficiently clear on the basis of a reduction of CH forming with silica compounds, in thermal treatment, more resistant calcium silicate hydrates of different composition and physical nature, or on the basis of the formation of a more crystalline tobermorite or hydrogarnets (171). Nevertheless, an indirect evidence of the protective effect of  $\text{C}_x\text{S}_y\text{H}_z$  tobermoritic gels on cements against (sodium) sulfate attack determined by expansion measurements is given by the better behaviour of industrial cement pastes and pastes obtained from mixtures of different calcium silicates and aluminates with gypsum, all of them treated in autoclave. An interpretation of the good behaviour has been proposed in terms of a covering of sensible  $\text{Al}^{3+}$  and  $\text{Fe}^{3+}$  ions in the weaker parts so resulting isolated from contact and interaction with  $\text{SO}_4^{2-}$ -ions (177). Moreover, steam curing affects better than normal curing to cements exposed to (magnesium) sulfate attack, specially if their silica content is high -low  $\text{C}_3\text{S}$  and probably relatively low  $\text{C}_3\text{A}$  contents- (178). In the same or similar sense could be invoked a higher difficulty of dif-

fusion of sulfates in solution through pastes poorer in CH and richer in tobermoritic gels, in the case of slag cements (179). The case of thermal treated -steam cured concrete- is one in which it seems that sulfate resistance (and durability in general) is much more affected by the nature and composition of the cement than by other physical factors -including thermal curing conditions- (180). On the other hand, it seems that sulfate attack on cement is more usual and important in cold than in warm weather conditions (171).

Sulfate attack is centered on calcium aluminates. Nevertheless, some points of view consider that though cement susceptibility to sulfate attack depends on its  $C_3A$  content, concrete mixes rich in cement even of medium to high content of  $C_3A$  are less attacked by gypsum waters than are poorer mixes made with low  $C_3A$  cements (181). Research work and publications on the effect of  $C_3A$  on cement behaviour is copious, as mentioned, but not always very useful to assess it duly, because of the lack of precision in describing real and/or experimental conditions (182). This is a general handicap in many features dealing with durability. Even more beneficial actions have been attributed to higher contents of  $C_3A$  in cements, in the case of a complex attack by  $Cl^-$  and  $SO_4^{2-}$  ions in sea-water (183).

On the other hand, the reaction mechanism of aluminates with sulfates and particularly with gypsum is far from being simple (171). Free energy calculations for possible reactions of various calcium aluminate hydrates -and calcium aluminate double salt hydrates- as  $C_4AH_{13}$ ,  $C_4A\bar{S}H_{12}$ ,  $C_4A\bar{C}H_{11}$ ,

$C_4A\bar{N}_2H_{10}$  and  $C_3A.CaCl_2H_{10}$  with sulfate ions show the possibility of their transformation into ettringite, on the basis of the corresponding negative free energy changes (45). Hydration of anhydrous  $C_3A$  may form hydrates of different calcium contents depending on the calcium concentration in the liquid phase. The more basic of them,  $C_4AH_{13}$ , may react in solid state even with very low sulfate concentrations to form expansive ettringite. The less basic  $CAH_8$  may be hydrolyzed to give CH and  $AH_3$ , which in solution may also react with sulfates to give ettringite as well, but not expansive, as it is formed from not crystallized compounds and it may accommodate in pores and free spaces (184).

According to different authors three or five main mechanisms have been invoked as causing sulfate attack, depending on the fact of taking into account or not the influence of cations (166) (185) (186). Such mechanisms seem to be:

- 1) formation of sulfoaluminates (ettringite) -schematically+:

- 2) formation of gypsum (schematically):

the acidic nature of sulfate attack causing surface deterioration by softening without expansion;

- 3) other reactions in which sulfate ions or sulfates are involved, as for instance formation of alkali sulfate crystals (when alkali sulfate concentration is high and conditions are propitious, for instance:  $\bar{N}\bar{S} + 10 H \longrightarrow \bar{N}\bar{S}H_{10}$  (mirabilite) also contributing to surface deterioration by spalling or splitting (166) (186);
- 4) formation of brucite (in the case of magnesium sulfate) with simultaneous formation of gypsum:  $\bar{M}\bar{S} + CH + 2 H \longrightarrow MH + \bar{C}SH_2$  both contributing to deterioration;
- 5) formation of hydrated silica (in the case of magnesium sulfate) with simultaneous formation of gypsum and brucite (schematically):

causing effects corresponding to 2) and 3) conjointly (166) (186).

Process 1) ascribed to  $C_3A$  is operative for very variable contents of it, according to different opinions and circumstances, but it seems that expansion is due to the water imbibing character of colloidal ettringite formed in the presence of CH at lower concentration of sulfates (187). Process 2) can also take place when sulfate concentration is high -more than 1000 ppm- (167), as for instance in some  $\bar{N}\bar{S}$  and  $\bar{M}\bar{S}$  more concentrated solutions of ground, sea-water and industrial waters (188). Processes 4) and 5) can take place simultaneously in some highly concentrated natural waters and some times in sea-water attack too. They are respectively characterized by elimination of portlandite and tobermorite (189). They can also take place simultaneously with processes 1) and/or 2) in the most complex cases of sulfate attack. Either of the two processes 4) or 5) or both are found in some long term sea-water attack on cements with medium contents of  $C_3A$  (188), but also in some laboratory tests carried out with very concentrated  $\bar{M}\bar{S}$  solutions. The results of such tests in general may not agree with the real ones in practice, as taking place in different conditions (189). Process 3) purely physical in nature, takes place by evaporation and concentration of salts in pores (186). As to the limit of  $C_3A$  content in cement determining the degree of acceptability of expansion due to process 1), opinions differ widely -from less than 2, 3 or 5 % till less than 7, 9, 10 or even 12 %- (166). This indicates the great influence of other not always or not well considered factors (189).

Aside from the old and well known theory on the formation of expansive ettringite -through a solid state reaction mechanism when the liquid phase containing

sulfate ions at sufficiently high concentration is oversaturated or saturated with CH (185)-, and that of the formation of non-expansive ettringite (by a through-solution process when the liquid phase is not saturated with CH), other mechanisms discarding ettringite action have been proposed to explain sulfate expansion (30). So, some opinions have been exposed in favour of monosulfoaluminate as causing sulfate expansion and deterioration instead of trisulfoaluminate. On the basis that in a paste of  $C_3A + C + \bar{C}SH_2$  expansion takes place when ettringite disappears and monosulfoaluminate forms, it has been assumed that expansive monosulfate is formed in cement pastes by reaction of  $C_4AH_{13}$  with sufficiently concentrated  $SO_4^{2-}$  ions by an anion exchange process (30) which could be schematically represented as follows:

Further increase of  $SO_4^{2-}$  ion concentration may transform monosulfate into secondary harmless ettringite by a through-solution process, its crystals precipitating in pores. The character (expansive or not) of the monosulfate depends -as in the case of ettringite- on the CH concentration in the liquid phase (185): if it is high, the lowered solubility of  $C_4AH_{13}$  hinders the accommodation of monosulfate in pores. And the exchanging-ion (anion) character of the process, essential for expansion, is confirmed on the basis of the replacement of  $SO_4^{2-}$  anions in monosulfate by other anions, for instance  $Cl^-$ , in  $CaCl_2$  solutions, according to the schema:

This might explain expansion of cement pastes in chloride ( $CaCl_2$ ) solutions by releasing of  $SO_4^{2-}$  ions, which once free and reaching the concentration needed to react with more  $C_4AH_{13}$ , may form more expansive monosulfate (30). These assumptions lead to a solution for avoiding sulfate expansion: the transformation of  $C_4AH_{13}$  into other more stable compound with a lower basal spacing, for instance, monocarboaluminate, by the action of finely ground  $CaCO_3$  added to cement (30).

Changes in ionic concentrations of solutions in contact with cement paste are important to interpretate the mechanics of the attack, as aggressive waters may leach calcium hydroxide from the paste and introduce anions in it. In the case of sulfate attack the greater amount of sulfate anions introduced corresponds to magnesium and ammonium sulfate solutions, which affords an explanation of the higher aggressivity of them (82).

In this respect three types of cations regarding sulfate attack may be considered: those forming soluble hydroxides; those forming sparingly soluble hy-

droxides; and those forming volatile or neutral compounds. Differentiations and effects take place in each case, as pointed out when dealing with the different types of attacks to concrete (30).

Sulfate attack seems to be produced through formation of gypsum, if this is not originally present:

In the attack of sodium sulfate or magnesium sulfate on cement, gypsum in both cases and sodium hydroxide or magnesium hydroxide are respectively formed at early ages (less than 3 days) according to:

But few ettringite is then formed (176).

In the case of sodium sulfate solutions, if the solubility product of CH is not surpassed, more gypsum is formed according to (schematically):

(for phases between  $C_2F$  and  $C_6A_2F$ ), and:

(for phases between  $C_2A$  and  $C_6AF_2$ ).

Increases of alkali concentration and/or of temperature make decrease the lime solubility according to I. Then gypsum precipitates, the formation of ettringite is at least stopped and ettringite still formed tends to dissolve. This explains the continuous growing of gypsum and the maximum attained by ettringite when comparing expansion by sulfate attack with the sulfate (ettringite and/or gypsum) contents in expanding specimens (176).

Leaching of lime takes also place to some extent:

increasing the alkalinity in solution if carbonation  $Ca^{2+} + 2 OH^- + CO_2 \rightarrow CaCO_3 + H_2O$  does not take place. Intensive carbonation could form thaumasite (especially at much longer terms) and plazolite  $CA \cdot CS \cdot \bar{C} \cdot H_2$ . In each case, when the solution has reached the conditions for gypsum precipitation, gypsum crystallizes (82). Thaumasite formation as needle-shaped crystals forming big masses with high silica content and low contents in  $SO_3$  and  $CO_2$  has been reported as taking place in concrete deterioration by sulfate attack (190).

In the case of magnesium sulfate solutions ettringite first formed is decomposed by the salt to form gypsum, and magnesium and aluminium hydroxides according to:

Brucite is also formed (82) and in greater amount when the alkalinity of the paste is greater than normally; this is the case when sodium silicate is added to portland cement to form grouts, as it affords an extra alkalinity depending on the molar ratio  $Na_2O/SiO_2$ . Seepage of  $Na_2O$  making the grout less compact may also contribute to facilitate magnesium sulfate attack in this case (191).

The better resistance to magnesium sulfate of portland cements with high iron-compound contents has been related to the fact that on hydration of brownmillerite in the presence of  $MgSO_4$ , Fe is displaced from places in the hydrated cubic phase (9).

A suggestive explanation has been given on the stronger but slower attack of calcium silicate hydrates (especially those of low basicity) by  $MgSO_4$  solutions than by  $Na_2SO_4$  solutions, on the basis of heterovalence and ionic radii of  $Mg^{2+}$  and  $Na^+$  ions (60) as follows: heterovalence and difference in ionic radii difficult or hinder the substitution  $2 Na^+ \longleftrightarrow Ca^{2+}$  whereas it favours the substitution  $Mg^{2+} \longleftrightarrow Ca^{2+}$ , the latter cations having the same valence and similar radii. On the other hand, adsorptive capacity of bivalent  $Mg^{2+}$  ions on calcium silicate hydrates is greater than that of monovalent  $Na^+$  ions. Furthermore, reaction products of calcium silicate hydrates with  $MgSO_4$ , i. e.,  $Mg(OH)_2$  (brucite) and  $CaSO_4$  (gypsum) are in bulk much less soluble than those with  $Na_2SO_4$ , i. e.,  $NaOH$  and  $CaSO_4$ . And finally, the protective action against ionic diffusion afforded by films of products formed by interaction of sulfates and calcium silicate hydrates depends on the structure of such films. This structure seems to be continuous, denser and more impervious for films formed from the more basic calcium silicate hydrates than for those formed from less basic tobermoritic compounds (60). In fact, it was known that the attack due to magnesium ion seems to be more intense on low  $C_3A$  cements and in the presence of higher amounts of hydrated lime (high  $C_3S$  cements), which today is clearly explained by the exchange between Ca and Mg in  $Ca(OH)_2$  and CSH to form  $Mg(OH)_2$  and MSH, the former potentially expansive, the latter much less or not hydraulic (58) (192).

In the case of ammonium sulfate attack an exchange of lime equivalent to the ammonium content takes place (82).

In conclusion, the mechanism of the alkali and/or magnesium sulfate attack on concrete seems to proceed through a front of ettringite penetration which causes cracks. Afterwards gypsum and/or brucite crystallize in the cracks causing either further expansion or the filling of cracks and pores (176).

In the case of gypsum attack on aluminates the kinetics as well as the nature of the intermediate and final products depend on the characteristics of the starting materials, on the presence, amount and concentration of  $Ca(OH)_2$ , on temperature, time, etc., even though the final compound causing deterioration be also ettringite. Differences have been attributed to variations in the d-spacings of hydrated starting, intermediate and final products (171). In the writer's opinion, if it is so when dealing with well defined (or better defined) and controlled more simple reacting compounds as are bare calcium aluminates, it is to be thought that the complexity must be necessarily much greater when dealing with not always well defined mixtures of compounds, as is the case of cements.

An early succinct summary of the hypothesis concerning expansion due to ettringite formation has been exposed (187). According to it, increases of volume have been invoked (193) (194) or questioned (195); crystallization pressure as a factor determining concrete rupture has been supported by the measurement of pressures created in the formation of calcium sulfualuminates in different conditions, reaching values up to  $200 \text{ kg/cm}^2$  (196); solid-state (194) (197) (198) or through-solution mechanisms (195) (199) have been proposed; suggestive osmotic pressure actions have been supported (200) or considered doubtful (201); thrust by anisotropic crystal growth has been advanced (202) or refused (203). More recently new points of view have taken into consideration another alternative hypothesis (187), according to which only colloidal ettringite of high specific surface formed in the presence of lime is highly expansive, if it is in contact with outer water. The expansion mechanism may be then a double-layer type of interparticle repulsion caused by a considerable adsorption of water around the ettringite, without changing its crystal lattice. This may also afford an additional explanation of why pozzolanic or slag cements and high-alumina cements with little or no  $Ca(OH)_2$  in their pastes exhibit much less expansion due to ettringite formation in sulfate attack (187). The conclusion is that attack involving ettringite formation not only depends on the (crystalline) nature of  $C_3A$  (182) -as pointed out elsewhere- but also on the nature of the ettringite formed, to the extent that its formation may produce either deleterious (disruptive) expansions or beneficial phenomena and effects -shrinkage compensation and self-stressing- (187). Other somewhat different viewpoint in the same sense is that ettringite formed in hydration at pH 11.5-12.0 by a through-solution reaction contributes to the strength and is not expansive, whereas secondary ettringite formed at pH 12.5-13.0 by a topochemical reaction may be expansive and destructive (159). It seems that ettringite formation by the one or the other mechanism depend upon the (ratio of) diffusions of  $SO_4^{2-}$ -anion and cations. This ratio being nearly 1 in the case of the lower pH-values,  $SO_4^{2-}$ ,  $Al^{3+}$  and  $Ca^{2+}$  ions meet together and form ettringite in spaces between grains -without

expansion-, whereas in the case of higher pH values the ratio is also higher and  $\text{SO}_4^{2-}$  and  $\text{Ca}^{2+}$  ions meet together with  $\text{Al}^{3+}$  ions around and on the cement grains containing aluminates (159).

In addition to what has been exposed more in detail elsewhere in this paper as regards of standard specifications and sulfate resisting cements, it is to be said here that limitations of  $\text{C}_3\text{A}$  and  $\text{C}_4\text{AF}$  do not solve the problem of sulfate attack, so that restriction of the condition of sulfate resisting cements to those meeting specifications for ASTM type V seems not to be justified. Instead, pozzolanic (fly-ash) cements made with clinker of less than 6,5 %  $\text{C}_3\text{A}$  and less than 12 %  $\text{C}_4\text{AF}$  have been proposed as sulfate resisting cements (204).

## 9. - SEA-WATER ATTACK

Much work has been done and very many publications on it have been produced dealing with sea-water attack to concrete and concrete behaviour in sea-water. Several International Congresses on Chemistry of Cements, on Navigation, RILEM Colloquia and Symposia, etc., have monographically devoted a good deal of paper to these themes. The treatment of them is obviously very difficult due to their great complexity. There is -or at least there has been- a tendency to consider sea-water attack on concrete as a well defined and homogeneous topic within the general field of concrete durability. It seems doubtful to accept such a homogeneity as being general, as potentially very variable physical factors such as climate -temperature or frost-; or mechanical factors such as erosion, streams, surfs, tidal and wave alternating actions, total or partial alternative immersion or biological factors, etc., join indissolubly their contribution to the mere chemical action due to salinity, to the corrosion of concrete by sea-water.

The mechanism of sea-water attack on concrete is aleatory and very complex, as many parameters difficult to isolate may contribute to the total damage (205). The attack acting on concrete submitted to alternative immersion and emersion in tidal zones manifests itself mainly as a physical effect of salt crystallization combined with carbonation and, of course, with mechanical, erosional and frost actions depending on local circumstances (206). In particular circumstances erosion actions of sea-water on concrete are strong. Their effects superimpose to chemical attack and facilitate it. Isolated or combined actions affect more to poor and/or to bad cured concretes (207). Combinations of physical and chemical actions correspond always to alternate immersion, whereas chemical attack alone is produced in total and permanent immersion (208). In the tidal zone alternative cycles of drying and wetting may produce concentration, crystallization and dehydration of salts (drying) and re-crystallization (wetting) processes in concrete mass, to which may contribute hygrometric and thermal action, insolation etc., as well as concrete porosity. Crystallization pressure of  $\text{Na}_2\text{SO}_4$  for instance crea-

tes an expansive force in the exposed part of specimens, similar to that caused by ettringite formation in the immersed part of them (25). Moreover, in the tidal zone a complicated process of cement deterioration takes place based on diffusion mechanisms. Diffusion is negligably slow when considering the penetration of water in concrete, but not always in the case of salt solutions, as gradients may be considerable if salt concentration in some pores and voids is much higher than in others. Complication may be even greater if either the water or the dissolved components react chemically with the hydrated compounds of the cement paste. Anyway, high gradients of osmotic pressure may be created and much more so if salt concentration increases by evaporation. If saturation is raised, crystal formation and crystal growth may take place so generating hydraulic and/or crystallization pressure similar to that of the ice formation, with the corresponding disruptive effect (209). Furthermore, complexity of sea-water attack on concrete, as referred to prestressed ocean structures has been exposed in a not exhaustive manner (210).

On the contrary, it has been timidly claimed that the attack of sea-water on cement and even the resistance of cement paste to sea-water attack seem often to be imprevisible and highly variable. In any case, so far they are considered as matters not yet elucidated, from VICAT and MICHAELIS onwards (211) (212). The reason is the great complexity of sea-water attack on concrete as the result of a number of superimposed mechanical, physical and/or chemical actions, which take place in very different conditions. It is impossible to avoid in practice such an overlapping of actions and thus many variables are simultaneously operative, and as many parameters are affected in various ways and to different extents in each moment and circumstance.

The total effect produced by sea-water attack is in general neither that corresponding to the sum of individual effects of each cause (as it is sometimes higher or much higher), nor proportional to a given (isolated) action. For instance, sea-water attack is in most cases weaker than that to be expected from the  $\text{SO}_4^{2-}$ -ion concentration, as compared with that of sulfate solutions (213). Attack by sea-water weaker than that of  $\text{MgSO}_4$  solutions of similar concentration has been attributed to a greater solubility of ettringite and gypsum in chloride solutions rather than to a lower level of reaction of sulfates in the presence of chlorides (214). Anyway it seems to be clear that sulfate attack is different in the presence than in the absence of chlorides (215). To such an extent, that in the presence of chlorides (sea-water) a positive action of  $\text{C}_3\text{A}$  in cement has been attributed to retardation of  $\text{Cl}^-$ -ion diffusion and reinforcement corrosion, quite apart from  $\text{SO}_4^{2-}$ -ion aggressivity (183). The greater solubility of ettringite in the presence of chlorides makes it to crystallize from solution in pores, in a harmless form without causing expansion (214). Though the presence of chlorides in the attack of cement by sulfates (as in the case of sea-water attack) has been considered in general as beneficial, other opinions are in support of an activation of the

aggression, the intermediate chlorinated compounds formed being noxious, as they finally form ettringite. (208).

The fact that sea-water attack is weaker than that of sulfate solutions of similar concentration would seem to shift partially the deterioration mechanism of cement paste by sea-water to the side of leaching and solution (non-expansive) processes (27). Anyway, distinction has to be made between degree of reaction -even expansive in nature-, real expansion produced, and damaging effects of it, as in fact, observed swelling and deterioration are not always proportional to the amount of ettringite formed, though expansive ettringite formation and leaching of calcium hydroxide by dissolution in the presence of magnesium salts seem to be the two principal factors conditioning the attack (205).

In fact, sea-water attack may respond to each of the several accepted mechanisms of sulfate attack or, what is more probable and general, to various of them simultaneously (167), as concentrations of sulfates may reach from less than 4000 to 7000 ppm (189).

The most general, wide ranging and complete attack by sea-water on cement up to its ultimate consequences is characterized:

- a) by elimination of calcium, either by solution of substitution for magnesium -cation exchange-, i.e., leaching of portlandite CH, formation of brucite MH or transformation of the  $C_xS_yH_z$  type of calcium silicate hydrates into the more complex and less or not hydraulic  $C_x.M_x.S_y.H_z$  magnesium type of compounds (15);
- b) by formation of secondary dense expansive ettringite through reaction of sulfates with CH giving first secondary gypsum  $C\bar{S}H_2$ ;
- c) by (subsequent) strong carbonation converting ettringite into thaumasite  $C\bar{C}.C\bar{S}.CS.H_{15}$  (16) (212) with previous formation of silica (70) (190), calcite and/aragonite (216) (217);
- d) by crystallization of gypsum;
- e) by formation of  $C_3A.CaCl_2.H_{10}$  which first prevents the immediate formation of ettringite, but being unstable in the presence of sulfates finally tends to form ettringite;
- f) by penetration of  $Cl^-$  ions in tobermoritic gels  $C_xS_yH_z$  (15) (16).

Processes a) and b) due to the action of  $SO_4^{2-}$  and  $Mg^{2+}$  ions seem to be in general more important, though action c) -moderate carbonation- and d) may also take place to some extent. So, calcite and aragonite may be formed in a progressive attack on the surface and in the paste, either of portland or slag cements, and either for short or for long periods of contact with sea-water. Brucite -solide MH- is formed on the surface or in the mass of portland cements only (218) -other previous opinions are that even in slag cements pastes MH may appear in the attack of them by synthetic sea-water (214), mainly in short contacts, whereas

secondary gypsum has been detected in surface attack of both cements during long contacts, and in mass attack of them during shorter contacts. Sometimes ettringite formed in the attack of pastes during short contacts is not found in surface attack, neither during short or long contacts, probably due to its unstability and/or to a low or very low content of  $C_3A$  in cement (219). In other aspect, processes e) and f) are favoured by the fact that penetration of  $Cl^-$  ions in pastes progresses deeper and more rapidly than that of  $SO_4^{2-}$  ions (220).

In deep and prolonged attack by sea-water on cement calcite, aragonite, secondary gypsum, ettringite and thaumasite in addition to brucite are formed (212). Gypsum and thaumasite are more abundant in the more longly and/or deeply attacked cement pastes, whereas ettringite predominates in the more slowly and slightly damaged ones. The ratio ettringite/thaumasite is lower in the former than in the latter. This seems to indicate that ettringite is formed first and transformed later into (isostructural) thaumasite by a carbonation process -also responsible for the formation of calcite and aragonite- and probably by a more or less simultaneous substitution of Al by Si, the silicium being afforded either by formation of more or less alkali and/or earth-alkali (expansive) silicates containing alkalies from either the aggregate or the cement (or both), or by silica gel formed in the carbonation itself, affecting the calcium silicate hydrates (212). This generally very slow transformation could be imagined as taking place by steps, with formation of intermediate compounds (190). In a parallel way, regarding compounds formed and destroyed by a complex attack of sea-water, ettringite, gypsum and brucite, as well as hydrocalumite may appear, and portlandite crystals and tobermorite gels may disappear. This indicates on the one hand, that acidic action by carbonation may also take place; on the other hand, that slag cements and pozzolanic cements can be, as in practice they are, more resistant to long term action of sea-water (189).

Processes involving ettringite formation can be reduced or eliminated by using cements of no or very low content of  $C_3A$ ; but when processes involving lime dissolution occur over long terms, cements with low content of  $C_3A$  -even lower than 3 %- may be affected. This shows that in preventing sulfate acidic action in long term sea-water attack a low content of CH in the hydrated cement paste, i.e., a low  $C_3S/C_2S$  ratio in clinker (188) is even more important than a low content of  $C_3A$  in anhydrous cement, at least in general (166).

At this point it should be interesting to emphasize the -at least potentially- very good performance of ternary pozzolanic (fly-ash)-slag cements made with clinkers of low  $C_3A$  content having an adequate  $C_3S/C_2S$  ratio. All this means that the prescription of a type V ASTM portland cement to prevent long attacks by sulfate concentrations higher than 1000 ppm may not be sufficient in all the cases. As far as performances of different types of cements in sea-water

are concerned, results of long term French experiences have recently been reported (15) (208) (221).

Sea-water attack has been also centered in the action of magnesium sulfate reacting with calcium hydroxide to form gypsum -through an irreversible process (222) (223)-, which, in turn, reacts with calcium aluminate to form the well known expansive ettringite:

The depressing action of chlorides in the sulfate attack may be attributed not only to an increase of the solubility of expansive calcium compounds (222) (223) but even to a greater instability and decomposition of them in chloride solutions when the content of  $\text{C}_3\text{A}$  in cement and the sulfate concentration are high. For smaller contents of  $\text{C}_3\text{A}$  it is possible that no ettringite is formed in the presence of chlorides and no attack of sea-water on cements take place (209).

The fixation of  $\text{Mg}^{2+}$  -obviously- and the loss of  $\text{Ca}^{2+}$  by cement pastes are greater in sea-water (as in  $\text{MgCl}_2$  and  $\text{MgSO}_4$  solutions) than in pure water, and they are also greater the higher the initial content of calcium compounds in cements (224). Moreover, in cements attacked by sea-water it has been stated that no monosulfoaluminate is formed, because of the lack of CH necessary to form  $\text{C}_4\text{AH}_{13}$ , necessary in turn to transform slowly the trisulfoaluminate previously and rapidly formed into monosulfoaluminate, thus

This is another of the main differences between attacks by sea-water and mere sulfatic waters: the presence of stable trisulfoaluminate and the absence of monosulfoaluminate -and portlandite- (222). An additional difference is connected with carbonation. Carbonation is insignificant under sulfate solutions and under sea-water due to the lower solubility of  $\text{CO}_2$  in them; but in any case aragonite is preferentially formed in sea-water carbonation instead of vaterite and/or calcite, due perhaps -basicity apart- to the higher solubility of vaterite in chloride solutions. These do not permit, even in basic media, either the formation of vaterite or its subsequent transformation into calcite (222). Moreover, aragonite is the denser, harder and less soluble form of crystallized calcium carbonate, and consequently the more apt to be formed stably in the more difficult conditions. Anyway, protection by carbonation is practically absent on cement in contact with sea-water (222).

Insoluble brucite may also be formed by another mechanism such as

which may accumulate in pores and voids of a fairly dense concrete, so reducing further action of sea-water on it. But the solubility of  $\text{CaCl}_2$  is high and those of  $\text{Ca(OH)}_2$  and  $\text{CaSO}_4$  are much higher in sea-water than in plain water. This may explain a much greater leaching of lime from porous and permeable concrete in sea-water (209).

As far as an explanation of the weaker attack of sulfates in the presence of chlorides is concerned, as is the case in sea-water attack- it has been invoked that a part of the aluminate in the cement paste forms the FRIEDEL's salt, and only the remainder aluminate forms ettringite (214). Nevertheless, whatever the explanation may be, experiments carried out with portland and blastfurnace slag cements submitted to sodium and magnesium sulfate solutions, either pure or each of them containing sodium chloride or sodium bicarbonate, have revealed the following facts: first, that the stronger attack corresponds to the greater formation of ettringite, particularly in the case of magnesium sulfate attack; second, that the FRIEDEL's salt is formed from monosulfate and/or from aluminate hydrate, or even from anhydrous aluminate, but not from the trisulfate; third, that the monochloroaluminate thus formed (by penetration and diffusion of  $\text{Cl}^-$ -ion more rapid and deep than those of  $\text{SO}_4^{2-}$ -ion and more than those of  $\text{K}^+$  and  $\text{Na}^+$ -ions) is not stable in the presence of sulfates, which transform it into trisulfate on attack (59) (214) -this transformation dissapoint the use of sea-water for mixing concrete (a very controverted matter) (208) particularly if cement is rich in  $\text{C}_3\text{A}$  (59)-; and fourth, that as a main consequence of the preceeding results, the high content of  $\text{Cl}^-$ -ion in sea-water has no essential effect on sulfate attack. Much greater influence seems to be attributable to the presence of sodium bicarbonate dissolved in sea-water, as it reacts with CH forming calcite on surface, so hindering or retarding the penetration and diffusion of attacking sulfates (214). Calcite may also be formed in the absence of previously dissolved sodium bicarbonate, or by the action of atmospheric  $\text{CO}_2$ , but its formation is much slower and takes place to a much lower extent, so that it cannot hinder sulfate penetration, attack and damage. In the same way  $\text{Mg(OH)}_2$  formed in the attack by  $\text{MgSO}_4$  does not influence the sulfate attack; but if  $\text{Mg(OH)}_2$  and  $\text{CaCO}_3$  are formed together, a protective effect similar to that of calcite is afforded (214).

Anyway, chlorides, sulfates and magnesium ions may form chloroaluminate, sulfoaluminate, brucite and magnesium silicate without visible expansion, while free pore space permits the free growing of crystals -mainly of those of ettringite-. Afterwards, delayed hydration of  $\text{C}_3\text{A}$  crystals closed in anhydrous silicates of the bigger grains of clinker gives place to a new formation of ettringite near to and all around of the  $\text{C}_3\text{A}$  crystals. This "secondary" ettringite enables further penetration and diffusion of attacking  $\text{SO}_4^{2-}$ -ions (58).

Observations carefully carried out have shown that the layers of concrete attacked from outside to inside contain successively aragonite (the form of calcium carbonate formed in the presence of magnesium salts), brucite, CSH + MSH surrounded by chloroaluminates and sulfoaluminates. Sometimes aragonite in the first layer and brucite in the second one have protective effects as mentioned (214), by enhancing compaction and imperviousness of the attacked paste (205). On the other hand, in superficial attack either of alite pastes or of portland cement pastes exposed to water, NaCl and  $\text{MgSO}_4$  solutions, and sea-water, calcite, aragonite and varite have been observed as products of carbonation, and gypsum and brucite as products resulting from the action of  $\text{MgSO}_4$ . In each case calcium hydroxide and calcium silicate hydrates are affected to different extents, and different forms of calcium carbonate are preferentially formed depending on experimental conditions (160).

Whatever may be, sea-water attack is quite different from that of pure sulfate solutions -and generally smaller due to surface protection of concrete (by brucite formation and carbonation, if so), by the simultaneous presence of anions other than sulfates (chlorides) and different cations. Moreover, the relative influence of cations in aggressivity depends on the  $\text{SO}_4^{2-}$ -ion concentration (23).

Isolated mineral components of portland clinker submitted to sea-water attack show that penetration of  $\text{Cl}^-$  accelerates the hydration of  $\text{C}_3\text{S}$  and  $\beta$ - $\text{C}_2\text{S}$  pastes, and that penetration of  $\text{SO}_4^{2-}$ -ions (and the consequent formation of gypsum) depends on the density or porosity -related to the degree of hydration and to the morphology- of the pastes in which may have, as mentioned, a beneficial influence as far as silicate hydration is concerned (225). But sea-water action on hydrated  $\text{C}_3\text{A}$  and  $\text{C}_4\text{AF}$  pastes consists mainly and primarily in the formation of monosulfate-like phases  $\text{Ca}_3(\text{SO}_4, \text{Cl}_2) \cdot x\text{H}_2\text{O}$ , which in the presence of  $\text{Ca}(\text{OH})_2$  and by penetration of  $\text{SO}_4^{2-}$ -ions finally form ettringite. Almost the same occurs in magnesium sulfate solutions free from  $\text{Cl}^-$ -ions (a solid solution of monosulfate and  $\text{C}_4\text{AH}_{13}$  is first formed). The chemical changes in pastes of  $\text{C}_3\text{A}$  and/or  $\text{C}_4\text{AF}$  produced by sea-water action cause morphological changes of structure accompanied by an increase of porosity, especially in the case of  $\text{C}_4\text{AF}$ . These changes are to be added to the pure chemical action in the case of sea-water attack to hydrated silicates, aluminates and ferrite-aluminates (225). On the other hand, secondary ettringite formed at later ages from  $\text{C}_3\text{A}$  occluded in anhydrous silicate crystals may cause local strains and cracks in concrete, which may in turn facilitate further penetration and diffusion of  $\text{SO}_4^{2-}$ -ions (58) (59).

Attack by sea-water brine at 80°C on mortar of ordinary portland cement, fly-ash cement and high-alumina cement shows damages attributed to expansive crystallization of gypsum and to lime leaching by ionic exchange of Ca by Mg in tobermorite (or in hy-

drated calcium compounds of the high-alumina cement pastes), in which a soft talk-like product is also formed. In the case of high-alumina cements the proportion in which both mechanisms participate in the attack may be variable, depending on the composition and nature of the cement. The product of the attack seems to correspond to a complex double hydroxide of  $\text{Mg}^{2+}$  and  $\text{Al}^{3+}$ , that ratio Mg/Al in it being also variable. (225 bis).

In general, as to the influence of the temperature on the attack by saline solutions and artificial sea-water, it has been recently reported that the penetration of  $\text{SO}_4^{2-}$ -ions, the attack of  $\text{MgSO}_4$  solutions and the corresponding expansions and damages by ettringite and gypsum formation are more intense at lower temperatures; conversely, in penetration of  $\text{Cl}^-$ -ions, formation of chloroaluminate and attack by  $\text{MgCl}_2$  no influence of temperature has been observed (226).

As far as cements are concerned, it is difficult to establish correlations and to draw conclusions relating cement types and their resistances to sea-water, as whatever the type of cement, strong attack always leads to the destructive formation of calcite, aragonite and non-hydraulic magnesium silicate (205). Being obvious that sea-water attack may act leaching lime from cement and forming ettringite with hydrated aluminates, it seems that portland cements resisting sea-water attack must be low in  $\text{C}_3\text{S}$  and  $\text{C}_3\text{A}$  (25). Some recent interesting results have been reported according to which ASTM type II portland cements -and to some extent type V cements also- mixed with water containing different amounts of either  $\text{CaCl}_2$  or NaCl, or some other salts to compose artificial sea-water ("ocean mixtures"), give at 28 days higher strength than the same cements mixed with plain water. Moreover, cements mixed with NaCl solutions and cured in "ocean mixtures" give even much higher resistances. This last result is surprising and no satisfactory explanation seems to be for it, at least for the moment (227).

It has been invoked that ettringite from ASTM type I cement (mainly formed in sea-water and by action of sodium and magnesium sulfate on  $\text{C}_3\text{A}$ ) crystallizes with expansion, whereas that of ASTM type V cement, resulting from  $\text{C}_4\text{AF}$  precipitates and remains as a non-expansive gel (202). On the other hand, laboratory and field experience have shown that under certain conditions sulfate resisting portland cements may be damaged at long terms by sulfates (228).

Ettringite, other complex hydrated calcium aluminates, gypsum, brucite, MSH formation and leaching of CH in cement paste by sea-water action depend mainly on the various proportions of the different crystalline forms of  $\text{C}_3\text{A}$ : cubic, orthorhombic and tetragonal in cement, and on their texture and grain size, rather than on the total amount of  $\text{C}_3\text{A}$ , as each of these forms reacts in different way. Attack and damage depend consequently on this, as well as on the fact that the  $\text{C}_3\text{A}$  crystals may be more or less surrounded and protected by other big silicate crystals (58) (59) (205). As mentioned elsewhere one could perhaps in-

fluence the crystalline condition of the  $C_3A$  in cement through a deeper knowledge of the stability relationships of  $C_3A$  at higher temperatures by mineralization with fluorite in clinker formation by fusion or by other non traditional burning processes. In fact, in the substitution of  $Ca^{2+}$  by  $Na^+$  -ions in the cubic  $C_3A$  a part of this is converted into stabilized orthorhombic and tetragonal solid solutions. Two of the three possible forms in cement coexist. The hydration kinetics of each of them being different in pure water, the speed of hydration of the cubic form is greater than that of the orthorhombic form and this in turn is greater than that of the tetragonal form. Moreover, to a faster hydration of  $C_3A$  corresponds a faster hydration of  $C_3S$  too. In contact with sea-water cements with cubic  $C_3A$  give more ettringite than chloroaluminate; the opposite is valid for cements with orthorhombic or tetragonal  $C_3A$ . Ettringite formed at short terms (as still mentioned) may be non-expansive, as crystallized from solution and with free space at disposal; whereas that formed much later may cause expansion, as formed locally in solid phase, without previous solubilization of alumina, and without free space for accommodation (15).

On the other hand, the penetration of  $Cl^-$ ,  $SO_4^{2-}$  and  $Mg^{2+}$  -ions in the reticulated  $C_xS_yH_z$  tobermoritic compound -though more compact than the corresponding fibrous compound- makes the former more porous, and weaker as far as the substitution of C by M to form partially less hydraulic (or non-hydraulic)  $C_x \cdot M_x \cdot S_yH_z$  is concerned. This leads to a greater friability of the paste (15).

As far as synthetic mixtures of  $C_3S$ ,  $C_3A$  and  $CSH_2$  are concerned,  $C_3S$  hydrates faster and  $C_3A$  slower in sea-water than in pure water. Proportions of hydration products in sea-water (ettringite, gypse, brucite and magnesian tobermorite) depend on the crystalline form of  $C_3A$  too. Cubic  $C_3A$  gives more of the three former products, tetragonal  $C_3A$  gives more of the latter, and orthorhombic  $C_3A$  behaves in an intermediate manner (15).

A question arises here as to the greater or smaller harmfulness of the weakening due to the more abundant magnesian tobermorite formed in the case of cements or synthetic mixtures richer in tetragonal  $C_3A$ , in comparison with that due to expansion caused by the more abundant ettringite formed in the case of cements richer in cubic  $C_3A$ . In the author's opinion this uncertainty, joined to the interdependence of both causes of degradation -among others and together with several others- could clear some of the abnormal, uncommon, unexpected and always inexplicable results and behaviours of some cements in some circumstances.

To the potential multiple variability so far exposed as far as the chemistry of cements, is concerned it is to be added those of the environment and of the concrete as regards its composition, permeability, capillarity and capillary suction, absorption capacity, pore system, etc. All the possible combinations of such potentially very variable factors intrinsic and extrinsic to concrete, overlapping to each other in all the very many possible forms and proportions, lead us, theore-

tically at least, to an extremely complicated picture of the real and practical sea-water attack on concrete. And probably they also lead us to the discouraging conclusion that the doubtful homogeneity invoked for sea-water attack as one of the main topics in concrete durability does not exist in a great majority of cases. This may be one of the reasons why some results of research work done in real practical conditions and/or of testing methods carried out in laboratories do not agree with each others, or even they are -or seem to be- mutually contradictory, when otherwise expected. As a result it is really difficult to establish correlations between cement types and their performances -for instance on the basis of short term losses in strength- the main guarantee for resistance to chemical attack being in general a high degree of compacity obtained, other things being equal, with a high cement content in concrete. The probability of such guarantee may increase by using intrinsically more resistant cements. Regarding portland cements nominally resisting sulfate and sea-water attack, some doubts already exposed have arisen many years ago on their guarantee, which now-a-days are well justified and explained (15) (229).

In the perhaps extreme but possible and even very probable complex situation of sea-water attack to concrete, simplifications, generalizations and extrapolations may be very dangerous. For instance, as far as the pure chemical aspects of the problem is concerned, attempts have been made as it has been already pointed out, to assimilate sea-water attack to sulfate attack, despite the knowledge that the action of  $SO_4^{2-}$  -ions of sea-water on cement is but very slow and secondary, due to the presence of  $Cl^-$  -ion at a high concentration (223) (224). If not so, portland cements with lower contents of  $C_3A$  would resist sea-water action better than those richer in  $C_3A$ , according to the largely supported opinion. But it is not always so, as portland cements with very low, low and high  $C_3A$  contents have been almost equally and strongly damaged, as in the case of attack by  $MgCl_2$  concentrated solutions (224).

This is so because in the case of sea-water attack a so-called "intrinsic" resistance of cements to  $SO_4^{2-}$  -ions depending on the nature and amount of their  $C_3A$  is not the only operative one. The resistance of cements to very high concentrations of  $Cl^-$  -ions and the possibility that brucite is formed filling the pores are probably much more important in the corrosive processes in sea-water as a whole. On the other hand, in very cold sea-water the action of sulfates is even much less important (230).

In the case of specially high saline sea-water, as for instance that of the Dead Sea (231) -much more concentrated in alkaline, calcium and chloride ions and less concentrated in sulfate ions-, in addition to brucite calcium chloroaluminates and magnesium oxychlorides instead of sulfoaluminates are also formed during cement attack. Something similar occurs when the attack on cement is produced by highly concentrated sea salt deposits in which strongly

corrosive kainite  $\text{KCl} \cdot \text{MgSO}_4 \cdot 3\text{H}_2\text{O}$  is formed, and a severe threefold corrosion process produced by  $\text{SO}_4^{2-}$ ,  $\text{Cl}^-$  and  $\text{Mg}^{2+}$ -ions takes place (232).

These facts explain, as mentioned elsewhere, the much better behaviour in sea-water of cements containing highly silicic slags over a certain proportion -to be fixed between 65 and 80 %- compared with that of ordinary portland cements, and even of other sulfate resisting cements -including portland, pozzolanic and high-alumina cements (224) (231) (232) (233) (234) (235). And much more so if the portland clinker has a low content of  $\text{C}_3\text{A}$ , a high  $\text{S}/(\text{A} + \text{F})$  ratio and a low  $\text{A}/\text{F}$  ratio (234).

Even better results are obtained by using ternary cements composed with low  $\text{C}_3\text{A}$  portland clinker, slag and pozzolan of adequate nature and composition, and in adequate proportions (232).

From a strict chemical point of view all these well known experimental facts are logical. Slag cements with 60-70 % of a highly silicic slag; pozzolanic cements -even made with a clinker rich in  $\text{C}_3\text{S}$ , provided that the pozzolan has a high content of active silica (about 90 %) and a low content of reactive alumina and iron compounds- (234); and ternary cements, on the one hand they all have a low content of  $\text{C}_3\text{A}$ ; on the other hand they are able to fix  $\text{CH}$ , so eliminating or reducing the formation of solid portlandite (additionally they make difficult the formation of ettringite). Moreover, they are able to form tobermoritic gels in higher proportions (234).

In conclusion, corrosion produced by solutions of  $\text{MgSO}_4$  and  $\text{MgCl}_2$  containing  $\text{NaCl}$ , as is the case in sea-water, is lower on binary or ternary composed (blended) cements. This is much more so the lower the content of free  $\text{CH}$  and/or of the more basic hydrated aluminates in their pastes, other things being constant (236).

From a more physical point of view, the higher amount of tobermoritic gels formed contributes to increase the imperviousness and to lower the penetrability of the cement paste, so protecting it from further attack. Furthermore, gels cover other sensible phases isolating them from the contact with aggressive media and inhibiting or retarding their corrosion.

In the case of pozzolanic cements as compared with normal portland cements, the effect of this physical action has been ascribed to a different proportion of phases, more than to a different nature of the phases formed. This difference in proportion of phases -particularly portlandite and tobermorite- leads to a structure of the cement paste with different physical characteristics. Among them, a greater impermeability and a greater resistance to ionic diffusion of  $\text{SO}_4^{2-}$ -ions through the more abundant tobermoritic gels (234).

In different aspect, very variable external and generally not well known circumstances condition the behaviour of different cements in such a way that it is not always sufficient to make reference to portland, pozzolanic or slag cements in terms of their chemical

composition and that of their constituents. This is sometimes less important as compared with other influencing physical factors considered either favourable or not (236) (237). But it seems clear that when the attack progresses from outside to the inside of the material, depending on its initial porosity and absorption increasing with time, this attack is weaker if the cement is adequately resistant (238).

The result is a combination of physical and chemical factors which mutually combine and reinforce, acting together simultaneously and indissolubly. A question arises: in which way and relative proportion do the whole of each of these two factors operate in each circumstance and moment?. Otherwise, which of the two factors is temporarily more important and finally decisive?. It seems obvious that there cannot be a general answer to this question. Each particular case will have its own answer, though unknown in most of them. Anyway, the importance is relative; it cannot be absolute.

This is one of the reasons why the influence of the porosity of cement pastes, mortars and concretes -open and total porosity, size and geometry of the pores, pore size distribution- seems to be so decisive in sea-water durability studies. Particularly when the behaviour of different types of cements and concretes is investigated. This has lead to affirm that if the compacity of the material is high, its behaviour is good, independently of the nature of its cement; but if the compacity is low, then the nature of the cement may have a greater influence on the chemical resistance of the material to corrosion (239). More drastically it has been expressed that when the volume of pores is less than 30 %, no attack is produced by sea-water, whatever the cement may be (235), particularly if good concrete is permanently placed under low waters. In addition, this may lead to understand a series of facts difficult to explain, as for instance the different and sometimes opposite results as far as the behaviour of cements of the same type, class and quality in sea-water is concerned; the different behaviour of one and the same cement when other variables -for instance, porosity- are involved; the alternations in the order of the behaviour -from better to worse- of different types of cements when the porosity of their respective pastes -or some other factor, including the nature of the aggressive medium (5)- varies in different aspects.

And finally this may lead to the discouraging but interesting conclusion that it will not be possible lawfully to compare results of studies and research work done in common in different countries or institutions, as far as the real and practical behaviour of different cements in various conditions is concerned, if these studies and research work are not based on the knowledge, measurement and control of the porosity of the materials involved; or at least on the guarantee that porosity is acceptably similar in all the cases and consequently it is not a variable to be taken into consideration as such.

Otherwise, one cement with a lower "intrinsic" chemical resistance might behave better than another one with a higher "intrinsic" chemical resistance, provided that the porosity and penetrability of the material made with the former be lower than that of the similar material made with the latter. The same could be said of capillary suction and rise, of absorption (233) and of many other physical factors more or less related to porosity -not always well defined and differentiated, as for instance, hygroscopicity-, when external conditions are propitious to the influence of such factors.

Furthermore, it must be added that when corrosive dislocations are mainly produced by mere physical actions due to crystallization of salts from very concentrated solutions, the behaviour of the material involved depends much more on its physical structure and of its cement paste than on the chemical nature of the cement itself.

And nevertheless things are not always so simple as to generalize and accept without caution the preceding observations. For instance, in the mentioned case of the Dead Sea, materials with a higher w/c ratio -and consequently with a higher porosity- have given better results, because they had more free space to accommodate with less or no dislocation the large amount of salts formed in a very complex process of crystallization (231).

In connection with the studies whose aim is to establish an order of behaviour of different cements in given experimental -laboratory or external field- conditions, it must be said that sometimes some not well known or uncontrolled influence may act. If the order obtained is that to be expected, then there is a tendency to minimize the importance of such influences, because one does not think about them, even if there is a certain probability that they may invalidate the comparison of results; but if the resulting order is different from that to be expected, then it is more probable that such influences are taken into account, and a greater importance is attributed to them (235).

Moreover, the order may depend on very peculiar circumstances. For instance, in the repeatedly mentioned case of the Dead Sea, mass concrete made with an ordinary portland cement behaves better than similar mass concrete made with a sulfate resisting portland cement, provided that the former is mixed with Dead Sea water instead of pure or distilled water. The explanation seems to be clear: in an ordinary portland cement richer in  $C_3A$  mixed with water containing a high concentration of  $Cl^-$ -ions a great proportion of chloroaluminate is formed; whereas in a sulfate resisting portland cement poorer in  $C_3A$ , mixed with pure water, normal calcium aluminate hydrates are formed, which are able to experiment subsequent expansive complex reactions causing dislocation (231). At least one of the factors contributing to corrosion -that depending on the deteriorating reactions of  $C_3A$ - is minimized in the former case and maintained at its expected level in the latter case. In

dependently that probably some other factors may be involved, this particular result is obviously not to be generalized.

## 10. - METHODS OF TESTING

Much controversy has been developed and much more could be still promoted on the item of test methods for cement and concrete durability. Complication, poor effectiveness, difficulty to reproduce real conditions, to interpretate and evaluate results and to apply statistical methods to them, as well as the need of a scientific basis either for destructive or non-destructive accelerated testing procedures for durability in order to guarantee a minimum of reliability, reproducibility and simplicity of them, have been aspects clearly exposed ( 4 ). A relatively recent and detailed summary of testing methods for sulfate attack has been published in connection with the extensive work on sulfate resistance carried out by the U.S. Bureau of Reclamation ( 240 ).

Some studies have been conducted to put in clear if different methods of testing lead to the same or similar results, specifically as far as the behaviour of different cements is concerned. Such studies are interesting when comparing methods based on the same or similar (comparable) principles. The results of such comparisons not always are concordant. An interesting conclusion in this respect is that LE CHATELIER-ANSTETT-BLONDIAU method (241) and ASTM C 452-68 method lead to results which seem to be concordant (242). In the author's opinion this is precisely due to the fact that in both methods the condition of similarity of principles is accomplished. Nevertheless, such concordance not always is in good agreement with the real behaviour of cements in practice, or even in other different test conditions, as far as some types of cements other than portland are concerned; for instance, pozzolanic cements containing good silicious natural pozzolans ( 5 ) (241).

In general, the methods used to study, to test or to evaluate concrete durability are indirect methods in which some parameters of the material more or less related to its "durability" are considered. This is so because of the ambiguity of the definition of durability, and this in turn because of the empiricism which considers that effects are by far more important than causes and mechanisms ( 3 ). In this sense the main difficulty in comparing results is that methods to assess durability may operate on various types of specimens of neat cement pastes, mortars or concretes, submitted to different aggressive media, in field or in laboratory, in very different experimental conditions. These methods may consider changes in weight, volume or length, strength or composition -detected in each case by chemical, XRD, IR spectroscopy, thermal analysis, etc.-, or they may be based on techniques of ultrasonic pulse time, optical microscopy, energy dispersive X-ray analysis, etc. Most of the methods show either weakness or drawbacks in measuring progressive deteriora-

tion of concrete, and according to their experimental conditions they may cause very variable degrees of damage depending on the different mechanisms of attack involved in them, either isolately or conjointly, simultaneously or successively (243). These appreciations are in agreement with the author's opinion on the difficulty and the risk to interpretate and evaluate test results, and, what is probably more important, to generalize and extrapolate them in all the cases to real practice.

The examples of the criticism made to different types of test methods could be innumerable, but the main of them refer to the adequation or inadequation of the methods to particular types of cements. One of such examples: some viewpoints on methods of testing sulfate resistance consider that in the case of slag cements those accelerated methods based on introduction of sulfate ions (gypsum) in specimens producing a deterioration "from inside" are not adequate. Otherwise, methods based on contact of specimens with aggressive sulfate solutions, which cause an attack "from outside" give reliable results as applied to slag cements. These results, when referred to specific conditions, may be related to the  $C_3A$  content in clinker and/or to the slag content in cement involved (244). But as far as the influence of the  $C_3A$  content is concerned, it must be taken into account that each of the polymorphic forms of  $C_3A$  in clinker behaves differently - as detailed elsewhere - in sea-water attack, as cubic form seems to be more sensible than tetragonal form. Independently of the little knowledge about the factors governing the formation of individual forms in clinker, the foregoing considerations claim for an idoneous method to determine the different polymorphic forms of  $C_3A$ . In this respect the fact that calculation of  $C_3A$  content by BOGUE's formulae gives results in general higher than those obtained by X-ray diffraction - and also different than those resulting from optical microscopy - seems to be important. All these difficult problems are related to the limiting specifications for  $C_3A$  in cement standards (182).

In the author's opinion it should be clearly declared in each case what must be understood by "an adequate testing method": one favouring some given types of cements, though its results are not clearly in agreement with their behaviour in practice, or another one in which the situation is the contrary?. Independently of the fact that some methods seem to favour to some cements - and consequently to impair others - as far as their real performance in practice is concerned; the so-called "accelerated" methods of testing generally do not give sufficiently reliable results.

As far as accelerated methods of testing durability are concerned, based on increasing of tensions and stresses, temperature, pressure, concentration, porosity, percolation, surface of contact, surface-to-mass ratio; on decreasing of specimen size; on alternating (wetting-drying, freezing-thawing or immersion-emersion) conditions or renewal of aggressive media; on previous introduction of the attacking agent into the cement paste, etc., and in general on all what tend to enhance

intensively and/or extensively the contact between cement or concrete and aggressive media, it must be considered if they really (technically and scientifically) represent natural or practical conditions, or if (on the contrary) their arbitrary empiricism introduces new disturbing factors not present in practice, which may alter the mechanisms and/or the kinetics of the real aggressive process. If so, the methods may affect (at least quantitatively when not also qualitatively) the results, so that no reliability can be expected ( 3 ) (245). Other aspect concerns the relationships between the properties and parameters observed or measured in tests, the processes (mechanisms and kinetics) taking part in the attack and the damaging effects produced, as these latter, for given processes even expansive and disruptive in nature may be absent, depending - often mainly - on real and testing conditions and/or materials, rather than on processes themselves (245). All this may have important consequences when comparing behaviours of materials which otherwise - i.e., in practice - would perhaps show a different performance ( 3 ).

Methods have been proposed as being of general application to almost every type of cement using medium-size bars of normal mortar semi-immersed in magnesium sulfate solutions and measuring the strength of both, immersed and exposed part (172). Nevertheless, accelerated tests generally do not provide a quantitative measure of the prospective service life of concrete, even under ordinary conditions. They are intended to evaluate rapidly in either absolute or relative terms the resistance of concrete to specified exposures and they may be helpful in comparing the prospective durability of individual concretes. The value of such tests depends on their degree of simulation of service conditions in practice, and on the extent to which they reproduce the responses of concrete in such conditions. They are needed because of the lack of possibilities to evaluate quantitatively those properties of concrete which control its response to environments, and consequently they must produce the same or very similar effects than those occurring in practice, on the same material as used in practice. Such conditions are always difficult to be accomplished ( 29 ). Approaches to it can be reached if accelerated methods of testing take into account: type and nature of the attack (weakening by leaching -lixiviation- or by chemical reactions involving ion exchange; disruption by volume changes due to crystallizations); the corresponding type of laboratory exposure; the criterium to evaluate the attack, so that laboratory results can give reliable indications on resistance of cements and concretes to specific aggressions, consistent with field experience ( 29 ).

To such extent it is so considered that suggestions have been made in the sense that even by theoretical considerations on sulfate attack on concrete, it should be possible to foresee its resistance, better than by results based on accelerated tests carried out in highly concentrated aggressive solutions ( 82 ). So, it is thought that the problem is to select those accelerated methods the "more adequate" in each case for each

particular purpose. For instance: it seems to be evident that in comparing the relative chemical resistance of different types of cements, elongation measurements are not always sufficiently indicative, and the same could be said about methods based on neat paste testing and/or on "internal" attack (172). More useful in this respect seem to be methods based on indexes of aggressivity defined as the ratio of flexural strength of prisms in aggressive media and in pure water at the same ages. And much more so if the age is not excessively short (better 180 days than 56 days, for instance). In this respect, as far as differential behaviour of several types of cements is concerned, relatively short periods of observation do not permit to establish any clear conclusion, as results are not sufficiently discriminative; even they may be contradictory (246). Improvements in results can be obtained if these ratios of strengths are represented in function of the logarithm of the age (days), or if a mean value of them at different ages is taken as representative of the comparative behaviour of different cements. In this respect KOCH & STEINEGGER method more or less modified (improved) in its application seems to be of more general use than are other methods determining only the cement resistance to calcium sulfate, either acting "from inside" or "from outside" (247). An interesting alternative developed to assess cement resistance to sulfate attack is that based on the measurement of the compressive strength of small cubes immersed in sulfate solutions at constant pH-value ( 9 ) ( 245 ). Another new method proposed seems to be rapid, giving reliable results which permit to evaluate the behaviour of different cements, so contributing to solve the problem of lack of correlation between laboratory testing and field performance of concrete (228).

The method of K&S permits to evaluate and interpretate the influence of  $C_3A$  content in portland cements (249) -always with the reserves and limitations exposed elsewhere in this paper-. It also permits to evaluate the influence of the slag content in slag cements, that of the cation in the case of different sulfates, that of the concentration in the attack by sulfates or sea-water, etc. Thus its results seem to be in agreement with logical considerations on the composition of portland and slag cements and, as far as such cements are concerned, the method seems to agree with appreciations and conclusions of other more controverted methods such as LE CHATELIER-ANSTETT-BLONDIAU and ASTM (247) (250). Other methods seem to be particularly appropriated to assess on cement resistance to sea-water attack (251).

Some of the more drastic tests for cement susceptibility to sulfates (gypsum) -for instance the mentioned LE CHATELIER-ANSTETT-BLONDIAU method- operate with hydrated neat pastes. Their results may depend on the degree of hydration of the paste at the time of mixing it with gypsum, which in turn may depend on the type and other characteristics of the cement. So, in order to operate always in the same or very similar conditions of very advanced (if not total) hydration of the cements, a method has been develop-

ped to accelerate hydration maintaining all the other experimental conditions of the test. Acceleration is provoked by chemical action of vibration and percussion on the hydrating paste (252).

Some other points of view on accelerated methods state that all of them based on acceleration procedures other than those consisting in the increase of the surface/volume ratio of the specimens risk of great deviations from real conditions and consequently their results may lead to highly erroneous interpretations and conclusions ( 25 ). This consideration advises that it is indispensable to compare every accelerated method with one or several slow methods during sufficiently long periods of time, before taking the rapid one into consideration, as the slower methods are generally much more in accordance with real results in practice (246). On the other hand, long term testing is recommended on concrete specimens submitted to semi-immersion conditions in saturated  $CaSO_4$  solutions and/or in sea-water; lean concrete of high w/c ratio and rich concrete of low w/c ratio, as well as monthly renewal of aggressive medium are also recommended ( 25 ).

As far as accelerated test methods for alkali-aggregate reaction are concerned, one of them has been quite recently proposed (253). Those based on heating-cooling or wetting-drying exposure do not show a close correlation between their results in terms of expansion observed and alkali content of cements, other influencing factors being simultaneously involved. Other standard methods of testing show a similar lack of correlation between expansion measured and susceptibility of aggregates, all depending in addition on the ratio of reactive silica to available alkalis, as compared with the most unfavourable ratio (29).

In the author's opinion all these facts put the question of whether specifications for low-alkali cements in cement standards and those for aggregates in some of the corresponding standards are sufficiently justified or not, specially the former ones implying harder and antieconomical conditions in cement manufacture, particularly nowadays when sparing energy and reducing fuel consumption in seriously recommended.

Finally, in order to overcome the insufficiency of present methods of testing durability in general, several proposals have been made -and are continuously made- to elaborate common test methods based on general (scientific and practical) principles, real experimental conditions, reliable results easy to evaluate and interpretate, to which statistics can be applied. In these aspects, pessimism due to the difficulty of the task, and optimism based on the work done and now running have been manifested (254) (255).

## 11. - STANDARD SPECIFICATIONS

Most countries produce and standardize cements resisting to some type of attack: sulfate attack (gypsum and/or other sulfates), sea-water attack, carbonic acid attack, etc.. Some other countries tend to this type of standardization and so in recent time Japan, among others, has included in the Japanese portland cement standards those corresponding to the chemical composition of sulfate resisting cements, comparing their requirements with those of many other foreign standards (256).

In general, the problem of standard specifications for chemically resisting portland cements is linked to that of the recommendations for using one or another type of portland cements, or of cements other than portland, in each particular case of foreseeable aggressivity. This is a point in which some confusion may be created due to differences in criteria of different countries, not precisely based on scientific and/or technical viewpoints, but sometimes on commercial interests.

In the case of portland cements it seems to be a general qualitative agreement as to the conditions to be fulfilled for their chemical resistance to sulfates or to sea-water attack, for instance. Something different occurs in the case of cements other than portland, as countries possessing natural pozzolans claim for the use of pozzolanic cements, whereas other countries lacking of such pozzolans invoke the use of fly-ash cements, and finally other countries with traditionally produce and use successfully blast-furnace slag cements consider them as the more adequate. This may create confusion to an impartial observer and much more so because each of the mentioned cements has properties which make it at least partially apt to be used in some given cases of aggressivity. The confusionism may arise when trying to generalize and extrapolate the use of one or another of such cements in all the instances.

It is very difficult to explain, among others, the fact that very large variations are observed in the behaviour of good concretes made with more or less sulfate resisting portland cements in contact with (sodium) sulfate. On the other hand, such laboratory results agree with field results. Moreover, some pozzolans with low water requirement in pozzolanic cements of moderately low  $C_3A$  and  $C_4AF$  contents improve substantially the behaviour of cements in sulfate attack. All these facts lead to question the perhaps excessive importance attributed to the more stringent limitations of  $C_3A$  and  $C_4AF$  contents, as far as the sulfate resistance of portland cements is concerned (182) (204).

In a recent general report on sulfate resistance of cements, concerning last works published up to 1977 it is stated that, according to the literature, sulfate resisting portland cements should be used when sulfate resisting concrete is required; that phase composition of cements does have a significant influence on sulfate resistance of concretes, though not so much as the bibliography and the standards indicate (1).

In the author's opinion this is an important point for consideration as, generally speaking, some papers probably tend to overestimate some experimental results, and some standard specifications tend to secure and to guarantee -perhaps too emphatically- the performance of some cements in some aggressive conditions. If so, this leads to consider once more if the (excessive?) rigour of some standard specifications is always sufficiently justified. And so much so as the problem of limiting the  $C_3A$  content of portland cement in standards to make it more resistant to sulfate attack may have implications in cement manufacture, cement properties and cement behaviour, other than those concerning durability. So, the limitation of  $C_3A$  content in cement standards should be considered very carefully (182). On the other hand, limitations of  $C_3A$  and/or of  $x C_3A + y C_4AF$  and/or  $C_3S$  in standards do not consider influences of clinker burning and clinker cooling conditions (257).

From practical points of view, as far as cements resisting sulfate attack are concerned, it is obvious the much emphasis put in aluminate phases. Nevertheless, ferritic phases are also affected, and this has been also emphasized in discussing the chemistry of sulfate attack in terms of differences in  $C_3A$  and ferrite phase contents of cement clinkers (8) (240). In the author's opinion this leads to the conclusion that specifications concerning portland cements resisting sulfate attack must take into account not only the  $C_3A$  content, but also the  $C_4AF$  content, either as the bare sum or as some sort of "composed" sum. In fact, portland cement resistance against attacks of different degree has been expressed in terms of chemical and/or potential composition. More particularly in terms of the A/F ratio and in terms of  $C_3A$  and/or ( $x C_3A + y C_4AF$ ) -and some times  $C_3S$ - contents. (6) (23) (257). (Concrete Yearbooks, ACI Manuals of Concrete Practice, DIN 1164 Standards, ASTM, Soviet, Spanish, etc. Standards). Consequently, portland cements low in all of the mentioned parameters are considered as being adequately sulfate resistant, and in each case different specified limits for  $C_3A$  and/or for the ("composed") sum of  $C_3A$  and  $C_4AF$ , depending on country standards and local conditions as mentioned are fixed. For instance, resistance to sea-water attack is defined in the French specifications by the following two prescriptions:  $C_3A \leq 10\%$  and  $C_3A + 0.27 C_3S \leq 23.5\%$ . Other similar prescriptions are imposed by several other standards; those of ASTM are:  $C_3A \leq 8\%$  and  $C_3A + C_3S \leq 58\%$ . Different limitations of  $C_3A$  in norms seem not to be always fully justified, as it has been broadly observed that there is no close correlation between  $C_3A$  content of portland cements and their resistance to sea-water attack (25). A closer correlation seems to exist between  $C_3A$  content and resistance of portland cements to gypsum attack (gypsum soil waters). So, portland cements resistant to soil waters with sulfate contents above certain limits must be low in  $C_3A$  and  $C_4AF$ , the

maximum contents of them being variable with national standards. As in the previous case they affect to the  $C_3A$  content and to a simple or "composite" sum of  $C_3A$  and  $C_4AF$ . For instance, ASTM and French Standards specify  $C_3A \leq 5\%$  and  $2 C_3A + C_4AF \leq 20\%$ ; and Soviet and Spanish Norms prescribe  $C_3A \leq 5\%$  and  $C_3A + C_4AF \leq 22\%$  (6) (25). All these limitations, particularly those concerning  $C_3A$  are always subjected to the criticism based on the decisive influence of the different crystalline forms of  $C_3A$  in cement, on durability (205) (258). So, it seems not possible to consider the attack on  $C_3A$  without discrimination. The various forms of it still identified and characterized: cubic orthorhombic and tetragonal react in different way with sea-water. Cubic  $C_3A$  gives more ettringite, gypsum and brucite, whereas tetragonal  $C_3A$  induces the formation of more MSH than the other two forms in the cement paste as already mentioned, (182) (205).

In the author's opinion the difference is important, as it may affect even to the qualitative nature of the attack: gypsum, ettringite and brucite formation imply mainly a disruptive action by expansion due to crystallization pressure and crystal growth, whereas the formation of non-hydraulic magnesian tobermorite compounds by cation exchange implies a lixiviating action causing softening and weakening of the structure of the cement paste.

As far as limitations of  $C_4AF$  in one or another form are concerned, they seem to contradict in any way the statement that portland cement rich in iron compounds resist better the magnesium sulfate attack (9).

"Synthetic" portland cements obtained by mixing pure phases have shown that for a moderate content of  $C_3S$  (50 %) and even for a low content of  $C_3A$  (1 %) the susceptibility of the cement is higher (its behaviour is worse) when  $2 C_3A + C_4AF$  exceeds than 20 %. The performance is improved if the  $C_3S$  content is lowered to 35 %. Nevertheless, great differences have been observed between behaviours of laboratory cements obtained as mentioned and industrial cements (257), due to minor components (manganese, phosphorous, titanium) absent in the former (27) (257), as stated elsewhere in this paper. Such differences cannot be neglected when stipulating values and limitations of potential composition of portland cements in standards, as they may qualify quite differently the same cement according to a given limiting specification. For it, results obtained with industrial cements seem to be much more independent -or even contradictory- as related to those to be expected from "theoretical", "rational" or "logical" considerations. Among industrial cements such differences are not only due to minor components, but also to the manufacturing processes -burning, cooling, etc.-, which determine the glassy or crystalline condition of  $C_3A$  and other aluminate and/or ferrite solid solutions (257). So, specifications based on calculated potential composition are of little

significance, as similar compositions may correspond to different behaviours. The question arises of whether these differences based on minor components and on manufacturing process peculiarities, generally not taken into account in standards, may explain some or many of the sometimes apparently confuse or contradictory results. The author's opinion in this respect is inclined to be moderately affirmative.

Cements containing slag, or natural pozzolan, or fly-ash, generally in high proportion -much higher in the case of slag cements (always over 50 %) (25) may be adequate as far as durability is concerned. The mechanism by which such materials are operative may be common to all of them or specific of each of them. The common mechanism is the dilution of the clinker portion of cement, and hence that of  $C_3A$  and  $C_4AF$ , and the different nature of the calcium silicate hydrates formed. The specific mechanisms are based on the hindering of the formation of  $Ca(OH)_2$  saturated solutions -and hence that of highly basic  $C_4AH_{13}$ -, as well as the fixation of (almost) all the  $Ca(OH)_2$  in the case of pozzolanic and fly-ash cements (23) (184); and on the much less  $Ca(OH)_2$  formed in the case of blast-furnace slag cements, which consequently form much less gypsum and secondary ettringite (59). So, the performance of slag cements in saline attack (chlorides, sea-water) is in general much better than that of portland cements, and so much so the higher their slag content (162). But on the other hand, such slag cements perform well in sea-water provided that concretes are fully immersed; not as well if concretes are (partially) exposed to air (25).

In a similar way to what happens with limitations established in cement standards for composition of portland cements, the limits established to fix the aggressivity degree of sulfatic water and soils are very variable and depend on countries and organizations. Those of DIN 4030 and of ancient CEM-BUREAU Working Party, as well as those of TGL Standards (DDR) seem to be sufficiently explicit and detailed (23). It can be said in a summarizing and general manner that attack on concrete is sure and its consequences may be important if one or several of the following conditions are fulfilled:  $pH < 4.5$ ; aggressive  $CO_2 > 60$  mg/l;  $SO_4^{2-}$ -ion concentration  $> 3000$  mg/l.

## 12. - CEMENT

One of the main problems in durability of concrete is that of the more suitable cements for a given type of attack depending on aggressive media and conditions. In a general manner it can be said for instance that, independently of the well known conditions to be fulfilled by any concrete to resist better whatever type of chemical attack, neither high-early strength cement nor ordinary portland

should be used for concrete resisting sulfate attack, owing to the two more important mechanisms of deterioration: lime leaching and expansive sulfoaluminate formation, depending on the nature and amount of sulfates (calcium, magnesium, sodium, ... with very different solubilities in the ratios of 1 to 150 to 200) and on the nature and composition of the cements (170). On the other hand, sulfate resisting portland cement or better, blast-furnace slag cements or pozzolanic cements should be used (170). In some special cases supersulfated cements or high-alumina cements are more adequate (170). The same conclusion has been reached as to the behaviour of sulfate resisting and moderate heat portland cements and fly-ash cements in contact with magnesium sulfate solutions (169).

As almost always, not only chemical but also physical factors are involved in durability, and hence the difficulty and the incertitude of some results in laboratory testing and in practice. For instance, the importance of the age of test pieces (or that of real concrete) -i.e., the degree of hydration and hardening-, as well as the influence of testing conditions has been revealed by studies made in Germany (as well as in many other countries) on concretes exposed to sea-water attack at Wilhelmshaven. Conclusions were drawn contrary to real practical results, as far as the behaviour of portland and slag cements containing pozzolanic ("trass") materials. Premature erosion on concretes of low maturity -so much so as pozzolans behave in general as inerts at early ages in hard thermal and weathering conditions- may explain the abnormal results observed (259). So, the hardening rate of the cement -as well as its curing conditions- as factors determining the early strength, have a great influence in the performance of the cement, independently of its chemical nature. This is the reason why some slag cements show sometimes a worse behaviour, and also why the performance of pozzolanic and slag cements specially -but in general of every cement- is better the longer the curing period in adequate curing conditions (2) (260).

When attempting to correlate the chemical nature of the cements, either in terms of their chemical analysis or of their calculated potential composition, (in the case of portland cements) with their performance in aggressive media, attention must be paid to the nature and proportion of the possible added materials, as well as to the chemical nature of the clinker. In fact, additions may modify the fineness (granularity, granulometry) of the resulting blended cements as compared with that of the corresponding portland cements, so that the former may give more capillary adsorptive -and hence less durable- pastes in function of their higher content of finer particles than the latter (261). But, on the other hand, additions may afford chemical properties and actions in benefit of a better durability.

The behaviour in sea-water of synthetic slag cements obtained from synthetic clinkers with various contents of  $C_3S$  and  $C_3A$  and slags with various C/S ratios

-basicities-, mixed in different proportions, shows that the influence of the clinker composition is greater than that of the slag. The clinker influence depends on its contents of  $C_3S$  and  $C_3A$ , and that of the slag on its C/S ratio and/or on its A content. In both cases the relationship is inverse. The influence of the cement itself depends on the ratio slag/clinker, particularly for ratios lower than 65 %. Moreover, it seems that for higher ratios slag cements resist sea-water attack regardless of the compositions, either of clinker or of slag (262).

One reason for it may be that the cation exchange of Mg by Ca between  $C_xS_yH_z$  and sea-water to give a non-hydraulic  $C_x.M_x.S_yH_z$  (in the limit  $M_xS_yH_z$ ) is much more restricted in the case of slag cements than in the case of portland cements (15) (208).

On the other hand, slag cements are also more resistant than portland cements to saline and thermal water containing alkaline and magnesium sulfates and chlorides, as salinity accelerates the development of their strength. They resist also better to carbonic attack, fairly rapid on them but not progressing (263). To saline solutions of  $MgCl_2$ ,  $MgSO_4$  and mixtures at different temperatures slag cements behave much better than sulfate resisting cements, and these better than ordinary portland cements (264).

Nevertheless, some doubts have been expressed as to the resistance of slag cements to sulfate attack when the  $Al_2O_3$  content of the slag is high. Increasing substitutions of  $SiO_2$  by  $Al_2O_3$  in artificial vitreous slags reveal increasing drops in strength of laboratory slag cements. Such cements with normal blast-furnace slags perform considerably better when the slag content increases from 35 to 50 %, particularly if their fineness increases too (179). Moreover, cements with 50 % of slag content seem to be able to resist sulfate attack if the alumina content of the slag is low and the  $C_3A$  content of the clinker is lower than 10 %. This means that a normal portland cement clinker may be used to produce a sulfate resisting cement provided that at least 50 % of a slag poor in  $Al_2O_3$  is added to it and the mixture is ground to sufficient degree of fineness. This also means that the chemical composition of the slag and its proportion in the slag cement condition the behaviour of the slag cement in sulfate attack more than does the clinker nature (265). This, as applied to normal (commercial) slag cements as far as their resistance to sulfate attack is concerned, seems to be at least partially different from -in opposition with?-similar considerations as applied to special (synthetic) slag cements -both slag and clinker being synthetic- as far as their resistance to sea-water attack is concerned, as above mentioned (262). Nevertheless, much lower contents of slag -about 10 to 15 %- have been invoked as being beneficial to the sulfate resistance of portland cements made with clinkers with up to 7 to 9 % of  $C_3A$  (266).

Portland cements with low  $C_3A$  and/or low ( $x C_3A + y C_4AF$ ) content -limits depending on country stand-

ards- are considered resistant to sulfate attack (23) (25) (184) (257). This chemical resistance of portland cements has been attributed to the formation, on their hydration, of more complex hydrates with a more resisting structure, containing simultaneously lime, alumina and silica, or lime, alumina, iron oxide and silica (267) (268).

In connection with the increase of sulfate resistance of portland cements, improvements have been achieved by using additions containing phosphorous ( $P_2O_5$ ) and fluorine (electro-thermo-phosphorous slags) to clinkerizing raw mixtures. The effect is the lowering of both  $C_3A$  content and  $C_3S/C_2S$  ratio, to a considerable extent (269) (270). Very special cements highly resistant to sulfates are those portland cements containing barium in proportions of about 4 to 6 % of  $BaO$  (271).

An interesting observation has been made concerning the generally accepted resistance of cements with A/F ratios lower than 0,64 and consequently exempt of  $C_3A$ , at least "nominally" (FERRARI cements). It is considered that  $Na_2O$  not combined as sodium sulfate may form in the clinker, as is well known,  $NC_8A_3$ , but according to:

the consequence is the lowering of  $C_3S$  content in favour of  $C_2S$ , and that of  $C_4AF$  in favour of  $C_2F$ , with simultaneous formation of an unexpected and undesirable phase (in general  $N_xC_{(9-x)}A_3$  in which  $x > 0,3$ ), which is susceptible to sulfate attack. This may lower the sulfate resistance of cements free from  $C_3A$ , particularly when high  $Na_2O$  and low  $SO_3$  contents are present in raw material and raw mixes. This could also afford an explanation, at least in some cases, of the abnormally bad behaviour of some cements free from  $C_3A$  (272).

Really it has been but very little advanced in deciding whether portland cements with lower contents of  $C_3A$  -eventually with lower contents of  $C_3S$  too- or cements other than portland -slag cements, pozzolanic cements- behave better or worse when exposed to sulfate or sea-water attack. A brief but very significative discussion has been developed ten years ago (27). According to it, independently of the nature and concentration of the sulfate(s) involved and of the details and circumstances of test pieces and test procedures, etc., the behaviour of "pure" portland cements or that of "composite" cements will depend, other things being equal or similar, on the composition of clinkers and additions. Variability observed -even in terms of contradictory or not logical results- is fatally due to the fact that neither clinkers nor additions are chemically pure and easily defined compounds and that finally, cement chemistry is far from being a chemistry based on pure substances reacting through simple and well defined processes obeying to well known kinetics and stoichiometry. So, not always the experimental results permit to accept that, for instance, portland blast-furnace slag cements perform better than portland cements or conversely (27) (273).

But in general, systematic studies on portland cements with null (0 %), medium (about 8 %) and high (about 12 %) contents of  $C_3A$ , as well as on slag cements containing (relative) high (75-80 %), medium (65 %) and low (50 %) slag contents have clearly revealed that, for example, the attack by sodium and magnesium sulfates, either alone or containing sodium chloride or sodium bicarbonate, is always related to the amount of ettringite formed in each case. The better behaviour of the cements is inversely related to the content of  $C_3A$  of portland cements and directly related to the slag content of slag cements (214).

In the case of sulfate resistance in general many good arguments have been invoked in favour of the better behaviour of pozzolanic cements (and slag cements). Surveys of them have been afforded (274) (275) emphasizing different possible actions. Thus the fixation of  $Ca(OH)_2$  with formation of more complex hydrates (267) (268) (276). Or the higher protective action on susceptible alumina compounds exerted by impervious films of different calcium silicate hydrates (204) (277) -with higher S/C and S/A ratios in the case of pozzolanic cements and with higher S/C and lower S/A ratios in the case of blast-furnace slag cements- (15). Protection also causes retention of lime from leaching (274). Or the more abundant gels lowering ionic diffusion (particularly that of  $SO_4^{2-}$  ions) through pastes (278) of lower penetrability and higher impermeability (279) (280), despite their higher porosity and water demand (156) (274). Emphasis has also been put on the instability of ettringite in the presence of pozzolans (281) and in the absence of  $Ca(OH)_2$  (274).

All these explanations in addition to some others (268) (277), seem to show that not only a mechanism alone of the several possible is always responsible for the higher resistance of some cements to sulfate attack, but probably various of them acting together are responsible in most of cases.

From a strictly chemical point of view sea-water attack should be stronger on pozzolanic cements than on portland cements. The reason could be that sea salts in bulk, and more particularly magnesium salts, cause a substantial decrease of pH in saturated solutions of  $Ca(OH)_2$  up to 9,5, unless solid  $Ca(OH)_2$  in excess or hydrated cement paste are present in contact with solutions or sea-water. When hydrated paste is that of a pozzolanic cement, excess of  $Ca(OH)_2$  may not be available, and pH may not be maintained at a high value (282).

Pozzolanic cements with 25 to 35 % of pozzolan (or an adequate fly-ash instead) and slag cements with no less than 65 to 70 % of slag -considered as equivalent to portland cements with less than 3 %  $C_3A$  and 5 %  $Al_2O_3$ - may be estimated as sulfate resisting cements, specially if their clinker component corresponds to that of a sulfate resisting portland cement (26). Another similar statement indicates that for sulfate contents in water higher than 400 mg/l or in soils higher than 300 mg/kg, portland cements with less than 3 %  $C_3A$ , slag cements with high content of slag (25) -more than 70 % (162)- and slag cements from

clinker with less than 3 %  $C_3A$  and slag with less than 13 %  $Al_2O_3$  are considered as being resistant (283).

Slag cements submitted to sea-water attack form much less secondary ettringite than portland cements due to the much lower content of  $Ca(OH)_2$  in their hydrated pastes (1) (59). The same is valid for pozzolanic cements through a mechanism of fixation of  $Ca(OH)_2$  (58).

It has been stated that differences in behaviour of more resistant pozzolanic cements to sulfate attack are observed, depending more on the quality of the pozzolan than on the clinker composition as referred to ASTM II and V types of portland cements (8) (240). On the other hand, fly-ashes considered as pozzolanic materials may afford higher resistance to sulfate attack. But it has been also claimed (284) that some fly-ashes act in the reverse sense, so that specifications of requirements for fly-ashes are needed, as for instance those of ASTM. Moreover, it has been observed that when fly-ashes act positively, the increase in sulfate resistance is greater the higher the content of their fine fraction. This leads to think in a physical effect of enhanced compacity in the cement paste caused by the fly-ash, superimposed to its pozzolanic -chemical- action (8). This is also in the line of some patents of sea-water resistant concretes of low porosity, made with very finely ground cements.

Favourable modifications in the structural compactness of the cement pastes may be achieved by adding "water (soluble) glass", either to portland or to slag cements. In the case of the former significant amounts of  $Ca(OH)_2$  are present in their pastes, which facilitates a marked attack by acid waters and soil waters containing alkali and earth-alkali sulfates and chlorides, owing to the well known formation of ettringite due to water and ionic penetration. In the case of slag cements no  $Ca(OH)_2$  is present in their denser pastes. In both cases additions of water glass contribute to densify the cement paste so difficulting the penetration and diffusion of aggressive agents (285).

Sodium chloride accelerates the hydration of slag in slag cements, so contributing to a more rapid formation of abundant tobermoritic gel phases of lower basicity, and to reduce the porosity and permeability -penetrability- of the cement paste. This is a reason why in some cases, as for instance, that of cements for boring oil-wells -i. e., used at higher temperatures and pressures- their performance is better when mixed with salt solutions -specially sodium and magnesium chlorides- similar to those found in the ground, to which oil-well cements must resist (286).

The chapter dealing with the behaviour of cement pastes modified by the presence of synthetic resins, plastics polymers and in general organic materials added to cements or concretes would be extremely wide if treated. This is not the case now and here, but by the way it could be said that the performance of such differently modified binding materials is very variable depending mainly on the behaviour of the organic modifying materials, as far as its alkaline hydrolysis is

concerned, in the presence of cement alkalinity in aqueous pastes (287). The performance may be no good, unless the material is resistant to the hydrolytic action of  $Ca(OH)_2$  (288).

The improvements afforded by heat treatments (steam curing) of cements at normal pressure and specially at higher pressures (autoclave) to their sulfate resistance is greater for cements originally not highly resistant, i. e., for those having a fairly high content of  $C_3A$  (27). Hydrothermal treatments modifying the composition and the structure of hydrates formed may also alter the behaviour of cement pastes against corrosion. Silicate hydrate phases may undergo different actions, not only due to their higher or lower basicity and density, but also depending on their higher or lower specific surface. Less basic tobermoritic calcium silicate hydrates of higher density have also a higher specific surface than the less dense and more basic ones. This implies a different behaviour, for instance as far as carbonation is concerned. This may also affect the nature of the more or less protective films formed in the attack by alkaline or magnesium sulfates; this explains the better behaviour of the more basic calcium silicate hydrates resulting in hydrothermal treatments of cements when in contact with such sulfates (60).

As special cements presenting the main advantages of portland cements and high-alumina cements (with none of the major inconvenients of either of them) as far as general chemical resistance is concerned, the so-called "alumina-belite cements" have been proposed (289). These cements are defined by a special lime-saturation factor and by silica and alumina moduli corresponding to ordinary portland cements. Their prevailing phases are  $CA$ ,  $\beta$ - $C_2S$  and  $C_{12}A_7$ . Other phases as  $(CA)_3CS$  and  $(CS)_2CS$  are considered responsible for the increased chemical resistance of such cements manifested in sodium, calcium and magnesium sulfate solutions, as well as in sea-water (chlorides). Thus, these cements have been proposed for sea-water works and dam construction (289). On the other hand, it has been recently stated the very good performance of high-alumina cements in soil water and sulfate attack (25).

It would appear that in sulfate attack at early ages the type of cement is less significant than the quality of the concrete. Nevertheless, the use of a sulfate resisting cement is even then better, particularly if concrete quality is not exceptional, though it is doubtful if this assertion is equally valid for longer term behaviour of such cements in the same conditions (26).

Anyway, one of the more efficient measures to prevent the rapid and intense effects of a chemical attack (whatever it may be) on cement and concrete is to avoid a premature contact of aggressive media with the material, when this has not yet reached an adequate degree of hardening (2) (259) (260).

When relating sulfate resistance of portland cements to their potential calculated  $C_3A$  contents, observations have been made on the convenience of correcting

cement analysis for minor oxides of titanium, phosphorous and manganese, as the criteria (limiting values of  $C_3A$ ) to separate cements of good or poor sulfate resistance may substantially vary (27). Anyway, cement composition and particularly  $C_3A$  content is much more important -with the cautions and reserves exposed elsewhere in this paper- in intermediate and lean concrete mixes than in rich mixes, according to the previously exposed (26). This is once more a proof of the greater importance of compacity as a physical factor, as compared with the chemical composition of the cements (27). Better resistance to magnesium sulfate attack is offered by portland cements of high iron-compounds content (9). This seems to contradict in part the standard limitations affecting  $C_4AF$  content.

In addition to classical opinions of the reasons for higher resistance of cements other than portland to sulfate attack, an original hypothesis has been advanced according to which the scarcity or the lack of calcium hydroxide in hydrated pastes of pozzolanic, slag or high-alumina cements induces the formation of non colloidal and non expansive ettringite. The ultimate reason seems to be the lack of a double-layer-type interparticle repulsion, otherwise produced by a large water adsorption (187).

Expansive cements have been proposed as more adequate to resist sulfate attack, due to their higher content of calcium sulfoaluminate hydrates and more particularly ettringite, as monosulfate is susceptible to react with sulfates to form at longer terms secondary (expansive) ettringite causing cracking:

The behaviour is much better in the case of expansive (shrinkage compensated) cements made with ASTM type II or type V, than in the case of those made with type I cement clinker.

Anyway, for equal  $C_3A$  content expansive cements behave better than ordinary portland cements from the same clinker, and so much so the lower the  $C_3A$  content in each case. The different behaviour of different expansive (shrinkage-compensated) cements in sulfate attack is probably to be related to  $Al_2O_3/SO_3$  ratio, i. e., to the different contents of reactive alumina in them. Reactive alumina is defined as total alumina minus "relatively" inactive alumina (that combined as  $C_4AF$  or in solid solution with calcium silicates), minus alumina fixed in the form of ettringite by  $SO_3$  of cement, on hydration. Reactive alumina may act on ettringite previously formed to convert it in monosulfate, ready to form the undesirable secondary ettringite at longer terms.

When desintegration of concrete has an internal origin due to attack by sulfates contained in the aggregates -exceptionally by excess of gypsum in cement too- a general relationship seems to exist between expansion,  $C_3A$  content of the cement and total  $SO_3$  present in concrete, including that of the cement itself. Nevertheless, the many exceptions as far as

the content of  $C_3A$  is concerned, indicate that other factors of the cement composition may have a great influence on the sulfate resistance of cement. The influence of  $C_3A$  is more evident for the higher concentrations of  $SO_3$  in concrete. Even in this type of attack pozzolanic cements show better performance (260).

In the case of alkali-silica reaction, and consistent with the explanation generally accepted for the corresponding expansive process (27) (122), the use of adequate very finely ground mineral admixtures and reactive materials in concrete, in addition to, or in substitution of a part of cement (which is equivalent to add pozzolanic materials to clinker), may avoid or reduce the expansive effects of the reaction. So, natural pozzolans (trass) blast-furnace slags and fly-ashes -and even cristobalite and silica glass- in cements may be effective, as well as true expansive materials contained in natural rocky reactive aggregates when finely ground to form powders of high specific surface and mixed with concrete (21) (27).

As far as acid attack by waters with pH-values lower than 4.5 is concerned, it is always strong on any type of cement, so that whatever this may be, it behaves more or less in the same manner, i. e., bad (283). Nevertheless, waters with pH-values higher than 6 do not cause strong deterioration on ordinary portland cements, and high-alumina cements without any protection may resist waters with pH-values between 4 and 6 (25).

Pozzolanic cements and slag cements are considered to be more resistant to lixiviation of  $Ca(OH)_2$  caused by soft waters (1) than are portland cements, particularly if these are rich in  $C_3S$  (25). Portland cements are not adequate for very pure waters or for mineral or aggressive  $CO_2$  containing waters (25), specially if these are considered as very strongly or strongly aggressive ones (23). High-alumina cements perform well for extremely aggressive pure waters, as some spring waters may be (25). But recent conclusions show that slag cements with higher contents of slag resist much better than portland cements intense attack produced by continuous and prolonged carbonic acid action (88).

Among the many physical factors influencing the durability of concrete, in addition to the chemical and mineralogical composition of the cements and partially depending on it, it must be mentioned the porosity of the paste, partially depending on the fineness of the cement as well. Both, composition and fineness do in fact determine the strength characteristics of the cement paste. Furthermore, the porosity is in a narrow relationship with the strength (290) (291), and in turn with the durability of hydrated pastes.

All these relationships may be even more complex due to the fact that (total) porosity, size of pores, pore-size distribution and kinetics of pore formation in cement pastes -influencing their permeability and penetrability- depend to some extent on the chemical and mineralogical composition of the cement, as men-

tioned. Thus, total (integral) porosity of portland cements high in alumina is greater than that of portland cements of lower alumina content, due to a slightly higher formation of contraction pores. Moreover, at 28 days of hydration the total porosity in pastes of portland cements richer in  $C_3S$  is lower than that of cements richer in  $C_2S$ , though large pores and gel pores are more abundant in the former case than in latter case. On the other hand, variations in pore-size distribution take place along the time, so that at latter ages the pore content in the range of 100 to 1000 Å diminishes. This occurs mainly and sooner in cement pastes of portland cements rich in  $C_3S$  and  $C_3A$ .

This interdependence between cement composition, cement fineness and pore structure of the paste is even more complex due to the influence of other variable factors on the paste itself and on concrete, such as w/c ratio, concrete compaction, concrete curing, etc. This is another factor contributing to difficult the understanding of concrete behaviour in chemical attack.

The influence of the voids and pore systems of concrete, as well as their modification caused by admixtures (air-entraining agents) is also discussed when dealing with de-icing salts and chloride attack (1). Optimum amount of micro-voids, void distribution and distance between voids seem to be necessary for an adequate resistance of concrete (21).

Anyway, it seems to be clear that the nature and structure of the cement paste, as far as its porosity and chemical composition are concerned, determine its permeability and also the penetrability of salts and different ions in it. Details of these influences on ionic diffusion and penetration are also given when dealing with de-icing salts attack (155).

### 13. - FINAL CONSIDERATIONS AND FUTURE PROSPECTIVES

The obvious considerations derived from the foregoing exposition, from the General Introduction onwards, are: a) that whatever the definition and limitation of the subject on cement and concrete durability, this is a very complex matter not always possible or easy to simplify; b) that many variable factors of very different nature are almost always indissolubly involved in durability problems; c) that the influence -isolated or superimposed actions and effects- of these factors not always are either quantitatively -or sometimes even qualitatively- in a clear and direct relationship with the factors themselves.

As a consequence, empiricism has predominated in a good deal of the research work carried out on durability, and confusing or contradictory results not easy to explain or even erroneous have been obtained. These facts, in addition to repetitive tasks not always conducting to the same or similar conclusions, may explain the relatively poor progress reached in the studies on durability, as compared with the effort made to achieve them. This would seem to be a pessimistic appreciation.

So, when prospecting the future of cement durability research one might express a hope and a wish, rather than make any sort of prophecy or prediction, which is always risky.

Remembering the considerations in the General Introduction of this paper, the author's hope is that research, from now on, progress along rational paths on basic scientific foundations, avoiding empiricism as much as possible. Interdisciplinary cooperation is needed, as physical, physicochemical and chemical aspects are involved in cement and concrete durability, so that all the possible different ideas and points of view must be taken into due consideration to cover all the many different features of the problem.

Fundamentals of inorganic chemistry of silicates, colloidchemistry, physico-chemistry of surfaces, adsorption phenomena, electrochemistry, crystalchemistry, etc., must be applied to cement and concrete corrosion studies in a systematic and rational manner. On the other hand, doctrine on physics of porous bodies and capillary systems, solid-state physics applied to complex solid macro-systems, etc., must also be focused in due way to such studies.

Intensive intercommunication between specialists in such disciplines working on cement is always absolutely necessary. Even better should be a previous consensus between them at world level to set the bases of a general scientific -long term- research project on durability. Within it, partial research programs should be developed by groups, either in parallel or complementarily, to put in clear the many dark points and unknowns still standing. In fact it should be necessary a sort of "normalization" or "standardization" of the research lines and procedures, in a similar way as it is admitted the convenience and the need of applying standard methods to test durability even empirically.

In these partial research programs it should be convenient to proceed by induction starting from the simplest problems in which as many variable factors as possible should be eliminated as such. Ideally only one variable factor should be investigated in each program, which in principle could be the cement in a series of programs, and the aggressive medium in another series of them. The result of the combination of both series of programs would be the knowledge of several orders of intrinsic chemical resistance of the various types of cements to different kinds of attacking chemicals and media in given -and successively variable- conditions. This or something similar depending on the priorities established in the research programs should be prior to attempt to draw dubious conclusions from work carried out under much more complex circumstances involving two, three or more variable factors.

Certainly, this does not correspond in principle to real situations in practice, in which many variable factors are involved in a very complex manner, overlapping each other. Certainly too that some specific and practical problems of durability require rapid and effective solutions easier to achieve in general

by empirical ways and means. But this must never be confused with what should be the "science of chemical attack on cement", as a part of a broader "science of building materials and construction". On the other hand, induction procedure obviously implies further consideration of all the many and important factors involved, which cannot be neglected and either overestimated or underestimated.

Of course, this is not the first time that similar ideas have been exposed, but in the author's opinion it is worth insisting on them once again, mainly because previous warnings in the same sense seem not to have been sufficiently taken into consideration.

It is clear that such a systematic research method may appear tedious and discouraging, as it is really arduous. Furthermore, everybody is inclined to think that his own ideas, projects and methods are a sort of panacea which may lead to total and general solutions. But really there are but two alternatives: one is to organize and "standardize" a scientific, rational and systematic work in common, so that each conclusion of it can be considered with a high level of probability as firmly established and having a validity the most general possible, without resorting to undue and enthusiastic extrapolations and generalizations; other is to continue as before and even now, which implies much (unprofitable) work and repetitive tasks dubiously efficient, with the risk to reach in this way the only valid conclusions already well known for many years ago and almost always invoked, particularly when no other clear and interesting conclusions are possible: the main if not the only property which determines the durability of concrete is a good compactness as a guarantee of low porosity, penetrability, absorption, capillary raise, etc.; and the main (elemental) rules to protect cement and concrete from chemical attack are those being in opposition to the well known ones normally applied to accelerate durability tests: to preclude or to reduce as much as possible the time and/or the surface (mass) contact between cement and aggressive media, either isolating and protecting the former or draining the latter; to neutralize or to weaken as much as possible the aggressive agent and the aggressive conditions before the former may enter in contact with concrete and before the latter - temperature, concentration, pressure, circulation, percolation, etc. - may act accelerating the attack.

But this sort of "rules of thumb" obviously true in a great part, do not solve the problem of durability as considered from the strict point of view of the chemistry of cement and that of the chemical attack on cement and concrete.

And finally, the author's wish is that if the foregoing ideas repeatedly exposed in one or another way in previous occasions are really valid, they be put in practice as soon as possible with the highest care, interest, enthusiasm, perseverance and efficiency.

## TABLE DES MATIERES CONTENTS

Pages\*

I-0	<b>THEME I – Influence des matières premières, des combustibles et des procédés de fabrication sur la structure et les propriétés des clinkers.</b> Influence of raw materials, fuels and manufacturing processes on clinker structure and properties.
I-1	N.H. Christensen, V. Johansen (Danemark) Mineralizers and fluxes in the clinkering process. II. Kinetics effects on alite formation. Minéralisateurs et fondants dans la clinkérisation. II. Effets cinétiques sur la formation d'alite.
I-6	A.I. Boikova (URSS) Cement minerals of complicated composition. Composants complexes des clinkers.
I-12	Surendra N. Gosh (Inde) Synthesis of dicalcium silicate and tricalcium silicate phases. Synthèse du silicate dicalcique et du silicate tricalcique.
I-17	B.V. Volconski, L.G. Soudakas, A.F. Kraplia, L.G. Bernstein (URSS) Contrôle de la microstructure et de l'activité des clinkers. Control of microstructure and activity of clinkers.
I-21	M. Handke, Cz Paluszkiwicz, G. Sieminska (Poland) Spectroscopic studies of $\text{Ca}_3\text{SiO}_5$ polymorphism. Les études spectroscopiques du polymorphisme du $\text{Ca}_3\text{SiO}_5$ .
I-26	I.G. Abramson, B.V. Volconski, S.K. Daniouchevski, G.G. Egorov, Y.V. Nikiforov (URSS) Formation du clinker dans un grand flux d'électrons accélérés. Clinker formation in high-energy flux of accelerated electrons.
I-29	V.V. Kafarov, M.A. Verdian (URSS) Modèles mathématiques et leur application à des fins d'optimisation des processus de broyage et d'élévation de la qualité du produit. Mathematic models and their application for optimizing crushing processes and improving quality of products.
I-34	Y.V. Nikiforov, R.A. Zosoulia (URSS) Cristallisation du périclase et constance du volume des ciments. Crystallization of periclase and soundness of cements.
I-37	M.E. Noudel, G.S. Krykhtine (URSS) Activation mécanique des matières premières pour la fabrication du ciment. Mechanical activation of cement raw materials.
I-42	A.V. Bessmertnykh, V.K. Khokhlov, V.V. Cheloudko (URSS) Etude thermodynamique de la cinétique de la formation de l'alite. Thermodynamic studies of alite formation kinetics.
I-47	M.G. Tolochkova, V.P. Riasine, K.G. Kolenova, V.N. Sergueev (URSS) L'oxyde ferreux dans le clinker. Ferrous iron in clinker.
I-51	C. Brisi, B. de Benedetti (Italie) Sur les solutions solides dérivant du $\text{C}_2\text{F}$ par remplacement des atomes Fe par Mn et Al. Researches on the phase originated from $\text{C}_2\text{F}$ by substitution of iron atoms with Mn and Al.
I-56	S. Chromy (Tchécoslovaquie) Granularity influence of limestone and quartz on the reactivity of cement raw material. Influence de la finesse de broyage du calcaire et du quartz sur la réactivité du cru.
I-61	M. Schultz (URSS) Thermodynamics of closed systems applied to the annealing of clinker. Thermodynamique des systèmes clos appliquée à la cuisson du clinker.
I-67	P. Goma (Espagne) Fonction généralisée de clinkérabilité. Generalized clinkerability function.
I-73	I.F. Petersen (Denmark) The pore structure and the grindability of clinkers. La structure poreuse et la broyabilité des clinkers.
I-79	I.S. Valkova, R.G. Dogandzhieva (Bulgarie) Producing Portland cement clinker using blast-furnace barric-manganese slag. Utilisation de laitiers contenant BaO et MnO dans la fabrication du clinker de ciment Portland.
I-84	A.K. Chatterjee, V.K. Arora, T.N. Verma, D.V. Ramana Rao, D. Ghosh (India) Clinker - Raw Meal - Coal Interrelations in some Indian cement plants. Corrélations entre clinker, cru et charbon dans certaines cimenteries indiennes.

\* La pagination comporte tout d'abord un chiffre romain correspondant au numéro du thème, suivi d'un numéro de page à l'intérieur du thème. Dans chaque thème, les communications ont été publiées dans l'ordre où elles sont parvenues au Secrétariat Général du Congrès pour permettre une publication plus rapide.

The pagination consists of a roman numeral corresponding to the theme number, followed by a page number in the interior of the theme. In each theme the communications have been published in the order they reached the General Secretariat of the Congress, in order to accelerate the publication.

I-90	I. Teoreanu, H. Balasoiu, C. Radovici, D. Ciomartan (Roumanie)	Influence des micro-additions d'oxyde de chrome (III) sur la composition chimique et minéralogique des clinkers de ciment portland. The influence of chromium sesquioxide micro-additions on the chemical and mineralogical composition of portland cement clinkers.
I-95	V. Valkov (Bulgarie) M.M. Sitchiov (URSS) L. Gigova (Bulgarie) Yu. V. Nikiforov (URSS)	Common influence of BaO and Mn <sub>2</sub> O <sub>3</sub> on the obtaining and the properties of the portland cement. Influence des additions de BaO et Mn <sub>2</sub> O <sub>3</sub> sur la fabrication et les propriétés des ciments portland.
I-99	Udo Ludwig, Albrecht Wolter (R.F.A.)	Formation and stability of C <sub>3</sub> S and alites. La formation et la stabilité du C <sub>3</sub> S et des alites.
I-104	K. Karibayev, A. Paschenko, K. Bekishev, D. Aldiarov, B. Taymasov (URSS)	Dispersing and plasticizing admixtures to cements. Des ajouts disperseurs et plastifiants des ciments.
I-108	S.K. Sinha, S.K. Handoo, A.K. Chatterjee (India)	Comminution and dissociation characteristics of Indian limestones. Broyabilité et décarbonatation des calcaires indiens.
I-114	U. Ludwig, S.E. Ibrahim (R.F.A.)	Burnability of industrial Portland cement raw mixes. Cuisabilité des crus du ciment de Portland industriel.
I-119	M.V. Ranga Rao, Kamal Kumar, (India)	A comparative study of the effect of heating rate in 2-stage and 4-stage suspension preheater kiln installations. Etude comparée de l'influence de la vitesse de chauffe dans les fours avec préchauffeurs à deux et à quatre étages.
I-124	M. Ono, M. Akita, K. Hikita (Japan)	Effect of Na <sub>2</sub> O on the stability of calcium aluminoferrite under the reducing atmosphere. Effet du Na <sub>2</sub> O sur la stabilité de l'aluminoferrite de calcium sous atmosphère réductrice.
I-128	Dr. M. Maultzsch, M. Gierloff, Dr. P. Schimmelwitz (RFA)	Aging of cement through long term storage. Vieillessement du ciment lors du stockage à longue durée.
I-134	A. Derdacka-Grzymek, J. Grzymek (Pologne)	Mécanisme de la stabilisation dans la transformation polymorphique beta-gamma C <sub>2</sub> S. Polymorphic Phase change of beta-gamma Ca <sub>2</sub> SiO <sub>4</sub> .
I-140	O.P. Mtchedlov-Petrosian, V.I. Satarine, N.P. Kogan, A.G. Kholodny, E.P. Kostinski (URSS)	Intensification du processus physico-chimique de clinkérisation. Intensification of physico-chemical process of clinker formation.
I-145	B.S. Albats, L.S. Filippova, Y.R. Krivoborodov (URSS)	Physical and chemical grounds for granulation of clinker. Bases physico-chimiques de la formation des granules de clinker.
I-150	W.A. Klemm, I. Jawed (USA)	Minéralisateurs et fondants dans le processus de clinkérisation. III. Aptitude à la cuisson de mélanges synthétiques et industriels. Mineralizers and fluxes in the clinkering process. III. Burnability of synthetic and industrial raw mixes.
I-156	V.Z. Pirotski (URSS)	Problèmes physico-chimiques du broyage du clinker portland. Physico-chemical problems of grinding of portland cement clinker.
I-161	M. Gawlicki, W. Nocun-Wczelik (Pologne)	L'influence du traitement thermique sur la transition $\beta \rightarrow \gamma$ -C <sub>2</sub> S. Influence of thermal treatment on the transition $\beta \rightarrow \gamma$ -C <sub>2</sub> S.
I-166	I.F. Ponomarev, P.O. Gaydjourov, A.P. Zoubekhine, V.V. Kitaev (URSS)	Particularités cristalochimiques et propriétés des phases du clinker de ciment portland en fonction des conditions de cuisson et de refroidissement. Crystal chemical peculiarities and phase properties of portland cement clinker depending on the conditions of burning and cooling.
I-170	T. Knudsen (Danemark)	On particle size distribution in cement hydration. L'effet de la granulométrie sur l'hydratation du ciment.
I-176	A. Pachtchenko, G. Baklanov (URSS)	Influence des basaltes sur la clinkérisation et les propriétés des ciments. Basalt influence on the clinker formation process and cement properties.
I-182	B. Werynski, A. Werynska (Pologne)	Raw material effect on clinker quality. L'influence de matières premières sur la qualité de clinker.
I-189	B. Matkovic, V. Carin, T. Gacesa, R. Halle (Yougoslavie)	Reactivity of belite stabilized by Ca <sub>5</sub> (PO <sub>4</sub> ) <sub>3</sub> OH. Réactivité de la bélite stabilisée avec Ca <sub>5</sub> (PO <sub>4</sub> ) <sub>3</sub> OH.
I-195	Asok K. Sarkar, Della M. Roy, Roderick M. Smart (USA)	Mineralizers and fluxes in the clinkering process. I. Phase equilibria in the CaO-Al <sub>2</sub> O <sub>3</sub> -Fe <sub>2</sub> O <sub>3</sub> -SiO <sub>2</sub> system with calcium fluosilicate. Minéralisateurs et fondants dans la formation des clinkers. I. Equilibre des phases dans le système CAFS avec du fluosilicate de calcium.
I-201	P.V. Zozulja, E.A. Rodionov (URSS)	Mineral formation and reactive capacity of portland cement raw mixtures. Influence de la composition du cru sur la clinkérisation et la réactivité du ciment.

- I-206 Y. Ono (Japan) Microscopical estimation of burning condition and quality of clinker.  
Estimation microscopique de la résistance du ciment.
- I-212 E. Demoulian, P. Gourdin, F. Hawthorn, C. Vernet (France) Anomalies de cuisson - structures microscopiques - propriétés des clinkers et ciments.  
Burning anomalies - microscopic structures - clinkers and cements properties.
- I-218 J. Moisset, B. Cottin, A. Rouanet, A. Petit (France) La céélite dans les ciments portland obtenus par fusion.  
Celite phase in portland cements from molten products.
- I-223 P. Gourdin, E. Demoulian, F. Hawthorn, C. Vernet (France) Polymorphisme de l'alite et du  $C_3A$ . Statistiques.  
Alite and  $C_3A$  polymorphism. Statistics.
- I-229 I.V. Kravtchenko, A.M. Dmitriev, I.E. Kovaleva (URSS) Influence de la température d'apparition des bains fondus eutectiques et des particularités de la structure cristalline des phases réagissantes sur la structure et les propriétés du clinker.  
Influence of melt eutectic temperature and peculiarities of crystalline structure of reacting phases on structure and properties of clinker.
- I-235 G.R. Gouda (USA) Effect of raw materials on cement process and properties.  
Influence des matières premières sur la fabrication du ciment et ses propriétés.
- I-241 V.V. Timachev, A.P. Ossokine, E.N. Potapova (URSS) Sur le mécanisme de la cristallogénèse dans les microzones des grains de clinker.  
Mechanism and kinetics of crystal formation in the microvolumes of clinker grains.
- I-247 M. Kovacs, K. Benei (Hongrie) Caractéristiques de la matière adhérente causant des troubles de fonctionnement et leur élimination.  
Characterisation and elimination of adherent layers causing operational troubles.
- I-252 Y. Le Jean (France) Influence du mode de broyage du clinker et des constituants secondaires sur la réactivité des ciments et sur la rhéologie.  
Clinker grinding method and secondary components - their effect upon cement reactivity and rheology.
- I-259 I. Luginina (URSS) Neutralisation des additions indésirables dans la matière première.  
Neutralisation of undesirable admixtures in raw materials.
- I-264 L. Opoczky, T.K. Mrakovics (Hongrie) Problems of the simultaneous and separate grinding at the production of blast furnace slag cement.  
Problèmes du broyage simultané ou séparé dans la production des ciments de laitier.
- I-272 O.P. Mtchedlov-Petrosian, T.Y. Chetkina (URSS) N.I. Sapojnikova I. Talaber, K. Bosci (Hongrie) Corrélation de la cinétique des réactions de clinkérisation à l'état solide avec les constituants minéraux et les conditions du traitement thermique.  
Correlation between kinetics of solid-phase reactions of clinker formation and mineral composition and thermal treatment conditions.
- I-276 H. Hornain, M. Regourd (France) Fissuration et broyabilité du clinker.  
Cracking and grindability of clinker.
- I-282 W. Kurdowski, M. Handke, G. Sieminska (Pologne) The effect of  $Al_2O_3$ ,  $BaO$  and  $B_2O_3$  admixtures on  $C_3S$  structure.  
L'effet des additions  $Al_2O_3$ ,  $BaO$  et  $B_2O_3$  sur la structure du  $C_3S$ .
- I-288 W. Kurdowski, Z. Weliszek (Pologne) Formation of syngenite during cement grinding.  
Formation de la syngénite au cours de broyage du ciment.
- I-292 S. Takagi, A. Kawashima (Japan) Processing characterization on the industrial scale cement production.  
Prévision de la qualité d'un ciment, en production industrielle.

II-0 **THEME II - Hydratation des ciments portland sans constituants secondaires.**  
Hydration of pure Portland Cements.

- II-1 J. Bensted (Grande-Bretagne) Early hydration behaviour of sulphate resisting and white portland cement.  
Comportement initial lors de l'hydratation de ciment portland à haute résistance aux sulfates et de ciment blanc.
- II-7 P. Kittl, C. Suchicital, A. Goldschmidt (Chili et Brésil) Study on the evaporation product of the liquid phase of a cement paste.  
Etude du produit de l'évaporation de la phase liquide d'une pâte de ciment.
- II-12 I.P. Vyrodov (URSS) On physico-chemical foundations of hydration and setting of binding systems.  
Phases physico-chimiques de l'hydratation et de la prise de liants hydrauliques.
- II-18 Surendra Nath Gosh (Inde) Some applications of infrared spectroscopy in the fields of cement and concrete.  
Quelques applications de la spectroscopie infrarouge dans le domaine du ciment et du béton.
- II-25 V.S. Ramachandran, J.-J. Beaudoin (Canada) Hydration of  $C_4AF$  + gypsum : study of various factors.  
Hydratation du  $C_4AF$  + gypse : étude des divers facteurs.

- II-31 F. Hannawayya (Suède) Study of the structure and crystallization properties of tricalcium silicate ( $C_3S$ ) and  $\beta$ -dicalcium silicate ( $\beta$ - $C_2S$ ) hydrate and the new calcium silicate hydrate. C-S-H (III), C-S-H (I<sup>1</sup>) and C-S-H (II<sup>2</sup>).  
Etude de la structure et de la cristallographie du silicate tricalcique ( $C_3S$ ), du silicate bicalcique  $\beta$  ( $\beta$ - $C_2S$ ), et du silicate calcique hydraté C-S-H (III), C-S-H (I<sup>1</sup>) et C-S-H (II<sup>2</sup>).
- II-37 C. Tashiro (Japon) The effects of several heavy metal oxides on the hydration and the microstructure of hardened mortar of  $C_3S$ .  
Effets de quelques oxydes de métaux lourds sur l'hydratation du  $C_3S$  et sur la structure fine des corps durcis.
- II-43 F.G. Buttler, S.R. Morgan (Grande-Bretagne) A thermoanalytical method for the determination of the amount of calcium hydroxide in systems containing hydrated Portland cement.  
Une méthode de l'analyse thermique pour la détermination quantitative de l'hydroxyde de calcium dans des systèmes contenant du ciment portland hydraté.
- II-47 Kazutaka Suzuki, Suketoshi Ito, Sumio Shibata, Namitsugu Fujii (Japon) Hydration and strength of  $\alpha$ -,  $\alpha'$ -, and  $\beta$ -dicalcium silicates stabilized with Na-Al, K-Al, Na-Fe, and K-Fe.  
Hydratation et Résistance de  $\alpha$ -,  $\alpha'$ -, et  $\beta$ -dicalcium silicates stabilisées par Na-Al, K-Al, Na-Fe, et K-Fe.
- II-52 S.A. Mironov, I.I. Kourbatova, O.S. Ivanova, S.A. Vyssotsky (URSS) Durcissement du ciment à des températures au-dessous de zéro.  
Cement hardening under below zero temperature.
- II-58 C. Tashiro, J. Oba (Japon) The effects of  $Cu(OH)_2$  on the hydration of  $C_3A$ .  
Action du  $Cu(OH)_2$  sur l'hydratation du  $C_3A$ .
- II-64 D.L. Rayment, A.J. Majumdar (Grande-Bretagne) The composition of CSH phase(s) in hydrated  $C_3S$  paste.  
Composition des phases HSC dans la pâte hydratée de  $C_3S$ .
- II-71 I.B. Zacedatelev (URSS) Caractéristiques thermochimiques du ciment et accélération de durcissement du béton.  
Thermochemical characteristics of cement and acceleration of concrete setting.
- II-76 Z.M. Larionova, L.P. Kourassova, (URSS) Les variations de phase et les propriétés du ciment durci.  
Phase change and properties of hardened cement paste.
- II-82 Zonghan Lou, Xianyu Xu, Ren Han (Chine Populaire) On ettringite and modification of slag cement.  
Sur l'ettringite et l'amélioration des ciments de laitier.
- II-88 Feipeng Zhang, Zhifa Zhou, Zonghan Lou (Chine Populaire) Solubility product and stability of ettringite.  
La stabilité de l'ettringite et le "produit de solubilité".
- II-94 Tang Ming-Shu, Han Su-fen, (Chine Populaire) Effect of  $Ca(OH)_2$  on alkali-silica reaction.  
Effet de  $Ca(OH)_2$  sur l'alkali-réaction.
- II-100 N.B. Singh, P.N. Ojha (Inde) Effect of glucose on the hydration of portland cement.  
Action du glucose sur l'hydratation du ciment portland.
- II-106 Z. Sauman, F. Vavrin (Tchécoslovaquie) Conditions of the Hydroxyl Ellestadite Formation in Mixtures containing Calcium Sulphate.  
Les conditions de la formation de l'hydroxyle-ellestadite dans les mélanges comprenant du sulfate de calcium.
- II-111 A. Bezjak, I. Jelenic, V. Mlakar, A. Panovic (Yougoslavie) A Kinetic Study of Alite Hydration.  
Etude cinétique de l'hydratation de l'alite.
- II-117 Z.B. Entine, Ou I. Papiachvili, L.S. Klioneva (URSS) Formation de la structure des ciments avec fausse prise.  
Structure formation of cements with false setting.
- II-123 M. Regourd, J.H. Thomassin, P. Baillif et J.C. Touray (France) X-Ray photoelectron spectrometry investigation of the early stages of  $C_3S$  hydration. The role of NaF admixture.  
Etude par la spectrométrie de photoélectrons XPS des stades initiaux de l'hydratation de  $C_3S$ . Rôle de l'adjuvant NaF.
- II-129 V.D. Glukhovskiy, P.V. Krivenko, R.F. Runova (URSS) Condensation properties of dispersed products of portland cement hydration and rehydration.  
Propriétés agglomérantes des composants dispersés du ciment, après leur hydratation ou leur réhydratation.
- II-135 B. Osbaeck and E.S. Jons (Danemark) The Influence of the Content and Distribution of Alkalies on the Hydration Properties of Portland Cement.  
Influence du contenu et de la répartition des alcalis sur les propriétés d'hydratation du ciment Portland.
- II-141 H.M. Jennings, P.L. Pratt, (Grande-Bretagne) On the reactions leading to calcium silicate hydrate, calcium hydroxide and ettringite during the hydration of cement.  
A propos des réactions produisant le silicate de calcium hydraté, l'hydroxyde de calcium et l'ettringite pendant l'hydratation du ciment.

II-147	A. Zelwer (France)	Propriétés électrocinétiques à la surface des minéraux du ciment portland. Electrokinetic surface properties of portland cement minerals.
II-153	R. Krstulovic, T. Feric, P. Krolo (Yougoslavie)	Study of kinetics of industrial cements hydration. Vitesse d'hydratation des ciments industriels.
II-161	Slanicka Stefan (Tchécoslovaquie)	Influence of Water-Soluble Melamine Formaldehyde Resin on Hydration of $C_3S, C_3A + CaSO_4 \cdot 2H_2O$ mixes and cement pastes. L'influence de la résine hydrosoluble de mélamine-formaldéhyde sur l'hydratation des pâtes préparées de $C_3S$ , du mélange $C_3A + CaSO_4 \cdot 2H_2O$ et des pâtes de ciment.
II-167	E.D. Shchukin, E.A. Amelina, E.P. Andreeva, S.I. Kontorovich (URSS)	Agglutination (bridging) of Particles during Hydration Hardening and the Effect of Surface Active Additives. Agglutination des particules pendant l'hydratation et le durcissement des ciments. Influence des ajouts tensio-actifs.
II-172	M. Ono, M. Nagashima, M. Saito (Japon)	The stiffening of mortar accompanied with the early hydration of cement. Le raidissement du mortier accompagnant l'hydratation initiale du ciment.
II-176	R. Sanzhaasuren, E.P. Andreeva, N. Stukalova (URSS)	On the mechanism of Hydration Hardening of Portland Cement Ferrite Phase. Mécanisme de l'hydratation et du durcissement de la phase ferritique des ciments Portland.
II-182	I. Jawed, D. Ménétrier, J. Skalny (USA)	Early hydration of calcium silicates : surface phenomena. L'hydratation initiale des silicates de calcium : phénomènes de surface.
II-188	T. Ciach, J. Dyczek, M. Petri, L. Westfal (Pologne)	Materials from the Synthetic Tobermorite. Matériaux comportant de la tobermorite de synthèse.
II-192	K. Nakagawa, K. Isozaki, Y. Watanabe (Japon)	Hydration and strength of normal portland cement admixed with anhydrous calcium sulfate. Hydratation et résistance du ciment portland normal additionné d'anhydrite.
II-198	T.V. Kouznetsova, I.V. Kravtchenko, (URSS)	Le rôle des aluminates et des sulfoaluminates de calcium dans l'élaboration de propriétés de la pierre de ciment. Part played by aluminates and calcium sulfoaluminate in formation of properties of cement stone.
II-203	E. Sakai, M. Daimon, R. Kondo (Japon)	Very early hydration of tricalcium silicate. L'hydratation aux premiers âges du silicate tricalcique.
II-209	A. Bonin (France)	Eventement et raidissement des ciments. Air aging and stiffening of Portland cements.
II-214	P. Galtier et B. Guilhot, M. Murat (France) A. Bachiiorini et A. Negro (Italie)	Réactivité de l'aluminate monocalcique vis-à-vis de l'eau. Reactivity of monocalcium aluminate.
II-219	C. Vernet, E. Demoulian, P. Gourdin, F. Hawthorn (France)	Cinétique de l'hydratation du ciment portland. Hydration kinetics of portland cement.
II-225	F.G.R. Gimblett, K.S.W. Sing, Z. Mohd. Amin (Grande-Bretagne)	Influence of pretreatment on the microstructure of calcium silicate hydrate gels. Influence du prétraitement sur la microstructure des gels de silicate de calcium hydraté.
II-232	D. Menetrier, B. Cottin, P. Barret (France)	Etude analytique des C-S-H obtenus par action de la chaux sur la silice. Analytical study of C-S-H obtained by the action of lime on silica.
II-237	A.V. Oucherov-Marchak, A.M. Ourjenko, O.P. Mtchedlov-Petrossian (URSS)	Calorimétrie des liants. Calorimetry of binders.
II-242	D.M. Roy, (USA) M. Daimon, K. Asaga (Japon)	Effects of Admixtures upon Electrokinetic Phenomena During Hydration of $C_3S, C_3A$ and Cement. Effet des adjuvants sur les phénomènes électrocinétiques au cours de l'hydratation de $C_3S, C_3A$ et du ciment.
II-247	V.M. Kolbasov, N.A. Kozyreva, (URSS)	Modifications of Structure and Properties of Cement Stone. La modification de la structure et propriétés des ciments hydratés.

## II. Kinetics Effects on Alite Formation

### *Minéralisateurs et fondants dans la clinkérisation.*

### *II. Effets cinétiques sur la formation d'alite*

N.H. CHRISTENSEN    F.L. Smidth et Co.A/S  
V. JOHANSEN        COPENHAGUE, Danemark.

RESUME : L'influence de certains produits d'addition sur la vitesse de la réaction  $C + C_2S \rightarrow C_3S$  a été étudiée dans des conditions isothermes à des températures comprises entre 1350 et 1500°. Sont exposés, dans cette communication, des résultats expérimentaux concernant l'effet cinétique du spathfluor, du gypse et des alcalis sulfatés ou non sulfatés. Alors que le spathfluor a un effet accélérateur, les autres produits essayés ont une action retardatrice sur la formation de l'alite.

Ces effets chimiques sur la formation de l'alite peuvent être attribués à des modifications dans la composition de la phase liquide, de son coefficient de diffusion, de la force qui engendre cette diffusion, ou d'une combinaison de ces facteurs. Les effets cinétiques observés sont, pour une grande part, sous l'influence de cette force. Les résultats semblent indiquer qu'il existe une relation entre ces effets et les concentrations relatives, dans la bélite et l'alite, des produits ajoutés.

SUMMARY : The effects of some additives on the rate of the reaction  $C + C_2S \rightarrow C_3S$  have been studied under isothermal conditions between 1350°C and 1500°C. Data on the rate effects of fluorspar, anhydrite, and sulfated and unsulfated soda and potassia ore presented. Whereas fluorspar acts as an accelerator, all the other additives studied are observed to retard alite formation.

Chemical effects on the alite formation reaction can be attributed to changes in melt content, melt diffusivity, and driving force for diffusion, or combinations of these. The rate effects observed in the present study are to a large extent associated with influences on the driving force. The results suggest a relationship between the effects of these additives and their relative concentrations in  $C_2S$  and  $C_3S$ .

## INTRODUCTION

In this presentation we shall report on results of kinetic studies of the alite formation reaction,  $C + C_2S \rightarrow C_3S$ . In particular, effects of various fluxing or mineralizing agents upon this reaction will be discussed. The need for kinetic studies on this particular reaction step, separate from the other reactions occurring in burnability studies, was pointed out by R. Kondo twenty years ago (1). Results from his study (2) have greatly improved our insight into the mechanism of the alite formation reaction and, indeed, of the overall clinkering process. By applying a modification of a sandwich (diffusion couple) technique introduced by Kondo and Choi (2), we have been able to collect further information concerning the effects of alumina, ferric oxide and magnesia on the reaction rate (3), and the same technique has also been applied in the present investigation. The advantages of this method are that results are easily interpretable in terms of the fundamental principles for diffusion controlled reactions, and that fineness of the reactants has no influence on the reaction rate measured.

## EXPERIMENTAL PROCEDURE

Batches of about 200 g were prepared from analytical grade reagents with known ignition losses; the ignited batch compositions are given in Table I. At the high temperatures, A-compositions with LSF > 100% consist of  $C + C_3S + \text{melt}$ , whereas B-compositions with LSF ≈ 80% consist of  $C_3S + C_2S + \text{melt}$ .

TABLE I					
Tablet type	weight %				
	CaO	SiO <sub>2</sub>	Al <sub>2</sub> O <sub>3</sub>	Fe <sub>2</sub> O <sub>3</sub>	MgO
1 A	72	22	3	2	1
1 B	66	28	3	2	1
2 A	72	22	6	0	0
2 B	66	28	6	0	0

Each batch was homogenized, calcined at 1050°C, compacted into tablets (1 cm · 1 cm Ø), heated at 1500°C for one hour, ground into a powder, and divided into portions of ~20 g. To some of these portions the required amount of  $CaF_2$ ,  $Na_2CO_3$ ,  $K_2CO_3$ ,  $Na_2SO_4$ ,  $K_2SO_4$  or  $CaSO_4$  was added. At least one portion of each batch was left undoped as a reference sample. After further grinding, the portions (including the reference) were again compacted, heated at 1500°C for one hour, and then air-quenched. One flat surface of each tablet was polished as the final preparation for the isothermal diffusion couple burn.

An A- and a B-tablet were stacked with their polished surfaces in contact. The couple was introduced into an electrically-heated

vertical tube furnace, whose temperature stability over 20 hours was ±30°C. After a known period of heating time,  $t$  seconds, the couple was air-quenched, cut perpendicularly to the original join, polished, etched and studied under the reflection microscope. A region consisting of  $C_3S + \text{solidified melt}$ , sharply demarcated from the A- and B-zone, had developed, and its width,  $x$  cm, was measured optically at 5-10 positions. Further details of this technique are given in Ref. (3).

Analysis of the fluorspar-doped samples showed that about 10% of the added fluoride had evaporated during the latter part of the preparation of the tablets. Such minor evaporation was not considered important for the interpretation of these studies.

Samples associated with the study of the effects of alkalis and sulfates were analysed for  $SO_3$ ,  $Na_2O$  and  $K_2O$ , at the stage prior to the diffusion couple experiments, as well as after further heat-treatment duplicating that of the couple experiments. Here the volatility of the alkalis and  $SO_3$  often was >30%, and differences between volatilities of potassia and soda, sulfated and unsulfated, in A-tablets or B-tablets, were conspicuous.

For various reasons, the alkali and sulfate contents chosen to characterize each couple were those measured in the corresponding B-tablet, just prior to the diffusion couple burn. The actual concentrations during the burn of interest have thereby been overestimated; the magnitude of this error is greater for the more volatile than for the less volatile constituents. Since the more volatile constituents proved to have the most marked rate effects, the errors associated with adoption of the procedure selected tend to diminish, rather than to accentuate, the differences in rate effects.

## RESULTS

According to the theory for diffusion couples (3), the width,  $x$ , should increase with the square root of the heating time,  $t^{1/2}$ . Plots of  $x$  versus  $t^{1/2}$  or of  $x^2$  versus  $t$ , should therefore be linear, and this was found to be the case for most series, cf. Fig. 1.

The rate constants,  $k$ , which are related to the slopes of these lines ( $x^2 = kt$ ), should be a function of sandwich composition and temperature only. Dividing the rate constant for a doped sandwich,  $k_d$ , by the rate constant for an undoped sandwich from the same batch,  $k_0$ , both measured at the same temperature, gives a measure for the rate effect caused by the added agent. Values of  $k_d/k_0$ , together with other important parameters, are shown in Table II.

The data for  $CaF_2$  in Table II show that fluorspar doping causes a marked increase in rate, although the further effect upon

Fig. 1 - Plots of the square of product layer width, versus heating time for some couples specified in Table II, 1450°C.

TABLE II			
Sandwich type	Additive wt. %	Temp. °C	$k_d/k_o$
1	0.44 CaF <sub>2</sub>	1350	2.4
1	0.84 -	1350	2.6
1	1.80 -	1350	2.9
1	0.44 -	1500	1.4
1	0.84 -	1500	1.6

1	1.00 K <sub>2</sub> O b)	1400	0.74
1	1.00 -	1450	0.66
1	1.00 -	1500	0.55
2	0.90 -	1475 d)	0.63
2	0.90 -	1500	0.60
1	0.46 Na <sub>2</sub> O a)	1450	0.59
1	0.86 Na <sub>2</sub> O b)	1450	0.23
1	0.90 SO <sub>3</sub> c)	1450	0.46
1	1.10 -	1450	0.39

a) added as carbonate, no sulfate present  
 b) added as sulfate, a roughly equivalent SO<sub>3</sub> amount still present after firing  
 c) added as CaSO<sub>4</sub>  
 d) sandwich type 2 (A2/B2) did not grow together at temperatures  $\leq 1450^\circ\text{C}$

increasing the concentration above 0.5-1% is small, indicating that some saturation is being approached. The factor 2.4-2.6 is almost the same as that caused by raising the reaction temperature from 1350° to 1500° without fluorspar addition (3). Thus these results corroborate Klemm et al.'s finding (4) that addition of 1% CaF<sub>2</sub> permits achievement of the same rate of alite formation at a temperature 150°C lower than without CaF<sub>2</sub>.

Dusting, caused by the beta/gamma belite transformation, completely excluded the preparation of couples having 5% CaF<sub>2</sub>, and somewhat complicated the measurements of the product width in the couples with 2% CaF<sub>2</sub>, due to crack formation. With 2% CaF<sub>2</sub>, growth of the product layer was markedly slowed down after one hour, probably owing to an excessive solid-state sintering of the alite grains, which was observed at 1500°C.

The addition of alkalis and gypsum always retarded alite formation, i.e.  $k_d/k_o < 1$ . No significant difference in rate effects was observed between the type 1 and type 2 samples examined, cf. Table II. The retarding effect of K<sub>2</sub>SO<sub>4</sub> appeared to increase slightly with rising temperature.

In order to normalize the various effects measured at 1450°C to a common scale, it has been assumed that  $k_d/k_o$  varies linearly with additive concentration.  $k_d/k_o$  can then be calculated for either 1 g of oxide in 100 g of clinker, or for the weight of oxide equivalent to 1 g of K<sub>2</sub>O per 100 g of clinker. The results are given in Table III.

TABLE III					
$k_d/k_o$ calc. for	K <sub>2</sub> O		Na <sub>2</sub> O		SO <sub>3</sub>
	+SO <sub>3</sub>	-SO <sub>3</sub>	+SO <sub>3</sub>	-SO <sub>3</sub>	+CaO
1 g oxide	0.66	0.09	0.10	0.11	0.43
1 g K <sub>2</sub> O equiv.	0.66	0.09	0.41	0.41	0.53

It is seen from Table III that on a simple weight basis, unsulfated potassia and soda in both forms are most effective, while sulfated potassia is much less effective. This finding is in good agreement with observations of KRAMER and ZUR STRASSEN (6). However, on the potassia equivalent basis the picture is somewhat modified.

#### DISCUSSION

Our data on CaF<sub>2</sub> effects agree well with literature findings. However, certain of the reports on the alkali and sulfate effects previously recorded are not consistent with our findings (7). Although it appears that all authors have found unsulfated alkalis to be retarding agents, some have found that alkali sulfates and gypsum (anhydrite) may act as accelerators.

These discrepancies may at least partly be accounted for by noting that in some instances quoted in ref. (7), the undoped reference samples contained little or no melt phase at the chosen burning temperatures, while melt may have been formed when additive was present. In such a case, an acceleration of the reaction is to be expected.

It should also be borne in mind that, when sulfate is present, alkalies, in particular potassia, tend to accumulate in a separate sulfate phase (8,9). Addition of gypsum to a reference material containing unsulfated alkalies may therefore cause transformation of the alkali from a more inhibiting to a less inhibiting state, i.e. an improvement of burnability is to be expected. On the other hand, addition of excess gypsum may again cause regression in the burnability.

Differences in volatility, and the fact that these studies (7) related to the overall clinkering process, rather than to C<sub>3</sub>S formation alone, may also have contributed to the discrepancies.

Growth of the product layer in a diffusion couple is governed by the term  $\alpha \cdot D' \cdot \Delta c$  (3). Here  $\alpha$  is the volume fraction melt in the product layer (C<sub>3</sub>S + melt);  $D'$  is the effective binary diffusion coefficient for the melt;  $\Delta c = c_a - c_b$ ,  $c_a$  is the concentration of CaO in the melt in equilibrium with C + C<sub>3</sub>S, and  $c_b$  the concentration of CaO in the melt in equilibrium with C<sub>2</sub>S + C<sub>3</sub>S.  $\Delta c$  is the driving force for diffusion through the melt in the product layer; hence, changes in  $\Delta c$  are to some extent representative of changes in the driving force for the alite formation reaction (10).

In the present study, little change in  $\alpha$  is to be expected as a consequence of the added compounds, and microscopic examination of our samples has confirmed this expectation. The observed changes in rate constants must therefore be attributed to changes in  $D'$  and/or  $\Delta c$ .

Butt et al. (11) reported that the viscosity of a clinker melt increased, and the tracer diffusivity for Ca in the same melt decreased, when the concentration of unsulfated soda or potassia in such melt was increased. If these relations also represent changes in  $D'$  for melts remaining in equilibrium with C<sub>3</sub>S while additive concentration varies, then the rate effects observed in our investigation may be accounted for through variations in  $D'$ , as far as the unsulfated alkalies are concerned.

However, Butt et al. (11) also observed that the melt viscosity decreased for increasing content of Na<sub>2</sub>SO<sub>4</sub>, K<sub>2</sub>SO<sub>4</sub> and CaSO<sub>4</sub>. These observations are not consistent with our findings that these additives act as retarders, unless we accept that  $\Delta c$  has

been negatively affected.

In fact, the occasional observation that the alite formation reaction is totally inhibited, or even reversed, by the addition of alkalies (6,8,12), cannot be explained as a result of a change in  $D'$ , but must be caused by a marked decrease in driving force, so that lime and belite can coexist in equilibrium, i.e.  $\Delta c$  is zero.

$\Delta c$  can be deduced from a relevant phase diagram; the width of the C<sub>3</sub>S primary field at the temperature in question is determined by  $\Delta c$ . Unfortunately, no diagram is available for the sulfate-containing systems of interest. However, D.M. Roy et al. (part I, preceding paper) have shown that the C<sub>3</sub>S primary field is widened when (A+F) is partially replaced by CaF<sub>2</sub>. Similarly it is also known that alkalies cause a narrowing of the C<sub>3</sub>S primary field (13). It therefore appears that effects on  $\Delta c$  contribute to the observed effects of CaF<sub>2</sub> as an accelerator, and of alkalies as retarders.

Since  $\Delta c$  is related to the thermodynamic driving force, it is also affected by the partitioning of the added constituents between the solid phases C, C<sub>3</sub>S and C<sub>2</sub>S; CaF<sub>2</sub> preferentially dissolves in C<sub>3</sub>S, while alkalies preferentially dissolve in C<sub>2</sub>S. Such considerations also help to explain other examples of chemical effects upon alite formation reaction rates (10).

#### CONCLUSION

The addition of a modest quantity of a foreign constituent may cause a change, positive or negative, in the rate of the alite formation reaction at constant temperature. Such effect is the net result of changes in: Content of melt, diffusivity of melt, driving force for diffusion. The most marked negative rate effects are associated with decrease in driving force. The most marked positive effects on the rate are associated either with increase in melt content from zero, or with increase in driving force. It would be reasonable to link the traditional terms fluxing and mineralizing effects to these two mechanisms, respectively.

# Cement minerals of complicated composition

## *Composants complexes des clinkers*

A BOIKOVA Doctor, Institute of Silicate Chemistry of the Academy of the USSR, Leningrad.

RESUME : On a effectué la synthèse et l'étude physico-chimique des alites, bélites, aluminates et aluminoferrites provenant de divers crus ou mélanges complexes; ces éléments peuvent être considérés comme des solutions solides multicomposant dans  $C_3S$ , dans  $C_2S$ , des oxydes de  $Na_2O$ ,  $K_2O$ ,  $MgO$ ,  $Al_2O_3$ ,  $Fe_2O_3$ ,  $TiO_2$ ,  $P_2O_5$ , dans  $C_3A$  de  $Na_2O$ ,  $K_2O$ ,  $MgO$ ,  $Fe_2O_3$ ,  $SiO_2$ ; et dans  $C_6A_2F$  de  $Na_2O$ ,  $K_2O$ ,  $MgO$ ,  $MnO$ ,  $SiO_2$ ,  $TiO_2$ .

Les compositions synthétiques ont été choisies en partant des résultats de l'analyse à la microsonde électronique des phases du clinker des produits industriels. Le traitement à haute température des compositions choisies provoque la formation d'alite monoclinique, de bélite  $\alpha$  -,  $\alpha'_z$  -,  $\beta$  -, de la phase aluminate cubique et d'aluminoferrite orthorhombique avec la matrice composée de  $C_6A_2F$ .

Les compositions chimiques des produits finals synthétiques sont indiqués. Les diagrammes de diffraction des rayons X montrent que les phases complexes sont dérivées de  $C_3S$ ,  $C_2S$ ,  $C_3A$  et  $C_6A_2F$ . Les paramètres cristallins ont été calculés et la densité a été mesurée. L'examen microscopique a été effectué sous lumière transmise et sous lumière réfléchie. Une distinction claire entre les cristaux  $\alpha$  -,  $\alpha'_z$  -,  $\beta$  de la bélite a été faite.

La particularité des phases contenant des impuretés est la capacité de former des cristaux imparfaits et des produits mal cristallisés. De telles phases possèdent une activité plus grande à l'action de l'eau, que les mêmes phases bien cristallisées. Des phases activées peuvent être obtenues par le choix des mélanges d'impuretés et du régime thermique approprié.

L'hydratation aux premiers et derniers âges a été étudiée. L'analyse des courbes cinétiques montre que le cours du processus d'hydratation de chaque phase est particulier et différent de celui des composants purs :  $C_3S$ ,  $C_2S$ ,  $C_3A$  et  $C_6A_2F$  et des phases de composition simple.

SUMMARY : The synthesis and the physico-chemical investigation have been made of alites, belites, aluminates and aluminoferrites of complicated composition which can be regarded as multi-component solid solutions of  $C_3S$  and  $C_2S$  with oxides  $Na_2O$ ,  $K_2O$ ,  $MgO$ ,  $Al_2O_3$ ,  $Fe_2O_3$ ,  $TiO_2$ ,  $P_2O_5$ ; of  $C_3A$  with  $Na_2O$ ,  $K_2O$ ,  $MgO$ ,  $Fe_2O_3$ ,  $SiO_2$ ; of  $C_6A_2F$  with  $Na_2O$ ,  $K_2O$ ,  $MgO$ ,  $MnO$ ,  $SiO_2$ ,  $TiO_2$ .

The synthesized compositions have been chosen according to the results of electron-probe microanalysis of the clinker phases of commercial products. The high-temperature treatment of the chosen compositions led to the formation of the monoclinic alite, the  $\alpha$  -,  $\alpha'_z$  -,  $\beta$  - modifications of belite, the cubic aluminate phase, the orthorhombic aluminoferrite whose matrix is composed of  $C_6A_2F$ .

The chemical compositions of the final synthesis products are given. The X-ray diffraction patterns show that the complex phases are derivatives of  $C_3S$ ,  $C_2S$ ,  $C_3A$ ,  $C_6A_2F$ . The unit cell parameters have been calculated and the density has been measured. Microscopic examinations in transmitted light and in reflected light have been made. A clear distinction between  $\alpha$  -,  $\alpha'_z$  - and  $\beta$  modifications of belite has been observed.

The peculiarity of the phases containing the complex of impurities is the capability to form imperfect crystals and poorly crystallized products. Such phases show a greater activity to the action of water compared to the same phases which are well crystallized. The activated phases can be obtained by choosing the set of impurities and the appropriate thermal schedule.

Early and later hydration has been studied. The analysis of kinetic curves show that the course of hydration process of each phase is peculiar compared to "pure"  $C_3S$ ,  $C_2S$ ,  $C_3A$ ,  $C_6A_2F$  and to the phases of a more simple composition.

A study of cement minerals of complicated composition analogous to phases of commercial clinkers is one of the main tasks of the common problem of composition, structure and properties of the real clinker phases. The formation of these complex phases is first of all possible owing to the crystal chemical structural peculiarities of "pure" matrix compounds  $C_3S$ ,  $C_2S$ ,  $C_3A$ ,  $C_4AF$ . Cement minerals consist of such elements (Ca, Al, Fe, Si) which possess the greatest ability (compared to others) to substitutions by various isomorphic elements.

The real conditions of cement production - the chemical composition of raw materials and the heat treatment schedule - provide the formation of cement minerals containing many impurities.

The minerals were synthesized by annealing the batch of initial components the amounts of which were calculated according to compositions chosen from results of the electron-probe microanalysis of the phases of commercial clinkers. The annealing schedule (temperature, exposure, cooling rate) varied depending on the mineral synthesized.

The compositions of all products obtained were determined by chemical analysis. The identification of the phases, the determination of the homogeneity of the samples were made using microscopic and X-ray methods.

#### ALITES OF COMPLICATED COMPOSITION

Table 1 gives the compositions of complex alites A, B, C, alite D with five impurity atoms - Na, K, Mg, Al, Fe, and alite E with three impurity atoms - Mg, Al, Fe. For comparison purposes the samples of  $C_3S$  were synthesized and studied.

TABLE I					
Sample	Alites				
Oxide	A	B	C	D	E
CaO	71.13	71.03	71.62	71.89	71.58
SiO <sub>2</sub>	25.72	24.95	25.24	24.83	26.40

Σ	100.07	100.55	100.30	99.72	100.09
Σ impur.	2.95	4.00	3.07	3.00	2.11

As an example we give the formula of one of the complex alites in atomic and in the generally accepted form:

alite B:  $Ca_{103.87}Si_{34.05}Na_{0.61}K_{0.24}Mg_{1.85}$

$Al_{1.95}Fe_{0.98}Ti_{0.32}P_{0.29}O_{180}$

$3.04CaO \cdot SiO_2 \cdot 0.009Na_2O \cdot 0.004K_2O \cdot 0.054MgO \cdot$

$0.029Al_2O_3 \cdot 0.014Fe_2O_3 \cdot 0.009TiO_2 \cdot 0.004P_2O_5$ .

Microscopic examination showed that each alite is a homogeneous well-crystallized phase with slightly increased refractive indices compared to pure  $C_3S$  and with higher birefringence.  $N_g - N_p$  for alites is 0.005-0.008 and for pure  $C_3S$  is 0.003.

X-ray analysis showed that all alites are monoclinic; the unit cell parameters for them and refractive indices are given in Table II.

TABLE II						
Alite	a, Å	b, Å	c, Å	$\beta^\circ$	$N_g$	$N_p$
A	12.261	7.059	25.064	$89^\circ 44'$	1.729	1.722
B	12.252	7.054	25.018	$89^\circ 23'$	1.728	1.720
C	12.263	7.056	25.049	$89^\circ 54'$	1.727	1.720
D	12.249	7.048	24.988	$89^\circ 57'$	1.728	1.722
E	12.243	7.050	25.018	$89^\circ 43'$	1.724	1.719

The unit cell parameters for  $C_3S$  calculated by us are:  $a = 12.218$  Å;  $b = 7.119$  Å;  $c = 25.148$  Å;  $\alpha = 89^\circ 54'$ ;  $\beta = 89^\circ 42'$ ;  $\gamma = 89^\circ 43'$ . The refractive indices are:  $N_g = 1.717$ ,  $N_p = 1.714$ .

The X-ray diffraction pattern of complex alite B resembles that of pure  $C_3S$  (Fig. 1). X-ray patterns of the other alites are not given as they are of the same type.

Fig. 1 - Fragments of the X-ray diffraction pattern of  $C_3S$  (curve I) and alite B.

The melting temperatures of alites measured on a heating microscope are close to each other:  $2055^\circ C \pm 10^\circ$  (for  $C_3S$   $2070^\circ C \pm 10^\circ$ ). The experimental density of alites is 3.18-3.20 g/cm<sup>3</sup>, the calculated density 3.13-3.17 g/cm<sup>3</sup>.

The IR spectra demonstrate (Fig. 2) that the lattice distortion caused by impurities shows up in the diffuse character of the curves. The decrease of intensity of the bands in the absorption maximum, the broadening of the bands, and as a result, the merging of some of them are due to disorder in distribution of cations in the lattice of the solid solutions and to the distortion of the structural elements.

The hydration kinetic curves (Fig. 3) were obtained using the results of X-ray analysis. The parallel runs permitted to make sure of the reproducibility of the process the general character of which can be revealed with sufficient accuracy by X-ray analysis.

The samples were prepared in paste form with a  $w/c=0.4$ , the experimental temperature was  $20^\circ\text{C}$ . The observation over the course of hydration during the first days was made every two hours and further in the standard terms.

Fig. 2 - IR spectra of  $\text{C}_3\text{S}$  (curve I) and alite B.

Fig. 3 - Degree of hydration of  $\text{C}_3\text{S}$  (---) and alites B (—), A (···) and C (-x-).

The analysis of the hydration process shows that at early hydration (in the given experiment for the first 1-2 h) the values of the degree of hydration of alites and  $\text{C}_3\text{S}$  are close to each other. The hydration of alites A and B proceeds slower. But further it is with these alites that the stage of acceleration of the hydration reaction proceeds most intensely. After completion of this period all complex alites hydrated to a considerably greater extent than  $\text{C}_3\text{S}$ ; the value of  $\alpha$  was greatest for alites A and B.

Although in structural relation the complex of impurities causes the usual transformation of triclinic  $\text{C}_3\text{S}$  to monoclinic alite, the influence of impurities on the hydration activity appears to be rather effective. Complicated monoclinic alites are more reactive than those with one or two impurities. Thus after 28 days the degree of hydration of the monoclinic alite B is twice that of the monoclinic solid solution of  $\text{C}_3\text{S}$  with  $\text{ZnO}$ .

#### BELITE

The compositions of  $\alpha$ -,  $\alpha'$ -,  $\beta$ -modifications of belite with a complex of impurities in the lattice are shown in Table III. The preparation of each of the modifications

appeared to be possible by choosing an appropriate heat treatment schedule. Belites can be produced homogeneous if the total amount of impurities does not exceed 6%. The amount of impurities in the different modifications can vary but not significantly.

TABLE III						
Belite	$\alpha$	$\alpha'$	$\beta$	$\beta$	$\beta$	$\beta$

The formula of  $\alpha$ -,  $\alpha'$ -,  $\beta$ -belites in atomic and oxide forms can be represented as follows:

$\alpha$ (A):  $\text{Ca}_{1.94}\text{Si}_{0.92}\text{Na}_{0.06}\text{K}_{0.03}\text{Mg}_{0.02}\text{Al}_{0.05}\text{Fe}_{0.04}\text{Ti}_{0.006}\text{Mn}_{0.001}\text{O}_4$ ;

$\alpha'$ (B):  $\text{Ca}_{1.97}\text{Si}_{0.92}\text{Na}_{0.02}\text{K}_{0.04}\text{Mg}_{0.02}\text{Al}_{0.06}\text{Fe}_{0.03}\text{O}_4$ ;

$\beta$ (C):  $\text{Ca}_{1.94}\text{Si}_{0.91}\text{Na}_{0.01}\text{K}_{0.02}\text{Mg}_{0.04}\text{Mn}_{0.001}\text{Al}_{0.06}\text{Fe}_{0.02}\text{Ti}_{0.01}\text{P}_{0.01}\text{S}_{0.003}\text{O}_4$ ;

$\beta$ (D):  $\text{Ca}_{1.94}\text{Si}_{0.92}\text{Na}_{0.02}\text{K}_{0.04}\text{Mg}_{0.02}\text{Al}_{0.06}\text{Fe}_{0.03}\text{O}_4$ ;

$\beta$ (E):  $\text{Ca}_{1.94}\text{Si}_{0.92}\text{Na}_{0.02}\text{K}_{0.04}\text{Mg}_{0.02}\text{Al}_{0.06}\text{Fe}_{0.03}\text{O}_4$ ;

$\beta$ (F):  $\text{Ca}_{1.94}\text{Si}_{0.92}\text{Na}_{0.02}\text{K}_{0.04}\text{Mg}_{0.02}\text{Al}_{0.06}\text{Fe}_{0.03}\text{O}_4$ ;

$\beta$ (G):  $\text{Ca}_{1.94}\text{Si}_{0.92}\text{Na}_{0.02}\text{K}_{0.04}\text{Mg}_{0.02}\text{Al}_{0.06}\text{Fe}_{0.03}\text{O}_4$ ;

$\beta$ (H):  $\text{Ca}_{1.94}\text{Si}_{0.92}\text{Na}_{0.02}\text{K}_{0.04}\text{Mg}_{0.02}\text{Al}_{0.06}\text{Fe}_{0.03}\text{O}_4$ ;

$\beta$ (I):  $\text{Ca}_{1.94}\text{Si}_{0.92}\text{Na}_{0.02}\text{K}_{0.04}\text{Mg}_{0.02}\text{Al}_{0.06}\text{Fe}_{0.03}\text{O}_4$ ;

$\beta$ (J):  $\text{Ca}_{1.94}\text{Si}_{0.92}\text{Na}_{0.02}\text{K}_{0.04}\text{Mg}_{0.02}\text{Al}_{0.06}\text{Fe}_{0.03}\text{O}_4$ ;

$\beta$ (K):  $\text{Ca}_{1.94}\text{Si}_{0.92}\text{Na}_{0.02}\text{K}_{0.04}\text{Mg}_{0.02}\text{Al}_{0.06}\text{Fe}_{0.03}\text{O}_4$ ;

$\beta$ (L):  $\text{Ca}_{1.94}\text{Si}_{0.92}\text{Na}_{0.02}\text{K}_{0.04}\text{Mg}_{0.02}\text{Al}_{0.06}\text{Fe}_{0.03}\text{O}_4$ ;

$\beta$ (M):  $\text{Ca}_{1.94}\text{Si}_{0.92}\text{Na}_{0.02}\text{K}_{0.04}\text{Mg}_{0.02}\text{Al}_{0.06}\text{Fe}_{0.03}\text{O}_4$ ;

$\beta$ (N):  $\text{Ca}_{1.94}\text{Si}_{0.92}\text{Na}_{0.02}\text{K}_{0.04}\text{Mg}_{0.02}\text{Al}_{0.06}\text{Fe}_{0.03}\text{O}_4$ ;

$\beta$ (O):  $\text{Ca}_{1.94}\text{Si}_{0.92}\text{Na}_{0.02}\text{K}_{0.04}\text{Mg}_{0.02}\text{Al}_{0.06}\text{Fe}_{0.03}\text{O}_4$ ;

$\beta$ (P):  $\text{Ca}_{1.94}\text{Si}_{0.92}\text{Na}_{0.02}\text{K}_{0.04}\text{Mg}_{0.02}\text{Al}_{0.06}\text{Fe}_{0.03}\text{O}_4$ ;

$\beta$ (Q):  $\text{Ca}_{1.94}\text{Si}_{0.92}\text{Na}_{0.02}\text{K}_{0.04}\text{Mg}_{0.02}\text{Al}_{0.06}\text{Fe}_{0.03}\text{O}_4$ ;

$\beta$ (R):  $\text{Ca}_{1.94}\text{Si}_{0.92}\text{Na}_{0.02}\text{K}_{0.04}\text{Mg}_{0.02}\text{Al}_{0.06}\text{Fe}_{0.03}\text{O}_4$ ;

$\beta$ (S):  $\text{Ca}_{1.94}\text{Si}_{0.92}\text{Na}_{0.02}\text{K}_{0.04}\text{Mg}_{0.02}\text{Al}_{0.06}\text{Fe}_{0.03}\text{O}_4$ ;

$\beta$ (T):  $\text{Ca}_{1.94}\text{Si}_{0.92}\text{Na}_{0.02}\text{K}_{0.04}\text{Mg}_{0.02}\text{Al}_{0.06}\text{Fe}_{0.03}\text{O}_4$ ;

$\beta$ (U):  $\text{Ca}_{1.94}\text{Si}_{0.92}\text{Na}_{0.02}\text{K}_{0.04}\text{Mg}_{0.02}\text{Al}_{0.06}\text{Fe}_{0.03}\text{O}_4$ ;

$\beta$ (V):  $\text{Ca}_{1.94}\text{Si}_{0.92}\text{Na}_{0.02}\text{K}_{0.04}\text{Mg}_{0.02}\text{Al}_{0.06}\text{Fe}_{0.03}\text{O}_4$ ;

$\beta$ (W):  $\text{Ca}_{1.94}\text{Si}_{0.92}\text{Na}_{0.02}\text{K}_{0.04}\text{Mg}_{0.02}\text{Al}_{0.06}\text{Fe}_{0.03}\text{O}_4$ ;

$\beta$ (X):  $\text{Ca}_{1.94}\text{Si}_{0.92}\text{Na}_{0.02}\text{K}_{0.04}\text{Mg}_{0.02}\text{Al}_{0.06}\text{Fe}_{0.03}\text{O}_4$ ;

$\beta$ (Y):  $\text{Ca}_{1.94}\text{Si}_{0.92}\text{Na}_{0.02}\text{K}_{0.04}\text{Mg}_{0.02}\text{Al}_{0.06}\text{Fe}_{0.03}\text{O}_4$ ;

$\beta$ (Z):  $\text{Ca}_{1.94}\text{Si}_{0.92}\text{Na}_{0.02}\text{K}_{0.04}\text{Mg}_{0.02}\text{Al}_{0.06}\text{Fe}_{0.03}\text{O}_4$ ;

$\beta$ (AA):  $\text{Ca}_{1.94}\text{Si}_{0.92}\text{Na}_{0.02}\text{K}_{0.04}\text{Mg}_{0.02}\text{Al}_{0.06}\text{Fe}_{0.03}\text{O}_4$ ;

$\beta$ (AB):  $\text{Ca}_{1.94}\text{Si}_{0.92}\text{Na}_{0.02}\text{K}_{0.04}\text{Mg}_{0.02}\text{Al}_{0.06}\text{Fe}_{0.03}\text{O}_4$ ;

$\beta$ (AC):  $\text{Ca}_{1.94}\text{Si}_{0.92}\text{Na}_{0.02}\text{K}_{0.04}\text{Mg}_{0.02}\text{Al}_{0.06}\text{Fe}_{0.03}\text{O}_4$ ;

$\beta$ (AD):  $\text{Ca}_{1.94}\text{Si}_{0.92}\text{Na}_{0.02}\text{K}_{0.04}\text{Mg}_{0.02}\text{Al}_{0.06}\text{Fe}_{0.03}\text{O}_4$ ;

$\beta$ (AE):  $\text{Ca}_{1.94}\text{Si}_{0.92}\text{Na}_{0.02}\text{K}_{0.04}\text{Mg}_{0.02}\text{Al}_{0.06}\text{Fe}_{0.03}\text{O}_4$ ;

$\beta$ (AF):  $\text{Ca}_{1.94}\text{Si}_{0.92}\text{Na}_{0.02}\text{K}_{0.04}\text{Mg}_{0.02}\text{Al}_{0.06}\text{Fe}_{0.03}\text{O}_4$ ;

$\beta$ (AG):  $\text{Ca}_{1.94}\text{Si}_{0.92}\text{Na}_{0.02}\text{K}_{0.04}\text{Mg}_{0.02}\text{Al}_{0.06}\text{Fe}_{0.03}\text{O}_4$ ;

$\beta$ (AH):  $\text{Ca}_{1.94}\text{Si}_{0.92}\text{Na}_{0.02}\text{K}_{0.04}\text{Mg}_{0.02}\text{Al}_{0.06}\text{Fe}_{0.03}\text{O}_4$ ;

$\beta$ (AI):  $\text{Ca}_{1.94}\text{Si}_{0.92}\text{Na}_{0.02}\text{K}_{0.04}\text{Mg}_{0.02}\text{Al}_{0.06}\text{Fe}_{0.03}\text{O}_4$ ;

under polarizing light owing to higher birefringence.

$\alpha'$ -belite differs from  $\alpha$ - and  $\beta$ -forms in striations of the surface in one, two and three directions. The refractive indices are as follows:  $N_g = 1.732$  and  $N_p = 1.719$ ;  $N_g - N_p = 0.013$ . The exact determination of  $N_g$  and  $N_p$  is difficult.

$\beta$ -belite are crystals of a yellowish color with a rough spotty surface (not striated).  $N_g = 1.733-1.735$ ;  $N_p = 1.714-1.718$ . Each modification contains some amount of belites of the other form.

X-ray diffraction patterns of  $\alpha$ -,  $\alpha'$ - and  $\beta$ -belite are shown in Fig. 4. The presence of reflections 350, 341, 122, 231 permits to assign  $\alpha$  to  $\alpha'$ .

Fig. 4 - X-ray diffraction patterns of polymorphic modifications of belite: I -  $\alpha$ -(A); II -  $\alpha'$ -(B); III -  $\beta$ -(C).

Noteworthy is the  $\beta$ -belite (D). The broadening of many reflections in the X-ray pattern is evidence of imperfect crystallization. It is apparently such a belite that is structurally most close to belites of commercial clinkers which are usually called "products of imperfect crystallization". The change in the heat treatment schedule of this belite leads to form either  $\alpha'$ - or well crystallized  $\beta$ -modification. This unstable form of belite is closer in hydration activity to the  $\alpha$ -form.

The  $\alpha'$ -form is the most "sensitive" modifi-

cation to the lattice rearrangement. The accurate regulation of the heat treatment schedule and impurity concentrations can lead to obtain, in our opinion, more than two varieties of the  $\alpha$ -form.

The IR spectra of belites (Fig. 5) indicate structural transformations due to the influence of impurities and heat treatment conditions. The diffuse character of the spectra increases from one modification to another and demonstrates disorder in distribution of cations in the lattice and the distortion of the structural elements.

Fig. 5 - IR spectra of  $\alpha$ - (curve I),  $\alpha'$ - (II),  $\beta$ - (III) belites and of  $\beta$ -belite with  $B_2O_3$  (IV).

The hydration kinetic curves of belites (the averaged curves from the parallel runs) were obtained using the X-ray method (Fig. 6). The curves show a considerably higher reactivity of  $\alpha$ - and  $\alpha'$ -belites compared to  $\beta$ -belites. Attention is drawn to the high active  $\beta$ -belite D (curve III) imperfectly crystallized.

Fig. 6 - Hydration kinetic curves of belites: I -  $\alpha$ -(A); II -  $\alpha'$ -(B); III -  $\beta$ -(D); IV -  $\beta$ -(C); V -  $\beta$ -(E); VI -  $\beta$ -(F).

The increase of hydration activity of belites can be attained not only by providing the appropriate conditions for the formation of most reactive  $\alpha$ - and  $\alpha'$ -modifications of complicated composition but also by producing imperfect crystals.

The study of belite phases is of interest due to their high content in some cements. A valuable property of belite is the capability to yield active forms.

## ALUMINATE PHASE

The peculiarities of the fine structure of  $C_3A$  provide the most favourable conditions for distribution in the lattice of a considerably greater amount of impurities than in the silicate phases. The presence of large holes in the  $C_3A$  lattice promotes the realization of different schemes of hetero-valent isomorphous substitutions and permits the distribution of elements with larger ionic radii.

The synthesized homogeneous samples of the aluminate phases contain not more than 13 wt % of impurity oxides. It was observed that if the initial batch contained more than 5 wt %  $Fe_2O_3$ , then a certain amount of the aluminoferrite phase well identified microscopically and by X-rays always appeared in the product formed. Most often the aluminoferrite phase crystallized in the form of fine intergrowths with the aluminate phase.

The composition of the synthesized cubic aluminate phase after the data of chemical analysis is as follows (wt %):  $CaO$  - 56.68;  $Al_2O_3$  - 29.31;  $Fe_2O_3$  - 5.75;  $Na_2O$  - 0.48;  $K_2O$  - 0.64;  $MgO$  - 0.67;  $SiO_2$  - 5.84;  $TiO_2$  - 0.12;  $P_2O_5$  - 0.08. The total amount of impurity oxides is 13.58 %.

The formula of this phase in atomic and oxide forms has the following appearance:  
 $Ca_{2.74}Al_{1.56}Na_{0.042}K_{0.037}Mg_{0.045}Fe_{0.20}Si_{0.26}Ti_{0.004}P_{0.003}O_6$ ;  
 $3.52CaO \cdot Al_2O_3 \cdot 0.03Na_2O \cdot 0.02K_2O \cdot 0.06MgO \cdot 0.12Fe_2O_3 \cdot 0.34SiO_2 \cdot 0.005TiO_2 \cdot 0.002P_2O_5$ .  
 The density of the  $\alpha_3$  phase is  $3.14 \text{ g/cm}^3$  (for pure  $C_3A$   $3.09 \text{ g/cm}^3$ ). The parameter  $a = 15.234 \text{ \AA}$  (for pure  $C_3A$   $a = 15.255 \text{ \AA}$ ).

The phase contains some amount of calcium aluminoferrite detected microscopically and by X-ray analysis. The X-ray diffraction patterns for  $C_3A$  and for cubic aluminate phase are analogous (Fig. 7).

Fig. 7 - X-ray diffraction patterns of  $C_3A$  (I) and of the aluminate phase (II).

As shown by kinetic curves of Fig. 8, the hydration process of the aluminate phase (curve II) proceeds like that of pure  $C_3A$  and solid solutions of  $C_3A$  with  $Na_2O$ .

Fig. 8 - Hydration kinetic curves of  $C_3A(I)$ , aluminate phase (II) and monoclinic solid solution of  $C_3A$  with  $Na_2O$  (III).

The peculiarity of the aluminate phases is that in the formation process of different crystalline forms the main role belongs to alkalis, whereas the hydration activity depends on the set of all impurities. Detailed results on the study of the aluminate phases will be reported at the Seminar A.

## ALUMINOFERRITE PHASE

The aluminoferrite phase, like the aluminate phase, is capable to distribute in its lattice a considerably greater amount of impurities than alite and belite owing to the peculiarities of structure. The occurrence of octahedral and tetrahedral positions with  $Fe^{3+}$  and  $Al^{3+}$  in the aluminoferrite lattice promotes the variety of substitutions of these atoms for isomorphous impurities. The structure of aluminoferrites is most favourable for occupancy of the lattice sites by  $Mg, Si, Mn, Cr$  and  $Ti$ .

The compositions of the synthesized homogeneous phases are given in Table IV.

TABLE IV				
Sample Oxide	AF-2	AF-3	AF-4	AF-6
$CaO$	46.60	50.02	50.15	49.98
$Al_2O_3$	23.54	19.41	21.30	18.08
$Fe_2O_3$	23.86	20.83	20.97	19.80
$Na_2O$	-	0.25	0.11	0.18
$K_2O$	-	0.18	0.11	0.26
$MgO$	0.66	3.21	2.96	3.30
$MnO$	1.56	1.04	0.27	0.56
$SiO_2$	2.17	3.87	3.62	6.78
$TiO_2$	2.48	1.99	1.04	1.34
$P_2O_5$	-	0.08	-	0.26
$\Sigma$	100.87	100.88	100.53	100.54
$\Sigma$ impur.	6.87	10.62	8.11	12.68

As an example, the formula of aluminoferrite AF-2 in atomic and oxide forms is as follows:  
 $Ca_{1.94}Al_{1.08}Fe_{0.70}Mg_{0.04}Mn_{0.05}Si_{0.08}Ti_{0.07}O_5$ ;  
 $5.56CaO \cdot 1.54Al_2O_3 \cdot Fe_2O_3 \cdot 0.11MgO \cdot 0.15MnO \cdot 0.24SiO_2 \cdot 0.21TiO_2$ .

The unit cell parameters of AF-2 are:  $a = 5.29 \text{ \AA}$ ;  $b_0 = 14.57 \text{ \AA}$ ;  $c_0 = 5.54 \text{ \AA}$ ; for  $C_6A_2F$ :  $a = 5.27 \text{ \AA}$ ;  $b = 14.54 \text{ \AA}$ ;  $c = 5.53 \text{ \AA}$ .

All aluminoferrite phases obtained are of the same type, possess analogous X-ray patterns and are similar to the aluminoferrite  $C_6A_2F$ . Figure 9 demonstrates as an example the X-ray diffraction pattern of the aluminoferrite AF-2 and that of  $C_6A_2F$  for comparison. The matrix of all synthesized aluminoferrites whose compositions were chosen according to the electron-probe microanalysis of commercial products appeared to be the aluminoferrite  $C_6A_2F$ .

Fig. 9 - Fragments of the X-ray diffraction patterns of  $C_6A_2F$  (I) and AF-2 (II).

Aluminoferrites of complicated composition are often distinguished by an imperfect crystallization. The most imperfectly crystallized is the aluminoferrite AF-6. But the quality of the crystals is influenced not only by the set of impurities but also by thermal conditions. Although the structure of AF-6 is so distorted that all reflections are strongly broadened and some of them diffused, nevertheless the character of the whole X-ray pattern remains similar to that of  $C_6A_2F$  (Fig. 10).

Fig. 10 - X-ray diffraction pattern of AF-6.

The X-ray diffraction pattern of AF-6 is distinguished also by the irregular shift of reflections at angle  $2\theta$  of  $32-35^\circ$ ,  $45-50^\circ$  and  $58-61^\circ$  what is due to the unit cell distortion.

Aluminoferrites of commercial clinkers are

also poorly crystallized. One of the significant causes of the lattice distortion is mainly the heterovalence type of isomorphic substitutions which requires the charge balance, disturbs the microsymmetry and electrostatics of the structure. The distortion is due to the different sizes and different valency of the substitute pairs of atoms, such as  $Si^{4+} - Al^{3+}$ ,  $Mg^{2+} - Al^{3+}$ ,  $Ti^{4+} - Fe^{3+}$ ,  $Mn^{2+} - Fe^{3+}$ ,  $Mg^{2+} - Fe^{3+}$ ,  $Si^{4+} - Fe^{3+}$ .

The influence of a complex of impurities affected first of all the hydration properties of the aluminoferrite phase (Fig. 11). The phase of complicated composition AF-2 appeared to be most reactive during the first days of hydration and its reactivity at all stages of hydration exceeds that of the studied aluminoferrite solid solutions of a more simple composition.

Fig. 11 - Degree of hydration of aluminoferrites: I - AF-2; II -  $C_6A_2F$ ; III -  $C_6A_2F$  with 3.8% MgO and 2.4%  $SiO_2$ ; IV -  $C_4AF$  with 3.5% MgO and 1.2%  $SiO_2$ .

## CONCLUSION

Cement minerals of complicated composition analogous to phases of commercial clinker can be regarded as multi-component solid solutions.

The preferential location of each impurity in that or another matrix mineral and the total amount of impurity oxides in the limiting solid solutions depend on the peculiarities of fine structures of  $C_3S$ ,  $C_2S$ ,  $C_3A$  and  $C_6A_2F$ .

The contents of impurity oxides in the limiting solid solutions do not exceed the following approximate quantities (wt %): 4.0-4.5% in the alite; 6% in the belite; 10-11% in the aluminoferrite and 13% in the alumininate.

The presence of a complex of impurities and the appropriate thermal conditions may lead to form cement minerals with strongly distorted structure. In industrial conditions the clinker phases (especially belite and aluminoferrite) are most often products of imperfect crystallization. Imperfectly crystallized phases are most active in the process of interaction with water.

The present paper reports the results of unaccomplished investigations. In further work attention will be paid to the preparation and study of the activated phases.

## Synthesis of dicalcium silicate and tricalcium silicate phases

*Synthèse du silicate bicalcique et du silicate tricalcique.*

Surendra Nath GHOSH Ph. D. Cement Research Institute of India, New Delhi.

RESUME : En chauffant les mélanges crus contenant un corps réactif (gel de silice) et en y ajoutant des minéralisateurs, le taux de formation des phases  $C_2S$  et  $C_3S$  peut être considérablement augmenté. Des minéralisateurs tels que le  $CaF_2$  et le  $NaF$  ont été utilisés et on a fait varier le temps de cuisson d'une demi heure à une heure. La conversion du mélange cru en ces phases était supérieure à 90 % dans le cas d'une seule cuisson.

On a aussi étudié la température de décomposition du  $CaCO_3$  dans le mélange par la méthode ATD/ATG. L'effet des cations sur la décomposition du  $CaCO_3$  a été observé et mis en corrélation avec le rayon ionique des cations.

SUMMARY : The rate of formation of  $C_2S$  and  $C_3S$  phases can be increased considerably by heating the raw mixes containing reactive material (silica gel) and addition of mineralizers. Mineralizers, such as  $CaF_2$ ,  $NaF$  were used and total retention time varied from 1/2 hour to 1 hour. The conversion of raw mix to these phases was above 90 % in a single firing.

The decomposition temperature of  $CaCO_3$  in the raw mix was also studied by DTA/TGA. The effect of cations on the decomposition of  $CaCO_3$  was observed and correlated with the ionic radius of the cations.

## INTRODUCTION

The synthesis of the silicate phases,  $C_2S$  and  $C_3S$  attracted the author's attention during the course of studying the action of mineralizers on the formation of ordinary Portland cement (OPC). Reports on obtaining a fairly good strength OPC with low percentage of alite (1) and on the preparation of reactive - belite (2) were of special interest. Considerable work has been reported in the past by various authors on the synthesis, reactivity, etc., of  $C_2S$  phase and this has been covered recently (3). The synthesis of  $C_3S$  phase of high purity has been a subject of interest over the years and among others had been dealt elegantly by Odler and Dorr (4). The present research was undertaken to:

- i/ increase the kinetics of formation of these phases,
- ii/ stabilize the phases in certain desirable polymorphic/solid solution states, and
- iii/ understand qualitatively the kinetics and stabilization characteristics.

Preliminary results of the work carried out over a period of one year or so are being presented here, some of which were communicated as short notes earlier (5-7). Needless to mention the complexities and involvement for carrying out this work are quite demanding.

## EXPERIMENTAL

Techniques, such as rapid heating to the sintering temperature, use of reactive starting materials, e.g. silica gel and additions of mineralizers were adopted. Reagent grade  $CaCO_3$ , mineralizers (2%) and commercially available silica gel (colourless) were used to make the batches (5g. each). These batches (passing 40 $\mu$ ) in the form of pressed pellets, were introduced in a platinum holder in a quench furnace normally preheated to the temperature of sintering and kept for a period of 1/2 hours to 1 hour in general. The sintered materials were air-quenched and analysed by chemical, XRD, IR, microscopy, etc.

## RESULTS

The dissociation temperatures of  $CaCO_3$  in mixes containing  $CaCO_3$  and  $SiO_2$  (2:1) in presence of NaF were studied by DTA and TGA. These results are shown in Fig. 1. Decomposition temperatures corresponding to the DTA peaks with the highest weight loss were taken though several peaks with weight losses were observed in DTA/TGA traces of the samples (5). The decomposition temperatures of  $CaCO_3$  in mixes containing  $CaCO_3$  and  $SiO_2$  (3:1) with different mineralizers were studied as shown in Table - I.

The synthesis of  $\beta$ - $C_2S$  phase with the addition of 2% NaF was studied over the temperature range 800-100°C and some details of the results are given in Table - II and Fig. 2.

TABLE + I

Mineralizer	Percentages of addition		
	2%	4%	6%
LiF	540 (w)	560 (m)	530 (m)
	620 (w)	710 (s)	675 (s)
	850 (m)	880 (m)	830 (m)
NaF	790 (s)	560 (vw)	540 (vw)
	825 (m)	595 (w)	575 (w)
	859 (m)	745 (s)	705 (s)
		1020 (m)	845 (m)
			930 (m)
$CaF_2$	875 (s)	865 (s)	850 (s)
	1110 (vw)	890 (m)	
		1015 (vw)	1010 (w)
$SrF_2$	845 (vw)	820 (s)	835 (s)
	917 (s)	870 (m)	870 (p)
			1010 (vw)
$BaF_2$	785 (w)	830 (s)	810 (s)
	875 (s)	880 (m)	870 (p)
		980 (vw)	980 (vw)

W = Weak, m = medium, vw = very weak, s = strong

All are endothermic peaks. DTA peaks without any mineralizer are at 560 and 940°C.

Fig. 1. Dissociation temperature of  $CaCO_3$  in mixes of  $CaCO_3$  and  $SiO_2$  (2:1) with various amounts of NaF. Endothermic DTA peaks corresponding to the highest Wt. loss considered.

TABLE - II

Slow heating (10°C/min)		Abrupt heating to sintering temperatures	
800°C	1000°C	Raw mix decarbonated at 800°C and fired abruptly at high temperature	Raw mix fired at 1000°C and above
Formation of $\beta$ -C <sub>2</sub> S phase with 2.5% free lime	Formation of $\beta$ -C <sub>2</sub> S phase with free lime 4%; no reduction in free lime content with increasing retention time	At 850, 900 and 1000°C, the quality of free lime was around 2%	Up to 1000°C free lime content was around 2% but it increased at higher temperature

Fig. 2. XRD traces of raw mixes of  $\text{CaCO}_3$  and  $\text{SiO}_2$  (2:1) and 2%  $\text{NaF}$ . Mix I heated abruptly to 1000°C for 1/2 hr; Mix-II fired abruptly at 1000°C for 1/2 hr after decarbonation at 800°C and Mix-III heated to 1000°C for 1/2 hr (10°C/min).

With a retention time of 1-2 hours, the formation of  $\alpha'$ -phase in presence of  $\text{B}_2\text{O}_3$  (1-3%), and  $\gamma$ -phase in presence of  $\text{FeO}$  and excess  $\text{CaO}$  were also studied.

The formation characteristics of  $\text{C}_2\text{S}$  phase in the presence of different mineralizers are outlined in Table - III. The total percentage of addition of mineralizers was kept to 2% and the batches were heated abruptly to sintering temperatures.

#### DISCUSSION

The lowering of the decomposition temperature of  $\text{CaCO}_3$  by the addition of mineralizers is not only important from the viewpoint of heat saving but also from the fact that  $\text{CaO}$  released at a lower temperature is more reactive which is quite well known.

A number of intermediate compound formations is indicated which leads to the decomposition of  $\text{CaCO}_3$  in stages. Imlach (8) observed two types of mechanism in the decomposition of  $\text{CaCO}_3$  in some plant raw mixes. The decomposition of  $\text{CaCO}_3$  in the presence of  $\text{NaF}$  is of considerable interest (Fig. 1). The temperature has been lowered to 555°C from 880°C (0%  $\text{NaF}$ ) and further up to 6% of addition of  $\text{NaF}$ , there was a continuous fall in temperature and then again from 12 to 16%. The effect of cations on the decomposition of  $\text{CaCO}_3$  in mixes of  $\text{CaCO}_3$ :  $\text{SiO}_2$  (3:1) is presented in Figs. 3 and 4.

The formation of  $\alpha'$ -C<sub>2</sub>S along with  $\beta$ -C<sub>2</sub>S in the presence of  $\text{NaF}$  was observed and it was found that with the addition of gypsum or  $\text{CaS}$ , the  $\alpha'$ -phase disappeared. High conversion rate (~96%) for the formation of  $\alpha'$ - and  $\gamma$ -C<sub>2</sub>S phase was observed (2 hours retention at 1450°C in a single firing).

The formation of  $\text{C}_2\text{S}$  phase in the presence of  $\text{CaF}_2$  was observed at as low a temperature as 850°C with a retention time of 2 hours. The free lime contents as determined chemically are 3.9% (1300°C), 2.13% (1350°C) and 2.32% (1400°C) with total retention time of 1 hour. An XRD trace of a mix heated to two hours (total retention time) is shown in Fig 5. Recent work (9) has shown that the percentage of  $\text{CaF}_2$  addition could be reduced to as low 0.5%. This indicates that a still purer  $\text{C}_2\text{S}$  sample can be synthesized. The formation of  $\text{C}_2\text{S}$  in the presence of fluorides and other mineralizers is shown in Fig. 6. The line marked 'A' represents a raw mix containing  $\text{MgO}$  (0.5%) and  $\text{Al}_2\text{O}_3$  (0.25%) besides  $\text{CaF}_2$ .

TABLE - III

Temperature of heating	CaF <sub>2</sub>			NaF			CaSO <sub>4</sub> ·2H <sub>2</sub> O			CaHOP <sub>4</sub>			CrO <sub>3</sub>			F <sup>-</sup> +PO <sub>4</sub> <sup>-3</sup>			F <sup>-</sup> +PO <sub>4</sub> <sup>-3</sup>			+SQ <sup>-2</sup> <sub>4</sub>			+ CrO <sub>3</sub>		
	*A	B	C	A	B	C	A	B	C	A	B	C	A	B	C	A	B	C	A	B	C	A	B	C	A	B	C

G = Good;	VG = Very Good;	W = Weak	* C <sub>3</sub> S = A
L = Low;	H = High;	F = Fair	C <sub>2</sub> S = B
VH = Very High;	VG = Very fair	VL = Very low	Free lime = C

These are relative value as obtained from XRD line intensities.

Fig. 3. The lowering of decomposition temperature of CaCO<sub>3</sub> in mixes containing CaCO<sub>3</sub> and SiO<sub>2</sub> (3:1) and mineralizers.

The kinetics for this mix (alite composition) is the fastest as observed qualitatively on a comparative basis. The lines marked 'M' represent batches containing CaF<sub>2</sub> + CaHPO<sub>4</sub>·2H<sub>2</sub>O + CrO<sub>3</sub> (1:0.5 : 0.5:0.5); and <sup>2</sup>(0) represents CaF<sub>2</sub> + CaHPO<sub>4</sub> (1:1). LiF is apparently volatilized away at higher temperatures.

Fig. 4. Effects of ionic radii of cations of mineralizers (as mentioned in Fig. 3) on the dissociation temperature of CaCO<sub>3</sub>.

The kinetics of C<sub>3</sub>S formation process cannot be expressed by a single kinetic equation (10,11). In the presence of CaF<sub>2</sub>, the primary phase field of C<sub>3</sub>S gets enlarged and this may be one of the reasons for increased kinetics (9). The formation of intermediate compounds, such as (C<sub>2</sub>S)<sub>2</sub> or (C<sub>3</sub>S)<sub>3</sub>, CaF<sub>2</sub> as reported (12) besides reactive polymorphic form of C<sub>2</sub>S at higher temperatures (10,11) may influence the kinetics of formation. The early liquid formation (in the case of C<sub>3</sub>S) is also deemed responsible for the increased kinetics of C<sub>3</sub>S formation. Details of some of which has been reviewed recently (13). A theoretical approach using polyhedral model to understand the stabilization of orthosilicate system has been

outlined by Moore (14) but the recent experimental work by Barnes et al (15) is rather interesting to note. They found it difficult to correlate any affinity of a particular ion to go into solid solution in the lattice of a particular  $C_2S$  form.

Fig. 5. An XRD trace of  $C_2S$  obtained by the rapid heating technique (total retention time-2 hr at  $1400^\circ C$ )

Fig. 6. The formation of  $C_2S$  phase in presence of mineralizers using rapid heating technique. XRD line intensity ratio of CaO and  $C_2S$  used.

#### CONCLUSION

The rate of formation  $C_2S$  and  $C_3S$  phases can be increased considerably by rapidly heating the mix containing reactive material (silica gel) and by additions of mineralizers. The purity of these materials can be improved by a judicious combination of these techniques.

### RESUME :

On a procédé aux études microscopiques de plus de dix mille échantillons prélevés dans des fours rotatifs de sept cimenteries préparant la masse crue par la voie humide et sèche.

On a analysé les conditions thermiques de production de ces échantillons, dont plus de deux mille ont été soumis aux essais physico-mécaniques.

On a établi, pour les clinkers industriels, l'identité de types de microstructures qui ont ensuite été classés. On a montré que la succession des passages d'un type à l'autre est régulièrement liée à la variation de l'intensité du traitement thermique. D'autre part, on a apprécié quantitativement l'influence directe de la microstructure sur l'activité hydraulique ( $R_{28}$ ). C'est sur cette base qu'ont été mis au point et introduits dans l'industrie les principes de contrôle de la cuisson du clinker, en s'appuyant sur la microstructure en qualité de principal paramètre d'estimation.

### SUMMARY:

Over 10 thousands samples from rotary furnaces at seven cement plants with wet and dry production processes have been subject to microscopic investigations.

The thermal conditions of sampling have been analyzed and over 2 thousands of said samples have been subjected to physical and mechanical tests.

The uniformity of types of the industrial clinker microstructures have been found out with corresponding classification provided. It has been proved that the sequence of transfer from one type to another is regularly dependent on variations of thermal treatment intensity. On the other hand, the direct influence of the microstructure on the hydraulic activity ( $R_{28}$ ) has been quantitatively estimated. On this basis the clinker calcination control principles have been developed and implemented in the production to be used as the basic criterion of clinker activity.

l'interdépendance entre la microstructure du clinker et son activité hydraulique a été l'objet d'études de nombreux chercheurs depuis Le Chatelier et Thornebom (1, 2). Dans les années 30 et, surtout, ces dernières années, les études en cette direction ont été développées de façon suffisamment sérieuse, mais en dépit de ces efforts l'utilisation pratique de cette interdépendance dans l'industrie est restée jusqu'à aujourd'hui très limitée.

Les études de plus de 10 mille couches minces prélevées dans 7 usines différentes simultanément aux essais physico-mécaniques de plus de 2 mille éprouvettes de clinkers, la confrontation des conditions concrètes d'obtention de ces éprouvettes aux états de phase des minéraux du clinker ont permis d'établir une série de régularités.

Il s'est avéré que malgré la diversité des matières premières et des conditions technologiques des productions concrètes, la microstructure de leurs clinkers présente des traits communs. Cette communauté est avant tout la conséquence de l'identité de méthode utilisée pour l'obtention du clinker : la cuisson. Notons toutefois, que les microstructures des clinkers fondus ou des clinkers obtenus par la voie radiative diffèrent en principe des clinkers cuits.

Les résultats de l'étude menée permettent de distinguer quatre types principaux de microstructures embrassant pratiquement tous les cas étudiés (fig. 1a, b, c, d).

Le 1-er type (fig. 1a) se caractérise par une cristallisation incomplète et peu prononcée des principales phases, allant jusqu'à l'absence complète de formes morphologiquement déterminables. En règle générale il s'accompagne d'une distribution irrégulière des minéraux.

Le 2-ème type (fig. 1b) présente une abondance de phases silicates finement cristallisées (moins de  $20\mu\text{m}$ ). Deux variantes se rencontrent à répartition irrégulière (en amas) et régulière de minéraux.

Le 3-ème type (fig. 1c) est constitué de microstructures avec de formations assez volumineuses d'alite et de bélite aux contours flous. Ce type se caractérise par des agrégations au sein d'une même granule. Les secteurs du type 3 sont souvent associés aux secteurs du type 2 et 4.

Le 4-ème type (fig. 1d) comprend des cristaux d'alite et de bélite aux formes nettes en majorité de dimension supérieure à  $30\mu\text{m}$ . Le trait essentiel de ce type de clinkers est la régularité de distribution des phases. La limite supérieure des dimensions des cristaux ne dépasse pratiquement pas  $60\mu\text{m}$  malgré la présence quelquefois de gros cristaux (jusqu'à  $200\mu\text{m}$ ) isolés.

Il est nécessaire de souligner que, pratiquement, chaque éprouvette de clinker constitue une association d'éléments différents en microstructure. Aussi dans nos études a-t-on, au préalable, apprécié l'homogénéité des éprouvettes pour n'analyser que cel-

les d'entre elles dans lesquelles l'apport de l'un des 4 types était dominant et constituait au moins 70 %.

Fig. 1a

Fig. 1b

Fig. 1c

Fig. 1d

Les différences limites dans la résistance des clinkers ( $R_{28}$ ) en rapport avec les variations de microstructure établies par nos études atteignent 120 à 180 kgf/cm<sup>2</sup>. Ces chiffres correspondent à ceux trouvés par d'autres auteurs (3, 5). Les meilleurs clinkers, sous l'angle de la résistance à 28 jours, sont les clinkers du 4-ème type.

L'influence des conditions spécifiques à l'entreprise se manifeste principalement dans le niveau de l'activité hydraulique du clinker mais ne se répercute pas sur l'importance du rôle de la microstructure. C'est ainsi, par exemple, qu'on a établi qu'avec une teneur moyenne en alcali dans la matière première de l'ordre de 1,5 % la marge de variation de la résistance, due au changement de la microstructure, était de 370 à 510 kgf/cm<sup>2</sup>, tandis qu'à l'usine utilisant une matière première de faible teneur en alcalis (environ 0,5 %) cette marge oscillait de 420 à 600 kgf/cm<sup>2</sup>. Une attention particulière était attachée aux problèmes de stabilité de la phase alitique. Il a été établi que même les stades initiaux de la désintégration, observés le plus souvent au sein des microstructures parfaites, entraînaient des chutes de résistance de l'ordre de 30 à 50 kgf/cm<sup>2</sup>.

L'expérience de postcombustion en laboratoire des clinkers du 1-er type à 1450 °C a montré que l'amélioration de la microstructure est le corollaire logique d'un traitement thermique poussé du matériau. L'étude des régimes thermiques de fonctionnement des fours a montré que la séquence des variations de la microstructure, résultant de l'intensification de la cuisson par l'élévation de la température dans la zone de cuisson ou du temps de maintien du matériau à des températures dépassant 1300 °C, de même que de l'accroissement de la "réceptivité thermique" du mélange brut constitue une constante de l'entreprise consi-

dérée, et, pour les entreprises différentes, ne varie qu'en détails, en principe, de nature non substantiels. La marche générale des variations du type 1 au type 4, en passant par les structures du type 2 et 3, se conserve dans ce cas. On est ainsi arrivé pour la première fois à établir une échelle de microstructures traduisant la liaison de l'état de phases des clinkers avec la résistance et le régime thermique. Une telle échelle (à 8 degrés) nous a servi de critère pour le contrôle de la cuisson du clinker, opération qui dans tous les cas (plus d'une dizaine) nous a permis d'éllever la résistance moyenne du clinker dans les entreprises de 30 à 40 kgf/cm<sup>2</sup>.

La nature de l'influence de la microstructure sur la résistance se manifeste essentiellement dans la différence de l'état de la surface des particules de ciment obtenues après mouture. (Il est bien entendu qu'on compare des ciments moulus dans les mêmes conditions et jusqu'à obtenir les mêmes caractéristiques standard.) La figure 2 fournit les différences caractéristiques entre les formes des particules obtenues a) à partir du clinker du type 1 et b) à partir du clinker du type 4. Vraisemblablement le développement du contour des particules dans le second cas est le facteur contribuant à l'élévation de la résistance du matériau en voie de durcissement. En tout cas la différence de forme des particules observée constamment s'accompagne de variations dans les caractéristiques de la poudre de ciment telle la chaleur de mouillage, la cinétique de dégagement de chaleur (6).

Fig. 2a

Fig. 2b

En conclusion de l'étude menée on peut dire que la microstructure du clinker est justement le critère qui doit être utilisé pour la commande des fours de cuisson et le contrôle du processus. Il faut en outre souligner les avantages majeurs de la microstructure devant la teneur en résidus d'oxyde de calcium, utilisés jusqu'à aujourd'hui comme critère principal.

# Spectroscopic studies of $\text{Ca}_3\text{SiO}_5$ polymorphism

## *Les études spectroscopiques du polymorphisme du $\text{Ca}_3\text{SiO}_5$*

M. HANDKE, Cz. PALUSZKIEWICZ, G. SIEMINSKA, School of Mining and Metallurgy, Institute of Materials Science, Krakow, Poland.

RESUME : On a étudié sur des échantillons pulvérisés, les modifications polymorphiques du  $\text{Ca}_3\text{SiO}_5$  stabilisé par  $\text{ZnO}$ , en utilisant les méthodes de Raman au rayon laser et la spectroscopie infrarouge avec transformation de Fourier. Les modifications polymorphiques ont été déterminées par la diffraction aux rayons X. La spectroscopie vibrationnelle constitue une méthode complémentaire à la diffraction aux rayons X et donne des informations sur l'arrangement des atomes dans les couches superficielles des cristaux. On a proposé une hypothèse, déduite des résultats spectroscopiques, sur la structure réelle du  $\text{Ca}_3\text{SiO}_5$  ainsi que le mécanisme de sa transformation polymorphique. Conformément à cette hypothèse, on peut considérer la structure du  $\text{Ca}_3\text{SiO}_5$  comme composée de couches silicatées et de couches d'oxyde de calcium. Quelques polymorphes du  $\text{Ca}_3\text{SiO}_5$  présentent des structures polytypes.

SUMMARY : Laser Raman and Fourier transform IR investigations have been performed on powdered samples of  $\text{Ca}_3\text{SiO}_5$  polymorphs obtained by stabilization with  $\text{ZnO}$ . Types of polymorph have been established by X-ray measurements. Vibrational spectroscopy is a complementary method in comparison with X-ray diffraction and gives information about short range order in crystal. The hypothesis deduced from spectroscopical results concerning real structure of  $\text{Ca}_3\text{SiO}_5$  crystals has been proposed as well as the mechanism of polymorphic transitions of  $\text{Ca}_3\text{SiO}_5$  forms. According to this hypothesis  $\text{Ca}_3\text{SiO}_5$  structure can be regarded as layer structure consisting silicate and calcium oxide layers. Some of  $\text{Ca}_3\text{SiO}_5$  polymorphs are polytypic forms.

## INTRODUCTION

There are many papers /1,2,3,4,5/ concerning phase transitions of the tricalcium silicate and structure of its different forms. The fundamental work is Bigare et al. paper /4/. The polymorphism of the  $C_3S$  using X-ray and thermal analysis methods as well as microscopic investigations have been established. On the base of these papers an existence of six crystalline forms should be accepted up to decomposition temperature of  $C_3S$  /1250°C/. Three of these forms are tridlinic, two - monoclinic and one is rhombohedral /the highest-temperature phase/. The phase transition cycle of the  $C_3S$  can be shown as follows :

Trümel, Fix and Heinke /6/ have confirmed that the  $C_3S$  is the stable phase also at the 1300 - 1800°C temperature range but the existence of another forms at these temperatures is not confirmed. It is possible to find, in some papers, information about other  $C_3S$  modifications; for example Uchikawa /7/ has found five additional weak effects on the DTA curves and has attributed them to additional phases structurally close to basic  $C_3S$  modifications.

X-ray studies carried out using Guinier camera /1/ at different temperatures have shown that at the temperature 1100°C the crystal lattice of the  $C_3S$  is hexagonal one and about 30 reflections on the diffractogram are ascribed to the  $R3m/C2_2$  space group which corresponds to the structure proposed by Jeffery /8/. A temperature decrease causes characteristic changes of the 204, 204 and 220 reflection shapes in the  $2\theta = 31^\circ - 33^\circ$  and  $51^\circ - 52^\circ$  angle range. In this angle range the changes connected with the  $C_3S$  polymorphic transitions are especially easy to observe. During the phase transition at 1050°C the crystalline symmetry changes from rhombohedral to monoclinic / $R \rightarrow M_{II}$ /; this transition is only a small displacement of the elements in a unit-cell but the symmetry reduces rapidly from  $R3m/C2_2$  to  $Cm/C_2$ . Considering the hexagonal symmetry  $R3m$  it can be confirmed that only two its subgroups exist :  $C_3$ -trigonal and  $C_2$ -monoclinic. The splitting of the 204 and 220 reflections shows the change of a crystal system and this decides of the monoclinic system. The parameters of the monoclinic unit-cell expressed by the hexagonal system differ minimally i.e.

$$\Delta a = 0,02 \text{ \AA}, \Delta c = 0,13 \text{ \AA} \text{ and } \gamma \text{ by } 0,12^\circ.$$

The phase transition at 990°C is not connected with the symmetry change, so the second monoclinic phase of  $C_3S$  / $M_{II}$ / is of the same space group  $Cm/C_2$ . On the diffractogram more distinct splitting of the 201, 204 and 220 doublets is observed. The  $M_I \rightarrow M_{II}$  transition is connected with a very small thermal effect.

At the 980°C temperature occurs the transition with considerable thermal effect and change of the symmetry from monoclinic to triclinic / $M_I \rightarrow T_{III}$ /. On the diffractogram next splitting is observed of the mentioned above reflections to the triplets. There are more reflections of this form on the diffractogram and it is impossible to explain them without an increase of the unit-cell parameters. In this case pseudohexagonal parameters  $a$  and  $b$  should be doubled to about 14 Å, so the structure of the  $T_{III}$  form must be described as super-unit-cell with four times quantity of atoms in comparison to the previous structures.

At the 920°C the strongest thermal effect is observed connected with the  $T_I \rightarrow T_{II}$  transition but without change of

the symmetry and the unit-cell parameters. The unit-cell of this system is of trivial symmetry. On the diffractogram further splitting of the triplets can be seen.

The phase transition at the 600°C does not cause the change of the symmetry, but diffractograms change significantly that certifies further increase of the unit-cell parameters by the next double  $a$  and  $b$  parameters.

Now the unit-cell has four times more of the atoms than the unit-cell of the  $T_I$  and  $T_{II}$  forms, and sixteen times more than the  $M_{II}$ ,  $M_I$  and  $R$  forms.

Among these five general accepted polymorphic transitions of the  $C_3S$ , only the  $R \rightarrow M_{II}$  is the transition of the second type without thermal effect. The  $T_{III} \rightarrow T_{II}$  transition is practically unobserved in the X-ray diffraction /the same diffractograms/ but it is accompanied by the strong thermal effect connected with the transition to the second super-lattice.

The  $C_3S$  crystals can form solid solutions with different additional cations. The investigations of Bigare et al. /4/ have shown that many of these cations can stabilize different crystalline modifications of the  $C_3S$ .

#### PREPARATION OF THE DIFFERENT CRYSTALLINE MODIFICATIONS OF THE $C_3S$ AND THEIR DEFINITION USING X-RAY DIFFRACTION

The samples have been prepared by the stabilization with admixed ZnO. The stabilizer concentration has been chosen as in the paper /4/. For better comparison of the results ZnO has been introduced to the low-temperature  $T_I$  form the structure of which does not require the stabilization. Owing to this procedure the sample defected by additional admixture has been obtained but its concentration did not cause structural changes. There were samples prepared with the following ZnO concentration /% weight/: 0,5, 1, 2, 3 and 5 that corresponds to the  $T_{III}$ ,  $T_{II}$ ,  $M_I$ ,  $M_{II}$  and  $R$  modifications. The zinc has been introduced as the water

solution of  $\text{Zn}/\text{COOCH}_3 \cdot 2\text{H}_2\text{O}$ . To the adequate quantity of the zinc acetate water solution the mixture of the  $\text{CaCO}_3$  and the  $\text{SiO}_2$  has been introduced in the molar ratio 3:1. This suspension was dried at the temperature  $100^\circ\text{C}$ , further holded at the  $1000^\circ\text{C}$  /decarbonization/ and next after grinding -  $1500^\circ\text{C}$ . The heating at  $1500^\circ\text{C}$  was repeated up to getting the clean phase of  $\text{C}_3\text{S}$ , which was controlled using X-ray diffraction and IR spectra.

Figure 1. X-ray diffractograms of the  $\text{C}_3\text{S}$  polymorphic modifications stabilized by  $\text{ZnO}$ .

Figure 1 shows diffractograms of the different  $\text{C}_3\text{S}$  forms stabilized by  $\text{ZnO}$  of different concentration. The diffractograms were registered in the ranges most characteristic for these forms:  $2\theta = 31^\circ - 34^\circ$  and  $50^\circ - 53^\circ$ . The indices of the reflections were found accordingly to the paper [2]. It is easy to remark that the reduction of the crystal symmetry and increase of the unit-cell dimensions cause the splitting of the singlet 204 reflection in the rhombohedral structure to the doublet in the monoclinic and to the triplet in the triclinic one. The behaviour of the singlet 220 reflection is the same. The same angle range registered using Guinier camera could show more complicated, fine structure of these two reflections which confirms the

formation of the superlattice for the temperature modifications. These measurements agree with the results of previous works and synonymously define the samples and allow to confirm the getting of  $\text{T}_{\text{III}}$ ,  $\text{T}_{\text{II}}$  or  $\text{T}_I$ ,  $\text{M}_I$ ,  $\text{M}_{\text{II}}$  and  $\text{R}$  forms. This identification is necessary for basic spectroscopic investigations.

#### SPECTROSCOPIC RESULTS

Figures 2a and 2b show the spectra of the same samples the diffractograms of which were presented in fig.1. On these spectra

Figure 2. a/ FIR spectra of the  $\text{C}_3\text{S}$  polymorphic modifications stabilized by  $\text{ZnO}$ ; b/ MIR spectra of the  $\text{C}_3\text{S}$  polymorphic modifications stabilized by  $\text{ZnO}$ .

continuous changes with the increase of the stabilizer concentration are observed. According to the selection rules of the vibrational transition the disappearance of some bands with the increase of the crystal symmetry is not observed. Instead of this the characteristic band broadening is observed. It is especially visible in the  $800 - 1050 \text{ cm}^{-1}$  /Si-O bond stretching vibrations in the  $\text{SiO}_4$  tetrahedron/ and  $100 - 400 \text{ cm}^{-1}$  /lattice vibrations/ ranges. This observation shows the broadening of the vibration energy levels so, the selection rules do not operate. These could be only one explanation of this experimental fact - the increase of disorder of crystalline lattice. It has been shown in the paper [9] that in the medium infrared range spectra the Si-O bond vibrations are observed, which are mostly effected by the arrangement of oxygen ions, because in the vibrations mainly these atoms motions are observed in relation to more static cations. The increase of the lattice disorder -

-which is shown by the spectroscopic data - concerns mainly the sublattice of the oxygen ions, less - the cation sublattice.

From the theory group calculations made for the rhombohedral structure of  $C_{3v}S$ .
